Stantec BMS is based on a 'bottom-up' approach and utilizes inventory data and inspection to produce a set of Element and Project-Level analysis results. These results are then used at the Network-Level (Thompson et al, 1999, Ellis et al (2008)). Stantec BMS produces results at three (3) levels of analysis: The Element-Level, the Project-Level and the Network-Level. Stantec BMS combines Element-Alternatives at the Element-Level into Project-Alternatives, each of which represent a possible multi-year strategic action plan to maintain the serviceability of the structure at a desired level. The analytical framework of Stantec BMS maintains consistency between the Element-Level, the Project-Level and the Network Level. Results at Element and Project Levels are used at the Network-Level. This means that any decisions made at one level can serve to constrain results at another level.

The analyses are organized into three levels of detail, as shown in Figure 1. The levels are:

1. Element level, which focuses on a selected structural element of one bridge. This tool uses a Markovian deterioration model and a set of feasible treatments to produce multiple Element Alternatives, each of which is a possible corrective action to respond to deteriorated conditions. Functional improvements are also included at this level.

2. Project level, which combines Element Alternatives into Project Alternatives, each of which represents a possible multi-year strategy to maintain service. The tool uses models of initial costs and life cycle costs to evaluate the Project Alternatives.
3. Network level, which combines the Project Alternatives on multiple bridges into Program Alternatives, each of which is a multi-year plan for work on all or part of a bridge inventory, designed to satisfy budget constraints and performance targets while minimizing life cycle costs.

Each level of analysis in this framework provides a set of evaluated alternatives to feed the broader-scale tool to its left. All three levels are designed to stay consistent with each other, so if a change is made at one level, the remaining levels will adjust appropriately.

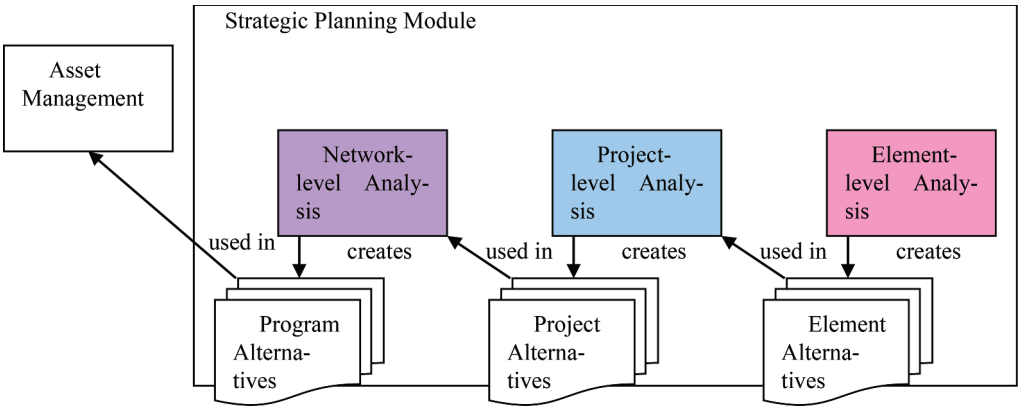

Figure 1. Levels of analysis.

On the other hand, in going from left to right in Figure 1, network-level analysis provides a context for the project level, because the network-level budget constraint affects which Project Alternatives can be programmed. For example, in a very constrained funding scenario many bridges will have to select the Do-Nothing alternative.

Similarly, the project-level analysis provides a context for the element level, influencing the cost-effectiveness of individual element treatments such as in the case when element treatments are combined at the same time to minimize traffic control costs, Ellis et al (2008).

3 OVERVIEW OF NBDTI'S BRIDGE MANAGEMENT SYSTEM (BMS) REQUIREMENTS

Specific requirements for NBDTI's BMS for structures are summarized below. Using their new BMS, the NBDTI desired to be able to:

1. Utilize the widely accepted bridge and culvert inspection methodology used in other provinces of Canada, OSIM (MTO 2018).
2. Standardize and centralize structures inventory information so it is easily accessible for users with different access levels across various departments.
3. Operate a multi-window user interface for all inventory, inspection, multimedia and analysis results while having context sensitive help.
4. Integrate with Department GIS and other internal systems.
5. Adopt an accepted and rational bridge condition index (BCI) that could be used to compare conditions between individual structures and as a network average performance measure to set performance targets. MTO, 2008).
6. Provide measures of criticality and risk that could be used in decision-making.
7. Develop of NBDTI-specific structure deterioration and cost models.

8. Establish prioritized work programs for their highway network using a lifecycle cost analysis and benefit-cost (B/C) framework.
9. Implement enhanced multi-media document management in the BMS.
10. Receive training in bridge management and the use of BMS.

4 IMPLEMENTATION AND CUSTOMIZATION OF BRIDGE MANAGEMENT SYSTEM

The system was able to be customized off-the-shelf to suit NBDTI practices and much of the implementation consisted of this customization process.

Inventory data and Department drop-down lists were customized for the BMS. A large number of screen labels and drop-down changes were required to match NBDTI terminology. Since NBDTI had been using a legacy bridge inventory and inspection system for many years, there were several legacy features that the Department wished to be added to the BMS. These features included a document management tool (Figure 2) which enables users of the BMS to track legacy documents such as microfilm, manage load rating file information, and record current location of these key frequently used documents. This tool supplements the existing document tools in the BMS which handle documents and all multimedia associated with inspections. A NBDTI-specific capital planning screen was added, and links within the BMS to internal legacy tools such as a photo management application, internal network folders, and the department GIS were added. Several complex reports were also added to the system to match those produced by the legacy system(s).

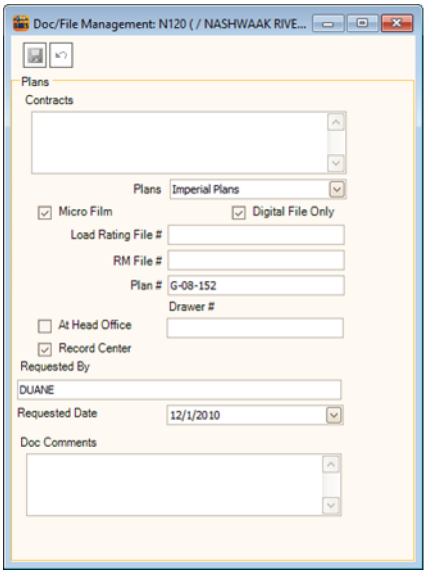

Figure 2. Document administration screen.

As is standard with a BMS implementation, Department-specific deterioration models (Figure 3), cost models, and analysis parameters were developed using expert elicitation and experience from the project team and knowledge from other similar jurisdictions in Canada that use the BMS.

A risk analysis module was included with the BMS (Figure 4 and Table 1), which required new structure level and element level engineering inputs. A new element level criticality rating was introduced Ellis et al (2012). Training on collecting the inputs required for this new analysis was provided as part of the two-week inspection training course provided to NBDTI staff during the project.

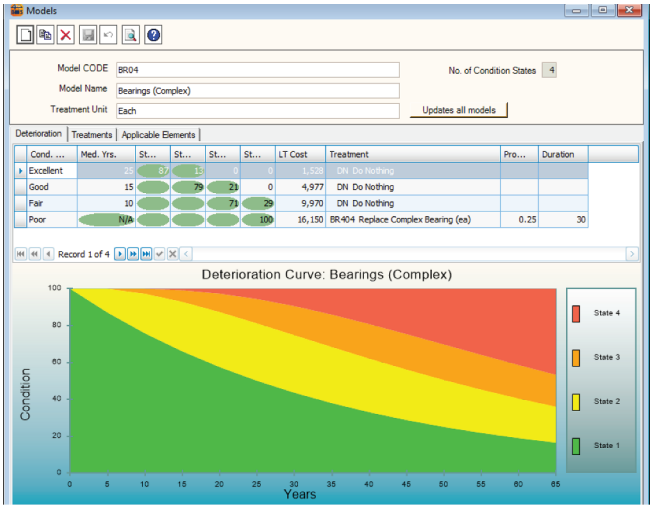

Figure 3. A sample deterioration model.

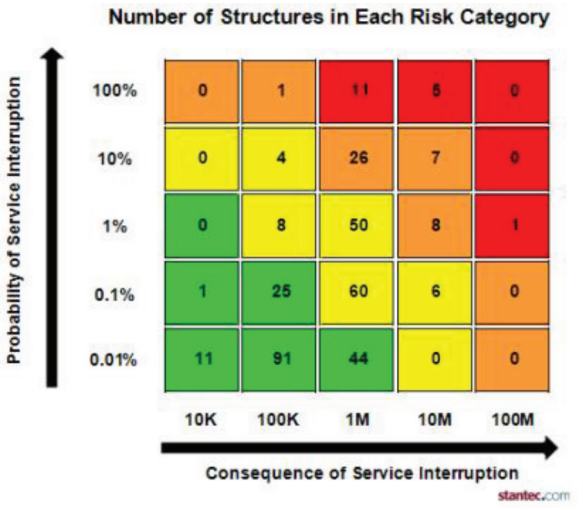

Figure 4. Network risk profile (number of structures).

Table 1. Network risk distribution (Deck Area).

Risk Level	Deck Area (sq.m.)	%
High	7,352	5.45%
Medium-High	22,782	16.89%
Medium	75,464	55.94%
Low	29,307	21.72%
Total	134,906	100.00%

5 CHALLENGES AND LESSONS LEARNED DURING THE IMPLEMENTATION

5.1 *Challenges*

In striving to meet NBDTI's goals, challenges were encountered during the BMS implementations. Overall, implementing two large complex asset management systems (structures and pavements) in parallel challenged resources for the consultant and department project team. The award time of the project (early 2020) was just a few weeks before the province and country went into pandemic lockdown. The project team had to accomplish nearly all tasks remotely, lacking the opportunity to have in-person workshops. Understandably this presented extenuating challenges, which were ultimately overcome due to the dedication of the project team.

Some specific challenges are listed below:

1. NBDTI has a long history of bridge management, including a legacy inventory and inspection system that had been in use for decades; there were features and functionality that NBDTI wished to customize in the new BMS, which increased the level of customization.
2. NBDTI had been using the specified (Ontario Structure Inspection Manual) OSIM inspection methodology, but it was a modified approach which meant that existing element and inspection information was not directly applicable to the new system.
3. Using the bridge management system to migrate inventory data and accept new inspection data while developing the customized system to suit NBDTI practice challenged the software development team to provide a constantly changing but usable system.
4. In developing BMS cost and deterioration models, it was found that the Department did not have deterioration data in an OSIM compatible format.
5. NBDTI wished to establish links to existing integrated systems from within the new BMS so the users could seamlessly use BMS with internal applications.

5.2 *Lessons learned*

In general, an effective communication plan among the project team proved essential to ensure project success, especially having to work remotely. This included regularly scheduled meetings and progress documentation and sign-off/approvals at various stages. The communication plan helped to communicate the expectations, changes needed, and scheduling restrictions, to ensure timely deliverables.

Every agency has specific customization needs. This is especially so if there is a long history of legacy systems usage. It is essential that knowledgeable working level staff be available from department and consultant to make the necessary conversions, and this was achieved provided throughout the project.

Due to the flexibility of the BMS interface, it was possible to provide users with different access levels across various departments depending on user needs, achieving one of the Department requirements.

Preferably, compatible inspection data is available at the start of the project but if not, it is better to wait until the system is implemented before inputting inspection data. It was challenging to collect over 2,000 inspections and enter this data while the system was being finalized. While this approach is possible, it consumes resources.

6 SUMMARY

NBDTI recently implemented a bridge management system for their bridges and other type of transportation structures. The new BMS was implemented as a COTS system.

As a result of the successful customization and implementation, the BMS can assist NBDTI in:

1. Providing capabilities to model future structural deterioration and recommend appropriate maintenance and rehabilitation.
2. Ensuring effective use of financial resources.
3. Extending management philosophies into short-term and long-term planning.
4. Helping manage network data and information.
5. Effectively communicating management requests.
6. Each year NBDTI is responsible for allocating the capital budgets to support its programs and fulfill its long-term strategic goals. Using the new systems will allow NBDTI to invest wisely and justify allocating funds needed for their assets.

ACKNOWLEDGEMENTS

This project was sponsored by the New Brunswick Department of Transportation and Infrastructure (NBDTI). Sincere thanks are extended to NBDTI staff Glen MacDonald, Sheldon Smith, and Tracy MacDonald for their invaluable contributions and support throughout the BMS implementation. The authors recognize and appreciate the assistance provided by Katie Lawlor, Joshua Fox, Joyce Brown, and Veronica Pelkey also with NBDTI.

ABSTRACT: Predicting bridge deterioration is essential to an effective bridge management. Understanding the evolution of bridge performance in specific periods is fundamental to anticipating future needs and planning appropriate interventions. In this context, this paper aims to analyze Bridge Management Systems (BMS) that use deterioration prediction models and the methods employed. To perform this analysis, 12 BMSs from 12 countries were selected, considering the number of publications and citations related to the subject of "Bridge Management System" in each country. When examining the information from these systems, the significant importance of predictive models is evident. More than half of the systems (67%) use some type of deterioration prediction model, 25% do not use prediction models, and 8% did not obtain any information. Moreover, it is common to observe the countries that collaborate the most in BMS research adopt these models in their systems. Among the systems that employ deterioration prediction models, three main types were identified: physical, deterministic, and probabilistic models. In analyzing the bridge prediction models, it was found that 67% of them are based on probabilistic approaches using Markov chains, 11% are deterministic, 11% are physical models, and in 11% of the cases it was impossible to obtain information. These results highlight the preference for probabilistic approaches in modeling bridge deterioration, considering the uncertainty associated with the process. Such predictive models perform a crucial role in effectively managing bridges, enabling the anticipation of maintenance needs and the proper allocation of resources. In summary, the implementation of bridge deterioration prediction models is widely adopted in management systems worldwide, with probabilistic models based on Markov matrices being the most widely used. Understanding these models and their application can provide valuable insights for developing efficient and sustainable management strategies for bridge maintenance.

Keywords: Bridge, Deterioration Prediction Model, Bridge Management System, Physical Model, Deterministic Model, Probabilistic Model

1 INTRODUCTION

Effective bridge management plays a crucial role in maintaining the long-term performance, safety, and operational efficiency of these structures. Achieving this involves meticulous planning and execution of interventions. The core goal of bridge management is to optimize these interventions, seeking to attain optimal performance while minimizing associated risks. This process forms a solid foundation for informed investment choices. A fundamental component of this procedure involves the capability to forecast bridge deterioration as time progresses. Gaining insights into how the performance of structures evolves within specific timeframes is vital for enhancing the efficiency of intervention planning. Aiming to understand the processes underlying deterioration prediction and to identify the methods prevalent in bridge

DOI: 10.1201/9781003483755-235

management systems globally, this paper conducts a review covering a detailed analysis of the models employed to predict bridge degradation in management systems worldwide.

2 METHOD

To perform the bibliometric review, we used the Scopus database platform. The search was carried out in August 2023, using the term "Bridge Management System" in "Titles, Abstracts and Keywords". Only documents in English published in the 21st century (2001-2023) were considered. A total of 686 documents were found and analyzed. VOSViewer, Bibliometrics, and the Scopus platform tools were used in the analysis. After a thorough review of existing methods to predict deterioration in BMS, the three methods employed by the selected systems were chosen for the analytical review of this paper.

The bibliometric review identified the main countries producing studies on BMS and the most relevant areas of concentration in the academic products. The selection of the countries analyzed was based on two clearly defined criteria: the presence of at least twelve documents and a minimum of 200 citations for each country. Based on this analysis, the twelve countries with the highest academic outputs and citations were chosen for a more detailed analysis. For this review, selection criteria for the BMSs were established based on the following aspects: the current use of the system, and the choice of only one system per country (giving priority to the first system developed and the number of structures).

3 BIBLIOMETRIC REVIEW

Table 1 lists, the 12 largest most collaborative countries regarding scientific production in the area, considering the minimum criterion of 12 documents and 200 citations.

Table 1. List of selected countries, number of documents and citations.

Country	Nº documents	Citations
Australia	42	406
Canada	79	654
Germany	12	223
Ireland	13	323
Italy	33	303
Japan	57	337
Portugal	36	297
South Korea	44	474
Switzerland	24	294
Taiwan	25	237
United Kingdom	28	324
United States of America	157	2501

Figure 1(a) illustrates the substantial impact of the United States in this domain, evidenced by its extensive document count and network connections. This dominance can also be attributed to its pioneering role in spearheading research in this field. Upon analyzing the keywords, we extract the primary research domains within BMS, with two focal points emerging in relation to deterioration prediction: "Life Cycle" and "Deterioration," as depicted in Figure 1(b).

During the early 21st century, research within the realm of bridge management systems underwent a substantial surge. This upswing can be attributed primarily to the establishment of numerous systems in the 1990s and 2000s (Adey et al., 2014). While the output of related documents has since reached a steady state, the topic remains pertinent on a global scale. The annual distribution of research papers is illustrated in Figure 2.

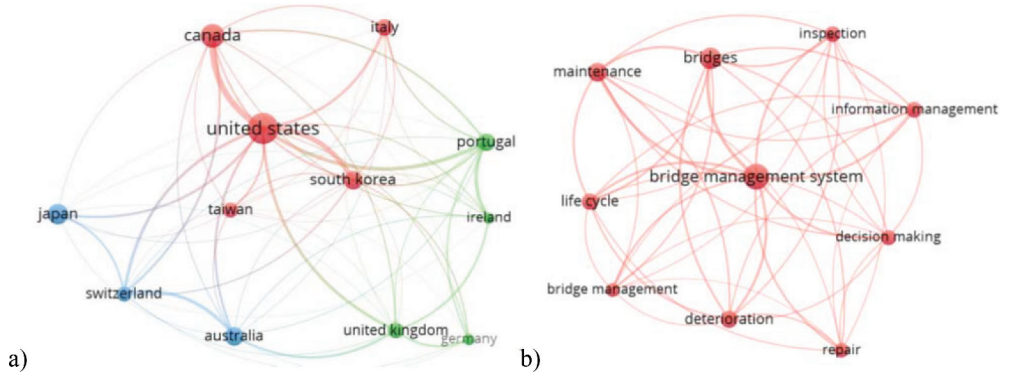

Figure 1. a) Connection between the selected countries; b) Keywords Analysis.

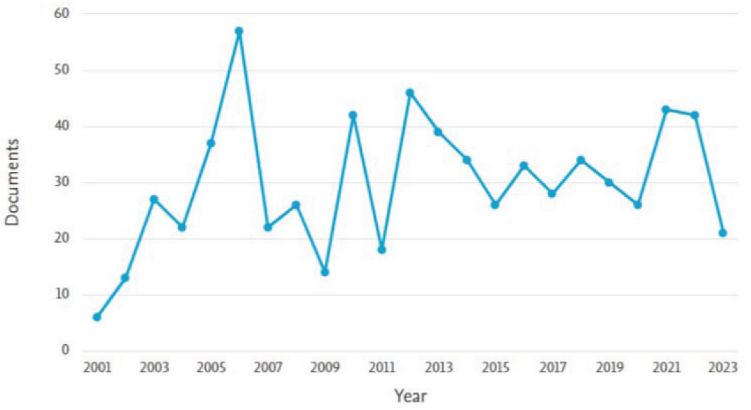

Figure 2. Documents by year.

In 2006, Figure 2 displays a pronounced peak, which can be ascribed to the occurrence of the 3rd International Conference on Bridge Maintenance, Safety, and Management (IABMAS). This event encompassed 34 publications dedicated to BMS, thus emerging as the primary contributor of papers for that year and century. Furthermore, it's noteworthy that the IABMAS congress, taking place biennially, instigated several publication spikes during even-numbered years such as 2006, 2010, and 2012.

In the realm of journals, notable contributions within the BMS domain encompass the Journal of Bridge Engineering, Journal of Infrastructure Systems, Structure and Infrastructure Engineering, and Transportation Research Record, as delineated in Table 2. Among these, the Structure and Infrastructure Engineering journal stands out with the highest number of publications (32), while the Journal of Bridge Engineering takes the lead in terms of citations (805).

Table 2. Journals with more publications.

Journal	Doc.	Citations
Journal of bridge engineering	22	805
Journal of infrastructure systems	15	357

Transportation research record	30	291

4 ANALYTICAL REVIEW

4.1 *Bridge management system*

The foundation for a bridge to maintain its performance over its lifespan, ensuring a specific degree of safety and functionality, lies in how interventions are meticulously planned and executed. Bridge management seeks to optimize these interventions, aiming to ensure optimal performance while minimizing associated risks. This approach significantly contributes to the foundation of investment decisions (Oliveira, 2019).

A Bridge Management System (BMS) is structured into three primary categories: database management, data analysis, and decision support. The initial category pertains to data encompassing inventory details, evaluations of the bridge through inspections, cost-related information, and records of enhancement and preservation activities. These evaluations form a fundamental bedrock for data analysis, supplying vital inputs required for efficient information processing. Following this processing stage, the definition of analysis parameters follows, wherein each system must process and prioritize the most pertinent factors. Deterioration prediction and cost models constitute the most employed factors within this context (Adey et al., 2014). Lastly, decision support amalgamates insights derived from data analysis to serve as a bedrock and assist in making decisions and carrying out tasks, in a consistent and technically proficient manner.

Among the systems under scrutiny, the pioneering development and implementation transpired with KUBA, the Swiss Bridge Management System, in 1989. Shortly thereafter, in 1992, the USA introduced Pontis, which is currently known as AASHTOWare BrM. Subsequent instances emerged between 1996 and 2006 for the remaining systems, as detailed in Table 3.

Table 3. Selected BMS from each country (Adey et al., 2014; Habeenzu et al., 2021; Hsien-Ke et al., 2017; Mendonça et al., 2016).

Country	BMS	First Version
Australia	NSW	1996
Canada	OBMS	2002
Germany	GBMS	-
Ireland	EIRSPAN	2001
Italy	APTBMS	2004
Japan	RPIBMS	2006
Portugal	GOA	1999
South Korea	KRMBS	2005
Switzerland	KUBA	1989
Taiwan	TBMS	1999
United Kingdom	SMIS	1999
United States of America	AASHTOWare BrM	1992

Among the systems examined, AASHTOWare BrM in the United States is particularly noteworthy, covering a total of 750,908 structures, show in Figure 3. This predominance is justified by the adoption of this system by most states for the management of their structures. In 2021, 41 of the 50 asset management agencies in the United States used AASHTOWare BrM as part of their operations (AASHTOWare Bridge Management, 2021).

4.2 *Bridge deterioration prediction models*

The ability to anticipate the progressive decline of bridges over time plays a crucial role in the effective management of these structures. Understanding the performance trajectory of these constructions at defined intervals is essential to anticipate future requirements and plan appropriate medium to long-term interventions.

When examining the data from the twelve BMSs covered in this study, the significant importance of predictive models becomes evident. Over half of the systems (67%) employ some form of

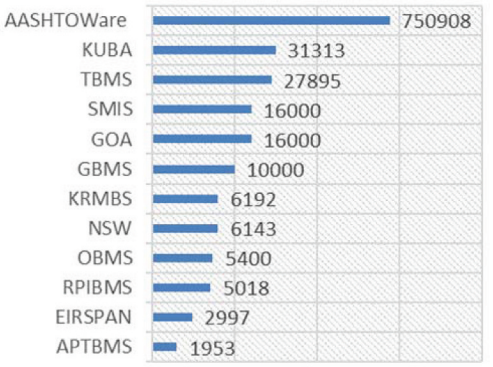

Figure 3. Number of structures in the selected BMSs (Adey et al., 2014; Habeenzu et al., 2021; Hsien-Ke et al., 2017; Mendonça et al., 2016).[1]

deterioration prediction model. These models are particularly prevalent in countries that stand out for their advanced research in BMS. Notably, the five countries leading in research in the field of bridge management systems generally incorporate deterioration prediction models in their respective systems. Of the systems investigated, eight BMSs adopt some form of deterioration prediction model (67%), while three do not make use of this feature (25%). For one of the systems, no information on the presence of such models was accessible (8%), as illustrated in Figure 4(a). All data collected are thoroughly presented in Table 4.

Table 4. Predicting deterioration in BMSs (Adey et al., 2014; Liao & Yau, 2011; Mendonça & Brito, 2014; Roelfstra et al., 2004).

BMS	Deterioration prediction models
NSW	Probabilistic deterioration prediction model in a system separates from the BMS
OBMS	Probabilistic deterioration prediction models by Markov chains
GBMS	Physical models for predicting deterioration (chlorides, carbonation and corrosion)
EIRSPAN	No deterioration prediction model
APTBMS	Probabilistic deterioration prediction models by Markov chains
RPIBMS	Probabilistic deterioration prediction models by Markov chains
GOA	No deterioration prediction model
KRMBS	Deterministic deterioration prediction model
KUBA	Probabilistic deterioration prediction models by Markov chains
TBMS	No deterioration prediction model
SMIS	-
AASHTOWare BrM	Probabilistic deterioration prediction models by Markov chains

Among the systems that adopt deterioration prediction models, three main models developed for integration into management systems are identified: physical models, deterministic models and, finally, probabilistic models that make use of Markov chains. In the examination of the prediction models applied to bridges, it is evident that 67% of them adopt a probabilistic approach based on Markov matrices, 11% are deterministic in nature, 11% are physical modeling and in 11% of the cases it was not possible to access detailed information on the elaboration of the model, as illustrated in Figure 4(b).

1. Data taken from the references may not correspond to the actual number of bridges in each system.

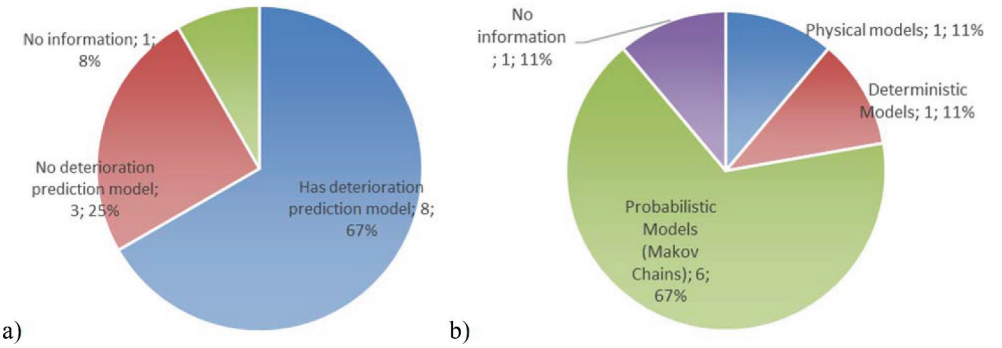

Figure 4. a) Predicting deterioration in BMSs; b) Type of deterioration prediction models used in BMSs.

4.2.1 *Physical models*

The deterioration of a structure emerges from the complex interaction of several physical processes within the system, interrelated with the materials used and the specific environmental conditions. To represent these degradation processes, either in the mechanical or chemical aspect, physical models have been developed to depict structure deterioration (Papadakis, 2013; Santamaria et al., 2019; Zambon et al., 2018).

Physical models addressing corrosion and carbonation are often preferred as they can clearly identify the main causes of deterioration in transportation infrastructure (Papadakis, 2013; Zambon et al., 2018). There are several models available for predicting the service life of reinforced concrete structures, considering factors such as chloride depassivation of reinforcement. The predominant formulations assume that the process is governed by diffusion (Andrade et al., 2019).

Some physical models that have not been implemented in the studied management systems can be explored in more detail in works such as Vieira et al. (2018) and Zambon et al. (2018). It is noteworthy that only the German GBMS system adopts physical models, which include chloride-induced corrosion and carbonation, for degradation prediction purposes.

4.2.2 *Deterministic models*

Based on mathematical or statistical equations, deterministic models establish connections between historical condition states and the service life of bridges. These structures may also incorporate additional factors that influence degradation. The main methods employed for the formulation of these models comprise projection curve fits, regressions, and the linear approach (García-Sánchez, 2016; Moscoso, 2017; Souza et al., 2023).

Among the most elaborate deterministic models today are regressions, which include both linear and non-linear regressions. In this context, the aim is to establish an empirical relationship between one or more variables, in which one of the variables is considered dependent on the others, which act as independent variables, if they are relevant. Regression analysis, in its essence, explores the interdependence between a variable of interest Y_i and one or multiple explanatory or predictor variables $X^{(j)}$.

Numerous researchers have been actively involved in crafting deterministic methodologies utilizing regression analyses to appraise the deterioration of bridges. Illustratively, notable references include the works of Jeong et al. (2017); Kim et al. (2019); Lu et al. (2019) and Souza et al. (2023). The KRMBS originating in South Korea stands as the singular management system that adopts a deterministic approach for the prediction of deterioration.

4.2.3 *Probabilistic models*

The process of deterioration in bridges, a synergistic interplay of multiple agents occurs, rendering the analysis of their individual influence rates unfeasible, as such, the phenomenon of deterioration takes on a probabilistic bias, where probabilistic deterioration models consider that deterioration over time is unknown, but there exists a probability for deterioration to unfold according to a certain law (Almeida, 2013; Oliveira, 2019).

The probabilistic degradation forecasting model predominantly employs Markov matrices, formed, for instance, by annual transition probabilities between different levels of condition states. This approach enables the prediction of the evolution of this performance parameter over time. This model finds common use in contemporary bridge management systems, primarily due to the relative ease in assembling data that allows for the identification of transition probabilities between different levels of this performance parameter.

Predicting bridge deterioration through Markov matrices involves stochastic processes, implying random processes that govern the behavior of a system over time, based on probabilistic considerations. These processes are categorized according to both Condition State and time, into discrete or continuous (Mishalani & Madanat, 2002).

Models classified by their state as discrete can be further divided into time-based or Condition State-based models. According to Mishalani & Madanat (2002), time-based models predict the probability of the time interval required for a change in the condition state of a bridge to occur. On the other hand, state-based models are models of deterioration that, within a chain Markovian process, predict the probability of a given bridge maintaining its condition state or changing its state within a fixed time span. State-based models can still consider the timing between discrete-time Markov processes and continuous-time Markov processes.

Various authors also have developed other models, including Calvert et al. (2020); L. Li et al. (2014); Manafpour et al. (2018); Santos et al. (2022) and Wellalage et al. (2015).

Eight management systems employ probabilistic models based on Markov matrices, as detailed in Table 4. Roelfstra et al. (2004) proposed a Condition State (CS) prediction of reinforced concrete highway bridges, using matrices calculated from simulated data, based on a model of chloride-induced reinforcement corrosion, to implement it in the Swiss KUBA system.

5 DISCUSSION AND CONCLUSION

In a comprehensive examination centered on a New York bridge, the work conducted by Xu & Azhari (2022) harnessed a predictive deterioration model to forge a bridge management strategy founded upon risk assessment. The findings revealed a substantial reduction in annual and overall costs when juxtaposed with conventional management methodologies, boasting an impressive 29% decrease in total expenses compared to the standard protocol. This underscores the effectiveness of a model-driven approach to bridge management. This aspect substantiates the adoption of bridge prediction models within the majority of analyzed systems, thereby enhancing safety, cost efficiency, and efficacy in managing these transportation infrastructures.

The most basic model is the physical one, but its applicability is often limited by the complex interaction of deterioration processes on bridges. This model is characterized by high uncertainty, stemming from a phenomenon-based approach rather than inspection data, which in turn restricts its capacity for updates. Both deterministic and probabilistic methods seek to strike a balance between the intricacies of development and the quality of the resulting model. While the deterministic model is easier to construct, it lacks precision and usefulness without complete information. For example, the absence of construction year data affects the accuracy of condition-age relationships. On the other hand, the probabilistic model requires more data but can have this data simulated, offering flexibility and precision. Unlike the deterministic approach, it's not bound by construction year or interventions. The deterioration curve in this model is anchored in time, not age, which makes it more dependable with an increased dataset.

These considerations steer bridge management systems toward the development of probabilistic models, particularly those rooted in Markov processes. It is worth noting that while not yet widely adopted in bridge management systems, deterioration prediction models utilizing artificial intelligence are steadily gaining ground and proving to be a viable alternative. This is evidenced by studies conducted by researchers such as Carvalho et al. (2019); Li et al. (2023); Miao et al. (2022); Santamaria Ariza et al. (2020) and Santos et al. (2022).

Bundesanstalt für Straßenwesen (BASt), Bergisch Gladbach, Germany

ABSTRACT: In recent years, Structural Health Monitoring (SHM) has become a useful and increasingly widely used tool for supporting lifetime extensions of existing bridges with known structural deficiencies or indications of potentially critical damages or damage processes. At the same time, methods and tools are emerging, which enable monitoring-informed predictive maintenance of new and existing bridges based on digital twins. The monitoring process – starting from the definition of monitoring actions and ending with decisions based on monitoring outcomes – is complex and requires expertise in structural engineering, operation and maintenance of bridges, metrology, and data analytics. To support German road authorities, engineering consultancies, building contractors and other stakeholders of the bridge management, the Federal Highway Research Institute (BASt) has initiated the development of a new guideline for applying SHM as part of the management of road bridges. The guideline will present various use cases and for each identified use case, it will propose a proven monitoring scheme. In addition, the guideline will provide guidance on assessing the benefits of SHM as well as a common approach to managing monitoring data as a systematic basis for integrating monitoring data in the bridge management. This contribution discusses the motivation, objectives, and scope of the guideline, describes its use case centric structure and outlines the proposed data management.

1 INTRODUCTION

Germany's road infrastructure is facing several challenges, including a significant increase in traffic and a high average age of bridge structures. The maintenance management of bridges is currently based on standardized inspections, which largely assess the condition of the structure visually and manually. At the same time, the development of procedures and technical requirements for Structural Health Monitoring (hereinafter referred to as "monitoring" for short) has progressed to the point where it is one of the most widely used tools for reliably determining the structural condition of bridges and, if necessary, predicting developments. Monitoring describes the process of recording and processing measured values over a representative period of time and combines all the necessary tasks from the installation of sensors to the evaluation of the analyzed data. At present, the use of monitoring is largely limited to event-related (reactive) measures. However, the great potential of monitoring lies in the future support of predictive maintenance.

DOI: 10.1201/9781003483755-236

A survey conducted in 2020 among experts of federal and state road authorities found that the use of monitoring is limited to existing damage and deficiencies (Hindersmann, 2021). According to the survey, barriers include a lack of knowledge about the applications and benefits of monitoring, the procurement process of monitoring services as well as the handling of data storage.

Within the framework of the coordination committees for the maintenance of engineering structures, it was decided to promote the targeted use of monitoring. This approach is to ensure that the structures can be operated safely over the long term. The aim is to contribute to a reliable, safe, and sustainable infrastructure. The operators of the structures are to be supported by best practice examples, training and standardized procedures for the use of monitoring. This objective will additionally be emphasized by the fact that the German standard which regulates bridge inspections is currently revised and the next version will include monitoring as a standard inspection routine (Marzahn et al., 2023). Further, two guidelines regarding monitoring of bridges and other engineering structures have been developed recently in Germany (DBV, 2018), (DGZfP, 2022).

Against this background, the specific objective of a research project founded by the German Federal Highway Research Institute (BASt) is to produce a brochure-type guide for the practical application of monitoring of road bridge structures. Since a brochure will not cover all issues or questions that may arise in the context of a monitoring application in detail, an additional compendium-type report will be published. This report will not only cover technical issues but will specifically and additionally address issues such as the assessment of the monitoring's economic feasibility, how to tender and award monitoring installation and operation services, and what peculiarities should be considered when drafting contracts.

A variety of typical and executed monitoring applications on road bridges has also been described within the guideline. Ordered in monitoring use cases, their typical utilizations as well as their typical benefits are described, supplemented by model cases. The collection primarily compiles use cases that are already frequently used, though they are complimented by some rare cases.

Typically, measurement data and partially processed data too are currently held by the operator of the monitoring system. There is no principal data transfer from the specialist service provider to the client, mostly only reports. As more and more monitoring applications are implemented for the various use cases, standardization of procedures and the establishment of data management systems for the resulting data is of central importance. In addition to the reported and visually displayed results, the road administration also has the task of storing the processed measurement data in a machine-processable form, with the aim of using this data as a basis for a renewed evaluation, but also as a data basis for future interval-based evaluations. Within the project the basics for the design of suitable data management systems will be extracted as well as the question will be processed, how the inclusion of user agreements can be anchored in the contracts that govern how the data is to be described and how it is to be transferred.

This paper presents a procedure to obtain information on the current state of the art of the use of monitoring on road bridges in the federal and state road authorities in Germany. Based on this state of the art, a guideline for the application of SHM and a report are developed. The content of this paper is determined by the focus of the guideline, which is based on the best possible applicability to the use of monitoring within the maintenance process.

2 THE GUIDELINE DEVELOPMENT PROCESS

In preparation of the guideline an expert workshop with representatives of the state road and the federal highway authorities was planned to acquire the specific requirements and particularities. The workshop is supposed to be a key component of the project, as the project results and the guideline brochure can only be tailored to the administrations requirements through contact with the addressees. The workshop was carried out in two stages. The first stage involves as many stakeholders as possible, who are surveyed in order to get a feeling for the concerns of the addressees. An online tool was used to conduct the structured survey. Depending on the attendees' roles, alternative or additional questions were asked. The results of this survey were used to prepare for an expert workshop, where as the second stage they were presented and discussed.

2.1 *Online survey*

In an online survey, which was aimed at road bridge management authorities, monitoring system providers and bridge monitoring companies, we sought to understand the challenges hindering the implementation of monitoring. With 137 participants (35 persons from road bridge authorities), key findings include:

- Common Challenges: 43% reported that they had issues before, related to data handling and evaluation, procurement processes or vandalism/measurement faults.
- Guideline Awareness: While guidelines like DBV-guideline (DBV, 2018) or DGZfP- guideline (DGZfP, 2022) are recognized, full utilization is not yet established.

Figure 1 shows where the most frequent problems occurred related to monitoring.

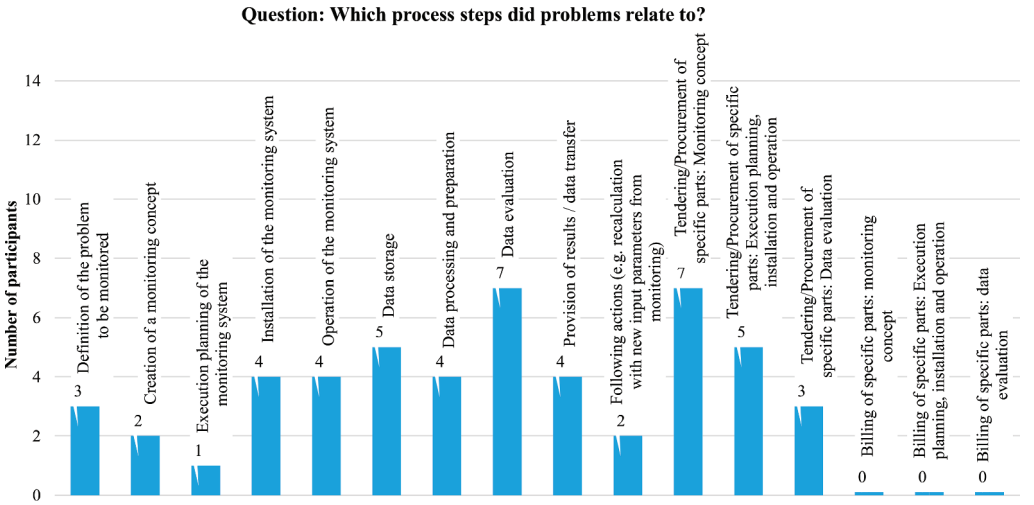

Figure 1. Results of the online survey on the topic: Which process steps did any problems relate to?.

2.2 *Expert workshop*

To get more detailed information and to be able to ask further questions, an expert workshop was conducted, involving representatives from the state road and the federal highway authorities, as well as the inviting BASt, BAM and MKP GmbH. The workshop addressed key issues raised in the earlier online survey. A key outcome of the workshop was the realization of the insufficient acceptance of the monitoring topic, as well as the associated guidelines. The following reasons were identified:

- Lack of a standardized process for guideline implementation in road authorities.
- Importance of active involvement of road authorities in guideline creation.
- Existing guidelines being fee-based, leading to administrative challenges.

To boost acceptance of the guideline created within this project and its brochure within the infrastructure sector, key strategies have been outlined. Firstly, there is an exploration of official introduction methods to establish credibility. Secondly, active involvement of states and recipients is emphasized, including a review process and acknowledgment of contributors. Thirdly, BASt commits to free publication to alleviate financial barriers. Lastly, a comprehensive publicity plan involves a BASt webinar, conference presentations, and potential post-project seminars for broader dissemination. These strategies collectively aim to ensure the guidelines' official, collaborative, and cost-free nature, fostering increased recognition and utilization within the infrastructure community.

3 SCOPE OF THE GUIDLINE

3.1 *Monitoring use cases*

The various possible uses of monitoring are summarized in the following section in the form of monitoring use cases. The project-specific use cases can be derived from project objectives and represent processes that contribute to the achievement of the defined objectives (BMDV, 2019).

Several use cases have already been identified in Hindersmann (2021), Hindersmann et al. (2023) and Nieborowski et al. (2023). These are use cases that are already frequently used in practice or which will have potential for future application. Currently, the use of monitoring is largely limited to event-related (reactive) measures (monitoring of known damage, monitoring of deficits from recalculation or construction). However, the great potential of monitoring also lies in supporting predictive maintenance.

The cases are structured within the guideline based on the template of the sample cover letter and the use case profile from BIM Deutschland (BIM = building information modeling) (BMDV, 2019). The preparation in the form of fact sheets is intended to achieve a clear and plausible presentation of the comprehensive possibilities for the use of monitoring in order to reduce barriers. For each use case, the initial task, the implementation and the benefits are described and concrete examples are used to illustrate the application in practice.

The following list summarizes the various use cases, described in the guideline:

- Known localized damages,
- known deficits from recalculation or construction,
- determination of effects,
- support for regular inspection procedure,
- accompaniment for major buildings,
- maintenance and reinforcement measures,
- load tests,
- predictive life cycle management,
- birth certificate,
- measures during the construction period,
- protection of buildings during neighboring construction work.

3.2 *Economic feasibility studies*

Before implementing a monitoring scheme, bridge owners and operators are concerned with determining its benefit-cost ratio. To evaluate this ratio, the expected costs associated with the future usage of a road bridge with and without monitoring have to be estimated. This is an intricate task since these expected costs depend on:

- the future development of the condition and performance of the bridge,
- the quality of the monitoring system and data processing,
- the possible monitoring outcomes,
- the future decisions associated with those monitoring outcomes (i.e., decisions on actions such as traffic restrictions, inspection, maintenance, bridge replacement etc.) and
- the direct and indirect costs associated with those actions as well as the costs of installing, operating, and maintaining a monitoring system.

The difference between the expected costs of operating a bridge without and with monitoring is the net value of information (VoI) provided by a monitoring system (Kamariotis, et al., 2022). If this metric is positive, the costs of a monitoring system are justified by its benefit.

A generic framework for quantifying the VoI of SHM systems is outlined in Straub, et al. (2017) and a practical concept for determining the VoI of threshold monitoring systems for road bridges and its implementation in a software tool is presented in Schubert, et al. (2020). Based on the existing (scientific) literature and the expertise provided by the German road authorities, the planned guideline will (a) highlight similarities and differences between

existing procedures for assessing the economic feasibility of maintenance actions and analyses for evaluating the benefit-cost ratio of monitoring systems and (b) provide practical advice on evaluating this ratio. It will also discuss situations in which such analyses are less relevant.

3.3 *Procurement process*

As described in Section 2 and also as shown in Figure 1, one of the most challenging areas for the bridge authorities when introducing monitoring into their daily work is the implementation of tendering, awarding and contracting activities. This is due to the novelty of monitoring as a technique to determine bridge safety measures. The lack of knowledge mostly regards the following points:

- What are the required services to be tendered and provided?
- Who are the players and which specifications and expertise potential bidders must provide?
- What are appropriate award criteria?
- What constraints need to be considered when drafting the contract?
- How liability claims need to be regulated and formulated?

Based on the authors' experience with the use of monitoring on road bridges, suggestions are made for the procedure. With regard to tendering, parts of the overall service can be tendered separately, depending on the requirements. There are also different types of tenders, depending on whether specific service points or the entire service is functionally tendered. The right choice is influenced by a number of factors. The brochure will provide suggestions for choosing the right type and scope of tender. The brochure also recommends criteria that should be considered when negotiating contracts. In addition to price, these include quality assurance criteria such as the qualifications of the bidders. This is particularly important in view of the fact that from time-to-time vendors "promise the moon". When drafting contracts, there are a number of special issues that need to be addressed and are not part of a classic bridge inspection. For example, how to deal with a temporary outage of parts the measurement equipment, e.g., due to vandalism. Minimum response times may need to be defined. Rules may also need to be established for very long measurements, to take into account the additional costs of aging measurement equipment that may need to be replaced. Liability issues also need to be addressed.

3.4 *Measurement technology*

In general, instrumentation combines all technical components of a monitoring system. This includes not only the actual sensors, but also components for signal transmission and data processing and storage. A classical monitoring system consists of sensors, sensor connection components, data acquisition systems, and a measurement computer, where further external components can be connected. To assist in the best practice application of monitoring in bridge condition assessment, the guideline lists and presents the various aspects that influence the selection of measurement technology. The selection of the measurement technology needs to be based on the monitoring concept. This concept takes into account all aspects of the technical implementation of a monitoring task in the monitoring system. Besides the actual monitoring objective this includes further aspects such as the type and size of the structure to be monitored, requirements for long-term stability or, if necessary, interchangeability, taking into account economic criteria. In addition, important requirements for the selection of the sensor technology such as measurement range, measurement accuracy, sensitivity, measurement resolution and sampling frequency must be defined. Last but not least, possible technical and environmental influences must also be taken into account. The guideline also describes the various technical components of conventional monitoring systems. In addition, new types of IoT monitoring systems (IoT= internet of things), usually organized in sensor network structures, are briefly discussed. The relationship between the measurement task and the measurement technology is presented to assist road bridge authorities. For each of the 15 different measurement tasks, the intent and the measurement task are shown, and possible measurement methods and sensor technologies are assigned.

In the final section, the best known and most commonly used sensors are summarized. For the sensors mentioned, typical applications, measurement and target variables are described. Further, the measurement principle is presented and, if necessary, comments on advantages and disadvantages or special notes on application limitations are given.

3.5 *Data management*

From the perspective of road authorities, managing the data generated by SHM applications is challenging, but it can be very valuable for future inspections and new methods that are offered by manufacturer and the SHM community. The current way of dealing with monitoring data, which typically includes time-series data from sensors and images in a variety of formats, quantities, and qualities, is that most of the data handling is done by the specialist service provider for structural measurements (SSPSM). Some very advanced road authorities in the field of SHM also fulfill the role as a SSPSM and specialist planner for SHM, already. In addition to services such as continuous monitoring of anomalies and exceeded limits, the SSPSM typically provides a report at defined points in time or at the end of the monitoring project, where the measurements are evaluated in detail and combined with various types of numerical analysis, modal analysis, structural assessment, and prognosis using models and data from external sources. This report is a document that includes plots and other visualizations of the data and the statements of the structural assessment at one point in time. The data management on the SSPSMs side is addressed in national, see e.g. (Empelmann, et al., 2023) and international literature, see e.g. (Rigotti, et al., 2022). The focus of this contribution is to solve the data management challenges as a governmental task for road authorities to preserve all relevant information regarding the asset stock in a long-term perspective. According to the results of the before mentioned survey, in only one third of the cases monitoring data is, in addition to the report, stored at the road agency for later use or reuse for other purposes, see Figure 2a. This is mostly due to difficulties in negotiating how the data should be structured and stored, and how it can be technically shared between private companies and public authorities. The need for recommendations on data management is considerable, as more than half of the participants in the survey indicated, see Figure 2b.

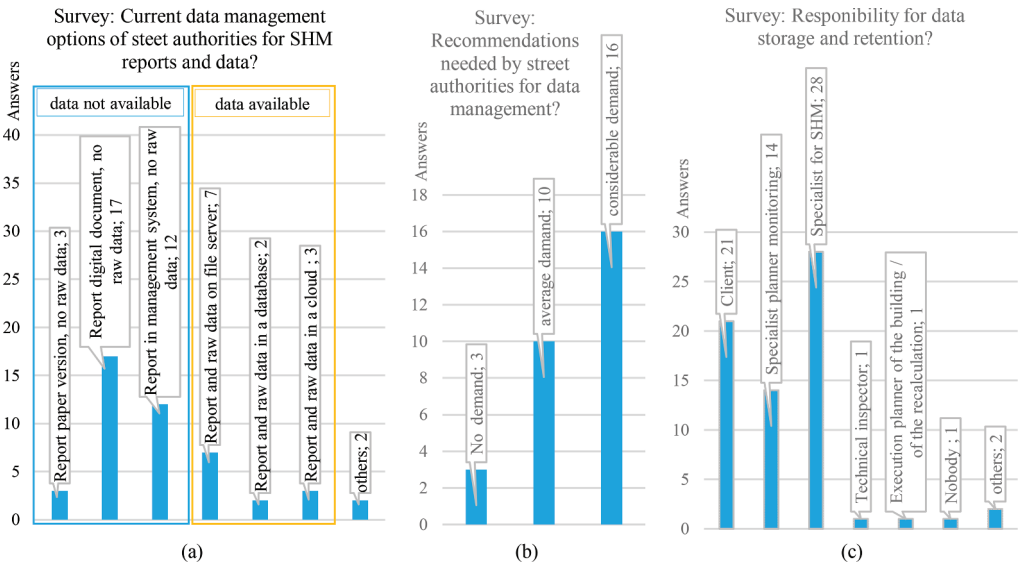

Figure 2. Survey result (a) currently used procedures for road authorities to store reports and data (multiple answers - 37 participants); (b) demand for recommendation in the field of data management (single answer - 29 participants); (c) responsibility for data storage and retention (multiple answers - 37 participants).

The need and responsibility to store the monitoring data exists for two stakeholders: for SSPSM/mounting planner and the owner/client, see Figure 2c. While the SSPSM need to handle the data that they acquire and analyze according to the contract, the road authorities need to be able to receive, archive and share the data for a specific infrastructure element. While for the administrative side, it is less important (unless the role of the structural assessment is fully covered by the road authority) to analyze the data in detail. The import interests and needs for road authorities has been collected during the expert workshop and taken from the survey evaluations. The requirements were captured in the form of *user stories*, that are short notes in a defined order:

'As a <role> I can <capability>, so that <receive benefit>'

This user stories are visualized as a user story map and will be made available as a collection to the road authorities to prioritize, their individual requirements when evaluating a data management software or development road map. One result of the discussion was that the value of SHM data, data governance and data sovereignty is a responsibility that needs to be addressed by road authorities, but currently the road authorities do not have structured processes to continuously evolve their capabilities to receive, archive and share SHM data including quality control, see (Herrmann, et al., 2017) and accounting. To fill this gap two business processes have been developed for the structured receipt of data from monitoring project, see Figure 3. The business process 1 starts with a given monitoring challenge. Depending on if the monitoring is part of a BIM tender of a new building (e.g. birth certificate), the tender of a monitoring concept or for a SHM installation the clients communicate their needs and technical capabilities for data management which are elaborated, extended and made compatible to the monitoring concept and current state of the art by the specialist planner and the SSPSM. This so-called employer's data requirement (EDR*)* is a document that specifies the data format, meta data, naming schemas, semantic linkages to models, data interfaces, limitations (API-calls, data amount), data delivery cycles, delay limits, pre-computed data evaluations, data aggregations, general purpose visualizations and quality/completeness checks, that SSPSM needs to deliver the data. The road authority acknowledges the filled EDR, when it satisfies their expectations and specifications. This EDR document will be stored along the data with revision tracking, so that each user of that data will find the relevant details about how the data can be retrieved and interpreted. As this is challenging, the EDR's template and the road authority's requirements should evolve with further monitoring projects.

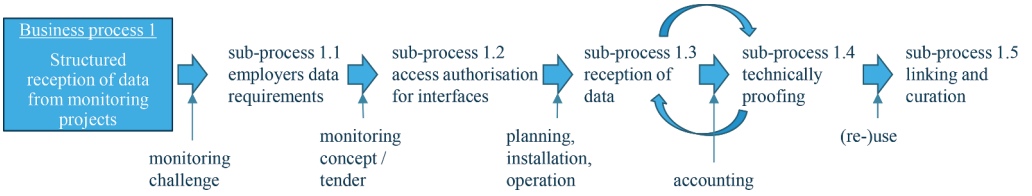

Figure 3. Business process 1 for road authorities to negotiate and realize the data delivery of SHM data acquired by the SSPSM.

After the EDR is finalized in the business process the road authority grants access to all required technical interfaces and the SSPSM delivers the data and meta data repeatedly, as agreed. The road authority checks the data delivery, using automated workflows and still needs to make the data source available in the used asset management systems, like 'SIB Bauwerke' or other catalogs, so that it will be findable and accessible. The business process 2 describes how the SHM data is used from a typically independent stakeholder that oversees the assessment of the structure, see Figure 4. If the SSPSM/specialist planner is also doing the assessment, then the responsibility to deliver reusable data with good meta data description and sufficient change/error management is even higher. Otherwise, the data may be unintelligible or even misinterpreted.

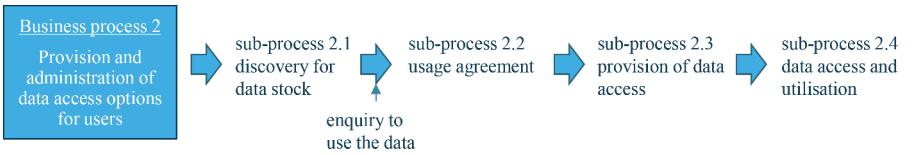

Figure 4. Business process 2 for road authorities to discover and share the available SHM data for structural assessment of structures under their responsibility.

The business process 2 involves the discovery of the available information about a realized monitoring activity on a structure and negotiates a usage agreement that gives both sides confidence of how the data and the access authorizations can be used, stored, and passed on. The road authority finally grants access, and the data can be used for any automated and manual data workflow.

The obligation to preserve the data long-term, that should typically be as independent from vendor-specific software, like database programs, helps to cleanly separate or export it so that it is available to a broad variety of dash-board solutions and digital-twin platforms. So, the data management might develop in the direction of a data broker in a healthy eco system of data producers and consumers for totally new business cases and maintenance routines.

4 SUMMARY

The maintenance management of Germany's road infrastructure is currently based on standardized inspections, where the structural condition is largely assessed visually and manually. The development of procedures and technical requirements for structural health monitoring is nowadays advanced and a widely used tool to reliably determine the structural condition of bridges and, if necessary, to predict future developments. Nevertheless, within the maintenance scheme of Germanys existing road bridges, monitoring is only used in exceptional cases. There are many reasons for this, but the most important is a lack of knowledge and experience in the practical application of monitoring. As part of a research project, the authors aim to develop a guideline for the application of monitoring measures on road bridges as an assistance instrument for the bridge administration bodies. This paper explains how an online survey as well as an expert interview workshop with participants from the road bridge authorities were used to extract the key issues that are still considered to be a challenge and for which a standardized procedure will be beneficial. These key issues include a lack of awareness about the structural use cases for which monitoring should be applied to provide information or improve the integrity of bridges as well as what the appropriate measurement technology will be, depending on the use case. Most importantly, a standardized monitoring process is missing or unknown as well as the parties necessarily involved in that process. In addition, there is a lack of knowledge about how the value of monitoring can be determined through economic feasibility studies and how the monitoring services can be tendered and awarded. A separate area of concern is data management. Here, the guideline suggests approaches and describes important boundary conditions to be considered.

The final guideline offers solutions to all these topics. In addition to a detailed guideline edition in the form of a report, the most important statements are condensed and published in a short and concise brochure. The whole process of guideline development was attended by consultation and discussion with the addressees from state and federal road authorities. This is understood as a necessary basis for the successful introduction and acceptance of the guideline.

The paper is based on parts of the research project carried out at the request of the Federal Ministry for Digital and Transport, represented by the Federal Highway Research Institute, under research project No. 15.0707/2022/LRB. The authors are solely responsible for the content.

Overview of the use of BIM for bridges across Australia and New Zealand

Nigel G. Powers
National Transport Research Organisation

ABSTRACT: Australia's freight task, and to a lesser extent in New Zealand, is growing at a rapid rate due to unprecedented population growth, coupled with increased demand from our trading partners in Asia and rapid changes in technology, e-commerce, and consumer behavior. A significant proportion of freight is transported using the road network and to remain competitive this network needs to facilitate fast, efficient, and effective access. This is a significant challenge with an ageing bridge network, regularly experiencing extreme climatic conditions and the freight industry constantly pushing to increase access and allowable loads.

Expectations on road infrastructure managers like Federal, State and Territory Governments, local government and private operators is very high and has become heightened even further with scrutiny via social and other forms of media. At the same time, there are significant pressures on government to provide greater level of service for other infrastructure they manage like schools, hospitals and law enforcement.

The above challenges create significant pressure on road infrastructure managers to minimize spend on the management of the network while attempting to meet the high expectations of the community. The use of Building Information Modelling (BIM) for bridges is seen as one of the tools that can assist road infrastructure managers in meeting the above challenges. To date its uptake has been limited with some authorities adopting BIM for major bridge structures and on recent large-scale projects but wider adoption is very limited.

The BIM survey outlined in this paper is part of the work being conducted by Task Group 5.6 – BIM in Structure Management for the International Association for Bridge and Structural Engineering (IABSE). This paper will explore the adoption of BIM across Australia and New Zealand and what is required for more significant adoption.

1 INTRODUCTION

1.1 *Australia and New Zealand challenges*

Australia's freight task, and to a lesser extent in New Zealand, is growing at a rapid rate due to unprecedented population growth, coupled with increased demand from our trading partners in Asia and rapid changes in technology, e-commerce, and consumer behavior. Overall, in Australia transport logistics was valued at over A$110 billion in 2010 (ACIL Allen Consulting, 2014) and has been steadily increasing since.

A significant proportion of freight is transported using the road network and to remain competitive this network needs to facilitate fast, efficient, and effective access. This is a significant challenge with an ageing bridge network, the regularly extreme climatic conditions and the freight industry constantly pushing to increase access and allowable loads. The majority of bridges we built and designed before 1950 to now outdated standards and for much lesser loads.

Expectations on road infrastructure managers like Federal, State and Territory Governments, local government and private operators is very high and has become heightened even

DOI: 10.1201/9781003483755-237

further with scrutiny via social and other forms of media. At the same time, there are significant pressures on government to provide a greater level of service for other infrastructure they manage like schools, hospitals, and law enforcement.

The above challenges create significant pressure on road infrastructure managers to minimize spend on the management of the network while attempting to meet the high expectations of the community. The use of Building Information Modelling (BIM) for bridges, also known as Bridge Information Modelling (BrIM) is seen as one of the tools that can assist road infrastructure managers in meeting the above challenges.

1.2 *IABSE task group 5.6 - BIM in structure management*

In November 2020, the International Association for Bridge and Structural Engineering (IABSE) formed Task Group 5.6 - BIM in Structure Management (Task Group 5.6). Task Group 5.6 aims to connect Bridge Management Systems (BMS) with existing BIM solutions, based on Open BIM standards.

The Mission Statement/Objectives of Task Group 5.6 is:

The Task Group aims to connect BMS (Bridge Management Systems) with existing BIM solutions, based on Open BIM standards. The complexity of maintenance/inspection requires organized, automated, open and transparent digital processes, which should consider both - structure and asset management data.

The BMS (Bridge Management System) aims to complete digital storage and exchange of data, cost as well as deterioration, optimization and analysis models and their interoperability with existing BIM solutions.

The vision includes 3D/4D/5D/6D software and hardware independent data exchange between different software technologies during life cycle and beyond, considering also monitoring, sensor equipment and damages on the structure along time axis. Open BIM technology for the interoperability from technical, semantic and organizational point of view is of main interest. (IABSE, 2023)

The Scope & Limitation of the group is:

As template for further structures only bridges will be focused.

Conceptually the connection of BIM model to BMS and vice versa should be focused. Therefore the existing documents, researches and current open BIM standard capability will be used.

Existing software solutions and BMS providers should be invited to present their possible consideration resp. realization of BMS connection in their established BIM workflows and BIM viewers.

The final goal is the IDM (Information Delivery Manual) – explaining how to connect BIM model with BMS and vice versa – in form of SED. (IABSE, 2023)

2 INPUT FROM THE INDUSTRY

2.1 *Bridge asset owners input*

To progress the research being undertaken by Task Group 5.6, input was required from bridge asset owners and operators across the world. It is important to understand the current situation worldwide, with the outcomes to be reported and inform further research and development. This will help to understand current operations, requirements and expectations. Ultimately it will help to develop a common standardized structure to exchange data between different systems, putting bridge asset owners in control to influence the process.

2.2 *Survey*

Task Group 5.6 developed a bridge asset owner survey in late 2022 into early 2023. To assist in achieve the goals of the project, the survey covered the following areas and asked the following questions:

- Introductory questions – covering how assets are managed?
  - How often do you have periodical inspections of your bridges?
  - Are these performed by your organization or is someone from outside hired to do this?

- How are data from inspection and maintenance and other information about the structure stored?
- How do you reference findings to the structure? Are you e.g., using a structured approach with unique IDs and standardized characterizations? Do you reference drawings or BrIM models?
- How is your budget for inspection and maintenance decided and how do you prioritize within this budget?
- Is your organization interested in BrIM and or BIM?

- General questions – covering how changes are identified, recorded, and managed?
  - How do you handle these changes today?
  - What is your system to prioritize repairs?
  - How do you arrive at the decision to restrict usage of a bridge?
  - Are all bridges/assets in your network stored in one common database, or is it fragmented to many systems?
  - Is all information split up in database format, or is your BMS appended with text files?
  - Do you have projects or cooperations with academia or software providers on improving your bridge information modeling, if so, what is your roadmap?
  - Access control could be important in some cases, e.g., to limit access to different types of information. Is this a feature that will be mandatory for you in the future?
  - How is your approach today for rating your current asset value and managing maintenance priorities?
  - How do you wish this process was?
  - Which factors need be considered or included in this process?
  - How do you ensure that the information in your asset management is correct?

- Visualization – covering asset data.
  - What type of visualization do you consider useful for you? This could be projection of damage onto the structure, tabulations of development of damage with time, or other information.
  - Could you expand on how you do this today, and identify features you wish to be available?
  - Which level of detail of damage description seems reasonable to you?
  - Based on your experience, could you elaborate on how important it is that that the dataset, model and visualization contain up-to-date information?
  - What would be an acceptable updating period?
  - What level of visualization detail do you think is minimum needed, and what level is optimum?
  - For which structural parts do you desire geometrical details of degradation (e.g., loss of effective concrete cover or loss of cross-section of rebars), and for which structural parts would a color code of degradation suffice (e.g., effectiveness of drainage, water circulation)?
  - What plans do you have to utilize this feature in your asset management system in the short and long term?
  - How do you store inventory data today?
  - Are foundation properties included in your models today (e.g., observations of settlement, scouring etc.)?

- Round-up Questions – covering asset systems.
  - What three key features will your perfect asset management system have, and how often will you use these features?
  - What nice-to have features do you wish were easily available from your dataset of current bridges?
  - What is your personal view of the hierarchy between BrIM and BMS? I.e., which one is the user front end and which the axillary data base in the background?

In February 2023, Task Group 5.6 circulated the survey to bridge asset owners across the world seeking their input into this important initiative.

3 SURVEY RESULTS – AUSTRALIA AND NEW ZEALAND

This paper will focus on the responses from bridge owners across Australia and New Zealand

3.1 *Survey participants*

The survey was sent to all government road and transportation authorities across Australia and New Zealand as they are responsible for a large proportion of road bridges across the two countries. The following organizations generously gave of their time to complete the survey:

- New Zealand Transport Authority (NZTA) – Waka Kotahi
- Main Roads Western Australia (MRWA)
- Department of Infrastructure and Transport (DIT), South Australia
- Department of State Growth (DSG), Tasmania
- Department of Infrastructure, Planning and Logistics (DIPL), Northern Territory

3.2 *Survey results*

The following sections outlines the key aspects of the responses to the survey from the survey participants in Australia and New Zealand.

3.2.1 *Bridge inspections, data, and BIM*

There was significant alignment between the respondents regarding bridges inspections and data. Regarding inspections, all have set frequencies for their bridge inspections although there is some variability in the timeframes as can be seen in Figure 1 below. The difference is timeframe is mostly driven by risk with older structures and those in poor condition having a shorter timeframe than newer structures, in good condition and good capacity. Inspections are undertaken by a mix of internal and external resources.

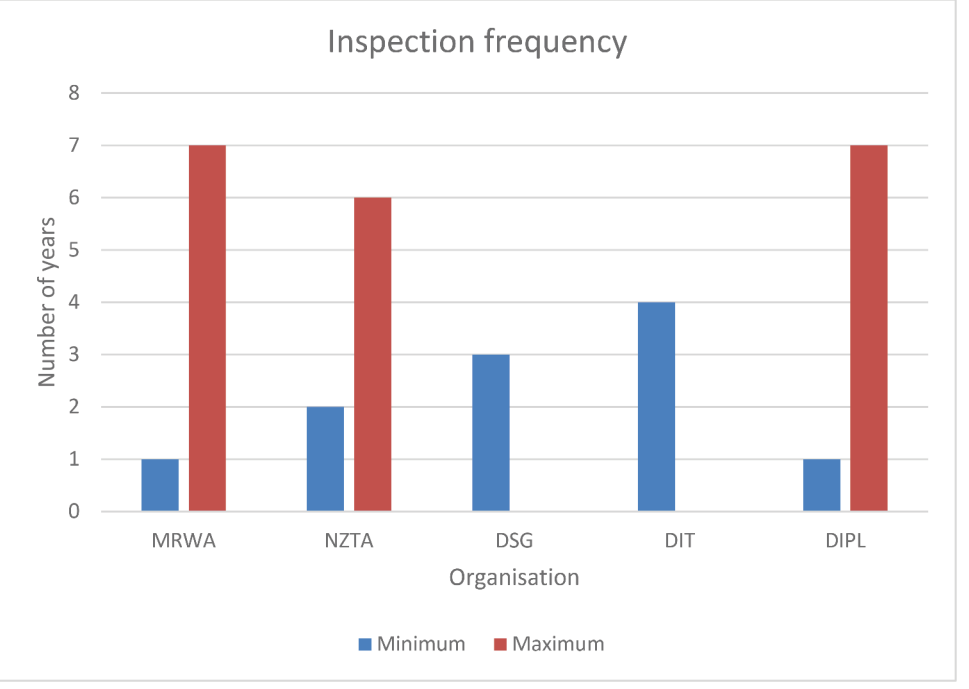

Figure 1. Bridge inspection frequency.

The data obtained for bridges and related structures is generally contained within a bridge or asset management system which has been specifically developed for each bridge owner. Overall, they all have individual asset identification for their structures electronically and/or physically on-site represented with an identification plate or similar marking. The data obtained from inspections is used to assist with the prioritization of works with all respondents acknowledging budgets are tight.

Overall, there is a very low uptake with BIM with all focused-on asset systems or BMS. There is some interest in adopting BIM in the future although the responses seem to indicate pessimism regarding its benefits.

3.2.2 *Bridge management*

Overall, there was also a significant amount of alignment on the management of bridges and data and systems supporting it. From a systems perspective, all are using a BMS to capture data on their bridges and related structures. In general, these systems have been developed specifically for the bridge owner. The data contained within the BMS is a mixture of formats depending on the dataset. Inventory information is held in basic, transferable format within the BMS but other aspects like reports and photos are saved in different formats.

The quality of data in the BMS is controlled in three main ways. Firstly, access is generally restricted to those within the organization and those external that have approval to use. The other two ways are related to the verification of the data contained in the BMS. Verification is often undertaken at the source of creation, i.e., the inspection report quality reviewed before being finalised. The other main approach was auditing within the system based on standards set by the bridge owner.

The use of data within the BMS was consistent within the responses received. The prioritization of funding and remedial works was often based on the most severe defects but also had an overlay of risk. The action of restricting bridge usage was in general based on the full assessment of all data to hand. The data required, as indicated by the respondents included:

- Damage extent,
- Cost of repair,
- Safety,
- Condition rating,
- Probability of failure,
- Level of Service,
- Legal,
- Risk,
- Environmental,
- Whole of Life Cost,
- Heavy vehicle usage, and
- Sustainability

The outcome of the assessment would require higher level approval due to the level of risk.

The valuation of structures was an area where there were some differences across the respondents with numerous different approaches. Some respondents had systems specifically for valuations, some utilize financial tools, others use overall bridge ratings and some it is a simple written assessment. Overall, there was agreement on the desire to have an automated way to conduct bridge valuations utilizing data within their system.

3.2.3 *Visualization*

Throughout this section of the survey there was strong alignment between the respondents in most areas. If they were to adopt BIM, the bridge owners wanted to have the following details:

- Damage overlay,
- Key Performance Indicators,
- Historical information on damage,

- Details on works programs including repairs undertaken,
- Material data for the structure,
- Geospatial information,
- Inspection data,
- Drawings,
- Photos, and
- Bridge Rating Index.

On the visualization of the data provided in the BIM most favored photos and inspection reports with some being open to schematic and simplified system data. The optimal solution though would be a combination of photo representation with as-built details. The respondents were all aligned with wanting details of degradation for all components, but all had minimal/incomplete data on foundations for their structures. Regarding the data kept in the BIM, most saw the updating of the data as critical with some of medium importance. The preference was for updating every 6-12 months but that depends on the level/risk for the structure.

At the time of the survey all respondents favored using a BMS over BIM with only some having interest or plans to further explore BIM. The features desired in their perfect BMS include:

- Quick/easy to find information,
- Easy upload of data,
- Automated,
- GIS referencing,
- Include all asset data include inspection records,
- Program management functionality,
- Risk and criticality,
- Load capacity,
- Status bar or dashboard for individual structures and the overall network,
- Tracking against Level of Service, and
- Backlog reporting.

4 CONCLUSION

Australia and New Zealand are facing significant challenges in the management of their road bridge infrastructure. The transportation of freight is critical for their economies, but their bridge stock is ageing and built to outdated standards. To continue to support the community and growth in their economy they need to seek ways to improve the way they manage their structures, and the utilization of BIM is one possible avenue.

The adoption of BIM is limited in Australia and New Zealand based on the responses to the survey. There is some interest, but all are focused on the management of their structures using a BMS. There appears to be a level of skepticism around the benefits of BIM. Some have used BIM for large bridge construction projects but not in the management of the lifecycle of an asset. Based on the responses this appears to be in part due to the lack of understanding of BIM and how it would complement their existing BMS. Also, based on the comments to the survey, there is concern that the level of investment in BIM would not be returned by the benefits of adopting it.

For BIM to be adopted across Australia and New Zealand a greater understanding of what BIM is and its benefits is required. An outline of the return on investment is required as it could take a significant investment of both time and resources to implement such as system. It would also require bridge owners to move away from familiar systems that mostly suit their current requirements.

ACKNOWLEDGEMENTS

I would like to acknowledge the following:

- IABSE Task Group 5.6 Chair Vanja Samec and the members of the Task Group for their contribution to the survey and collation of results.
- The bridge asset owners that generously gave their time to respond to the survey.
- Asanka de Silva, National Transport Research Organisation for his assistance in the collation and review of survey results for Australia and New Zealand.

BIM-data of baseline digital twins for a new bridge maintenance system

C.S. Shim, G.T. Roh, D.H. Kang & J.W. Park
Chung-Ang University, Seoul, South Korea

ABSTRACT: With the growing deterioration of bridge structures in traffic networks, there is an urgent need for a reliable method to assess and predict bridge performance using diverse data sources. Building Information Modeling (BIM), currently being implemented in new construction projects, holds promise for providing crucial information to establish a maintenance baseline model by collecting and consolidating data from design to construction phases. However, the maintenance of existing bridges is hindered by a reliance on document-oriented information and the lack of effective integration of individual data within current bridge management systems (BMS) and information systems for inspection and repair records. To overcome these limitations, this paper aims to define key management factors and deliver a baseline digital twin model at the completion stage for maintaining existing girder-bridges. Additionally, inspection and maintenance history data generated during the maintenance stage are incorporated into the digital twin model. The paper presents the definition of BIM data for constructing a baseline digital twin specifically for common types of girder-bridges and demonstrates its functional implementation. A data-driven information delivery is presented for a typical prestressed concrete girder bridge. The effectiveness of the proposed approach is evaluated through actual examples of existing bridges.

1 INTRODUCTION

The increasing proportion of aging bridge structures emphasizes the urgent need for an appropriate maintenance plan and reliable method to assess and predict bridge performance using diverse data sources. Building Information Modeling (BIM), currently being implemented in new construction projects, holds promise for providing crucial information to establish a maintenance baseline model by collecting and consolidating data from design to construction phases. However, the maintenance of existing bridges is hindered by a reliance on document-oriented information and the lack of effective integration of individual data within current bridge management systems (BMS) and information systems for inspection and repair records. A system based on the concept of digital twins, which involves expanding this idea to introduce 3D models and related data into maintenance management systems, has been proposed (Jeon et al. 2023). In this process, a high-reliability, integrated data-driven information delivery system is required from design to operation [2]. To progress from the member-level data through the entire life cycle of a bridge using the data-driven system, a data management regime and optimization process are required. Data becomes the minimum unit of information required for business units and each stage, and utilizing this, digital models and updates in various aspects are carried out.

To overcome and satisfy these limitations and requirements, this paper aims to define key management factors and deliver a baseline digital twin model at the completion stage for maintaining existing girder-bridges from member unit to bridge system. Additionally, inspection and maintenance history data generated during the maintenance stage are incorporated

DOI: 10.1201/9781003483755-238

into the digital twin model. The paper presents the definition of BIM data for constructing a baseline digital twin specifically for common types of girder-bridges and demonstrates its functional implementation. A data-driven information delivery is presented for a typical pre-stressed concrete girder bridge. The effectiveness of the proposed approach is evaluated through actual examples of existing bridges.

2 DEFINITION OF DATA

The scope of BIM data extends from the member level that makes up the bridge to the system level. Depending on the life-cycle of the bridge, the data is segmented by a member, and accordingly, updates or exchanges of each piece of information take place. For flexible information exchange and optimization, it is essential to structure key information at each stage. And, to effectively utilize standardized data, pre-agreed data definitions between designers, fabricators, and assemblers must allow for seamless information exchange. The data for components is broadly categorized into geometry, material, performance, and external conditions (alignment, climatic conditions, fabrication, and construction-related schedules, etc.). Each piece of information is interlinked and dependent on data from the planning or design stages onward. Once such a system and procedures are established, the optimization of the data system occurs, ultimately enabling the utilization of accumulated data in the stages of sharing and maintenance. This leads to the establishment of a Digital Twin Model system for evaluation and prediction. Figure 1 illustrates the data flow of prestressed girders and the corresponding BIM model updated by this information.

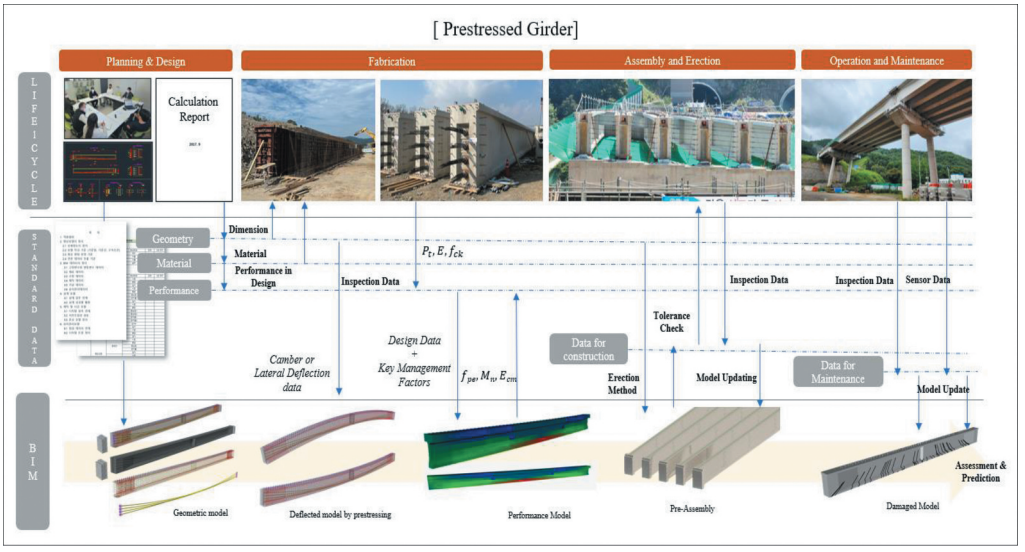

Figure 1. Data and model updating flow during the life-cycle of the prestressed girder.

The Digital Engineering Model, defined by applying data at each stage from the existing 3D geometric model, allows for a comprehensive examination of Design for Manufacture and Assembly (DfMA). This involves performance evaluation at the member level, consideration of information updates during fabrication and assembly stages, and application and evaluation in the design phase, all through the utilization of data and models. Additionally, it enables advanced checking of assembly for connection joints through pre-assembly simulation

of precast or prefabrication components, facilitating the early identification of assembly collisions. Once a system is established through data and data-based Digital Engineering Models (DEM) from the assembly stage to the as-built phase, the entire process's information and framework are managed as a baseline digital twin.

The baseline digital twin model is bifurcated into two branches for structural assessment during the operation and maintenance stages. Integrated information from these branches is utilized for evaluation and prediction. One branch comprises member force-related information for assessing the performance of components or bridges, while the other involves condition assessment by inputting or managing inspection data via the bridge maintenance management system.

To assess the strength and condition of structures, key management factors at the component level are necessary from the design stage. For instance, in the case of a girder bridge, structural components include girders and deck plates in the superstructure, and piers and abutments in the substructure. Updates for each component's key factors are based on information entered throughout the lifecycle. In the case of prestressed girders, during the design phase, factors such as geometric dimension section, concrete compressive strength, prestress material, and tension force are determined based on specifications for bending and shear strength. In the fabrication and as-built stages, actual values obtained from material tests, such as concrete compressive strength and elastic modulus related to the properties of materials, and the actual tension force specified in the tension report may differ from the design values, leading to inevitable variations in component strength.

Additionally, for prestressed concrete members, it is necessary to include data elements representing behaviors with time-dependent characteristics, such as relaxation, creep, and shrinkage, to accurately evaluate the performance of the structural member. However, determining precise values for these variables is challenging. Therefore, a stepwise management approach is adopted, using deflection values of members or strain data through sensors as indirect data. To achieve this, factor settings for component strength assessment are required, and these factors are continuously updated based on the input data. For prestressed girders, proposed key management factors include effective prestress stress (f_{ps}) and concrete elastic modulus (E_{cm}). The information input and updated throughout the lifecycle of the prestressed girder are presented in Table 1.

Ultimately, to assess the bridge system after the As-built stage, a system-level analytical model consisting of key factors of components is constructed. Based on data from field load tests conducted on the actual bridge, the lateral load distribution ratio is updated. Subsequently, a system is established to evaluate the member forces using standardized inputs in the common domain.

Table 1. Data definition for prestressed girder during its life-cycle

	Geometry Data	Material	Schedule(Date)	External Condition	Performance
Design	Dimension	F_{ck}, E_{cm}, f_{ps}, E_s	-	Bridge Alignment Humidity Temperature	M_{n_design} V_{n_design}
Fabrication	Deflection	F_{cm}, E_{cm}, $f_{first\ tension}$	Concrete casting(Date) 1st Prestressing(Date)	Humidity Temperature	$M_{n_fabrication}$ $V_{n_fabrication}$
Assembly	Deflection Inspection Data	F_{cm}, E_{cm}, $f_{second\ tension}$	Erection(Date) Deck(Date) 2st Prestressing(Date) Continuous(Date) Superimposed(Date)	Relative Location Humidity Temperature Support Condition	$M_{n_assembly}$ $V_{n_assembly}$

3 BRIDGE MANAGEMENT SYSTEM

When data, including design stage to construction stage information for each structural component of a bridge, is transferred to the Bridge Management System (BMS), maintenance procedures based on Building Information Modeling (BIM) are implemented in earnest. Periodically conducted public damage assessments and records of restoration are documented through various methods such as data, images, 2D inspection drawings, etc. This information is loaded or mapped onto the maintenance system, and it is visualized as shown in Figure 2. Damage information is typically mapped on a face-unit basis on the drawing of the structure and managed. However, the existing mapping approach, where image storage is designated as the management unit at the face-unit level, imposes challenges regarding storage space for the entity responsible for structure management. Damage information is managed as data before the mapping input stage, and since this data allows for individualized progress verification through shape modeling or numerical visualization methods, management through damage vectorization is possible rather than using the conventional mapping approach (Shim et al. 2019).

A sophisticated code system tailored for assessing bridge damages streamlines the automated compilation and quantification of defect data. Utilizing diverse image sources obtained from Unmanned Aerial Vehicles (UAVs) and Ground Penetrating Radar (GPR), in conjunction with damage maps, various image mapping techniques were employed with distinct approaches to visually represent the scrutinized data (Shim et al. 2019). The amassed inspection data and damage records for each bridge component can be systematically gathered, providing a robust foundation for informed decision-making. By harnessing federated data, digital twin models can be meticulously crafted for both individual bridge members and entire bridges (Jeon et al. 2024). These digital twin models, rooted in accumulated data, can effectively manage key performance indicators, enhancing the overall monitoring and assessment of bridge integrity.

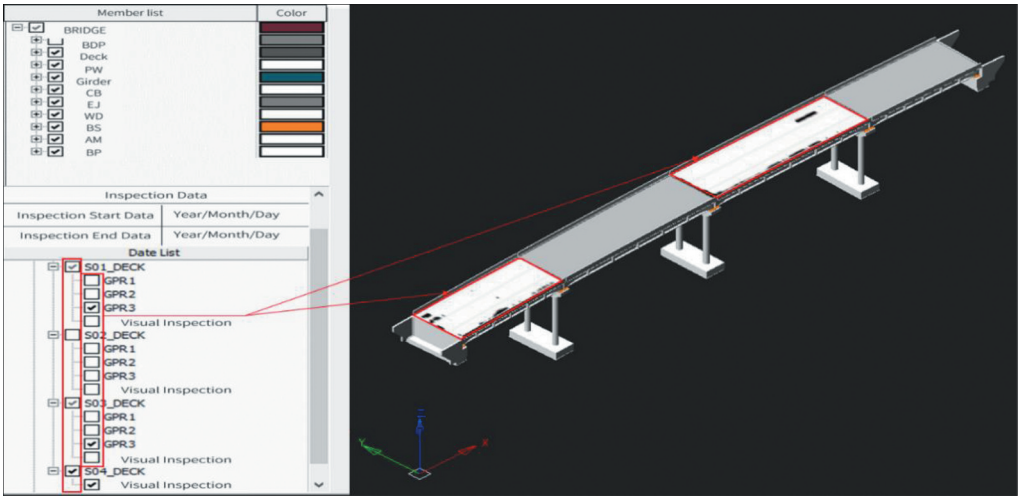

Figure 2. The bridge digital model with mapped damage information in BMS.

4 IMPREMENTATION TO A PRESTRESSED BRIDGE

4.1 *Prestressed concrete girder bridge*

The baseline digital twin concept is currently being applied to an expressway bridge in Korea. The bridge is comprised of prestressed concrete (PSC) girders with span lengths of 35m and 50m. In Figure 3, the bridge layout and the girders before erection on the shoe are illustrated. Steel lateral crossbeams and full-depth precast decks are assembled alongside the PSC girders.

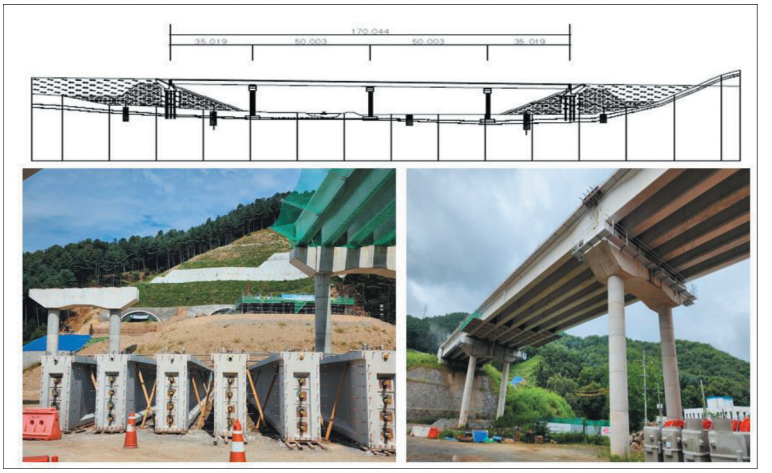

Figure 3. A prefabricated PSC bridge for implementation (In Korea).

In this project, we estimated the displacement of girders during the manufacturing phase through camber measurements. Utilizing the DEM, we predicted the deformations of girders based on camber measurement data over time and construction schedules, estimating concrete elasticity and initial prestress stress. These data can be collected by a common data environment (CDE) in a construction project. Figure 4 illustrates values related to the determination procedure of concrete elasticity and prestress stress after the first tensioning. The initial input concrete elasticity of 33,980 MPa and the initial prestress after short-term losses, such as elastic shrinkage and friction, were 1144 MPa in design phase, showing a significant difference from the values after actual tensioning. These results highlight the dependency of deformations on prestress and concrete properties as well as external influences, with key factors varying among girders within the same span. To construct a baseline digital twin model for the bridge, accurate assessments of material properties from production to hypothesis, and understanding the internal stresses, strengths, and stiffness of the actual components through updates, are essential.

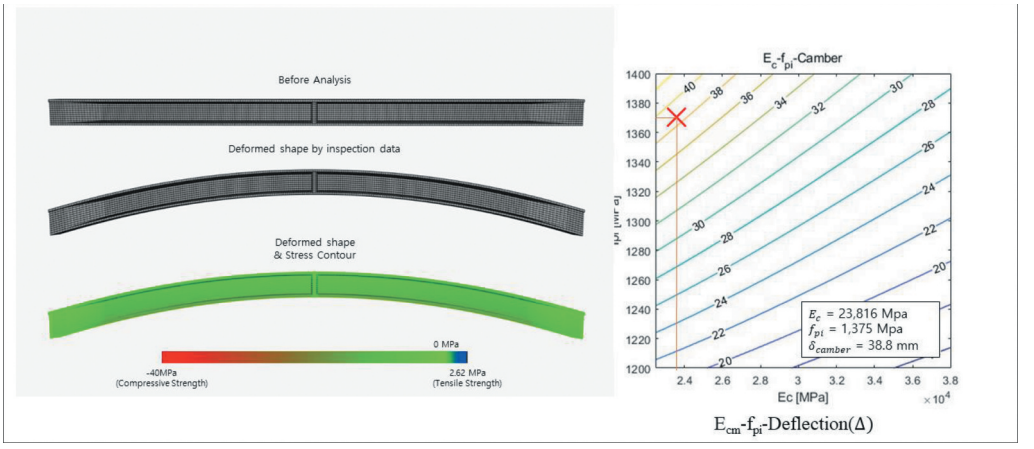

Figure 4. Key management factor of prestressed girder calculated from camber data.

5 CONCLUSION

As the number of aging bridges and the resulting cost of repairs continue to increase, the need for effective maintenance and performance evaluation becomes increasingly important. This

paper contributes to addressing these challenges by proposing a comprehensive definition of Building Information Modeling (BIM) data, establishing the foundation for generating baseline digital twins tailored to the maintenance requirements of common girder-bridges. The significance of a standardized data delivery system for bridges is underscored, particularly emphasizing the critical role of actual data during fabrication and assembly phases to ensure the reliability of baseline models and their as-built data at handover.

Three key points emerge as pivotal in advancing the efficacy of digitalized information delivery in bridge maintenance:

1) Recognizing the pivotal role of consistent data delivery between construction phases, this study emphasizes the necessity for a standardized approach. Notably, the inclusion of actual data during the fabrication and assembly phases is highlighted as crucial for establishing a dependable baseline model and ensuring accurate as-built data during handover.
2) The identification and selection of key indicators emerge as a critical aspect in evaluating the key performance of bridge members. Structural simulations for various scenarios are recommended as a means to comprehensively represent these indicators, providing insights into the diverse conditions and challenges that a bridge may encounter throughout its service life.
3) To facilitate effective data collection from construction projects, the establishment of a collaborative system, such as a Common Data Environment (CDE), is proposed. This collaborative framework can streamline data sharing and communication, fostering a cohesive approach to data collection from various stakeholders involved in the construction process.

In conclusion, the proposed framework not only establishes a robust basis for creating baseline digital twins for girder-bridges but also advocates for a standardized approach to data delivery, the selection of meaningful key indicators, and the implementation of collaborative systems for efficient data collection. These elements collectively contribute to an enhanced understanding of bridge performance and support informed decision-making in the realm of bridge maintenance.

Condition integration in BIM for existing bridges

M. Köhncke & S. Keßler
Chair of Engineering Materials and Building Preservation
Helmut-Schmidt-University/ University of the Federal Armed Forces Hamburg

ABSTRACT: Existing bridges are prone to different load action and exposure condition, which can alter their conditions and which could lead potentially to damages. Damages like cracks or spalling can affect the structures' durability and could reduce its service life. Consequently, Building Information Modelling (BIM) should continuously consider these changes in order to be able to assess the overall conditions of bridges or their components and to estimate their remaining service life at any point in time. Up to today, BIM is primarily a tool to supervise the design and construction phase and it requires further improvement to explore its potential for the operation phase of existing structures. A first step in this direction is the representation of damages in BIM, which ranges from linking photos or documents to fully integration of alphanumerical and geometric information. This contribution compiles and discusses the advantages and drawbacks of the existing approaches of damage integration in BIM and provides further guidance to use the knowledge on existing damages for the object-orientated damage analysis and the condition-based inspection planning.

1 INTRODUCTION

The administration of existing bridges is strongly depending on the information about the condition of the bridges. Currently, most information on existing bridges is still paper-based or in the form of scanned documents (Seitner et al. 2022). Even with Bridge Management Systems (BMS) only a part of the necessary bridge information is digitally available. This leads to a major issue for the progressing digitalization of administrations and authorities. While some information is partly machine-readable, it is often not machine-interpretable. Another advantage of digitalization is the accessibility of the information. Due to the long service life of bridges, exceeding 50 years, someone is not able to take care of one special bridge throughout its entire service life, from design to demolition. Changes in the responsible persons is necessary in bridge administration and these changes should not lead to loss of crucial bridge information. However, there is a risk of information loss over time, particular with paper-based documentation that underlies sometimes degradation due to poor storage conditions. Digital storage of the documentation seems to be less affected by these circumstances due to the smaller storage places needed for equivalent amount of information. Sometimes the documentation and further information on newer bridges are already stored in datacentres, which specialise in data storage and fulfil higher requirements on storage conditions. One approach connected with the digitalization is the method Building Information Modelling. The method BIM aims to overcome these issues by establishing one standard for the geometrical and alphanumerical representation of information of buildings in a centralized digital way. BIM is mostly used in the design and construction phase of buildings (Borrmann et al. 2021b). There are some approaches for the generation of BIM models for existing buildings, but these approaches are not widely used. These approaches often use optical methods like laser scanning or photogrammetry to set up a geometrical

DOI: 10.1201/9781003483755-239

model as a basis for a BIM model. This geometrical model will then be enriched with alpha-numerical information (Bednorz et al. 2020).

One challenge associated with this procedure is the representation of condition and other operation phase related information. For example, the geometrical model could show that some parts of a concrete beam are missing due to spalling, but the model itself lacks this awareness.

This contribution starts with a short overview of the use of BIM for bridges. Then some different approaches for damage representation are introduced followed by some use cases. Finally, a conclusion is drawn and a short outlook is given.

2 CURRENT USE OF BIM FOR BRIDGES

BIM aims to overcome the loss of information throughout the building lifecycle, which occurs during changes of the lifecycle phases and changes in stakeholders. These changes often lead to duplication of work because different software share no common interface or information gets distributed via PDF files and needs to be taken over manually to a different software (Borrmann et al. 2021b). BIM started in the design and construction phase in the building sector and slowly expanded to the infrastructure sector and other lifecycle phases. This expansion led to some gaps in use of BIM for bridges and especially in the operation phase. The transfer of BIM for existing buildings is still in progress and need development in different areas. This includes legal question who ownerships of the model after the design phase and organizational issues regarding how different stakeholder can work together without sharing the same software (Volk et al. 2014).

The standard data format for BIM is the Industry Foundation Classes (IFC), which determines the connection and storage of information (Borrmann et al. 2021a). The IFC-Bridge standard was one big step forward to the use of BIM in infrastructure, especially for bridges. However, the implementation of the standard in common BIM related software is still in progress. Nevertheless, there are already use cases for BIM for existing bridges. Besides the generation of as-built BIM models (Bednorz et al. 2020) there are approaches for the use of BIM models in bridge inspections (Hill et al. 2022) or for the support of Structural Health Monitoring (SHM) (Li et al. 2022). This contribution focuses on use cases of object-orientated damage analysis and the condition-based inspection planning. The execution of these use cases needs further information on the bridge's condition. Various approaches for representing conditions and damages will be presented in the following section.

3 APPROACHES FOR CONDITION AND DAMAGE REPRESENTATION

The needed information for the representation of conditions and damages highly depends on the use cases. In the context of BIM, this concept is named Level of Information Need (LOIN). It serves as an alternative draft to the Level of Development (LoD), which generalizes levels from the initial design stages to the as-built BIM model, which contains all the information on how the building was actually built. Apart from the general information necessary across use cases, like bridge number, span, construction type, construction year and current condition rating there are further information on the bridge depending on the construction type, which are useful for the administration of bridges. This information can be supplemented with information on the condition derived from inspections and tests.

According to the German standard for engineering structures in connection with roads, this information is usually stored in documents like the structure file and the inspection report (Bundesministerium für Verkehr, Bau und Stadtentwicklung 2004). Often, these documents are paper-based and partially digitalized for example in the database "SIB-Bauwerke". The storage of this information in BIM requires concepts for the representation of condition and damage information. Further requirements for the documentation of inspections of engineering structures are given in the German standard for maintenance of engineering structures

(Bundesministerium für Verkehr und digitale Infrastruktur 2017). This standard defines all necessary information, which need to be included in an inspection report. These are the main building part or construction part, which define the part the damage is assigned to. The damage description includes quantification of the damage and the assessment in the categories of durability, stability, and road safety on a scale from 1 to 4. Furthermore, the damage must be assigned to a suitable damage example and a statement is made whether the damage requires inspection in every visual inspection, even annually. Optional information may include the amount of the damage with dimensions, specific location relative to the building part, changes observed in the damage over time, and photos or sketches of the damage. Some of this information are inherent in the position of a damage in a digital representation for example, the main building part or the quantification of the damage in the geometrical parameters. Others need to be included separately in the representation via alpha-numerical attributes. For example, a beam gets the following attributes with the given values. The crack attributes are in alignment with the damage examples with the annex of German standard for maintenance of engineering structures (Bundesministerium für Verkehr und digitale Infrastruktur 2017).

Table 1. Example alpha-numerical attributes of a crack.

attribute	value
crack	yes
GUID	936DA01F-9ABD-4D9D-80C7-02AF85C822A7
crack_lenght [mm]	150
crack_width [mm]	5
crack_wet	yes
damage_example	025-08
frequent_inspection	yes
crack_location	3m from pillar 3, direction east
crack_type	transverse crack
assessment_stability	0
assessment_durability	3
assessment_road_safety	0

These attributes are machine-readable and compatible with different software. The disadvantage with this approach is the unclear description of the crack's position, which could lead to misjudgement of severity or traceability. The Globally Unique Identifier (GUID) is an attribute that allows the distinction between different building parts, which have the same attributes but are located in different locations. Every building part or BIM model element should have a GUID to give it a unique name for identification purposes.

Additional, these attributes can be extended with links to photos or sketches of the damages to give the person in charge of the structure a visual impression of the damage. This visual impression is easily implemented and offers the possibility to compare the damage over time. However, this approach lacks machine-readability of the information.

Another opportunity is the representation via geometrical or optical information. This approach depends on the method for the capturing of the optical or geometrical information. For example, a laser scan only contains points in a coordinate system based on distance measurements without further information regarding the association of a point with a specific building part. Currently there are research projects attempting to automate the segmentation of point clouds (Morgenstern und Raupach 2022). Especially for cracks, the missing measurement of depth is an issue. A different optical representation is the integration of photos from photogrammetry onto the surface of the building parts. This step goes beyond simply linking a photo, offering the opportunity to capture the condition of a whole structure at once. However, similar to linked photos, the information is visually interpretable for humans but not

machine-interpretable. First approaches on damage classification through deep learning are promisingly (Rodrigues et al. 2022). These approaches should not be seen as isolation, they can also be combined to achieve the desired result. Nevertheless, the damage representation enables further digitalization, illustrated through two use cases.

4 USE CASES FOR DAMAGE REPRESENTATION

One typical use case for damage representation is the conduction of further investigations of a damage known as object orientated damage analysis. The guideline for the object-orientated damage analysis in Germany outlines different necessary information during the conduction. For example, a textual description of damages should be supplemented with sketches. This underscores the need for a combination of alpha-numerical and geometrical information in the damage representation. Especially, the damage location is crucial for the assessment of a damage due to the variation of loads and resistance with position (McGuire et al. 2016). The current paper-based documentation of damage locations lacks the opportunity for quick further processing in different software or partial automation.

One result of an object-orientated damage analysis or the derived measurements could be the change of building information. Due to the current use of different software and databases in administration of existing bridges, repeated input of the same information is unavoidable throughout the entire process chain. A BIM based approach has the advantage that this change can be made in the same software environment. Therefore, the transmission or the repeated input in another software is not necessary. Even the integration of the results of an object-orientated damage analysis in BIM is an option. This allows for the centralization of not only the condition but also the assessment, streamlining the work of the responsible person.

Like the object-orientated damage analysis, the planning of condition-based inspections also requires detailed information on damage location and damage properties. The consideration of different damages with information on the different locations on the bridge enables a consolidated assessment. Therefore, up-to-date information on the main parameters of a bridge and environmental conditions is required. This information can be obtained by structural health monitoring (SHM) systems. Changes in the monitored parameters reaching a defined threshold can then trigger an alarm and the planning of a condition-based inspection. The exemplary integration of sensor data from an accelerometer in BIM via a GUID of the sensor is shown in Figure 1.

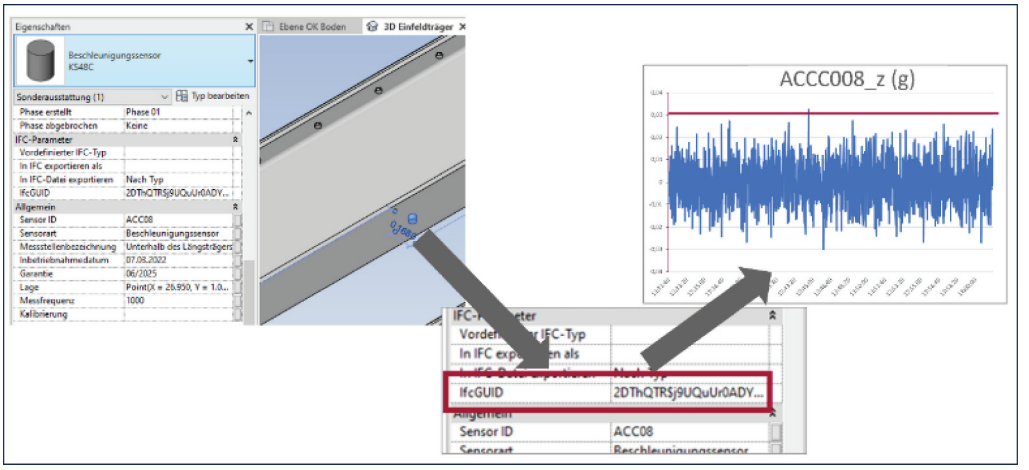

Figure 1. Integration of sensor data in BIM.

The planning of condition-based inspections could also benefit from BIM. For example, the central provision of condition information e.g. interpreted sensor data, connected with a representation of the damages in a BIM model, could simplify the selection of suitable non-destructive testing methods and necessary devices for inspection. The connection between SHM and BIM could facilitate the use of condition-based inspection. Unfortunately, the guidelines in Germany need to be adjusted to the new possibilities in inspection. Until this point, the advantages of condition-based inspection over time-based inspection cannot be fully realized.

5 DISCUSSION AND ANALYSIS

The increase in service life necessitates higher requirements in the availability and durability of the necessary structural information. The digital representation of condition information in BIM seems promising. The introduced approaches have different advantages and disadvantages concerning the practicability and the opportunity for further processing. Often, the practicability comes with a decrease in the possible automation. For example, the first mentioned approach, involving the sole integration of alpha-numerical attributes into building parts is easily done within the modelling software for BIM. On the upside, these attributes are machine readable, so this information can be transferred to other software with less effort and enabling further processing for tasks such as evaluating which category is rated worst for a particular damage. However, on the downside, these attributes are not machine interpretable which means that a software does not recognize the semantic information about the damage, only that a damaged building part differs from a non-damaged one. . Semantic information can be included in the geometric representation of a damage in IFC, but the geometric modelling of each damage is time-consuming. However, it offers the possibility that algorithms can use this information for sophisticated assessments of whole structures. Photos, like attributes in the building parts, can be read by machines but not interpreted correctly. It does not matter whether the photo is linked to a building part or assigned to its surface, further processing like labelling of damages and assigning photos to building parts is necessary until robust deep learning algorithms are included in the administration software and the labelling and assignment is automated. Until then, the required effort for digital representation should always be considered in the context of use cases and anticipated benefits.

6 CONCLUSION AND OUTLOOK

Depending on the use case, different approaches for the integration of condition and damage information are appropriate. For example, the integration of the condition rating of a structural component could easily be accomplished using an attribute. While the integration of damages like spalling requires a geometric representation for the estimation of the quantity for the repair measure. The condition and damage information integration in BIM could lead to progress in the digitalization of the administration of existing bridges, thereby, to a simplification and an increase in the administration efficiency. There are two key advantages in times of decreasing financial and personnel resources in the administration of infrastructure.

The current development in the generation of as-is-BIM models, together with the integration of SHM and the renewal of the guidelines and standards, could also enable the change to more condition-based inspection. The condition-based inspection approach could lead to a better allocation of resources for the maintenance and inspection of existing bridges than time-based inspections.

Cloud-based asset management for image-based inspections of infrastructures

G. Morgenthal & M. von Butler-Helmrich
Institute of Structural Engineering, Bauhaus-Universität Weimar, Weimar, Germany

ABSTRACT: The continuous safety and performance of infrastructures is of particular importance for a modern society. Demands for resource efficiency in the construction sector will require significantly longer service lives for structures in the future. New digital maintenance strategies can make this goal achievable. To realize the full potential of such digital maintenance strategies, asset management systems need to incorporate a heterogeneous and linked set of data and information such as condition data, digital models of the geometry and damage characteristics. At the same time, all available data and information must be easily accessible for decision makers to evaluate the current state of the structures and derive maintenance actions from it. This paper presents a cloud-based asset management platform that incorporates digital twin models obtained from automated image-based inspection and damage detection methods, enabling predictive maintenance based on permanent storage and tracking of highly accurate information about the location and extent of damage.

1 INTRODUCTION

In a modern society, the continuous availability and performance of infrastructure systems is of fundamental importance for quality of life, as they fulfill important supply functions and ensure the mobility of the population. Furthermore, demands for resource efficiency in the construction sector will require significantly longer service lives for structures in the future in the interests of conserving resources. At the same time, the time required for inspection and retrofitting measures should be minimized, as should the overall cost of maintaining the structures.

However, the current status quo for inspections are time-consuming and costly manual visual inspections that follow guidelines and regulations defined by each country or infrastructure owner. The results of these inspections, e.g. identified damage entities, are documented in a descriptive manner in bridge management systems, such that condition indices are derived and the planning of maintenance actions is enabled. While these regulations differ among others by the inspection intervals, the rating of individual damages, the method used for obtaining the overall condition index, and the components of the bridge management system (for an overview see for example ARCHES 2009, ASCAM 2012 and Chase et al. 2016), they all have in common a relatively high degree of subjectivity as shown by Bennetts et al. (2021). Further, a spatially accurate tracking of damage propagation over time is hardly achievable. Studies (Naraniecki & Marx 2019) on the robustness of condition indices show that the information value of these indices is limited and that the condition rating trends can vary considerably, even for similar structures.

A great potential for optimizing the inspection results derives from high-quality digital data on the structural condition, which enable a density of information for condition assessment that significantly exceeds the results of conventional structural inspections. Furthermore, Morgenthal et al. (2022) have shown that life cycle concepts based on multidimensional performance indices for a predictive maintenance can only be realistically implemented on the basis of digital data. The fundamental objective of digitized structural maintenance must therefore be a condition assessment that accounts for all relevant degradation processes of a structure by

DOI: 10.1201/9781003483755-240

(1) recording the current condition as accurately as possible, i.e. changes, especially damages, are reliably detected and characterized by location and damage extent,
(2) ensuring a close temporal monitoring of the damage development, and
(3) deriving quantitative evaluations on the condition of the structure or parts of the structure, aggregated from individual damages.

Digital methods, which can also be used in a complementary manner (see for example Simon et al. 2022), primarily include the already established technologies of continuous sensor-based monitoring as well as imaging methods. For the application of imaging techniques in structural condition assessment the authors have developed a scientific methodological framework (Morgenthal et al. 2019). The geometrically referenced linking of all data occurring in the process chain described there and the condition information extracted from it is based on the concept of a digital twin of the structure. The geometrical model of the structure is obtained by a high-resolution 3D reconstruction from the image data through photogrammetry, and with the INFRA//TWIN platform (INFRALYTICA 2023) a cloud-based software implementation with a high-performance web front end is available, which can be used for a related structure management.

This paper discusses the steps and requirements needed to generate digital twins of infrastructures that link highly accurate and detailed geo-referenced 3D building models with damage data that can be automatically generated using artificial neural networks or entered through manual inspections on the virtual model. Further, case studies are presented of projects where highly heterogeneous data sets of image-based inspections are integrated into the cloud-based asset management platform.

2 FROM IMAGES TO DIGITAL TWIN MODELS – BEST PRACTICE AND REQUIREMENTS

2.1 *Image data acquisition*

Various options are available for the acquisition of image data. Figure 1 shows examples of manual recording and the use of camera arrays and unmanned aerial systems (UAS or "drones") for (semi) automated data acquisition.

Figure 1. Examples of data acquisition techniques for generating image data (left: manual data acquisition, center: semi-automated data acquisition with customized camera array, right: automated data acquisition with UAS along pre-generated flight paths).

The use of image data for a structural condition assessment requires reliable detection of damage in the images, such that a minimum image quality (sufficiently low-noise, depth- and motion-focused as well as high-resolution) must be achieved. The limits of what can still be recognized in the image result from various factors, such as

- the physical relationships of the camera technology (object resolution or GSD)
- the acquisition conditions (wind, direct or indirect sun light, etc.),

- the relative camera orientation w.r.t. the surface of the structure, and
- the methods used for the image post-processing.

Furthermore, a systematic overlap of the images is required in addition to the minimum image quality to facilitate a photogrammetric 3D reconstruction to obtain a georeferenced 3D model of the structure (see Section 2.2). In this case an automated acquisition with pre-planned acquisition positions should be preferred to a manual acquisition. This can be done in different levels of detail according to the area-related required resolution as presented by Debus & Rodehorst 2021.

2.2 *Creation of linked digital models*

The transformation of the information contained in the acquired 2D image data into linked, digital 3D models, which can be used for the assessment of the structural condition of the structure, essentially requires three steps that run in parallel, each using intermediate results from the other processes: the photogrammetric reconstruction and georeferencing, the damage detection and classification in the images, and the linking of the data.

In order to create a common reference system and thus to be able to link all data later in a location-related manner, a 3D model is generated from the images by means of photogrammetric reconstruction. For structural inspection purposes, the structure-from-motion algorithm according to Schonberger & Frahm (2016) is usually applied. In this step, it is also important to georeference the reconstructed models. For this purpose, fixed points, which are clearly recognizable in the images, must be surveyed by tachymetry during the data acquisition. Besides ensuring the representation of the existing (as-built) geometry of the structure, the georeferencing provides a uniform coordinate system (e.g. national coordinate system or a local, project-related coordinate system) so that the following aspects become possible:

- several models of a structure at different levels of detail, depending on the focus of the investigation, can be combined into a common 3D model or replaced in certain areas,
- models of the same part of the structure captured during different data acquisition campaigns can be superimposed in a way that allows deformations or changes between the campaigns to be determined, and
- the reconstructed models of the 3D structure can be further set into relation to other digital models, such as simulation models.

To assess the condition of the structure, the extent and severity of existing damage must be quantified and classified accordingly. This requires sufficient image quality (see Section 2.1) to reliably detect anomalies in the image data. The damage can be either detected and classified using pre-trained artificial neural networks or entered through manual inspections on the virtual model. Through the relationship between 2D image data and 3D model from photogrammetric reconstruction, the extent of damage that spans multiple images can be determined by projecting it onto the 3D model. In addition, georeferencing allows the exact measurement of the damage geometry (e.g. crack width as presented by Benz & Rodehorst (2021)).

The data generated during an image-based inspection represents a very heterogeneous data set, both due to the file types that are used and due to the type of representation of the structure (e.g. geometry via a 3D point cloud, surface information in 2D image data, extracted damage information, location-related notes during data acquisition, etc.). In order to be able to make a holistic assessment about the condition of the structure, the data must be linked with each other so that (automatically) accumulated information can be derived. One possibility for geometrically highly accurate linking of heterogeneous data collected, even across multiple acquisition campaigns, is to use the multi-model approach and voxel-based methods, such as those proposed by Taraben et al. (2022a) and Taraben & Morgenthal (2022b). In this case, the synchronization of the informational coupling of the physical structure and the digital image according to Boje et al. (2020) is not ensured by continuous monitoring but at discrete points in time. In terms of the definition according to Errandonea et al. (2020), the application of the digital twin described thus falls between a condition-based and a predictive maintenance strategy. The following paragraphs mainly deal with the enhancement of the digital image.

2.3 *Condition evaluation and predictive maintenance*

The georeferenced and linked model created from the 2D image data (see Section 2.2) represents the necessary information for an assessment of the structural condition. In this context, the assessment can be carried out manually, assuming that an appropriate visualization is enabled and linked data can also be easily displayed, or (semi) automated, assuming that full linking of the data is available. The latter was shown, for example, for the determination of the condition index by Taraben et al. (2022a) by applying procedures currently used in practice.

Since the fully linked digital model can also contain other data in addition to the damage and structural data, key performance indicator-based methods (see for example Stipanović et al. 2017) can be applied to the condition assessment of the structure. Such methods allow for multi criterial predictive maintenance for example proposed by Bukhsh et al. (2020). Strategies for automatically generating condition metrics and performance indices as a basis for representing and interpreting the state of a structure will represent a viable research field for the foreseeable future.

3 CASE STUDIES OF CLOUD-BASED ASSET MANAGEMENT

3.1 *Example 1: Visual structural inspection in a digital twin*

The recorded and processed data from image-based methods is suitable for significantly reducing subjectivity in evaluation processes. On the one hand, a manual inspection can be carried out on the visualized 3D building surface and the linked 2D image data. On the other hand, anomalies on the surface can be measured digitally in both 3D and 2D space, as shown in Figure 2 (left).

Even if this ensures easy accessibility to all areas of the structure and excludes the effects of the weather, damage can be overlooked during the inspection process, especially in the case of very large surface areas. This is where the use of neural networks is suitable for automated damage detection. Using machine learning methods, detection is carried out by classifying relevant damage on the basis of prior training with annotated damage images. The relationship between the image and the 3D model means that damage detected in the image data can be projected onto the 3D model and geometrically referenced there and, if the image data is of sufficient quality, automatically measured. The result are georeferenced annotations, as shown in Figure 2 (right), containing information about damage characteristics such as type and extent. The automatically detected anomalies highlighted on the 3D model can then be evaluated in the same way as the conventional inspection process or linked with the other data in the digital twin of the structure to automatically determine the condition of the structure. Such methods can be a valuable support tool for damage detection and documentation.

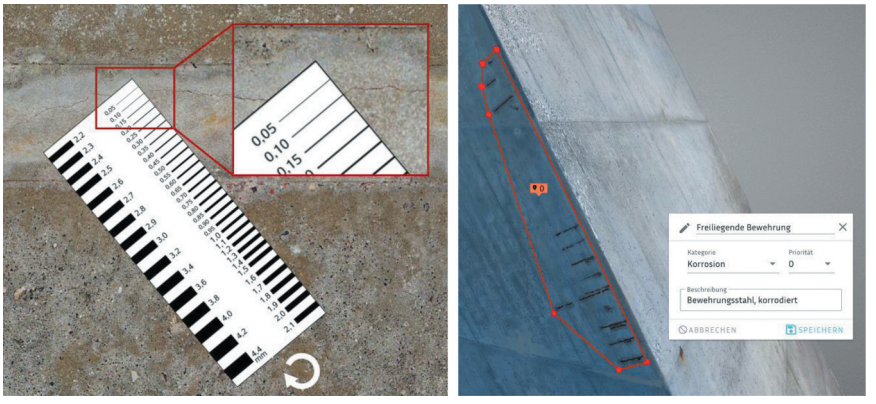

Figure 2. left: Manual measurement of crack width on the textured surface of a photogrammetrically reconstructed 3D model using a digitally superimposed crack width ruler; right: Display of an inspection note stored in the Digital Twin with categories of the evaluation (here: using the example of the INFRA// TWIN platform (INFRALYTICA 2023)).

The georeferenced location of the annotations also ensures that the conclusions and categorizations drawn for the assessment can be found directly on the 3D model of the structure and directly linked to any damage.

Although the surface of the photogrammetrically reconstructed model (corresponding to the underlying image data) achieves a very high resolution, it may be necessary in individual cases to include the original image data and the extent of damage recognizable there in the assessment. Thanks to the relationship between the 3D model and the 2D image data set from the photogrammetric reconstruction storage in the digital twin, the partial image data set associated with a 3D point can be found and displayed at any time, as shown as an example in Figure 3.

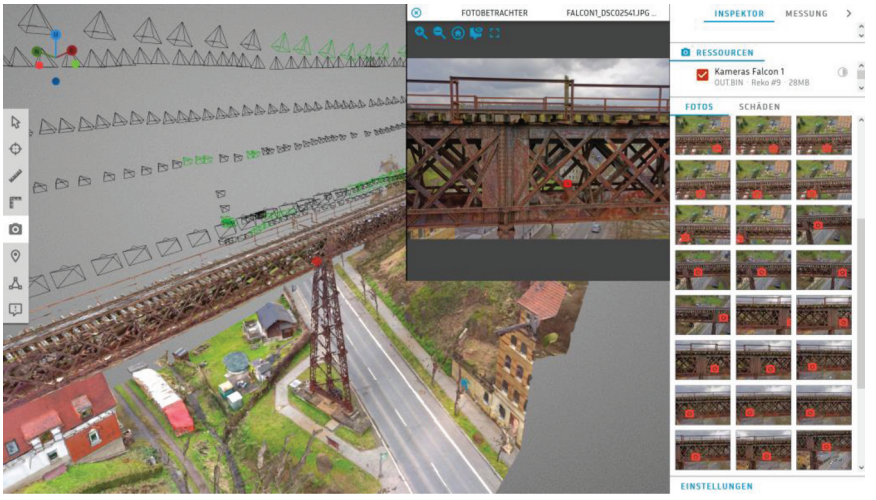

Figure 3. Display of a partial image dataset corresponding to the point selected on the 3D model incl. highlighting in green of the camera positions from which the selected point is visible and red camera symbol for highlighting the selected point in the images (here: using the example of the INFRA//TWIN platform (INFRALYTICA 2023)).

The precise georeferencing (usually within 10 mm) makes it possible to observe and compare the change between different images even without automated evaluation. Furthermore, georeferencing enables the extent of damage to be measured directly on the 3D structure model (see Figure 4). The link to the 2D image data allows the measured distances and areas to be recorded in the images with the real dimensions even if the representation is distorted.

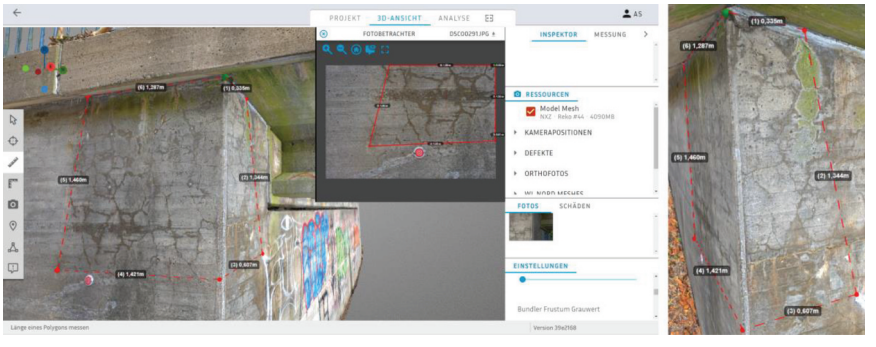

Figure 4. Measuring of damage dimensions (right: detailed view) on the georeferenced 3D building model (here: using the example of the INFRA//TWIN platform (INFRALYTICA 2023)).

3.2 *Example 2: Automated damage detection and progress monitoring*

Manual annotation of each individual damage in the image data is very time-consuming, especially with a large number of damage entities. The use of neural networks trained for the application area (including surface material and damage types) enables automated detection. The damage annotated in this way and stored in a database can then be referenced to the 3D model for further interpretation and linked in the digital twin, as shown in Figures 5 and 6.

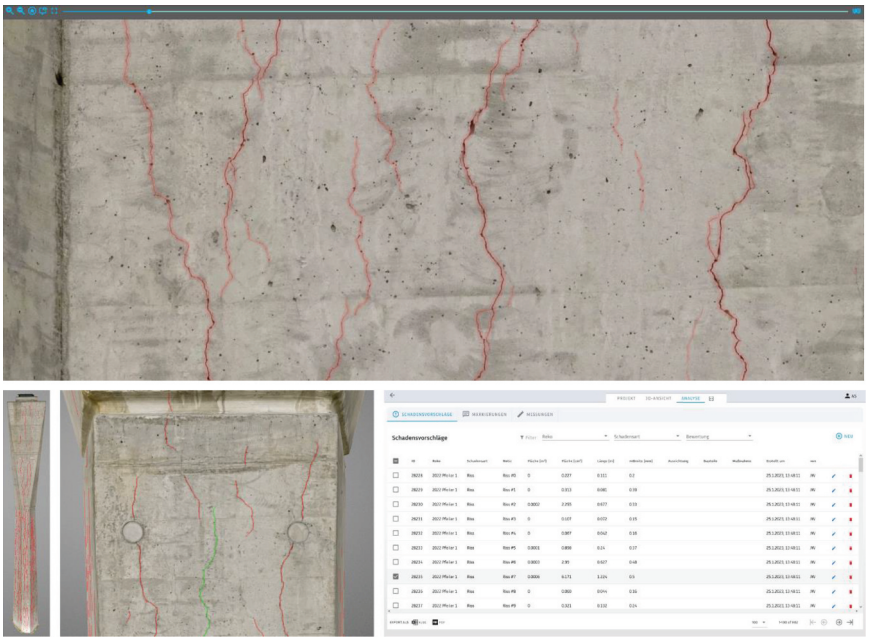

Figure 5. Visualization of cracks detected automatically with a neural network in a photo (top: image view with semi-transparent AI heatmap of crack detection) and projected onto the surface of the textured 3D model (bottom) incl. the link between damages selectable on the 3D model and their storage in a backend database (here: using the example of the INFRA//TWIN platform (INFRALYTICA 2023)).

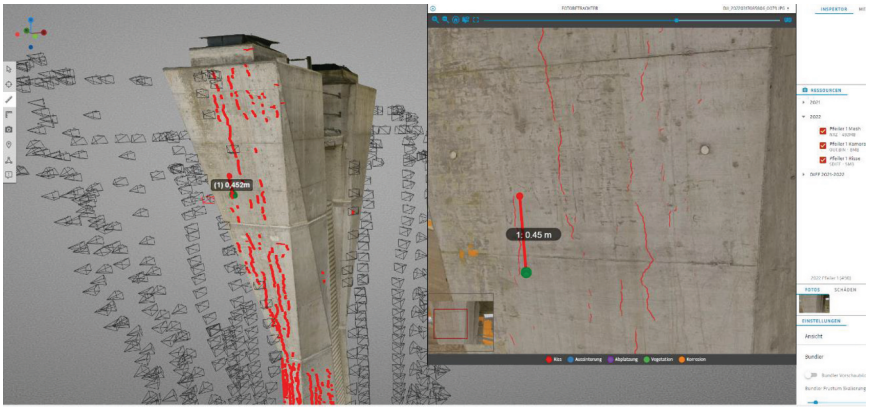

Figure 6. Visualization of cracks in the original image and the 3D-referenced crack pattern (here: using the example of the INFRA//TWIN platform (INFRALYTICA 2023)).

Meaningful applications of asset management platforms are also in the response of natural hazard mitigation and support of disaster response activities. Image data from e.g. flood events can be generated by drones fast and repeatedly and 3D models of affected areas can be provided through automatic data analysis and provision through cloud platforms in near real time (Schwarz et al. 2023). This allows crisis management and personnel on the ground to be provided with important information on structural deterioration, access restrictions and trends of flood propagation, see Figure 7.

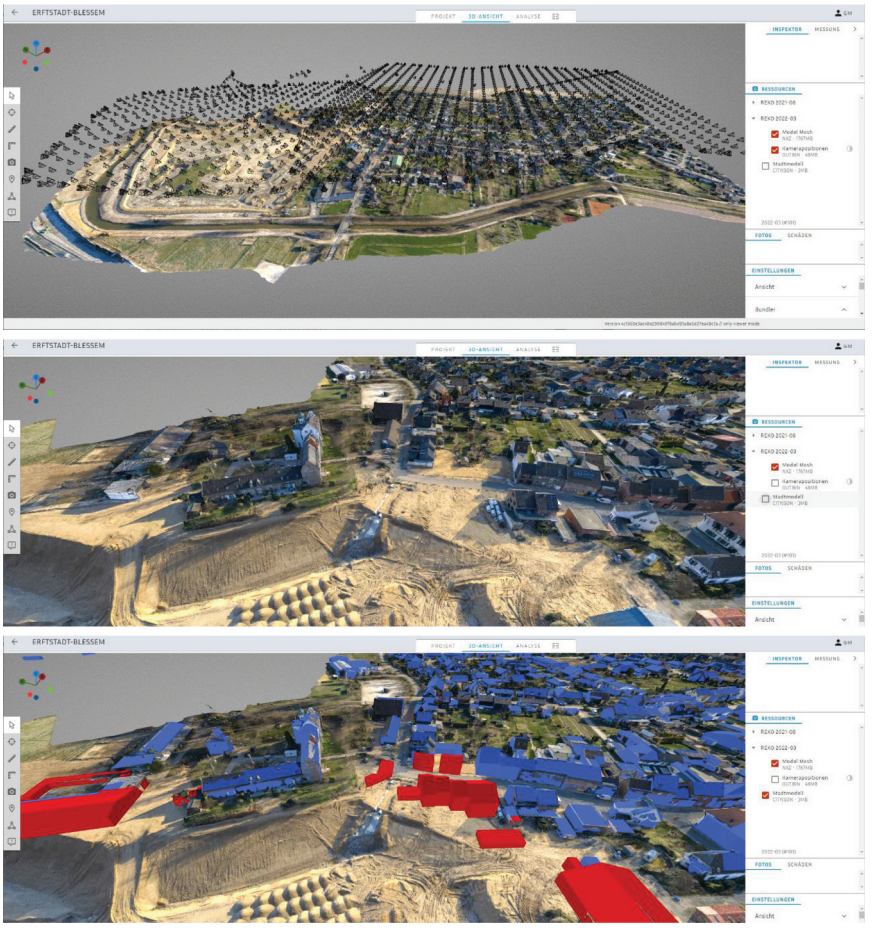

Figure 7. Visualization of flood affected areas based on drone imagery: drone positions (top), 3D model view (middle) and with damage interpretation models (degree of damage color coded, see Schwarz et al. 2023).

4 CONCLUSIONS AND DISCUSSIONS

The regular inspection of structures is essential to ensure the safety, serviceability and durability of infrastructures. The time, personnel and resource-intensive process of structural inspection can be supported by digital methods in the future, whereby the image-based structural inspection presented in this paper has particular potential.

Image-based digital structural inspection is suitable for achieving the three objectives of structural inspection effectively and efficiently thanks to the high-resolution image data and

its georeferenced linking in the digital twin. The paper presents possible application scenarios. When using the methods, however, it should always be noted that digital structural inspection cannot completely replace conventional structural inspection and must be subject to careful quality control in order to ensure that the generated image data contains sufficient information. In particular, digital structural inspection can provide valuable support in order to limit manual inspection to particularly critical areas and to reduce any subjective influences in the condition assessment with the help of automated evaluation algorithms. Further applications in disaster response are indicated.

ABSTRACT: Over the past two decades, Building Information Modeling (BIM) has emerged as a prominent facet of the digital transformation within the AEC sector. However, this transformational focus has predominantly centered on the design and construction of new bridges, overshadowing the critical realm of existing bridges constructed before the advent of BIM. The operational and maintenance phase of a bridge's lifecycle is the longest and most cost-intensive, heightened by the growing concerns of fatal accidents, climate change impacts, and the aging infrastructure of numerous bridges globally. This has sparked a global interest in shifting from a reactive to a preventive approach to bridge maintenance, entailing the seamless integration of digitalization into the operations and maintenance (O&M) lifecycle. The digital transformation of operation and maintenance processes carries the potential to significantly reduce costs and, most importantly, safety.

1 INTRODUCTION

The IABSE Task Group 5.6 has a dedicated mission: to bridge the gap between Bridge Management Systems (BMS) and existing BIM solutions. This initiative is grounded in Open BIM standards but accentuates the critical role of data models. The foundational concepts for this implementation were extensively deliberated upon at the IABSE Congress held in New Delhi, India (Aas-Jakobsen et al. 2023). The journey began with the identification and systematic categorization of use cases that facilitate the harmonious integration of Bridge Management Systems and BIM for existing bridges.

The pivotal stakeholders in this endeavor are the bridge owners and regulatory authorities, whose perspectives are paramount in shaping this market-oriented initiative. In our vision, the establishment of a universally accepted standardized framework for data exchange between disparate systems empowers bridge owners. This framework will grant them control over their bridge infrastructure's data, enabling informed and timely decision-making. The culmination of intensive interviews with bridge authorities and owners from around the world has led to the

DOI: 10.1201/9781003483755-241

creation of a comprehensive review document. This review will serve as the guiding compass for recommending the future integration between Bridge Management Systems and Open BIM.

2 VISION OF LINKING BIM TO BMS FOR BRIDGES

Many bridge owners hope that BrIM (Bridge Information Modeling) will be used throughout the structure's life cycle, from initial design to building, operation, and maintenance, and finally removal and recycling at the end of service – a one-stop shop for information. As part of a BMS, operation and maintenance data are currently collected in various forms and kept in multiple repositories. To maximize maintenance of individual structural assets and manage the asset as a portfolio of structures, BrIM and BMS should be linked so that information may be shared effortlessly, even for existing structures that do not yet have a BrIM model.

The complexity of maintenance/inspection requires organized, automated, open and transparent digital processes, which should consider both structural and asset management data.

It is assumed that the BMS aims to integrate digital storage, exchange of data, cost as well as deterioration, optimization and analysis models and their interoperability with existing BIM solutions (Hajdin & Samec 2022).

The vision of this work aims to form a foundation for 3D/4D/5D/6D software and hardware independent data exchange between different software technologies during life cycle and beyond, considering also monitoring, sensor equipment and damages on the structure along time axis. Open BIM technology for the interoperability from technical, semantic and organizational point of view is of main interest. Thus, the work is based on the following formulation:

BIM model should be the driver and front end and will provide a link to the BMS system. The BIM model should allow for bi-directional information flow with the BMS system (and other systems linked to the BIM) such that information is not duplicated. The aim of our TG is searching for all requests from BMS systems (in form of use cases) in order to report missing attributes within exiting Open BIM systems.

It is in the following assumed that in addition to structural information the BrIM model include or reference the design basis, which include location, bridge type, traffic definition, metocean data, information on hazard, geotechnical design data, geological design data, seismic input, etc. The focus of this work has been to the structural system.

In order to prioritize the direction of the work the following workflow was defined as shown in Figure 1:

- Identify and systematize use cases for linking BMS and BIM for bridges.
- Prioritize use cases based on market input.
- Propose structure for connecting BMS and BrIM.

The first step (Use Cases identification and systematization) was completed and reported in (Aas-Jakobsen et al. 2023). Relevant use cases for a BrIM model over its lifetime are identified, including their potential and eventual extension of IFC standard. Currently, IFC standard (widely recognized and used Open BIM standard) is used as the reference data scheme. For the future it is important to underline, that IFC is not the only possible exchange format.

This paper is describing the concept of BrIM and BMS linkage and its validation. For this purpose, stakeholders, bridge authorities worldwide have been answering a set of questions,

Figure 1. Workflow.

prepared by IABSE TG 5.6. Their point of view, requirements and practical needs will lead to the last step: development of missing parts within BrIM.

Our work is based on our hypothesis:

- The BrIM shall allow for bi-directional information flow;
- Information should not be duplicated in the connected systems.

3 USE CASES

In order to structure the work all tasks which BrIM, and BMS could be used for was sorted into use-cases. These were categorized into five groups: object data, data management, visualization, maintenance & repair information and user interface. All identified use case were described and the advantages with linking BrIM and BMS was identified, as well as necessary update of the IFC data scheme. The below discussion gives an overview of the main findings.

3.1 *Object data*

Object data is information needed for the object. The general bridge data should consist of existing documentation of the bridge from the construction site (including interventions after construction stage), geometrical model of the bridge as built (Isailovic & Hajdin 2022) or after retrofitting, geo location of the structure, hazard information, design basis, statical report, geological report, full set of drawings, reports from construction supervision (including deviations and vulnerable areas), bridge owner, designer, constructor, construction year, traffic class, traffic load, bridge class, generation of design codes, seismic zone, monitoring plan and instrumentation, time specification. Potentially all existing bridge data can be imported into the BIM tool.

Extended definition of structural and non-structural member specification shall be delivered on member topology, geometric extent and cross sections, materials, information of reinforcement, prestressing, surface treatments, environmental exposure, degree of strength utilization, geotechnical members like piles, anchors, appurtenances like bearings, expansion joints, etc., location of monitoring sensors and time dimension.

A mechanism is needed, which would identify the status of each element in the structure. The status should be able to reflect initial, unchanged, modified, replaced, added, and demolished entities. In addition, it should be able to reflect updated documentation in BMS system, including e.g. instrumentation. Storage should be organized such that historical data could be visualized and compared to similar structure and objects on other bridges.

Inspection and maintenance activity on bridge element should be stored in BrIM for planning and logging purposes. Damages must be stored in a way that it could be monitored and visualized and serve as input to a damage model. Modification, demolition, and construction of new elements need to be updated in BrIM and its geometric changes must be added such that visualization is possible. Thus, time stamp of changes is needed.

3.2 *Data management*

Data management is related to how the data and information in the model is used. The main purpose is to prepare the ground for fund optimization.

There are several BMS worldwide, all BMS have essentially a management process for all bridges, where one needs to identify the bridge, know its condition and act upon it when required. These three tasks are grouped into three main modules: i) Inventory; ii) Inspection; iii) Intervention. With evolution in technology and focus on the needs of bridge owners, these three main modules have been split into more specialized modules.

Since BMS in principles has to deal with a huge number of bridges, it is important to have a unique ID which can be used to link data relating to that particular bridge from other sources. BrIM model shall identify all the data fields that are essential for communication with BMS.

Currently existing structures are documented by 2D drawings. In the near future it is currently not realistic to automatically convert these drawings to full BrIM models. An alternative is to create simplified BrIM models that holds the information needed to communicate with BMS. Since BMS information contain information about how the structure develop with time, this parameter has to be added to the IFC scheme for seamless communication, as time and date stamp is critical in assessment of progression of deterioration within the bridge element. Deterioration modelling module is critical in BMS as it is based on the deterioration model created under this module that the management decision making during the Risk assessment and Priority and ranking tools are achieved. In addition to the 4^{th} dimension, we propose to add a 5^{th} dimension which describe the severity of distress in the element at that particular time zone.

3.3 *Visualization*

The visualization of information on a 3D numerical model of a bridge is crucial in the development of the link between BMS and BrIM. Indeed, an easy access to bridge information in its context, such as inventory data or bridge elements' conditions, can significantly improve maintenance workflows from inspection on site to prioritization of repair actions.

This use case aims to allow the visualization of generic data of the bridge: bridge type, geometric position of elements, material specifications, number of spans, dimensions, etc. These data can be presented under two forms: 3D view or table view. Besides, several milestones of the bridge life should be available: "as-built" model, "as-is" model, etc. (Tomczak et al. 2022).

3.4 *Maintenance and repair information*

Being fully aware of the complexity of various types of bridge damages (and their underlying deterioration mechanisms), the focus of our interest are not just its visible symptoms. In fact, rather than reinventing the common perception of damages in BMSs, the idea is to find the way to use BrIM for documenting damages which are identified in a traditional routine inspection process, based on a visual observation. Additionally, the focus might be extended to parameters for the damage evolution prediction.

In an object-oriented system, such as BrIM, each damage will be represented by an instance of certain class (i.e. type), described by certain set of attributes (i.e. properties). In principle damage classes are already implicitly defined in damage catalogs of various BMSs. The sets of properties describing damage types are included in catalogs too. Although similarly organized, damage descriptions differ between various BMSs. To make data communication between different BMSs easier, finding a consensus on damage description is necessary. This means that any damage type should be described by a set of properties which is a common denominator for majority of BMSs.

In BrIM terms, modeling of damage means enabling the new BrIM functionality of modifying the intact geometry of the damaged element by introducing damage location, affected area of an element, damage photos, relationship between the damage object and the affected element, etc.

For the bridge management, historical information is crucial both for documenting the historical development of damage, as well as for documenting element replacement, addition, and/or geometry adjustment. For this purpose, an extension of IFC schema is required.

Damage evolution prediction, performed by BMS, should be associated with particular BrIM element or the entire model. It can be done by externally referencing the damage evolution data and, perhaps, assigning a time attribute to it.

3.5 *User interface*

In the context of efficient maintenance of motorways and tunnels as-built drawings have been reworked to show the exact location of maintenance items and quantities for planning of maintenance rotations, tracking progress and tracing the history of interventions (e.g. refurbishment and partial replacement). The digital availability of detailed asset documentation simplifies the distribution and update of information (Sacks et al. 2018).

Exact and current asset information is even more vital for rescue teams. Also, for the online documentation of maintenance, immediate status update, quantity surveying and the billing workflows the use of portable tablet computers greatly improves the speed of processing and mobility of teams. The ultimate vision of utility managers is an augmented reality tool to look through solid material (pavement, concrete) onto hidden assets with their exact coordinates, network topology and status information.

Another advanced use of real-time interfaces with a digital twin is the use case of structural monitoring, either in temporary installation to measure the structural response for decision making, or in permanent big-data applications such as detecting changes in temperatures, humidity, forces, strains or vibration frequencies identify latent deterioration processes. The monitoring platform may just record data for later interpretation by postprocessing, or it may permit configurating new interfaces in the field, and even allow (by virtue of cloud computing) to run structural simulations and interpret the measurement data on the spot.

4 EXTENSION OF IFC FORMAT

Linking BrIM and BMS through extension of the IFC format opens up for seamless communication between the system. This will give the bridge owner the possibility to combine information stored during the design phase with data collected in the operation phase, thus, opening up for more informed and effective operations of individual structures, as well as easier comparison between structures.

The following key extension of IFC were identified:

- Introduction of time stamp to track change on elements and information.
- Introduction of unique IDs for elements.
- A mechanism which can store status of elements such as initial, unchanged, modified, replaced, added, and demolished entities. This could be done through a *IfcLifetime* entity type with attributes like *BirthDate* and *DeathDate*. By introducing IfcLifetime entity, the current as-is geometry of a bridge would be determined at any moment in time, as shown in Figure 2.
- Place holder for inspection and maintenance plans.
- Maintenance and repair functionality including deterioration prediction, costing and optimization.
- Connection to structural assessment software.
- Definition of damage properties and damage information modelling.
- A system that handles visualization of current status of the structure including accurate position of damage and vulnerable zones.

The proposed extension will work for both new structures with BrIM models and structures without BrIM models. For the latter, very simplified models can act as place holders for information and exchange with BMS, and then be expanded into the realistic models when needed.

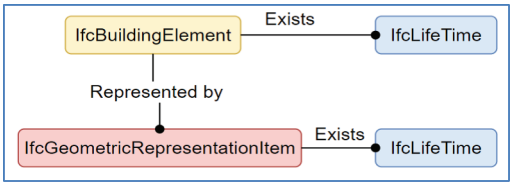

Figure 2. EXPRESS-G diagram illustrating the use of the proposed *IfcLifeTime* entity type.

5 BMS IN KOREA

In Korea, the BMS is meticulously tailored to cater to the distinct information needs of cable-supported bridges and conventional bridges. Specifically, for cable-supported bridges, the BMS incorporates sophisticated information systems such as a comprehensive health

monitoring system and a condition rating system equipped with detailed damage records. On the other hand, common bridges are overseen by an information system that meticulously tracks inspection and repair records for the entire bridge structure. The BMS dedicated to common bridges systematically accumulates invaluable inspection data, repair records, and essential information for the comprehensive assessment of bridge conditions and safety. This meticulous management extends to bridges owned by public agencies, ensuring a holistic approach to monitoring and maintaining the integrity of critical infrastructure.

Following the government's mandate for mandatory BIM adoption in public construction projects, the as-built BIM deliverables have assumed the role of foundational data for a BIM-based BMS (Nguyen et al. 2021). The IFC models submitted must undergo a conversion process to establish proper data links and optimize memory for seamless visualization. As maintenance tasks generate diverse data, encompassing images and Non-Destructive Evaluation (NDE) data, the primary objective is to efficiently transfer existing data to the new BMS, minimizing the need for manual input during this transition. Simultaneously, transitioning from the existing file-based maintenance system to a data-driven model, enabling Database-to-Database (DB-to-DB) transfers, presents a formidable challenge for bridge owners. This shift underscores the complexities inherent in modernizing maintenance systems while adhering to evolving technological standards (Won et al. 2021). In recent developments, public authorities have instituted a systematic approach for data accumulation throughout the project delivery, with the adoption of ISO 19650 as the standardized framework for handover data delivery (Shim et al. 2019). The architectural and data specifications of the as-built BIM must now factor in the specific requirements for new data and tasks that arise during the maintenance period as shown in Figure 3. Given the imperative of accurately assessing the key performance metrics of existing bridges facing deterioration, the new BMS is poised to offer a well-federated and dependable stream of data, ensuring comprehensive and reliable insights throughout the entire lifespan of the bridges. This strategic alignment ensures that the BMS is not only responsive to immediate project needs but also anticipates and addresses the evolving demands of bridge maintenance and performance assessment over time.

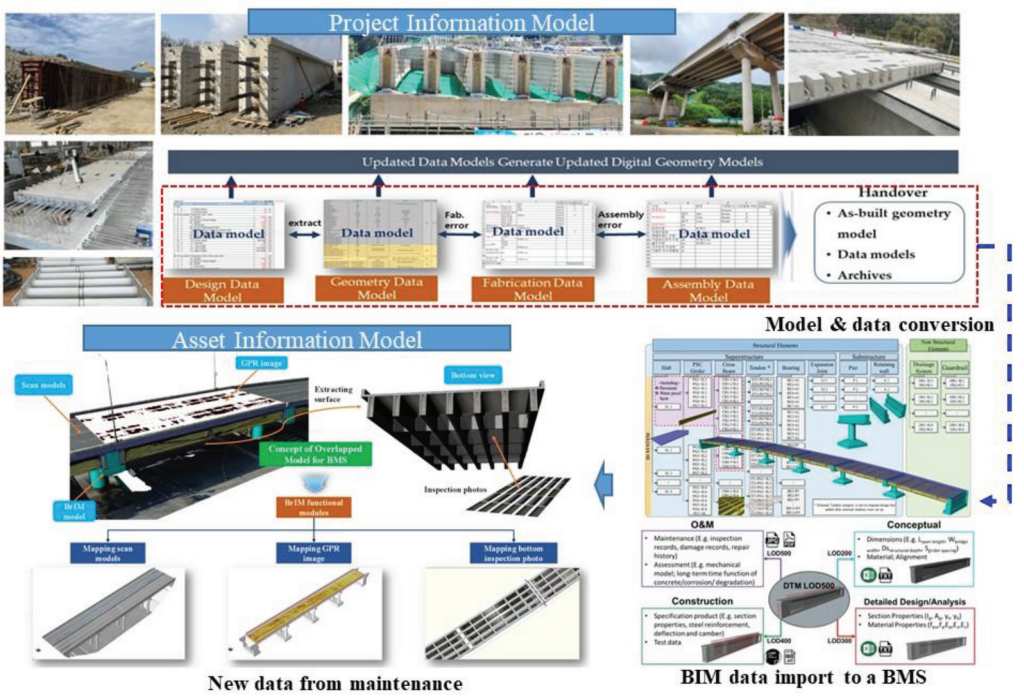

Figure 3. Information delivery from as-built BIM to BMS.

6 BMS IN SOUTH AMERICA

At the onset of 2015, the Technological Development Corporation established the BIM Forum in South America as a technical and permanent platform. This forum unites key professionals and institutions associated with Building Information Modeling (BIM) to channel technical concerns, knowledge, and information. Its purpose is to contribute knowledge and experiences from companies and professionals. The primary goal is to disseminate, develop, and foster best practices in all aspects of BIM, encompassing road infrastructure and bridges (Valenzuela et al. 2023).

The main countries involved in the BIM Forum include Argentina, Brazil, Colombia, Chile, Ecuador, Peru, among others, providing a foundation for various initiatives in each country. For instance, in Chile, the national strategic program "Construye 2025", under the "Plan BIM", aims to ensure that companies participating in future public tenders develop projects that are constructible and operable. These projects should contain integrated modeling and databases, demonstrating a comprehensive understanding of the BIM concept.

In alignment with this, the Roads Directorate, as part of its Bridges 2020-2030 program, has incorporated the BIM methodology within the lines of development and implementation (MOP 2022). The focus is specifically on the implementation of BIM in road infrastructure works, particularly in bridges, during certain project phases.

Academic support has played a crucial role in developing BIM, enhancing the technical capacity and skills of professionals. The primary application of BIM is evident in the design stage, especially for complex or unique bridges (cable-supported), under a master plan of road infrastructure, or specific requests during construction (e.g., Maipo bridge Pan-American route).

Highlighted projects include the "Trincheras Structural Project Concesión Américo Vespucio Oriente AVO1 (2018-2019)" in Chile, which was developed in BIM by the Concessionaire. Notable projects in Colombia include the "Intercambio vial San Juan con la Carrera, Medellin (2021)" and the "Troncal Alimentadora PLMB, Cali (2022)", both involving comprehensive BIM applications from site study and design coordination to visualization using VR + AR.

Costa Rica showcases studies involving the interaction between road infrastructure and bridges, such as the coordination of design on national road 1.

Currently, BIM implementation has extended to Operations and Maintenance (O&M), integrating methodologies for inspection and data review of pathology. Examples include Colombia's application to footbridges and initiatives in Chile by Municipalities, the Ministry, and EFE (Railway authorities) to digitalize O&M activities for existing structures (Seguel & Seguel 2021).

In conclusion, South America has developed several standards aligning with international requirements, as proposed by BIM Forum Argentina. These standards encompass fundamental concepts applied to design, construction, and operation, defining dimensions from 3D to 7D, implementation phases, and areas of application (architecture, infrastructures, including bridges), each at different stages of adoption in various countries and structures.

7 VALIDATION OF CONCEPTS

Various authorities, in total 22, in different countries have been interviewed over six months, using therefor developed questionnaire.

In general, bridge owners face the dual challenge of managing unique assets and determining the most effective inspection means. Various methods and systems are used for this purpose. The documentation of bridges with their conditions due to bridge inspections and the management of structures is generally done in a structured and digital manner. Either specially developed or commercially available systems are used for this purpose. It can be concluded that digital structure management with the recording of structure conditions has already arrived in principle in the institutions surveyed. Still, it must be assumed that different approaches to structuring, processing, and presenting the data exist.

The data that is or should be included in a bridge management system mainly relates to documenting conditions or condition developments. On the one hand, the relevance of

categorized and thus generalized condition descriptions in the form of condition grades, point- or scoring systems becomes apparent. These provide essential decision-making aids in higher-level management by making structures comparable. On the other hand, the survey of visualization requirements shows that component-related condition information and documentation, particularly damage and damage development, are also of considerable relevance. The respondents showed a clear preference for a representation that enables a linked representation of, e.g., damage details and affected components. While a photorealistic representation of buildings or parts of buildings is predominantly not considered necessary in this context, a significant proportion of respondents consider this valuable information in damage documentation. This underlines the heterogeneity of the data to be processed. There are different levels of consideration at which different types of condition descriptions become relevant. The required condition descriptions range from generalized categorization to highly detailed reports of individual damage incidents with additional documents such as photos or sketches. Neither BrIM nor BMS systems alone can fulfil all these requirements suitably. Instead, a flexible combination of the two approaches seems promising.

Another critical point is the provision of the collected bridge data. The challenge here lies in the different data users with varying legitimate interests. In addition to authorization levels that may become necessary due to administrative structures, a small proportion of the data is often publicly accessible. In Europe, for example, this requirement results from the INSPIRE (Infrastructure for Spatial Information in the European Community) directive of the European Commission. According to this directive, all 34 member states have been obliged since 2007 to make certain geodata sets (including transport networks and associated infrastructure facilities) available to the public. For many authorities, this makes the possibility of differentiating the provision of data according to different rights even more relevant. This is also reflected in the interviews conducted, in which most respondents stated that various levels of access control are also implemented in the existing systems.

The findings underscore the challenges in developing a system that combines a Bridge Management System (BMS) and Bridge Information Modeling (BrIM). The sector's complexity, varying needs, and preferences highlight the need for a nuanced and flexible approach to bridge asset management systems.

8 HIERARCHY OF BRIM AND BMS

BrIM is expected to significantly minimize errors, accelerate project delivery time, and cut implementation costs. However, research indicates that, despite the wealth of data generated using building management systems (BMS) of varied degrees of sophistication, the building operation and management stage is falling behind. Our survey includes the challenging question about hierarchy between BrIM and BMS, including GIS based system. It is consequently important to understand both frameworks, BrIM and BMS, as future linked data bases, improving the evaluation of bridge performance in use and provide feedback to the design stage, perhaps resolving design-related performance issues.

9 CONCLUSIONS

The current challenge for majority of existing bridges represents the fragmented data: data describing the structure and historical information on how the bridge has been managed is stored in many different formats and location, thus, it is fragmented. There is a lack of standardization of obtaining information about the state of the structure and its structural properties. For existing bridges currently data is stored in several formats. Several BMS systems exist worldwide, but not incorporated in Open BIM systems.

The BrIM model should allow for bi-directional information flow with the BMS system (and other systems linked to the BIM) such that information is not duplicated in the connected systems.

Short overview of BIM-BMS situation from Korea and South America was presented.

The aim of IABSE TG 5.6 is searching for all requests from BMS systems (in form of use cases) to report missing attributes within exiting Open BIM systems. Open BIM technology for the interoperability from technical, semantic, and organizational point of view is of main interest. We need to consider as-built BIM deliverables for new bridges. In our vision, the establishment of a universally accepted standardized framework for data exchange between disparate systems empowers bridge owners. The culmination of intensive interviews with bridge authorities and owners from around the world will serve as the guiding compass for recommending the future integration between Bridge Management Systems and Open BIM. Survey results from bridge owners and authorities worldwide will help us in prioritization of use cases and serve as further development input for software authorities. Further steps about will be reported in the next papers.

Strategies for effective bridge information management with OpenBIM

C. Gragnaniello, G. Mariniello & D. Asprone
Department of Structures for Engineering and Architecture, University of Naples Federico II, Naples, Italy

ABSTRACT: This study focuses on the efficient management of infrastructure information using BIM (Building Information Modelling) models. With a specific emphasis on the assessment and maintenance of bridges, it examines the impact of using level of information need (LoIN) in BIM models and defines data schemas for guidelines related to bridge management. The paper highlights the definition of I-BIM models and interoperability. Applicability is demonstrated through an I-BIM digital model case study and the verification of information delivered.

1 INTRODUCTION

1.1 *Bridge information management*

The management of bridges is crucial to ensure their safety, efficiency, and durability over time. Infrastructure plays a key role in aiding the mobility of people and commodities, enabling development, and connecting countries [1]. However, with urban development and population growth, the volume of loads and vehicles crossing bridges has increased, causing high stress and deterioration on bridges. In addition, over time the materials used for bridge construction undergo a natural aging process.

Therefore, it becomes essential to adopt infrastructure management practices that aim to control the vulnerability of works and plan maintenance in a timely and efficient manner [2].

This involves several activities, such as periodically inspecting bridges to identify any signs of damage, assessing structural capacity to ensure that they can withstand the expected loads, and planning preventive maintenance actions [3,4].

In this context, the Bridge Management System (BMS) is a key tool for monitoring, assessing, and managing the condition of bridges. This provides a comprehensive view of the health of the infrastructure and identifies specific maintenance needs. BMS originated in the United States with the Pontis study initiated in 1975, evolving over time and providing a model for the development of similar systems around the world [5,6].

Over time, the concept of BMS has spread globally, adapting to the specific needs of different countries and regions. Nowadays, many countries have implemented or are implementing advanced bridge management systems that use increasingly sophisticated assessment and monitoring technologies and methodologies.

The evolution of BMS is an ongoing process, with an increasing emphasis on digitization, the use of advanced technologies such as Building Information Modeling (BIM), and the adoption of proactive approaches to infrastructure management [7,8,9].

Building Information Modeling (BIM) represents a digital methodology that is based on the creation and management of information models for buildings and infrastructure. Within BIM models are detailed and integrated information, including geometric, graphical, and documentary data describing the characteristics of constituent elements.

In the realm of existing bridges, BIM offers significant advantages. Studies, such as McGuire et al. [10], underscore BIM's capacity to optimize infrastructure management,

DOI: 10.1201/9781003483755-242

particularly for bridges. Furthermore, Hagedorn et al. [8] propose the use of BIM to manage transportation infrastructure assets, focusing on data description and updating, preparation of informational containers, integration with existing asset management systems, and the design of an informational portal.

I-BIM models streamline the assessment and maintenance of bridges by utilizing a single database, facilitating efficient and integrated management of bridge information. They enable the integration of damage data and inspection records within the same model, simplifying structural condition assessments without the need for data comparison across disparate sources, as shown by Nguyen et al. [9].

In addition, BIM models allow for the formulation of optimal maintenance based on on-site data. Shim et al. [11] propose a data schema for BIM models to establish a maintenance system for cable-stayed bridges, which effectively organizes data and demonstrates significant time-saving potential for maintenance work.

Ultimately, I-BIM models empower stakeholders to make informed decisions and execute efficient infrastructure management strategies for existing bridges.

1.2 *Scope of study*

The increasing adoption of BIM presents a significant challenge in ensuring the accuracy and certification of I-BIM models. This study addresses this challenge by concentrating on defining Levels of Information Need (LoIN) within bridge management processes, following EN 17412-1:2020 guidelines [12]. Specifically, it aims to answer the question of how to check I-BIM models to prevent errors during the delivery phase.

This study is divided into four sections: the second describes an approach that involves all the resources needed in a BIM management process, with a focus on bridge field. Moreover, in the third section is applied the methodology to a case study of a viaduct on a highway in Italy, to optimize the delivery of the project. Finally, the discussion and conclusions highlight the importance of clearly define the information requirements in a preliminary phase, to verify the consistency of I-BIM model delivered, with the support of CDE.

2 A BIM-BASED APPROACH TO IMPROVE BRIDGE MANAGEMENT PROCESS

The proposed approach considers the use of BIM as the main tool for information management of existing bridges. Emphasis is placed on the importance of defining the owner's information requirements in advance to ensure the creation of management models in line with specific requirements. This approach is based on the use of a Common Data Environment (CDE), an interoperable digital data sharing environment that facilitates collaboration among stakeholders by engaging them in an effective information flow. The CDE is structured into four distinctive folders: Work in Progress (WIP), Shared, Published, and Archive, according to ISO19650-1:2018 [13].

This approach optimizes the use of information requirements for data transmission, known as Exchange Information Requirements (EIRs). EIRs outline the requirements of the developer during the management of the bridge, including all activities necessary to preserve its structural integrity, which are outsourced to specialists in the field. EIRs include Levels of Information Need (LOINs), which are then translated into a machine-readable version: the Information Delivery Specification (IDS).

The main objective of this approach is to precisely define the location of all these elements within the CDE, and their use to optimize the information management of bridges, as shown in Figure 1. Initially, the various working groups collaborate within the WIP folder, where only they can access and work confidentially. However, for the models to comply with the requirements, it is essential that they have access to the EIRs at the beginning of the process. Next, the information moves to the Shared folder, which is also accessible to the owner, that allow the models to be shared and consolidated into a single federated model. These individual models or the federated model can be checked for consistency and conformity using IDSs. If

discrepancies are identified, the model is flagged and corrected by the corresponding working group before being moved to the Published folder.

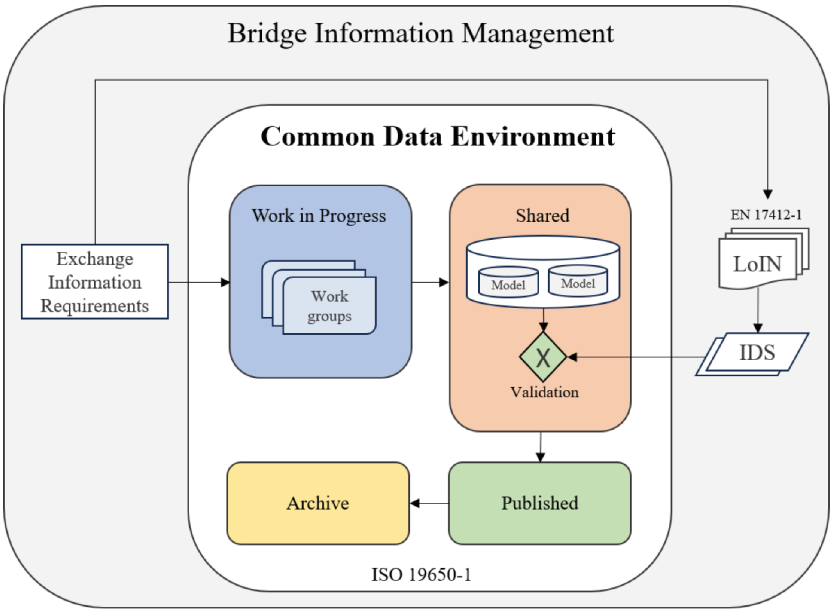

Figure 1. BIM-Based approach for bridge information management.

3 CASE STUDY: THE MORO VIADUCT

The "Moro" viaduct, constructed with prestressed reinforced concrete, consists of 25 spans, each spanning 45 meters. Its deck, approximately 19.10 meters wide, accommodates two lanes for traffic, separated by a central barrier. The piles supporting the viaduct comprise two box-shaped shafts, each measuring around 8.30x3.30 meters, connected by a pulvino beam on which six beams rest. These piles have columns founded on a single plinth resting on piles, with historical interventions focusing on beam swelling, support maintenance, and partial cortical restoration. Over the years, the viaduct has undergone several restorations, mainly concerning beam swelling, support maintenance, and cortical restoration of some parts of the beams.

The need for the Moro viaduct, translated by EIRs defined in the recruitment phase, was to have an I-BIM model with the geometric, documentary, and graphical information related to the bridge's actual state. In particular, the purpose of the model, to be delivered, was to be able to contain information related to the last inspections performed and the attention class in which the bridge fits, according to Italian regulations. For this purpose, it was defined a CDE, organized as described in Section 2, in a data sharing environment: usBIM.browser, by ACCAsoftware, to enable stakeholder collaboration in the infrastructure management process. In addition, the use of this data sharing environment allowed images of deterioration, documents, material tests and reports to be linked to the BIM model.

The I-BIM model (Figure 2) was created using the IFC4X3 standard, in accordance with the EIRs defined in the WIP folder. the IFC4x3 version, allows detailed representation of infrastructure elements, including bridges. With IFC 4x3 version, this bridge is coded as IfcBridge entities and fall under the IfcFacility category. Specifically, the model was developed by a block-based programming with tabular inputs and sections definition. The model represented the bridge as an IfcBridge entity and the constituent elements as IfcBridgeParts. The IfcBridgeParts were defined by the name of the part of the work they represent, with increasing numbering, while the spans were divided into IfcElements of beams, joints, supports, abutments, and foundations.

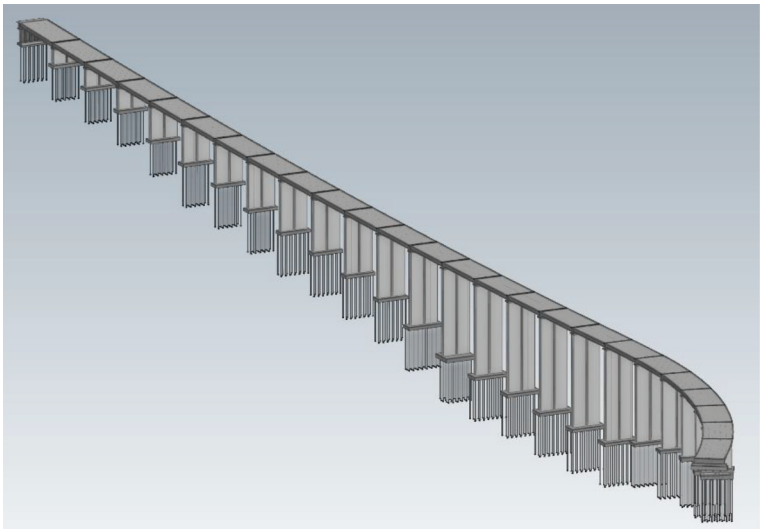

Figure 2. Case study I-BIM model.

Following the guidelines of EN 17412-1:2020 [12], the LoIN is defined by the purpose of the model delivery, namely the assessment of the bridge's condition. Additionally, the milestone is identified as the management phase where the owner acts. Furthermore, beams, columns, slabs, walls, piles, and footings are identified as the objects for which the LoIN is defined. Lastly, as alphanumeric information to manage the detected damage, a set of properties is defined as informational content: Pset_Condition.

Pset_Condition is composed by:

- AssessmentDate means the date on which the general condition of the asset/element is assessed.
- AssessmentCondition is the relative defectiveness value *DR*, calculated according to Italian "Guidelines for Risk Classification and Management the Safety Assessment and Monitoring of Existing Bridges" [3], represents the measurement of the condition state of the elements and is calculated in the following way:

$$DR = Gi \times k1 \times k2$$

In which *Gi* represents the weight of the defect; $k1$ represents the extension of the defect; $k2$ represents the intensity of the defect.

- AssessmentDescription is the qualitative description of the condition of the element considered for which it has been determined as the attention class value, approximately calculated according to the Italian Guidelines [3], attributed to the element depending on the value of the relative defectiveness index which characterizes it. If $DR < 5$, the attention class associated with the element is LOW; if $DR > 25$, the attention class associated with the element is HIGH; for all intermediate values between 5 and 25, the attention class associated with the element is MEDIUM.
- AssessmentType means the category of the last report concerning the assessment of the state of condition of the asset/element, or the type of assessment performed to evaluate the different items, in the case analyzed these are inspections.
- AssessmentMethod concerns the external reference to the assessment method or application used to perform the assessment.
- LatestAssessmentReport refers to the latest technical report on the condition, state of health of the asset/element.
- NextAssessmentDate is the date of the next condition inspection.

– AssessmentFrequency indicates the frequency with which the asset/element must be assessed, to have a clear estimate of their state of degradation.

After the insertion of all this information in the I-BIM model, the model was moved in Shared folder where the information produced must be verified. For this scope, applying the approach described in Section 2, it was generated and employed an IDS (Figure 3).

The IDS standard, developed by buildingSMART, with an XML language, translate LoIN into machine-readable language, ensuring coherence in BIM models [14]. As a distinguishing feature of the Open BIM approach, IDSs promote open data formats, fostering market development and interoperability. For the case study usBIM.IDSeditor was used to generate the IDS, which included all LoIN-specific information for the management phase.

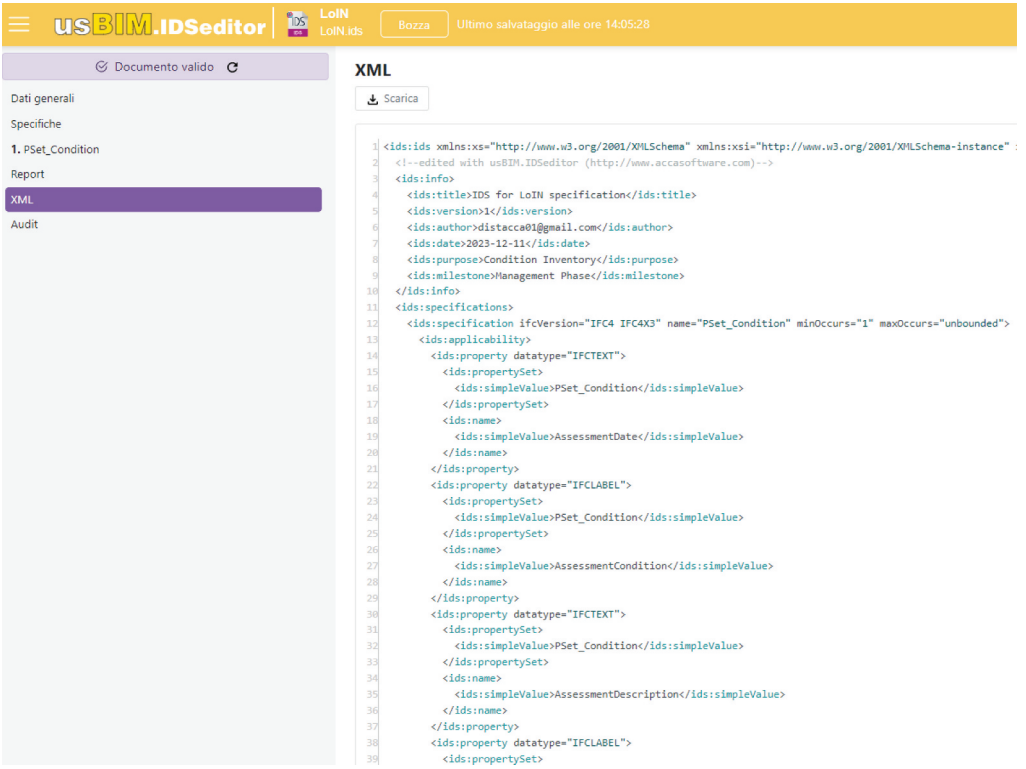

Figure 3. Example of IDS generation for the case study.

4 DISCUSSION

The use of the IDS made possible to verify the accuracy and adherence of the model against the pre-established information required, ensuring that the data and information provided were in accordance with expectations. This verification was carried out through usBIM.IDS, a tool directly applicable to our virtual environment containing the BIM model, which verifies the relevance of the information in real time. The tool usBIM.IDS notified the presence of all the information required. As shown in the following figure, if the information was missing, it would be notified and the IfcElement with the missing information would be highlighted with a different colour, in this case red. In addition, the error code for the failed verification is notified. In the present case, the code specifies that for that element, a specific requirement related to the insertion of the assessment data is not met. The model is therefore not verified, and a modification notification is

forwarded to the responsible team. After the modifications, the model is rechecked, and if it is verified through the IDS, it is shared in the published folder.

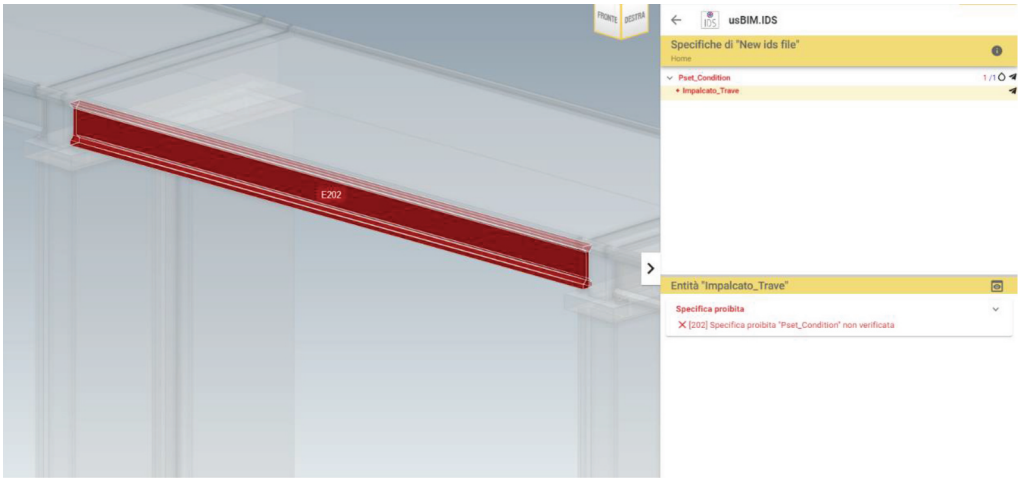

Figure 4. IDS verification for the case study.

The case study highlights the applicability of the proposed approach, which starts from the definition of specific needs related to I-BIM models and arrives at the possibility of verifying the information contained in the models themselves. The main result consists of an information checking strategy, to understand expeditiously what is missing in the model or what is contradictory to the specific needs. Therefore, it has been shown that through this procedure, it is possible to define whether in the I-BIM model of the case study information is present in the model or not, as shown in Figure 4, with the consequence of being able to reduce errors in the delivery phase.

5 CONCLUSIONS

The research has focused on exploitation of BIM approach to improve information management of existing bridges. The study particularly emphasizes the importance of specifying and verifying the information produced and exchanged, defining LoIN, and employing IDS, to check the data within BIM models. This approach is pivotal in all the process that involves model information sharing, fostering collaboration among stakeholders, and ensuring the consistency of data shared. The primary objective is a comprehensive understanding of all necessary information of bridge structures.

Specifically, the methodology is applied to a viaduct case study, in Italy, that shown the usefulness of a BIM-based approach to have a control on the I-BIM model shared, and suddenly identification of possible inconsistency in the delivery phase.

Finally, the application displays certain limitations, as the manual input required in the IDS generator. In addition, limited accessibility to tools such as usBIM.IDS limits their open use and potential for collaboration with infrastructure management stakeholders.

ABSTRACT: A novel replaceable low yield point steel coupling beam with corrugated web and demountable connection is proposed for establishing a rapid recoverable system of bridge piers or shear walls. Six specimens using different material and shape of the webs, with different height-to-span ratio, were prepared and tested under cyclic loading as per AISC 341-16. Three kinds of failure modes were observed, such as local bucking at flanges, welding fracture at the flange-to-endplate connection, combined welding fracture at the flange-to-endplate connection and shear bucking at corrugated web. The utilization of a small height-to-span ratio and low yield point steel in the web can enhance the ductility and energy dissipation capacity of proposed steel coupling beam. All the findings from present investigation may provide reference for the application of proposed replaceable low yield point steel coupling beam with corrugated web for bridges and buldings.

1 INSTRUCTIONS

Earthquake resilient bridge pier has been developed recently, which consists of the main structures (piers) and the replaceable components (energy-dissipating coupling beams). Traditional reinforced concrete coupling beams can be replaced by steel coupling beams in bridge piers or shear wall systems, due to good hysteretic performance, stable mechanical properties, and "fuse" characteristic for the steel coupling beams (Shahrooz et al. 1993, Chen et al. 2007, EI-Bahey et al. 2012). The replaceable steel coupling beams were applied between the bridge towers in the New San Francisco-Oakland Bay Bridge, McDaniel et al. (2003) performed the cyclic tests on three specimens and verified the effective of the stiffened steel coupling beams in reducing the displacement, but the welding fracture took place at failure state. Fortney et al. (2007) & Nikoukalam et al. (2015) proposed demountable steel coupling beams with bolt connector using small cross-section to make sure shear-yielding in advance.

Corrugated steel web (CSW) has high shear strength and out-of-plane stiffness, which has been widely used in the steel girder bridges and shear walls (Wang et al. 2018, Qiu et al. 2022). Hajsadeghi et al. (2014) investigated the seismic performance of the coupling beams with CSWs by finite element simulations, considering the corrugation shape, thickness, and corrugated inclined angle of the CSWs, showing that the CSW coupling beams have excellent energy dissipation capacity. Aydın et al. (2016) conducted quasi-static tests on beam-to-column joints adopting steel coupling beams with CSWs, and concluded that the steel coupling beams with CSWs had the same seismic performance as the steel coupling beams with thicker steel plates. Zhang et al. (2017) proposed a recoverable assembled beam-column joints with CSWs, which was proved to have high bearing capacity and ductility, ensuring the main structure (beam and column) remained in elastic state

DOI: 10.1201/9781003483755-243

under severe earthquakes. Wang et al. (2021) proposed a type of coupling beam with longitudinal arrangement of corrugated steel plate (CSP), and carried out loading tests on CSPs with different geometries. The test results showed that the yield load and initial stiffness were mainly affected by the aspect ratio of the CSP. Considering the demountable performance of the steel coupling beams with CSWs, Quan et al. (2022) proposed a novel demountable corrugated shear panel damper (DCSPD) and investigated the effects of three key design parameters, including the corrugation direction, the thickness of CSW and flange.

In addition, experimental studies indicated that low yield point steel (LYP steel) with higher performance in terms of plastic deformation, ductility and energy dissipation than the common carbon steel, is preferred as the materials for earthquake-resistant components (Saeki et al. 1998). However, more stiffeners were required to avoid premature out-of-plane buckling when the flat webs of the coupling beams were made of LYP steel, and the failure mode of the coupling beams were mostly fracture of welding seam at web-to-stiffener (Zhuang et al. 2022).

Therefore, this paper proposed a novel replaceable LYP steel coupling beam with corrugated web (LCSW coupling beam), which can be designed as a shear coupling beam between two non-energy dissipating segments or as a flexure-shear coupling beam at the beam-to-column joint. The LCSW coupling beam consists of corrugated web with LYP steel, the top flange, the bottom flange, and the endplates. Six specimens with different height-to-span ratio, shape and material of the webs have been fabricated and tested under cyclic loading to investigate their seismic performance, such as the failure mode, stiffness degradation, residual deformation, and hysteretic energy dissipation.

2 EXPERIMENTAL INVESTIGATION

2.1 *Test specimens*

A total of six specimens were prepared and tested under the quasi-static cyclic loading. Figure 1 and Table 1 illustrate the structural details and main parameters of these specimens. The main different parameters considered in test specimens were the shape of the web (corrugated or I-shaped web), the material of the web (steel with yielding strength of 345MPa-Q345 or 160MPa-LYP160), and the height-to-span ratio [$H/(h_w+2t_f)$ =2.2 or 1.7]. The nomenclature of test specimens is shown in Table 1. For example, LCB22 shows the specimen with the height to span ratio of 2.2 using LYP160 steel corrugated web.

2.2 *Material properties*

The material properties of the flanges (Q345), the stiffener (Q235) and the webs (Q345 or LYP 160) were obtained from standard tensile coupon tests per BS EN ISO 6892-1 (BSI 2020). The properties obtained are modulus of elasticity (E_s), yield stress (f_y), ultimate tensile strength (f_p), and the ultimate elongation rate (δ). The results are given in Table 2 as average values of three coupon specimens.

2.3 *Test setup and measurements*

The test setup is shown in Figure 2a, a hydraulic actuator connected to the reaction frame, with load and displacement capacities of 500kN and 500mm, respectively, and with built-in load cell, was used to push and pull the test specimen through transmission beam bolted at the top endplate of specimen. The bottom endplate of test specimen was bolted to the ground beam.

Prior to the formal test, a preloading with 30kN was conducted to check the good contact between the support and loading equipment. After preloading, the lateral loading was applied to the test specimen by displacement-control method (see Figure 2b), as per AISC 341-16

6	LCB17	LYP160	CSW	1.7	360	600

Table 2. Material properties.

Steel	Elastic modulus E_s /GPa	Yield strength f_y /MPa	Peak strength f_p /MPa	f_p/f_y	Ultimate elongation rate δ/%
LYP160	195	198	379	1.91	33.34
Q235	202	339	488	1.44	20.17
Q345	196	385	538	1.4	18.21

(AISC 2016). The lateral displacement was defined as positive when the actuator was push to the west.

The arrangement of the strain gauges and the LVDTs are shown in Figure 3, note that the arrangement of the strain gauges for the specimens with flat web corresponds to that of the

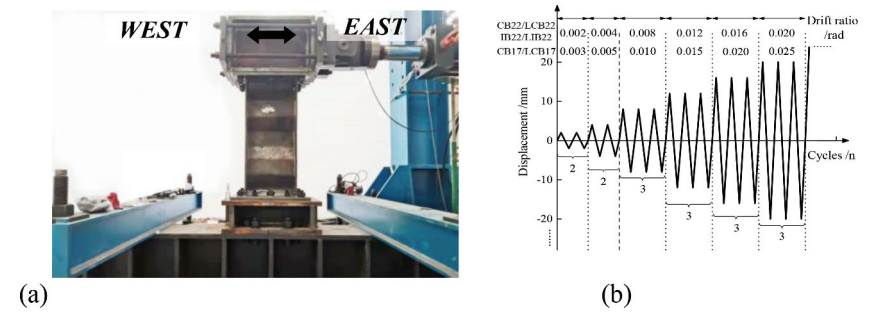

Figure 2. Test setup and loading protocol: (a) Sketch of test setup; (b) Loading protocol.

specimens with CSW. All the information obtained from the transducers, gauges, and load cells were automatically recorded by a data acquisition system at regular intervals during the test.

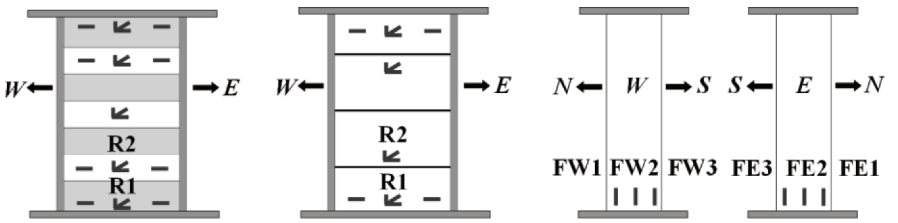

Figure 3. Measurement arrangement: (a) Layout of strain gauges and LVDTs.

3 TEST RESULTS AND DISCUSSIONS

3.1 *Failure process*

The failure process and phenomena were described under different lateral drift ratio. The lateral drift ratio was defined as the ratio of the lateral displacement to the height from the actuator to the bottom endplates. The failure process and modes for each specimen are shown in Table 3 and Figure 4, respectively.

Table 3. Failure process of test specimens.

	Damage features at drift ratio/rad						
Specimens	FB	WB or CSWB	WF	PWF	WT	Failure modes	Failure at drift ratio/rad
QCB22	0.030	0.057	NA	NA	NA	FB	0.057
QIB22	0.062	NA	0.020	0.065	NA	WF	0.065
QCB17	0.027	0.056	0.046	0.066	0.066	Combined WF & CSWB	0.066
LCB22	0.044	0.052	0.052	NA	NA	Combined WF & CSWB	0.052
LIB22	0.044	NA	0.056	NA	NA	WF	0.056
LCB17	0.052	0.056	0.070	NA	NA	Combined WF & CSWB	0.070

Note: FB- Flanges Buckling; WB or CSWB- Web Buckling; WF- Welding Fracture at flange-to-endplate; PWF- Penetrated Welding Fracture; WT- Web Tearing; NA- Not Applicable.

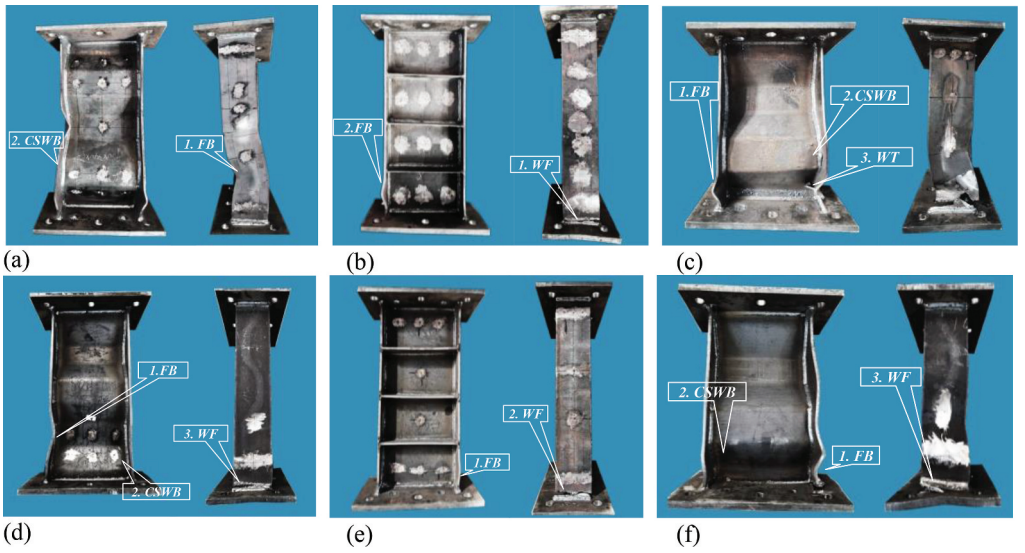

Figure 4. Damage features of specimens: (a) QCB22; (b) QIB22; (c) QCB17; (d) LCB22; (e) LIB22; (f) LCB17. (Note: 1, 2 and 3 represent the order of damage).

Three typical failure modes were observed, including local buckling of steel flanges, the welding fracture at flange-to-endplate connection, and the combination of welding fracture at flange-to-end plate connection and shear buckling of CSWs. In comparison to specimens with CSWs, specimens QIB22 and LIB22 with stiffened I-shape web did not present obvious local buckling of steel flanges due to three stiffeners attached on both sides of the web. Specimens QCB17, LCB22 and LCB17 all exhibited different degree of shear buckling at CSW near flange-to- bottom endplate connection. Moreover, the buckling degree at the CSW was more significant for the specimens with smaller height-to-span ratio (specimen QCB17, specimen LCB17). The buckling degree at the CSW was more significant for specimen using LYP160 steel (specimen LCB17) than that for the specimen using Q345 steel (specimen QCB17). So, both height-to-span ratio and LYP steel significantly influence the hysteretic deformation of the replaceable coupling beams. In addition, no obvious plastic deformation of high-strength bolts was found at the connection when all the specimens failed, thus the replaceable steel coupling beam could be easily demounted and assembled.

3.2 *Hysteretic curves and skeleton curves*

Figure 5 shows the hysteretic curves of test specimens, in terms of the relation between applied force and drift ratio. In the elastic-plastic stage, hysteretic curves show obvious nonlinearity due to yielding of steel webs or flanges, the slope of hysteretic curves decrease gradually with the increase of displacement amplitude, showing an obvious residual deformation due to plastic deformation of steel plates and relative slip at endplates caused by bolt connection. Besides, the energy dissipation capacity was enhanced gradually at the elastic-plastic stage. At the failure stage, the strength and stiffness decreased significantly due to cumulative damage of the test specimens, but the structures can still dissipate energy due to large displacements.

Figure 6 presents the comparison of the skeleton curves for specimens with different parameters. The strength hardening stage of the specimen with LYP160 steel is more obvious than that of the specimen with Q345 steel (see Figure 6a and Figure 6b). In terms of the lateral load in the positive direction, specimen LCB22 and specimen LCB17 reached the peak load (230.7kN, 282.6kN) at the drift ratio of 0.043 rad and 0.051 rad respectively, while the average peak load of QCB22 and QCB17 are smaller. Thus, the usage of LYP steel in the CSW increases the peak load. After the peak loading, the lateral force of test specimens with CSWs

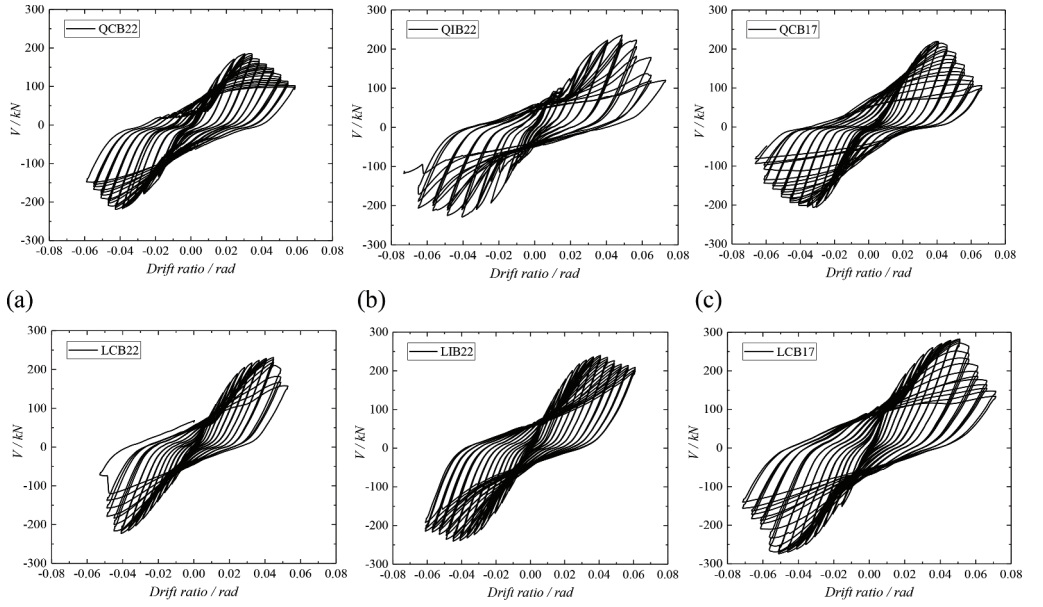

Figure 5. Hysteretic curves: (a) QCB22; (b) QIB22; (c) QCB17; (d) LCB22; (e) LIB22; (f) LCB17.

made of LYP160 steel decreased more obviously than that of test specimens with CSWs made of Q345 steel after the peak loading. Figure 6c shows the comparison of the skeleton curves for test specimens whose web were made of LYP160 steel, LCB17 has superior performance than other two specimens (LIB22 and LCB22) in terms of loading capacity and ductility.

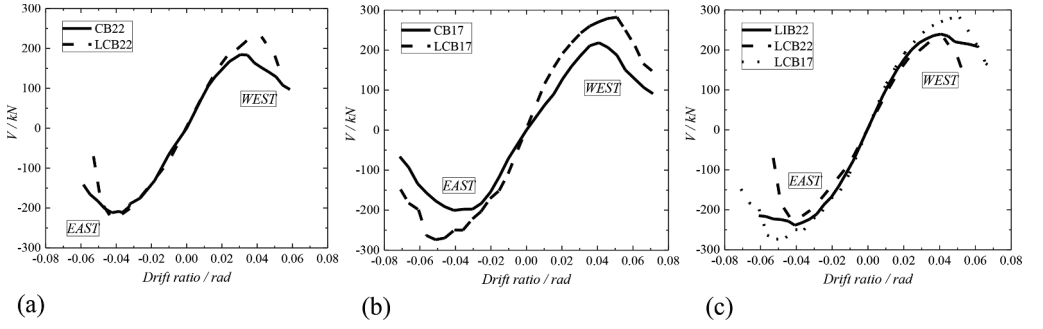

Figure 6. Skeleton curves: (a) LCB22/QCB22; (b) LCB17/QCB17; (c) Specimens with LYP160.

Overall, the utilization of LYP steel in the web improves the loading capacity of test specimens due to continuous strength hardening of LYP160 steel. However, the lateral deformation of the specimens with LYP160 steel CSWs is obvious, leading to local buckling of the flanges and reduction of lateral force. Thus, the flanges of steel coupling beam should be designed to prevent local buckling before ultimate lateral loading.

3.3 *Stiffness degradation*

The relation between stiffness degradation and the lateral drift ratio for all specimens are shown in Figure 7. The stiffness decreases as the lateral drift ratio increases, the stiffness of

specimen LCB17 is greater than that of the other specimens. The stiffness of the specimens with LYP160 steel webs is higher and the stiffness degradation is slower than those of the corresponding specimens with Q345 steel webs. Moreover, the stiffness degradation of the specimens with LYP160 steel webs behaved stably till peak loading, while the stiffness decreased rapidly during the failure stage owing to obvious shear buckling of CSWs with LYP160 steel and the excessive local buckling of steel flanges.

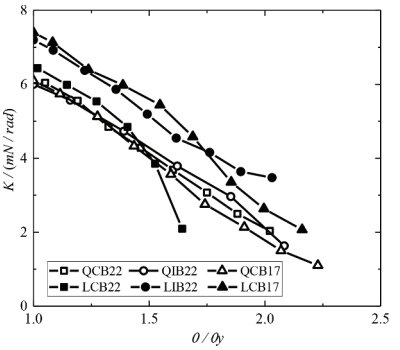

Figure 7. Stiffness degradation curves.

3.4 *Strain development*

Figure 8 shows the variation of the measured strain with the lateral drift ratio. The yield strain ε_{y1} and ε_{y2} are approximately 1000$\mu\varepsilon$ and 2000$\mu\varepsilon$ for LYP160 and Q345 steel steel respectively, which can be calculated according to the material properties of steel in Table 2 and are also presented in Figure 8.

The normal strains on the west flange were in compression while on the east flange were in tension when subjected to push loading. The strain values at the flanges were small before the rotation reached 0.020rad (see Figure 8a). As the lateral drift ratio increased, the west flange yielded first. The CSW did not yield when specimen QCB22 reached the yield point (0.029rad). When the lateral drift ratio reached to the ultimate point (0.039rad), the CSW entered the plastic stage until the specimen was damaged. The failure mode of QCB22 was flanges buckling. Thus, the energy dissipation capacity of the CSWs was not effectively utilized.

When the lateral drift ratio of specimen LCB22 reached the yield drift ratio θ_y (0.032rad in Figure 8b), only the strain at east flange (FE1) reached the yield strain. With the increase of the rotation, the strain at west flange (FW1) and east flange (FE1) increased significantly till the peak load. The strains at the flanges had just entered into plastic stage. Additionally, the shear strain at the CSW (R1) reached yield strain at the lateral rotation of 0.030rad, and the strain increased rapidly after the yield drift ratio θ_y, then reached the maximum around the peak load. The CSW with LYP160 steel deformed more obviously than the flange did after yield point thus became the main energy-dissipating component. Specimen LCB17 presented similar pattern of strain development as specimen LCB22 did (see Figure 8c).

Overall, the advantage of specimens with LYP steel in the web over the specimens with Q345 steel is that the web can enter into yield state earlier, increasing the energy dissipation capacity. During strength hardening stage, the stain at web (especially the web using LYP steel) increased significantly, and then the web became the main energy-dissipating component.

3.5 *Energy dissipation*

Figure 9a, b and c show energy dissipation coefficient (E) per cycle, the energy dissipation and cumulative energy dissipation of all test specimens, respectively. In the elastic stage (Δ/Δ_y<1), the dissipated energy of each specimen increases slowly. With the increase of displacement,

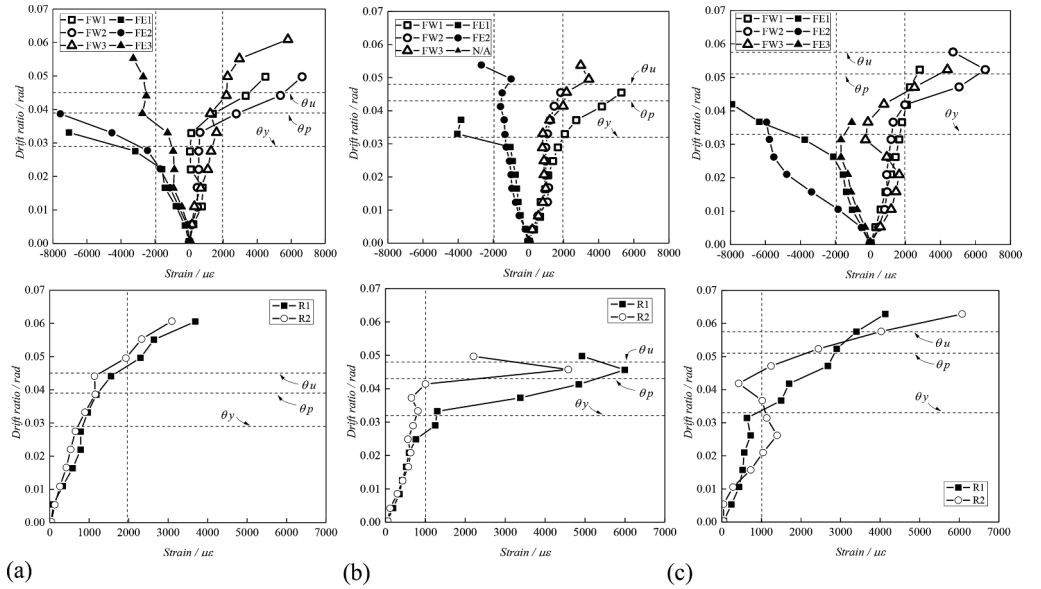

Figure 8. Measured strain development of specimens: (a) QCB22; (b) LCB22; (c) LCB17.

energy dissipation curves increased rapidly from yielding to failure of test specimens. For each loading level, the energy consumption of the second and third cycles was smaller than that of the first cycle (see Figure 9a and b). The energy dissipation coefficients (E) were in the range of 0.5 ~ 1.75 at failure stage showing good energy dissipation capacity for all test specimens.

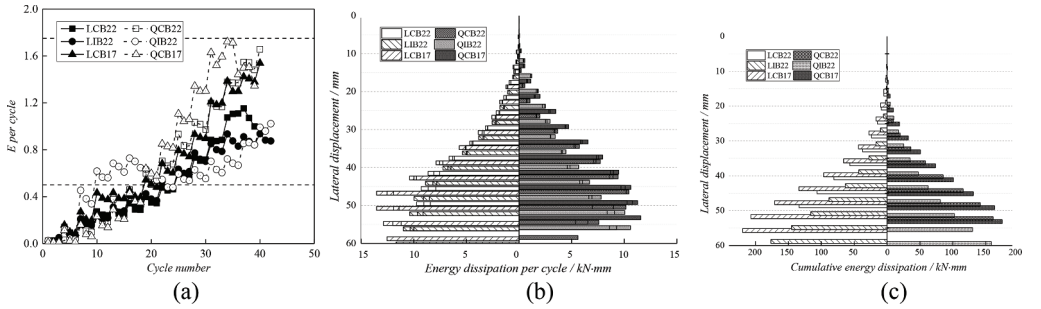

Figure 9. Comparison of energy dissipation capacity: (a) Energy dissipation coefficient per cycle; (b) Energy dissipation per lateral loading level; (c) Cumulative energy dissipation.

Specimens LCB17 and QCB17 with height-to-span ratio of 1.7 had the best energy dissipation among all the test specimens (see Figure 9b and c). Additionally, the utilization of LYP160 steel in the webs further improved the energy dissipation capacity, as the comparison between QIB22 and LIB22, between QCB17 and LCB17. The energy dissipation of specimen QCB22 was slightly higher than that of QIB22. Therefore, application of LYP160 steel and CSW in replaceable coupling beam improves its energy dissipation capacity.

4 CONCLUSIONS

(1) Three types of failure modes occurred for LCSW coupling beams under cyclic loading: local buckling of steel flanges, welding fracture at flange-to-endplate connection, and

combination of welding fracture at flange-to-endplate connection and shear buckling of CSWs. The replaceable steel coupling beam can be easily demounted and assembled since no obvious plastic deformation of high-strength bolts observed when the steel coupling beams failed.

(2) Height-to-span ratio and utilization of LYP steel significantly influence the cyclic behavior of the replaceable coupling beams. The utilization of LYP steel in the web improves the energy dissipation capacity, but enlarges the lateral deformation leading to local buckling of flanges.

(3) Application of LYP160 steel in the CSW coupling beams with smaller height-to-span ratio (1.7 in this paper; specimen LCB17) can enhance the hysteretic performance.

(4) The specimens with LYP160 steel in the web make their webs enter into yield state earlier, so the web becomes the main energy-dissipating component during strength hardening stage.

Fatigue life extension for cracked OSDs using semi-rigid pavement layer

B. Wang

R. Gong, D. Wang & A. Chen
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: The main problem of fatigue cracks on orthotropic steel deck (OSD) is the reduction of local stiffness that harms bridge serviceability, which may lead to pavement damages, lower driving comfort, and even corrosion on the top of the deck. Hence, measures to extend the fatigue life should be implemented to address these issues. This paper proposes to use a semi-rigid pavement made by methyl methacrylate (MMA) mortar on OSDs with existing fatigue cracks. The fatigue test is designed for a three-phase process: I) Pre-damage phase in which fatigue loading is applied on OSD specimens; II) Fatigue life extension phase in which fatigue loading is applied on the damaged OSD specimens with added semi-rigid pavement layers; III) Extra phase in which fatigue loading is increased to achieve the eventual failure of specimens. As a result, the specimens are always failed due to the penetrating crack at the rib-to-deck weld root. The crack is initiated in Phase I, then grows to penetrate through the deck plate first, and the semi-rigid pavement layer in the following phases. It can be addressed that the performance of the interface between MMA mortar and OSD is kept in a good shape, so that the semi-rigid pavement layer can not only help the prevention of crack growth, but also provide sufficient carrying capacity by forming a composite structure combined with the OSD.

1 INTRODUCTION

Orthotropic steel deck (OSD) is a popular structural type when building the mid-span and the large-span bridges. But the numerous welded joints on OSDs may lead to fatigue cracks under traffic loads in long-term services, as has been widely reported all over the world. Typical fatigue-prone welding details include rib-to-deck welds, rib-to-rib butt welds, rib-to-diaphragm welds and cut-outs.

To solve the fatigue issue on OSDs, studies have been carried out with respect to various welded joints. For the rib-to-rib butt welds, the rib-to-diaphragm welds, and the cut-outs, it is sound to reinforce the cracked detail by adding extra steel or FRP plates, which is quite effective in reducing the stress intensity factor (SIF) at the crack tip (Wang et al., 2016; Jiang et al., 2021). As for the rib-to-deck welded joint, however, the reinforcement tends to improve the stiffness of the OSD by adding structural layers, rather than to work on the cracked areas itself. It is mainly due to the difficulties in detecting and repairing the fatigue cracks on this detail, especially those grow to penetrate the deck plate.

Early studies based on cases of actual bridges have shown significant improvements in the fatigue performance of OSD by adding a concrete layer. For the reinforcement of the Caland Bridge in the Netherlands, it is concluded that by adhesively bonding a high-performance concrete layer on the OSD, the stress amplitudes at critical locations are reduced by about 60% to 92% (de Jong, 2007). Similar reinforcement is also proved feasible on OSDs, including the sandwich steel plate systems (de Freitas et al., 2017), the ultra-high-performance concrete (UHPC)

DOI: 10.1201/9781003483755-244

layer (Shao et al., 2019), and the steel-concrete composite system using waveform deck plates (Su et al., 2016).

It is worth noting that the aforementioned case study on Caland Bridge indicates that the strengthening layer can act solely to bear the loads even when the original OSD is completely damaged. It hence suggests that there is no need to adopt this kind of strong reinforcement until the penetrating cracks grow to have a length of about 100-150 mm (de Jong, 2007). In other words, for OSDs with limited-sized cracks, it is possible to fully consider their residual carrying capacity and carry out reinforcement using materials with moderate stiffness and ductility.

Therefore, for the fatigue life extension of OSDs, this paper proposes to use a semi-rigid pavement made by methyl methacrylate (MMA) mortar in a local zone on the OSD with existing cracks. It can be considered not only as the functional layer for the waterproof and driving comfort, but also as the structural layer that helps to reduce the crack growth rate. For the purpose, a fatigue test is designed by using different loading phases on OSD specimens with a semi-rigid pavement layer, as given in Section 2. In Section 3, the results are analyzed by comparion with those from specimens without the MMA layer, which manifests the effect of life extension of this approach. Accordingly, the conclusions are drawn in Section 4.

2 FATIGUE TEST DESIGN

2.1 *Specimens*

The specimen is designed for the rib-to-deck welded joint of OSD, which includes the deck plate and one U-rib. With respect to the common design in the current bridges using OSDs, the deck plate has a thickness of 12 mm or 14 mm, and the size is 800 mm × 400 mm. The U-rib is 280 mm in height, and the width is 300 mm at the top and 150 mm at the soffit. The specimens are all made of Q345D steel. According to the common way of OSD production, the test specimens were manufactured by CO2 gas metal arc welding, and the automatic welding is used on both sides of the U-rib synchronously, which helps to reduce the welding deformations and residual stresses. Also for investigating the effect of semi-rigid pavement, MMA is used as the extra layer by adhesively bonding on the specimen. It provides not only the function of waterproofing and bonding, but also considerable mechanical performances.

The boundary conditions on the specimens are simply supported on both sides. The rollers are set to contact with the specimen to provide the hinge, through which the forces are transmitted to the base of the test platform. During the experiment, the loads are applied on the top of the MMA layer or the deck plate (when there is no MMA layer). The loading area is 200 mm × 100 mm, with the position right above the rib-to-deck welded joint. The fatigue test specimen with the MMA layers is shown in Figure 1.

During the test, the strains near the weld root/toe on the deck and the rib are measured. For different longitudinal positions, strain gauges are installed on nine sections of the

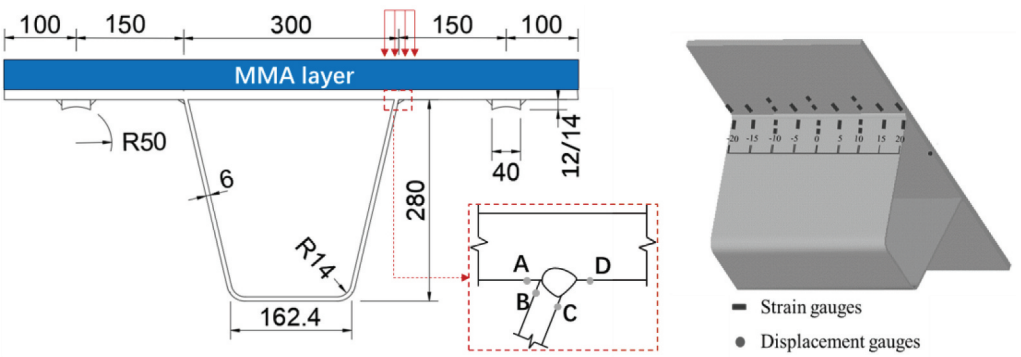

Figure 1. Design of the test specimens and the measuring points.

specimen, with an interval of 5 cm. Hereinafter, they are noted by the distance to the middle of the specimen, i.e. ±20 cm, ±15 cm, ±10 cm, etc. Each strain gauge is installed with a distance of about 5 mm to the root/toe, noted as measuring points A~D with respect to the position (see Figure 1). Additionally, for the C/D series with better accessibility, extra strain gauges are installed on three sections, with a distance of about 14 mm to provide the gradient.

2.2 *Verification test*

A verification test is first conducted to give a preliminary understanding of the effect of the MMA layer. The MMA layer on the OSD is 55 mm thick, and the load applied on the specimen is 30 kN. Figure 2 demonstrates the assembly of the test and the failure mode of the specimen in the end.

Accordingly, the fatigue life of this specimen is about 1.03×10^6 cycles, and the failure is caused by the crack initiated at the rib-to-deck weld root, which grows to penetrate the deck plate and the MMA layer above. Comparably, the previous fatigue test on specimens without having an MMA layer shows that the fatigue life is about 0.26×10^6 cycles (Wang et al., 2021). It means that a four-time fatigue life is given by adding the MMA layer.

Based on the strain data during the test, it can be stated that auxiliary stiffness provided by the pavement layer significantly reduces the stress amplitude at critical positions. Compared to unpaved specimens, the hot spot stress amplitude decreased from 251.98MPa to 164.89 MPa. According to the Basquin equation, the fatigue life can be estimated,

$$N(\Delta\sigma)^m = C \tag{1}$$

The reduction of hot spot stress by about 34.5% will result in a significantly larger fatigue life of OSD. By assuming that the exponent m equals three, the fatigue life is about 3.56 times the original one, which is quite close to the test results.

Based on the results, the fatigue life extension by adding an MMA layer is validated, and the design in the following tests can be given. The MMA layers are determined to have a thickness of 40 mm, for the sake of the test time and loading conditions.

Figure 2. Verification test on the OSD specimen with MMA layer.

2.3 *Load sequence*

Despite that the above verification test indicates a significant improvement in the fatigue life of OSD, further fatigue tests are required for the sake of the reinforcement for OSDs with existing cracks. Considering that the pavement is replaceable for actual bridges, the MMA layer can be added at a certain stage of the life cycle of OSDs. Hence, the load sequence in the test is designed to have three different phases.

1) Phase I: The fatigue load is applied on specimens without MMA layers. It produces pre-cracks on specimens, and the consumed fatigue life and the corresponding damages can be also estimated based on existing test results. Also for the recording of the crack status in this phase, a group of beach marking load cycles is applied in the end.
2) Phase II: The MMA layer is paved on the OSD specimen. The fatigue loads are then applied with beach marking loads in between, which are designed based on the previous study (Wang et al., 2019) to provide the crack growth progress during the test. The specimen may fail in this phase, and the fatigue test can be terminated.
3) Phase III: By the end of Phase II, the OSD should be severely damaged, while it is not always possible to address the fatigue cracks and to estimate the remaining test time. Only in this case, Phase III is applied, in which the load is increased by about 40% to show the failure mode of the specimen.

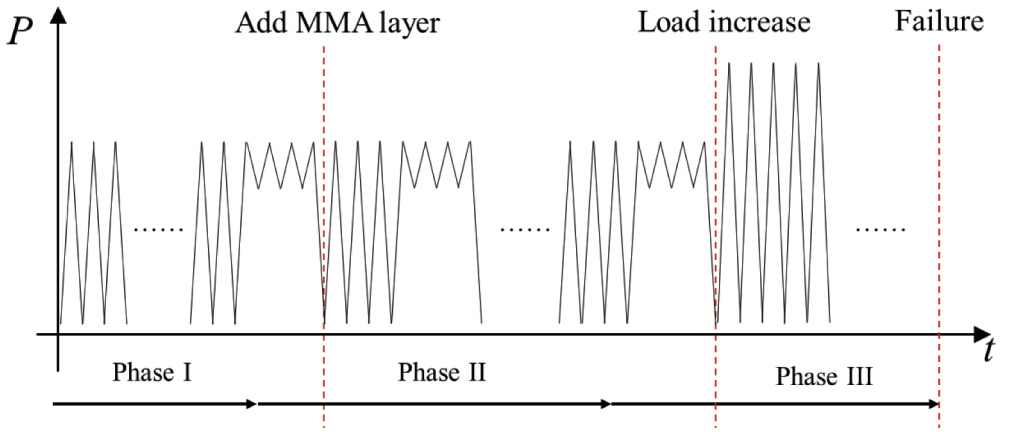

Figure 3. The three-phase load sequence of the fatigue test.

3 TEST RESULTS AND DISCUSSIONS

3.1 *Summary*

Based on the test design, a total of six specimens were tested, including three of them using 12-mm-thick decks, and the rest three using 14-mm-thick decks, which are noted as D12 and D14, respectively. The maximum fatigue loads are 25 kN and 35 kN, for the D12 and D14 groups, respectively, and the minimum loads are always set to 1 kN to keep the stability during the dynamic test. The loading frequency is 2Hz.

In order to manifest the effect from the MMA layer under different crack conditions, different cycle counts were used in Phase I, which are determined with respect to the variation of strains at critical locations. Because of the relatively large life in crack initiation and early-stage crack growth, the majority of the fatigue life of OSD is mainly consumed in this phase. The test conditions and the results are summarized in Table 1.

Table 1. Summary of the tests.

Specimen	P_{max} in Phase I&II (kN)	P_{max} in Phase III (kN)	Fatigue life (cycles)		
			Phase I	Phase II	Phase III
D12-1	25	35	350000	800000	347288
D12-2	25	\	500000	470607	\
D12-3	25	\	470000	730786	\
D14-1	35	50	328800	370000	112961
D14-2	35	\	401200	158557	\
D14-3	35	\	330000	333986	\

As a result, the specimens are always failed due to the penetrating crack at the rib-to-deck weld root. The crack is initiated in Phase I, and then grows to penetrate through the deck plate first, and the MMA layer in the following phases. In addition, it is worth noting that the interface between the MMA layer and the deck plate remains in good form even after the fracture by vertical cracks, as shown in Figure 4. Hence, it can be stated that the MMA layer can be easily implemented by adhesive bonding to OSDs, which shows the advantage in practical cases of bridges with existing fatigue cracks.

Figure 4. Failure of specimens due to penetrating cracks at the rib-to-deck weld root.

3.2 *Strain data analysis*

To better show the effect of the MMA layer, the strain data are analyzed. Since the specimens failed due to fatigue cracks at the rib-to-deck weld root, the data from the strain gauges for A series measuring points are specifically concerned. The data from A series measuring points on Specimen D12-2 and D14-1 are demonstrated in Figure 5, providing typical strain histories of the two-phase test and the three-phase one.

It is clear that, in Phase I, the strain at the crack site is decreasing, while those near the crack site are increasing, indicating the stress concentrations nearby. After adding the MMA layer, strain data from all gauges are reduced significantly. Consequently, the strain data can be kept in a relatively stable range in Phase II. Yet, the crack may continue to grow and affect the MMA layer, which demonstrates the brittle fracture behavior and thus leads to a rapid

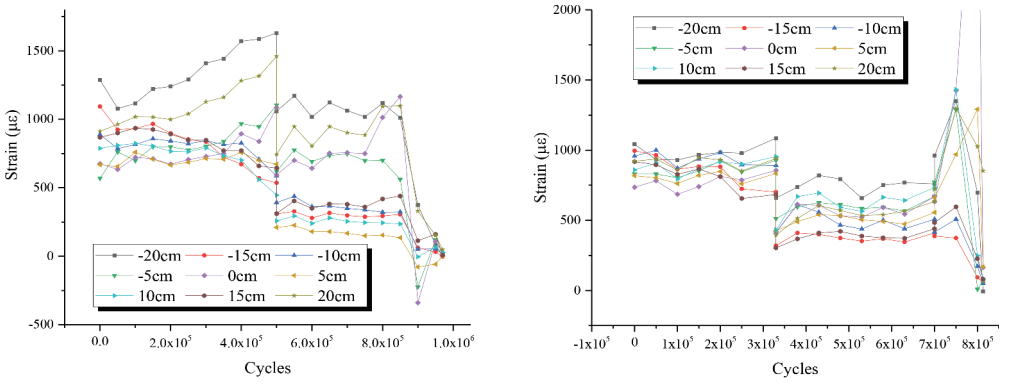

Figure 5. Typical strain histories of specimens: a) a two-phase test (Specimen D12-2) and b) a three-phase test (Specimen D14-1).

decrease for all strain data. Finally, the large deformations can be observed until they get out-of-limit, and the specimens are considered failed due to the fatigue cracks.

In a quantitative analysis on the strain data, it shows that the MMA layer can result in a strain reduction by about 40 to 55 percent. The effect can be even more prominent with the thinner MMA layer when compared with the verification test using a 55-mm-thick one. It can be attributed to the better usage of the mechanical performance of the MMA layer when the OSD is suffering severe fatigue damage. On the other hand, the 40-mm-thick MMA layer in the test can also provide better strength of the interface when connecting to the steel deck plate. As shown above, the well-behaved interface is observed after specimen failure. In contrast, the thicker layer may result in slower internal drying, affecting the curing effect, and leading to shrinkage and cracks during the curing process, thus reducing the adhesive strength with the steel deck plate.

3.3 *Estimation of OSD fatigue life extension*

The fatigue life extension by adding the MMA layer can be estimated based on the test results. Given that the fatigue crack is always initiated at the weld root near the section next to the longitudinal end, namely the one at ±15 cm, the strains from those measuring points are used to calculate the nominal stresses. The fatigue damage in each phase is then estimated using the S-N curve obtained by previous tests, which gives a fatigue strength of FAT 121.8 using the nominal stress method (Wang et al., 2021). Following the Miner's rule, the total damage can be provided by the summation of damage in each phase.

Table 2 presents the estimation of fatigue damage for all specimens in different phases. Obviously, the total damage of each specimen is larger than 1, though the results are quite scattered. It is not only induced by the randomness in fatigue issues of OSD, but also the paving process of the MMA layer that affects the material itself and the interface. Despite so, the worst cases, i.e. Specimen D12-2 and D14-2, have a total damage of about 1.9, meaning a 90% extension of fatigue life. Additionally, it is worth mentioning that the two specimens are loaded with a high cycle count in Phase I, causing severe damage before the MMA layer is paved.

Table 2. Estimation of fatigue damage.

		Fatigue damage D			
Specimen	Nominal stress (MPa)	Phase I	Phase II	Phase III	Total
D12-1	187.5	0.638	1.458	1.737	3.833
D12-2	190.3	0.954	0.898	\	1.852
D12-3	198.2	1.012	1.574	\	2.586
D14-1	198.6	0.712	0.802	0.714	2.228
D14-2	232.0	1.385	0.548	\	1.933
D14-3	253.0	1.478	1.496	\	2.974

4 CONCLUSIONS

This study presents a method to extend the fatigue life of OSDs with existing fatigue cracks by using the semi-rigid pavement layer made by the MMA mortar. Through the fatigue test, it can be stated that the MMA layer shows promising effects for this purpose. It not only helps prevent crack propagation, but also provides sufficient load-carrying capacity by forming a composite structure with OSDs. Based on a rough estimation of fatigue damage, a significant improvement in fatigue resistance can be provided, showing at least a 90% increase in fatigue life obtained for the test specimens. In addition, the interface between the MMA layer and the OSD is kept in good shape during the test, indicating that adhesive bonding can be also a practical way when connecting this type of reinforcement layer to the original OSD structures.

ABSTRACT: A new type of steel cap beam is proposed in this paper, combined with common steel plate composite girder bridges. Numerical simulation and scaled model test are used to study the static performance of hybrid structure which consists of steel cap beam and concrete column. In the test, the steel cantilever beam had the characteristic of bending and shear force under eccentric load and the root section was the most unfavorable. However, due to welding defects, the local buckling occurs at webs. By comparing the result of numerical and experimental study, in the state of ultimate bearing capacity, local buckling of webs is more likely to occur at the middle or the root section of steel cantilever beam, depends on whether there are welding defects at the transversal diaphragms. Specifically, the safety factor of steel cap beam in the test with welding defect is 2.8 while that of the finite element model without welding defect is 4.

1 INTRODUCTION

In recent years, traditional on-site pouring of concrete construction has been unable to meet the requirements for rapid and sustainable construction, and precast prestressed concrete bent caps have been preliminarily applied with the development of bridge assembly construction technology. However, problems such as the difficulty of transportation and hoisting caused by the excessive weight of precast bent caps, the large investment of component formwork and the inability to test the quality of grouting materials, make it difficult to be widely used [1-3].

Steel cap beam can effectively solve these problems and are mostly used in railway bridges instead of city bridges in China. Several scholars studied the structural form and mechanical properties of steel cap beam, [4] proposed a full prefabricated large-cantilevered high strength steel-UHPC composite bent cap and a theoretical calculation method for prediction of the ultimate flexural capacity on the basis of test result. [5-6] used the finite element method to study the parameters affecting the mechanical properties of steel cap beams and compared them with concrete cap beams. [7] studied the mechanical properties of the Hanshin Expressway by finite element and model test methods.

In this paper, scale model test and finite element method are used to study the static performance of the steel cap beam-concrete column hybrid structure, mainly focusing on the ultimate bearing capacity state of steel cap beam, conducting in-depth research on the failure modes of steel cap beam and causes, and summering reasonable safety factor of the structure.

2 TEST PREPARATION

2.1 *Design*

The specimen named as SLM is designed and manufactured with a 1: 4 scale ratio. As shown in Figure 1, the steel cap beam mainly consists of roof, webs, base plate and stiffener, and is welded by Q345 steel plates with different thicknesses, while the total length of the steel cap beam is 5.385 m, that of the cantilever beam is 1.893 m. The steel cantilever beam is subject to bending moments and shear force, whose shear force diagram is stepped because the shear force acts only above the diaphragms. Therefore, the section at 1.38 m from the end of the cantilever beam is set as the dividing section between thick plate and thin plate, while the thickness of the top plate, bottom plate and web of the outer cantilever beam end are 6mm, 6mm and 5mm, that of plates at other sections are 9mm, 9mm and 6mm respectively.

The size of concrete column in Figure 1 is 0.375m (transverse) × 0.55m (longitudinal)×2m, which uses vertical φ10 ribbed steel bars, φ4 transverse bars φ4 stirrups and C40 concrete. After bundling bars into cages, pouring into C40 concrete on site and curing for 2 weeks, the concrete column will be ready for installing steel cap beam and test.

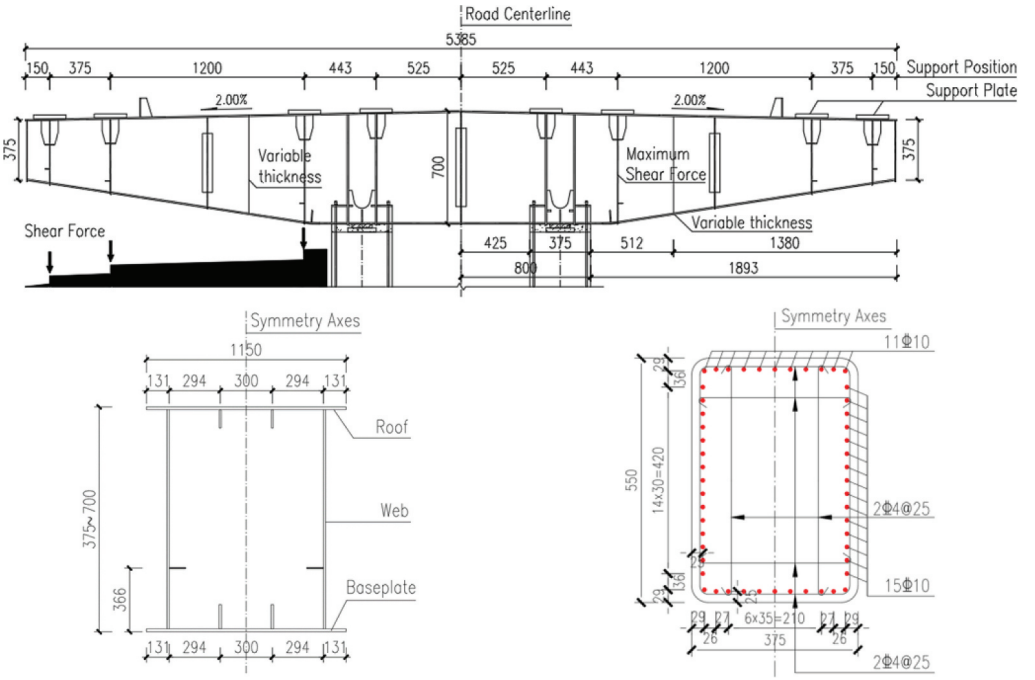

Figure 1. Design of steel cap beam and concrete column (Unit:mm).

As shown in Figure 2, a new type of reinforced flange anchorage connection structure is proposed for the joint section of steel cap beam and concrete column, which mainly consist of steel cap beam, flange, concrete column, rebars and UHPC. During the construction, steel cap beam is placed above the temporary support at the top of the column and nuts are tightened after rebars of concrete column passes through the reserved hole on plates of flange and steel cap beam, and finally pouring UHPC between the base plate of steel cap beam and the top section of concrete column.

2.2 *Loading system*

As shown in Figure 3, the loading system is a self-reaction device, including H-shaped steel beams and hydraulic jacks above the steel cap beam and steel base under the concrete columns, connected and tightened by prestressed steel tendons. The loading system passes

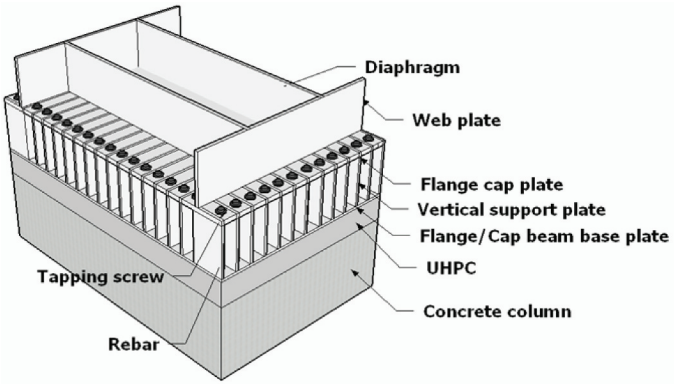

Figure 2. Reinforced flange anchorage connection.

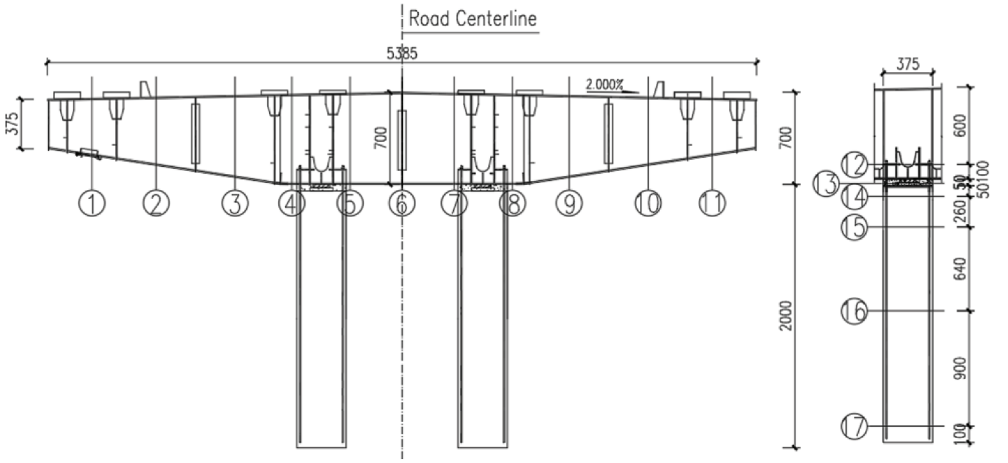
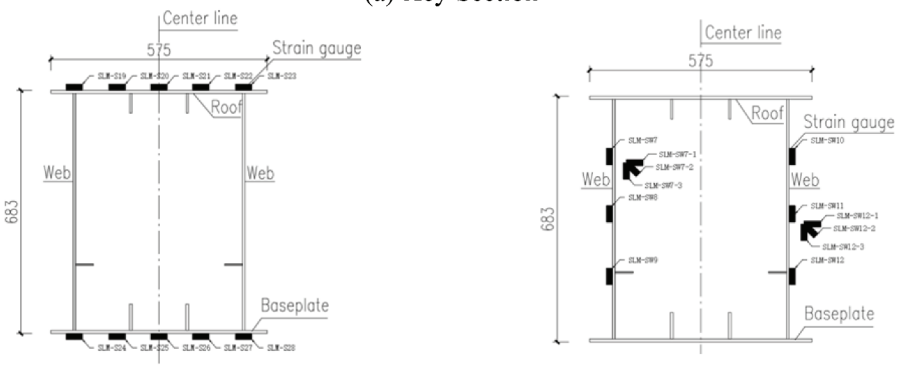
vertical pressure on each support position of the steel cap beam through lifting jacks, and pre-loading is performed at the beginning of the experiment by applying 20kN each jack. The formal loading is divided into four loading stages: ① Four jacks provide 148.6kN respectively. ② The jacks at the end of cantilever beam provide 365.5kN of 17kN/level, and other jacks provide 209.6kN of 10kN/level. ③ Load in the same manner as ② until the steel plates yields; ④ Load until structural failure. (The average yield strength of steel is about 440MPa and the average ultimate tensile strain is about 600MPa).

Figure 3. Test on site.



2.3 *Measuring arrangement*

Figure 4 shows the measuring arrangement of the test. The section 1~11 are set symmetrically on both side of the steel cap beam, while 3~5 unidirectional strain gauges are pasted on the roof and base plate to measure the transverse strain of the steel plate, 1~3 three-dimensional strain gauges are pasted on the web to measure the vertical shear strain.



3 TEST RESULTS

3.1 *Failure model*

When the load at the end of cantilever beam on both sides was 1023kN and that of the root was 592kN, the failure occurred. Specifically, the steel cantilever beam deformed violently and

(a) Key Section

(b) Measuring Arrangement of Section4

Figure 4. Measuring arrangement.

produced a loud sound inside the box girder, and alone with the obvious deflection at the end of cantilever beam, three webs had local buckling failure at section 3 and section 9.

As shown in Figure 5, it was obvious that the local buckling of three webs occurred at the connection between the transverse rib and roof or the base plate, which deformed inward and developed about 45 °, possibly caused by the principal stress.

After the test, the steel cantilever beam was cut and the internal condition of the beam was observed. We found a welding defect that the transverse stiffeners and diaphragms were

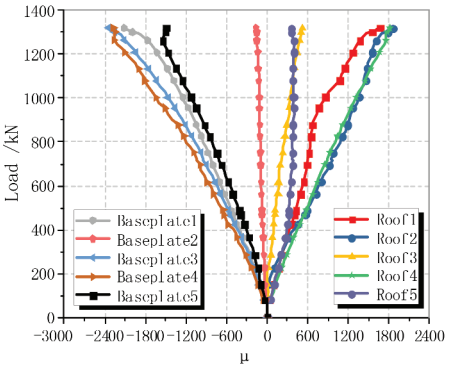


Figure 5. Failure model.

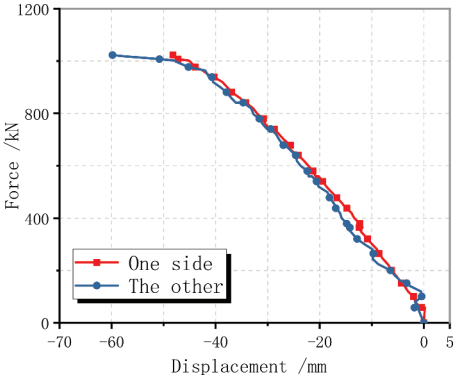
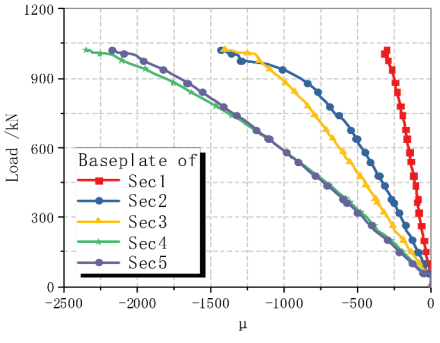
welded to the base plate respectively, but they were not welded together, which was different from the design. Considering that this diaphragm was close to the section for different plate thickness, local buckling may occur at this section instead of the root of cantilever beam due to the welding defects here, just as the test results.



3.2 *Mechanical properties*

Figure 6 indicates the curve between the load and the strain or displacement of the key section of steel cap beam. Curve in Figure 6(a) is the load and the strain of the roof or base plate of section 4, where positive numbers represent tensile strain and negative numbers represent compressive strain. Specifically, five strain gauges are pasted on each plate and every curve shows obvious linear relationship between load and strain during the elastic phase of steel plate, and plateaus or mutations in the plastic phase. Curve in Figure 6(b) shows the linear relationship and the platform between the load and the vertical displacement of section 1. Figure 6(c) and Figure 6(d) respectively indicate the curve of the load and the maximum transverse strain of the base/roof plate form section 1 to section 5, from which we can conclude that section 4 is the most unfavorable.



Moreover, it is obvious that the roof plate is tensile and the base plate is compressed, while webs are subjected to shear force. In section 3 that local buckling occurs, the tensile strain of the roof plate is 2594με and the compressive strain at the bottom is 1408με, also the shear strain of the web is 1318με. Although the strains at section 4 is higher than that of section 3, welding defects make section 3 more vulnerable.

4 FINITE ELEMENT ANALYSIS

4.1 *Finite element model*

The ANSYS is used to calculate and analyze the static capacity of the hybrid structure pier. The shell181 element is used to simulate the steel cap beam and the solid65 element is used to simulate the concrete column and the UHPC post-pouring section, and the link8 element is used to simulate the reinforcement. Figure 7 shows the finite element model, and the bottom of the concrete column is constrained by all degrees of freedom, the load size and application position are consistent with the test above.

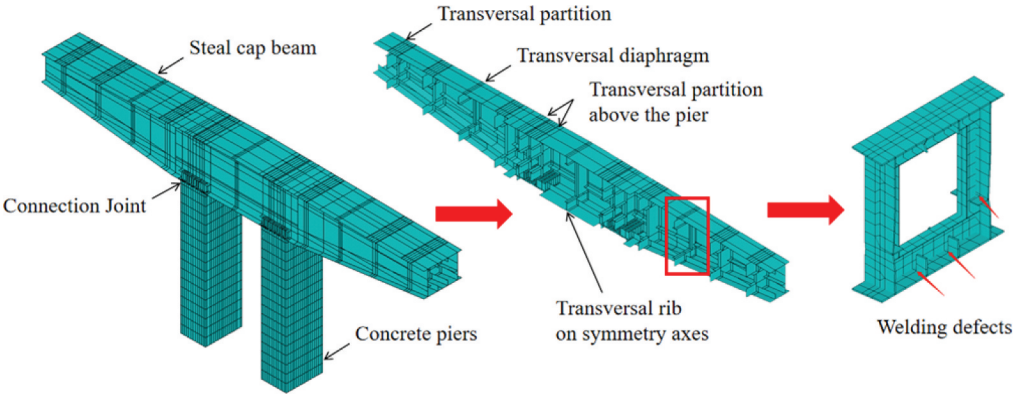

Figure 7. Finite element model.

4.2 *Results*

The calculation is divided into two situations. On the one hand, while considering the welding defects in Section 3.1, the stiffeners of base plate are disconnected from the diaphragm, both of which are only connected to the base plate respectively in the finite element model. In this case, it is found that the ultimate bearing capacity of the structure is about 1100kN, very close to 1023kN in the test, and local buckling occurs at the webs near the diaphragm when the structure fails, moreover, the transversal stress cloud is highly consistent with the test, as shown in Figure 8.

On the other hand, establish an FEM of the steel cap beam without welding defects by extending the stiffeners to connect with the diaphragm. Different from the results above, the load at the end of cantilever beam is 1488kN and that at the root section is 853kN, far higher than structure with welding defects. Obviously, in the ultimate bearing capacity state, the stress of the structure has not reached the maximum strength of the steel, so local buckling is more likely to occur at section 4 due to principle stress than at the middle of the steel cantilever beam.

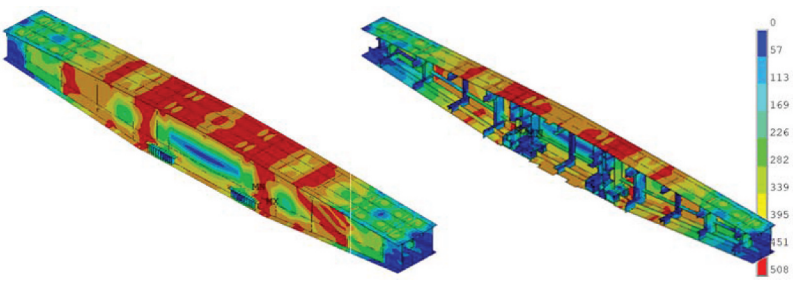

Figure 8. Mises stress diagram of FEM in ultimate Bearing capacity state (Unit:MPa).

4.3 *Safety factor*

Based on finite element analysis and model test results, to the steel cap beam with welding detects, the ratio of the load in ultimate bearing capacity state to serviceability state is about 2.8, however the safety factor of the steel cap beam without welding defect is 4 by finite element analysis. Therefore, the design of the structure is safe and can be optimized.

5 CONCLUSION

Based on the experimental and numerical study above, we can conclude that

(1) In the test, the steel cantilever beam had the characteristic of bending and shear force under eccentric load and the root section was the most unfavorable. However, due to welding defects, the local buckling occurs at webs, which deformed inward and developed about 45 °, possibly caused by the principal stress.
(2) By comparing the result of numerical and experimental study, in the state of ultimate bearing capacity, local buckling of webs is more likely to occur at the middle or the root section of steel cantilever beam, depends on whether there are welding defects at the transversal diaphragms.
(3) The safety factor of steel cap beam in the test with welding defect is 2.8 while that of the finite element model without welding defect is 4, and local buckling occurs at different places of webs.

Real-time multi-objective topology optimization method via deep learning

Cheng Xiang
College of Civil Engineering, Fuzhou University, Fuzhou, China

Airong Chen, Dalei Wang & Rujin Ma
College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: The goal of bridge design is to design and construct an elegant and safe bridge that meets all functional requirements at an acceptable cost. Topology optimization has emerged as a powerful tool for innovative bridge design. However, the inherent drawback of high computational cost in current topology optimization remains unresolved. Moreover, relevant research that mainly focuses on a single objective fails to meet the safety and usability requirements of the bridge. Therefore, in this paper, an iteration-free multi-objective topology optimization (MOTO) method based on deep learning is proposed in this paper, which can not only improve the computational efficiency of MOTO, but also meet the different structural demands. Firstly, a MOTO mathematical model based on constraint programming method was established, and the dataset with stiffness, strength and material consumption as optimization objectives was constructed. Secondly, based on the self-attention mechanism, a novel network is constructed, and trained. Finally, the performance of the proposed method was evaluated in terms of efficiency and accuracy. Results show that a significant reduction in computation cost of MOTO problem was achieved with little sacrifice on the performance of design solutions. The proposed method can provide new ideas for multi-objective design of bridges and promote the improvement of bridge design level.

1 GENERAL INSTRUCTIONS

Structural optimization seeks to pursue structures with higher efficiency (such as higher performance, lower costs, lightweight). Within the field of structural optimization, topology optimization (TO) is dedicated to identifying the optimal distribution of material within a given design domain under different constraints (loads, boundary conditions and volume fraction). Over the past few decades, TO has experienced rapid development, leading to the emergence of numerous numerical methods (Sigmund and Maute, 2013), such as SIMP, evolutionary approaches, level-set method and moving morphable components method (MMC). Despite their widespread adoption, traditional methods for solving TO are hindered by their computational expense, necessitating a large number of design variables and iterations during the optimization process. This computational inefficiency significantly hampers the practical application of TO, highlighting the urgent need for new methods to enhance its efficiency and practicality.

With the popularity of deep learning (DL), it has brought about significant advancements in various domains, and several DL methods have been developed in recent years to accelerate the topology TO process. Sosnovik and Oseledets (2019) give the first attempt to integrate DL by regarding TO as an image segmentation task. With the convolutional encoder-decoder architecture, the near-optimal structures can be obtained without any iteration. Yu *et al.* (2018) proposed an iteration-free method that utilizes a CNN to predict a low-resolution solution, which is subsequently fed into a GAN to enhance its resolution. Wang *et al.* (2021) and

DOI: 10.1201/9781003483755-246

Xiang *et al.* (2022) proposed a deep CNN with perceptible generalization ability for TO, enabled by a specially designed initial physical field input tensor, which can obtain 2D or 3D optimized structures in a split second even with previously unseen boundary conditions.

Some recently proposed advanced network architectures have also been introduced into TO task to improve the prediction accuracy. For instance, the attention mechanism, as the core of Transformer, is integrate into the TO task as a means to improve the predicting accuracy by *Zheng et al.* (2021). Seo and Min (2023)introduces the graph neural networks for accelerating topology optimization in irregular design domains, achieving near-optimal topologies by encoding complex non-Euclidean data into Euclidean form. Recent years also witnessed the adoption of physics-informed neural network (PINN) in TO with the aims at improving the accuracy of DL-based TO method. For instance, Zhang *et al.* (2021) gained the optimized structures by adopting the PINN that incorporating physical information of compliance into the loss function and replacing the element density update in TO with the neural network parameter update. Nevertheless, the PINN-based method required hundreds of FEA and frequent network parameter updates, making it even more time-consuming than conventional methods and failing to deal with the efficiency issue.

The aforementioned research has demonstrated the significant potential of integrating DL with TO. However, these studies mainly take the global response of compliance as the optimization objective, while in practical structural design processes, structural optimization involves a trade-off among different optimization objectives. For instance, it is often necessary to ensure structural stiffness while also achieving a reasonable stress distribution to avoid stress concentration (Xiang *et al.*, 2022). The existing research, which is primarily focused on specific optimization objectives, clearly falls short of meeting real-world requirements. Therefore, this paper presents an iteration-free method based on DL to address MOTO problem, with the aim of advancing the practical applications of TO technology. The remaining sections of the paper are organized as follows. In Section 2, a typical MOTO problem is introduced, and a mathematical model is formulated to achieve the MOTO. In Section 3, a dataset is generated for MOTO problem, and a novel UNet-based neural network is designed. Section 4 evaluates the performance of the neural network. Finally, Section 5 concludes the paper.

2 TYPICAL MULTI-OBJECT TOPOLOGY OPTIMIZATION PROBLEM

Currently, the compromise programming method is primarily used to address multi-objective optimization problems when the sub-objectives have different natures. Its fundamental idea is to normalize multiple sub-objective functions, allowing the objective function values to vary between 0 and 1, and then transforming the problem into a single-objective optimization problem by applying weights to each sub-objective. However, TO is commonly tackled using sensitivity-driven methods. The significant disparities in both the physical meanings and numerical values among different objectives may pronounced oscillations throughout the optimization process.

This research employed the constraint-based method that establish a primary optimization objective among multiple sub-objective functions. Subsequently, the other optimization objectives are treated as constraint conditions. In line with prevailing research, for the proposed MOTO problem, we employ compliance as the primary optimization objective, while treating stress and material consumption as constraints, as shown in Equation 1. This approach seeks to enhance optimization outcomes by prioritizing the minimization of compliance, while simultaneously addressing issues related to high stress scenarios and potential stress concentration phenomena. As a result, the optimized structure not only exhibits substantial stiffness but also satisfies the necessary strength requirements and considerations for economic performance. The mathematical model for minimizing compliance design under volume and stress constraints can be expressed as:

$$min\text{: } c(x) = \boldsymbol{U}^{\boldsymbol{T}}\boldsymbol{K}\boldsymbol{U} = \sum_{i=1}^{N} E_i(x_i)\boldsymbol{u}_{\boldsymbol{i}}^{\boldsymbol{T}}\boldsymbol{k}_{\boldsymbol{0}}\boldsymbol{u}_i$$

$$\text{s.t. : } \boldsymbol{K}\boldsymbol{U} = \boldsymbol{F}$$

$$V(x)/V_0 = V_f \tag{1}$$

$$\sigma_{vm}^{max} \leq \sigma_{vm}^{*}$$

$$0 < x_{min} \leq x_i \leq 1,\ i = 1, 2, \cdots N$$

Where c is the compliance, $\boldsymbol{K}$ is the global stiffness matrix, $\boldsymbol{U}$ is the global displacement vector, $\boldsymbol{F}$ is the global force vector, $\boldsymbol{k_0}$ is the element stiffness matrix for an element with fully distributed solid material, $\boldsymbol{u_i}$ is the element displacement vector, N is the number of elements in the discrete design domain, $V(x)$ and V_0 are respectively the material volume and the design domain volume, and V_f is the pre-defined volume fraction, σ_{vm}^{max} is the maximum von Mises stress value, σ_{vm}^{*} is the target stress constraint, x_i represents the relative density of the i-th element, x_{min} is a lower bound for the design variable, which is designed to avoid singularity. The element's Young's modulus $E_i(x_i)$ is determined by the element density x_i:

$$E_i(x_i) = x_i^q E_0 \tag{2}$$

Where, E_0 is the stiffness of the material, and q is a penalization factor in SIMP.

With regard to the local nature of stress (Le *et al.*, 2010), the popular p-norm global stress measure is adopted for approximating the maximum stress as follows,

$$\sigma_{vm}^{max} = \sigma_{PN} = \left(\sum\nolimits_{i=1}^{N} \sigma_{vm,i}^{p}\right)^{\frac{1}{p}} \tag{3}$$

Where $\sigma_{vm,i}$ denotes the von Mises stress of the i-th element, and p is the stress norm parameter, which is set as 6 for dataset generation following.

The level of stress constraint, denoted as σ_{vm}^{*}, will exert a significant influence on the topological structure of the design. Since in the proposed MOTO problem, σ_{vm}^{*} is introduced to optimize the stress distribution during the compliance optimization process, it is first required to know the stress level under the circumstances of minimizing compliance with volume constraints only, i.e., σ_0. The upper and lower limits of σ_{vm}^{*} are determined iterative: when the optimized structure under σ^* is equivalent to the optimized structure with the minimum flexibility under only V_f, it is considered that σ^* at this time has no effect on structural optimization, and this stress is the upper limit of the constraint stress σ_{vm}^{u} of the structure. When the stress constraint and V_f cannot be satisfied simultaneously, it is considered that σ^* at this time is the minimum stress value σ_{vm}^{l}. The stronger the constraint, the greater the impact on structural topology optimization, while the linear interpolation method cannot consider high stress areas much, so it is decided to use exponential interpolation method:

$$\sigma_{vm}^{*} = \frac{a}{b + S_f^k}\sigma_0 = \frac{\sigma_{vm}^{u}\sigma_{vm}^{l}}{\sigma_0\left(\sigma_{vm}^{l} + S_f^k\left(\sigma_{vm}^{u} - \sigma_{vm}^{l}\right)\right)}\sigma_0 \tag{4}$$

Where S_f is the stress fraction, defined by drawing upon the concept of volume fraction V_f: when $S_f = 0$, the stress constraint does not affect the topology results, and when $S_f = 1$, the stress exerts maximum influence on the results. k represents the exponent, which is set as 0.75.

3 THE PROPOSED NETWORK FRAMEWORK FOR MOTO

3.1 *Dataset generation and input tensor design*

Given that the MOTO problem is inherently nonlinear in nature, it is tackled using the MMA algorithm (Svanberg, 1987), which primarily capitalizes on the sensitivity of both objective and constraint functions in relation to design variables. Considering the intricacy of MOTO problems, this study aims to commence with the comparatively simple cantilever beam design domain and utilize the established MOTO mathematical model for data generation. A total of

20,000 samples were generated, with a distribution ratio of training set: validation set: test set = 8:1:1. During data generation, the load is applied to the free end of the cantilever within the load range illustrated in Figure 1, with a magnitude of 1.5N. To mitigate stress concentration, the load is evenly distributed across two adjacent nodes (i.e., 0.5N per node). The V_f and S_f are uniformly distributed. The construction of training samples follows specific guidelines:

1) Resolution: 40×80
2) Volume fraction V_f: 0.3-0.7 (Uniform distribution in increments of 0.1)
3) Stress fraction S_f: 0.0-1.0 (Uniform distribution in increments of 0.1)
4) Filtering method: density filtering with filtering radius of 1.5

In theory, the final topology form is a complex mapping of the initial conditions based on the optimization objective and constraints, this is also the theoretical basis for neural networks to solve TO problems. Since the initial conditions play an important role in determining the optimal topological forms of the structures, the way in which they are organized is closely related to the performance of the network. At present, there are usually two types of input modes of initial conditions, one is the mode of direct input, i.e., the load action position and the constraint position are directly input into the neural network (Yu et al., 2018). The other is the mode of indirect input, that is, the above-mentioned information is indirectly displayed through the initial physical fields (Wang et al., 2021, Yu et al., 2018). After trying different kinds of tensor types, the information-rich direct input tensor derived from the direct input mode, is found the optimal one for the MOTO problem. Specifically, the input tensor constitutes a 2-channel tensor (each channel of size 41×81), where the first channel encompasses information regarding boundary conditions and V_f, while the second channel represents load constraints and S_f information. Figure 1 provides an example of this input mode.

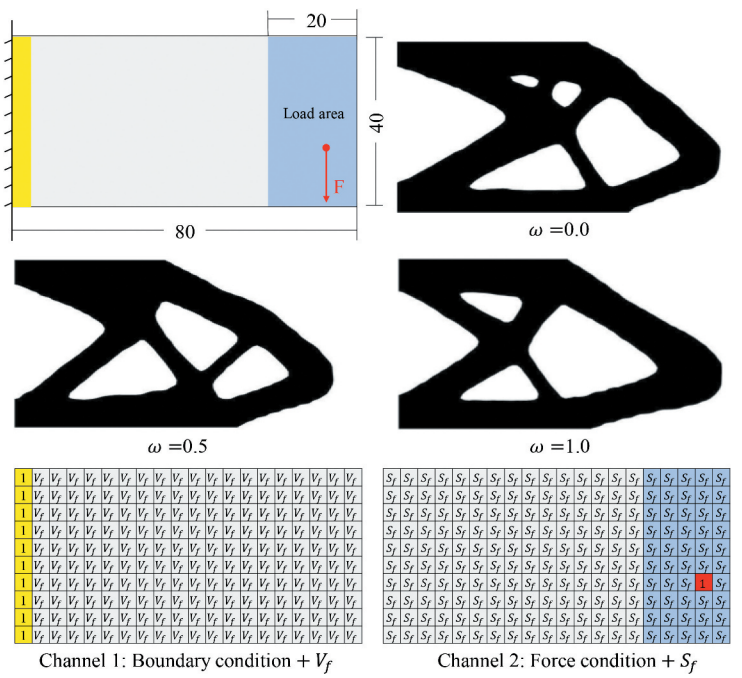

Figure 1. The optimized structures under different S_f and the information-enriched direct input tensor.

3.2 *The architecture of the neural network*

In current researches, a fundamental issue leading to structural disconnection arises from the lack of correlation between adjacent elements in disconnected positions. To address this

challenge, the self-attention mechanism, being the core unit of the transformer framework, demonstrates significant potential. By leveraging this mechanism, it becomes feasible to capture correlations among different input elements, thereby establishing stronger connections within the model and expanding the perceptual field range. Therefore, based on the self-attention mechanism, a novel extension of Unet called Shifted Windows Attention and Partial Convolution Unet (SWPUnet) is proposed, as illustrated in Figure 2.

SWPUnet retains the fundamental structure of Unet, encompassing three components: encoding, decoding, and skip connections. Compared to Unet, the key enhancement of SWPUnet, lies in the incorporation of shifted windows attention (SWA) (Liu *et al.*, 2021) within the skip connections. This enables the model to better capture the correlation between adjacent elements and enhance its attention to the regions with material distribution. The SWA module includes several SWA blocks, after tries many times, the optimal configuration of SWA, the structure of SWA block, as well as the participation of the self-attention mechanism in SWA blosk is presented in Figure 2.

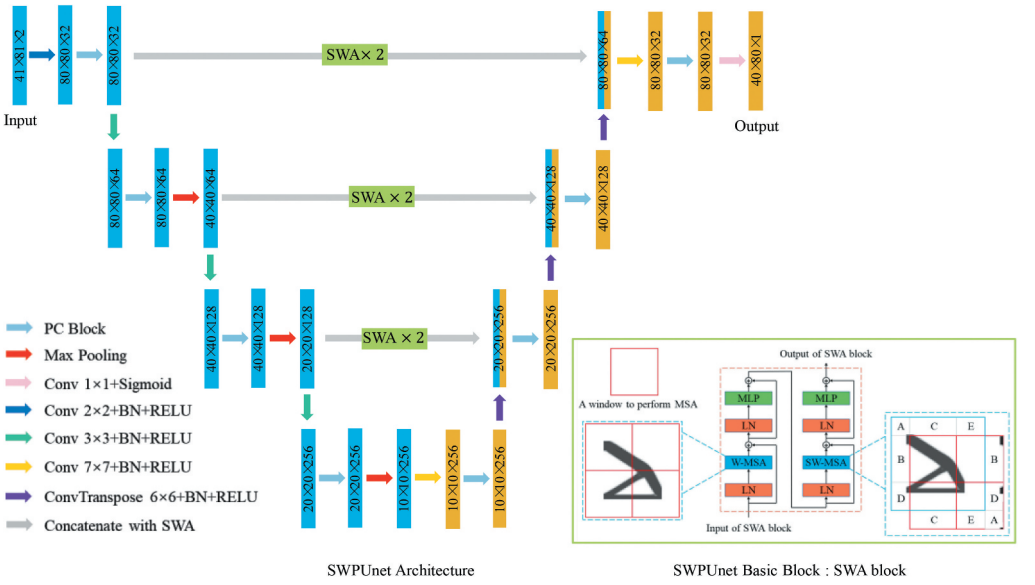

Figure 2. The architecture of SWPUnet.

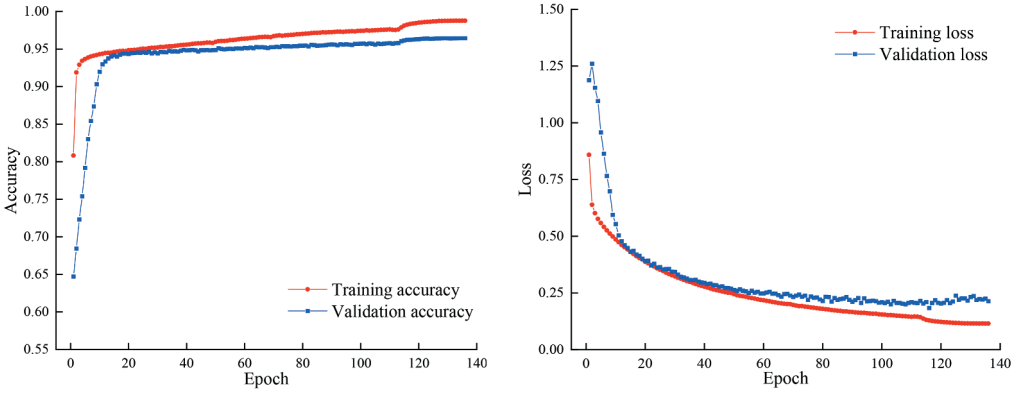
3.3 *Training the network*

During the training process, the Adam algorithm (Kingma and Ba, 2014) was used to optimize the weights and biases of the networks to minimize the loss between the predicted structures and the simulated structures. The cross-entropy loss function is used in the training process. Besides, the L2 normalization is also widely used in designing loss functions to prevent overfitting. The mathematical formulation for the loss is expressed below:

$$Loss = -\frac{1}{N}\sum_{i=1}^{N}\left(y_i log h(x_i) + (1-y_i)\log(1-h(x_i))\right) + \frac{\lambda}{2}\sum_i \omega_i^2 \tag{5}$$

The first term is the cross-entropy loss, where y_i represents the ground truth of the i-th sample, $h(x_i)$ is the predicted structure from the neural network. The second part of the equation represents the L2 normalization, λ is the regularization weight, ω_i is the weight coefficient of the network, and N represents the total number of items being evaluated.

Figure 3 shows the history of loss on the training set and validation set during the training process. The validation loss reaches its minimum value of 0.18 at the 116th epoch, while the training loss still goes down and the overfitting appears. Therefore, the training process is stopped after 136 epochs.



4 PERFORMANCE EVALUATION OF THE PROPOSED METHOD

The trained SWPUnet was used to predict the optimized structures with the samples in the test dataset. After that, the accuracy (i.e., the compliance, stress fraction, volume fraction, and pixel accuracy) as well as the efficiency of the proposed method was evaluated by comparing the obtained results with that of the conventional method.

In most cases, the proposed method and the conventional method can obtain almost the same final structures and von Mises stress distribution, as shown in Figure 4(a). The compliance error (E_c), p-norm stress error ($E_{\sigma_{PN}}$), volume fraction error (E_v), and pixel accuracy error (E_{pix}) of the predicted structures are -7.50%, -5.08%, 0.84%, and 5.18%, respectively. However, in terms of computational efficiency, compared with the traditional method that hundreds of iterations of finite element analysis and sensitivity analysis are required in the optimization process, the proposed iteration-free method can directly predict the optimized structure. The average computation time of the conventional method is 15.76 s, while the proposed method, once properly trained, can give a near-optimal result in 0.0076 s (9.4×10^{-4} s for data preprocessing and 4.42×10^{-3} s for model prediction), only 0.026% of traditional methods, with the efficiency improved by 99.97%. It should be noted that the considerable time of generating the dataset and training the neural network are not included. These results shows that the proposed method can effectively solve the MOTO problem without sacrificing structural performance. Details of the results are shown in Table 1.

Nevertheless, 5.9% samples in the test set appeared large error. Here, samples with E_c or $E_{\sigma_{PN}}$ greater than 20% are defined as large error samples, for it deviates from the optimization objective seriously. The reasons for significant errors can be mainly attributed to two factors. Firstly, there is a high sensitivity of stress to changes in the structural topology, which may result in significant stress concentrations in parts of the structure, even when the results obtained by two methods are similar to each other, as evidenced by the first case in Figure 4 (b). Another reason is the presence of disconnected structures in the results obtained by the DL method, as illustrated in the second case of Figure 4 (b). Similar observations have also been reported in related works (Yu et al., 2018, Wang et al., 2021), this can be attributed to the fact that the neural network training primarily focuses on the principle of pixel similarity. Therefore, in cases where the material distribution is inconsistent but the pixel similarity is close, the model will not penalize such instance.

Besides the unacceptable results, nearly half of the results are a pleasant surprise, that is, samples that performs better than traditional methods in the results, highlighting the significant advantages of the proposed approach. Here, it is defined that the predicted results of the proposed method outperform to the traditional method if the E_v of the result is within 1%, while the E_c and $E_{\sigma_{PN}}$ is smaller than -1%. Under these circumstances, the results of the DL method have smaller mean σ_{PN} than that of the conventional method, and better meet the optimization objective with little violation of constraint. Part of the samples of deep learning methods outperformed traditional methods in predicting results, as illustrated in Figure 4 (c).

a) Training and validation accuracy. b) Training and validation loss.

Figure 3. The accuracy and loss on training and validation set of the neural network during training.

Table 1. Comparison of the results between the proposed method and the conventional method.

	E_c	$E_{\sigma_{PN}}$	E_V	E_{pix}	OR	LER	Time saved
Average	-7.50%	-5.08%	0.84%	5.18%	49.75%	5.90%	99.97%

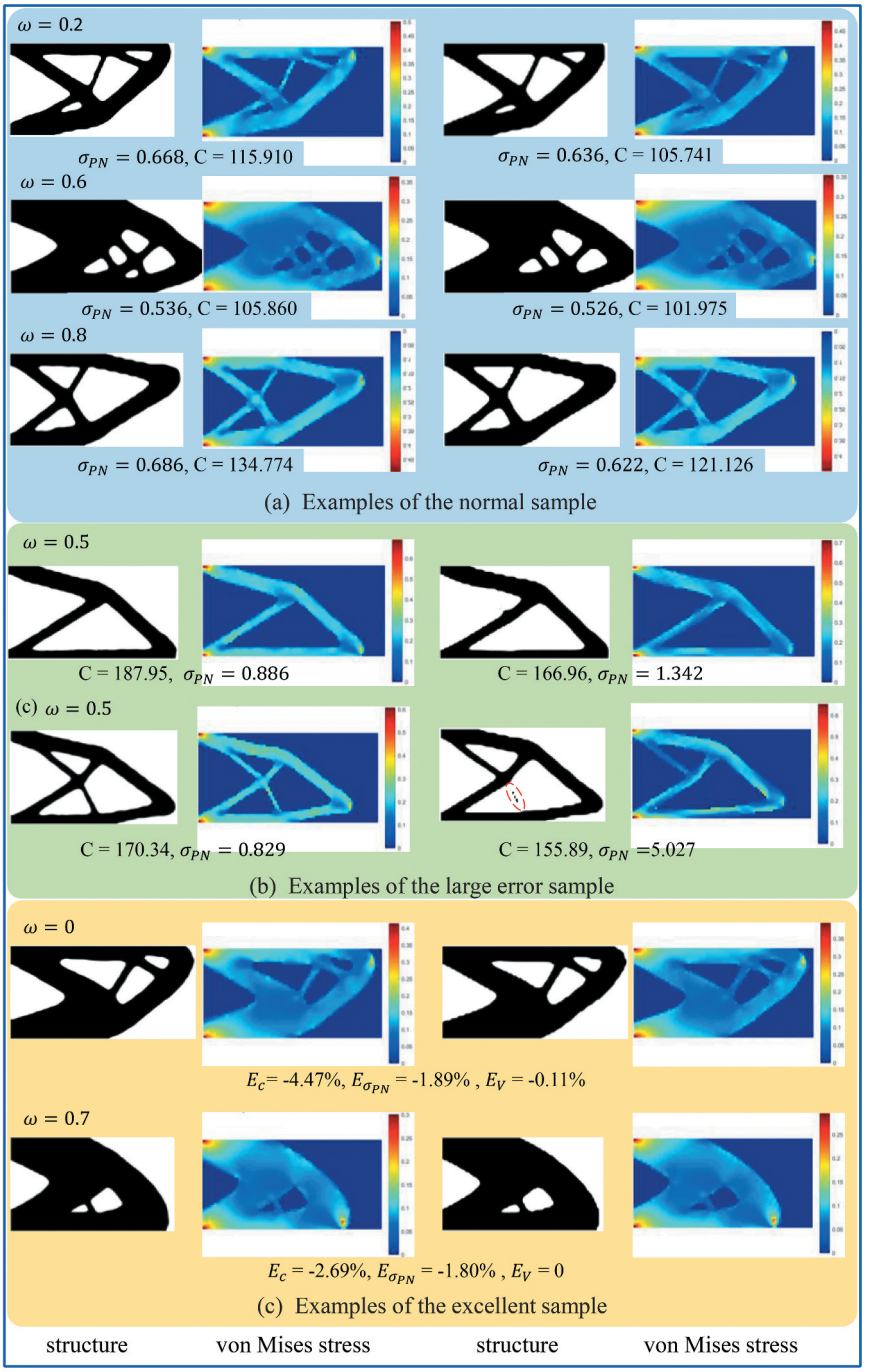


Figure 4. Comparison of traditional method and the proposed method.

5 CONCLUSION

In this paper, an iteration-free MOTO method based on deep learning is proposed in this paper, which significantly improve the calculation efficiency, and successfully extend the DL-based TO method to a multi-objective situation. In addition, nearly half of the predicted optimized structures performs better than tradition method, which shows the great potential and broad application prospects of the proposed method in the practice of innovative bridge design, particularly when considering diverse optimization objectives.

However, the method of using deep learning to deal with TO, especially the MOTO problem is still in its early stages. There are certain limitations both in this article and similar research. On the one hand, there appeared large errors for a few prediction results. The popular PINN may offer new insights for resolving this issue. On the other hand, current studies on the MOTO problem are confined to simple 2D cases, and expanding this approach to complex 3D bridge designs will be a crucial focus of our future work.

A method for stochastic modelling of fatigue stresses in orthotropic bridge decks subjected to local and global traffic loading

A.G. Johansen

F.-I.G. Giske
Multiconsult AS, Oslo, Norway

M. Storheim
Entail AS, Oslo, Norway

ABSTRACT: Fatigue loads and load effects are important aspects of the safety and resilience for many bridges. Long-span bridges are commonly designed with orthotropic steel deck bridge girders for weight optimization. Such bridge decks may be subjected to significant fatigue loading from heavy vehicle traffic, and in some cases the fatigue limit state will even be dimensioning for the stiffened deck plate. Typically, local wheel loads are assumed to dominate the fatigue stresses, and fatigue damage is calculated based on hot spot stress from local analyses. However, with increasing span length, global load effects from both traffic and environmental loads will increase in significance. This is particularly relevant for floating bridges, where the environmental loads may significantly contribute to the fatigue damage. Also, as more extreme suspension bridges and cable stayed bridges are sought, the combination of local and global effects will be important. With fatigue damage being highly nonlinear, fatigue analysis due to combined load effects is a challenging task, and a coupled approach is typically necessary to achieve sufficient accuracy. In this paper, a method to generate stochastic time series of hot spot stresses due to local and global load effects from traffic is proposed. The method is suitable for combination with other fatigue-driving load effects, achieving a reasonable total computational cost while maintaining accuracy.

1 INTRODUCTION

Orthotropic bridge decks may be subjected to significant fatigue loading from heavy vehicle traffic. As illustrated in Figure 1, the bridge deck will experience local load effects due to wheel pressure, as well as global load effects due to the global girder response. Typically, the local load effects are assumed to dominate. With increasing span length, the global load effects from both traffic and environmental loads are increasingly significant in the prediction of fatigue damage. This is particularly relevant for floating bridges, but also for other types such as suspension bridges and cable stayed bridges, with bridge technology being developed toward more extreme bridges. In this paper, a floating bridge is used as an example.

Orthotropic steel bridge decks are commonly used in long-span bridges and show good performance on long-span floating bridges as well. However, they have been prone to fatigue failure (Zhang et al. 2017). This type of bridge deck carries in-plane loads from global bridge deformations and out-of-plane loads from local loading such as traffic, and it is typically in areas where both these load types are present that cracks have been observed (Tsakopoulos & Fisher 2003). Matters are made more complicated by a difference in observed location of crack initiation in segmented model tests and full-scale structures (Chen & Lu 2013).

DOI: 10.1201/9781003483755-247

The stress amplitude and direction continuously change in a structural detail as a vehicle passes the bridge. Large efforts are made to improve the calculation methods, focusing on matters affecting the detailed response (Bohai et al. 2013, Zhiyuan et al. 2018, Ya et al. 2011) and the load pattern and combined loading mechanisms (Xu et al. 2012, Han et al. 2020, Zhang et al. 2013, Wu et al. 2012). Less work was found on the coupled local and global effect of loads such as traffic.

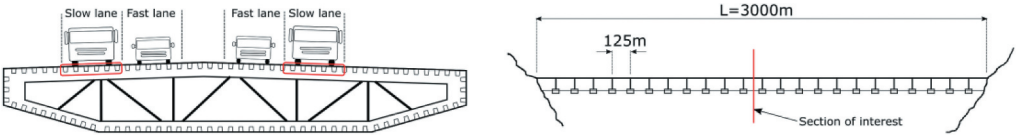

Figure 1. Orthotropic box girder for a four-lane bridge. Areas exposed to direct wheel loads and global loading are indicated in red boxes. A floating bridge is used as an example, considering a midspan section.

The motivation for the presented work is to provide a method that accounts for the combined local and global effect of fatigue loads from traffic in an accurate yet efficient manner. The outcome of the approach is synthetic time series of hot spot stresses which can be used to predict the fatigue damage from local and global traffic loads combined. Furthermore, the stress time series is suited for combination with a large set of environmental simulations of the bridge response, such that the total fatigue performance of the bridge from combined environmental and traffic loading can be assessed.

2 METHOD

The proposed method is motivated by structural details where both (i) out-of-plane stresses due to direct wheel loads and (ii) in-plane stresses due to global girder bending has significant contribution to fatigue. In the following these are denoted *local* and *global* load effects respectively. The proposed method has two main parts:

- Construction of vehicle influence lines, i.e. full stress histories at a fatigue hot spot for vehicles passing along the bridge, with both local and global load effects included.
- Application of a stochastic model for traffic simulation where a time realization of hot spot stress is established based on the individual vehicle influence lines.

2.1 *Global and local effects*

As illustrated in Figure 1, a 3 km span floating bridge is used as an example for the presented method. The bridge has four traffic lanes, two in each direction. The considered structural detail is a transverse welded splice in the deck plating at midspan between two pontoons. A location directly under the outer wheel path in lane 1 (slow lane) is considered, as shown in Figure 2. This detail is subjected to both global and local load effects and is of interest for floating bridges as both traffic and environmental loads may have significant contributions to fatigue. The stress of interest for the chosen detail is the normal stress in the bridge longitudinal direction, at the top of the deck plate. Three components contribute to this stress as illustrated in Figure 3, where bending of the bridge girder (global load effect), longitudinal stiffener (local load effect) and deck plating (local load effect) is shown.

The global contribution is accounted for by means of global influence lines. These can be obtained by stepping a unit axle load, e.g. a point load of 100 kN, along a global model of the bridge. The loads are applied for each traffic lane resulting in a set of sectional force influence lines $\boldsymbol{f}_{\text{infl}}(x, lane)$, where x is the load position along the bridge and *lane* is the lane number. In the general case, the stress influence lines due to global load effects can be calculated as

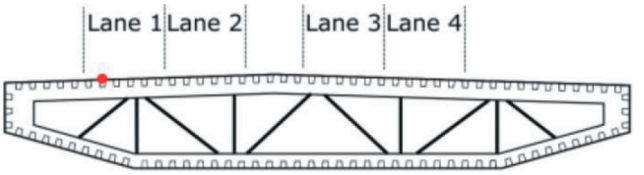

Figure 2. A transverse plate splice is considered with longitudinal stresses at the location shown in red.

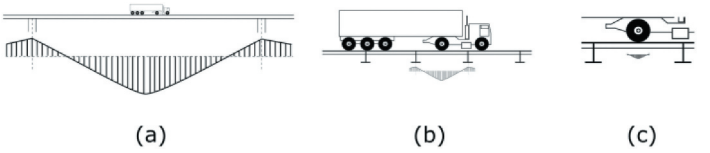

Figure 3. (a) Global girder bending. (b) Bending of longitudinal stiffener. (c) Bending of deck plating.

$$\boldsymbol{\sigma}_{\mathrm{G,infl}}(x, lane) = \boldsymbol{K} \times \boldsymbol{f}_{\mathrm{infl}}(x, lane). \tag{1}$$

Here, $\boldsymbol{K}$ is an n-by-6 matrix with stress transfer coefficients where n is the number of stress components in $\boldsymbol{\sigma}_{\mathrm{G,infl}}$, and $\boldsymbol{f}_{\mathrm{infl}}(x, lane)$ contains the sectional forces and moments:

$$\boldsymbol{f}_{\mathrm{infl}}(x, lane) = \begin{bmatrix} F_{x,\mathrm{infl}}(x, lane) \\ F_{y,\mathrm{infl}}(x, lane) \\ F_{z,\mathrm{infl}}(x, lane) \\ M_{x,\mathrm{infl}}(x, lane) \\ M_{y,\mathrm{infl}}(x, lane) \\ M_{z,\mathrm{infl}}(x, lane) \end{bmatrix}. \tag{2}$$

In the example considered here, the stress component of interest is the bridge girder normal stress $\sigma_{\mathrm{G,infl,n}}$. At the hot spot in question this component can be calculated by taking $\boldsymbol{K}$ as

$$\boldsymbol{K} = \begin{bmatrix} \frac{1}{A_x} & 0 & 0 & 0 & \frac{1}{W_y} & \frac{1}{W_z} \end{bmatrix}. \tag{3}$$

Here, A_x is the cross-section area at the considered section, W_y and W_z are section moduli for the stress point in question due to weak and strong axis bending respectively. The resulting global stress influence lines are shown on the left in Figure 4.

The local contributions are accounted for by means of a local FE model comprising a ~20 m section of the bridge girder with 4 m spacing between transverse frames. The model is a shell element model and is analyzed for unit axle loads, e.g. 100 kN, which are stepped along the length of the model. The loads are applied as pressure loads onto the deck plating according to the prescribed axle footprints in the traffic model. This results in a set of unit axle load influence lines $\boldsymbol{\sigma}_{\mathrm{L,infl}}(\tilde{x}, weave, axle)$ where $\boldsymbol{\sigma}_{\mathrm{L,infl}}$ is the vector of relevant stress components, $\tilde{x}$ is the axle position along the local model in the longitudinal direction, *weave* is the axle position in the transverse direction and *axle* is the axle type. In the example considered here, two stress components are relevant:

$$\boldsymbol{\sigma}_{\mathrm{L,infl}} = \begin{bmatrix} \sigma_{\mathrm{L,infl,m}} \\ \sigma_{\mathrm{L,infl,b}} \end{bmatrix} \tag{4}$$

These are the longitudinal membrane and bending stress components. These are mainly governed by stiffener bending (b) and plate bending (c) respectively, as illustrated in Figure 3. The normal stress at the weld toe location (top of deck plate) is obtained as $\sigma_{\mathrm{L,infl,n}} = \sigma_{\mathrm{L,infl,m}} + \sigma_{\mathrm{L,infl,b}}$.

The local stress influence lines are shown on the right in Figure 4 for axle type A. Weave 1-5 refer to transverse axle positions where the centre of one wheel footprint is located -200, -100, 0, 100, 200 mm from the hot spot, respectively. Here $\sigma_{\mathrm{L,infl,n}}$ is obtained by combination

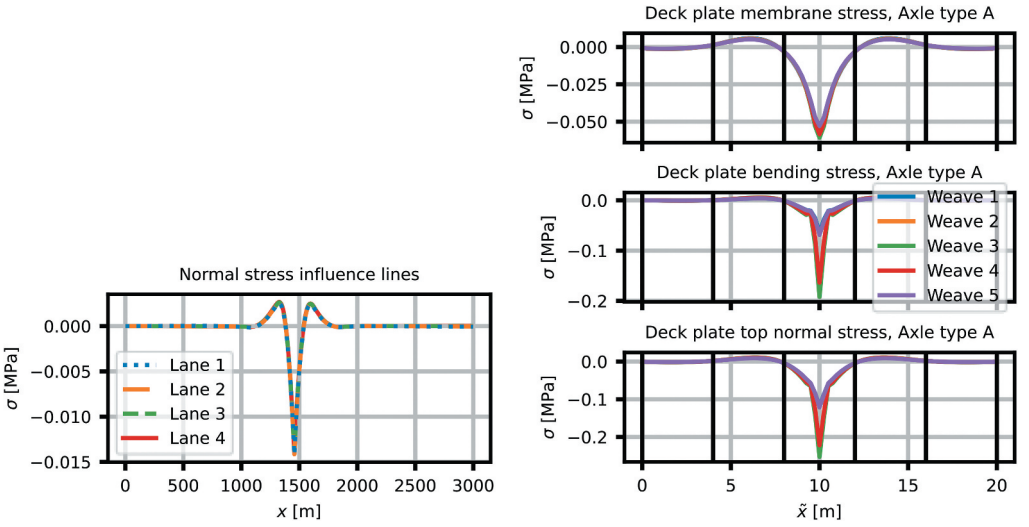

Figure 4. Global (left) and local (right) stress influence lines (stress per kN axle load) for the chosen fatigue detail. For the local stress (right), the deck plate top normal stress (bottom) is obtained by combination of membrane stress (top) and bending stress (middle).

of the membrane and bending components. Alternatively, depending on the FE software, the normal stress at the top of the deck plate can be read out directly.

2.2 *Vehicle stress histories*

The load specification is given by a fatigue load model for traffic. As an example, Fatigue Load Model 4 (FLM4) from the Eurocode (CEN, 2003) is considered. This model consists of five vehicle types, which are defined by the weight, position and wheel footprint of each axle. Vehicle type 3 from FLM4 is illustrated in Figure 5.

Based on the unit axle influence lines, vehicle influence lines are established for each vehicle in the traffic model. This is done by superposition of scaled and shifted influence lines for each axle associated with the vehicle. The axle influence lines are scaled according to weights and shifted according to axle position before they are summed to vehicle influence lines. The vehicle influence lines for local and global load effects are denoted by $\sigma_{\mathrm{L}}(\tilde{x}, \mathit{weave}, \mathit{veh})$ and $\sigma_{\mathrm{G}}(x, \mathit{lane}, \mathit{veh})$, respectively. $\tilde{x}$ and x now refer to the position of the first axle of the vehicle, and *veh* is the vehicle type. To account for vehicles driving in both directions, vehicle influence lines are established for both regular (front to rear) and reverse (rear to front) axle order. In Figure 6, the global and local vehicle influence lines are illustrated. In this example, we see that the local reverse vehicle influence lines correspond to the reverse of the regular ones. However, this would not be the case if the axle influence lines, cf. Figure 4 (right), did not have a symmetric shape. Globally, the axle order is less important, and the global vehicle influence lines are very similar.

Finally, by specifying the global location x_0 of the point $\tilde{x} = 0$ in the local model, the local and global stress components can be combined into a set of total vehicle influence lines for the complete hot spot stress $\sigma_{\mathrm{tot}}(x, \mathit{weave}, \mathit{lane}, \mathit{veh})$. For the lanes where vehicles are driving in the negative x-direction, the reverse local and global vehicle influence lines are combined. Otherwise, the regular ones are used.

Since the local and global load effects typically fluctuate on very different length scales, a non-uniform x-discretisation is preferred, with high density of data points only where local fluctuations are present. Another aspect is that the local load effects are only seen for vehicles in the lane directly above the detail in question, i.e. lane 1 for the considered example. This is illustrated in Figure 7 where the total vehicle influence lines for weave 3 of vehicle type 3 are shown

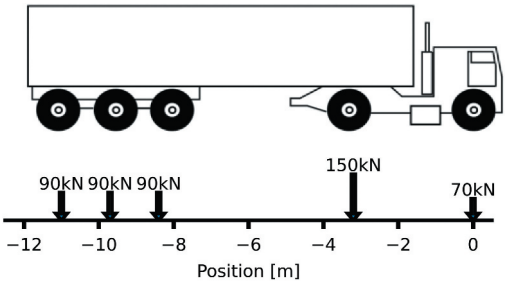

Figure 5. Axle weights and positions for vehicle type 3 of FLM4. Axle types are A, B, C, C, C front to rear.

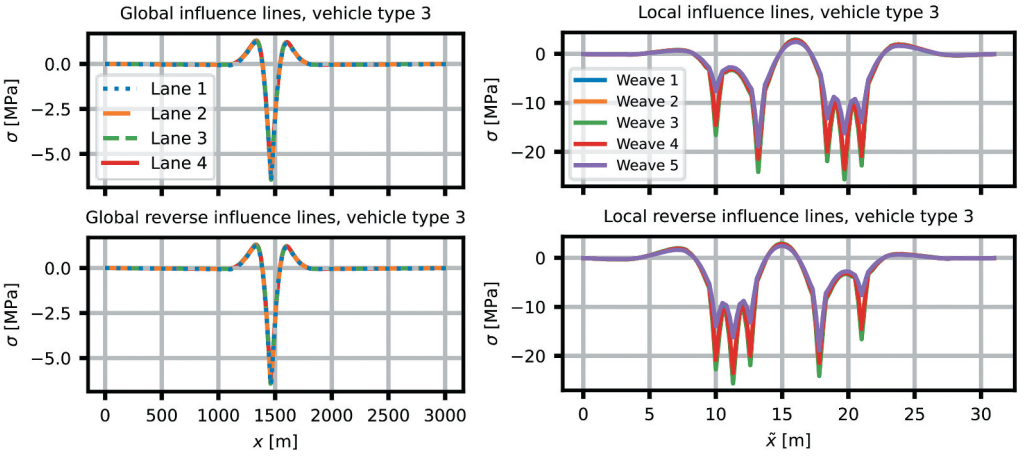

Figure 6. Global (left) and local (right) vehicle influence lines.

for all lanes. Lanes 1 and 2 have traffic moving in the negative x-direction, and it is seen that the local load effect in lane 1 is taken from the local reverse influence line in Figure 6.

2.3 *Stochastic load model*

Based on the individual vehicle influence lines, time realizations for the traffic load effects can be generated using a stochastic traffic model. The long-term distribution of vehicles is defined by the percentage of each vehicle type and the number of heavy vehicles per year in each lane. Considering the *long-distance* traffic type of FLM4, and an annual number of heavy vehicles per slow lane of $N_{\text{obs}} = 0.5 \cdot 10^6$ (traffic category 2), the long-term distribution is as given in Table 1.

From the long-term distribution, the number of vehicles of each type in each lane which statistically occur during the desired realization period, can be established. These vehicle numbers will in reality be random variables following the long-term distribution. However, by fixing the vehicle numbers for the given duration to their average values, we obtain realizations where the long-term distribution is preserved. In this way, a single short-term realization can be used to calculate yearly fatigue damage, without too large variation between realizations.

Once the number of vehicles for the desired realization period has been established, a simulation can be performed by applying the following steps:

1. Each vehicle is assigned a random weave position from a specified distribution. Typically weave 1-5 has a distribution of 7%, 18%, 50%, 18%, 7% (CEN, 2003).
2. For each lane the order of vehicles entering the bridge is picked at random.
3. For each lane the arrival times of vehicles entering the bridge are simulated using the Poisson process. This is described in Section 2.4 below.

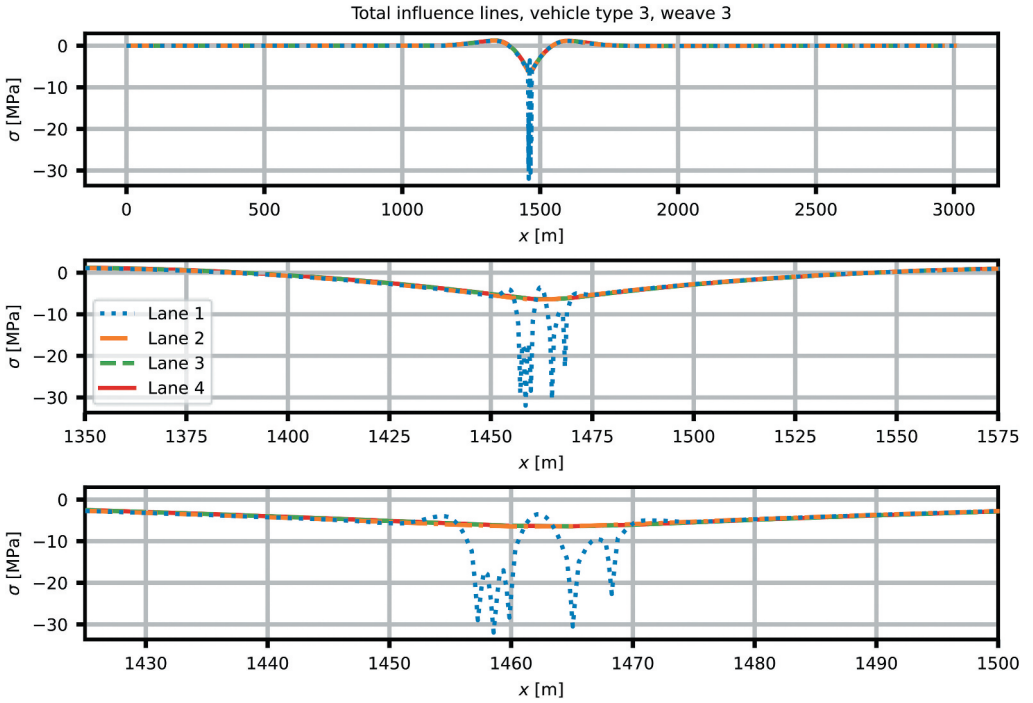

Figure 7. Total vehicle influence lines at considered hot spot for vehicle type 3 passing with weave 3. Local load effects are only included for the lane directly above the hot spot location (lane 1).

Table 1. Long-term distribution of vehicles.

Number of heavy vehicles					
Lane number	Lane 1	Lane 2	Lane 3	Lane 4	
Number per year	0.5e6	0.5e5	0.5e5	0.5e6	
Vehicle type distribution					
Vehicle type	Type 1	Type 2	Type 3	Type 4	Type 5
Percentage	20%	5%	50%	15%	10%

4. Vehicle influence lines are transformed to stress time series using a given vehicle speed. For the lanes where the traffic is moving in the negative x-direction, the influence lines are reversed.
5. A stress time series $\sigma(t)$ is generated by placing the vehicle time series at their respective arrival times and summing the contributions from each lane.

By simulating the arrival times explicitly, we can preserve the discretization of the influence lines with high resolution only when the local fluctuations occur.

2.4 *Simulation of arrival times*

Suppose N is the number of vehicles to be simulated within a specified duration T. First, we find the largest possible duration $T_{\max}$ such that any vehicle can arrive at $T_{\max}$ and still have its entire influence line pass within the duration T. The duration $T_{\max}$ is then split up as illustrated in Figure 8, where $t_2, \ldots, t_N$ are the $N-1$ interarrival times between the N vehicles and t_{sep} is the minimum allowed separation between the first axle of two vehicles. t_1 and t_{N+1} are buffer intervals that ensure random arrivals of the first and last vehicle in the time series.

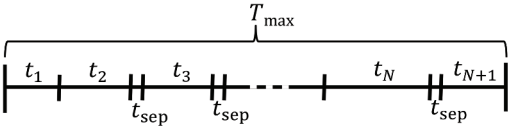

Figure 8. The duration $T_{\max}$ is split up by interarrival times and minimum allowed separations.

Phenomena described by an occurrence rate (i.e. number of events during a time interval) are commonly modelled using the Poisson process. For the Poisson process, the time between events is given by the exponential distribution with a rate parameter λ equal to the occurrence rate. Accounting for the minimum separations of t_{sep}, the intervals $t_1, \ldots, t_{N+1}$ represent $N+1$ events occurring during a time $T_{\max} - (N-1)t_{\text{sep}}$. Hence, we draw $N+1$ independent realizations $\tilde{t}_1, \ldots, \tilde{t}_{N+1}$ from an exponential distribution with a rate parameter

$$\lambda = \frac{N+1}{T_{\max} - (N-1)t_{\text{sep}}}. \tag{5}$$

The sum $\sum_{i=1}^{N+1} \tilde{t}_i$ will have an expected value of $T_{\max} - (N-1)t_{\text{sep}}$, but it will not exactly add up to this duration. To achieve intervals $t_1, \ldots, t_{N+1}$ that exactly add up to $T_{\max} - (N-1)t_{\text{sep}}$, a scaling is performed. Each interval is taken as $t_i = \tilde{t}_i / S$, where the scaling factor S is given by

$$S = \frac{1}{T_{\max} - (N-1)t_{\text{sep}} \sum_{i=1}^{N+1} \tilde{t}_i.} \tag{6}$$

It can be shown that S is gamma distributed with mean 1 and standard deviation $1/\sqrt{N+1}$. Thus, as long as N is reasonably large, the scaling factor S will be close to 1, and the exponential distribution of $\tilde{t}_i$ should be preserved for t_i in an approximate manner.

Having established the arrival time $t_{\text{arr},1} = t_1$ of the first vehicle and the interarrival times $t_2, \ldots, t_N$, the arrival time $t_{\text{arr},n}$ for vehicle number n is finally calculated as

$$t_{\text{arr},n} = t_1 + \sum_{i=2}^{n} \left(t_i + t_{\text{sep}} \right). \tag{7}$$

3 EXAMPLE RESULTS

A 10-hour simulation generated with the proposed method is shown in Figure 9, along with the contributions from each lane. Also, a more detailed view is shown for shorter time intervals around the time $t_{\min}$ when the lowest peak occurs. It is seen that in this case, the lowest peak is found when there is a simultaneous passing of two vehicles of type 3 in lane 1 and in lane 3. It can also be noted that the influence line from Figure 7 has been reversed, such that the effect of the front axle appears first in time. Based on the proposed methodology, time histories of hot spot stresses in relevant fatigue details can be established at a low computational cost. From there, cycle counting can be performed (e.g. by the rainflow method) to establish a stress range histogram where the "complete" effect of traffic is fully accounted for.

An interesting observation with the stochastic approach is an increase in stress when vehicles pass the considered cross-section simultaneously. This effect is illustrated in Figure 10, where the circles indicate events where the passings of vehicle type 3 in lane 1 have a simultaneous passing (less than 1.5s apart) of vehicle type 3 in lane 2 (red), lane 3 (green) or lane 4 (black). With type 3 being the heaviest and most common vehicle, it is seen that these passings capture the majority of the largest stress peaks, with simultaneous lane 4 (slow lane) passings being most common.

With the proposed method, several vehicles may contribute to the global response without a contribution to the local responses from direct wheel loads. Depending on bridge type and traffic model this effect may give a significant contribution to fatigue. A suspension bridge, for instance, will typically have global influence lines with a larger influence length, and the

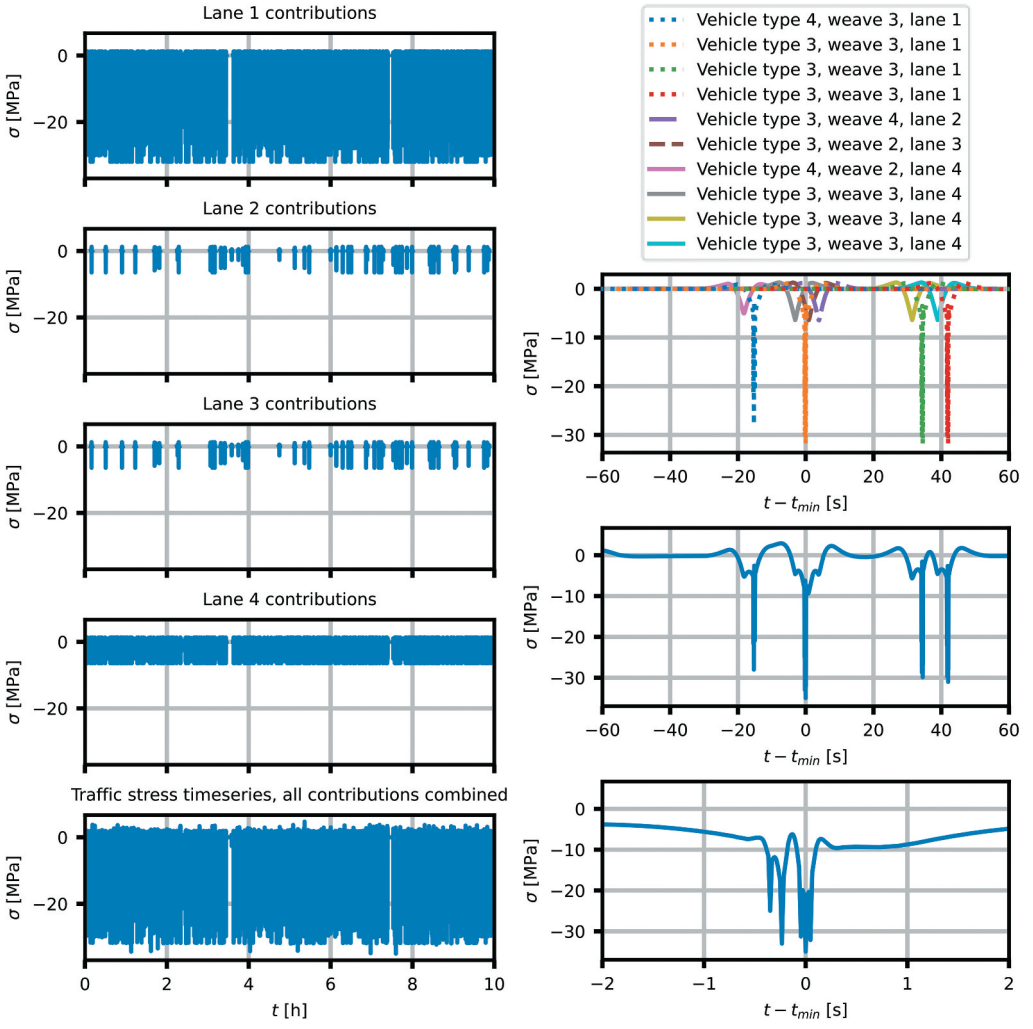

Figure 9. Left: A 10-hour simulation of hot spot stress showing contributions from each lane and finally the total combined stress. Right: Detailed view for shorter time intervals around the time $t_{\min} = 7.6$h when the lowest peak occurs. The upper plot shows the individual contributions from the different vehicles.

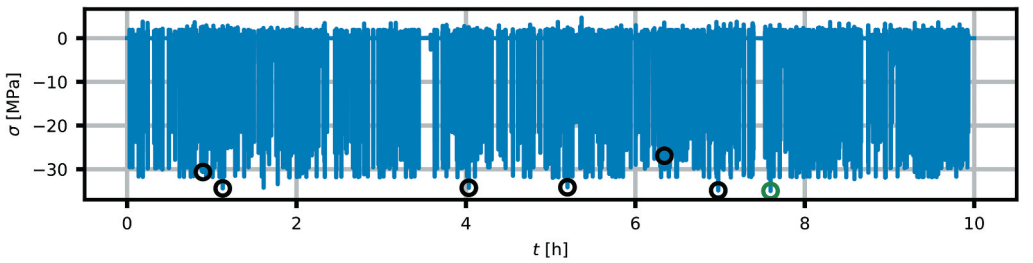

Figure 10. Circles indicate events where the passings of vehicle type 3 in lane 1 have a simultaneous passing (less than 1.5s apart) of vehicle type 3 in lane 2 (red), lane 3 (green) or lane 4 (black).

stress will vary more with the number of vehicles present on the bridge. In a deterministic

approach this effect would be tricky to account for. A more sophisticated model could also address daily variation such as rush traffic, varying vehicle speed etc.

4 CONCLUSION

The proposed method for stress time series generation can be used alone or in combination with environmental loading. This enables a thorough evaluation of the bridge fatigue performance, in which the combined effect of several dynamic processes can be captured at a computational cost that is feasible also in early design stages.

Application of microwave vibrometry in bridge monitoring & dynamic analysis

T. Bao & S. Bai
Inner Mongolia University of Technology, Huhhot, Inner Mongolia, China

ABSTRACT: Vibration measurement based on microwave sensing is a new non-contact vibration measurement technology developed on the basis of microwave radar micro motion sensing. Compared with the existing technology, its advantages include high sensitivity, multi scale, large detection range, strong environmental adaptability, low power consumption and miniaturization. In this paper, taking the Beijing-Baotou Railway Overpass as an example, the monitoring system based on microwave vibration measurement technology is used to extract the vibration monitoring data within six hours, and the data are analyzed in time and frequency domains. The signal characteristic indexes and the first two natural frequencies of the main bridge structure of the Beijing-Baotou Railway Overpass are calculated.

1 ENGINEERING BACKGROUND

In recent years, as large-span bridges have become more flexible and complex in both form and function, conventional means have struggled to grasp and predict their mechanical behavior under various operating environments and loading conditions. In the operation of bridges, ensuring structural safety and real-time structural health monitoring are major concerns not only for construction and design units but also for operation and management units. Therefore, it is necessary to adopt advanced monitoring means and automated monitoring technology to establish a bridge operation health monitoring management system with advanced technology, reasonable measures, practical and economical solutions, ease of management, openness, compatibility, and alignment with the needs of bridge management.

1.1 *Beijing-Baotou Railway Overpass*

The Beijing-Baotou Railway Overpass consists of left and right parts, with the left bridge spanning 2×75+3×(4×35)=570 meters and the right bridge spanning 2×35+2×75+2×35 +2×(4×35)=570 meters. The cross slope of the bridge deck ranges from 2% to 4% soil. The bridge starts at K123+138.5 and ends at K123+717.5, with a total length of 579 meters. The main bridge of the Beijing-Baotou Railway Overpass is a 2-span variable cross-section continuous steel structure (2×75 m), with a beam height ranging from 3.3 to 8.1 meters and a parabolic change ratio of 1.8 times. The approach bridge is a 35-meter cast-in-place continuous box girder with a height of 1.8 meters. The superstructure is made of C55 concrete, while C30 concrete is used for the approach bridge guardrail and C40 concrete for the main bridge guardrail. Anti-throwing nets are installed outside the bridge opening crossing the railway. The substructure of the main bridge consists of square column piers made of consolidated pier beams and C40 concrete. The substructure of the approach bridge consists of column piers, with the bent cap, pier shaft, tie beam, and retaining block made of C35 concrete, and the pile

DOI: 10.1201/9781003483755-248

foundation and cushion cap made of C30 concrete. The layout of the main bridge of the Beijing-Baotou Railway Overpass is shown in Figure 1.

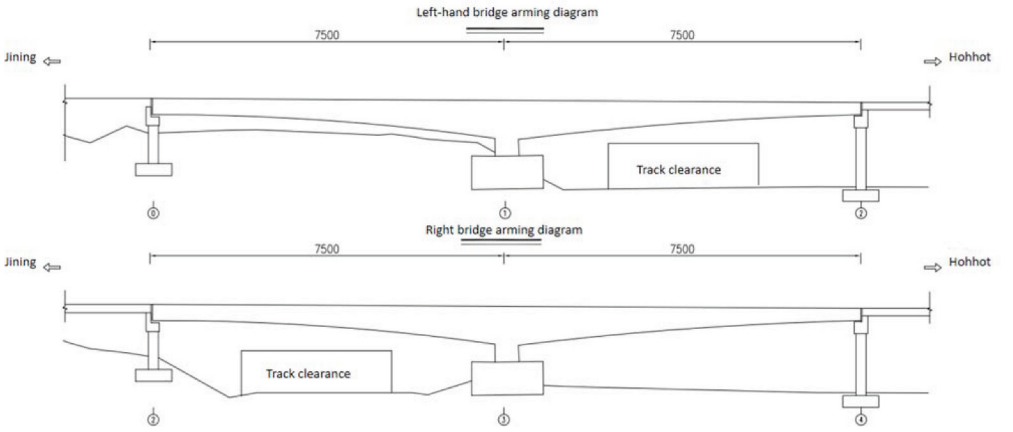

Figure 1. The layout of the main bridge of Beijing-Baotou Railway Overpass.

1.2 *Microwave vibrometry*

In monitoring the displacement influence line of bridge structures, arranging contact sensors is laborious and entails some risks. Optical fiber sensors, while accurate, have limited detection ranges in non-contact bridge vibration and deformation displacement monitoring. Large-scale distributed sensor measurement is required for the full-field synchronous test of large bridge structures, but sensor networking is complex, and the test efficiency is low, with high costs involved. The laser scanning method can expand the detection range to the meter level but can only achieve local bridge structure measurement, not meeting the requirements of full-field synchronous testing. The image method offers a large field of view but faces a contradiction between a large measurement range/field of view and high measurement accuracy. Achieving high-precision vibration and deformation measurement requires complex calibration and image stream data processing, demanding significant computation and vulnerable to environmental factors such as light. Given the challenges and limitations of existing technologies in vibration and deformation monitoring of large bridge structures, the sensor system based on microwave vibration testing provides a promising alternative for non-contact displacement measurement (Xiong et al., 2017, 2018, 2019, 2021; Ren et al., 2023). Vibration measurement based on microwave sensing is a new non-contact technology developed on the basis of microwave radar micro-motion sensing. Microwave radar transmits electromagnetic waves of a specific frequency and receives echo signals scattered by the target object. The movement of the target object generates nonlinear phase modulation, and the micro-motion information is derived by analyzing the modulation information of the baseband signal. Unlike widely used point sensors, microwave sensing can be considered a non-contact distributed sensing technology capable of extracting vibration displacement and deformation from numerous measuring points on the target structure within the observation range through a single device. It offers advantages such as high sensitivity, multi-scale capability, large detection range, strong environmental adaptability, low power consumption, and miniaturization. Currently, microwave vibrometry technology has been applied in vital sign monitoring (Ren et al., 2023), condition monitoring of aviation engine turbine blades, and holds promise in extracting displacement influence lines and health monitoring of large bridge structures (Xiong et al., 2020; Li et al., 2022).

This paper analyzes the vibration monitoring data of the main bridge of the Beijing-Baotou Railway Overpass within a six-hour period using microwave vibrometry technology and extracts its time-frequency and frequency-domain characteristic indicators to study the dynamic characteristics of the continuous rigid frame bridge under the influence of vehicles.

2 EQUIPMENT INSTALLATION

The commercial vibration and deformation microwave multi-point measurement instrument VDMM-L200, as shown in Figure 2-(a), has been successfully developed, with a measurement accuracy of ±2μm.

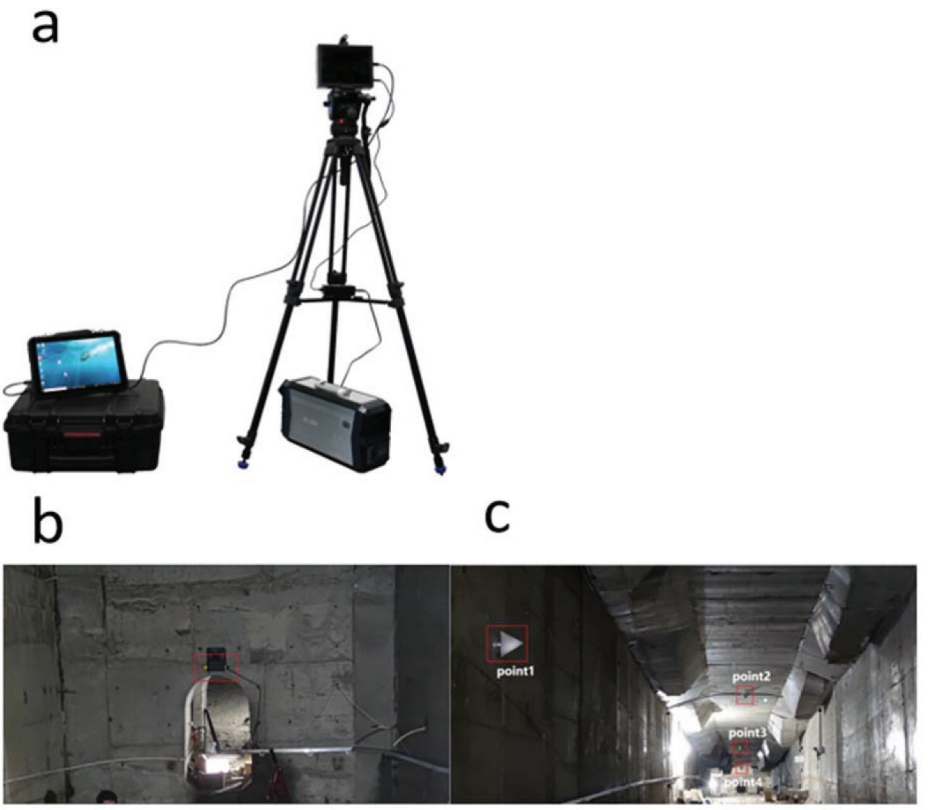

Figure 2. (a) Schematic diagram of microwave multi-point measurement instrument VDMM-L200;(b) Installation diagram of test instrument terminal;(c) Schematic diagram of target installation.

The testing distance is up to 200 meters, making it popular in the health monitoring field of large bridges and buildings. The microwave radar monitoring equipment is installed at the left pier, as indicated by the red box in Figure 2-(b). The target is installed in the box girder, as shown in Figure 2-(c), with the triangular reflector marked by the red box serving as the target. Measuring point 1 is located on the outer 1/2 side wall of the left side of the main bridge, while measuring points 2 and 3 are located on the top of the box girder. This paper utilizes the monitoring data from measuring points 1, 2, and 3, with a total monitoring time of 6 hours and a sampling frequencyf_s is set to 50Hz.

3 MONITORING DATA AND ANALYSIS

3.1 *Time domain analysis*

The deflection monitoring data for measurement points 1, 2, and 3 over a six-hour period are shown in Figure 3.

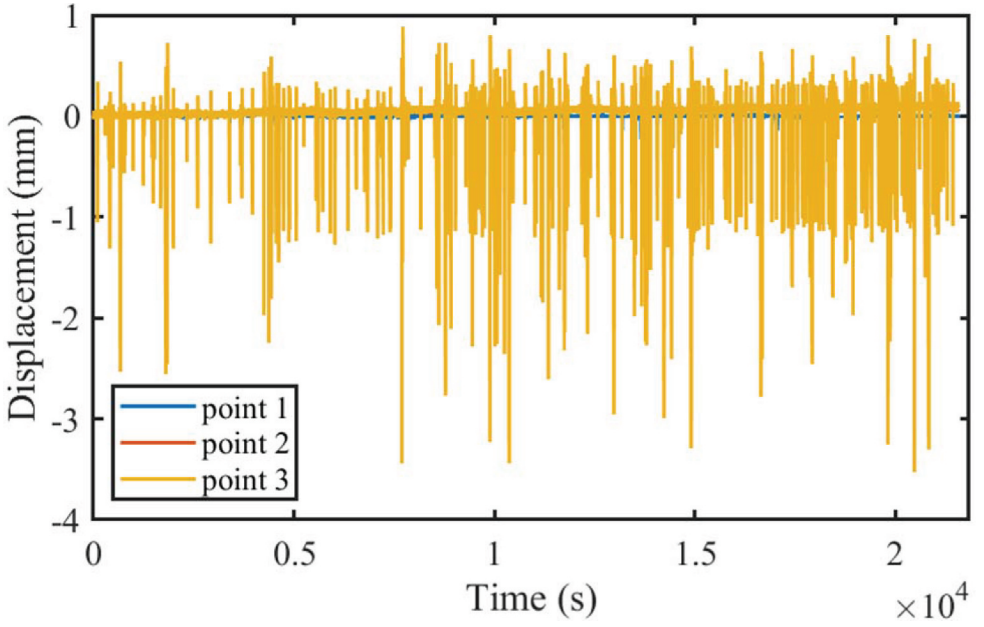

Figure 3. Waveform diagram of original monitoring data.

Applying Gaussian filtering to denoise the original signal, the window length is set to 15. The time history diagrams of measuring points 1, 2, and 3 after filtering are shown in Figure 4-(a)-(c).

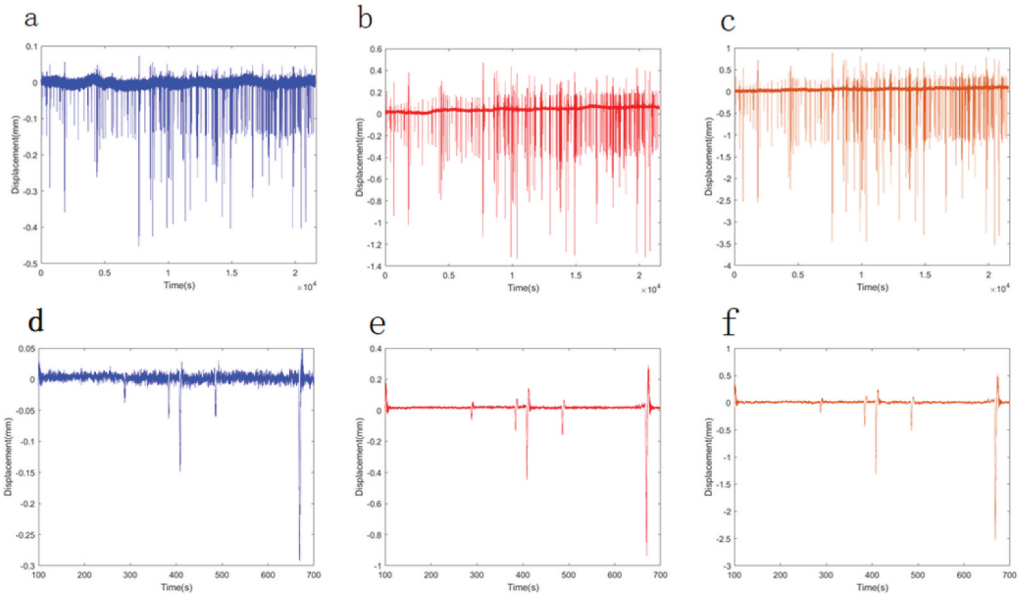

Figure 4. Waveform diagram of filtered monitoring data (complete) of point 1(a), point 2(b) and point 3(c);Waveform diagram of filtered monitoring data (partial) of point 1 (d), point 2(e) and point 3(f).

Taking the filtered monitoring signals of each measuring point within the range of 100s-700s as an example (Figure 4-(d)-(f)), it can be observed that each measuring point's waveform exhibits the following characteristics:

(1) The point will upturn when a vehicle passes but is not directly above the point.
(2) The vehicle causes bending and deformation at the measurement point when it directly passes over it.
(3) After a vehicle passes, the measuring point may buckle and exhibit free vibration.
(4) During vehicle passage, the deformation at the side wall where measuring point 1 is located is less pronounced compared to the deformation at the top of the box girder where measuring points 2 and 3 are situated. Within the 100s-700s range, the maximum deflections of measuring points 1, 2, and 3 are 0.2925mm, 0.9372mm, and 2.5314mm, respectively. The peak-to-peak values are 0.3424mm, 1.2282mm, and 3.0687mm, respectively. Across the entire time domain, the maximum deflections of measuring points 1, 2, and 3 are 0.4531mm, 1.3323mm, and 3.5243mm, respectively, with peak-to-peak values of 0.5252mm, 1.8025mm, and 4.4106mm, respectively. Time domain signal characteristics such as standard deviation (STD) and root mean square (RMS) can be extracted from monitoring data. The STD values for measuring points 1, 2, and 3 are 0.0249, 0.0680, and 0.1829, respectively, while the RMS values are 0.0253, 0.0772, and 0.1859, respectively.

3.2 *Spectrum analysis*

The time history curves of measuring points 1, 2, and 3 can be transformed through fast Fourier transform to revealing the spectrum distribution of the response, as depicted in Figure 5.

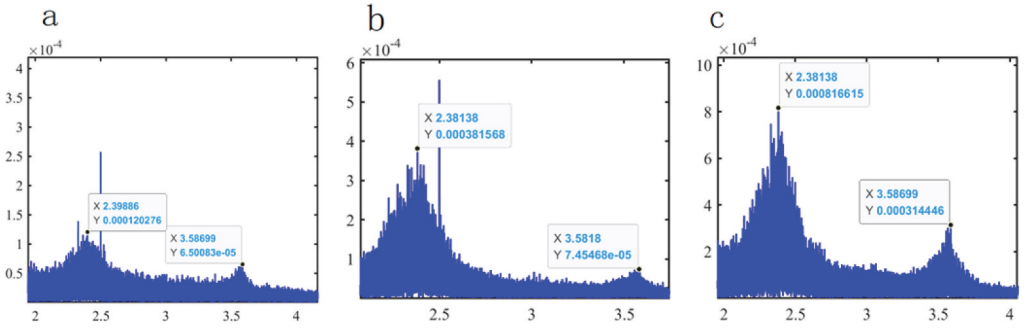

Figure 5. Spectrum diagram of measuring points 1(a), 2(b) and 3(c).

Through the spectrum diagram, the modes and corresponding amplitudes of the structure within the analysis frequency range can be determined. The frequency corresponding to the first peak on the spectrum curve represents the fundamental frequency of the structure. According to Figure 5-(a), the first-order natural frequency is 2.39886Hz, and the second-order natural frequency is 3.58699Hz. According to Figure 5-(b), the first-order natural frequency is 2.38138Hz, and the second-order natural frequency is 3.58180Hz. According to Figure 5-(c), the first-order natural frequency is 2.38138Hz, and the second-order natural frequency is 3.58699Hz. Based on the above data, the root mean square error of the first-order natural frequency is approximately 1.01%, and that of the second-order natural frequency is about 0.30%. It can be considered that the first-order and second-order natural frequencies obtained from the spectrum closely approximate the true values. The arithmetic mean value can be taken as the test result, yielding an arithmetic mean value of 2.38721Hz for the first-order natural frequency and 3.58526Hz for the second-order natural frequency.

4 CONCLUSION

This paper introduces the general situation of the Beijing-Baotou Railway Overpass project, utilizing microwave vibrometry technology to extract vibration signals at different positions

of the structure within a six-hour period, and studying the dynamic characteristics of continuous rigid frame bridges under random environmental excitation such as vehicle load and wind load. The following conclusions are drawn:

(1) During vehicle passage, the vibration signal of the measurement point exhibits the characteristics of upward-sinking-upward motion.
(2) Observing the maximum deflection and peak-to-peak value of each measurement point during the monitoring time, it was found that sidewall deformation was not significant, while top deformation of the box girder was relatively large. Two signal characteristics were calculated for the time-domain signals of each measurement point.
(3) Through spectrum analysis, the fundamental frequency of the bridge structure is 2.38721Hz, and the second-order natural frequency is 3.58526Hz.

Maintenance of large expansion joint in Honshu-Shikoku Bridges

M. Hongo, A. Moriyama, Y. Yano & Y. Yokoi
Honshu-Shikoku Bridge Expressway Company Limited, Kobe, Japan

ABSTRACT: Honshu-Shikoku Bridges have large and special expansion joints in order to deal with the deformation unique to long-span bridges, such as large longitudinal and in-plane displacement. There are several types of large expansion joints, and most of the link type expansion joints in Japan are used in the Honshu-Shikoku Bridges. The link type expansion joints installed in the Akashi-Kaikyo Bridge move up to ±1450mm. Although many minor damages were reported, maintenance of the link-type expansion joints is limited to small scale repairs or parts replacements. In order to continue to maintain more than 200 years, preparation for large-scale renewal work and replacement of these expansion joints expected in the future is necessary. This paper introduces the examples of damages and repair works of link-type expansion joints reported in the Honshu-Shikoku Bridges. Furthermore, the future maintenance strategies based on problems in maintenance over the past 30 years will be explained.

1 INTRODUCTION

Honshu-Shikoku Bridges Expressway Co., Ltd. (HSBE) operates and maintains three routes crossing the Seto-Inland Sea. Honshu-Shikoku Bridge consists of 17 long-span bridges including 10 suspension bridges, five cable-stayed bridges, one truss bridge and one arch bridge as shown in Figure 1. This group of long-span bridges in small area is very unique in the world. The Akashi-Kaikyo and Seto-Ohashi Bridges marked the 25th and 35th anniversary respectively in 2023. Honshu-Shikoku Bridges are important structures with no alternative route and must undertake a role as an emergency transportation route in case of a disaster.

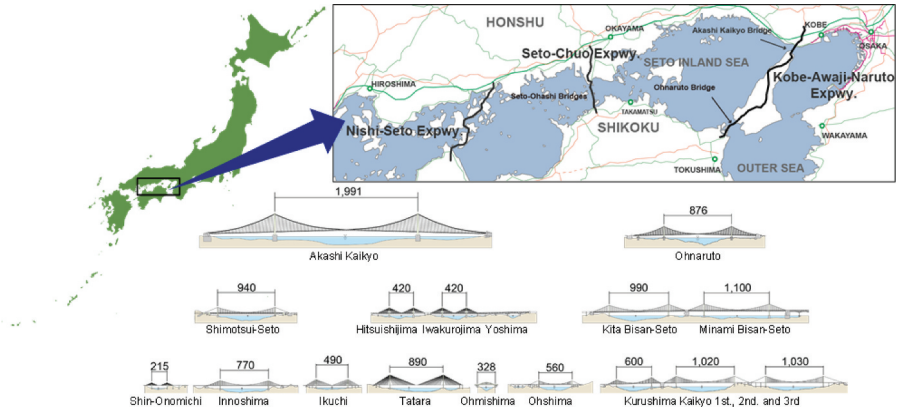

Figure 1. Location of Honshu-Shikoku Bridges.

DOI: 10.1201/9781003483755-249

The long-span bridges have large and special expansion joints in order to deal with the deformation unique to long-span bridges, such as large longitudinal and in-plane displacement. There are several types of large expansion joints. Four types of large expansion joint (finger type, rolling leaf type, link type and modular type) are mainly used for long-span bridges in Japan. Although each type has a unique structure, they have the same function in terms of dealing with the deformation. Especially, most of the link type expansion joints in Japan are used in Honshu-Shikoku Bridges including the Akashi-Kaikyo Bridge. Although many minor damages were reported, maintenance of the link-type expansion joints is limited to small scale repairs or parts replacements. In order to continue to maintain more than 200 years, preparation for large-scale renewal work and replacement of these expansion joints expected in the future is necessary.

In this paper, examples of damages and repair works of link-type expansion joints reported in the Honshu-Shikoku Bridges are explained. Furthermore, the future maintenance strategies based on problems in maintenance over the past 30 years will be explained.

2 LARGE EXPANSION JOINTS IN HONSHU-SHIKOKU BRIDGES

2.1 *Large expansion joints of long-span bridges*

Long-span bridges have large and special expansion joints in order to deal with the deformation unique to long-span bridges, such as large longitudinal and in-plane displacement. There are several types of large expansion joints as shown in Figure 2. Four types of large expansion joints (finger type, rolling leaf type, link type and modular type) are mainly used for long-span bridges in Japan. Although each type has a unique structure, they have the same function in terms of dealing with the deformation.

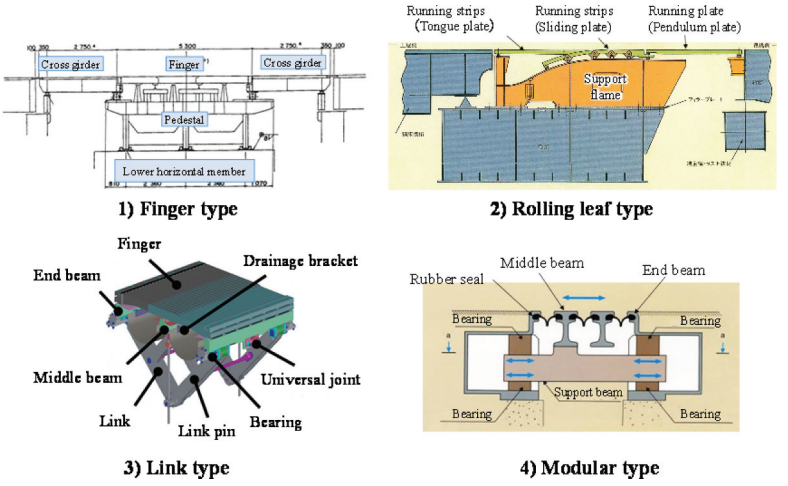

Figure 2. Large expansion joints for long-span bridges.

2.2 *Link type expansion joints*

In Japan, several types of large expansion joints are used as shown in Table 1 and especially most of the link type expansion joints are applied in the Honshu-Shikoku Bridges. In the Akashi-Kaikyo Bridge, designed movement range is up to +1,450mm and it indicates that the link type expansion joints are capable of dealing with large expansions and contractions (Figure 3).

Link type expansion joints are consist of link, link pin, bearing, middle beam, end beam, universal joint and finger (Figure 4). A link mechanism is applied as the load support mechanism, and the load is movably supported by the middle beam during expansion and contraction. Compared to other expansion joints, link mechanism is compact and suitable structural type for large expansion movement.

Link type expansion joints are capable of following displacement in all directions. For longitudinal displacement, the angle of the link mechanism changes. For transverse displacement, each unit follows by rotating in the horizontal in-plane around a universal joint. For vertical in-plane rotation, link and finger rotates around the connection of end beam. For horizontal in-plane rotation, each unit follows by displacement to expansion and contraction.

The unit width of the link type expansion joints is half the width of a lane, and each unit is removable, which has the advantage of superior workability in maintenance.

Table 1. Large expansion joints applied to bridges in Japan.

Expansion joint type	Honshu-Shikoku Bridges	Other Bridges in Japan
1) Finger type	Innoshima Bridge	Kanmon Bridge etc.
	Ohnaruto Bridge	
	Ikuchi Bridge	
2) Rolling leaf type	Shimotsui-Seto Bridge	Rainbow Bridge
	Kita Bisan-Seto Bridge	Hakucho Bridge
	Miani Bisan-Seto Bridge	Tempozan Bridge etc.
	Tatara Bridge	
	Kurushima-Kaikyo Bridges	
3) Link type	Akashi-Kaikyo Bridge	Kojimawan Bridge
	Hitsuishijima Bridge	
	Iwakurojima Bridge	
	Yoshima Bridge	
	Bannosu Viaduct	
	Ohshima Bridge	
4) Modular type	Ohmishima Bridge	Many bridges
	Yoshima Viaduct etc.

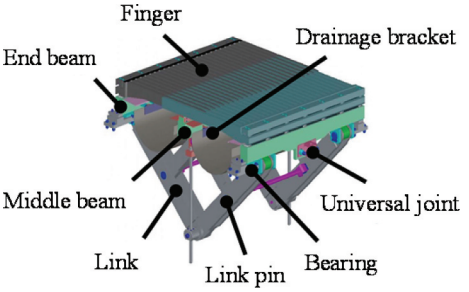

Figure 4. General view of link type expansion joints.

3 PROBLEMS OF LINK TYPE EXPANSION JOINTS

In this chapter, the major problems occurred in the past 30 years of maintenance of link type expansion joints. In the early stages of in-service, various types of damages have occurred due to the initial design of the expansion joint and structural improvements have been conducted each time. Failure and maintenance cases of link type expansion joints will be also explained.

3.1 *Noise problem during vehicle traffic*

Immediately after in-service, noise problem was reported during vehicle traffic. In order to determine the cause, investigation was conducted. The original structure had each independent finger pinned to the end beam. And it was found that the noise was caused by the gap between the pin and the pin hole, where the fingers bounce and hit as the wheel passes through. Figure 5 shows the mechanism of noise generation.

As countermeasures, two improvements were conducted as shown in Figure 6. First, the support structure of the fingers was changed. In detail, the pin that was causing noise was eliminated, and the anti-vibration rubber system was adopted to suppress the generation of noise and vibration. Second, the method of finger fabrication was revised. Originally, each steel plate separating finger was pinned and each finger could generate noise by moving individually. Therefore, casting integrated fingers were adopted instead of separating finger. By the two countermeasures mentioned above, noise problem caused by vehicle traffic was improved.

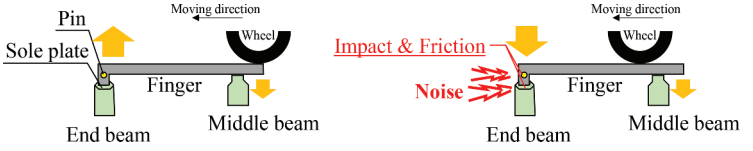

Figure 5. Mechanism of noise generation.

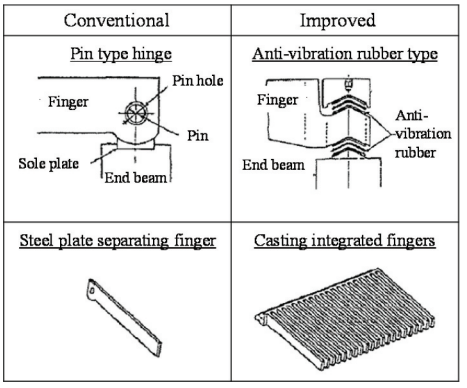

Figure 6. Improvement of support structure and finger.

3.2 *Breakage problem of finger*

Approximately five years after in-service, breakage problem of finger was reported. The vehicle passes through over the finger, a cause of the problem was investigated immediately. On the finger surface of link type expansion joints, a non-slip groove treatment is applied. As shown in Figure 7, previously non-slip groove treatment was conducted using flame cutting and the shape was rectangle. The corners of the groove profile were the cause of stress concentration, and fatigue cracks occurred due to the repeated wheel loading. In addition, residual

stress due to gas cutting during grooving was also considered. As countermeasures, flame cutting was replaced to machine cutting to deal with residual stress. And the shape of non-slip groove changed from rectangle to curved shape in order to reduce the stress concentration. After these improvements, there have been no reports of finger breakage.

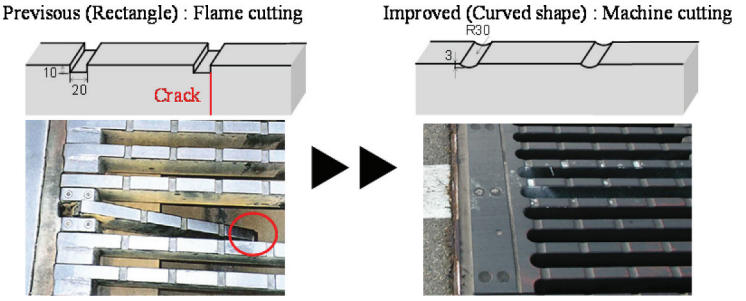

Figure 7. Improvement of finger shape of the surface.

3.3 *Failure and maintenance cases of link type expansion joints*

The damage caused by the initial design of the link-type expansion joint been described above, and a breakdown of link type expansion joint failures identified so far in the Honshu-Shikoku Bridges is shown in Figure 8. Damage resulting from poor construction or from the old structure described above is excluded. The majority of the cases are relatively minor failures such as deterioration of sealing due to aging, and cracking and peeling of the paint film. And failures related to the link mechanism has not been reported at this time.

Figure 9 shows the replacement of the universal joint. Corrosion of the universal joint leads to the restriction of transverse displacement. In order to prevent loss of rotational function of the universal joint, replacement is carried out at the appropriate timing. Loose bolts, etc. are repaired individually.

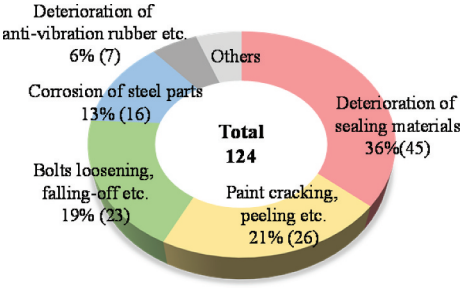

Figure 8. A breakdown of link type expansion joint failures identified in the Honshu-Shikoku Bridges.

Figure 9. Corrosion and replacement of the universal joint.

4 MAINTENANCE PLANS BASED ON PROBLEMS IN MAINTENANCE

The above chapters described problems that have been observed in link type expansion joints. In this chapter, strategies for maintenance management based on the problems that have occurred in maintenance are described.

4.1 *Reflection on maintenance related to deterioration of parts*

As mentioned above, the majority of the failure cases are relatively minor failures such as deterioration of some parts. Since components that have deteriorated over time need to be replaced on a periodic cycle, repairs and parts replacement are carried out based on the knowledge and experience that have been accumulated over the years. Table 2 and Figure 10 shows the estimated lifetime of rubber materials, sealing materials and painting based on the occurrence time of past deterioration. It shows that each component indicates the requirement for periodic replacement or repair of parts every 10 to 20 years.

These are all items that can be identified by close visual inspection, and are unidentified items that are structurally difficult to visually inspect, such as moving parts friction of the link mechanism. In order to understand the occurrence of deterioration and to consider the replacement period, a detailed investigation by overhaul will be conducted and the obtained results will be reflected to the maintenance plans.

Table 2. Estimated lifetime of parts (Link type expansion joint).

Parts name etc.	Estimated lifetime
Urethane rubber	10~20 years
Anti-vibration rubber	10 years
Dust rubber sealing for link	20 years
Seal ring for link	10 years
Painting layer	10~20 years

Figure 10. Deterioration of urethane rubber and anti-vibration rubber.

4.2 *Investigation of units standardization to ensure economic efficiency*

In order to accommodate the different design conditions of each bridge individually, the link type expansion joints applied in the Honshu-Shikoku Bridges have several designed movement ranges as shown in Figure 3 and each bridge has a variety of roadway widths.

Therefore, there is a wide variety of units when unit widths are included in addition to the designed movement range. Figure 11 shows the variation of unit width and designed movement range of link type expansion joint in Honshu-Shikoku Bridges. There are 28 types and a total of 214 units. There are also several units with very similar unit widths, indicating the possibility of standardization.

The size of the attached components of each type of unit varies slightly, which is one of the factors that increase production costs in maintenance. In preparation for periodic replacement

and repair of components and renewal of the expansion joint, investigations to standardize unit types and parts for the link type expansion joints in Honshu-Shikoku Bridges are currently underway. It is necessary to consider long-term maintenance and management from the design stage and standardization of parts is one of the efficient way when special structural members are applied.

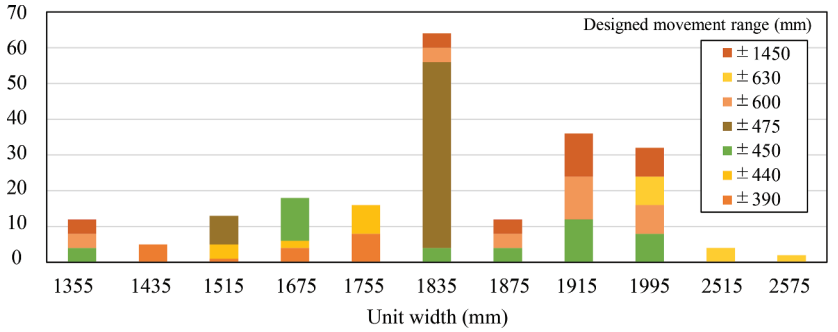

Figure 11. Variation of unit width and designed movement range (Link type expansion joint).

5 CONCLUSIONS

Link type expansion joints are applied to several long-span bridges in Honshu-Shikoku Bridges because of the compact structure and suitable structural type for large expansion movement. Although many minor damages were reported, maintenance of the link-type expansion joints is limited to small scale repairs or parts replacements. On the other hand, it is expected that large-scale repairs and renewal of the link type expansion joint will be more difficult due to its special characteristics, continuous maintenance, and technology inheritance. HSBE has started to discuss the standardization of the unit structure and the development of a maintenance policy for the long-term maintenance of the link type expansion joint.

Not only elastic devices, but also bridges with special structures require the establishment of a permanent maintenance system to prepare in advance for large-scale repairs and renewal associated with functional loss. It is necessary to consider long-term maintenance and management from the design stage when special structural members are applied.

HSBE will continue to undertake maintenance based on preventive maintenance in order to ensure that the long span bridge will be used over 200 years.

Fatigue behavior of steel plates subjected to marine environment

A. Chang & Q.Q. Yu
Key Laboratory of Performance Evolution and Control for Engineering Structures of Ministry of Education, Tongji University, Shanghai, China
Department of Structural Engineering, Tongji University, Shanghai, China

ABSTRACT: Fatigue refers to a phenomenon in which stress of metallic structures at failure is significantly lower than the yield strength after long-term periodic loads. Corroded steel structures characterized by reduced nominal cross sections and complex surface morphology are prone to fatigue damage, and have attracted much attention in the community of civil engineering. This study presents a comprehensive study on the fatigue behavior of corroded steel plates. Specimens were first placed in a neutral salt spray environment and then loaded by fatigue. Effects of different placement angles on the morphology and fatigue behavior of the steel plates were investigated. A 3D laser scanner was adopted to obtain the corrosion morphology and later applied in the numerical simulation. A three-dimensional finite element model was proposed to calculate the stress concentration factor (SCF) and strain concentration factor (SNCF) of the specimen.

1 INTRODUCTION

Corrosion is one of major causes of structural durability problems. The annual disposal or replacement of materials due to steel corrosion consumes plenty of financial and material resources. In 2014, the cost of corrosion in China was at least 2127.8 billion RMB(~ 310 billion USD), accounting for 3.34% of GDP that year(Hou et al., 2017). Even if surfaces of the steel is protected by coating and other methods, occurrence of corrosion cannot be prevented after a certain period of time (Czarnecki and Nowak, 2008). The surface morphology of corroded steel can be divided into uniform corrosion and non-uniform corrosion. Uniform corrosion refers to reduction of steel cross-sectional areas, thereby reducing the nominal strength of steel and reducing the elongation capacity of steel (Garbatov et al., 2014). Non-uniform corrosion represented by pitting corrosion causes stress concentration on the steel surface and led to crack initiation and development at the bottom of the corrosion pit (Xu and Wang, 2015). Fatigue strength of carbon steel may degrade by as much as 50-90% when it suffers corrosion damage under its service environment (Kainuma et al., 2014).

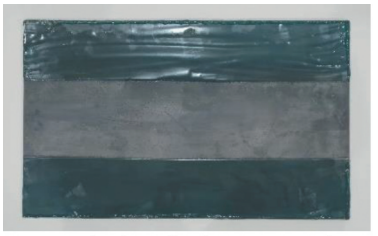
Much work has been conducted on analysis of stress concentration on corroded steel surfaces. Kainuma et.al. evaluated the stress concentration factor (SCF) of the corrosion pits on steel plates placed in a natural environment by finite element analysis (FEA). It was found that maximum stress occurred at the maximum corroded depth on the corroded surface (Kainuma et al., 2014). Cerit et.al explored the relationship between the SCFs and corrosion pits with different aspect ratios. The SCF value increased linearly with increasing aspect ratio (Cerit et al., 2009). Zeng et.al. investigated the SCFs of stepwise corrosion pits. For different types of stepwise corrosion pits, the same corrosion pit parameter had completely different effects on the SCF (Zeng et al., 2022).

In the existing research, the stress concentration analysis of corroded surfaces was mainly based on numerical simulation, but no actual stress-strain measurement was carried out. In this paper, the finite element method was used to combine the morphology of the corroded

DOI: 10.1201/9781003483755-250

steel plate obtained by 3D laser scanning, and the numerical simulation analysis of the corroded steel plate was carried out. The strain field of corroded surface was gauged by DIC method during the fatigue test. Based on the numerical results of the surface strain distribution, the effect of the corroded surface on the SCF and SNCF was analyzed.

2 EXPERIMENT PROGRAMME

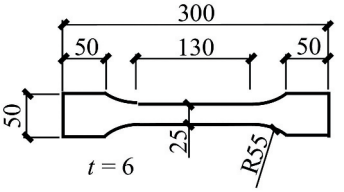


2.1 *Material and specimens*

The Q355b grade low-alloy steel was selected. The tested mechanical properties are given in Table 1. Three steel plates (500 mm×300 mm×6 mm) were exposed in the salt spray chamber, which were set in three angles to explore the effect of the salt spray angle, i.e., 0º, 45º, and 90º. Both ends of the plate were covered by using the epoxy resin to avoid corrosion of the clamping section (Figure 1a). The dog-bone specimens were cut from the rectangle plate by wire cutting. The dimension of steel dog-bone specimens were based on ISO 1099:2017 (ISO) (Figure 1b and Figure 1c). One specimen at each angle was cut for fatigue testing. They were set in spray chamber for 120 days, except for the 0º specimen, which was set for 240 days.

Table 1. Mechanical properties of Q355b steel.

f_y (MPa)	f_u (MPa)	δ (%)	E (10^5 MPa)
358.1	509.1	24.1	1.80



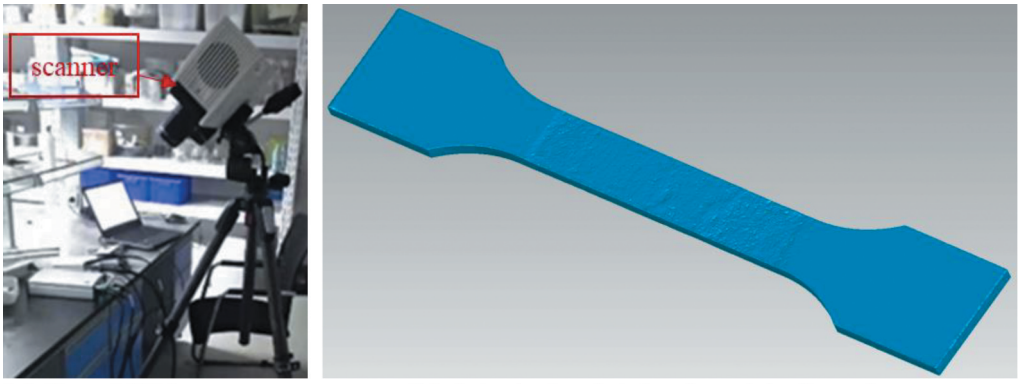
f_y - the yield strength, f_u - the ultimate strength, δ - the elongation ratio, E - the Young modulus.

(a) steel plate before corrosion

(b) dog-bone specimen for fatigue testing

(c) dimensions of the specimen for fatigue testing (unit in mm, not to scale)

Figure 1. Geometry and dimension of the test specimen.



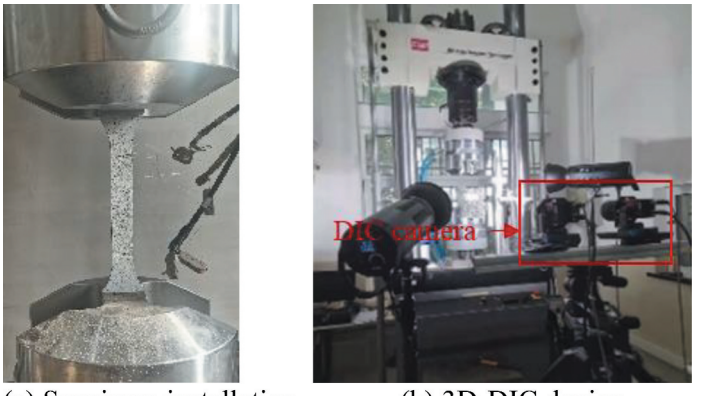
2.2 *Neutral salt spray accelerated corrosion test*

The salt spray tests were conducted according to ISO 9227:2006. The both sides of specimens were placed in a salt spray chamber fulfilled with salt fog generated by 5% weight NaCl and the temperature was 35 °C. Rust removal method was based on ISO 8407:2009(ISO). The

specimens after corrosion were first cleaned by a soft brush and then immersed into dilute hydrochloric acid solution for 20 minutes to scrub the tough rust. Next, they were rinsed with running water to remove the remains. Finally, they were dried with a dryer and weighed.

2.3 *Morphology scanning*

The specimens were scanned by Comet3D scanner with a minimum resolution of 20 μm to obtain the 3D surface morphology (Figure 2a). A typical point cloud model of specimen is illustrated in Figure 2b, which be used in finite element modeling.



(a) Comet 3D laser scanner (b) A typical point cloud model of specimen

Figure 2. Morphology scanning.

2.4 *Test set-up*

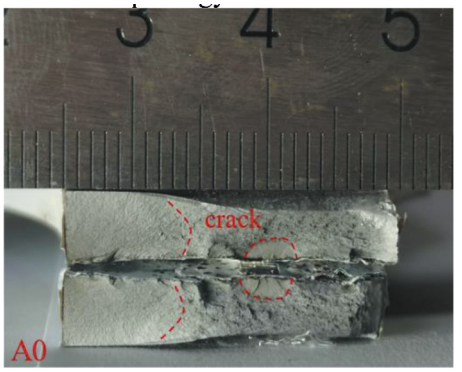
The tests were performed on an MTS 322 servo hydraulic testing machine with a dynamic load capacity of 250 kN (Figure 3a). Cyclic tensile loads were applied to all the specimens with a frequency of 20 Hz and a stress ratio R (minimum load/maximum load) of 0.1 with the waveform being sinusoidal. The maximum in the spectrum was 250 MPa, which was about 50% ultimate strength of the material. The beach marking technique was adopted to record the crack propagation. Three-dimensional digital image correlation (3D-DIC) technology was used to measure the surface strain field (Figure 3b). Before the fatigue test was loaded, a monotonic tensile test was performed to allow DIC to measure the surface strain field of the specimen.

(a) Specimen installation (b) 3D-DIC device

Figure 3. Fatigue test set-up.

Table 3 presents a summary of the test program and results.

The mass loss ratio (η) is a common parameter to evaluate the corrosion degree in order to characterize the magnitude of mass loss in the corroded area. Because of the uncorroded area protected by epoxy resin, the value was corrected based on the ratio of the corrosion area to the total area, which was 2.5 in this study. The mass loss ratio η is calculated by Eq. (1).



$$\eta = \frac{m_0 - m_1}{m_0} \times \alpha \tag{1}$$

where m_0 is initial mass of the specimen; m_1 is the mass of the specimen after corrosion, α is the ratio of the corrosion area to the total area.

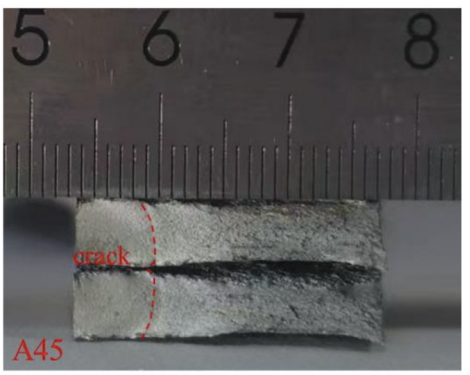


Table 2. Fatigue test results.

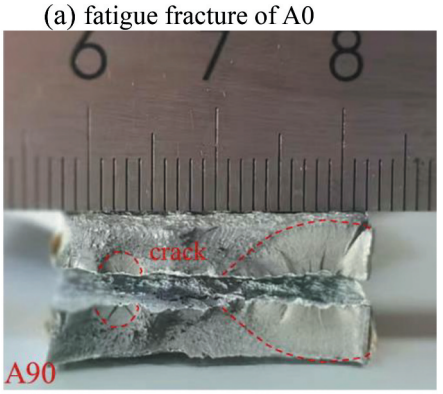
Specimens	Set angle	Corrosion time(days)	m_0 (g)	m_1 (g)	η	N
A0	0°	240	6647.0	6424.5	0.0825	582682
A45	45°	120	6671.0	6383.5	0.1075	417355
A90	90°	120	6664.5	6380.0	0.1050	229597



Cracks initiated at the corrosion pit on the surface of the specimen, and propagated simultaneously in both width and thickness directions. The crack front generally exhibited a semi-ellipse shape (Figure 4). At the late stage of crack development, the reduced cross-section

(a) fatigue fracture of A0

(b) fatigue fracture of A45

(c) fatigue fracture of A90

Figure 4. Fracture surface of specimens.

could not carry the maximum load applied in each cycle, and the specimen ruptured suddenly to produce the rough regions. In addition, multiple cracks were witnessed in Figures 4b and 4c due to the complex surface morphology.

With the strain field detected on the specimen surface before fatigue loading, stress concentration was observed, which was also in conformance with the location of fracture. The verification of fracture is described in 3.2.

With the increase of the η, the fatigue life of the samples dramatically decreased. It was also worth noting that, the specimens A45 and A90, with the approximate corrosion degree, were very different in fatigue life, which implied that corrosion morphology may have a greater effect on fatigue life.

3 FEM MODELING

3.1 *FEM model*

Three dimensional finite element models based on the configuration of tested steel plates were developed to simulate the experimental tests. The commercial software ABAQUS was employed. The steel plate were meshed using three-dimensional solid elements (C3D8R). The material properties refer to the material properties given in Table 1 for a elastoplastic constitutive model. one end of the model was fully fixed, the other was applied by a uniform tensile loading of 125 MPa, which was the maximum load in real fatigue test. A mesh size of 0.25 mm was selected for the corroded area (Cerit et al., 2009) and adaptive meshing was used to reduce the amount of elements (Figure 5b).

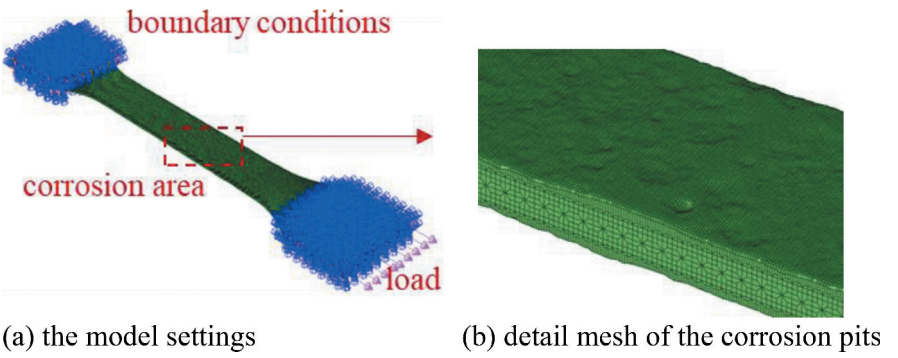


Figure 5. Typical FEM model of the corroded specimen.

3.2 *Strain field of numerical results*

The results of the three strain measurements or numerical method were shown in the Table 3. The finite element results and DIC results were shown in Figure 6.

Table 3. Strain comparison.

Gauges number	Position	DIC (με)	Strain gauges (με)	FEA (με)
0	Flat plate	1260	1095	1200
1	Corrosion pit	2071	1775	2746
2	Left side		1334	1454
3	Right side		1564	1667

The DIC measurement results were similar to the finite element strain distribution results. However, for corrosion pits, especially at the maximum strain, the measurement of the maximum strain may not be very accurate due to problems such as its resolution. The internal strain of the

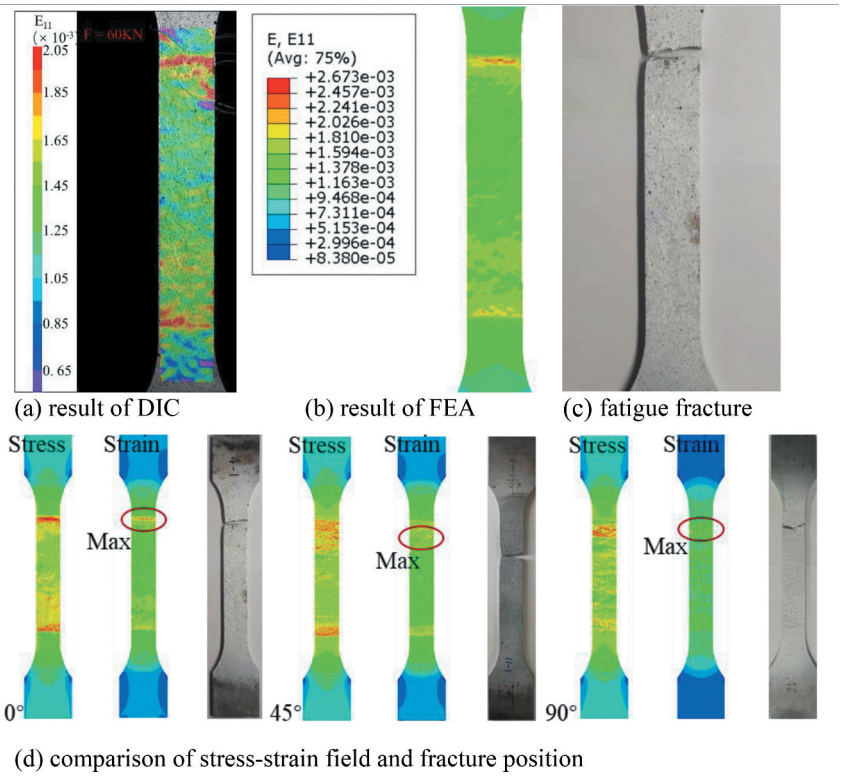

Figure 6. Strain field on the surface of the specimen.

corrosion pit often has a large abrupt change, and the DIC measurement had a high accuracy for the surrounding area of the corrosion pit. This inference can also be partially confirmed by the strain measurement near the corrosion pit in the strain gauge measurement, because it was actually more difficult to measure the strain at the bottom of the corrosion pit. At the same time, the reliability of the finite element calculation was verified by the strain gauges at each point, which had a error of about 10%. The SCF and SNCF on the surfaces of all the specimens were extracted according to Eqs. 2 and 3, respectively, and are performed in Figure 7.

$$K_\sigma = \frac{\sigma_{\max}}{\sigma_0} \tag{2}$$

where K_σ is SCF; $\sigma_{\max}$ is the maximum localized stress; σ_0 is the nominal stress of the specimen.

$$K_\varepsilon = \frac{\varepsilon_{\max}}{\varepsilon_0} \tag{3}$$

where K_ε is SCNF; $\varepsilon_{\max}$ is the maximum localized stress; ε_0 is the nominal stress of the specimen.

For different specimens, the variance of the SNCF was more obvious than that SCF (Figure), which may be caused by the higher maximum stress used in the fatigue test. At the same time, the SNCF seemed to have a higher explainability on the fatigue life of the specimen than the SCF. Due to the large stress, there are many areas on the surface of the specimen that enter the yield stage, but the areas with more significant strain concentration become the origin of the macroscopic cracks on the specimen. The SNCF of the specimen with the same corrosion rate was obviously different, which may be caused by the inconsistent surface morphology of the specimen under different placement angles.

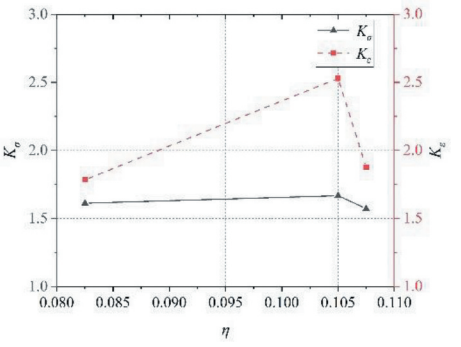

Figure 7. The SCF and SNCF of specimens.

4 CONCLUSIONS

In this study, steel plates were exposed to artificial salt fog spray and tested under fatigue. With the increase of the corrosion degree, the fatigue life significantly decreased. However, for the specimens with similar corrosion degree whereas different placement angle, the fatigue life differed much which may be due to the various specimen morphology. Finite element models were developed with the scanned surface characteristics and were validated in term of the surface stress distribution by using the experimental findings. The SCF and SNCF values of the samples were extracted and compared. It was found that the area where the strain is concentrated is more likely to be the basis for judging the origin of the crack.

Fatigue effect of welded gusset plate in steel-concrete composite bridge

S.L. Yan
CCCC First Highway Consultants Co.Ltd., Xi'an, China

S.Y. Jia
College of Aerospace and Civil Engineering, Harbin Engineering University, Harbin, China

S.W. Xu, J.N. Li & Y.Z. Wang

ABSTRACT: Steel-concrete composite bridges are widely used because of their good structural properties but suffer from fatigue problems due to increasing vehicle loads and speeds. In order to investigate the fatigue response at welded gusset plates of steel-concrete composite bridges, finite element models of long-span steel-concrete composite bridges with three loading conditions and different gusset plate thickness are established, and the stress time history analysis is carried out. Finite element results show that the under the most unfavorable condition among the three conditions, the maximum stress occurs when the fatigue vehicle passes through the critical point. When the gusset plate thickness is 20 mm, the stress peaks for TC1, TC2 and TC3 conditions are 23.3 MPa, 27.4MPa and 14.8 MPa, respectively. Stress peak values decrease with an increase in thickness. Stress peaks for 12 mm, 16 mm and 20 mm thicknesses are 47.1 MPa, 37.3 MPa and 27.4 MPa, respectively.

1 INTRODUCTION

Steel-concrete composite bridge is a new type of bridge structure that connects concrete decks with steel beams through shear connectors, and it is widely applied in the construction of long-span bridges. Due to the increasing vehicle loads and speeds, the burden on bridge structures has escalated, leading to occurrences of bridge fracture and damage incidents. Therefore, it is important to carry out research on the fatigue performance of steel-concrete composite beams under vehicular loading (Hassanin et al., 2020).

In recent years, scholars from various countries performed research on the fatigue behavior of steel-concrete composite beams. Some scholars focused on the mechanical behavior of shear connectors. Shear connectors are commonly used in steel-concrete composite bridges to connect the concrete bridge deck and the top steel structure, providing a mechanism for shear transfer across the steel-concrete interface (Ovuoba & Prinz, 2016). Li et al. (2022) found that the presence of transverse shear significantly reduces the vertical shear strength and stiffness of bolted connections. Alsharari et al. (2022) also found that during the service life of a bridge, loading may cause bolt fractures near the end of the bridge, resulting in overall bridge failure.

Some scholars conducted research on the fatigue life asssesment of steel-concrete composite bridges. EI-Zohairy & Salim (2018) found that under the action of vehicular loads, the static strength of shear connectors in steel-concrete composite beams decreases with an increase in the number of loading cycles, resulting in a decrease in the load-carrying capacity of the beams. Matsuoka et al. (2019) discovered that European design standards set limits on the

DOI: 10.1201/9781003483755-251

acceleration of the bridge deck for high-speed railway bridges, but the influence of localized vibration of the bridge deck components is rarely considered when establishing the bridge vibration response model. Bhetuwal et al. (2021) conducted a detailed analysis on the fatigue life of a steel-concrete composite bridge under the influence of pavement conditions. The results showed that bridges with poor road conditions have a lower fatigue life compared to bridges with better road conditions. Many scholars have conducted in-depth research in the field of bridge fatigue. Some researchers have carried out fatigue tests on steel-concrete composite beam specimens to study the fatigue failure mechanisms and damage processes of composite beams under fatigue loading. Leitão et al. (2011) found that steel-concrete highway bridges experience dynamic actions of varying amplitudes due to vehicle traffic, leading to crack initiation and propagation in the structure. Martínez-Muñoz et al. (2020) investigated the degradation of stiffness in steel-concrete composite beams after being subjected to fatigue loading. The results indicated that the stiffness degradation is related to the macroscopic behavior of material fatigue damage and shear connection degradation.

Some scholars carried out research on the repair mrthods of steel-concrete composite bridges. Uy & Craine (2004) conducted a study on the strengthening of steel-concrete composite beams and found that the post-tensioning method improves the fatigue life of the components. Stylianidis & Petrou (2019) proposed a new analysis method to predict the moment-curvature relationship and overall flexural response of steel-concrete beams reinforced with FRP.

In summary, existing research on the fatigue response analysis of welded gusset plates in steel-concrete composite bridges is relatively insufficient. In this study, finite element analysis are carried out of models of a 400-meter span steel-concrete composite bridge, to identify the most unfavorable conditions for the fatigue details of welded gusset plates, considering the effect of gusset plate thickness. The finite element analysis results has guiding significance for fatigue design of welded gusset plates in steel-concrete composite bridges.

2 MODEL INTRODUCTION

2.1 *Model description*

A four-span (100 m + 100 m + 100 m + 100 m) continuous steel-concrete composite beam is selected for analysis. The main beam cross-section is a box-shaped composite section, consisting of a concrete bridge deck and a ribbed steel main beam, as shown in Figure 1. The concrete bridge deck has a width of 16.5 m and a thickness of 280 mm, designed for a one-way three-lane traffic layout. The steel beam has a height of 4.5 m, with a top plate thickness near the mid-support point of 65 mm and 50 mm elsewhere. The slopes of inner and outer webs are 1:3.1 and 1:2.9, respectively. The web thickness near the mid-support point is 28 mm, while elsewhere it is 24 mm. Four longitudinal stiffening ribs are arranged according to the compression area of the webs, of which the size is 280 mm × 26 mm. The bottom plate has a width of 6.6 m, with a thickness near the mid-support point of 24 mm and 20 mm elsewhere. Longitudinal stiffening ribs for the bottom plate are plate-type stiffeners measuring 260 mm × 24 mm, spaced at intervals of 650 mm.

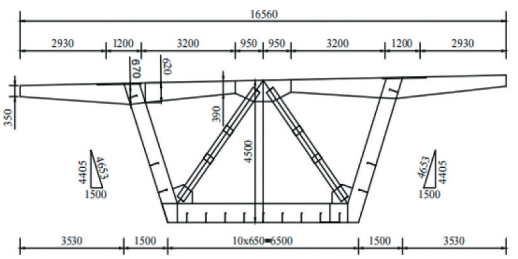

Figure 1. Cross-sectional diagram.

2.2 *Finite element model*

2.2.1 *Model establishment*

Figure 2 Illustrates the finite element model of the continuous steel-concrete composite beam bridge Employing solid elements for the bridge deck and shell elements for all steel members. The bridge deck was designed with three lanes corresponding to three different conditions (TC1, TC2 and TC3 from right to left). The connection between the bridge deck and the steel main beams was achieved using binding constraints.

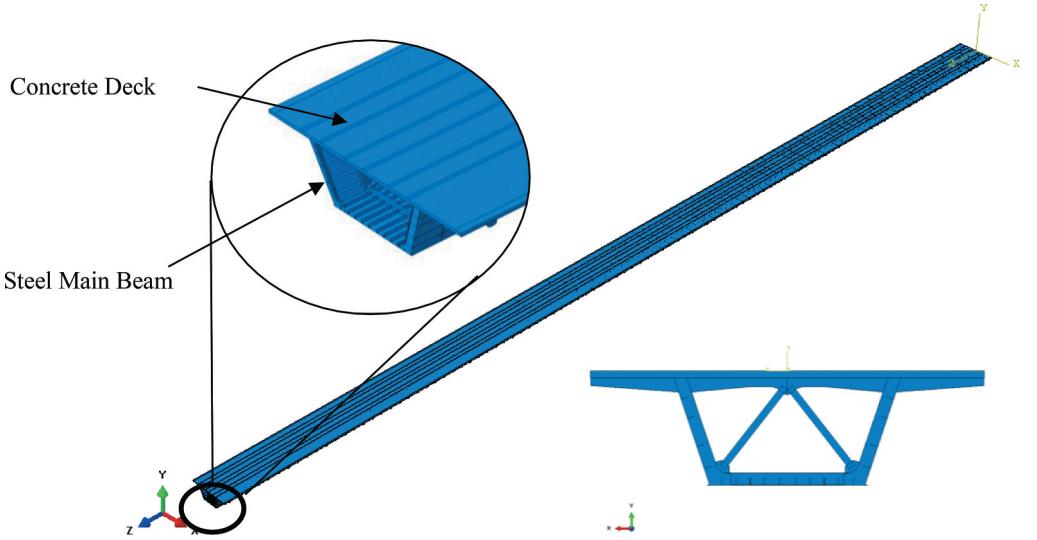

Figure 2. Finite element model.

The model was meshed using two different sizes. A Mesh of 0.2 m is applied to the entire bridge structure, while finer mesh of 0.04 m is applied specifically to the welded gusset plate at the critical region. Figure 3 shows the detailed mesh of the critical region.

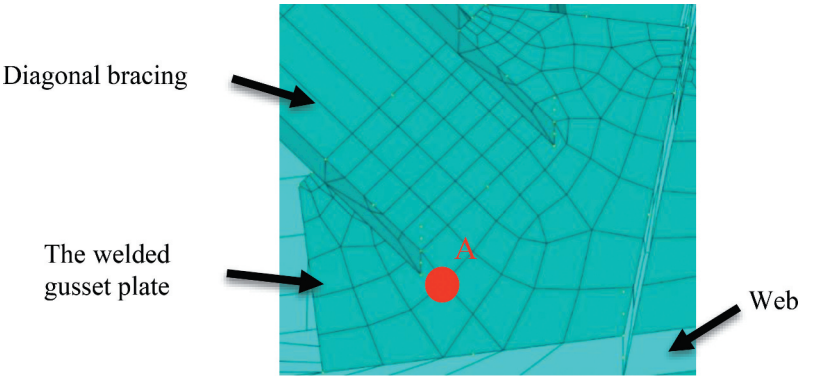

Figure 3. Mesh division at welded gusset plate.

2.2.2 *Material parameters*

The concrete bridge deck in the model is created using solid elements with C50 concrete material. The steel main beams are modeled using shell elements and constructed with Q345 steel material. The material parameters are shown in Table 1.

Table 1. Material parameters

Material	Density (kg/m³)	Young's Modulus (MPa)	Poisson's Ratio
C50	2500	3.25×10^4	0.2
Q345	7850	2.06×10^5	0.3

2.2.3 *Boundary conditions*

To ensure coordination of bridge displacement and deformation, the rotational constraints and translational constraints in the X and Z directions are released at the support point between the second and third spans of the bridge to simulate unidirectional (Y direction) movable bearings (BC-1). As for other support points, the rotational constraints and translational constraints in the X direction are released to simulate bi-directional (Z and Y directions) movable bearings (BC-2). Table 2 and Figure 4 show the layout of the bearings for the bridge.

Table 2. Boundary conditions.

Type*	U1	U2	U3	UR1	UR2	UR3
BC-1	Free	Fix	Free	Free	Free	Free
BC-2	Free	Fix	Fix	Free	Free	Free

*U1, U2, U3 are translations constraints in the X, Y, Z directions. UR1, UR2, UR3 are rotations about X, Y, Z directions.

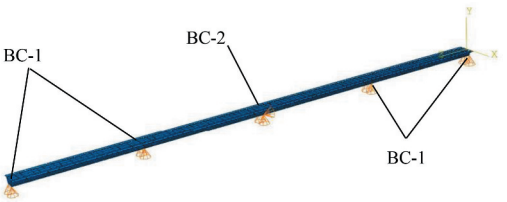

Figure 4. Bearing layout diagram.

2.3 *Load parameters*

Both permanent loads and variable loads are considered in the finite element analysis. Permanent loads can be divided into two stages. The first-stage permanent load is calculated based on the actual design drawings of the concrete and steel structures, considering their respective self-weights after adjusting for the corresponding component densities. The second-stage permanent load considers the bridge deck pavement, assumed to be 100 mm thick asphalt concrete, with a load intensity of 37.2 kN/m.

The fatigue vehicle model of Class II highways in General Specification for Design of Highway Bridges and Culverts (JTG D60) is adopted as variable loads. The fatigue load model for a single vehicle is illustrated in Figure 5. The standard values for the front axle load, middle axle load and rear axle load are 30 kN, 120 kN and 140 kN, respectively. These axle loads are distributed across two wheels, with a wheelbase of 1.8 m. The vehicle's moving speed is 10 m per second.

In order to achieve mobile loading in the software platform and obtain more accurate stress responses at fatigue details, concentrated loads are converted into equivalent distributed loads. Assuming the contact area of each front wheel with the ground is 0.2 m × 0.3 m and the contact area of each middle and rear wheel is 0.2 m × 0.6 m. The conversion results are shown in Table 3.

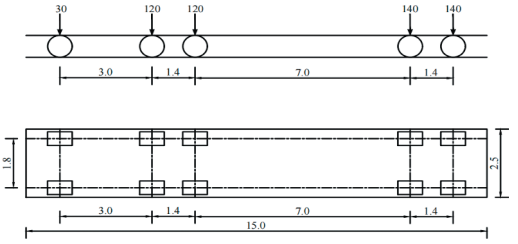

Figure 5. Single vehicle model for fatigue load.

Table 3. Equivalent distributed load parameters.

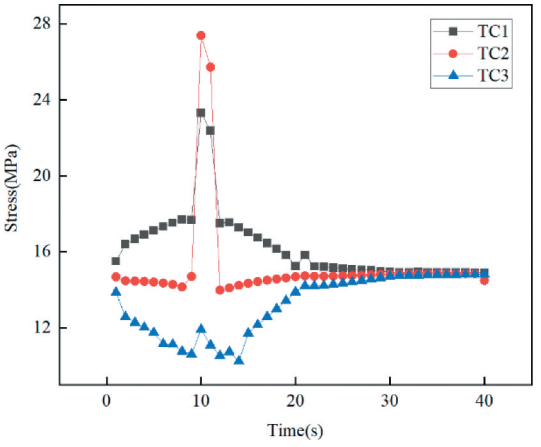
Axle Number	Axle Load(kN)	Wheel Load Area (m^2)	Equivalent Distributed Load(Pa)
1	30	0.06	250000
2	120	0.12	500000
3	120	0.12	500000
4	140	0.12	580000
5	140	0.12	580000

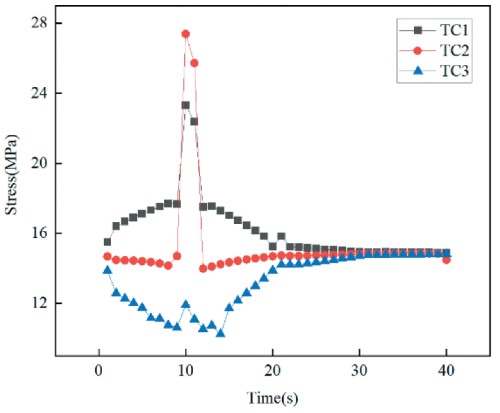
3 STRESS ANALYSIS

The gusset plate adjacent to the fourth span support (near the rightmost lane) was selected for stress analysis. For investigating stress responses at fatigue detail locations during the passage of vehicles, a stress focus point labeled as 'A' was placed at the typical fatigue crack initiation position of the gusset plate, as depicted in Figure 3.

3.1 *Stress-time history analysis*

Stress responses at the stress focus point are extracted as vehicles traverse the entire bridge under different conditions TC1, TC2 and TC3, corresponding to the three lanes (TC1 for the rightmost lane, TC2 for the middle lane, and TC3 for the leftmost lane). The stress-time history curves obtained for each lane are depicted in Figure 6.





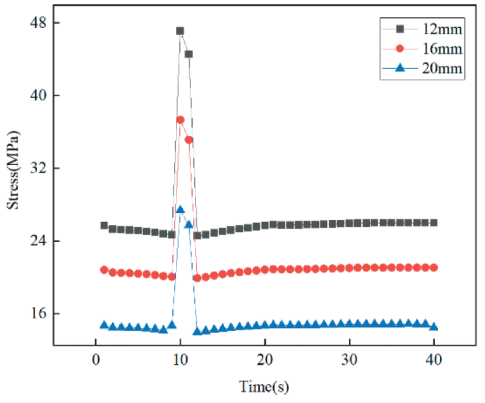


Figure 6. Stress-time history curves.

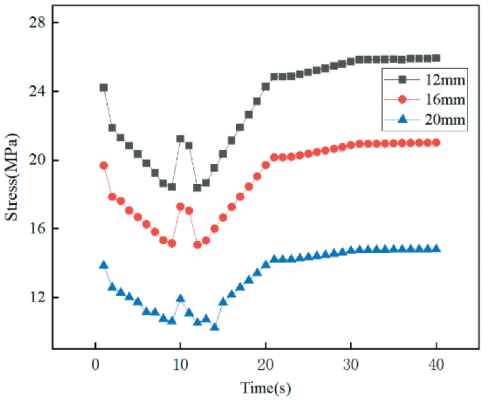

Based on the stress-time history curves, it is evident that when the fatigue vehicle travels in the middle lane (TC2 condition), the stress at the fatigue detail experiences higher levels.

(a) Stress-time history curves for different thicknesses under TC1 condition.

(b) Stress-time history curves for different thicknesses under TC2 condition.

(c) Stress-time history curves for different thicknesses under TC3 condition.

Figure 7. Stress-time history curves for different thicknesses under three conditions.

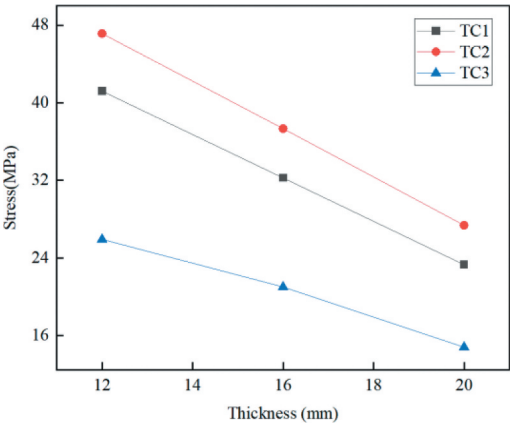

Figure 8. Stress peak curves for different thicknesses.

Conversely, when the fatigue vehicle operates on lanes further from the detail (TC1 and TC3 conditions), the stress at the fatigue detail remains lower. For TC1 and TC2 conditions, notable stress peaks are observed as the fatigue vehicle passes over the detail along the 'longitudinal direction. In TC3 condition, the maximum stress is witnessed as the fatigue vehicle departs from the bridge. The maximum stress peak at the fatigue detail for TC2 condition reaches 27.4 MPa, for TC1 condition it reaches 23.3 MPa, and for TC3 condition it reaches 11.9 MPa. Due to the influence of gravity, the stress levels tend to converge as the vehicle completes its passage.

In condition TC2, the stress peak at the focus point of the fatigue detail notably exceeds that under TC1 and TC3 conditions. When vehicle travels along the middle lane, it exerts the most substantial impact on the gusset plate, resulting in the highest stress.

3.2 *Analysis of the gusset plate thickness influence*

To consider the effect of varying gusset plate thickness on the stress response of fatigue details, finite element models with gusset plate thickness of 12 mm, 16 mm, and 20 mm are established. During the modeling process, while altering the gusset plate thickness in the same span bridge, other component dimensions remained constant. The stress-time history curves for different thicknesses under various conditions are depicted in Figure 7.

Figure 7 demonstrates stress peak values under various thicknesses and conditions. Under TC1 condition, the stress peaks at 41.2 MPa for 12mm thickness, 32.3 MPa for 16mm thickness, and 23.3 MPa for 20 mm thickness. For TC2 condition, the stress peaks at 47.1 MPa for 12 mm thickness, 37.3 MPa for 16 mm, and 27.4 MPa for 20mm. In TC3 condition, the stress peaks at 25.9 MPa for 12 mm, 21.0 MPa for 16mm, and 14.8 MPa for 20 mm thicknesses.

The stress peak curves for different thicknesses under various conditions are illustrated in Figure 8. Figure 8 illustrates that as the gusset plate thickness increases, the stress peak at the focal point decreases. The effect is uniform across different conditions, showing that thicker gusset plates result in lower stress at welding details. The stress peak values are maximum when the gusset plate thickness is 12 mm across all three conditions. Among these, the stress peak is highest under TC2 condition, reaching 47.1 MPa.

4 CONCLUSIONS

This paper established finite element models of a steel-concrete composite bridge and conducted finite element analysis to determine the unfavorable position and reveal the effect of gusset plate thickness on stress response. Based on the finite element analysis results, the following conclusions can be drawn:

(1) TC2 condition is the most unfavorable condition among the three conditions, under which the maximum stress occurs when the fatigue vehicle passes through the critical point.
(2) When the gusset plate thickness is 20 mm, the stress peaks for TC1, TC2 and TC3 conditions are 23.3 MPa, 27.4 MPa and14.8 MPa, respectively.
(3) Stress peak values decrease with an increase in thickness. Specifically, under TC2 condition, when the thickness is 12 mm, the maximum stress peak is 47.1 MPa. At 16 mm and 20 mm thicknesses, the stress peaks are 37.3 MPa and 27.4 MPa, respectively.

Evaluation of fatigue environment in welded parts of orthotropic steel deck

K. Yoshida & H. Sekiya
Department of Urban and Civil Engineering, Tokyo City University, Tokyo, Japan

ABSTRACT: Orthotropic steel deck is made by welding together thin steel plates and have excellent workability. However, many fatigue damages have been reported due to local deformation caused by passing vehicles. To implement appropriate maintenance management against this fatigue damage, it is important to analyze the strain response near the welded parts in the orthotropic steel deck. In this study, field measurements were conducted on in-service orthotropic steel deck bridges using a load truck. Triaxial strain gauges were used to measure the strain response near the welded parts in the orthotropic steel deck. Based on the measurement data obtained while the load car was running, the strain response, the magnitude and direction of the principal strain at different fatigue crack-prone locations were compared and discussed.

1 INTRODUCTION

Orthotropic steel decks have been used in many urban expressways and long-span bridges because they are lightweight and can be constructed in a short time. Orthotropic steel decks are composed of a deck plate with a thickness of about 12 mm and thin steel materials such as transverse and longitudinal ribs, which are welded together. The direct loading from the wheel load of the car causes the orthotropic steel deck structure to behave in a complex manner, resulting in locally high stress at the intersection of the members, which is thought to lead to fatigue damage. In recent years, fatigue cracks have been reported in the welds between deck plate and U-ribs under heavy traffic and an increasing percentage of heavy vehicles. Although these cracks do not lead to immediate bridge failure when they occur, if left unchecked, they can propagate and lead to pavement damage, lack of road surface flatness, and other roadway deterioration. (Japan road association, 1997).

To implement appropriate maintenance management against such fatigue damage, it is important to analyze the strain response near the welded parts in the orthotropic steel deck. In this study, measurement tests using a load truck were conducted on an in-service bridge to analyze the strain response near the welds between the deck plate and the U-ribs.

2 TARGET BRIDGE AND MEASUREMENT OVERVIEW

2.1 *Target bridge*

The target bridge in this study is a three-span continuous orthotropic steel deck box girder bridge with a total length of 166.2 m and span lengths of 51.7 m, 62.0 m, and 51.7 m, respectively. It is 15.95 m wide and consists of a first traffic lane, a second traffic lane, a ramp for entering and exiting the parking area, and road shoulders. The main dimensions of the target bridge are asphalt pavement thickness of 80 mm, deck plate thickness of 12 mm, and U-ribs with a height of 240 mm, width of 320 mm, and plate thickness of 6 mm. Figure 1 shows a cross-sectional view of the box girder to be measured and the loading position of the tires.

DOI: 10.1201/9781003483755-252

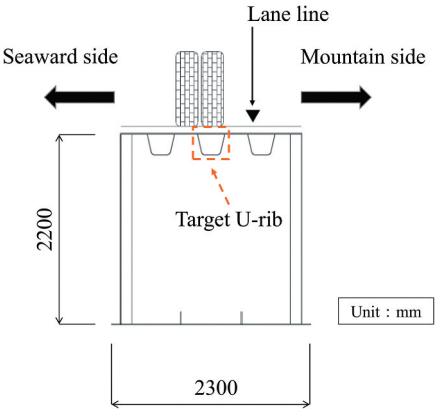

Figure 1. Cross-sectional view of the measurement location and tire position.

2.2 *Measurement method*

Measurements were taken at a section with a span length of 51.7 m, directly under the second traffic lane, in the general section of the box girder where there were no crossings of transverse ribs or other members. Figure 2 shows the geometry of the U-ribs and the position of the strain gauges attached to them. Triaxial strain gauges were used for measurement, and were attached to the deck plate and the U-rib at a distance of 10 mm from the weld end between the deck plate and the U-rib on both the seaward and the mountain sides (four positions). The sampling frequency of the strain gage is 500 Hz. Figure 3 shows the test vehicle used for the test. Ordinary trucks were used for the measurements. The test vehicle is four-axle vehicle with a total weight of 243.7kN. The front axle weight, the front rear axle weight, the rear front axle weight, and the rear rear axle weight are 46.9kN, 46.6kN, 74.6kN, and 75.6kN, respectively. Test vehicle traveling were also made six times. No lane closures were made during the measurement, which was conducted late at night when traffic volume was low. The load vehicle was driven at a speed of approximately 50 km/h.

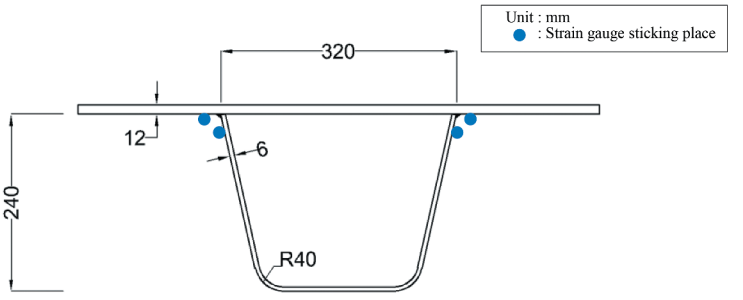

Figure 2. U-rib cross section and strain gauge sticking position.

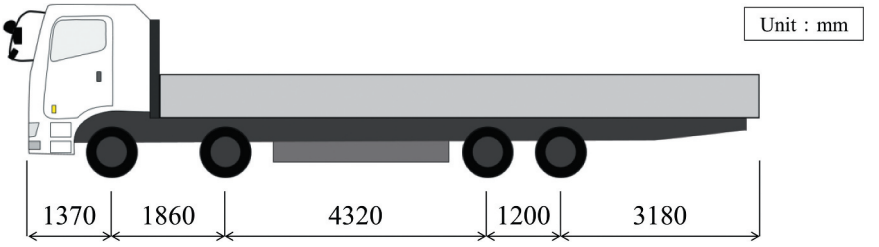

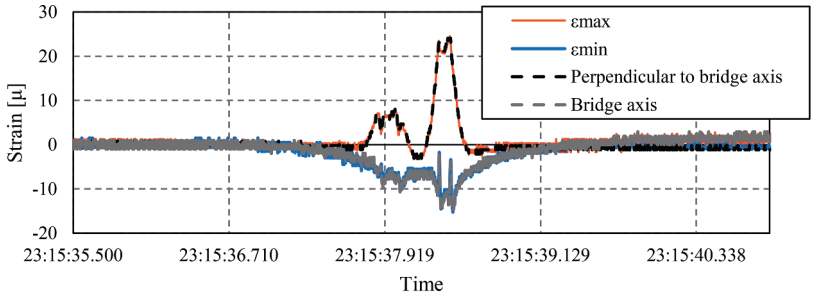

Figure 3. Test vehicle.

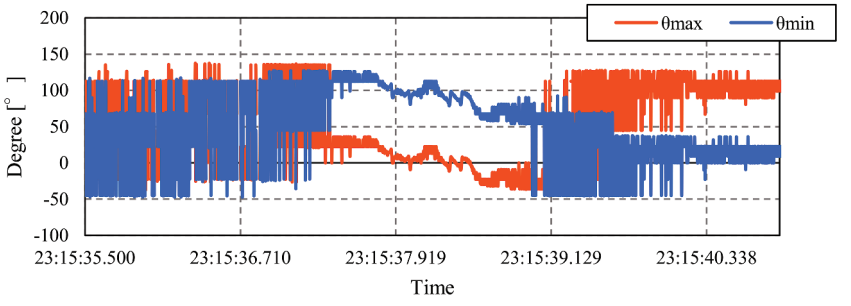
3 MEASUREMENT RESULTS

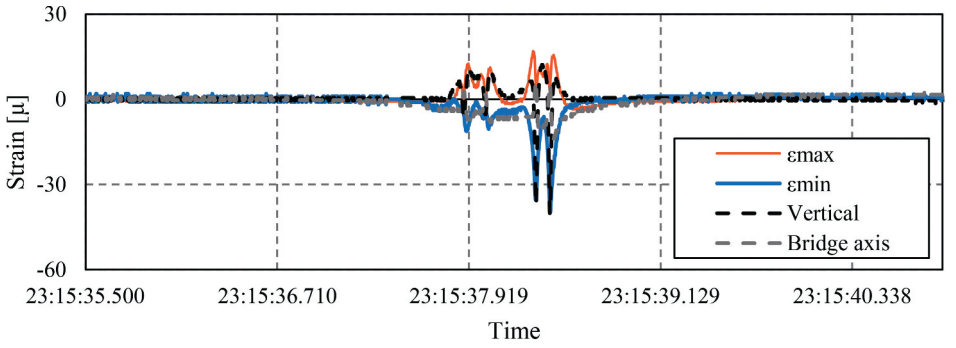


3.1 *Strain response of the deck plate on the seaward side*

Figure 4 shows the maximum and minimum principal strains calculated from the data obtained from the triaxial strain gauges attached to the deck plate on the seaward side, and the responses in the bridge axis direction and perpendicular to the bridge axis direction. The sharp responses in the minimum principal strain and in the direction of the bridge axis can be observed in four locations. This is thought to be due to the fact that the number of axles of the load car used in the test was four.

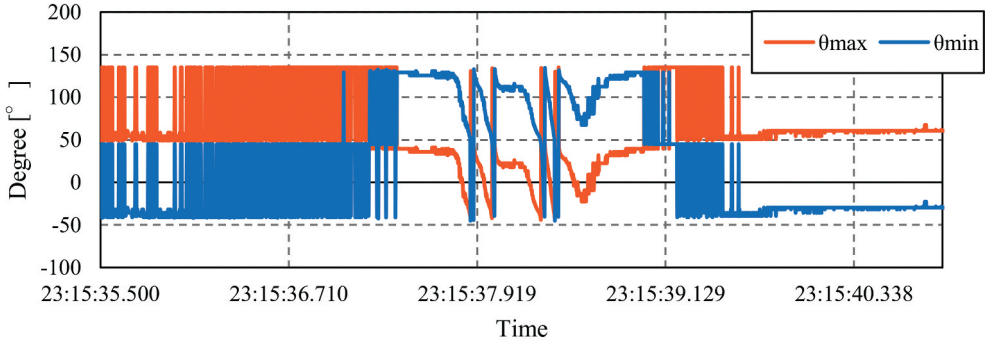
The peak values of the maximum and minimum principal strains at the time of vehicle passage were +24.5 μ for the maximum principal strain and -15.5 μ for the minimum principal strain, with the absolute value being greater for the maximum principal strain. It can be confirmed that the maximum and minimum principal strain responses are generally consistent with the responses in the direction perpendicular to the bridge axis and in the direction of the bridge axis, respectively. The maximum principal strain showed no response until the axles approached, and the response began to appear approximately 0.1 second before the first axle and changed to near 0 immediately after the axles passed, while the minimum principal strain began to gradually appear approximately 0.7 seconds before the axles passed and slowly changed to 0 after the axles passed. From this, it can be inferred that the influence line length is short in the direction perpendicular to the bridge axis and long in the direction of the bridge axis. With respect to the points where the strain response peaks at the passage of the load car, the maximum principal strain shows the largest response at the timing of the passage of the fourth axis, and the minimum principal strain also shows the smallest response at the time of the passage of the fourth axis. Figure 4(b) shows the respective angles of maximum and minimum principal strains on the seaward side of the deck plate shown in Figure 4(a). The angles

(a) Uniaxial strain response and principal strain response



(b) Principal strain angle

Figurer 4. Measurement results of the deck plate on the seaward side.

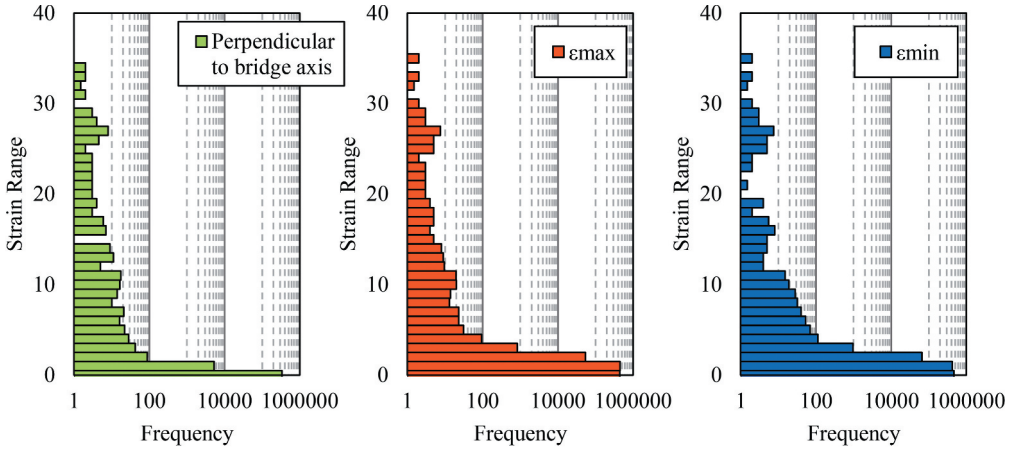


of principal strain at the deck plate are +0° and +180° in the direction perpendicular to the bridge axis and +90° and +270° in the direction along the bridge axis. Figurr 4(b) shows that the direction of the principal strain changes by about 50° before and after the passing of the load vehicle.

3.1.1 *Measurement results of U-rib on seaward side*

Figure 5 shows the maximum and minimum principal strains calculated from the data obtained from the triaxial strain gauges attached to the seaward side of the U-rib, as well as the vertical and axial responses of the bridge. Four sharp responses can be confirmed in Figure 5(a). It is thought that they are due to four axles of test truck. The maximum and minimum principal strain responses were generally consistent with the responses of the third and fourth axes in the vertical direction, but the results were inconsistent for other locations. The response in the bridge axial direction resulted in different strain values for both the maximum and minimum principal strains. The peak values of the maximum and minimum principal strains at the time of vehicle passage were +17.0 μ for the maximum principal strain and -40.0 μ for the minimum principal strain, with the absolute value being larger for the minimum principal strain. Figure 5(b) shows the respective angles of maximum and minimum principal strains of the seaward U-rib shown in Figure 5(a). The angles of principal strain at the U-ribs are +0° and +180° in the vertical direction and +90° and +270° in the bridge axis direction. Figure 5(b) shows that the angle of principal strain changes abruptly by a little less than +180° each time an axle passes through each axis.

(a) Uniaxial strain response and principal strain response



(b) Principal strain angle

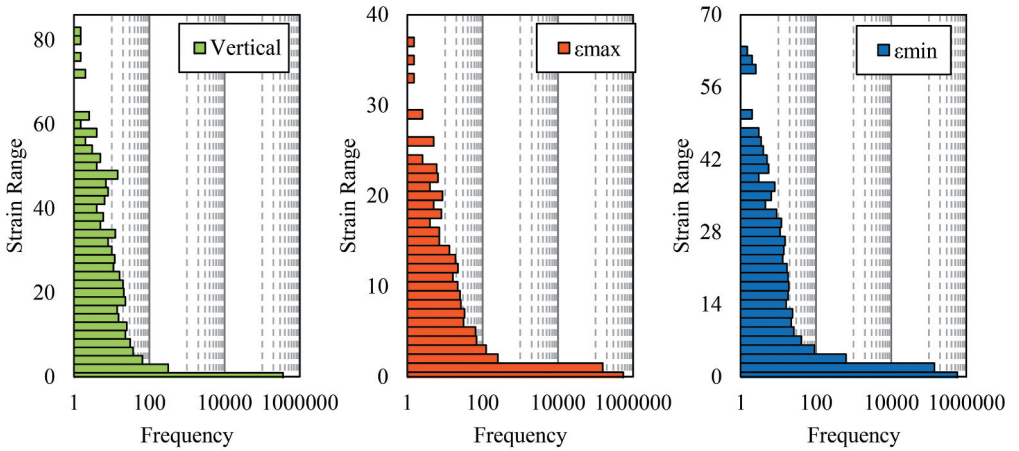


Figure 5. Measurement results of the U-ribs on the seaward side.

3.2 *Rain flow analysis*

Rainflow analysis was performed based on triaxial strain data from less than two hours of measurement testing. In this study, we utilized the Rainflow analysis to focus on the amplitude of strain response on the orthotropic steel deck. The analytical results for the deck plate on the seaward side in the direction perpendicular to the bridge axis, maximum principal strain and minimum principal strain are shown in Figure 6(a), and for the U-rib on the seaward side in the vertical direction, maximum principal strain and minimum principal strain are shown in Figure 6(b). From Figure 6(a), it can be confirmed that the maximum strain range in the direction perpendicular to the bridge axis and the maximum principal strain and minimum principal strain on the seaward side of the deck plate are generally the same. In the deck plate, the direction of the principal strain changes little, so it can be inferred that the results are identical to those obtained in the direction perpendicular to the bridge axis.

(a) Deck plate on the seaward side

(b) U-ribs on the seaward side

Figure 6. Rainflow analysis results.

Figure 6(b) shows that the maximum strain range for the seaward U-rib was 82 μ for the vertical direction, 35 μ for the maximum principal strain, and 63 μ for the minimum principal strain, with the vertical direction having the largest maximum strain range. Unlike the deck plate case described above, the U-ribs show an abrupt change in the angle of principal strain, which may account for the difference in the maximum strain range.

3.3 *Fatigue damage degree*

The fatigue damage degree was calculated using Equation (1) based on the results of the rainflow analysis calculated in 3.2.

$$D = \sum \left(\Delta\sigma_i{}^3 \times N_i\right) \tag{1}$$

D: fatigue damage degree, $\Delta\sigma_i$: strain range, N_i: frequency of $\Delta\sigma_i$. Based on the fatigue damage level, it is possible to evaluate the fatigue environment for active loading. Figure 7 shows the calculated fatigue damage values for the deck plate on the seaward side in the direction perpendicular to the bridge axis, maximum principal strain, and minimum principal strain, and for the U-rib on the seaward side in the vertical direction, maximum principal strain, and minimum principal strain. For the single axis in Figure 7, the results are shown in the direction perpendicular to the bridge axis for the deck plate and in the vertical direction for the U-ribs. Figure 7 shows that the highest fatigue damage degree of maximum principal strain response was obtained for the deck plate, and the highest vertical response was obtained for the U-ribs. Comparisons between the deck plate and U-rib sections showed that the fatigue damage levels differed significantly, with the U-rib vertical values approximately 3.6 times greater than the maximum principal strain of the deck plate.

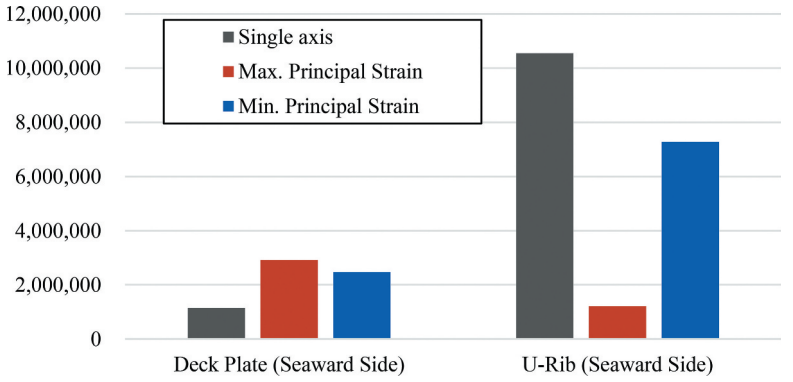

Figure 7. Fatigue damage degree calculation results.

4 CONCLUSIONS AND FUTURE STUDIES

Strain gauges attached to the orthotropic steel deck plate and U-ribs of the steel slab were analyzed for strain response during vehicle passage. The results are shown below.

1. The direction of the maximum principal strain in the deck plate was almost constant under test vehicle traveling.

2. The main strain direction of the U-ribs was not fixed in one direction and changed abruptly.
3. The strain ranges of the deck plates and the U-ribs were significantly different during vehicle passage, with the U-ribs having the largest strain range.
4. In the fatigue damage degree, the result based on the principal strain was not necessarily larger, and the fatigue damage degree of uniaxial was sometimes larger.

In the future, strain measurements will be conducted on slabs with Steel Fiber Reinforced Concrete (SFRC) pavement to verify the effect of strain reduction before and after SFRC pavement.

A study of the effect of skew angle on natural frequencies of bridge girders

M. Satomi, R. Handa, Y. Sugimoto & H. Onishi
Iwate University, Morioka, Japan

ABSTRACT: Vibration test is one of the quantitative inspection methods, but it is expected that the plane geometry of bridges will affect the results of vibration test. In skewed bridges, there are several cases of bearings failing due to girder rotation during earthquakes, and the skew angle may affect the dynamic behavior of the bridge. The authors created bridge specimens to investigate the effect of skew angle on the vibration characteristics of bridges. The skew angle was varied from 60° to 90° in 10° increments to investigate how the natural frequency changes. In addition, the authors performed the FEM analysis to complement the experimental results. Experimental and analytical results show that the primary natural frequencies increase due to the skew angle. And factors such as bearing conditions were also affect the vibration characteristics.

1 INTRODUCTION

In Japan, many of the bridges in service today were built after the high economic growth period, and more than 50% of bridges will be in service for 50 years in 10 years' time. Many of these bridges are managed by local governments, which have small budgets for maintenance and management. In addition, there are some problems such as a shortage of civil engineers engaged in bridge inspections and a decrease in maintenance budgets in local governments (MLIT, 2023). To solve these problems, more simplified inspection and quantitative inspection methods for bridges is required. One of the simple and quantitative inspection methods for bridges is vibration tests. Vibration tests can determine the health of bridges by calculating vibration characteristics such as the natural frequencies of bridges, and many studies have been conducted on bridge damage detections (Chiba et al. 2022, Furukawa et al. 2005, Mimasu et al. 2018). However, further research is needed on the factors that affect natural frequencies. In addition, bridge monitoring systems using FE models and vibration measurements have been studied (Ntotsios et al. 2008, Whelan et al. 2009). Vibration measurements can be performed remotely in real time and are one of the simplified inspections. Therefore, we need to understand the vibration characteristics of each bridge type. We expected that the plane geometry of bridges effects on its vibration characteristics (Watanabe et al. 2014). It is well known that the reaction force becomes non-uniform and torsion occurs in a skewed bridge. Several cases of bearing damage due to girder rotation during earthquakes have been reported, and skew angle is expected to affect the dynamic behavior of bridges (Fujiwara, 2016). However, there are few examples of studies on the effect of skew angle or experiments with varying the skew angle of the specimen, and the degree of effect of skew angle has not been investigated sufficiently. Therefore, in this study, vibration experiments were conducted to investigate the effect of skew angle on vibration characteristics of bridge girders. In these experiments, the skew angle was varied from 60° to 90° in 10°. In addition, the 3D FE model was created based on the experiment specimens, and FEM analysis was performed to study how the natural frequencies change as the skew angle changes. The analysis was performed with an increased pattern of skew angles to examine the trend of change in natural frequencies as change in skew angle in more detail.

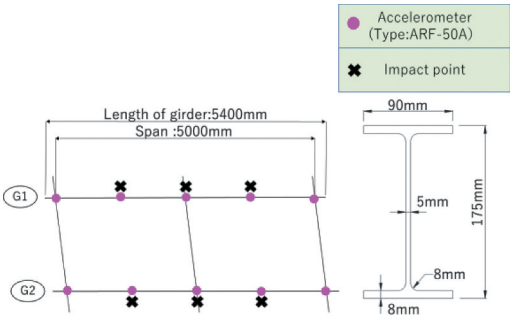

Figure 3. Measuring points of acceleration.

2 OUTLINE OF VIBRATION EXPERIMENT

2.1 *Test specimen*

In this paper, the test specimens were prepared assuming a small-scale bridge with two main girders. The overview of the specimen is shown in Figure 1 and the bearing section is shown in Figure 2. The specimens consisted of two main girders and three cross beams. The main girders were made of H steel of Japanese Industrial Standards (JIS standard) H175×90, with a girder length of 5400 mm and a span of 5000 mm. The cross beams were made of JIS standard Channel steel. The space of main girders was set to 750 mm, 1000 mm and 1250 mm, each with different sectional cross beams. Channel steel with cross sections of C125×65 for 750mm spacing, C150×75 for 1000 mm spacing and C200×80 for 1250 mm spacing was used. The

bearings were made of steel plates and round bar, and Teflon plates were placed between the bearings and the abutment to reproduce "pin-roller" as a bearing condition.

2.2 *Outline of experiment*

In this experiment, the vertical response acceleration was measured by applying vibration to the specimens of bridge girder to calculate the natural frequencies. Four patterns of skew angles of 90°, 80°, 70° and 60° were set as parameters. As another parameter, three patterns of girder spacing were set: 750 mm, 1000 mm and 1250 mm.

The locations of the accelerometers and impact points are shown in Figure 3. The specimens were subjected to vibration using a hammer. Since vibration form will vary depending on the impact positions, impact points were applied at 1/4, 1/2 and 3/4 of the span of each main girder. Response acceleration was measured at a total of 10 points on each main girder: at the bearing points on both sides of the main girder, at a quarter on the span, at the center of the span and at three quarter on the span. Accelerometers were installed on the upper surface of the lower flange of the main girder. Acceleration was measured at a sampling interval of 0.1 millisecond, for a total of 15 seconds (1 second before and 14 seconds immediately after the blow).

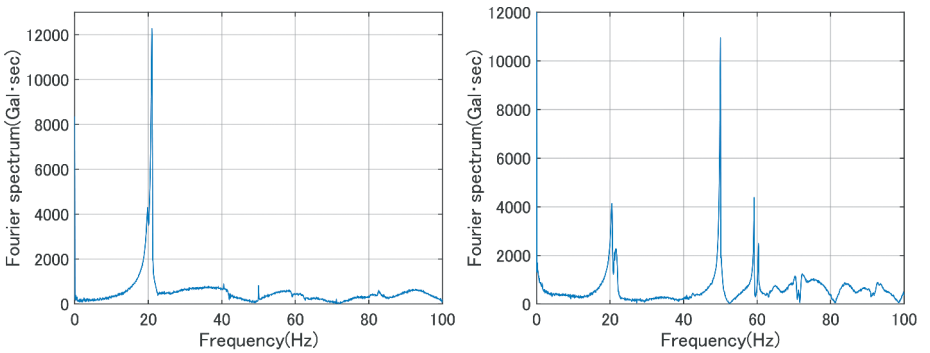

Figure 4. Example of amplitude spectrums.

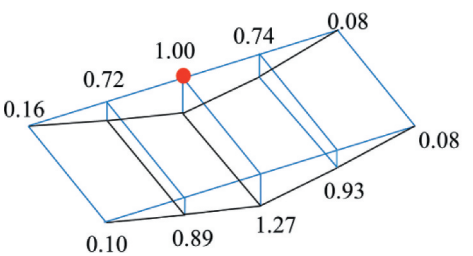

Figure 5. Mode of vibration (around 20 Hz).

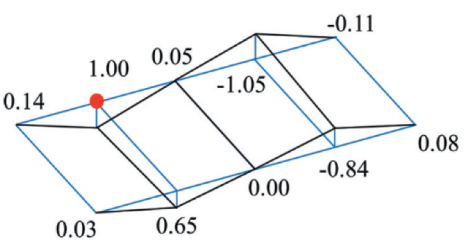

Figure 6. Mode of vibration (around 50 Hz).

3 EXPERIMENTAL RESULTS

3.1 *Comparison of amplitude spectrums*

mplitude spectrums processed the response acceleration data by Fast Fourier Transform (FFT) are shown in Figure 4. The amplitude spectrum when the impact point was the center of the span shows that two dominant frequencies appear around 20 Hz. In the experiment with different skew angles, it was also confirmed that the dominant frequency appeared around 20 Hz. These two dominant frequencies are considered to correspond to the bending and torsional natural frequencies.

The amplitude spectrum when the vibration applied at a quarter of the span shows that the dominant frequency appears around 20 Hz, similar to the result when the vibration applied at the center of the span. In addition, dominant frequencies also appeared around 50 Hz (Right of Figure 4). The similar results were obtained when the skew angle was varied, and when vibration applied at the three quarters of the span. These results show that the dominant frequencies vary depending on the point of the vibration.

3.2 *Vibration mode diagram*

Vibration mode diagrams were drawn to identify which vibration mode corresponds to the dominant frequencies obtained from the FFT.

The vibration mode diagram drawn using the dominant frequency around 20 Hz is shown Figure 5. The vibration mode diagram shows that the dominant frequencies near 20 Hz corresponds to the primary natural frequency. The two dominant frequencies correspond to bending and torsional natural frequencies.

The vibration mode diagram drawn using the dominant frequency around 50 Hz is shown Figure 6. The vibration mode diagram shows that the dominant frequencies at 50 Hz corresponds to the secondary natural frequency. Two natural frequencies, bending and torsional, were obtained as well as the primary natural frequencies.

3.3 *Natural frequencies*

The natural frequencies are summarized in Tables 1-3.

Table 1. Each natural frequency (Space of main girders:750 mm).

	Natural frequency (Hz)			
Skew angle	Bending primary	Torsional primary	Bending secondary	Torsional secondary
90°	20.14	21.13	49.90	-
80°	20.56	21.74	49.74	50.05
70°	20.68	21.44	49.94	49.98
60°	20.33	21.37	49.82	50.13

*Hyphen (-) means natural frequency could not be detected.

Table 2. Each natural frequency (Space of main girders:1000 mm).

	Natural frequency (Hz)			
Skew angle	Bending primary	Torsional primary	Bending secondary	Torsional secondary
90°	19.00	21.25	50.03	-
80°	19.91	21.21	49.74	50.05
70°	20.03	21.33	49.97	50.05
60°	19.61	20.37	49.82	49.74

Table 3. Each natural frequency (Space of main girders:1250 mm).

Skew angle	Natural frequency (Hz) Bending primary	Torsional primary	Bending secondary	Torsional secondary
90°	18.24	20.79	49.82	50.05
80°	18.88	20.98	49.82	49.74
70°	18.85	20.90	49.99	50.05
60°	18.77	21.21	49.94	50.17

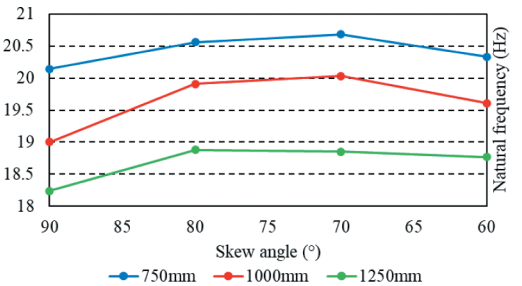

Figure 7. Bending primary natural frequency by space of main girders.

The natural frequencies vary by changing the skew angle on all patterns. For the bending primary natural frequencies, the other natural frequencies (the case of 80°, 70° and 60°) are larger than natural frequency at skew angle of 90°. Therefore, the bending primary natural frequency is larger in a skewed bridge than in a straight bridge. And while there is a slight variation between bending and torsion at the primary natural frequencies, there is minimal disparity at the secondary natural frequencies. The primary bending frequencies are consistently smaller than the primary torsion frequencies, but there is no consistent relationship at the secondary natural frequencies. For these results, the bending and torsional natural frequencies exist in a narrow range at the secondary natural frequencies and difficult to decompose.

Table 4. Comparison of experimental and theoretical values.

	Bending primary natural frequency (Hz)	Difference from theoretical value (%)
Theoretical value (pin-roller)	23.25	-
Measured value (750 mm)	20.14	-13.4
Measured value (1000 mm)	19.00	-18.3
Measured value (1250 mm)	18.24	-21.6

Table 5. Physical Properties Used In The Analysis.

Item	Physical property value
Poisson's ratio	0.3
Young's modulus (N/mm^2)	2.05×10^5
Density (ton/mm^3)	7.85×10^{-9}

The bending primary natural frequency for each girder spacing are shown in Figure 7. In terms of the difference in the girder spacing, the bending primary natural frequencies become smaller when the girder spacing is increased. The natural frequencies tend to decrease with

increasing girder spacing even when skew angle decreases. The bending primary natural frequencies tend to increase as skew angle decreases, but this is not the case for skew angle 60°.

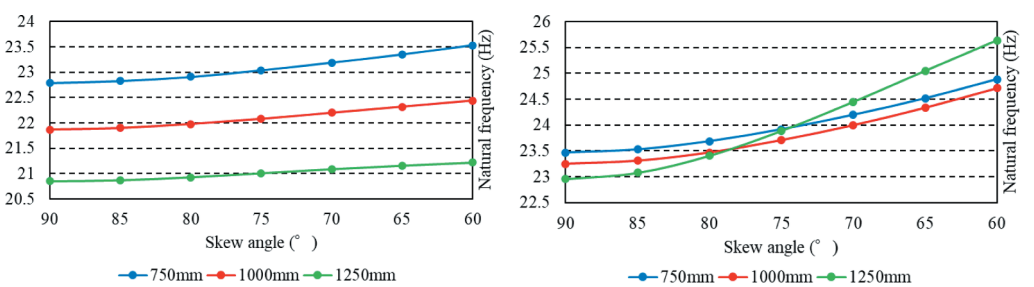
3.4 *Comparison with theoretical values*

The natural frequencies obtained from this experiment are compared with the theoretical values to evaluate the accuracy of the experiment. Based on previous studies, it is considered that the fundamental bending natural frequencies of two-girder bridges with two main girders can be obtained from the analytical solution for simply supported beams, and equation (1) is used to calculate the bending primary natural frequencies of the specimens (Yoneda et al. 2006).

$$f_\eta = \frac{1}{2\pi}\left(\frac{\pi}{L}\right)^2 \sqrt{\frac{E_S I_{SZ}}{w/g}} = \frac{1}{2\pi}\left(\frac{\pi}{L}\right)^2 \sqrt{E_S I_{SZ}} \tag{1}$$

where f_η = fundamental bending natural frequency; L = maximum span; E_s = Young's modulus of steel; I_{sz} = moment of inertia about the centroid axis of the section converted to steel; m = mass per unit length.

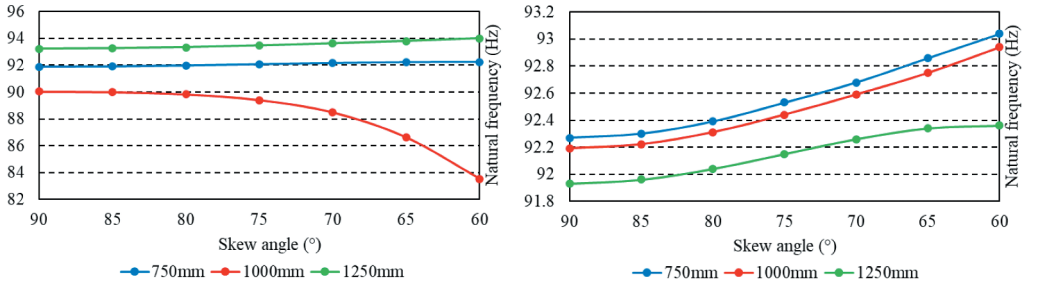
The theoretical value of the bending primary natural frequency was calculated to be 23.35 Hz. Compared to the measured values of the bending primary natural frequencies for each girder spacing, a difference of 13.4% was observed even for the girder spacing of 750 mm, which has the smallest difference. One of the reasons for this difference from the theoretical value is that the restraint of the bearing was not sufficient. In this experiment, the bearings and the abutment were not fixed, and the bearings may lift when vibration applied to the specimen.



4 FEM ANALYSIS

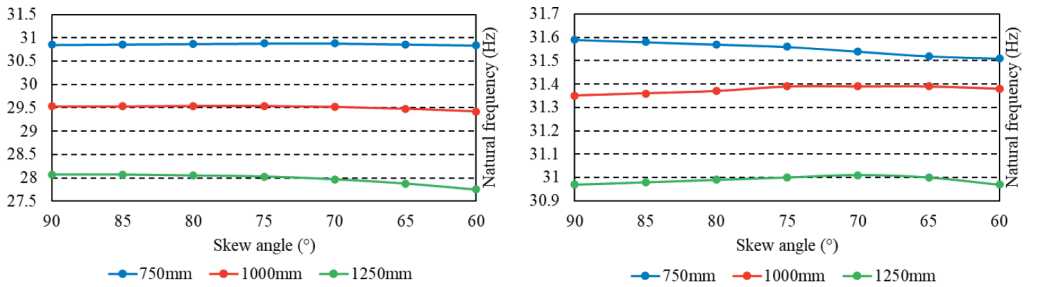
4.1 *Outline of analysis*

FEM analyses were conducted to examine the effect of bearing conditions and skew angle in more detail. 3D FE models were created by shell elements based on the experimental specimen. The steel physical properties used in the analysis are shown in the Table 5. Two type of bearing conditions were considered: "pin-roller" and "pin-pin". We also attempted to reproduce the bearing conditions in the experiment by introducing spring elements in the bearing and the stiffness of the spring was varied. Skew angle was varied from 60° to 90° in 5° increments in the analysis to examine the effect of skew angle in detail.



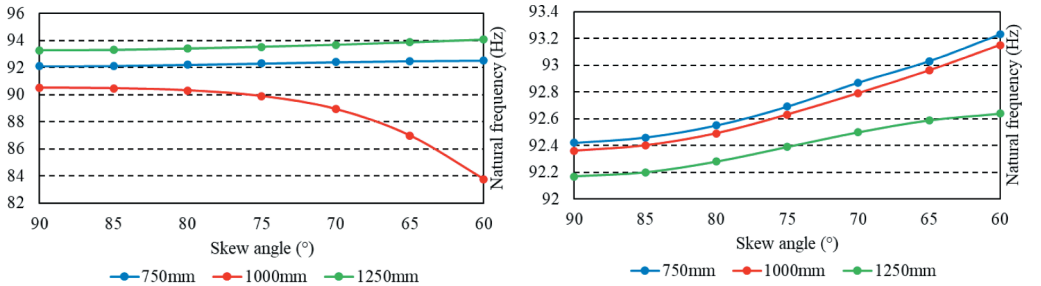
4.2 *Analysis results*

The results of the analysis are shown in the Figures 8-11. In term of the bending primary natural frequencies, when the bearing condition was "pin-roller", the natural frequencies vary with skew angle. In addition, the bending primary natural frequencies increased as the skew angle decreased. The torsional primary natural frequency also tends to increase with decreasing skew angle. A comparison of the bending primary natural frequency and torsional primary



(a) Bending primary natural frequency. (b) Torsional primary natural frequency.

Figure 8. Primary natural frequencies by girder spacing (bearing condition: pin-roller).

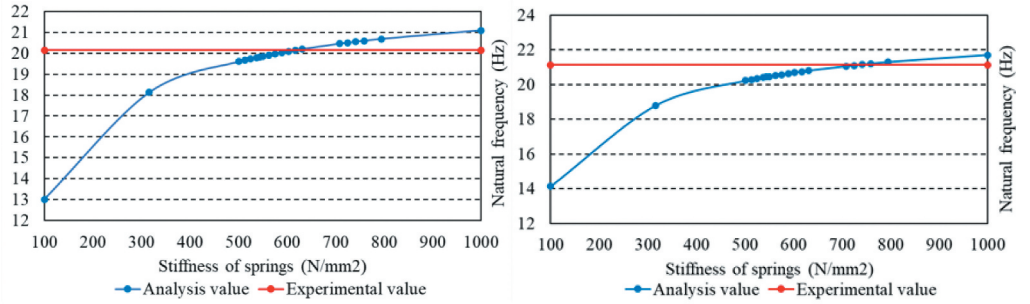


(a) Bending secondary natural frequency. (b) Torsional secondary natural frequency.

Figure 9. Secondary natural frequencies by girder spacing (bearing condition: pin-roller).

(a) Bending primary natural frequency. (b) Torsional primary natural frequency.

Figure 10. Primary natural frequencies by girder spacing (bearing condition: pin-pin).



(a) Bending secondary natural frequency. (b) Torsional secondary natural frequency.

Figure 11. Secondary natural frequencies by girder spacing (bearing condition: pin-pin).

natural frequency shows that the torsional primary natural frequency is more affected by skew angle. This trend is also observed for the secondary natural frequencies. These results show that torsional natural frequency is more affected by skew angle than the bending natural frequency. This can be attributed to the torsional behavior observed in skewed bridge. When the bearing condition was "pin-pin", the primary natural frequencies show almost no change in natural frequencies with the change in the skew angle. In the secondary natural frequency, the degree of effect of skew angle doesn't change as the bearing conditions change. These results show that the degree of effect of skew angle changes as the bearing conditions change at the primary natural frequency.

Focusing on the difference in girder spacing, the bending primary natural frequency tends to decrease as the girder spacing increases, similar to the experimental results. One of the reasons for this trend is the use of cross beam of different sections for each girder spacing. It is possible that the difference in the weight of the bridge girders due to the different sections affects the change in the natural frequency.

(a) Bending primary natural frequency. (b) Torsional primary natural frequency.

Figure 12. An example of comparison of analytical and experimental values when spring stiffness is varied.

4.3 *Reproduction of bearing conditions*

In chapter 3, we considered that the difference between the theoretical and experimental values was caused by the poor reproducibility of the bearing conditions. In order to improve the reproducibility of the bearing conditions, we attempted to reproduce the bearing conditions in the experiment. Since it was expected that the vertical restraint was not sufficient during the experiment, we introduce spring elements in the vertical direction and analyzed.

Figure 12 Shows an example of comparison between analytical and experimental values when spring elements is introduced, and the spring stiffness is varied. The results of the analysis showed that the introduction of vertical spring elements resulted in analytical value that were close to the experimental values. By varying the stiffness of the spring elements, the analytical values were close to the experimental values at all natural frequencies. However, at each natural frequency, the spring stiffness at which the experimental and analytical values were close is different. For this result, it is considered that introducing the spring elements not only in vertical direction but also in other direction is necessary to fully reproduce the bearing conditions. The results of these analyses show that the accuracy of the experiments can be improved by ensuring sufficient vertical restraint.

5 CONCLUSION

In this study, vibration tests and analysis were conducted to investigate the effect of skew angle on the vibration characteristics of bridge girders. The following findings were obtained from the results.

1) In the vibration test, the natural frequencies differed depending on the impact point because the vibration form of the structure differs depending on the impact point.
2) The natural frequencies of bridge girders were affected by the skew angle. FEM analysis showed that the primary natural frequencies tend to increase with decreasing skew angle and torsional natural frequency is more sensitive to skew angle than bending natural frequency.
3) In primary natural frequencies, the degree of effect of the skew angle on the natural frequencies of the bridge girders varied depending on the bearing conditions. In the "pin-pin", there was little change in the natural frequencies due to changes in the skew angle. On the other hand, for the secondary natural frequencies, the degree of effect of skew angle doesn't change regardless of the bearing conditions.
4) The sectional shape of the cross beam and the girder spacing also affect the natural frequencies because these effects are attributed to the changes in mass of bridge girders.
5) In FEM, introducing spring elements in the bearing section reproduces the actual bearing condition. By introducing spring elements in various directions, it is possible to completely reproduce the actual bearing condition.

In the future, reproducibility of bearing conditions in experiments needs to be improved. In addition, it is necessary to investigate vibration characteristics not only of the bridge girders but also of the girders combined with the deck slab through experiments and FEM.

ACKNOWLEDGEMENT

ABSTRACT: In some environments where the amount of road salts or airborne sea salt particles are relatively high, weathering steels can be corroded remarkably. Under such conditions, weathering steel is unable to form its protective layer of rust, necessitating additional protective measures such as painting. Before repainting weathering steel, it is essential to completely remove not only the protective layer of rust but also any corrosion products. These corrosion products are physically very hard, necessitating chipping before abrasive blasting. However, a single blast treatment is often insufficient to completely remove the corrosion products, requiring multiple repetitions. Despite this, it can be challenging to fully remove chlorides remaining in deeply corroded areas. Such residual chlorides often cause localized corrosion under the coating. Abrasive water-jet treatment (AWT) has been developed as a new method for preparation of weathering steel surface. Abrasive waterjet is one of the cutting technology for cutting harder materials, which has been developed in the 1980s. AWT can remove rust layer containing corrosion easily with the ultra-high pressure water of Mach 2 and abrasive materials. Additionally, during AWT process, the water temperature rises, which effectively helps wash away residual substances containing chlorides. Due to these merits, AWT is superior to conventional surface treatment methods in terms of the removal of thick rust as well as the cleaning of surface residues. In this study, AWT was applied to an actual corroded bridge where it located in Japan, and it was verified the efficiency of removing corrosion products and chlorides. The results demonstrated that both the corrosion products and residual surface chlorides were completely removed in a very short period of time.

1 INTRODUCTION

In the low corrosive environments, weathering steels form protective rust layers on its surface, so that the progress of corrosion can be suppressed. However, in some environments where the amount of road salts or air borne sea salt particles are relatively high, weathering steel can be corroded remarkably as shown in the Figure 1.

In cases where the weathering steel is unable to form protective rust layer, it becomes necessary to promptly repaint the steel surface. Because it is usually difficult to improve the corrosive environment at the crosslinking point due to spraying road salts or air-borne sea salt particles.

Before repainting weathering steel, it is essential to completely remove not only the protective layer of rust but also any corrosion products. These corrosion products are physically very

DOI: 10.1201/9781003483755-254

hard, necessitating chipping before abrasive blasting. After that, blasting and water washing should be repeated several times to remove corrosion products and chloride until the amount of chloride that is remaining on its steel surface is less than the Japanese standard requirement of 50 mg/m^2.

However, the chloride remaining the bottom of the corrosion pit can't be removed completely. So, those chloride that is remained on the steel surface often causes local corrosions under the painting. To improve these problems, Abrasive water-jet treatment (AWT) has been developed as a breakthrough method for preparation of weathering steel surface. This paper reports the results of field application of the AWT method on a heavily corroded weathering steel bridge.

Figure 1. Severe corrosion of weathering steel bridge.

2 AWT METHOD

Figure 2 illustrates the effectiveness of the AWT method in removing corrosion products and chlorides from steel surfaces. This is achieved by using a water-jet stream at pressures above 200 MPa, containing hard abrasive particles. This method was developed utilizing the principles of the existing material cutting technique, Abrasive waterjet technology. Additionally, the adaptability of AWT for surface treatment under various operational conditions, such as nozzle types, pressure, and standoff distance, has been demonstrated through the author's prior research. The prior research shows that the maximum erosion depth varies depending on factors such as the type of nozzle, the size of the abrasive, and the standoff distance. Additionally, it is indicated that the AWT-treated specimens exhibit higher maximum erosion depth than the blasted specimens in case of the AWT process using 80 mesh garnet and divergent nozzle at a same standoff distance 100mm. However, the amount of thickness reduction is several tens of micrometers than the blasted specimens. By applying the AWT method to severely corroded steels, the high-pressure water fluid is penetrated into the cracks in the corrosion materials, the corrosion materials can be easily peeled off and removed. Besides, the fluid reaches the bottom of the tiny corrosion pit deeply so that almost all chlorides that are remained on the steel surface can be remove completely. AWT can remove rust layer containing corrosion easily with the ultra-high pressure water of Mach 2 and abrasive materials. Additionally, during AWT process, the water temperature rises, which effectively helps wash away residual substances containing chlorides. Due to these merits, AWT is superior to conventional surface treatment methods in terms of the removal of thick rust as well as the cleaning of surface residues. Therefore, the effect of corrosion materials and chlorides removal is drastically high so that AWT effectively removes hard rust layers and chlorides within a single treatment to achieve the desired coating surface conditions above Sa2 1/2 and surface salinity below the Japanese standard requirement of 50 mg/m^2. Therefore, the ATW method is expected to be one of the economic methods that can reduce to one process compared with traditional blasting, which requires multiple repetitive processes to remove corrosion products and chloride. Besides, consumption of abrasive materials is curtailed to a quarter of that required for abrasive blasting, which drastically reduces the abrasive waste and makes this methodology significantly more environmentally compatible.

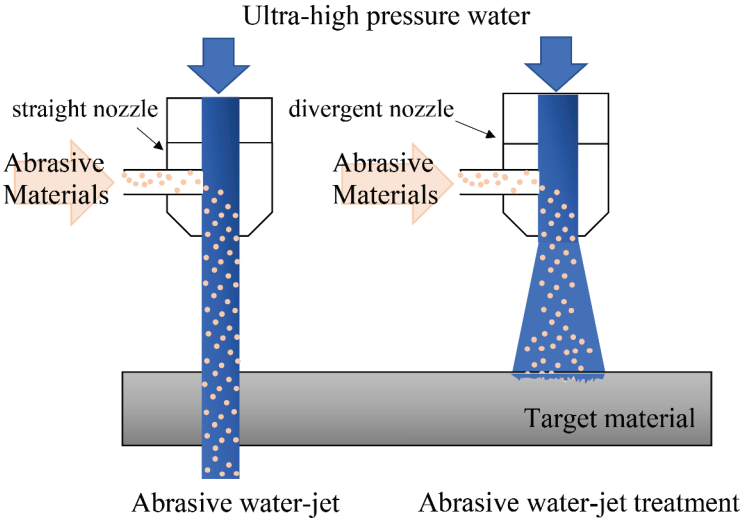

Figure 2. Overview of the AWT method.

3 FIELD TRIAL

3.1 *Outline*

In this study, the AWT method was applied to a severely corroded weathering steel bridge to assess its viability. This application demonstrated the AWT method's efficacy in eliminating corrosion products and chlorides from the structure. The bridge chosen for this test is a three-span continuous steel truss structure, built in 2001, and made of unpainted weathering steel. The bridge is located approximately 5km from the coastline and is affected by the sea breeze in Kagoshima - Japan, as shown in Figures 3 and 4.

The construction site is located more than 3km from the coastline (coastal coast of the Pacific Ocean) 2km, which can be applied to the non -painted weathering steel bridge, but the target bridge has been exposed air-borne sea salt particles amount of 0.09 to 0.97 MDD (dry gauze method: JIS Z 2382).

As a result, the effect of chlorides removal due to rainfall is hardly working because chlorides have always been supplied. Besides the bridge has been severely corroded owing to exposure to the moist environment (17°C, 75%RH). Therefore, severe corrosions have occurred in some parts of the bridge where are in wet situations in long times.

Figure 3. Bridge overview.

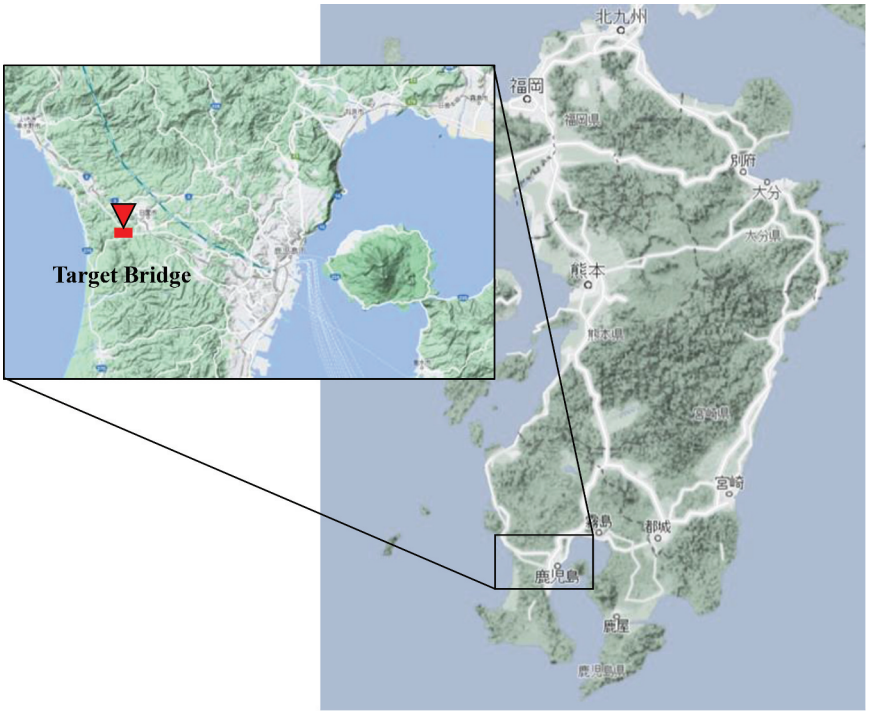

Figure 4. Bridge location.

3.2 *Trial method*

In this test, to verify the removal effects of corrosion products and chlorides in the severely corrosion areas using the AWT method, one of the diagonal member of truss bridge (19cm x 50cm) has been targeted.

The AWT method was applied to the target area until the severe corrosion could not be visually confirmed (about 120sec). As test condition, AWT was conducted with 80 mesh garnet, and standoff distance of 300mm. The detail test condition are shown in Table 1.

To confirm the corrosion removal efficiency of the AWT process, the method of measuring the amount of salt on the treated surface was conducted. Surface-soluble salts were measured using the Bresle patch test. The Bresle patch test was performed over a square patch of 1,250 mm^2 area in accordance with the ISO 8502-6 test method.

Table 1. AWT processing parameters.

Specimen	Nozzle type	Nozzle Diameter(mm)	Abrassive Materials	Stand-off Distance(mm)	Abrasive Supply	Pressure (MPa)	Water flow
AWT#80	AWT nozzle (Divergent)	5	Garnet #80	300	600	230	11.9

4 RESULTS OF FIELD TRIAL

Figure 5 shows the change in appearance of the treated surface after AWT process. Rust was observed before AWT, but immediately after AWT, the metallic color of the steel substrate can be observed on the entire surface. Consequently, it is apparent from visual examination

that the rust was removed entirely. Furthermore, the surface condition achieved the Sa2 1/2 level, which is optimal for quality before any coating or painting. Following the application of AWT, the quantity of salt residue on the treated surface was determined using the Bresle method, revealing values between 0 to 5mg/m^2. This is considerably below the standard threshold of 50mg/m^2. To further verify the chloride removal efficacy of the AWT method, the occurrence of flash rust was monitored over 96 hours after the treatment.

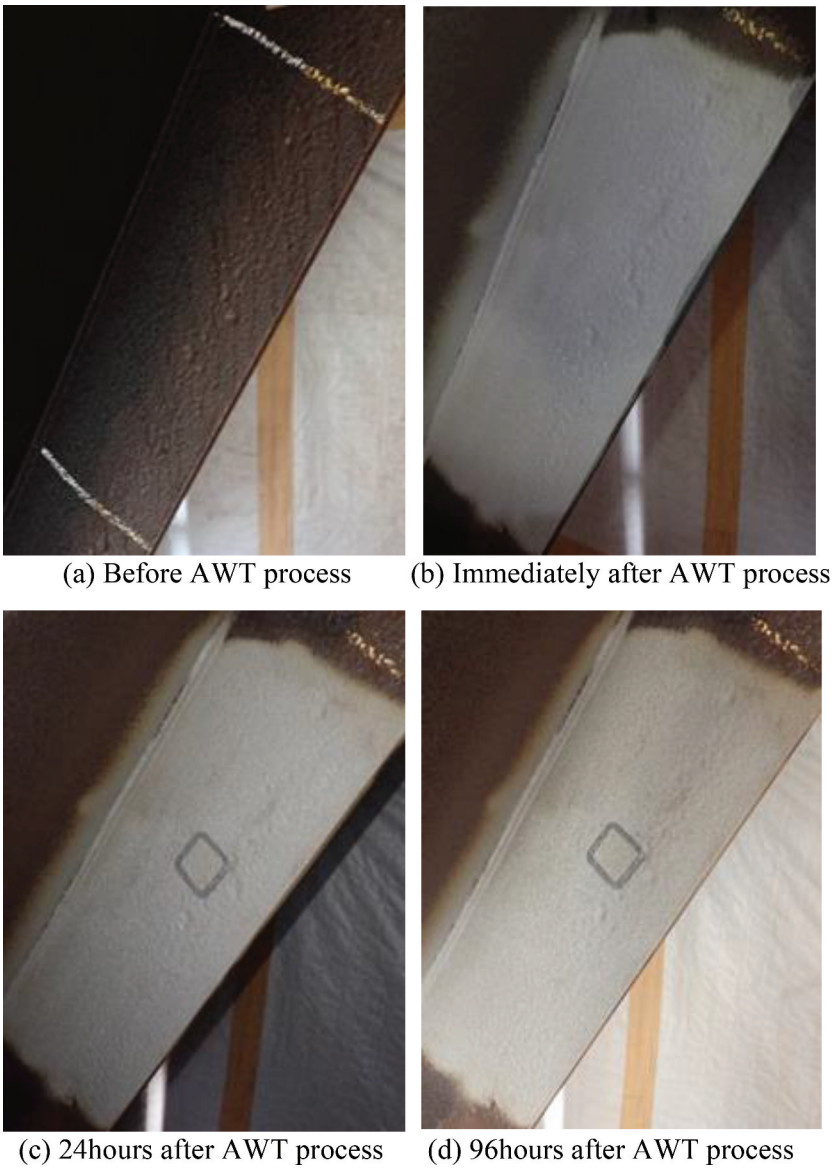

Figure 5. Surface condition after AWT process.

Figure 6 shows the pitting corrosion area that appeared on the steel substrate after the AWT process. Since corrosion products remain in deeply corroded areas, so that abrasive blasting is needed several times. On the other hand, in the case of the AWT method, it was confirmed that the pitting corrosion can be sufficiently removed in a single process.

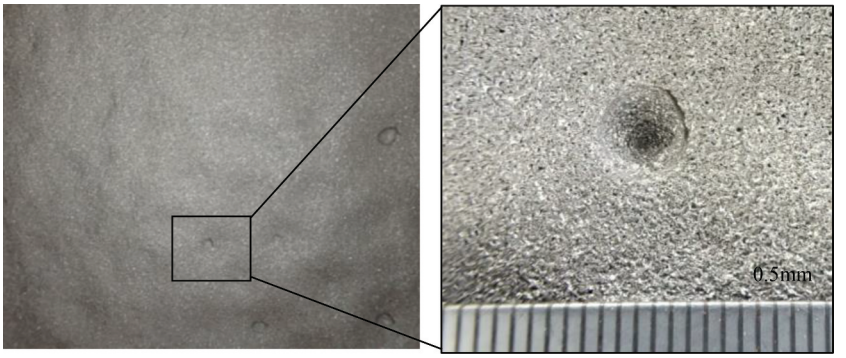

Figure 6. Surface condition after the AWT process.

5 CONCLUSIONS

The following are the main findings from tests of the AWT method's effectiveness in removing salt and rust from uncoated weathering steel bridges severely corroded by flying sea salt.

1) AWT method can achieve steel surface condition to Sa 2 1/2 level in a single process for severely corroded areas of weathering steel due to salt damage.
2) AWT method is effective in removing rust and chloride when applied to the severely corroded surface of weathering steel members.
3) The amount of chloride on the treated surface of heavily corroded weathering steel can be reduced to 0 to 5mg/m^2.

Analytical study on stress concentration zone of aseismic reinforced deck type arch bridge

M.O. Ouchi, T.S. Suzuki & H.S. Shirahata
Structural Safety Laboratory, Tamazutsumi, Setagaya-ku, Tokyo, Japan

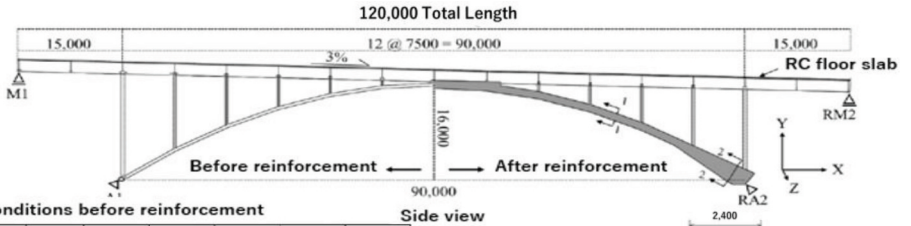
ABSTRACT: Number of bridges used long periods in Japan has increased and some damages for their members caused to heavy transportation become apparent. Therefore, design methods of bridges have often revised for lifetime improvement. However, there are some cases that a bridge constructed before the change need a reinforcement to adapt the new criterion. In this study, take up a deck type steel arch bridge and reveal its fatigue performance, furthermore, the effect and influence for fatigue of aseismic reinforcement that method is Strengthening the Arch rib using Concrete jacket by finite element analysis. As a result, the post member that connects an arch rib and a stiffening girder tends to occur fatigue damages, especially the shortest post is weakest member of the arch bridge. And the reinforcement produces an effect that reduces a displacement of whole structure or stress.

1 INTRODUCTION

In Japan, the number of bridges often older than 50 years is increasing every year. During their long service life, damage to members caused by strong earthquakes and fatigue damage caused by heavy traffic are becoming more and more significant. Although design methods for road bridges have been revised in response to this experience, it is necessary to consider the introduction of reinforcement measures for bridges constructed prior to the changes.

In this study, we focused on arch bridges, especially deck type steel arch bridge, for which fatigue damage is rarely reported. Deck type steel arch bridge in this study were constructed 50 years ago and were reinforced with reinforced concrete wrapped around the arch ribs to increase their stiffness, which is almost unprecedented in the past. (Kakimoto, 1998) The arch ribs, which are the main members of the bridge, were thickened by this reinforcement, and although there is no structural change in the floor assembly, the bridge as a whole has undergone a significant change. In this study, a deck type steel arch bridge is picked up and its fatigue performance is evaluated, furthermore, the effect and influence for fatigue of aseismic reinforcement that method is Strengthening the Arch rib using Concrete jacket by finite element analysis.

2 TARGET DECK TYPE STEEL ARCH BRIDGE AND ANALYSIS MODEL



2.1 *Outline of the subject arch bridge*

The deck type steel arch bridge under study was put into service when the Tomei Expressway was opened to traffic in 1969 and is classified as a Class B Road bridge. The structural outline of the bridge is shown in Figure 1, and the cross-sectional dimensions of the reinforced concrete reinforcing are the same as those used in actual construction cases.

DOI: 10.1201/9781003483755-255

2.2 *Outline of analysis model*

ABAQUS CAE/6.13 (Dassault Systemes, 2013) was used in the general-purpose finite element analysis. Shell elements were used for the steel members, and solid elements were used for the RC slab and the concrete reinforced section after reinforcement. The material constants given to these elements are shown in Table 1. The unit weight of steel was increased by a factor of 1.2 to account for the weight of bolts and reinforcement materials, which were omitted in the modeling. In the analysis considering material nonlinearity, bilinear stress-strain curves were used for the steel, and the constitutive law in the specifications for highway bridges was used for the concrete. In the seismic analysis, dynamic analysis was performed considering material and geometric nonlinearity, and linear static analysis was performed for the analysis with vehicle loads to investigate the weakness in fatigue.

3 ANALYSIS PROCEDURE AND RESULTS

3.1 *Analysis procedure*

The seismic waveforms used in the analysis were the waveforms of the 1968 Hyuga-nada earthquake for the L1 seismic motion and the 1995 Hyogo-ken Nanbu earthquake for the L2 seismic motion, both of which are for Class II ground. Seismic acceleration was input in the direction perpendicular to the bridge axis. In addition, only the dead load was considered for the loading condition.

3.2 *Evaluation method of the results*

Stress-strain (s-s) curves of the members were developed from the results, and the evaluation was based on the plasticization of the members. Since the effect of plasticization of main

members such as arch ribs on the entire bridge have not yet been clarified, plasticization of the main members is not considered as damage that is not easily repairable. In contrast, plasticization of secondary members such as lower transverse structures and tilted structures was allowed because they are relatively easy to repair.

The deck type steel arch bridges are classified as Class B bridges and must have a seismic performance2 against L2 earthquakes. Table 2 shows the definition of seismic performance in Japan. Based on this definition, we evaluated whether the bridge satisfies the required seismic performance against earthquakes based on the plasticization of the members.

3.3 *Analysis results*

3.3.1 *Results before reinforcement*

Figure 2 shows the S-S curves of the deck type steel arch bridge before reinforcement for the L2 earthquake, where the members of interest are the arch-rib joints and transverse supports, the arch-rib base, and the end-column base. None of the members did not plasticize during the L1 earthquake, and the results satisfied the requirements for seismic performance1.

In the L2 earthquake, all the arch ribs plasticized beyond the yield points indicated by the red dotted lines. The end columns, which are also primary members, did not plasticize. In addition, out-of-plane deformation occurred in the lower horizontal structure, which is a secondary member, and plasticization occurred. In the above results, it was judged that the subject arch bridge did not meet the required seismic performance2 due to the plasticization of the arch ribs, which were the main members.

3.3.2 *Results after reinforcement*

For the L2 earthquake, the reinforcement eliminated plasticization in the main members. However, plastic deformation was observed in a larger number of secondary members than before the reinforcement. However, as described in the previous section, this change is not problematic because the secondary members can be easily repaired.

The reinforcement was found to be effective in increasing the stiffness of the bridge as a whole, since plastic deformation of the main members no longer occurred, and in satisfying Seismic Performance 2, since the secondary members were able to absorb more seismic energy.

Table 2. Seismic performance specified in the specifications for highway bridges V in Japan.

Seismic Performance of bridges	Safety in seismic design	Seimic design serviceability	Seismic Design short term	Restorability long term
Performance of Bridges 1 Performance that does not soundness the integrity of the bridge due to earthquakes	Ensure safety against falling bridges	Ensure that the bridge functions as it did before theearthquake	Does not require restoration to restorefunctionality	Minor restoration is sufficient
Performance of Bridges 2 Performance that damages due to earthquakes are limited and that theearthquakes are limited and that thebridge can quickly recover its function	Ensure safety against falling bridges	Able to quickly recover its function as a bridge after an earthquake	Restoration to restore functionality can be handled by emergency restoration	Permanent restoration is relatively easy
Performance of Bridges 3 Performance that seismic damage is not fatal to the bridge	Ensure safety against falling bridges	——	——	——

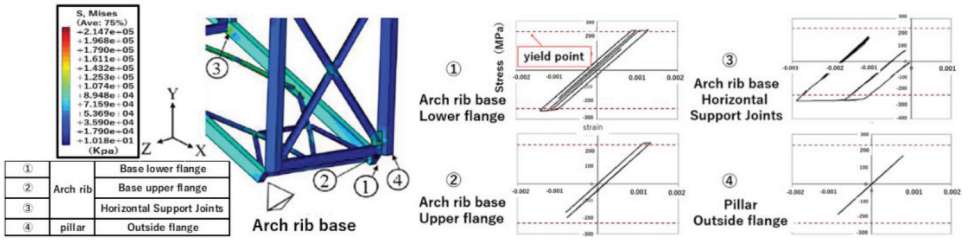

Figure 2. S-S curve for L2 seismic response of main member before reinforcement.

4 FATIGUE PERFORMANCE OF DECK TYPE STEEL ARCH BRIDGESWATASHIFECT OF REINFORCEMENT

4.1 *Analysis procedure*

Linear static analysis was conducted on the members which are expected to be subjected to fatigue damage by applying vehicle loads assuming heavy trucks, and the fatigue performance was evaluated from the stress and deformation behavior of the members. Three types of members were considered: ① vertical members, for which fatigue damage has already been reported; ② joints between stiffening girders and transverse girders; and ③ intersections between longitudinal girders and transverse girders, for which fatigue damage has frequently occurred, as shown in Figure 3. In order to clarify the differences in member length and location within the bridge, the area including the shortest vertical member adjacent to the arch crown was designated Part 1, and the area adjacent to it was designated Part 2.

In order to analyze these members with high accuracy, a method called zooming analysis (sub-modeling analysis) was used. The procedure of this analysis method is shown in Figure 3. The advantage of this method is that the same behavior can be reproduced, and accurate results can be obtained by performing the analysis on the overall model and then inputting the results of the overall model as boundary conditions to a sub model with a smaller element size that is cut from the model. In this study, static analysis was first performed on the entire arch bridge model with vehicle loads input, and then the sub models were used as the partial model and the detailed model in two stages. Three models of the focus member were created for each of Part 1 and Part 2, for a total of six models in the analysis. The same procedure was also used for the post-reinforcement model.

In the static analysis of the overall model, the load assuming a 3-axle 25-ton truck shown in Figure 4 was used in reference to the T-load specified in the specifications for highway bridges. However, due to the loading range, the load was equally distributed 20 tons to the four rear 2-axle wheels, or four loading surfaces (200 mm x 500 mm), where the load ratio is considered to be large.

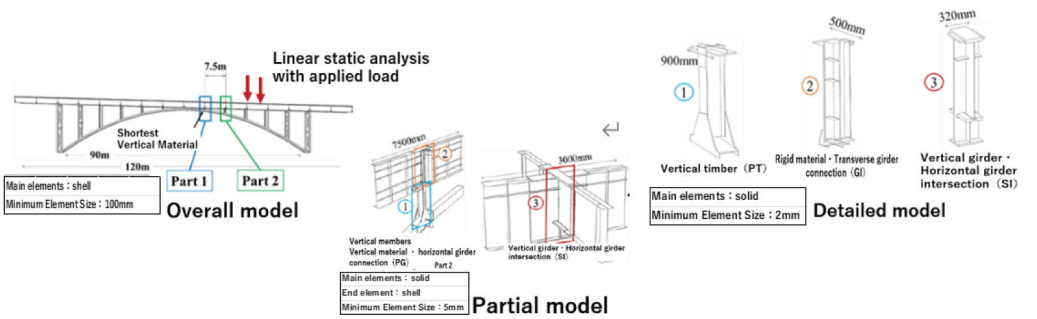

Figure 3. Zooming analysis procedure.

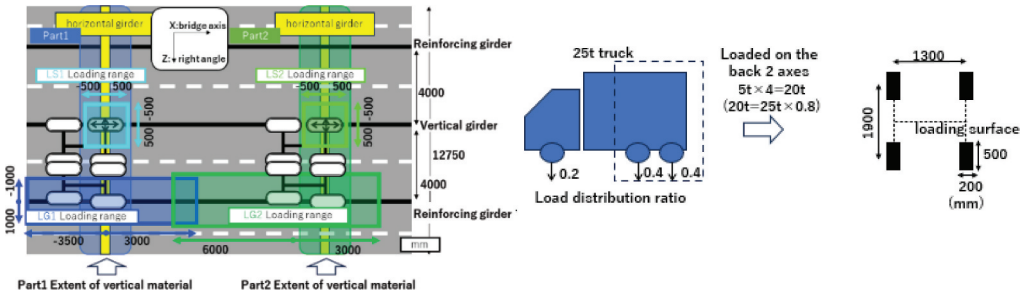

Figure 4. Load placement and travel range.

4.2 *Evaluation method of analysis results*

4.2.1 *Methods using stress influence surfaces*

The analysis was conducted by shifting the load, and the influence surface was created from the principal stresses obtained from the analysis. The load transfer was centered on the joints of the stiffening girders, longitudinal girders and transverse girders as shown in Figure 4, and the load at the joints of the transverse girders and longitudinal girders in the range including the Part1 vertical members is called LS1. Similarly, the load at the connection between the stiffening girder and the transverse girder in the area including the Part 1 vertical members is called LG1. The bridge axis direction is the X-axis, and the perpendicular direction of the bridge axis is the Z-axis, and the center of the joint is (0,0). The loads were shifted in the bridge axis direction and perpendicular direction by ±100 mm when focusing on the intersection of the vertical and transverse girders and by ±500 mm when focusing on vertical members and the joint between the stiffening girders and transverse girders. In the same way, the loads LS2 and LG2 were also shifted within the range including the Part2 vertical members.

4.2.2 *Method using hot spot stress*

When a fatigue crack initiates at a weld stop, the stress is maximum at the weld stop, but the stress at the stop is affected by the shape of the stop, so we used hot spot stress extrapolated from the base metal (hereinafter referred to as HSS), a method to evaluate the stress at the stop, which is affected by the shape of the stop. The HSS is calculated by extrapolating the stress from the reference point, which is located at a distance from the hot spot, using the weld stop as the hot spot. (Hobbacher, 2016)

The HSS was calculated from the analysis results of the load cases that showed the maximum and minimum values in the stress influence plane, and the difference was used as the stress range for fatigue verification by comparing it with the breakout limit of the constant amplitude stress of the welded joint. In the verification using HSS, the type of joints shall be either load-non-transmissive or load-transmissive cruciform welded joints, and the strength classes are E and F, respectively.

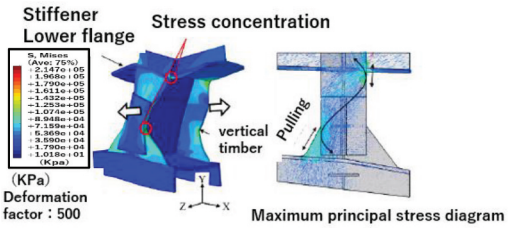
4.3 *Analysis results*

4.3.1 *Vertical members*

Figure 5 shows the deformation diagram of the Part 1 vertical material before reinforcement. The loading position is (X, Z) = (0,0) at LG1. The maximum principal stress diagram shows that secondary bending occurs in the vertical material. The out-of-plane deformation occurs at the vertical flange, and stress concentrations are observed at the bottom edge of the vertical member and at the welds between the vertical flange and the bottom flange of the stiffening girder. Since the stiffening girders and vertical members are welded, the HSS was calculated at this location. The results are shown in Figure 6. The stress range of the hotspots exceeding the

breakout limit indicates that fatigue cracks may occur at the welds of the vertical flanges. Since the Part 1 vertical members were completely wrapped around the concrete by the reinforcement, the HSS evaluation after the reinforcement is omitted because a comparison before and after the reinforcement is not possible.

The deformation of the vertical members in Part 2 was similar to that in Part 1, but the out-of-plane deformation of the vertical flange was different from that in Part 1. The stresses also tended to increase when the load moved to the arch crown side, i.e., to the adjacent Part 1 vertical member, and it was found that there was no difference depending on the member length. As shown in Figure 7, the displacement of the upper and lower edges of the reinforced Part 2 vertical members was smaller, and the secondary bending deformation was also slightly mitigated. However, there was no change in the out-of-plane deformation behavior of the vertical flange.



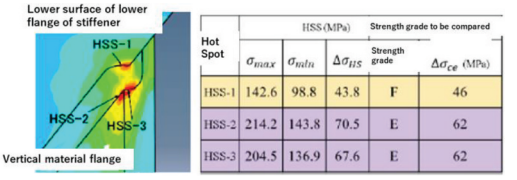


Figure 5. Deformation diagram of vertical material.

Hot Spot	HSS (MPa) σ_{max}	σ_{min}	$\Delta\sigma_{HS}$	Strength grade to be compared: Strength grade	$\Delta\sigma_{ce}$ (MPa)
HSS-1	142.6	98.8	43.8	F	46
HSS-2	214.2	143.8	70.5	E	62
HSS-3	204.5	136.9	67.6	E	62

Figure 6. HSS calculation results of the weld at the upper end of Part1 vertical material before reinforcement.

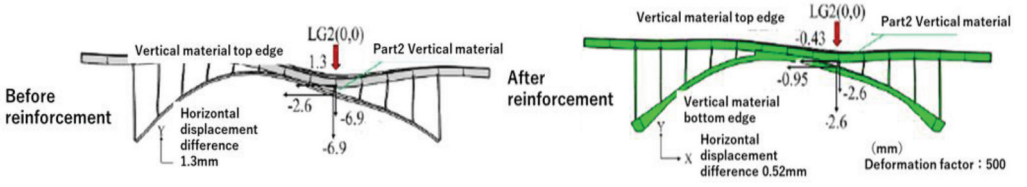

Figure 7. Effect of reinforcement on deformation of Part 2 vertical timbers.

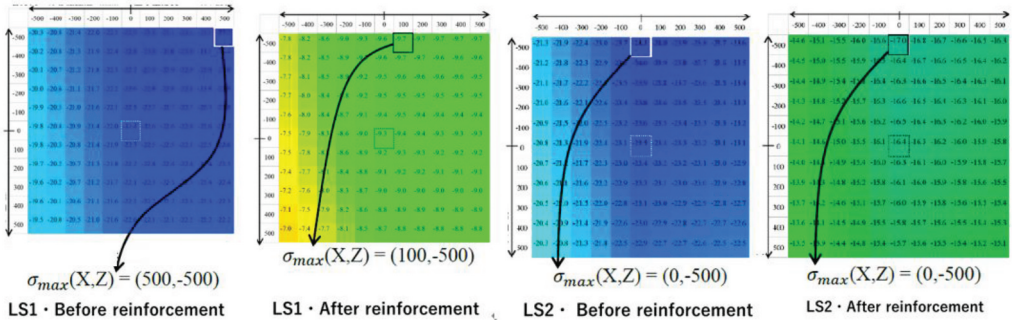
4.3.2 *Connection between stiffening girder and transverse girder*

There was little difference in the deformation of this member shown in Figure 3②under load loading before and after reinforcement. Stress concentration was observed at the upper end of the connection plate weld between the vertical stiffener of the stiffening girder and the transverse girder web at the top of the member. No significant changes were observed in the above deformation behavior or stress development in this member regardless of the location of the member or whether it was reinforced or not, as shown in Part 1 and Part 2.

4.3.3 *Vertical girder/ transverse girder intersection*

In this member shown in Figure 3③, stresses were relatively high around the intersection of the longitudinal girder and the upper flange of the transverse girder and were particularly concentrated at the scallop of the connection plate of the longitudinal girder. The deformation behavior did not change depending on the location of the member or whether it was reinforced or not.

Figure 8 and Figure 9 show the results of the stress influence surface and HSS calculations, respectively, focusing on the scalloped welds at the top of the longitudinal girder connection plate, which is the location of the maximum stresses described above. The stress increased when the axle moved across the longitudinal girder from the influence surface in the minus direction perpendicular to the bridge axis, that is, when the axle moved across the longitudinal girder.



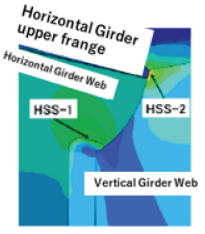


Figure 8. Stress affected surface of the weld at the top end of the longitudinal girder connection plate at the transverse girder web (LS).

Hot Spot	Before reinforcement						After reinforcement						Strength grade to be compared	
	Part 1			Part 2			Part 1			Part 2				
	σ_{max}	σ_{min}	$\Delta\sigma_{HS}$	σ_{max}	σ_{min}	$\Delta\sigma_{HS}$	σ_{max}	σ_{min}	$\Delta\sigma_{HS}$	σ_{max}	σ_{min}	$\Delta\sigma_{fi}$	Strength grade	(MPa)
HSS-1	-29.2	-38.7	9.5	-30.6	-41.3	10.7	-10.4	-16.6	6.2	-21.8	-30.6	8.8	E	62
HSS-2	-42.5	-48.6	6.1	-45.0	-48.9	3.9	-15.8	-20.6	4.8	-32.0	-34.8	4.8	F	46

Figure 9. HSS calculation results for welds at longitudinal and transverse girder intersections.

4.4 *Summary of results*

The hot-spot stress ranges focused on by each model are summarized and compared in Figure 10. As can be seen in the figure, the vertical member shown in Figure 3①, where secondary bending occurs, has the lowest fatigue durability among the vertical member, the connection between the stiffening girder and the transverse girder, and the intersection between the longitudinal girder and the transverse girder. Stress concentration occurs at the upper and lower ends of these members, and Part 1 vertical members adjacent to the arch crown, which have short member lengths, are particularly weak points in deck type steel arch bridges. Therefore, it was found that reinforcement measures are necessary mainly for the vertical members with short member lengths. On the other hand, the stress values and stress ranges of floor assemblies such as steel girders and steel slabs, where fatigue damage is frequently found, are lower than those of vertical members in the structure of deck type steel arch bridges.

In terms of stress effects, the stresses in the vertical members tended to be higher when the load shifted toward the arch crown and toward the outside of the bridge overhang. The outward movement of the load is considered to have increased the load-bearing ratio of the stiffening girders, and the vertical members directly below the stiffening girders were significantly affected. The addition of a vertical girder is considered to be an effective countermeasure. In addition, the stress in the floor assembly increases when the load shifts from just above the focus area to the center of the bridge. Therefore, it is considered that avoiding the position of the load or increasing the strength of the floor assembly is one of the ways to prevent fatigue. Comparison

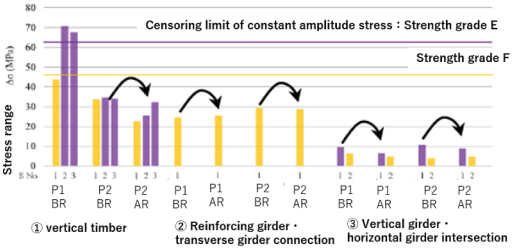

Figure 10. Comparison of stress ranges and truncation limits for each member.

of the results before and after reinforcement showed that the reinforcement reduced the stress in all members. This can be attributed to the decrease in overall bridge displacement due to the increased stiffness of the arch ribs. However, for the floor frames that were not structurally modified by the reinforcement, there were almost no differences in deformation behavior, stress state, or stress range between the pre- and post-reinforcement periods, and the reinforcement was not effective as an anti-fatigue measure. In addition, the fatigue durability of Part 2 vertical members, which could be compared by reinforcement, was confirmed, but secondary bending, which is the cause of damage, was still observed after reinforcement. Therefore, it is necessary to consider reinforcement measures to suppress the deformation.

5 CONCLUSION

In this study, finite element analysis was conducted to investigate whether seismic retrofitting of deck type steel arch bridge, which are considered to be inadequate for existing conditions, is also effective for fatigue retrofitting. The results are described below.

(1) For level 1 earthquake motion, plasticity did not occur even before reinforcement, and seismic performance 1 was satisfied. For level 2 earthquake motion, plasticity was observed, but the reinforcement eliminated the plasticity of the main members, thus satisfying Seismic Performance 2.
(2) From the viewpoint of fatigue, secondary stress concentration was observed at the upper and lower ends of the shortest vertical member connecting the arch rib and the stiffening girder before reinforcement, and fatigue damage was considered to occur. The stress value was about 100 MPa, but since this point was wrapped in reinforced concrete, it is considered that there was no stress concentration.
(3) The stress range at the top end of the second shortest vertical material was reduced from 35 MPa to about 25 MPa before and after reinforcement, respectively. The stress at the lower end was also reduced by 40 MPa. In addition, stresses at the joints between the stiffening girder and the transverse girder and between the longitudinal girder and the transverse girder were generally reduced by the reinforcement. The reason for this is that the stiffness of the arch ribs was increased, which suppressed the deformation of the bridge.
(4) However, the stress range increased by 1 MPa at the weld scallop at the intersection of the longitudinal and transverse girders. 5 MPa, which is sufficiently low compared to the fatigue design level of JSSC, is not considered to be a concern, but it should be noted that the stress range increased in some cases.

Rehabilitation methodology of a corroded steel-riveted highway bridge in an urban setting

I. Netzer & A. Kedar
Kedmor Engineers, Givataim, Israel

ABSTRACT: Current sustainability practices emphasize preserving existing bridges and extending their lifespan, as seen in the Namir Arches Bridge over the Yarkon River in Tel-Aviv. This 70-year-old Tied-Arch steel bridge faces challenges due to its corrosive coastal location and continuous use as a four-lane highway. The lack of maintenance and repetitive load-cycles over the years have led to deterioration. Ultrasonic field tests of the rivets revealed the bridge's condition, prompting the development of a rehabilitation plan involving the replacement of approximately 5,000 rivets. The replacement medium must have similar stiffness and capacity characteristics and avoid negative effects to the original plates. Options explored included: new rivets with a modern riveting machine, preloaded High-Strength Friction Grip (HSFG) bolts, and the chosen alternative of HSFG injection bolts. Beyond rivet replacement, the project addressed deteriorated abutments, and the replacement of expansion joints and safety barriers to ensure overall bridge functionality.

1 INTRODUCTION

1.1 *History of the Namir Arches Bridge*

The Namir Arches Bridge in Tel-Aviv, over the Yarkon river (Figures 1-2), was constructed in the mid 1950's to alleviate traffic congestion for northern to Tel-Aviv commuters. The bridge is a single 56 m span; the static scheme of the superstructure is a simply supported tied-arch bridge (Figures 3-4). The bridge was assembled on one riverbank and was moved to its final location utilizing the incremental launching method (Figure 5). The structural elemets are comprised of plates, angles and channels that are connected with rivets to create the structural members' sections and spliced connections (e.g., Figure 6). Two reinforced concrete abutments rest at either side of the river and are carrying the bridge and are loaded by four bearings: two roller bearings and two rocker bearings.

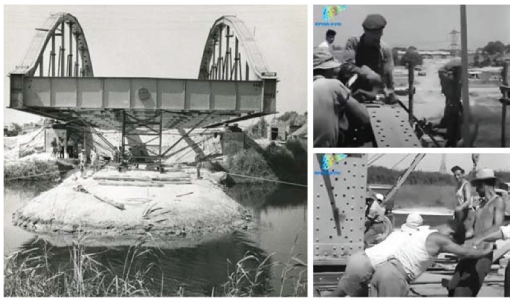

Figure 5. Photos of construction works: (L) cantilevering over the Yarkon River (TR) rivet installation (BR) launching was done mechanically by the on-site team (Israel State Archives).

1.2 *Current status of the bridge*

After approximately seventy years of continuous use, structural elements – both primary and secondary – exhibited significant structural damages (e.g., Figure 7). The current deteriorated state of the heavily corroded elements can be attributed to three predominant reasons:

a. Proximity to the Mediterranean Sea coastline: with a higher consistency of chlorides the effects of the corrosive environment are accelerated.

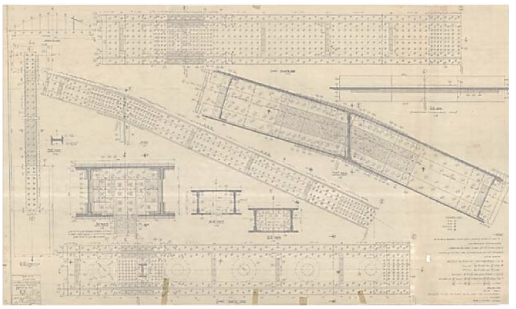

Figure 6. Example details of arch and hangar sections and splices (Netivei Israel – National Transport Infrastructure Company).

b. Fatigue cracking due to dynamic and repetitive load cycles: as this phenomenon was less known in the 1950's preemptive measures were not taken ahead and as a result damages were unsurprisingly seen in the higher stress regions.
c. Lack of maintenance over the years: in the past there were no structural retrofit works done to the bridge, rather just an architectural paint job for its now iconic blue color (Figure 1).

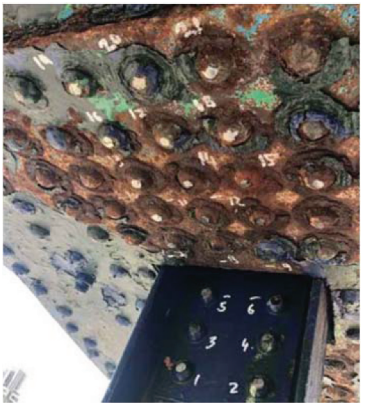

Figure 7. Corrosion in hangar-arch connection.

1.3 *Structural renovation – selection of design approach*

With the Namir Arches Bridge being in a poor state, the Tel-Aviv municipality has to address the issue. In terms of the detail level and the resulting design life extension period, there are several general approaches to be considered:

a. Rebuilding the bridge to meet current codes and standard practices, thus gaining a new and complete design life.
b. Retrofitting the existing bridge to meet current codes and standard practices, thus extensively prolonging its design life.
c. Rehabilitating the existing bridge to meet its original design criteria, based on codes and standard practices from the original design period. This will prolong the bridge's design life.

The Tel-Aviv municipality has selected to pursue the rehabilitation approach as it is expected to be the least costly, quickest to implement and leading to a more sustainable solution for the renovation of this urban construction site.

2 REHABILITATION DESIGN METHODOLOGY

2.1 *General background of the rehabilitation plan*

As mentioned above, the rehabilitation plan was devised with the objective of bringing the bridge back to a satisfactory operational state based on its original design and to increase its safety level in a sustainable fashion. Due to structural damages that were observed: the expansion joints, abutments and safety barriers were all designed to be replaced. Currently, whilst writing this text the Tel-Aviv municipality has begun work on the replacement of the expansion joints.

The most notable damage type, however, is that of the corroded rivets. In order to assess the degree of corrosion and its implications, a test program for a representative number of rivets was prepared. Kedmor Engineers were responsible for allocation of suspect rivets, based both on visual inspection and on expected vulnerable zones. EI-SHAR Metal Industries, an expert metallurgy lab, was responsible for the chosen test method and corresponding procedure; the ultrasonic field test was the selected method. Out of the 1,056 examined rivets approximately 15% were determined as unacceptable; around 10÷15% additional rivets were not able to be determined, deeming them as faulty as well; the remainder were found structurally acceptable. Prior to the field testing a calibration procedure was done. Ultrasonic tests were conducted on two different specimen types: a faultless rivet and a flawed rivet with a handmade visible damage cut in the shank of the rivet (Figure 8). Based on the test results an estimate placed ca. 5,000 rivets in need of replacement out of a total of ca. 20,000. It is of no surprise that most of the damaged rivets are in either high stress regions or near corrosion-inducive areas; even more so when the two cases coincide. Based on the findings a complete methodology for the replacement of faulty rivets is required.

Figure 8. Ultrasonic rivet test readings: (L) uncracked rivet; (R) cracked rivet.

Development of a rehabilitation plan for an existing bridge, specifically one with an outdated technology, requires meticulous planning and a strong understanding of the guiding principles of the structural behaviour, the mechanical properties and the material characteristics etc. From the outlook of the structural behaviour, it is crucial to understand that the bridge is comprised entirely of connected plates, angles and channels that are held by rivets. In addition, there are connection splices that are responsible for transferring from one set of a riveted cross-section to another. As the structure has already deformed and strained in the past, smooth operation is not to be expected and some difficulties are due: selection of any solution has to take that into account. Furthermore, the most important thing is to maintain joint action: when a rivet is replaced, it is imperative that it is replaced by a medium that has very similar stiffness, otherwise it will change the force distribution along the adjacent pieces. If the replacement medium is not stiff enough the older rivets will experience an increase in their respective applied loads that might cause a chain reaction. On the other hand, not every stiff alternative is a viable one. For example, although it has sufficient stiffness, utilizing welded a connection details replacement approach is not recommended due to the effect it has on the existing 70-year-old bridge structural steel plates. The welding causes the steel to become more brittle and reduce the fatigue strength.

Regardless of specifics, as only flawed rivets are to be replaced and the rest to remain in place, any approach will have to consider adequate compatibility between the existing and new elements as they must function together.

2.2 *Rehabilitation plan design alternatives*

Any design alternative should follow the aforementioned guiding principles. In the case of Namir Arches Bridge, there are a couple of key design criteria to consider: structurally, the replacement medium must exhibit rivet compatible behaviour with minimal to no slip. The fabrication process of rivets causes them to fill the plate-hole almost in its entirety giving very little room to experience movement (Ketchum 1919, Ghosh 2000). Operationally, the bridge is in the heart of the Tel-Aviv center and is an important traffic route. Therefore, the client's directive is that the bridge must remain operational throughout the rehabilitation works. Any design alternative must keep that in mind, and it is preferable that there will be as little closures as possible.

Several options were considered, primarily:

a. Installing new rivets with a new riveting machine: the benefit of using this structural solution is due to the inherent similarity of the systems. However, a clear disadvantage is the scarcity of professional equipment and personnel in the local market. Therefore, this option was not pursued.
b. Replacing the damaged rivets with High-Strength Friction Grip (HSFG) bolts: this is a common practice in the field of rehabilitation and/or retrofit projects of steel-riveted bridges (Åkesson 2010, Rickets 2017). In the case of Namir Arches Bridge very little, if any, preliminary treatment can be done on the plates; this is due to the client's condition that the bridge must remain operational. Resulting in expending significant efforts and resources to reach a lesser effectiveness due to low slip factor that is expected with varying degrees of corrosion throughout the bridge.
c. Replacing the damaged rivets with HSFG injection bolts: this design alternative suffers a negative grade due to the fact that it has not yet been utilized, neither by Tel-Aviv municipality nor in the Israeli market. Yet, it is still the most fitting design alternative from structural performance considerations as it poses a promising solution for the low slip factor of the HSFG bolts (ECCS 1994).

2.3 *Rivet replacement with HSFG injection bolts*

The injection bolt solution was developed in the Netherlands in the 1970's (Bouwman 1970) and was later established as a viable solution to replace rivets in existing structures (Kluwen 1981). The practice of replacing steel-riveted bridges (primarily railway bridges) with injection bolts can be seen in Northern and Western Europe.

Essentially, the system is similar to a typical bolted connection with a bolt thread and shank inserted in a designated hole joining several plates for a combined action. A drilled hole is administered in the bolt head and outer-to the shank diameter. An epoxy resin (or another

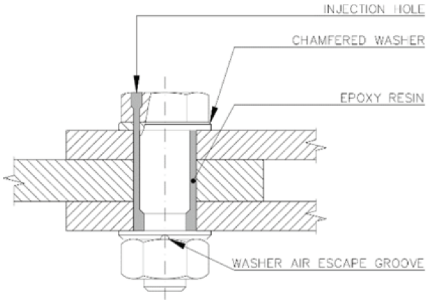

Figure 9. Injection bolt in a double lap joint (modified from ECCS 1994).

equivalent material) is inserted to fill the gap between the bolt shank and plates' walls (Figure 9). The force transfer mechanism is carried through bearing stresses rather than bolt shear in the shank/thread (e.g., Figure 10). The Injection bolts solution can also be applied for HSFG bolts. In that case, design for a dual action will include two different components. A shear component in the shear plane between the friction surfaces and a bearing stress component as detailed in Figure 10.

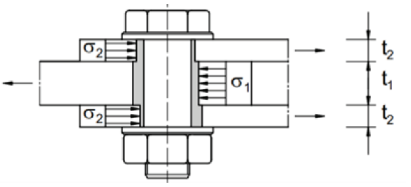

Figure 10. Stress distribution along bolt (EN 1993-1-8:2005).

The reason it is valid to assume joint action with these two components is due to the expected deformations regime. With the bolt hole filled and bearing compression surrounding and assuming sufficient stiffness, there is a de-facto non-slip behaviour leading to the HSFG participating in proportion. Nevertheless, in the Namir Arches Bridge project due to the unknown nature of the class of the friction surfaces and the expected slip factor, the bearing stresses of the injection bolts shall be designed as if there are no HSFG bolts at all. The latter shall be a secondary system assisting in increasing the redundancy of the rivet-substitutes. In addition, as the local market is inexperienced in design and execution of the injection bolts methodology, this 'belt + suspenders' approach was an advantage.

With the Namir Arches Bridge being in a corrosive environment close to the Mediterranean coast, durability considerations are crucial. The long-term durability of epoxy resin is negatively influenced by exposure to both wet and acidic environments (Uthaman et al. 2020), which can lead to degradation. It has been demonstrated that this phenomenon is mitigated by the preloading of injection bolts (Correia et al. 2016) and the application of a protective paint finish. This practice has performed well over the past 50 years (Grensigt and de Vries 2016). The epoxy resin specified in this project is RenGel SW404+HY2404, which is sufficient in the long-term for bearing stresses under 175 [MPa] (Kolstein et al. 2017).

2.4 *Meeting original design criteria*

With the Namir Arches Bridge being a rehabilitation project, the structural behaviour of the new elements needs to be assessed in comparison to the original design criteria. The first step is to adhere to the Allowable Stress Design (ASD) approach rather than the now common Limit State Design.

Upon review of the original calculation report, prepared by Eng. Shoshana Shacham (1955), and was luckily kept in pristine condition, it was clear that the allowable stress on each plate and rivet in the project was 140 [MPa]. Therefore, verification calculations of the bearing resistance of the resin were performed according to EN 1993-1-8:2005 cl. 3.6.2.

2.5 *Rivet replacement with HSFG injection bolts specification*

The procedure of rivet replacement with HSFG injection bolts shall be executed in several key phases. First, non-intrusive works; this entails preperation of the structural steel with sand blasting or other abrasive treatment. This is followed by carrying out the ultrasonic field tests for the bridge's rivets on-site and determining which rivets are disqualified and require replacement. Thereafter, establishing the workflow which methodically defines the order of which rivet is to be treated, in which element, within an element and with what time gap. For example, Figure 11 depicts the conceptual guideline replacement order of a few disqualified rivets in an element. This recommendation is aimed to increase the robustness whenever possible and to reduce unnecessary stresses in the plates.

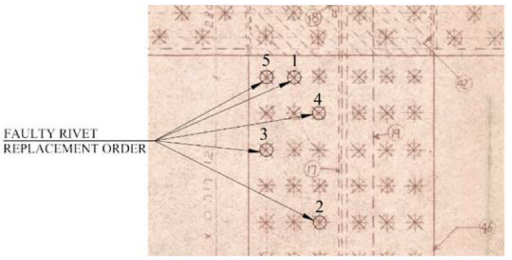

Figure 11. Rivet replacement order – conceptual guideline (modified from, Netivei Israel – National Transport Infrastructure Company).

Once a rivet has been disqualified a series of steps is to be carried in order to replace it with an HSFG injection bolt. Complete details are listed in the project specification; however, the main features can be summarized in making sure the drilled hole is clean from undesired outer agents and/or in a bad structural state. In addition, if necessary, a larger hole may be specified to accommodate the issue with a compatible larger bolt assembly. A partial list of the rivet replacement control table is shown below (Figure 12) for clarity. In essence, all bridge rivets were mapped according to the original design drawings to serve as a baseline for the replacement procedure (e.g., Figure 13 illustrates the interior plates and angles connections in the hangar-arch zone).

Finally, after finalizing with friction surfaces treatment for the open surfaces, the replacement HSFG bolts are preloaded in two phases with the resin injected between them. As the epoxy resin is a crucial component in the structural mechanism, details regarding the resin are included in the specification.

Figure 12. Rivet replacement by HSFG injection bolts control table (partial table, translated).

The methodology listed above is rather a guideline and not a recipe. While working on existing structures is never an easy task nor it is always as expected, in the case of the Namir Arches Bridge there are several issues that are worth mentioning.

First and foremost, the matter of access to small and closed spaces. This issue is true to both the required UT field tests of the rivets and more so to the replacement works, when required. Additionally, once the rehabilitation works of the structural steel rivets will commence unique and case-by-case specific details will be developed under the guiding principles of the methodical approach presented.

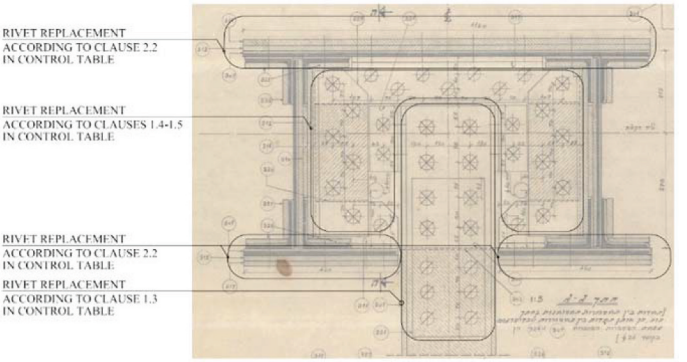

Figure 13. Detail B rivet replacement legend: hangar-arch connection (modified from, Netivei Israel – National Transport Infrastructure Company).

3 CONCLUSIONS

The rehabilitation project of the Namir Arches Bridge called for a tailor-made solution to prolong its design life and to ensure public safety throughout that period. Out of the aforementioned design alternatives, the HSFG injection bolts approach is the most suitable method with the remaining existing rivets kept in place.

This method results in a more robust product with an inherent greater redundancy at a relatively small premium.

S. Morichika & M. Saeki
Department of Civil Engineering, Tokyo University of science, Chiba, Japan

ABSTRACT: Orthotropic steel deck bridges are employed in many urban expressways in Japan. Many fatigue cracks, which might be caused by overloading vehicles and long in-service periods, are found in the orthotropic steel deck. Since the cracks affect the safety of traveling vehicles, adequate maintenance should be conducted. The objective of this study was to develop a method of detecting a crack propagating in the deck plate through the change in strain response. In this research, fatigue tests were performed using small specimens that imitated a section of the deck plate and the trough rib of an orthotropic steel deck. The size of the deck plate was 1000 mm in length, 280 mm in width, and 12mm in thickness. The trough rib was 100 mm in length. As a result of the test, strain changes due to fatigue crack propagation on the weld toe at the upper side could be detected by measuring strain changes.

1 INTRODUCTION

Orthotropic steel deck bridges are employed in many urban expressways in Japan. This is because it can shorten the construction period and is lighter than concrete slabs. Many fatigue cracks, which might be caused by overloading vehicles and long in-service periods, are found in the orthotropic steel deck. Magnetic Particle Testing and Ultrasonic Testing have been used to detect fatigue cracks. However, it is necessary to consider a continuous monitoring system for earlier detection in the future. Therefore, this study investigates a fatigue crack monitoring system based on strain response analysis using strain gauges. Specifically, the detection of fatigue cracks is attempted from changes in the measurement results of the strain gauge installed at the weld, as shown in Figure 1.

2 SUMMARY OF THE TEST SPECIMENS

The test specimens were small specimens that imitated the U-ribs of the steel deck plate. The dimension of the specimen is shown in Figure 2. The dimension of the specimen follows the design guidebook of road bridges in Japan (Japan Road Association 2020). The deck plate thickness was set to 12 mm. The depth and length of the U-rib were set to 280 mm and 100 mm, based on previous research (Murakoshi et al. 2012) and the conditions of the testing machine. The material (Mori et al. 2006) was SM490YA. The amount of weld penetration was 75% or more. Since this experiment was conducted for root cracks, grinder treatment was performed at the weld toe, as shown in Figure 1.

3 FE ANALYSIS TO STUDY LOADING CONDITIONS

This chapter describes the Finite Elements Analysis (FEA) to validate the specimen model and determine loading conditions.

DOI: 10.1201/9781003483755-257

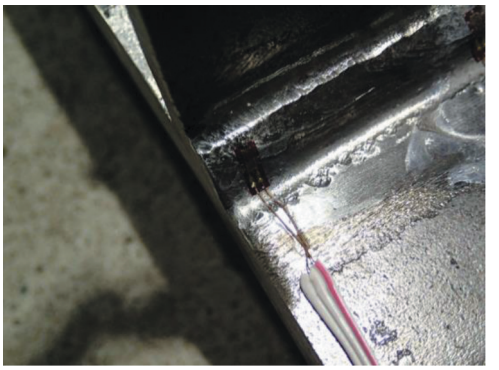

Figure 1. Strain gauge.

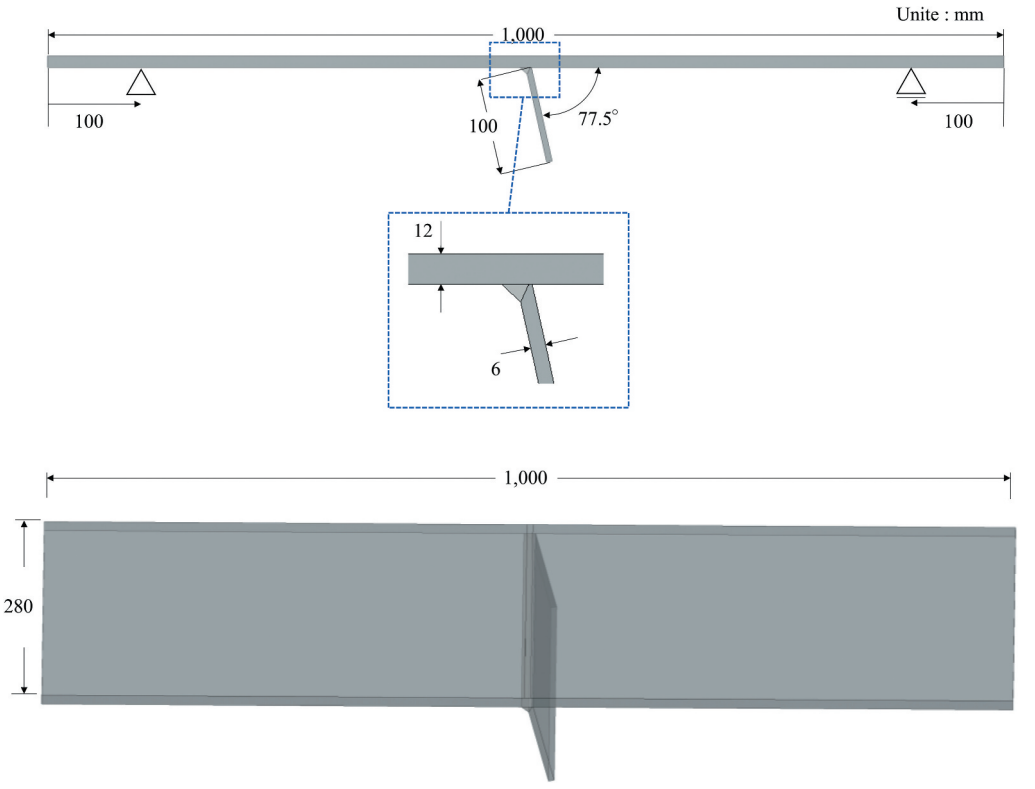

Figure 2. Dimension of the specimen.

3.1 *Investigation of loading position by FEA*

Loading positions were investigated by FEA. The software used for the FEM analysis was ABAQUS2022 Ver. 6.22. The specimen was modeled using solid element (C3D8R). The Young's modulus and Poisson's ratio of which are 205 GPa and 0.3, respectively. As stress concentration points, we focused on the weld toe at the upper side, the weld toe at the lower side, the weld roots at the upper side and left side of the weld between deck plate and trough rib, as shown in Figure 3. In the FEA, the effective notch method (Suganuma & Miki 2007) was used to evaluate the stress distribution in the weld root and toe. The radius of the effective notch was set to 0.5 mm. As shown in Figure 4, the loading position move at intervals of 50 mm. Assuming loading with a single tire, the loading area was 200 mm × 200 mm (square shape). The magnitude of

the load was set to 1 MPa. The Von Mises stress at the stress concentration points on the surface and in the center of the specimen are shown in Figure 5. The highest stress was observed at weld toe at the upper side in the center of the cross-sectional direction. Second and third highest stresses were the weld root at the upper side and the weld root at the left side, respectively. The maximum stress was found at the center of the specimen, just above the weld. FEA results showed that the cracks were most likely to initiate from the weld toe at the upper side. Grinder treatment was applied to the weld toe at the upper side to decrease the stress concentration, since the initial objective of the experiment was the detection of the fatigue crack from the weld root. Based on the FEA results, it was decided to place the load in the center of the specimen at an area of 200 mm × 200 mm. The loading patterns include crack introduction loading, beach mark introduction loading, and live load loading. The beach mark introduction loading was performed to investigate the relationship between strain response and crack propagation. The live load loading was performed to study the changes in the strain range under live loads. Crack introduction loading was applied with Sine waves of 10 kN maximum and 1 kN minimum at 100,000 to 150,000 cycles per cycle. The loading frequency was 2Hz to 4Hz. The beach mark introduction loading was given by Sine waves with a maximum of 10 kN and a minimum of 5.5 kN for 100,000 cycles per cycle. The live load was applied 50 cycles in each of the eight cases where the loads were set to achieve the assumed strain values.

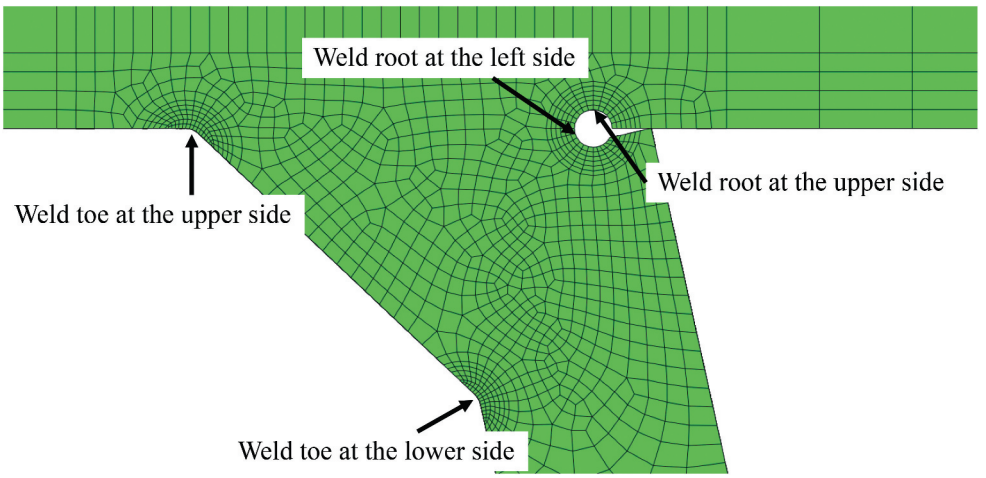

Figure 3. Stress concentration points.

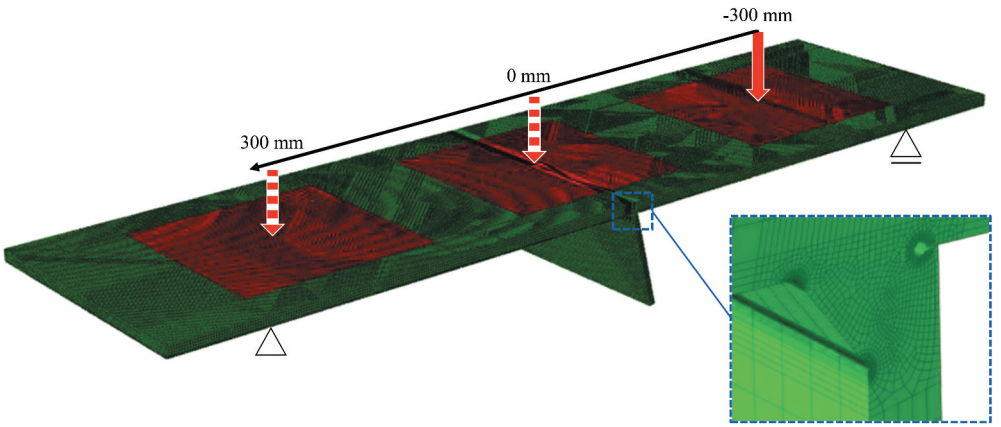

Figure 4. Consideration of loading position.

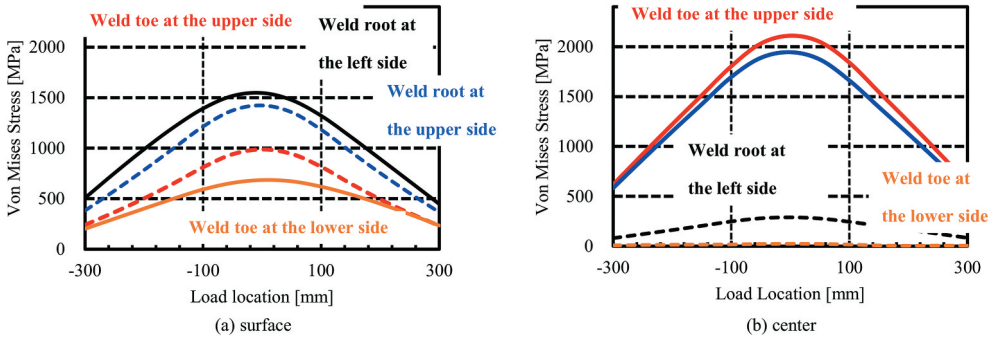

Figure 5. Comparison the stress concentration.

3.2 *Validation of FEA model*

FEM was used to examine the validity of the test specimens. The stress conditions between the U-rib model which includes the U-rib and the test specimen model which includes a part of U-rib were compared. The FEA model is shown in Figure 6. The load was applied to an area of 200 mm × 200 mm in the center of the specimen with the load of 1 MPa.

A contour plot of the Von Mises stress at the center of the specimen is shown in Figure 7. The stress distributions on the weld toe at the upper side are almost same. Furthermore, it can be confirmed that the stress is concentrated on weld root at the upper side. These results indicate that the trends of von Mises stress distribution for the U-rib model and the specimen model are similar.

Figure 6. FEA model.

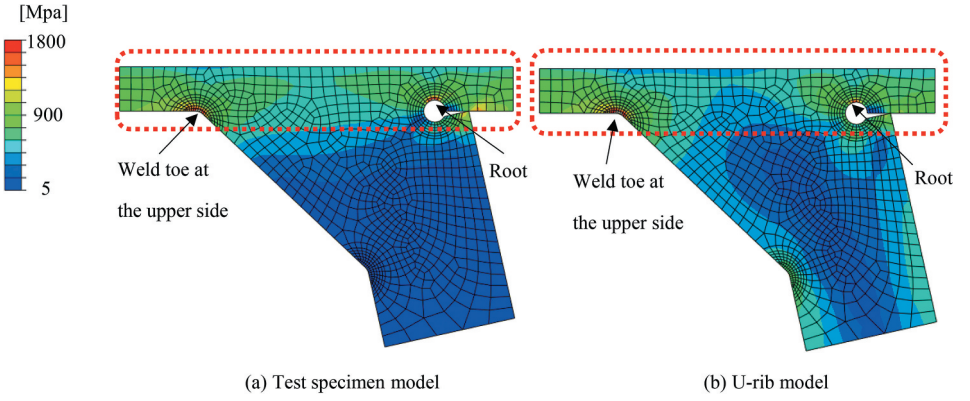

Figure 7. Comparison of stress distribution between test specimen and U-rib model.

4 SUMMARY OF MEASUREMENTS AND EXPERIMENTS

4.1 *Measurement locations*

Strain gauges were installed as sensors to measure the changes in strain response. Figure 8 shows the installation locations of the strain gauges and measurement number which is from

CH1 to CH17. CH1 to CH17 are strain gauges. CH1 to CH7 were installed for toe crack detection and CH8 to CH14 for root crack detection. CH17 was installed to confirm the strain response without the effect of the crack. Strain gauges were uniaxial and 3 mm length. The test set-up is shown in Figure 9. Fatigue tests are conducted by bending test.

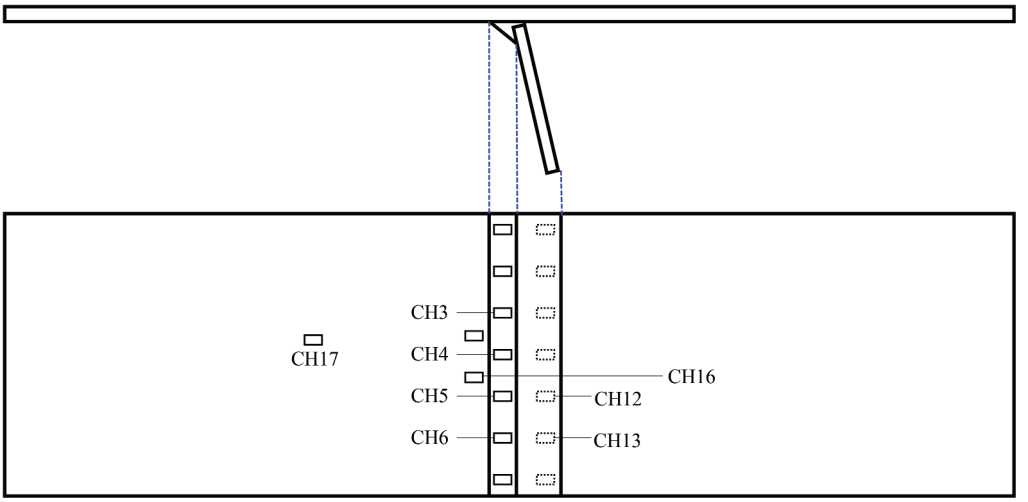

Figure 8. The installation locations and channels.

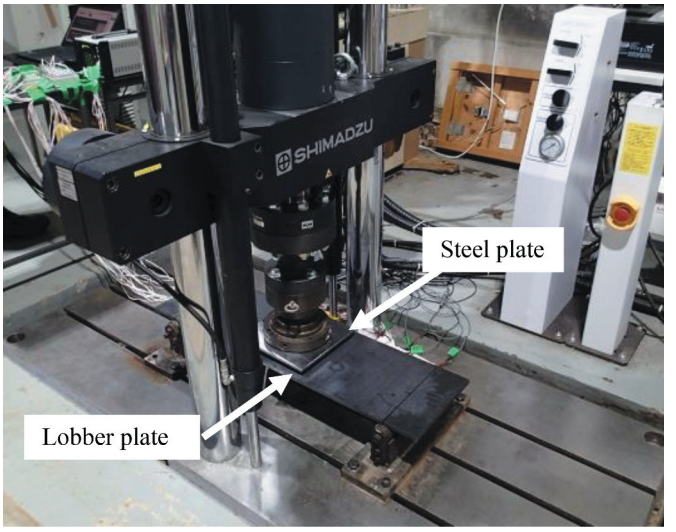

Figure 9. Fatigue test set-up.

5 RESULTS OF FATIGUE TEST

The crack initiated from the weld toe at the upper side which is between CH5 and CH6. The crack then propagated and penetrated by about 70%. Since the deflection was large, the fatigue test could not be continued. Therefore, it was cut using a thread saw. Figure 10 shows the test specimen after cutting.

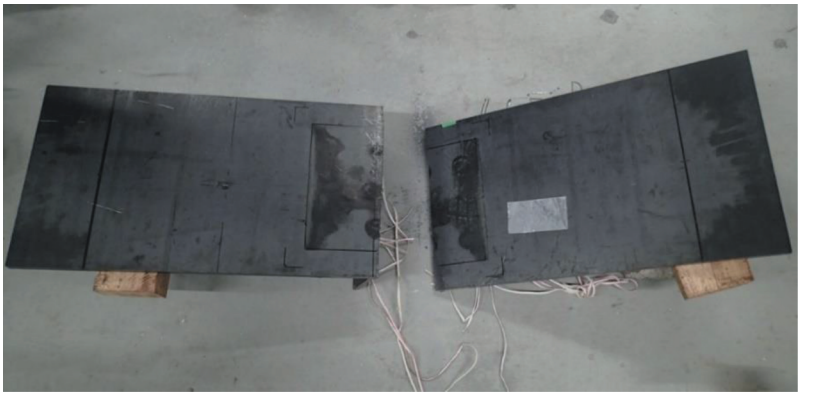

Figure 10. Test specimen after cutting.

5.1 *Beach mark*

Beach marks on the specimen fracture surface are shown in Figure 11. Beach marks were generated from 0.88 million cycles in each 0.1 million cycles. The crack initiation point was between CH5 and CH6 where is about 24 mm from CH5 and about 26 mm from CH6. The crack then developed on both sides. Fatigue cracks reached CH5 between 1.33 and 1.48 million cycles. Furthermore, the cracks reached CH6 about 1.39 million cycles. Cracks propagation in the direction of CH6 were found to have reached their ends between 1.58 million and 1.68 million cycles. Crack propagation began to accelerate from 1.18 million cycles, and 38.8 mm of crack propagation occurred between 1.58 million and 1.68 million cycles. Crack growth in the plate thickness direction was found to be slow, penetrating just above the crack initiation point at 1.68 million cycles.

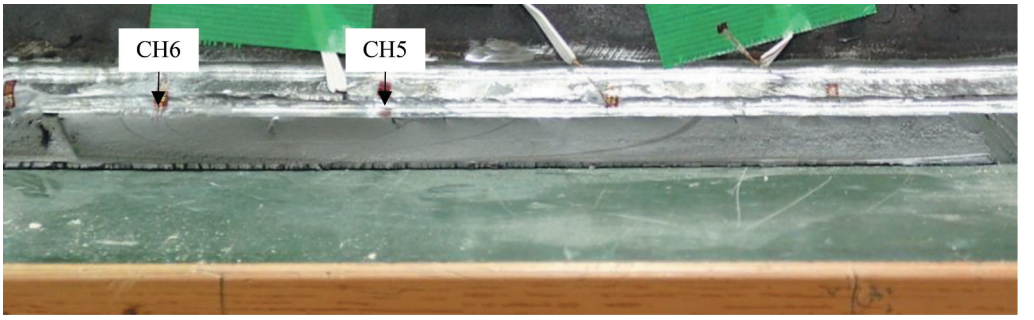

Figure 11. Beach mark.

5.2 *Strain measurement results*

The strain responses of CH3, CH4, CH5, CH6, CH12, CH13, CH16 and CH17 at 0.78 million cycles of crack introduction loading are shown in Figure 12. This amplitude is calculated for each loading cycles as the strain range, and is shown in Figure 13. In CH5, an increase in strain range was observed after 0.8 million cycles. The increase stopped at 1.32 million cycles, followed by a decrease. No change was observed in other CH. In all CHs, only CH5 showed the fastest change in strain response. The change in the strain range was calculated based on the strain range at 0.78 million cycles. The results are shown in Figure 14. The change in CH5 shows an increase of about 10% at 0.98 million cycles.

Beach mark shows that small cracks occur in about 0.88 million cycles. Considering the crack location and strain gauge strain variation, it is thought CH5 was able to detect a small

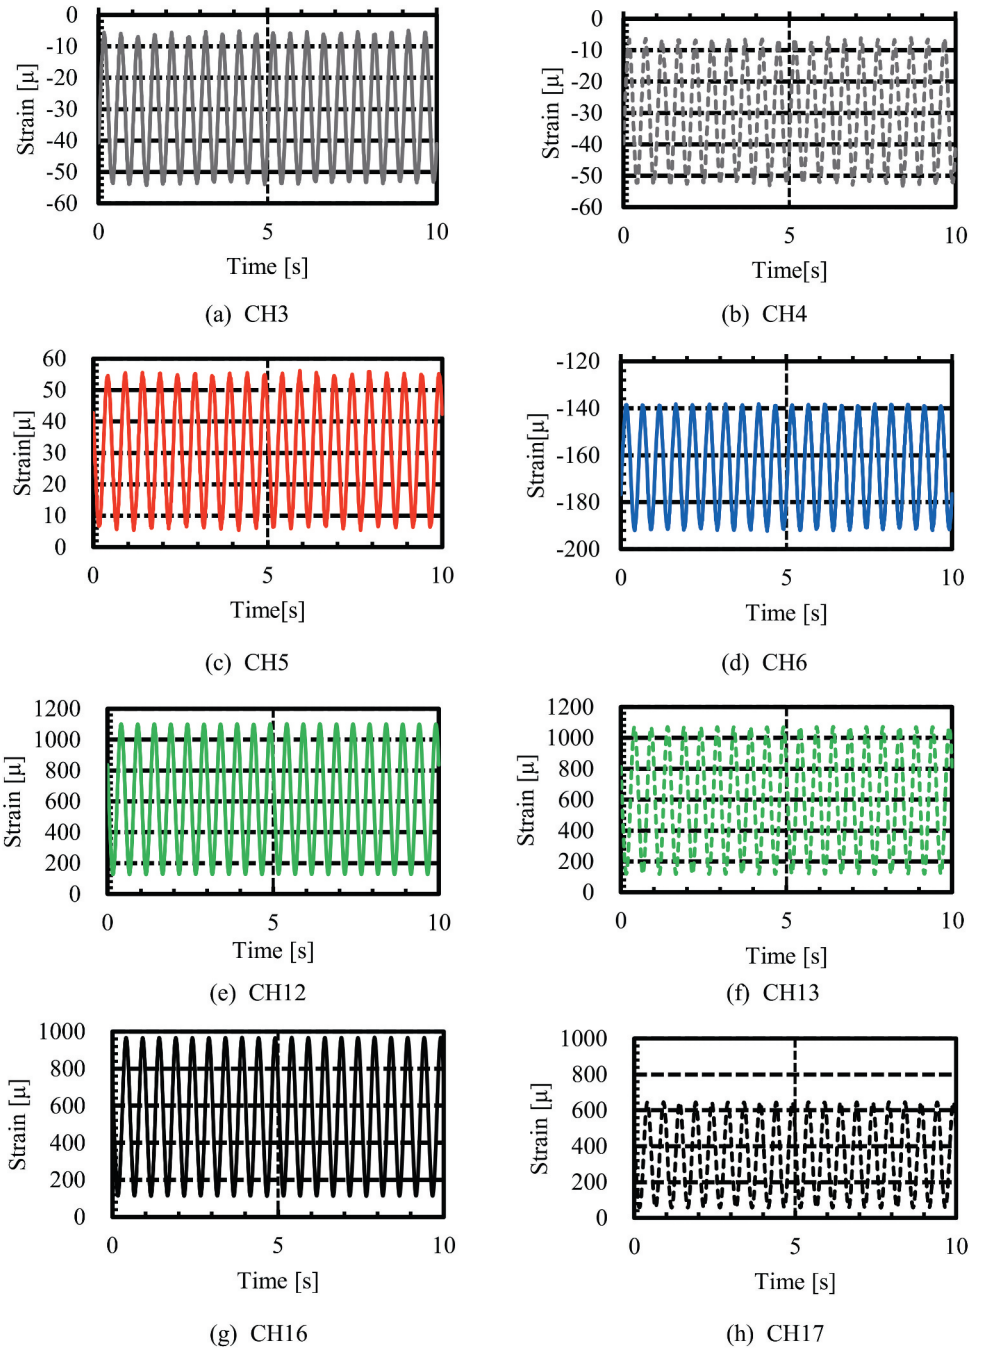

Figure 12. Strain response.

crack when the crack reached a distance of 15 mm from the sensor position. In CH6, strain range decreased by 10% when the crack propagated to 15 mm from the sensor. Furthermore, the strain range reached a maximum when the crack reached CH5. The strain range then decreased as the crack passed through CH5. When the crack propagated in the direction of CH6 and reached the edge of the specimen, the strain range of CH5 increased rapidly. These results indicate that strain gauges are able to capture the crack propagation.

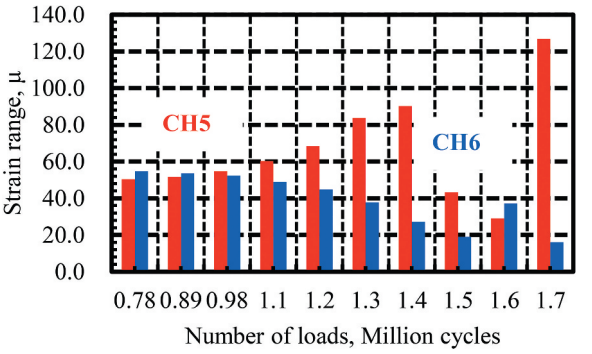

Figure 13. Strain range of loading cycles.

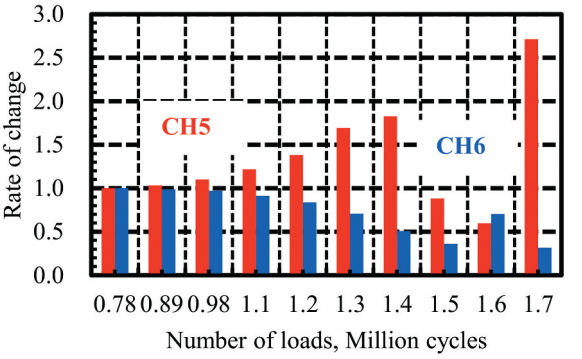

Figure 14. Rate of change in strain range.

6 SUMMARY

Strain changes due to fatigue crack propagation on the weld toe at the upper side could be detected by measuring strain changes. The strain changes due to fatigue crack could be detected by strain gauges which were installed 15 mm from crack position. When the crack reached the top of the sensor, the strain range reached a maximum and then showed a decreasing trend. In the future, we will conduct the experiment again to generate a deck-growth crack from the weld root. We will examine whether it is possible to detect deck-growth cracks by sensing strain gauges.

ABSTRACT: Due to the recent increase in traffic and vehicle weight, bridges are under severe service. As a result, many fatigue damages have been found during periodic inspections. Since it is expected that more fatigue damage will occur in the future, it is important to develop efficient and inexpensive maintenance methods. Therefore, in this study, experiments are conducted using small specimens that reproduce the out-of-plane gussets of steel bridges to verify the effectiveness of crack detection sensor. The specimens consist of a steel plate 90 mm wide, 700 mm long, and 12 mm thick, with a gusset plate 50 mm wide, 150 mm long, and 12 mm thick welded to it. Both materials were made of steel SM490 material and were not painted. The relationships between the response by the crack detection sensor and the conditions of fatigue crack are discussed.

1 INTRODUCTION

Bridges are in severe service due to the recent increase in traffic and vehicle weight. Therefore, many fatigue damages are found in steel bridges during periodic inspections. Fatigue damage occurs at locations where large strains occur repeatedly, such as at welded joints. When fatigue cracks are found by visual inspection, repair, and reinforcement should be considered according to the location of the cracks and their progress. Therefore, it is sometimes important to monitor the progress of fatigue cracks between the detection of fatigue cracks and repair or reinforcement.

Morichika et al. (2020) proposed fatigue crack detection using piezoelectric sensor. They conducted fatigue tests using I-digit fatigue specimens. The results showed that it is possible to detect the fatigue crack near the weld zone using a piezoelectric ceramic sensor as well as strain gauges.

In this study, we attempt to monitor the progress of fatigue cracks by utilizing a sensor used for crack detection in concrete. This crack detection sensor detects cracks by the breakage and emission of optical fibers caused by crack propagation. If this crack detection sensor can be applied to fatigue cracks in steel structures, it will be possible to easily determine fatigue crack growth during inspection. In this study, experiments using small specimens that reproduce the out-of-plane gusset of steel bridges are conducted to verify the effectiveness of the crack detection sensor.

The paper is organized as follows: Chapter 2 describes the experimental method. Chapter 3 describes the experimental results and discussion. Finally, Chapter 4 presents the conclusions.

2 EXPERIMENTAL METHODS

To verify the applicability of a crack detection sensor, which has the proven results in detecting concrete cracks, to fatigue crack detection, fatigue tests were conducted on a specimen

DOI: 10.1201/9781003483755-258

simulating an out-of-plane gusset. The objectives of this experiment were to verify the accuracy of fatigue crack detection, as well as to identify points for improvement.

Figure 1. shows the details of the crack detection sensor used in the experiments. The crack detection sensor is a sensor that detects cracks by the breakage and emission of light from an optical fiber as the crack propagates. The detection accuracy of the crack detection sensor is determined by the type of sensor and ranges from about 0.05 to 0.3 mm.

The crack detection sensor was attached in the same manner as the strain gauge was attached. The steel surface at the attachment point was smoothed with sandpaper, and the bonding point was cleaned with acetone. The sensor was then attached to the steel surface with adhesive.

The dimensions of the test specimen are shown in Figure 2. The dimensions of the specimen were 90 mm wide, 700 mm long, and 12 mm thick. A 12-mm-thick steel plate that imitated a gusset was welded to the center of the specimen as an all-around fillet weld with a weld leg length of 6 mm. All steels ware SM490YA, and no coated pavement was applied. The weld joint edges other than the focus point were machined by a grinder in advance to alleviate the stress concentration.

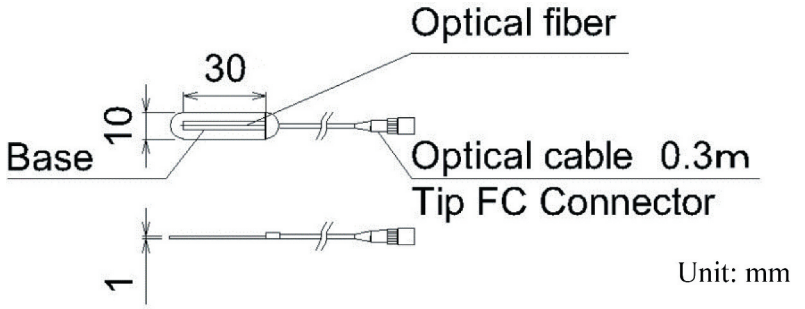

Figure 1. The details of the crack detection sensor.

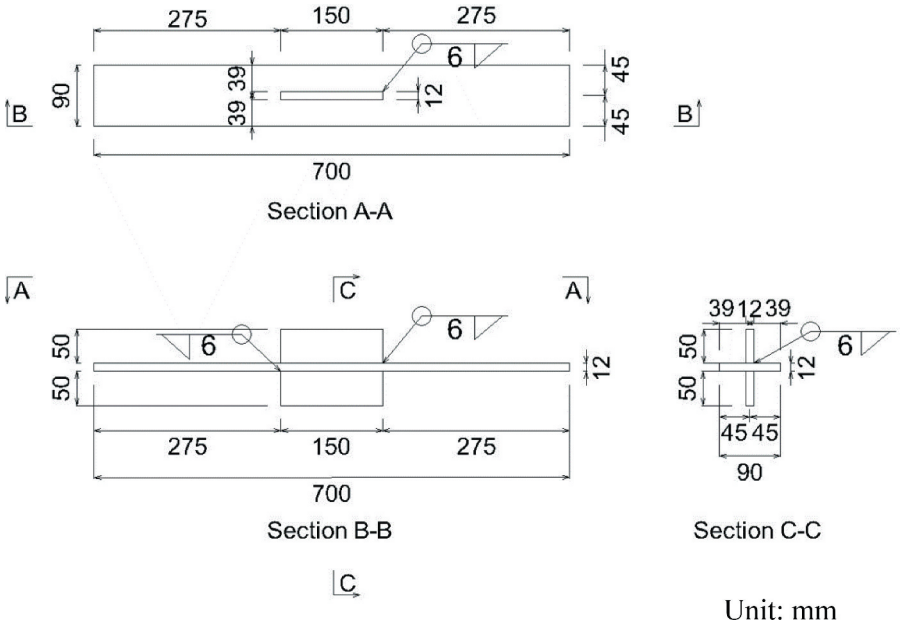

Figure 2. The dimensions of the test specimen.

The sensor locations are shown in Figure 3. In addition to the crack detection sensors, strain gauges were used to measure the nominal stress and to monitor the propagation of fatigue cracks. All strain gauges were 2 mm in diameter, and the sampling frequency was 100 Hz.

The fatigue machine with the specimen is shown in Figure 4. Two types of loading patterns, which include crack-introduced loading and beach-mark-introduced loading, were used as one cycle.

The loading pattern is shown in Figure 5. The crack initiation loading was intended for fatigue crack initiation and propagation, and the stress amplitude was set to approximately 120 MPa. The maximum and minimum loads were set to 135 kN and 5 kN, respectively, to achieve a load range of 130 kN, and 100,000 cycles of loading were considered as one set.The loading to introduce a beach mark to check the fatigue crack propagation was performed to introduce a beach mark.

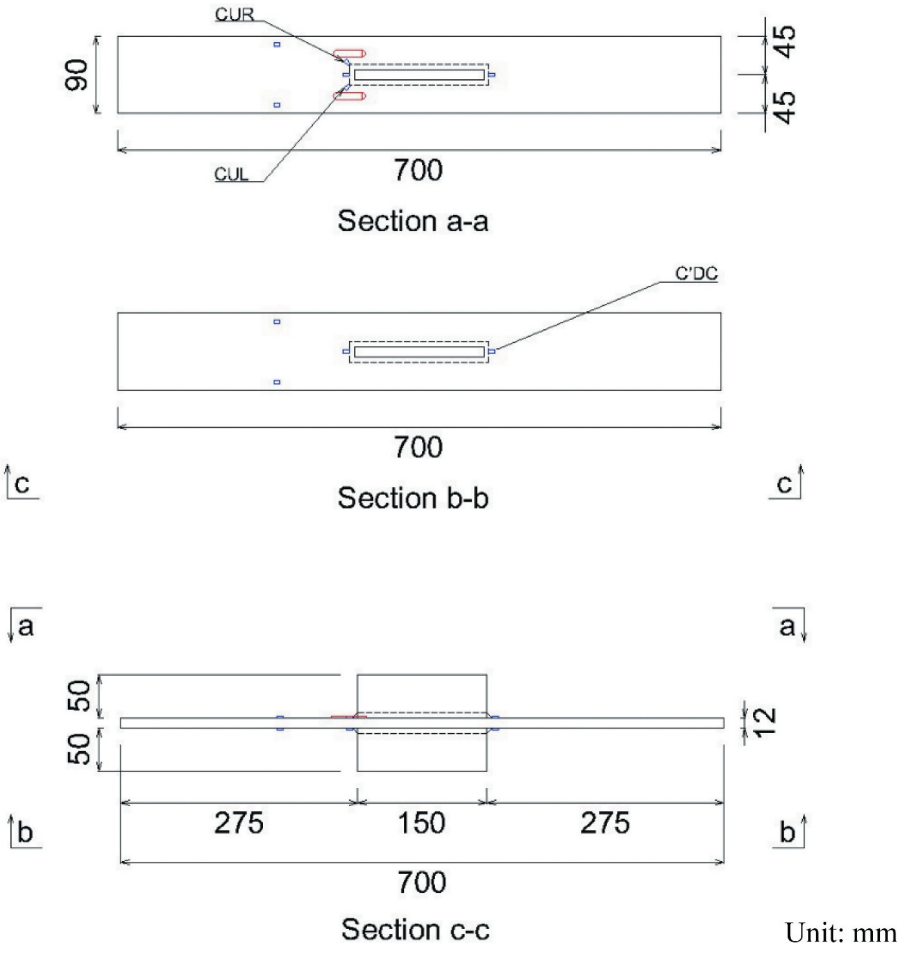

Figure 3. The sensor locations.

3 RESULTS AND DISCUSSION

The results of strain measurement using strain gauges, which were measured in conjunction with crack detection sensor, are shown in Figure 6.

In this experiment, fatigue cracks were assumed to occur at the points where strain gages CUR and CUL were attached. After 900,000 cycles of loading, the rate of change of C'DC had decreased, so grinder treatments were applied to remove it and prevent crack

Figure 4. Fatigue machine with the specimen.

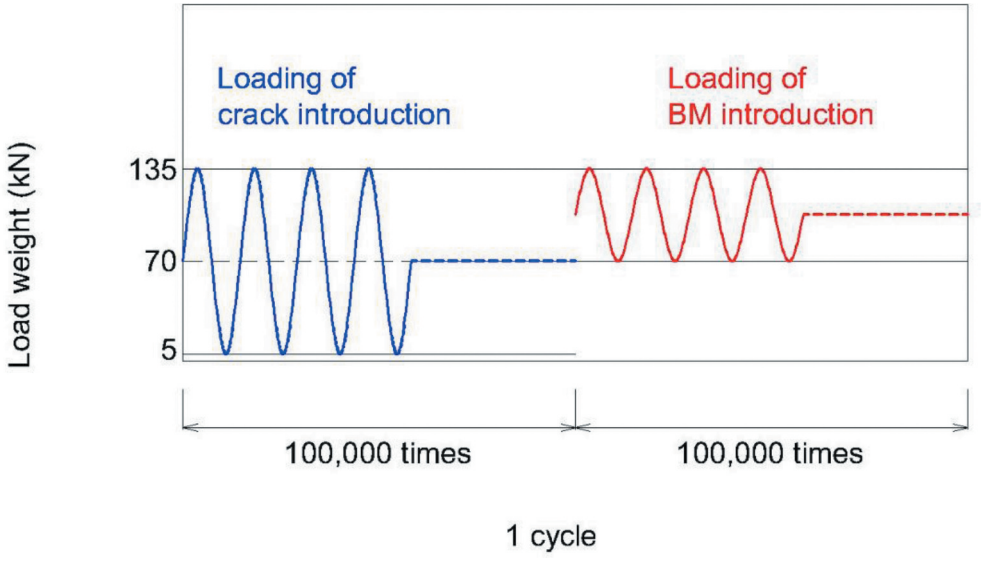

Figure 5. The loading pattern.

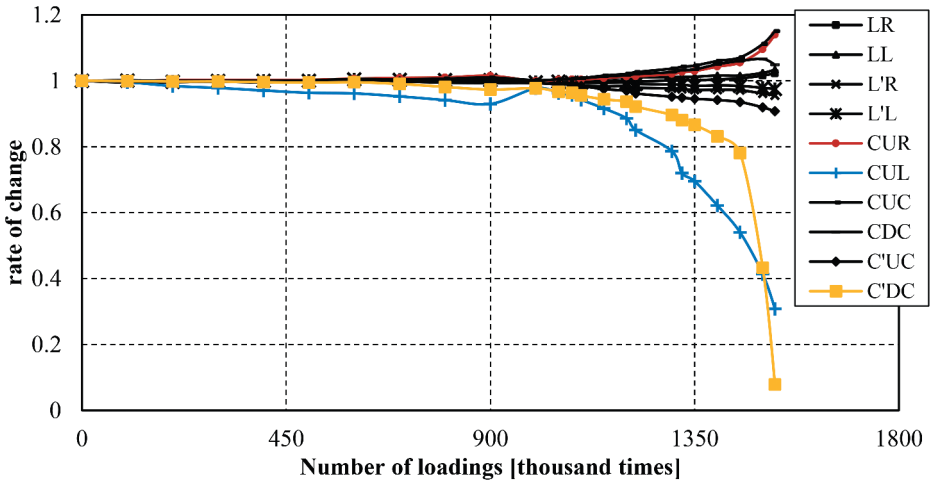

Figure 6. Strain measurement results using strain gauges.

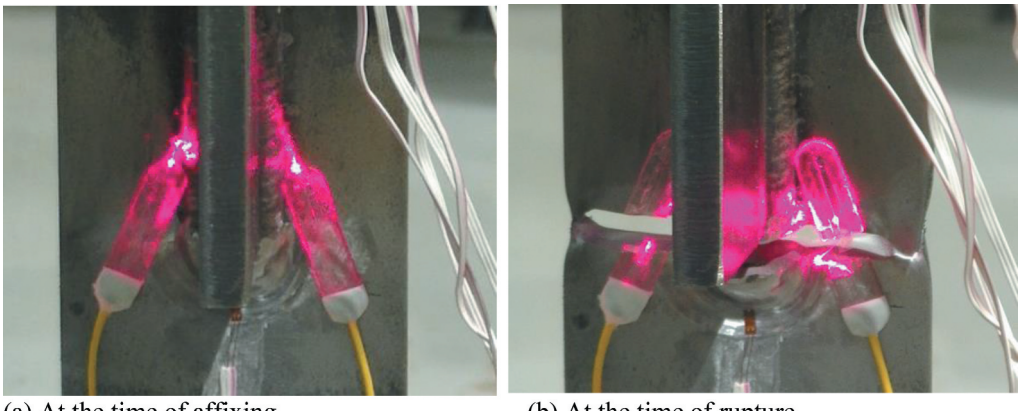
propagation. Thereafter, since the rate of change of CUL was decreasing, it was expected that fatigue cracks would initiate at the planned locations, but at 1.5 million cycles, a sudden change in C'DC occurred. After confirming the position of C'DC, a fatigue crack with a length of about 40 mm was observed from the gusset plate side, so the target location was changed to the position of C'DC, and the crack detection sensor was replaced.

The conditions at the time of attaching the crack detection sensor and at the time of specimen rupture at the end of the test are shown in Figure 7. (a)-(b), respectively.



In Figure 7. (a), it is considered that the optical fiber was slightly broken due to the reattachment of the crack detection sensor, and the entire fiber emitted a slightly red light before the fatigue crack reached the sensor. If the optical fiber is not damaged and is correctly attached, only the upper end of the crack detection sensor emits light (Figure 8.).

As the crack propagated and the crack width increased, the light at the top of the sensor became slightly weaker, and the light emission at the crack was confirmed.

However, it is important to verify the response of the crack detection sensor at small crack widths.

Figure 7 (b) shows that when the specimen ruptured, the sensor also ruptured, and a strong light emission was observed at the ruptured point.

The fracture surface of the specimen is shown in Figure 9. Figure 9. shows that six beach marks were observed between 1 million and 1.5 million times of crack introduction loading.

(a) At the time of affixing (b) At the time of rupture

Figure 7. Changes in detection sensors.

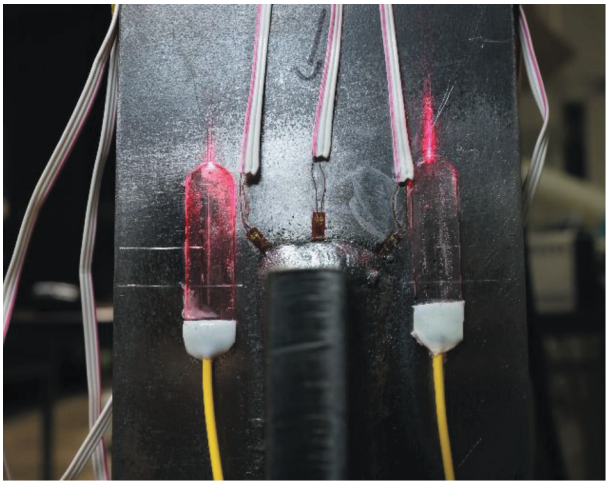


Figure 8. The correct state of the detection sensor when affixed.

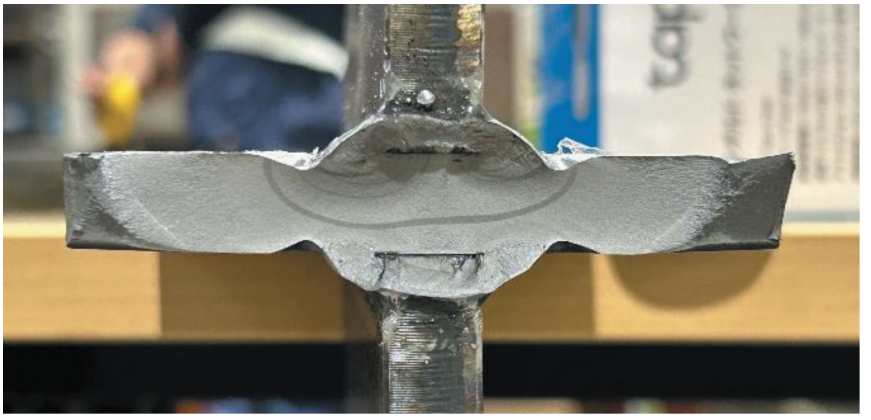

Figure 9. Fracture surface.

4 CONCLUSIONS

Although the crack detection sensor emitted light when the fatigue crack width was large or when the specimen was ruptured, the effectiveness of the sensor for small crack widths still needs to be verified.

In the future, we will continue to verify the effectiveness of the sensor using a crack detection sensor with high detection accuracy (detection accuracy: 0.05 mm).

ACKNOWLEDGEMENTS

Ms. Saito and Mr. Ohno supported the fatigue tests. We would like to express our gratitude to them.

Fatigue crack monitoring by measuring strain without loading

T. Ishikawa & N. Matsumoto
Kansai University, Suita-shi, Osaka, Japan

K. Komon
Asco Co., Ltd., Tottori, Japan

ABSTRACT: The authors have previously proposed a method to evaluate fatigue crack initiation by monitoring changes in strain near the weld toe under unloading conditions. In this method, the alteration in strains resulting from the release of residual stress is utilized. However, if fatigue cracking has already initiated, the change in strain under the unloading condition at the weld toe is minimal. Therefore, the authors shifted their focus to the area around the fatigue crack tip. In this study, it was discovered that fatigue crack propagation can be detected through changes in strain under unloading conditions. Furthermore, considering the application to monitoring in real bridges, wireless strain measurement logger with LPWA was used to measure the strain at the crack tip under unloading conditions. It was found that the measurement results of the strain logger with LPWA show the same tendency to those of dynamic strainmeters.

1 INTRODUCTION

Fatigue damage is a typical cause of damage to steel road bridges, and many cracks have been found on steel bridges, particularly on urban motorways and on heavily trafficked routes. Smaller fatigue cracks are removed by grinding, however when the fatigue cracks have propagated 10 to 50 mm, emergency counter measures such as stop-hole methods (Miki et al. 1990; Okura and Ishikawa 2002; Chen 2016) are applied in Japan, until permanent repairs are conducted. Therefore, the technologies to monitor the fatigue crack growth at a low cost during their tentative repair to permanent repair is strongly required. Monitoring is also considered for cases where the slow fatigue crack growth or for fatigue cracks in secondary members.

Various methods have been proposed for fatigue crack monitoring, they are fatigue damage monitoring sensors (Komon et al. 2003) and crack gauges. However, they are not suitable for periodic checks of crack growth. Recently, the introduction of monitoring systems utilizing communication standards such as LPWA (Low Power Wide Area) enabling low-power and long-term measuring, which although limited in the amount of data to be transmitted, is advancing for cost-effective monitoring (Kobayashi and Ohara 2019, Sekiya et al. 2020).

The authors propose a method to evaluate the initiation and progression of fatigue cracks by periodically measuring strains near the welded end of a fillet-welded gusset joint without loading. Previous studies have focused on the welded end near the crack initiation point. Strains near the welded end exhibit significant changes during fatigue crack initiation and propagation, as this method measures the strain change resulting from the released residual stress. Furthermore, strain measurements without loading eliminate the need for applied loading, making it suitable for static measurements. Hence, the proposed method aligns with cost-effective monitoring, such as IoT monitoring using LTE-M or LPWA. However, proposed method is not suitable for evaluation of already well growth fatigue cracks, because the residual stress is mostly released for longer fatigue cracks.

DOI: 10.1201/9781003483755-259

This study focuses on the strain changes in the main plate section where fatigue cracks propagate, specifically in the vicinity of the fatigue crack tip. Strain measurements during unloading conditions in the vicinity of the fatigue crack tip are conducted in fatigue tests to clarify whether the evaluation of fatigue crack progression can be achieved through changes in strains during unloading conditions. Additionally, considering the application to monitoring in real bridges the strain changes were measured under unloading conditions by a developed strain data logger with LPWA and transmitted to the web server. The measurement results of the strain loggers with LPWA were found to show the same tendency as those of dynamic strainmeters.

2 FATIGUE TEST

2.1 *Test specimens*

In this study, bending fatigue tests were conducted using out-of-plane gusset-joint specimens. The strain at the tip of fatigue cracks developed in the test specimen was measured during without loading using dynamic strainmeters and wireless strain measurement devices. The fatigue tests employed the plate bending fatigue test machine as described in the references (Yamada et al., 2007). For all specimens, the fatigue tests were conducted with a stress ratio, R, as -1, resulting in the average strain corresponding to the without loading conditions.

The out-of-plane gusset welded-joint specimens used in this study consisted of a 12mm thick main plate and a 12mm thick, 100mm high gusset plate fillet welded together using semi-automatic CO_2 gas shielded arc welding. Fillet welds with equal leg lengths of 6mm were used. The mechanical properties and chemical compositions of the steel plate used in this study are listed in Table 1. In all specimens, JIS-SM490Y with a guaranteed yield stress of 365 MPa was used.

Table 1. Material properties and chemical compositions.

Steel	Thickness (mm)	Yield stress (MPa)	Tensile strength (MPa)	Elongation (%)	Chemical compositions (%)				
					C	Si	Mn	P	S
SM490Y	12	434	567	26	0.16	0.44	1.37	0.018	0.007

2.2 *Definition of crack length*

In this study, the crack length, shown in Figure 1, was defined as follows:

$N_{5\%}$: the stage where fatigue cracks originated from the end of the fillet weld, and the strain range of gauge AL decreased by 5%;

N_b: the stage where fatigue cracks originated from the end of the fillet weld and started progressing away from the weld towards the main plate.

N_{10}: the stage where fatigue cracks progressed 10mm away from the end of the fillet weld.

away from the end of the fillet weld.

Subsequently, N_{20} and N_{30} are defined the stage where fatigue cracks progressed 20mm and 30mm away from the end of the fillet weld. The crack initiated from the back surface of the main plate was defined as N_f. The fatigue test was finished when the crack length reached to N_{30}.

2.3 *Strain measurement positions*

Figure 2 shows the strain gauges positions attached to the main plate of the test specimens. Similar to the reference (Ishikawa et al., 2022), the stress range was determined by multiplying Young's modulus of the steel (E_s = 200 GPa) by the average value of the

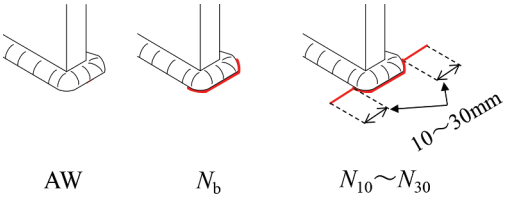

Figure 1. Definition of crack length.

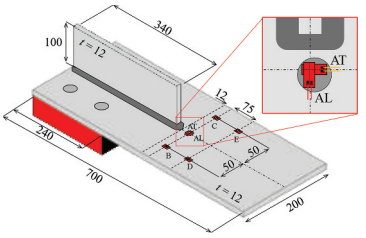

Figure 2. Out-of-plane gusset specimens.

strain range measured from strain gauges B and C during the initial loading. Figure 3 shows the strain gauge attachment positions at the crack tip. In specimen AW120, strain gauges with a gauge length of 5mm were attached radially at N_{10}, N_{20}, and N_{30} from the crack tip. In specimen AW90, strain gauges with a gauge length of 1mm were attached axially at ±5mm from the crack tip in the gusset axis direction and at N_{10}, N_{20}, and N_{30} in the crack propagation direction. Since the evaluation in this study focused on the progression of fatigue cracks, strain gauges were attached to AW120, and AW90 after N_b of fatigue crack progression.

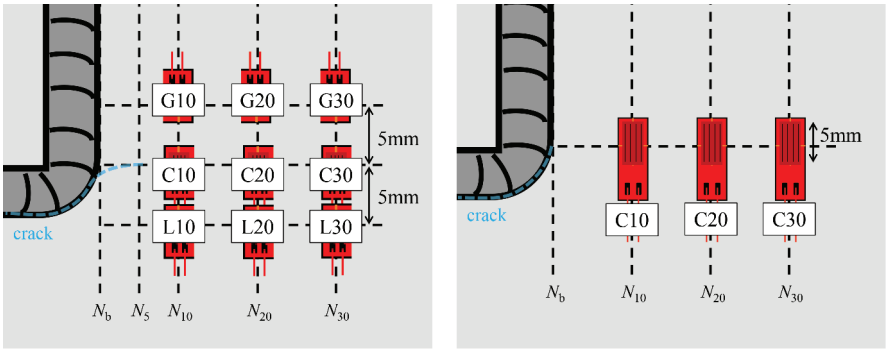

Figure 3. Strain gauges positions.

Table 2. Specimens and fatigue strength.

Specimens	Stress range (MPa)	Fatigue strength ($\times 10^4$)					
		$N_{5\%}$	N_b	N_{10}	N_{20}	N_f	N_{30}
AW120	122.1	10.2	21.4	34.8	45.6	45.6	54.9
AW90	90.8	35.5	63.9	96.9	119.3	131.8	142.1

3 STRAIN CHANGE UNDER UNLOADING CONDITIONS IN FATIGUE TEST

3.1 *Strain near the weld toe under unloading conditions*

Table 2 presents the fatigue test results for all specimens in this study and the fatigue strength for each crack length.

Figure 4 illustrates the relationship between the strain near the weld toe under unloading conditions since the start of the fatigue test and the number of cycles obtained from the fatigue test of AW120. This figure also includes the corresponding fatigue strengths. From Figure 5,

it can be observed that, due to the initiation and propagation of fatigue cracks, the strain under unloading conditions at gauge AL decreased as tensile residual stress was relieved. Gauges B and C show an increase in the strain under unloading conditions due to the redistribution of residual stress, while gauge AT exhibits an increase in compressive residual stress release. Gauges D and E, located away from the weld toe, show no significant changes. Therefore, even when fatigue cracks grow up to N_{30}, it is possible to evaluate the initiation and progression of fatigue cracks based on the changes in strain under unloading conditions near the weld toe, similar to the findings in the reference (Ishikawa et al. 2022).

Figure 5 represents the relationship between the strain change near the weld toe and the number of cycles from N_b in the fatigue test of AW120 under unloading conditions. It can be observed that the strain near the crack tip and near the weld toe changes with the growth of fatigue cracks. As can be seen from Figure 5, the change in strain under unloading conditions near the weld toe after the fatigue crack of N_b is smaller than the change of strain from the as-welded condition. Therefore, it is assumed that the change in strain under unloading conditions near the weld toe is not suitable for the monitoring of fatigue crack propagation, as the change in strain under unloading conditions becomes smaller for longer fatigue cracks.

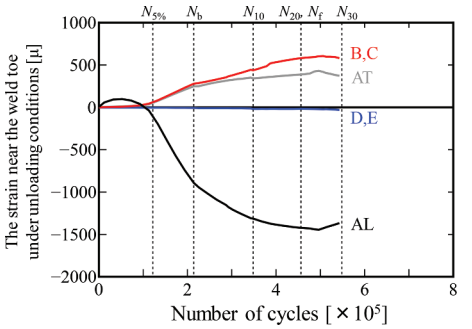

Figure 4. Strain change from as-welded condition.

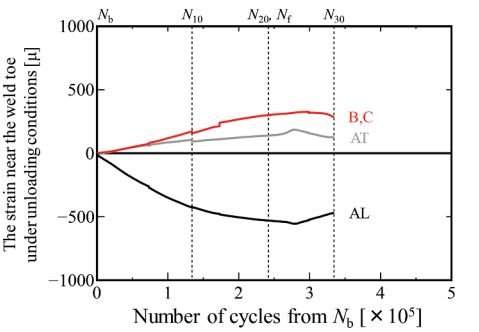

Figure 5. Strain change from N_b.

3.2 *Strain near the crack tip under unloading conditions*

Figure 6 presents the relationship between the strain change near the crack tip and the number of cycles from N_b in the fatigue test of AW120 under unloading conditions. It can be observed that the strain near the crack tip changes with the progression of fatigue cracks. From Figure 6, the strain near the crack tip under unloading conditions gradually increases with the progression of fatigue cracks. This is influenced by the redistribution of residual stress due to the progression of fatigue cracks and the transition of small-scale yielding at the crack tip with crack propagation. Additionally, it is noticeable that the strain increases sharply as the crack position approaches the strain gauges.

Figure 7 shows the results of magnetic particle inspection, MT, after the fatigue test of AW120. It can be seen from the figure that the crack tip aligns with the strain gauge. Since strain gauges were attached to match the center of gauges at N_{10}, N_{20}, and N_{30} with the crack tip in AW120, when the crack tip and strain gauge positions coincide, it indicates that the fatigue crack cut through the metal resistance of the strain gauge, making it unreadable just reaching each crack length. Therefore, it is considered that the evaluation of fatigue crack progression can be achieved not only by the values of strain under unloading conditions but also by the breakage of strain gauges.

Figure 8 illustrates the relationship between the strain near the crack tip under unloading conditions and the number of cycles from N_b, in the fatigue tests of AW90. From Figure 8, the strain near the crack tip under unloading conditions increases as the fatigue crack approaches the measurement position. This is considered to be due to the effect of small-scale yielding at the fatigue crack tip, similar to AW120. However, the strain under unloading

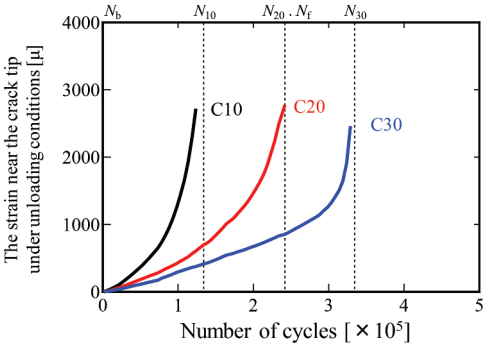

Figure 6. Strain change near the crack tip.

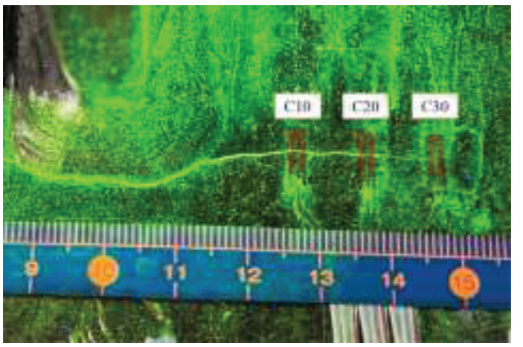

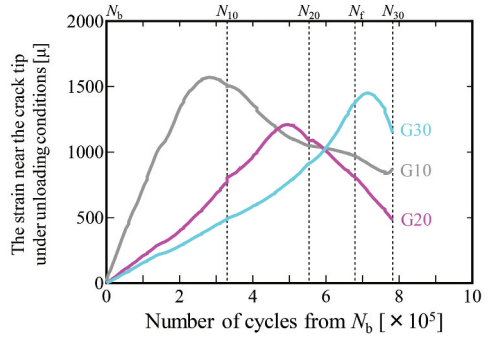

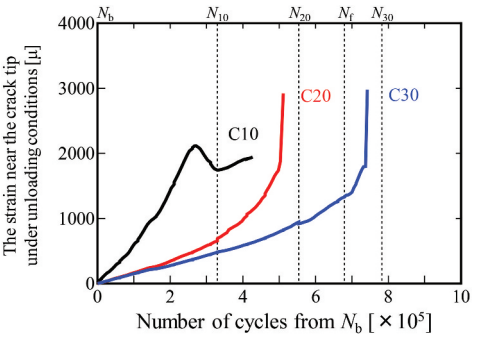

Figure 7. Fatigue crack on AW120.

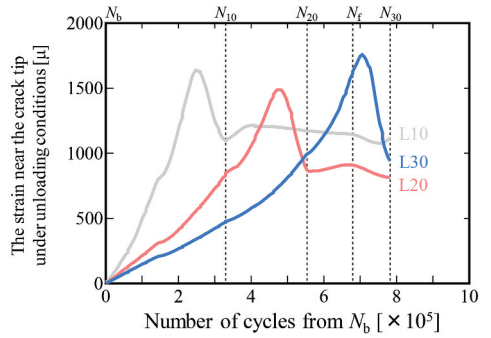
conditions at C10 for AW90 decreases as the fatigue crack approaches, in contrast to other positions. Figure 8(d) shows the results of MT after the fatigue tests of AW90. From the fatigue crack in Figure 8(d), it is assumed that this is due to the distance between the fatigue crack and the strain gauge positions where the strain decreases under unloading conditions. Therefore, at position C10 for AW90, where the strain change due to the small-scale yielding at the crack tip was smaller when the crack approached, the trend differed compared with the strain change in Figure 6. Therefore, it is clarified that when the crack tip and strain gauge positions do not coincide, strain under unloading conditions increases once as the fatigue crack approaches, but then tends to decrease.



Therefore, when fatigue cracks have already propagated, measuring the strain under unloading conditions around the crack tip is more suitable than near the weld toe.

(b) Strain change in C10, C20 and C30

(c) Strain change in L10, L20 and L30

(d) Fatigue crack on AW90

Figure 8. Strain change under unloading conditions and fatigue crack on AW90.

Additionally, considering that the cut of strain gauges serves as a fuse for crack detection, it is advisable to use longer strain gauges with a length suitable for capturing the tip of the fatigue crack. On the other hand, even when the fatigue crack is away from the crack tip, it was shown that the strain under unloading conditions also changes significantly. Therefore, even when the fatigue crack is relatively small, and the progression direction is unpredictable, it is possible to monitor the progression of fatigue cracks.

4 FATIGUE CRACK PROPAGATION MONITORING VIA IOT

4.1 *Strain data logger with LPWA*

In the fatigue test of AW120, considering the application to monitoring in real bridges, the wireless strain measurement logger with LPWA was used to measure the strain at the crack tip under unloading conditions. The wireless strain measurement equipment consists of a single-board computer (Arduino Uno R3), LPWA communication device (Sigfox Shield for Arduino: UnaShield V2S), and a 2-channel strain amplifier shield AD8426 (Robotshop) for strain measurement, as shown in Figure 9. This small IoT device amplifies the voltage obtained from the strain gauge, converting it into integer data ranging from 0 to 1,023 for a voltage range of 0 to 5V (strain measurement range approximately ±2,000μ). This wireless strain measurement device allows strain measurements at approximately 1,000Hz. To connect the strain gauge (1mm gauge length, 2.4mm base width) used in regular fatigue tests, a bridge was formed using 120Ω metal film resistors (VISHAY) with an allowable error of ±0.1%. With this configuration, measurements were conducted every 2 hours for about 3 seconds each using a 2,500mA secondary battery, enabling a monitoring duration of six months. Furthermore, using the same configuration, displacement was measured with 2 channels, and monitoring was possible for 18 months.

In this study, data measured with the wireless strain measurement device were transferred through LPWA Sigfox, and fatigue crack progression monitoring was conducted on an online platform.

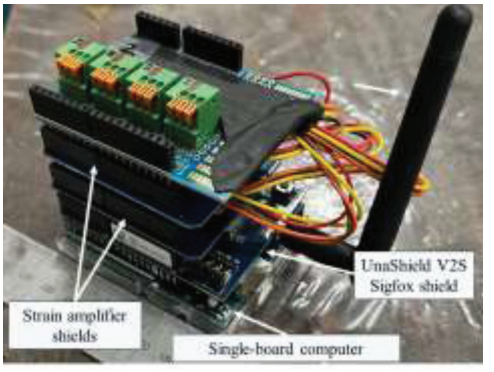

Figure 9. Strain data logger with LPWA.

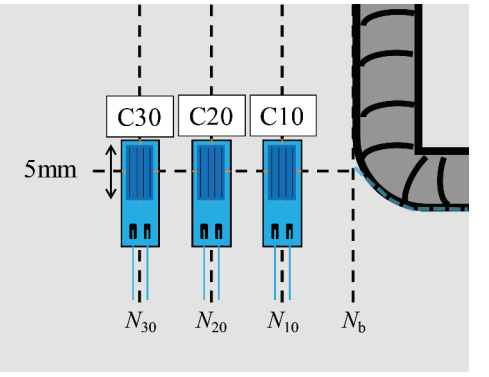

Figure 10. Strain gauges positions for IoT.

4.2 *Measurement positions*

To compare with the dynamic strain measurement in AW120, the strain gauges were attached right next to AL and next to the strain gauges B and C in Figure 2. For near the crack tip, the strain gauges of 5 mm gauge length were used as shown in Figure 10 for the wireless strain measurement with LPWA.

In this study, maximum and minimum strains were measured at the same intervals as the strains measured by dynamic strainmeters, for a period of approximately 3 seconds. The

average strain corresponding to the unloading conditions, which are average strains, was calculated and transmitted to the web server via LPWA.

4.3 *Results of fatigue crack growth monitoring via developed logger with LPWA*

Figure 11 shows the relationship between the change in strain under unloading conditions at strains AL, B and C and the number of cycles obtained from the fatigue test of AW120. The results obtained with the dynamic strainmeters (2,000Hz) from Figure 5 are also drawing. It can be observed from the figure that the strains under unloading conditions measured with the dynamic strainmeters and the wireless strain measurement logger are almost identical.

Figure 12 illustrates the relationship between the change in strain under unloading conditions at the crack tip and the number of cycles obtained from the fatigue tests of AW120. Similar to the measurements with the dynamic strainmeters in Figure 6, it can be seen that the strain under unloading conditions increases with the progression of fatigue cracks.

In AW120, the strain under unloading conditions increased by approximately 2,000 μ due to the fatigue crack growth. After that, the strain under unloading conditions remained constant at around 3000μ, this is because the fatigue crack propagation cut the strain gauge. In this manner, not only can fatigue crack growth be monitored from the change in strain under unloading conditions, but also alerts can be given by the cut of the strain gauge.

Therefore, as it was possible to monitor the fatigue crack growth using the strain data logger with LPWA, the developed wireless strain data logger could be used for the monitoring of fatigue crack growth on real bridges.

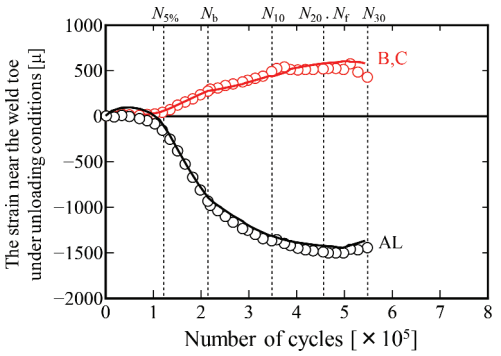

Figure 11. Strain change at AL, B and C.

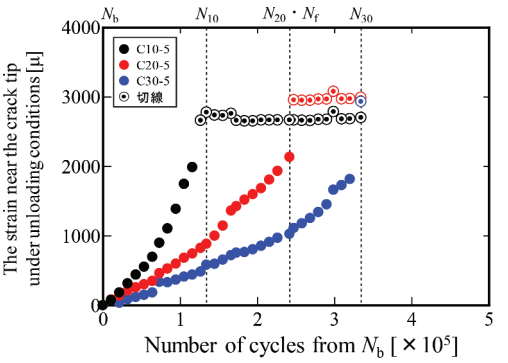

Figure 12. Strain change near the crack tip.

5 CONCLUSIONS

In this study, the authors focused on the strain changes near the crack tip under un-loading conditions for the crack propagation monitoring. Fatigue tests of out-of-plane gusset specimens were conducted to assess the propagation of fatigue cracks based on the changes in strain during unloading conditions. Additionally, the developed strain data logger with LPWA was used to measure the strain under unloading conditions. The main conclusions of this study are below:

1) Strain at the crack tip significantly increases during unloaded conditions due to the redistribution of residual stress and the small-scale yielding of fatigue cracks.
2) Longer strain gauges, capturing the tip of fatigue cracks more effectively, are recommended, as they can be used as an alert system when the fatigue crack propagation cuts the strain gauges.
3) Clear changes in strain during unloaded conditions were observed even in regions away from the crack tip, enabling the monitoring of crack growth in cases of relatively small cracks or unpredictable propagation directions.

4) Strain data loggers with LPWA were able to identify strain changes at the crack tip under unloading conditions and detect gauge cuts due to fatigue crack propagation. Thus, the feasibility of monitoring using IoT technology was demonstrated.

Mechanical properties of steel tube with partially bonded CFRP

Y. Maeda, M. Mizutani & T. Ishikawa
Kansai University, Suita-shi, Osaka, Japan

ABSTRACT: CFRP bonded repair is the one of the repair methods for corroded steel structures. The workability of this method is better than the conventional steel patch repairs. Therefore, this method is sometimes applied for deteriorated sign posts and lighting columns. However, the debonding of CFRP from adhesive ends is one of the concerns about the CFRP bonded repair. To prevent the debonding of CFRP in the repair design, the shear stress or energy release rate in the adhesive layer is applied to the design verification in Japan. In this study, to evaluate the shear stress in adhesive layer, the shear-lag theory was applied to the steel tubes repaired by partially bonding CFRP subjected to bending moment. Additionally, the shear-lag theory of multiple bonded CFRP partially was also derived for the repair of the steel tubes under bending moment. Then, finite element analysis was performed to confirm the validity of the derived equations.

1 INTRODUCTION

Steel tube structures are used for signposts, steel tube trusses, and steel piers. The bases of sign posts and steel bridge piers embedded in road pavements such as concrete or asphalt are prone to crevice corrosion. In addition, the base of sign or light posts are often strengthened by ribs, therefore corrosion and fatigue cracks also occur at rib welding. Carbon fiber reinforced plastic (CFRP) bonded repair is one of the repair methods for steel tubes (Linden et al. 2014, Matsumura et al. 2017). This method is easy to handle and provides corrosion protection because CFRP has excellent material properties such as lightweight and corrosion resistant. CFRP bond repair have many applications for the repair corroded steel bridge members (Moy and Bloodworth. 2007).

CFRP-bonded repair of steel members has to check the prevention of the debonding of CFRP and to consider the force transmission delay by the adhesive layer. Shear stress, principal stress, or energy release rate in the adhesive layer are the parameters of check the prevention of debonding of CFRP in Japan(Japan Society of Civil Engineers (JSCE) 2018).

For the repair of deteriorated steel tubes by CFRP bonding, it has to check the prevention of debonding of CFRP. In addition, CFRP bonded repair requires a longer bond length than the repaired region because the CFRP at the adhesive ends does not transmit the sectional forces enough (JSCE, 2018).

Equations for calculating the shear stress and energy release rate in the adhesive layer and the required bond length when the CFRP bonded to the entire circumference of a steel tube have been proposed (Mizutani and Ishikawa. 2022). These equations were based on the shear-lag theory. The shear-lag theory assumes that the shear force in the adhesive layer transmitted the sectional forces between members, and mechanical properties can be evaluated by solving differential equations derived from the balance of forces in an infinitesimal element. However, it is not applicable for the cases which CFRP is partially bonded for steel tube structures, such as CFRP bonded repairs of the base of steel signposts with welded ribs. Partial CFRP bonding repair might be applied the partial corrosion in steel tube structures. Therefore, the authors consider that it is necessary to derive a theory that corresponds to partial CFRP bonding.

DOI: 10.1201/9781003483755-260

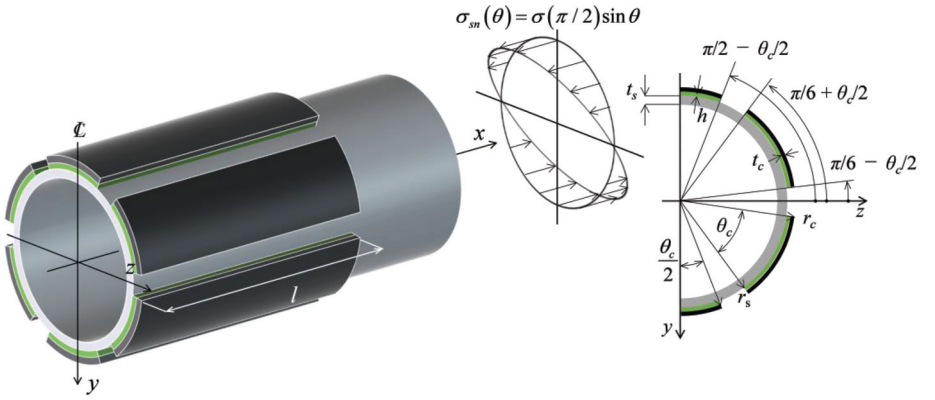

Figure 1. Dimension of partially CFRP bonded steel tube.

In this study, it is considered that the partially CFRP-bonded steel tube subjected to pure bending moments, as shown in Figure 1. The shared bending moments in the steel tube and CFRP, and the shear stress in the adhesive layer are derived by shear-lag theory. The derived shared bending moments and shear stress are validated using the finite element analysis. In addition, an equation for calculation of required bond length of partially CFRP bonded steel tube. Furthermore, the shear-lag theory for steel tubes with partially multiple CFRP bond repair is also derived.

2 SHEAR-LAG THEORY FOR PARTIALLY CFRP BONDED STEEL TUBE SUBJECTED TO PURE BENDING

2.1 *Dimension of model*

Figure 1 shows the steel tube with partial CFRP bond repair under pure bending. The CFRP is bonded symmetrically to the y and z axes in the range of θ_c in Figure 1. Therefore, the figure centers of the CFRP and steel tubes coincide. As shown in Figure 1, the outer radii of the steel tube and CFRP are r_s and r_c, respectively, the plate thicknesses of the steel tube and CFRP are t_s and t_c, and the thickness of the adhesive layer is h. The adhesive half-length of the CFRP is l.

2.2 *Differential equation and its solution*

The shear-lag theory for CFRP bonded steel tube has been proposed (Mizutani and Ishikawa. 2022). In this, the equations of shared bending moments of the steel tube and CFRP and the shear stress of the adhesive layer have been derived for the case of CFRP-bonded steel tubes subjected to pure bending. In the same way, the shared bending moment of the steel tube for the partially CFRP bond repair of steel tubes is derived by the following equation:

$$M_s = B_1 \cosh(c_b x) + B_2 \sinh(c_b x) + \xi_{0b} M \tag{1}$$

where,

$$c_b = \sqrt{\frac{G_e}{h}\left(r_s + \frac{h}{2}\right)^3 Z_b \frac{1}{E_s I_s} \cdot \frac{1}{1-\xi_{0b}}} \tag{2}$$

$$\xi_{0b} = E_s I_s / (E_s I_s + E_c I'_c) \tag{3}$$

E_s and E_c are Young's modulus of steel tube and CFRP, respectively, and I_s and I'_c are the sectional secondary moments of steel tube and CFRP, respectively.

In Equation (2), Z_b is the value of the definite integral with respect to the bonded range of CFRP. The number of partially CFRP bonded range is set to $2n$ by considering the symmetrical CFRP bonding. Z_b is given by the following equation:

$$Z_b = 4\int_{\theta} \sin^2\theta d\theta = n\theta_c \tag{4}$$

In the case of six part of CFRP bonding rage shown in Figure 1, Z_b is given by the following equation:

$$Z_b = 4\int_{\pi/6-\theta_c/2}^{\pi/6+\theta_c/2} \sin^2\theta d\theta + 4\int_{\pi/2-\theta_c/2}^{\pi/2} \sin^2\theta d\theta = 3\theta_c \tag{5}$$

The center of the bonded CFRP length is set to $x = 0$. The undetermined coefficient B_2 becomes zero because the bending moment M_s in the steel tube is symmetrical at $x = 0$. The undetermined coefficient B_1 is given by $B_1=(1\text{-}\xi_{0b})M/\cosh(c_b l)$ under the condition that the shared bending moment M_s in the steel tube at $x = l$ is equal to the applied bending moment M. Substituting the undetermined coefficients B_1 and B_2 into Equation (1), the shared bending moment M_s in the steel tube, is obtained. The shared bending moment M_c in CFRP is obtained from $M_c = M - M_s$. Therefore, the shared bending moment in the steel tube and CFRP and the shear stress in the adhesive layer are given by the following equations.

$$M_s = \left\{(1-\xi_{0b})\frac{\cosh(c_b x)}{\cosh(c_b l)} + \xi_{0b}\right\} M \tag{6}$$

$$M_c = (1-\xi_{0b})\left\{1 - \frac{\cosh(c_b x)}{\cosh(c_b l)}\right\} M \tag{7}$$

$$\tau(\theta) = \frac{c_b(1-\xi_{0b})}{(r_s + h/2)^2 Z_b}\frac{\sinh(c_b x)}{\cosh(c_b l)}\frac{I_s}{r_s}\sin\theta\sigma_{sn}(\pi/2) \tag{8}$$

where, $\sigma_{sn}(\pi/2)$ is the nominal stress ($\sigma_{sn}(\pi/2) = -M\, r_s/I_s$) acting on the steel tube end at $\theta = \pi/2$. The shear stress $\tau(\theta)$ in the adhesive layer is zero except the angle where the CFRP is bonded.

3 STRESS DISTRIBUTIONS OF PARTIALLY CFRP-BONDED STEEL TUBE

Finite element analysis was performed on the model subjected to pure bending moments using the analysis program Marc. The material properties applied to the analysis are listed in Table 1. The example of the analytical model is shown in Figure 2. The nominal stress acting on the steel tube end $\sigma_{sn}(\pi/2)$ is set as -100 N/mm^2.

The material property of CFRP in Table 1 takes into account the orthogonal anisotropy material of CFRP. CFRP is a composite material composed of carbon fiber and resin. It is known that when the volume of carbon fiber in CFRP is small, the shear deformation of the matrix resin cannot be ignored. A simple method has been proposed to account for the shear deformation of the matrix resin in CFRP into the height of the adhesive layer between the steel plate and CFRP for the shear-lag theory of CFRP bonded steel plates (Mizutani et al. 2019). This method is also used in this study. The shear-lag of CFRP can be accounted for by replacing the adhesive thickness h in Equation (2) with the converted adhesive layer thickness h' given by the following equation.

$$h' = h + \frac{t_c}{3}\frac{G_e}{G_{xy}} \tag{9}$$

Table 1. Dimension and material properties.

	Steel tube	CFRP

* In finite element analysis, the orthogonal anisotropy about the x-axis

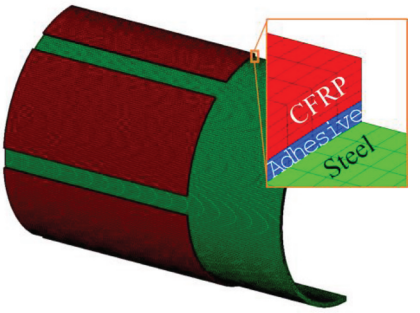

Figure 2. Example of FE model of partially CFRP-bonded steel tube.

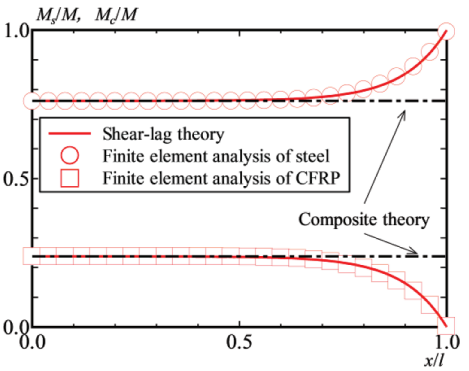

Figure 3. Shared bending moments of the steel tube and CFRP.

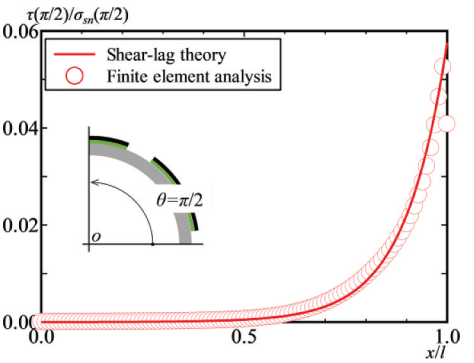

Figure 4. Shear stress in the adhesive layer.

where G_{xy} is the elastic shear modulus of CFRP in the x-axis direction.

Figure 3 shows the moment distribution of the analytical values and the theoretical values obtained from Equations (6) and (7). The vertical axis shows the shared bending moments M_s or M_c divided by the applied bending moment M. The horizontal axis is x divided by the half bond length l. The analytical values from the finite element analysis were converted from stresses in each section to bending moments. From Figure 3, it can be seen that the theoretical and analytical values have similar distributions. It can also be seen that the moments close to the composite theory as nearer to the center from the end of the adhesive.

The theoretical values of shear stress in adhesive layer obtained from Equation (8) and the analytical result are plotted in Figure 4. The vertical axis shows the shear stress $\tau(\pi/2)$ at $\theta = \pi/2$ divided by the applied stress $\sigma_{sn}(\pi/2)$ and the horizontal axis shows the distance x from the center of CFRP divided by the half bond length l. As can be seen from Figure 4, the theoretical and analytical values are good agreement.

4 REQUIRED BOND LENGTH AND CONVERGENCE VALUE OF SHEAR STRESS

4.1 *Required bond length*

As shown in Figure 3, the shared bending moments of the steel tube and CFRP close to the values of the composite theory as the x is close to zero. Until convergence to the composite theory, the sectional forces transmission between steel tube and CFRP is insufficient. Therefore,

it is necessary a longer CFRP bonding than the repair area of the steel tubes. The bond length outside the repaired area is called the required bond length (Mizutani and Ishikawa. 2022).

From Equation (6), if the bonded half-length l of the CFRP is sufficiently long, the moment in the steel tube converges to the value $\xi_{0b}M$ of the composite theory. For Equation (6) and $\xi_{0b}M$ to be equal, the bonded half-length l is infinite. Therefore, the rate of convergence of the steel tube stress to $\xi_{0b}M$, η_b is applied to determine the required bond length. The rate of convergence is defined by $\eta_b \geq M_s|_{x=0}/(\xi_{0b}M)$. The equation for the required bond length l_n in CFRP bonded steel tubes subjected to pure bending moment is given by the following equation;

$$l_n \frac{1}{c_b}\cosh^{-1}\left\{\frac{1}{\eta_b - 1}\cdot\left(\frac{1}{\xi_{0b}} - 1\right)\right\} = \frac{1}{c_b}\cosh^{-1}\left(\frac{1}{\eta_b - 1}\cdot\frac{E_c I'_c}{E_s I_s}\right) \tag{10}$$

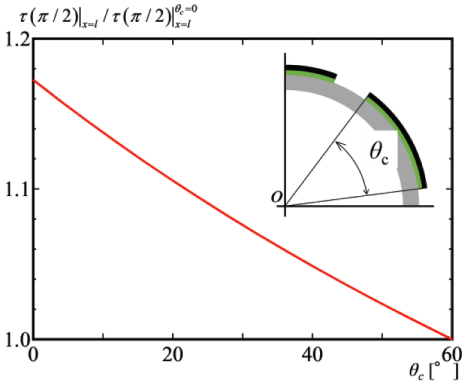

Figure 5. Shear stress in the adhesive layer.

4.2 *Convergence value of shear stress at CFRP end*

The energy release rate is one of the parameters used for design check of prevention of debonding of CFRP. The energy release rate is expressed as $G = (h\,\tau_e^2)/(2G_e)$ using the shear stress τ_e occurring at the CFRP end (JSCE. 2018). From Equation (8), if the bonded half-length l of CFRP is infinity, the shear stress $\tau(\pi/2)|_{x=l}$ at the CFRP end converges to the following equation;

$$\tau\left(\frac{\pi}{2}\right)\Big|_{x=l} = \frac{c_b(1-\xi_{0b})}{(r_s + h/2)^2 Z_b}\frac{I_s}{r_s}\sigma_{sn}(\pi/2) \tag{11}$$

Figure 5 shows the relationship between the range θ_c of bonding angles and the shear stress at the CFRP end. When $\theta_c = 60°$, the CFRP is bonded all around. As shown in Figure 5, the smaller the range of bonding angles, the higher the shear stress at the adhesive end. Therefore, the smaller the range of bonding angles is prone to debonding of CFRP. However, when θ_c=0°, there is no CFRP and no shear stress occurs.

The authors consider that the maximum value of shear stress shown in Figure 5 can be used to simplify the design check for the prevention of the debonding of CFRP. When the CFRP is bonded to the top of the steel tube, the shear stress is highest at $\theta = \pi/2$. The maximum shear stress at $\theta = \pi/2$ derived as θ_c in Equation (11) equals 0 is given by;

$$\tau\left(\frac{\pi}{2}\right)\Big|_{\theta_c=0} = \frac{M}{E_s I_s}\sqrt{\frac{G_e}{h}\cdot\frac{E_c I_c}{\pi(r_s + h/2)}} \tag{12}$$

Using Equation (12), the shear stress at the edge of the adhesive can be calculated simply, regardless of the adhesive angle. The shear stress value in Equation (12) can also be used to calculate the energy release rate.

5 EIGENVALUE ANALYSIS OF MULTI-LAYERED CFRP BONDED STEEL TUBE

5.1 *First-order simultaneous differential equations for strain*

Carbon fiber sheets and CFRP strand sheets are often used for CFRP bonded to steel tubes. These CFRP sheets are thin and are therefore bonded together in layers. Therefore, in this chapter, an eigenvalue analysis solution for steel tubes partially bonded with multiple layers of CFRP is conducted. The model is shown in Figure 6.

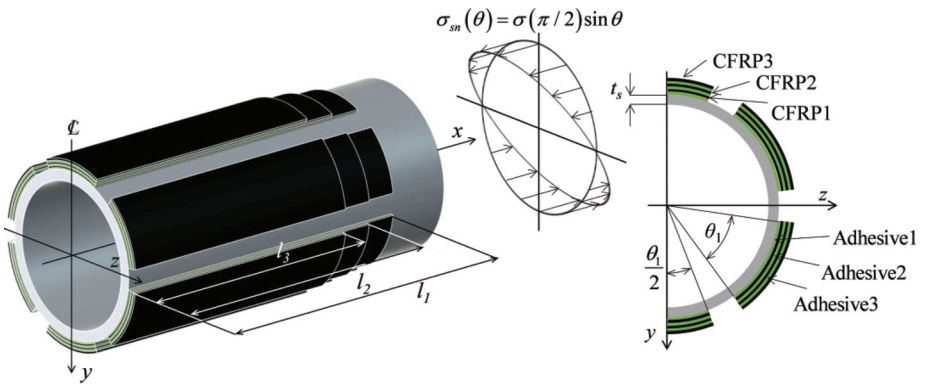

Figure 6. Dimension of multi-layered CFRP bonded steel tube.

Stress analysis methods based on eigenvalue analysis have already been proposed for steel tubes with multi-layer CFRP bonded repair around the circumference (Mizutani and Ishikawa. 2023). This method uses eigenvalue analysis to solve a first-order simultaneous differential equation based on shear-lag theory. This is because the calculation to solve the differential equation becomes more complicated as the number of CFRP layers increases.

In Chapter 2, the previous theory is extended to partially CFRP bonded steel tubes by considering the effect of the range of CFRP bonding angles (Z_b). The same extension was made for eigenvalue analysis in the case of multi-layer CFRP bonded steel tubes.

In eigenvalue analysis, the shared bending moments of the steel tube and CFRP and the shear stress of the adhesive layers are converted into strains and first-order simultaneous differential equations are developed. The simultaneous differential equations in matrix and vector form are given by;

$$d\varepsilon/dx = A_n\varepsilon \tag{13}$$

where $\boldsymbol{\varepsilon}$ is the strain vector. A_n is the coefficient matrix of the first-order simultaneous differential equations. The solution of Equation (13) is given by the following equation by solving the simultaneous homogeneous first-order differential equation expressed in matrix and vector form.

$$\varepsilon = Y_i\mathbf{C}_i = T_i e^{\Lambda_i x} T_i^{-1}\mathbf{C}_i \tag{14}$$

where T is a matrix consisting of the eigenvalue vectors of A_n. Λ is an eigenvalue of A_n and $\mathbf{C}$ is a vector of indeterminate coefficients. Vector $\mathbf{C}$ in Equation (14) is given by the boundary conditions and the continuity conditions of the strain in each axial segmental region of the members. Vector $\mathbf{C}$ is calculated from the following equation;

$$H\mathbf{C} = \mathbf{E} \tag{15}$$

where H is the coefficient matrix and $\mathbf{E}$ is the strain vector due to external forces and continuous conditions.

The vector **F**, which summarizes the shared bending moment in the steel tube and CFRP and the shear stress in the adhesive layer, is related to the strain vector **ε** by the following equation;

$$\mathbf{F} = G\sigma = GD\varepsilon \tag{16}$$

where

$$\mathbf{F} = \{\, M_s \quad M_{c1} \quad \tau_1(\pi/2) \quad \cdots \quad M_{ci} \quad \tau_i(\pi/2) \quad \cdots \quad M_{cn} \quad \tau_n(\pi/2) \,\} \tag{17}$$

$$\boldsymbol{\sigma} = \{\, \sigma_s \quad \sigma_{c1} \quad \tau_1 \quad \cdots \quad \sigma_{ci} \quad \tau_i \quad \cdots \quad \sigma_{cn} \quad \tau_n \,\}^T \tag{18}$$

$$\boldsymbol{\varepsilon} = \{\, \varepsilon_s \quad \varepsilon_{c1} \quad \gamma_1 \quad \cdots \quad \varepsilon_{ci} \quad \gamma_i \quad \cdots \quad \varepsilon_{cn} \quad \gamma_n \,\}^T \tag{19}$$

$$G = diag\{\, I_s/r_s \quad I'_{c1}/r_{c1}\, 1 \cdots I'_{ci}/r_{ci} 1 \cdots I'_{cn}/r_{cn} 1 \,\} \tag{20}$$

$$D = diag\{\, E_s \quad E_{c1} \quad G_{e1} \quad \cdots \quad E_{ci} \quad G_{ei} \quad \cdots \quad E_{cn} \quad G_{en} \,\} \tag{21}$$

M_{ci} is the shared bending moment in CFRP i, and $\tau_i(\theta)$ is the shear stress in adhesive i. I'_{ci} and E_{ci} are the cross-sectional second moment and Young's modulus of CFRP i, respectively, and G_{ei} is the elastic shear modulus of adhesive i.

The matrix A_n in Equation (13) is a sparse matrix with mostly zero components. Therefore, the non-zero elements of A_n are shown in the following.

when $i = 1$

$$a_{1,3} = (r_s + h_1/2)Z_1 G_{e1}/(E_s A_s) \tag{22}$$

$$a_{2,3} = -(r_s + h_1/2)Z_1 G_{e1}/\left(E_{c1} A'_{c1}\right) \tag{23}$$

$$a_{3,1} = 1/h_1 \tag{24}$$

$$a_{3,2} = -1/h_1 \tag{25}$$

when $2 \le i \le n$

$$a_{2i-2,2i+1} = \left(r_{c(i-1)} + h_i/2\right)Z_i G_{ei}/\left(E_{c(i-1)} A'_{c(i-1)}\right) \tag{26}$$

$$a_{2i,2i+1} = \left(r_{c(i-1)} + h_i/2\right)Z_i G_{ei}/\left(E_{ci} A'_{ci}\right) \tag{27}$$

$$a_{2i+1,2i-2} = 1/h_1 \tag{28}$$

$$a_{2i+1,2i} = -1/h_1 \tag{29}$$

where r_{ci} is the outer radius of CFRP i and h_i is the thickness of adhesive i. Z_{bi} is the value of the definite integral with respect to the circumferential bond angle of CFRP i, as in the Equation (4). However, the bond width of CFRP $i + 1$ must not exceed the bond width of CFRP i ($Z_{bi} \ge Z_{b(i+1)}$).

5.2 *Shared bending moments and shear stress distribution in partially multi-layered CFRP bonded steel tubes*

Finite element analyses were performed to compare the results of Eigenvalue analysis. The material properties are shown in Table 2. The misalignment of CFRP ends were set to 25 mm each, so that the CFRP lengths are $l_1 = 250$, $l_2 = 225$, and $l_3 = 200$ mm. However, the material constants of steel tubes are the same as in Table 1.

Figure 7 shows the shared bending moment distribution in steel tubes and CFRP. The vertical axis shows the shared bending moments M_s or M_c divided by the applied bending moment M. From Figure 7, it is shown that the eigenvalue and finite element analyses have similar distributions. Figure 8 shows the shear stress distribution in each adhesive layer. The vertical axis shows the shear stress $\tau(\pi/2)$ at $\theta = \pi/2$ divided by the applied stress $\sigma_{sn}(\pi/2)$. Figure 8, it is shown that Eigenvalue analysis and finite element analysis have also similar distributions. Therefore, the shared bending moments in steel tubes and CFRP and the shear stresses in the adhesive layers can be calculated by Eigenvalue analysis of multi-layered CFRP bonded steel tube.

6 CONCLUSIONS

In this study, shear-lag theory was applied to steel tubes partially bonded with CFRP. Equations of the shared bending moments in steel tubes and CFRP and the shear stresses in the adhesive layer were derived. The validity of the equations given by shear-lag theory was confirmed by the finite element analysis. Additionally, convergence values of the required bond length and shear stresses were also derived. Furthermore, it was shown that the eigenvalue analysis results of the multi-layered CFRP bonded steel tube were also in good agreement with the finite element results.

ABSTRACT: Brittle debonding at adhesive ends may occur when carbon fiber reinforced plastic (CFRP) bonded steel members are subjected to high stress or large deformation, such as compressive buckling. Therefore, to prevent CFRP debonding, the use of a highly ductile putty material (elastic putty) between the steel member and the CFRP has been proposed. From the results of the test and analysis, when the elastic putty is inserted or the CFRP bond length is short, the buckling loads given by the eigenvalue analysis tend to be higher than that obtained by the tests or finite element results. This is because the eigenvalue analysis assumes a perfect composite condition of the steel plate and CFRP. Therefore, in this study, the estimation of the elastic buckling load of CFRP-bonded defective steel plates is proposed by using eigenvalue analysis to take into account the effect of transmission delay by adhesives and elastic putty.

1 GENERAL INSTRUCTIONS

In steel structures, the load-bearing capacity is reduced by loss of cross-section due to corrosion. In Japan, for rehabilitation of damaged steel structures, carbon fiber reinforced plastic (CFRP) has been bonded to damaged steel members since 2000. CFRP is a composite material consisting of carbon fiber and resin. It is lightweight, highly elastic, and corrosion-resistant. However, brittle debonding at adhesive ends may occur when CFRP-bonded steel members are subjected to high stress or large deformation, such as compressive buckling (Okuyama et al., 2011; Cao et al., 2023).

To prevent CFRP debonding, the use of a highly ductile putty material (elastic putty) between the steel member and the CFRP has been proposed (Okuyama et al., 2011; Kazem et al., 2016). The use of elastic putty reduces the stresses concentration in the adhesive and prevents debonding. In addition, by inserting elastic putty, the CFRP can follow large deformations caused by compressive buckling without debonding. However, the use of elastic putty increases the bonding CFRP length by the transmission delay of the sectional forces from the steel member to the CFRP, as well as the stress reduction effect on the steel member becomes smaller than that without the elastic putty.

Uniaxial compression tests and eigenvalue analyses were conducted to evaluate the buckling loads of CFRP-bonded steel plate with and without elastic putty (Ishikawa et al., 2022). From the results of the test and analysis, when the elastic putty is inserted or the CFRP bond length is short, the buckling loads given by the eigenvalue analysis tend to be higher than that

DOI: 10.1201/9781003483755-261

obtained by the tests or finite element results. This is because the eigenvalue analysis assumes a perfect composite condition of the steel plate and CFRP.

Therefore, in this study, the estimation of the elastic buckling load of CFRP-bonded defective steel plates is proposed by using eigenvalue analysis to take into account the effect of transmission delay by adhesives and elastic putty.

2 ESTIMATION OF ELASTIC BUCKLING LOADS

This chapter presents an estimation method of the elastic buckling load of CFRP-bonded defective steel plates. The elastic buckling loads are calculated based on Euler's buckling equation.

The elastic buckling loads can be calculated against the beams with different cross-sectional stiffnesses shown in Figure 1. Okuyama et al. (2011) presented an equation to calculate the elastic buckling load derived from Euler's buckling equation for beams with two different cross sections (beams 1 and 2), as shown in Figure 2(a). This assumes the case of CFRP bonded to intact steel plates. However, for the eigenvalue analysis of CFRP-bonded defective steel plate in Figure 2(b), three regions (beams 1 - 3) as 1/2 symmetry are required. Therefore, the authors derive Euler's buckling equations for the three regions. For the beam (beam i) in Figure 1, the differential equation for the displacement $w_i(x_i)$ is the following equation:

$$\frac{d^4 w_i(x_i)}{dx_i{}^4} - \alpha_i{}^2 \frac{d^2 w_i(x_i)}{dx_i{}^2} = 0 \tag{1}$$

here,

$$\alpha_i = \sqrt{P/(EI)_i} \tag{2}$$

x_i is the axial position from the left end of each beam i; $(EI)_i$ is the bending stiffness of beam i; P is the applied load.

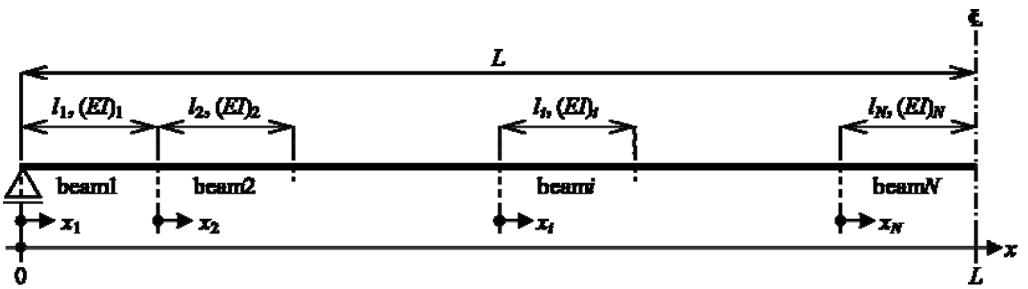
The general solution of Equation (1) is:

$$w_i(x_i) = C_{1i} \sin \alpha_i x_i + C_{2i} \cos \alpha_i x_i + C_{3i} x_i + C_{4i} \tag{3}$$

where,

$$x_i = \begin{cases} x & (i = 1) \\ x - \sum_{j=1}^{i-1} l_j & (i \geq 2) \end{cases} \tag{4}$$

C_{ji} is the undetermined coefficient for beam i (j = 1 to 4).



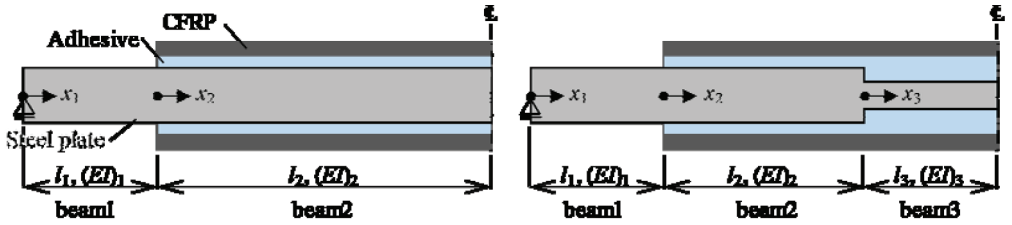


Figure 1. Simply supported beam with variable cross-sectional stiffness (1/2 symmetry).

(a) CFRP bonded intact steel plate (b) CFRP bonded defective steel plate

Figure 2. Beam with CFRP bonded to both sides of a steel plate (1/2 symmetry).

For beams 1 to 3 the total number of undetermined coefficients in Equation (3) is twelve. Each coefficient is given by the continuity and boundary conditions of the displacement $w_i(x_i)$, rotation angle $\theta_i(x_i) = dw_i(x_i)/dx_i$, bending moment $M_i(x_i) = -(EI)_i\, d^2w_i(x_i)/dx_i^2$ and shear force $Q_i(x_i) = -(EI)_i\, d^3w_i(x_i)/dx_i^3$ at each end of the beam i. Okuyama et al. (2011) and Mizutani et al. (2023) presented the equations for the undetermined coefficients in matrix and vector form as follows:

$$[B]\mathbf{C} = 0 \tag{5}$$

where, B is the coefficient matrix; $\mathbf{C}$ is the vector of undefined coefficients.

The condition for Equation (5) to have a non-trivial solution is:

$$\det[B] = 0 \tag{6}$$

For beams consisting of beams 1 to 3, such as CFRP bonded steel plates with sectional defect, the determinant of Equation (6) is the following equation:

$$\begin{aligned} &\alpha_1\alpha_2\cos(\alpha_1 x_1)\cos(\alpha_2 x_2)\cos(\alpha_3 x_3) - \alpha_1\alpha_3\cos(\alpha_1 x_1)\sin(\alpha_2 x_2)\sin(\alpha_3 x_3) \\ &-\alpha_2{}^2\sin(\alpha_1 x_1)\sin(\alpha_2 x_2)\cos(\alpha_3 x_3) - \alpha_2\alpha_3\sin(\alpha_1 x_1)\cos(\alpha_2 x_2)\sin(\alpha_3 x_3) = 0 \end{aligned} \tag{7}$$

The minimum applied load P (> 0) that satisfies Equation (7) is the elastic buckling load when the CFRP is bonded to the defective steel plate.

3 EVALUATION OF ELASTIC BUCKLING LOADS USING CONVERTED THICKNESS OF CFRP

Ishikawa et al. (2022) proposed a CFRP converted thickness for CFRP-bonded intact steel plate that focuses on the elongation of the steel plate with CFRP in Figure 2(a). This method was in good agreement with the results obtained by inserting elastic putty. However, this method is not applicable the CFRP bonded steel plate with sectional defects as shown in Figure 2(b). In this chapter, the converted thickness for Figure 2(a) is shown, followed by the converted thickness for Figure 2(b).

3.1 *Converted thickness of CFRP for CFRP bonded to intact steel plate*

A method for deriving the equivalent thickness of CFRP by focusing on the elongation of CFRP-bonded steel plates is presented. This method focuses on the axial displacement of the CFRP-bonded steel plate under compressive force. The axial displacement δ_s of the steel plate in the CFRP-bonded region is given by the following equation:

$$\delta_s = \int_0^{l_c} \varepsilon_s dx = \int_0^{l_c} \frac{N_s(x)}{E_s A_s} dx \tag{8}$$

where, ε_s is the axial strain of steel plate; l_c is the bonded half-length of CFRP; $N_s(x)$ is the axial force of steel plate; E_s is Young's modulus of steel plate; A_s is cross-sectional area of steel plate.

The axial force $N_s(x)$ of a steel plate is given by the following equation from the shear-lag theory (Ishikawa et al., 2013).

$$N_s(x) = \left\{ (1 - \xi_0) \frac{\cosh(cx)}{\cosh(cl_c)} + \xi_0 \right\} P \tag{9}$$

where,

$$c = \sqrt{\frac{b_c G_e}{h} \frac{2}{1 - \xi_0} \frac{1}{E_s A_s}} \tag{10}$$

$$\xi_0 = \frac{1}{1 + 2E_c A_c / E_s A_s} \tag{11}$$

$$G_e = \frac{E_e}{2(1 + \nu_e)} \tag{12}$$

b_c is the width of CFRP adhesion; h is the thickness of adhesive; G_e is the shear modulus of elasticity of adhesive; E_e is Young's modulus of adhesive; v_e is Poisson's ratio of adhesive; E_c is Young's modulus of CFRP; A_c is the cross-sectional area of CFRP.

Substituting Equation (9) into Equation (8) gives:

$$\delta_s = \frac{P l_c}{E_s A_s} \left\{ \frac{1 - \xi_0}{c l_c} \tanh(c l_c) + \xi_0 \right\} \tag{13}$$

On the other hand, the axial displacement of a steel plate based on the composite theory considering the converted cross-sectional area A_c' (= $b_c - t_c'$) with the thickness of CFRP as t_c', is given by the following equation:

$$\delta_s = \frac{P l_c}{E_s A_s} \cdot \frac{1}{1 + 2E_c A'_c / (E_s A_s)} \tag{14}$$

When the axial displacements of the steel plate in Equations (13) and (14) are equal, the equivalent thickness t_c' of CFRP is obtained by the following equation:

$$t'_c = \frac{E_s A_s}{2E_c b_c} \left\{ \frac{1}{(1 - \xi_0) \tanh(cl)/(cl) + \xi_0} - 1 \right\} \tag{15}$$

Since CFRP is bonded to a defective steel plate, as shown in Figure 2(b), in this study, the equivalent thickness t_c' of CFRP is calculated by substituting the bonding length l_n of CFRP on one side, excluding the defective section, into l in Equation (15). Using this converted thickness, when calculating the elastic buckling load from Equation (7), express its value as P_{VDcr}.

3.2 *Converted thickness of CFRP to CFRP bonded to defective steel plate*

As shown in the previous section, when CFRP is bonded to a defective steel plate subjected to compressive forces, the equivalent thickness of CFRP according to Ishikawa et al. (2022) is not

applicable. Therefore, the shear-lag theory (Ishikawa & Kitane, 2010) is used to derive the equivalent thickness of CFRP focusing on the axial displacement when CFRP is bonded to a defective section steel plate. The axial forces of the defective and reinforcing steel plates for a CFRP-bonded defective steel plate subjected to axial forces are given by the following equations, respectively:

$$N_s(x) = \{A_1 \cosh(c_d x) + \xi_d\} P \tag{16}$$

$$N_s(x) = [B_1 \cosh\{c(x - l_d)\} + B_2 \sinh\{c(x - l_d)\} + \xi_0] P \tag{17}$$

where,

$$c_d = \sqrt{\frac{b_c G_{ed}}{h_d} \frac{2}{1 - \xi_d} \frac{1}{E_s A_{sd}}} \tag{18}$$

$$\xi_d = \frac{1}{1 + 2E_c A_c / E_s A_{sd}} \tag{19}$$

$$A_1 = \frac{Z}{\cosh(c_d l_d)} \tag{20}$$

$$A_2 = 0 \tag{21}$$

$$B_1 = \xi_d - \xi_0 + Z \tag{22}$$

$$B_2 = \frac{c_d h_d}{ch} Z \tanh(c_d l_d) \tag{23}$$

$$Z = \frac{\frac{1-\xi_0}{\cosh(cl_n)} + \xi_0 - \xi_d}{1 + \frac{c_d h_d}{ch} \tanh(cl_n) \tanh(c_d l_d)} \tag{24}$$

$$l_n = l_c - l_d \tag{25}$$

h_d is the thickness of the adhesive at the sectional defect; G_{ed} is the shear modulus of elasticity of the adhesive at the sectional defect; A_{sd} is the sectional area of steel plate at defective section; l_n is the length of CFRP bonded area on one side of the reinforcement; l_d is the half length of the defective section.

Substituting Equations (16) and (17) into Equation (8), the axial displacements (δ_{sd} and δ_s) of the section deficient and reinforced sections, respectively, are given by:

$$\delta_{sd} = \frac{l_d}{E_s A_{sd}} \left\{ \frac{A_1 \sinh(c_d l_d)}{c_d l_d} + \xi_d \right\} P \tag{26}$$

$$\delta_s = \frac{l_n}{E_s A_s} \left[\frac{B_1 \sinh(cl_n) + B_2\{\cosh(cl_n) - 1\}}{cl_n} + \xi_0 \right] P \tag{27}$$

According to the composite theory of steel plate and CFRP, the axial displacements of the defective and reinforced sections are given by the following equations, respectively:

$$\delta_{sd} = \frac{Pl_d}{E_s A_{sd} + 2E_c A'_{cd}} = \frac{Pl_d}{E_s A_{sd} + 2E_c b_c t'_{cd}} \tag{28}$$

$$\delta_s = \frac{Pl_n}{E_s A_s + 2E_c A'_c} = \frac{Pl_n}{E_s A_s + 2E_c b_c t'_c} \tag{29}$$

When Equations (26) and (28) are equal, the converted thickness of CFRP in defective section, t_{cd}', is given by:

$$t'_{cd} = \frac{E_s A_{sd}}{2E_c b_c}\left\{\frac{1}{A_1 \sinh(c_d l_d)/(c_d l_d) + \xi_d} - 1\right\} \tag{30}$$

Furthermore, when Equations (27) and (29) are equal, the converted thickness of CFRP in reinforced section, t_c', is given by:

$$t'_c = \frac{E_s A_s}{2E_c b_c}\left[\frac{1}{\{B_1 \sinh(cl_n) + B_2(\cosh(cl_n) - 1)\}/(cl_n) + \xi_0} - 1\right] \tag{31}$$

Calculate the converted thickness t_{cd}' of the CFRP bonded to the sectional defective section by Equation (30) and the converted thickness t_c' of the CFRP bonded to the reinforced section by Equation (31), respectively. Using these converted thicknesses, when calculating the elastic buckling load from Equation (7), express its value as P_{VLcr}.

4 ELASTIC BUCKLING LOAD BASED ON EIGENVALUE ANALYSIS BY FINITE ELEMENT METHOD

In this chapter, the elastic buckling load is obtained from the eigenvalue analysis using the finite element method, and the validity of the elastic buckling load in Chapter 3 is confirmed. The eigenvalue analysis was performed using the finite element analysis program Marc.

Figure 3 Shows an example of the element division of the eigenvalue analysis model. The steel plate and adhesive (epoxy resin and elastic putty) were modeled with a 4-node plane stress element, and the CFRP was modeled with a 2-node linear beam element. The 1/2 symmetry model was used, the symmetry condition was given at the center of the member, and the

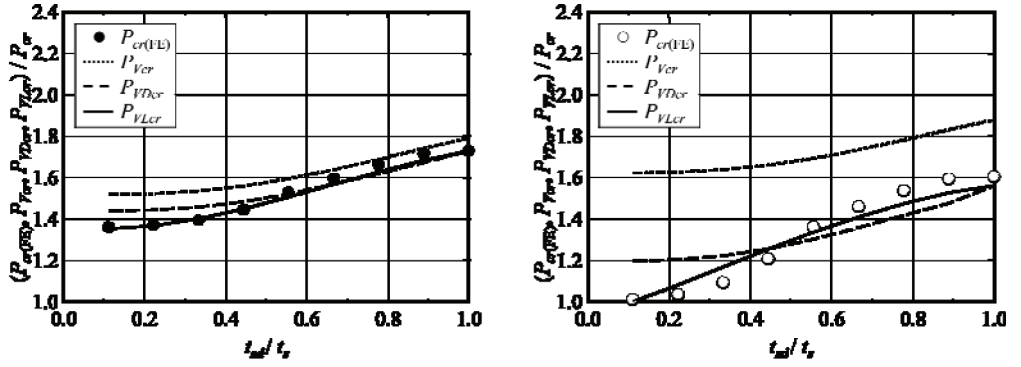
50	0.286	150	2.0×10^5	0.30

top end was pin-supported at the center of the steel plate thickness. Compressive loads were applied at the top of the model, and eigenvalue analysis was performed using the BUCKLE function (Lanczos method, convergence error 0.0001).



The material properties and dimensions of the steel plate, adhesive, and CFRP used in the analysis are shown in Tables 1 to 3. The section defect length of the steel plate was set to $2l_d$ =30 mm, and the remaining thickness of the plate, t_{sd}, was varied from 1 to 9 mm. The thickness of the CFRP was set to t_c = 0.286 mm.

Figure 4 shows the relationship between the elastic buckling load and the remaining thickness of the steel plate. The figure shows the effect of the remaining thickness of the steel plate on the elastic buckling load. The horizontal axis of the figure shows the remaining thickness of the steel plate t_{sd} divided by the thickness t_s of the intact section. The vertical axis is the buckling eigenvalue obtained by the finite element method or the elastic buckling load estimated in Chapter 3 divided by the buckling load P_{cr} (= 37.5 kN) of the intact steel plate only, as shown in the following equation:

$$P_{cr} = \frac{\pi^2 E_s I_s}{(2kl_s)^2} \tag{32}$$

where, I_s is the second moment of the weak axis of the steel plate ($b_s\ t_s^3/12$); l_s is the half-length of steel plate (l_s = 200 mm); k is the effective buckling coefficient (k = 1).

If the elastic putty is inserted in the calculations in Chapter 3, the adhesive thickness and shear modulus must take the epoxy resin and elastic putty into account. Therefore, the

(a) Without elastic putty (b) With elastic putty

Figure 4. Relationship between the elastic buckling load and the remaining thickness of the steel plate.

following equations were used to calculate the converted shear modulus of elasticity G_{Eq} and total thickness h_{Eq} of the adhesive when the elastic putty is inserted.

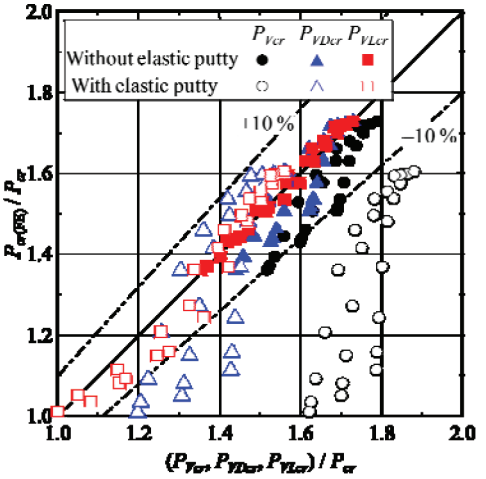


Figure 5. Relationship between eigenvalue analysis results and elastic buckling loads.

$$G_{Eq} = \frac{G_e(h_e + h_p)}{h_e + h_p G_e / G_p} \tag{33}$$

$$h_{Eq} = h_e + h_p \tag{34}$$

where, G_p is the shear modulus of elastic putty; h_p is the thickness of elastic putty. The defective section of the steel plate is assumed to be filled with epoxy resin, therefore, h_e includes the defective thickness of the steel plate.

The results of elastic buckling load estimation in Chapter 3 are compared with the results of eigenvalue analysis using the finite element method. In Figure 4, the results of the elastic buckling load P_{VDcr} using the CFRP equivalent thickness in Equation (15), the elastic buckling load P_{VLcr} for a defective steel plate in section using the equivalent thickness in Equations (30) and (31) are shown. Here, the elastic buckling load, P_{VLcr}, was calculated from Ishikawa et al. (2022) because CFRP adhesion to an intact steel plate occurs when t_{sd}/t_s = 1.0. The elastic buckling load P_{Vcr} from Okuyama et al. (2011), which assumes a composite beam of steel plate and CFRP, is also shown in Figure 4.

It is clear from Figure 4 that the elastic buckling load P_{Vcr} assuming a composite beam has a larger value than the eigenvalue analysis $P_{cr(\mathrm{FE})}$ of the finite element method, which does not agree when elastic putty is inserted. In addition, P_{VLcr} using Equations (30) and (31) is closer to the eigenvalue analysis $P_{cr(\mathrm{FE})}$ than P_{VDcr} using Equation (15). This is because P_{VLcr} takes into account the effect of force transmission at the section defect.

Figure 5 compares the results of the eigenvalue analysis with the elastic buckling load. For the calculation example in Figure 4, results for defect lengths of $2l_d$ = 10 and 20 mm are also included. The vertical axis in Figure 5 shows the eigenvalue analysis $P_{cr(\mathrm{FE})}$ obtained by the finite element method divided by the buckling load P_{cr} of the steel plate only, and the horizontal axis also shows the elastic buckling load P_{VDcr} or P_{VLcr} divided by the buckling load P_{cr}. Figure 5 shows that the buckling load P_{VLcr} using the converted thickness of CFRP in Equations (30) and (31) is within ±10 % of the buckling load $P_{cr(\mathrm{FE})}$ given by the finite element method in the calculation examples in this study. In addition, the buckling load P_{VDcr} using the converted thickness of CFRP in Equation (15) also has an error within ±10 % of the buckling load $P_{cr(\mathrm{FE})}$.

From Figures 4 and 5, the elastic buckling load P_{VLcr} can be estimated by using the converted thicknesses of CFRP in Equations (30) and (31) when elastic putty is inserted or when the cross-sectional deficiency is large. If no elastic putty is inserted or the cross-sectional defect is small, the elastic buckling load P_{VDcr} can be estimated by using the converted thickness in Equation (15).

5 CONCLUSION

This study presents an estimation of the elastic buckling load when CFRP is bonded to a defective steel plate. The proposed method was compared with the buckling eigenvalues obtained by the finite element method. The main results obtained in this study are as follows;

1) The axial force of a CFRP-bonded defective steel plate derived from shear-lag theory was used to show the converted thickness of CFRP focusing on the axial displacement.
2) Estimation equations for elastic buckling loads were derived for beams with three different cross-sections.
3) Estimation of the elastic buckling load using the proposed converted thickness is in good agreement with the results of the eigenvalue analysis using the finite element method.

ABSTRACT: Due to their lightness and cost effectiveness, orthotropic steel deck bridges are one of the most popular alternatives for bridges constructed in urban and metropolitan areas in Japan. However, fatigue is still a serious problem when considering durability in orthotropic decks. The present study focuses on the connection between trough ribs and crossbeams, particularly the welded joints around the slot at the bottom of trough ribs, where a great number of the fatigue cracks has been reported. A new fatigue retrofit method using TRS (Thread Rolling Screw), which secures the watertightness of trough ribs, was proposed for the connection between trough ribs and crossbeams in orthotropic steel decks and executed in a bridge in service. Dynamic loading tests and stress measurements under service load were performed in situ, before and after the execution of the retrofitting works to verify the effectiveness of the new retrofit method.

1 INTRODUCTION

Orthotropic steel decks, due to their lightness and short construction time are considered structurally advantageous for long-span bridges and also for bridges constructed in urban areas. However, orthotropic steel decks are also well known for their susceptibility to fatigue damages, what may compromise the structural durability in case no measures are taken. A large numbers of fatigue damages have been successively reported at the trough rib-to-crossbeam connections of orthotropic steel decks during routine inspections in Japan. In a previous paper (Ichinose et. al., 2021) friction-type one-side bolts were used to connect stiffening angles to trough ribs, but those bolts could not prevent water penetrating into trough ribs.

In the present paper, TRS (Thread Rolling Screw) were applied to connect stiffening angles to trough ribs to assure watertightness of the trough ribs as part of the "Research Project for Improvement of Fatigue Durability of Orthotropic Decks" (Sakano, 2018) to verify the effectiveness of a fatigue retrofit method proposed for trough rib-to-crossbeam connections in orthotropic steel decks. Stress measurements were carried out in a bridge in service, after the execution of the proposed retrofitting works and comparison were made with the results of stress measurement carried out previously before the execution of the retrofitting works (Ichinose et. al., 2018). Simultaneous to the field works, analytical studies and experiments in laboratory were also carried out as part of the referred Research Project and their findings were already partially reported. (Matsumoto et. al., 2018, Sakamoto et. al., 2018).

2 FIELD WORK

2.1 *Outline of the bridge*

The bridge selected for the field study was an orthotropic steel deck bridge completed in 1986 and retrofitted after the Hanshin-Awaji Great Earthquake. The 3-span continuous box-girder bridge, presented in Figure 1, is 214.790m long, with an average width of about 9.000m, which carried 2 traffic lanes. Stress measurements were carried out in the 62.790m lateral span and the location of the stress measurement was as presented in Figure 1. The figure also shows the bridge cross-section with the two traffic lanes.

The traffic volume on the bridge before the execution retrofitting works, according to the 2015 census, was about 36,640 vehicles (12 hours), of which 18.8% were heavy vehicles.

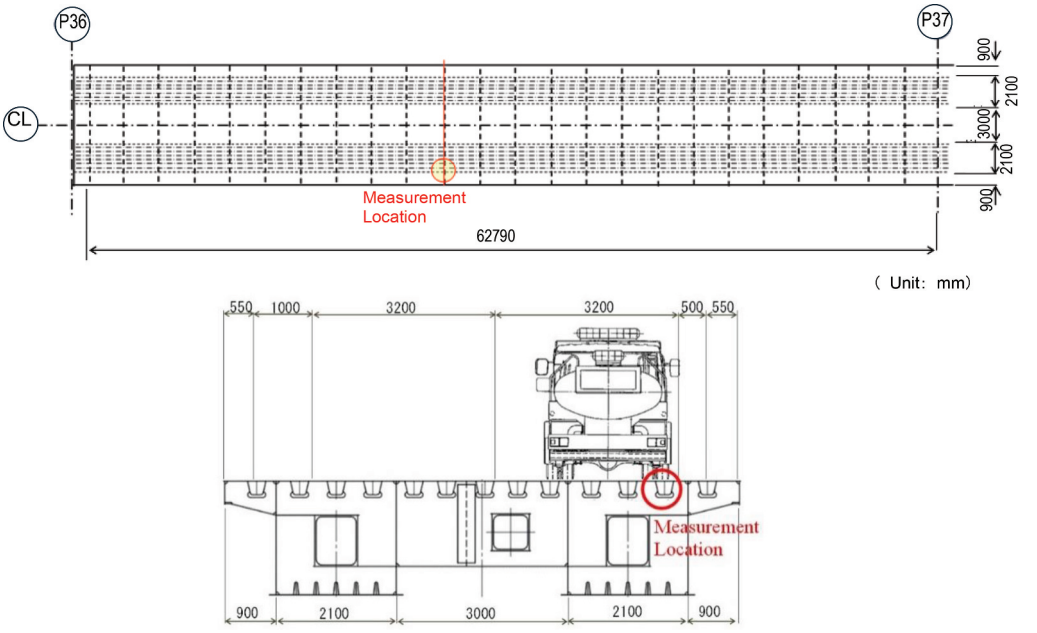

Figure 1. Measurement location (cross-section).

2.2 *Proposed retrofit method*

Fatigue retrofit method as shown in Figure 2 was proposed for trough rib-to-crossbeam connections in the orthotropic steel deck. As it is shown in the figure, two steel angle profiles were connected to both sides of the crossbeam web. One of the angle profile sides was connected to

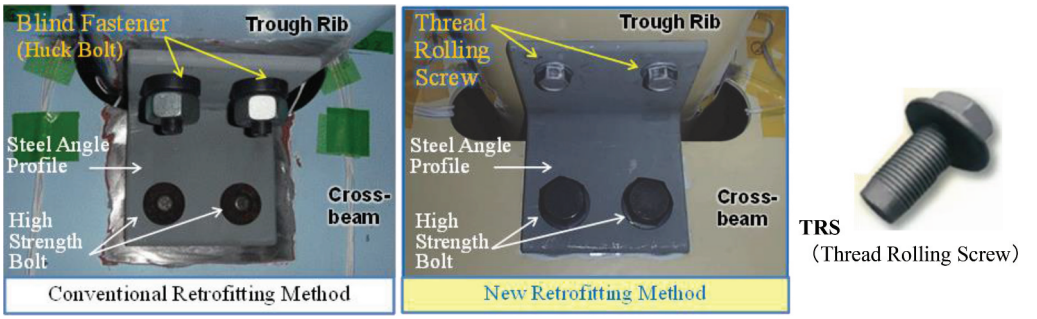

Figure 2. Retrofit methods of trough rib-to-crossbeam connections.

the bottom surface of the trough rib through TRS, instead of the friction-type blind fasteners (Huck bolts), which are conventionally used. The other side of the angle profile was connected to the crossbeam web through high tension bolts.

In previous studies the authors have found that the fatigue cracks on the welded joints around the slot at the bottom of trough ribs were caused by the relative horizontal movement of the bottom of the trough rib, and that connecting the bottom of trough rib to the cross-beam by a pair of angle profiles was effective to prevent such behavior of the trough rib. The new retrofit method was verified through fatigue tests and applied to actual structures (Ichinose et al. 2021, Tanabe et al. 2021).

The connecting angle profiles could have been installed using high-tension bolts, according to the conventional retrofit method. However, concerns on corrosion in the trough rib interior caused by air and water infiltration remained for the high-tension bolt connections, as well as for friction type one-sided bolts connections.

To prevent corrosion inside the trough ribs, TRS was proposed for trough rib side connection due to high air- and watertightness (Kagawa et al. 2018). The TRS is screwed into holes that are 0.5 mm narrower than its diameter, so that there is no space left between the TRS and base metal of the trough rib.

As the connecting mechanism of the conventional high-tension bolt is of friction type and the newly applied TRS connection is of bearing type, its influence on the effectiveness of the retrofit has to be verified. Therefore, field studies were carried out on angle profile retrofit applying TRS. The studies consisted of field measurements, including dynamic loading test and 72 hours continuous measurement of stresses under traffic load.

3 FIELD MEASUREMENTS

In order to clarify the stress conditions in the trough rib-to-crossbeam connections of the orthotropic steel deck before and after the execution of the retrofitting works and verify the effectiveness of the proposed retrofit method, dynamic loading test and 72 hours stress measurements under service load were carried out.

3.1 *Measurement points*

The measurement points and the respective strain gages are shown in Figure 3. Tri-axial gages were placed at a point 5mm from the cut-out welding toe on both sides of the crossbeam web and, at the trough rib, uni-axial gages were placed on each of the webs, 5mm from the weld toe. In addition, an uni-axial gage was placed at the bottom surface of the crossbeam lower flange in

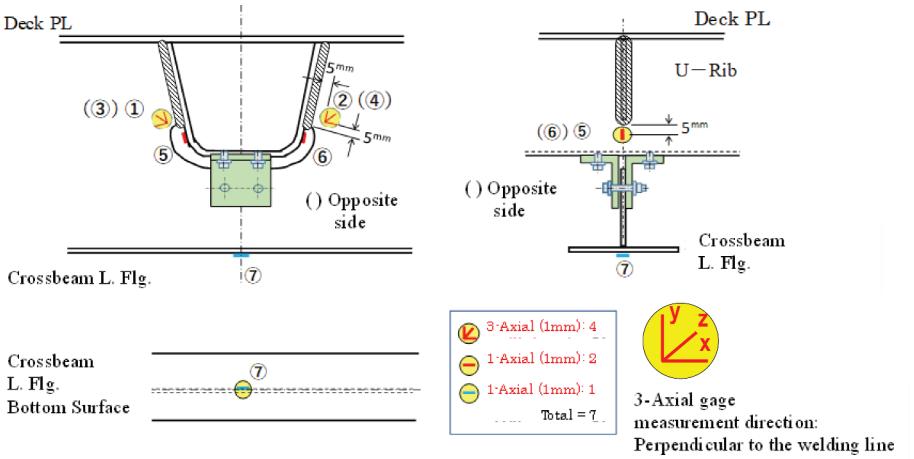

Figure 3. Measurement points and strain gage location.

order to confirm the overall behavior of the measurement area during dynamic load test and the 72 hours stress measurements. As shown in the figure, the measurements directions of the 3-axial gages were so that the direction x and y were, respectively perpendicular, and parallel to the welding line, and direction z was 45 degrees counter-clockwise towards the direction y.

3.2 *Dynamic loading test*

Dynamic loading test was carried out using the vehicle shown in Figure 4, a road sprinkler with a total weight of 137kN (front wheel = 42kN, rear wheel = 95kN). The vehicle drove on the bridge at a speed of about 60 km/h and positioned as shown in the cross-section in Figure 1.

The dynamic tests were carried out before and after the retrofitting works and stress measurements were performed at the same measurement points.

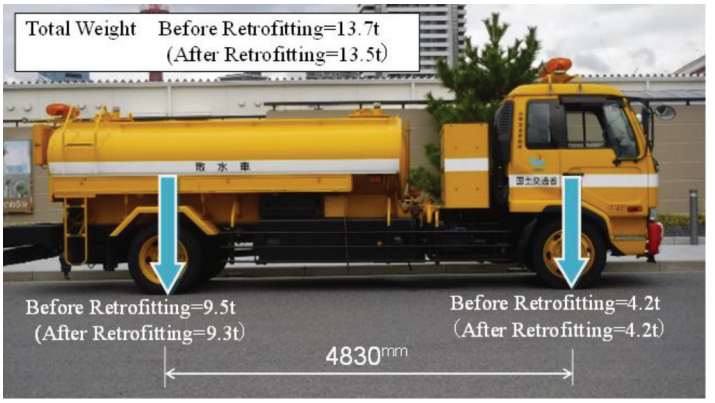

Figure 4. Testing vehicle.

3.3 *Stress measurements under traffic load*

After the dynamic loading test, 72 hours stress measurements under service load were carried out. The stress measurements were carried out according to the Guideline for stress frequency measurements (Provision) (Road Maintenance Technology Centre, 1996) and data of 3 consecutive weekdays (72hrs.) were collected. The analysis of the data was carried out applying both the peak-and-valley and the rain-flow methods.

4 RESULTS

4.1 *Dynamic loading test*

Although the dynamic loading test was carried out without traffic disruptions, each run of the test vehicle was carried out after assuring that no other vehicle was on the target span during the test to minimize the traffic influence. The test was carried out 3 times under the same loading conditions.

Figure 5 shows the maximum and minimum stresses measured at points ① to ⑦, when the test vehicle drove over the measurement location. The figure shows the measurements results for before and after the execution of retrofitting works. The maximum stress due to the test vehicle observed before the execution of the retrofitting works was about 13.5MPa (tension) at point ⑤, which decreased considerably to 6.1MPa after retrofitting. The minimum compression stress observed before retrofitting was -7.5MPa at point ③, which increased to -10.4MPa after retrofitting.

Tensile stress measured stress at point ① before retrofitting turned into compressive stress after retrofitting and compressive stress at point ④ turned into tensile stress after retrofitting, showing that the out-of-plane bending moment at the trough rib was constrained by the

addition of the angle profile at the bottom of the trough rib. This may be attributed to the fact that, the trough rib was slight asymmetric due to the transversal inclination of the road (deck) and also because the center of the retrofitting angle profiles did not coincide with that of the trough rib, causing the difference of behavior between point ① (and point ③), located at the left side of the trough rib and point ④ (and point ②), located at the its right side.

In addition, in the dynamic loading test, the maximum stress measured at the lower flange of the crossbeam, before retrofitting was 4.7MPa, whereas, after retrofitting, the measured stress was 4.6MPa, presenting almost no changes, from what it can be concluded that the crossbeam lower flange was not affected by the retrofitting works.

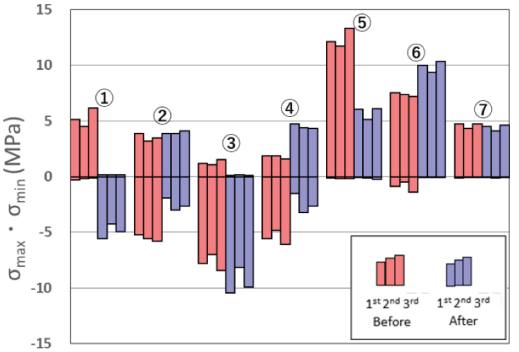

Figure 5. Dynamic loading test results (max. and min. stresses).

4.2 *Stress measurements under traffic load*

4.2.1 *Measured stress*

After the 3 days measurement, before and after retrofitting, the stresses were analyzed by the peak-valley method and their maximum and minimum values are shown in Figure 6. Before retrofitting, stresses at measurement points ① and ⑤ at the U-rib right side were predominately under tension, whereas and ② and ⑥, at the left side, were predominantly under compression. Stress at point ① was predominantly under tension and at point ③, on its opposite surface was predominantly under compression. However, after retrofitting, t point ② and ⑥ were predominantly under tensile stress and stresses points ① and ③ were predominantly compressive. The maximum stress measured before retrofitting, was 58 MPa, which was measured at point ⑤ at the left side of the U-shaped rib. This value decreased to about 48% (28 MPa) after retrofitting.

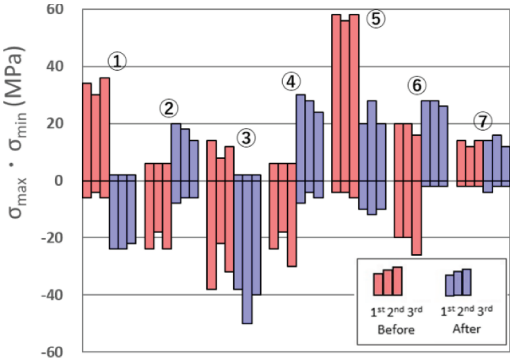

Figure 6. Max. and min. stresses according to the peak-valley method.

Figure 7 shows the variation of the stresses measured with time. The graphs show the stress variation for stresses measured when point ① presented the maximum value. As shown in the

graphs, stresses at points ① and ③, ② and ④, on the opposite surfaces of the crossbeam web, as well as ⑤ and ⑥, at opposite sides of the U-rib, presented opposite signs before retrofitting. After retrofitting, the stresses at these points presented the same signs as that of their respective pairs, showing that the crossbeam web out-of-plane flexure was restrained. In addition, the stresses decreased for all the measurement points.

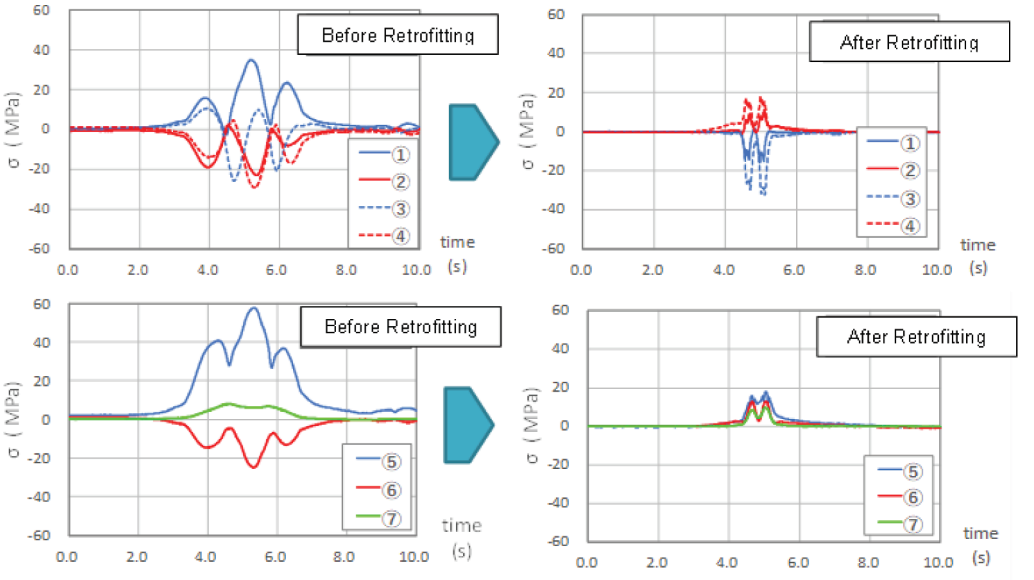

Figure 7. Example of stress variation (at maximum stress at point ①).

Figure 8 shows the histogram according to the peak-valley method for the measured stress at points ⑤ and ⑥. Stress at measurement point ⑤ before retrofitting varied from 20 MPa to 60 MPa and from -25MPa to 20MPa at point ⑥. After retrofitting, the stresses in the tensile range at point ⑤ decreased considerably, although there was a slight increase in the compression range. Tensile stress at point ⑥ presented a slight increase, whereas compressive stresses deceased to almost zero, after retrofitting. Both histograms configuration presenting similar shape after retrofitting.

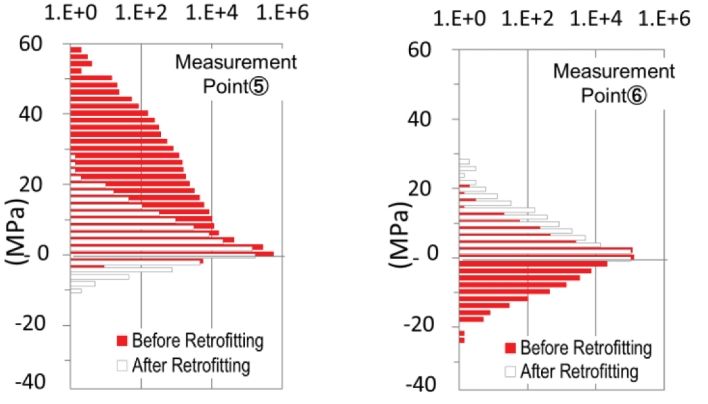

Figure 8. Measured stress histogram according to peak-valley method (measurement points ⑤ and ⑥).

It can also worth noting that, the maximum stress observed in the measurements under service traffic at the lower flange of the crossbeam before retrofitting was 14 MPa and, after

retrofitting, the maximum measured value for the same point was16MPa, whereas, the maximum stresses in the dynamic loading test was 4.7 MPa before retrofitting and 4.6 MPa after retrofitting, what represent a service traffic stress/dynamic load test ratio of about 3.0 times for before retrofitting and 3.5 times after retrofitting. This shows that during service load measurements a vehicle having an axle load equivalent to 29ton (before retrofitting) and 33ton (after retrofitting) have crossed the bridge during the period in which the measurements were being caried out.

4.2.2 *Stress range and fatigue life*

Table 1 presents the stress range and the fatigue life evaluated according to the Fatigue Design Recommendations for Steel Road Bridges (Japan Road Association. 2002). The maximum value for stress range was obtained at the measurement point ⑤ at the left side of the trough rib, where the measured stress exceeded 60MPa before retrofitting and the stress after retrofitting was reduced to 40% (below 40 MPa).

The shortest evaluated fatigue life was 55years (G class), at the measurement point ⑤, at the left side of the trough rib, which was extended to 30,000 years after retrofitting. For the other members, the stress life was over 10,000 years before retrofitting which improved to over 30,000 years, after retrofitting, proving that the structural durability has improved.

Table 1. Estimated fatigue life (before and after retrofitting).

	Member	Measurement Point	Class	2M-cycles Fatigue Strength (MPa)	Const. Ampl. Cut-off Limit (MPa)	Maximum Stress Range (MPa)	Equivalent Stress Range (MPa)	No. of Effective Cycles (cycles)	Fatigue Life (years)
Before Reinforcement	Cross-beam Web	①	F	65	46	40	-	-	∞
		②	F	65	46	30	-	-	∞
		③	F	65	46	50	49	2	20000
		④	F	65	46	36	-	-	∞
	U-Rib Side	⑤	G	50	32	64	39	608	55
		⑥	G	50	32	44	41	2	15000
	Cross-beam L. Flg.	⑦	D	100	84	16	-	-	∞
After Reinforcement	Cross-beam Web	①	F	65	46	26	-	-	∞
		②	F	65	46	28	-	-	∞
		③	F	65	46	52	51	1	34000
		④	F	65	46	38	-	-	∞
	U-Rib Side	⑤	G	50	32	40	38	1	37000
		⑥	G	50	32	30	-	-	∞
	Cross-beam L. Flg.	⑦	D	100	84	18	-	-	∞

5 CONCLUSIONS

From field measurements on the proposed fatigue retrofit method using TRS for the trough rib-to-crossbeam connection in an orthotropic steel deck bridge, the following can be concluded.

5.1 *On the measured stress*

Measurement of stresses before and after retrofitting showed that the horizontal movement of the trough rib in the bridge axial direction, as well as in the bridge transverse direction could be restrained. The maximum stress observed before retrofitting (point ⑤, 58MPa) was reduced to almost a half (28MPa) after retrofitting, confirming the effectiveness of the proposed retrofitting works.

In addition, measurements under service traffic showed that a vehicle having a maximum axle load equivalent to 33ton (after retrofitting) have crossed the bridge during the measurements.

5.2 *On the stress range and fatigue life*

The maximum value for stress range observed before retrofitting at point ⑤ (64MPa) was reduced by about 40% (40MPa) after retrofitting, which resulted in a considerable improvement of the expected fatigue life.

Internal redundancy approach for built-up mechanically fastened steel tension members in the United States

Jason B. Lloyd
Nucor Corporation, Charlotte, NC, USA

ABSTRACT: Two USA-based AASHTO Guide Specifications were published in 2018, with 2022 interims. They offer the analytical framework needed to revisit the way we evaluate redundancy in steel bridges considering system-level and member-level redundancy for new or existing bridges. For the last four decades, the steel bridge industry in the United States has become accustomed to determining redundancy through engineering judgement married to a single approach, namely load path redundancy (referring to the number of primary girder lines). Publication of these new AASHTO Guide Specifications enables designers and owners to design outside the box that we put ourselves in 40 years ago. In addition, the Guide Specifications also include a methodology to establish an inspection interval for a special inspection of internally redundant members (IRMs) that is of sufficient depth to reliably detect a severed component. This is a major departure from the calendar-based approach to setting inspection intervals and is a big step toward developing an integrated fractur control plan. This paper discusses the development of the AASHTO Guide Specifications for internal redundancy, exploring the historical context and providing a working example of how the evaluation of an existing structure could demonstrate inherent redundancy previously not considered within the US bridge industry.

1 INTRODUCTION

Built-up member bridge construction practices using wrought iron can be traced to as early as the late 18th Century. From the 1840's onward, construction of long-span wrought-iron bridges in the UK continued the advancement of riveted connections and use of built-up member construction. The dawn of rolled steel mills in the late 19th Century and early 20th Century further advanced the use of built-up construction, making it the most widely used form of building and bridge construction. Hot-driven rivets were predominantly used to fasten multiple components, such as plates and angles, together until the 1950's to 1960's when high strength bolts and welding processes became preferred methods of construction. Today, thousands of bridges possessing built-up members continue to serve highway and railway industries and many are well over 100 years old! They remain a vital part of the US and international infrastructure systems, and in many cases have become historic and iconic structures.

While built-up construction may not be the most economical design option in current markets, some applications, such as built-up through-girders, built-up tie girders or built-up steel bents, could be smart choices when taking advantage of internal redundancy. An internally redundant member is defined as a primary steel bridge member in tension, or with a portion of it in tension, which has redundancy within the cross section, such that fracture of one element will not propagate through the entire member cross-section and is discoverable by the applicable inspection protocol.

This paper summarizes research that contributed to an American Association of State Highway Transportation Officials (AASHTO) guide specification that offers provisions for

DOI: 10.1201/9781003483755-263

the evaluation of built-up members for internal redundancy. It is called the AASHTO *Guide Specification for Internal Redundancy of Mechanically-Fastened Built-up Steel Members* (referred to hereafter as the IRM Guide Spec).

2 OVERVIEW OF THE IRM APPROACH

The new AASHTO IRM Guide Spec is another method engineers in the USA can use to extend the service life of many iconic, historic and economically valuable bridges. The IRM Guide Spec also provides a fresh perspective on how internal redundancy might be exploited in new designs to mitigate the risk of potential fracture events. It provides the industry with quantitative analysis for the purpose of showing redundancy and establishing rational inspection intervals for built-up members that are realistic about what can be reliably found during inspections and for what duration undiscovered damage could be safely tolerated. All of this, however, must be kept in context when discussing new steel bridges, designed and built to the standards of the AASHTO Fracture Control Plan (FCP), which has resulted in zero fractures in the past 45 years. That said, in the past 60 years no built-up member classified as a fracture critical member (FCM; now referred to in the USA as a nonredundant steel tension member, NSTM) is known to have triggered structural collapse due to the fracture of a single component. However, that is the assumption put on these member types. Three known cases of component failure in built-up NSTMs are the Hastings Tied Arch Bridge, USA, (two separate fractures), Milton-Madison Bridge, USA, (experimentally severed for research, simulating fracture to observe structural response), and the North Fork Mollola River Bridge, USA. In all three cases, the built-up NSTM did not result in partial or complete failure of the bridge and the bridges continued to safely carry service loads until repairs could be made. Keep in mind that risk is the product of likelihood and consequence. The IRM Guide Spec helps engineers evaluate the consequence of a component fracture, conservatively ignoring likelihood, linking damage tolerance to rational inspection requirements.

2.1 *The internally redundant member analysis methodology*

In the USA, the designation of a NSTM is left to the bridge designer (in the case of new design) or inspector/owner (in the case of existing bridges) to determine. Traditionally this has been decided through engineering judgement based on the number of girder lines, not a set of engineering calculations. This implies that the decision to define a member as NSTM has largely been made without regard to internal redundancy. The mechanical separation of components within an IRM produces an inherent fracture resistance at the component boundaries known as Cross-Boundary Fracture Resistance (CBFR). Full-scale experimental research showed that mechanically fastened built-up members possess CBFR independently of the toughness of the steel (Hebdon et al., 2017a; Lloyd et al., 2021). This is a beneficial outcome for owners because a majority of built-up members were fabricated long before the AASHTO Fracture Control Plan (FCP) of 1978 began requiring a minimum toughness level in base metal. The IRM Guide Spec equally applies to new designs and existing members, including all built-up flexural and axially loaded members, as well as members subjected to a combination of flexural and axial loading (e.g. tied arch tension ties). Simplified solutions allowing for hand calculations have been developed for a majority of the member types to date and more are currently being researched.

2.2 *Progression of IRM analysis*

The basic steps of analyzing a built-up member for internal redundancy using the IRM Guide Spec are:

1. Screening; criteria such as condition and remaining fatigue life
2. Strength limit checks in the assumed faulted condition
3. Fatigue life check in the assumed faulted condition
4. Special inspection interval

The provisions of the IRM Guide Spec first require that the member be screened for certain conditions, such as the presence of unmitigated damage and remaining fatigue life, to ensure a high likelihood of reliable, long-term performance. New and existing members must also meet specified proportioning limits provided in the Specification. Existing members that do not pass the screening criteria should be automatically excluded from further evaluation. The IRM Guide Spec is not intended to justify leaving a fractured component of a member in service once discovered, nor any other damage that may prohibit reliable service.

In step 2, the factored load is calculated using the reliability-based load combination called, "Redundancy II". Researchers used the same reliability-based procedures to develop Redundancy II that were used to establish the various load combinations of AASHTO LRFD Bridge Design Specifications (Connor et al., 2018). Factored loads are used to compute after-fracture stresses for strength and fatigue assuming that a single component within the member cross-section has failed. For flexural members, the outer cover plate generally is assumed to fail. This assumption is made for two primary reasons. First, the outer plate experiences the largest live load stress making it most likely to fatigue. Second, assumption of the outer plate failure has the greatest effect on section modulus, creating the most critical after-fracture capacity check. For axial members this process is iterated considering failure of a different component each time to find the controlling case, taking advantage of member cross-sectional symmetry. Gross and net section properties are checked for remaining strength in the assumed faulted condition. Laboratory testing and finite element parametric studies demonstrated that when a component is severed, localized stress amplifications occur in the adjacent component(s) as a result of load redistribution into and out of the adjacent component. Stress amplification factors are provided in the IRM Guide Spec to account for the local stress effects of shear lag and localized bending. For the strength limit state checks, the local amplification is not important, however, because local yielding, slip and load redistribution allow the section to fully develop the cross-section. Thus, amplification factors are set to unity. Factored demands are then compared to factored resistance, identical to a typical strength check made during design. If it is found that the member possesses sufficient strength in the faulted condition, the analysis may continue. If not, the member is removed from further analysis (for existing members) or for new designs the member cross-section is simply adjusted and re-evaluated.

Following strength limit checks, the third step in the analysis is fatigue life in the faulted condition. Unlike for strength checks, when considering the fatigue limit states for the faulted condition localized stress amplification of the live load stress ranges must be taken into account. The IRM Guide Spec provides simple equations and tables having illustrative cross-section types to help the user determine amplification factors to apply for each case. Fatigue detail categories for members in the faulted condition are provided, as well. These were established through full-scale experimental testing of members following failure of a single component (Hebdon et al., 2017b; Lloyd et al., 2021; Lloyd et al., 2023). If the member possesses positive fatigue life in the faulted condition, then it has satisfied the provisions of the IRM Guide Spec. Following a US Federal Highway Administration (FHWA) approved procedure, as per the National Bridge Inspection Standards (NBIS), the member can be reclassified as an IRM, thus being removed from an owner's NSTM inventory.

The final step is calculation of the special inspection interval. The special inspection replaces the arms-length NSTM inspection without changing requirements for routine inspection. The IRM Guide Specs include a methodology to establish the interval for special inspections intended to locate any tension component that has possibly fractured. This inspection of IRMs is referred to as a "Special Inspection" as defined in the US Code of Federal Regulations and must be sufficiently thorough enough to reliably detect a severed component. Conceptually, this is a significant departure from the somewhat arbitrary, calendar-based 2-year interval intended to find small fatigue cracks. The reality is small fatigue cracks are difficult for inspectors to find reliably and for that reason we can say with confidence that internal redundancy has been serving us well in our built-up members for well over a century.

As a note of interest to the reader, the US-based National Steel Bridge Alliance (NSBA) has developed Excel spreadsheet tools that perform the IRM analysis for multi-component axial members, multi-component flexural members, and two-component members. These free

IRM evaluation tools can be found on the NSBA Design Resources website (See www.aisc.org/nsba/design-resources).

3 IRM EVALUATION EXAMPLE

The following is an evaluation example of a few sections of an existing bridge. The intent is to demonstrate the application of the IRM analysis methodology. This method can be used for both evaluation of an existing bridge, as is demonstrated, or for the design of a new structure. Constructing bridges using built-up mechanically fastened tension elements will not always be the most cost-effective approach. However, due to the inspection requirements within the USA for members classified as NSTM, the overall service life costs can be drastically reduced by using this approach for certain member types, without compromising safety and performance. A few examples that make sense are the tie girders of tied arches, two-girder bridges such as through-girders, or steel straddle bents.

3.1 *Background for example bridge*

The bridge used in this evaluation example is a twin structure, each with two riveted built-up girders with parabolically haunched webs. A photo of the underside of the bridge is shown in Figure 1. The bridge is 732.4 m long with two end spans of 33.9 m and 14 symmetric interior spans of 44.47 m each. The yield strength of the steel was not explicitly stated in the design drawings. However, it did state that the unit stress of the structural steel was 124 MPa. This most likely means the yield strength was between 227.5 MPa and 248.2 MPa. However, because it was not stated the plans, the yield and tensile strengths were taken from AASHTO Manual for Bridge Evaluation Table 6A.6.2.1-1, where for a bridge built in 1958 the yield strength is listed as 227.5 MPa and tensile strength as 455 MPa.

Figure 1. Photo of the underside of the twin, two-girder bridges.

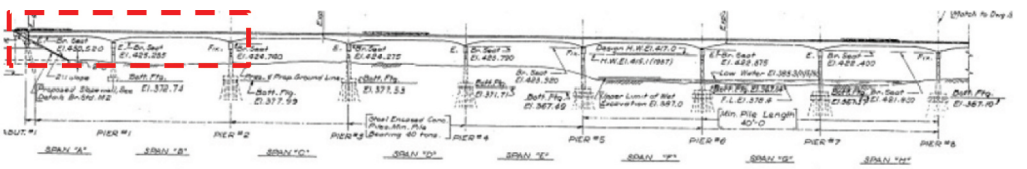

Figure 2. Original design drawings for the 1958 built-up riveted, two-girder bridge.

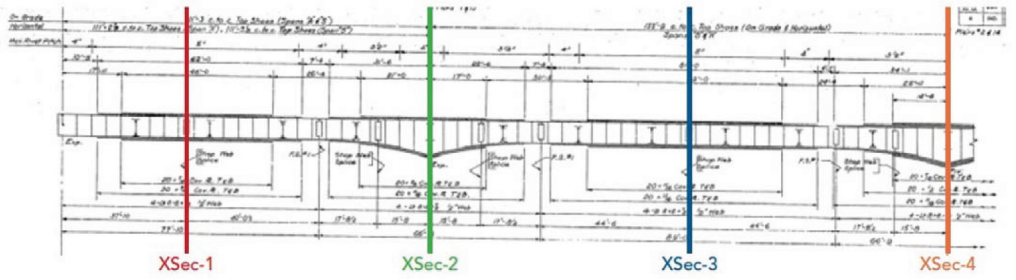

Figure 3. Blow-up elevation view of the built-up riveted girders (Span A and B), from Figure 2.

Figure 2 shows eight spans of the 16 symmetric spans of the bridge. The first two spans, shown encased within the red dashed line, are the two spans evaluated as part of this example (Span A & B). Note that the floorbeams are not included in the evaluation example. Due to the symmetry of the design, these girders make ideal candidates for quicker evaluation using "families" of identical members. This means that sections of the girders having the same dead and live load moments with the same cross-sectional properties, along with the same general condition, can be evaluated together. Any cross sections having different condition (e.g. section loss resulting in loss of capacity, unrepaired impact damage, etc.) or any having been repaired resulting in a different cross section (e.g. built-up plating to restore section), must be evaluated on an individual bases. This method proves advantageous for saving time when evaluating a bridge this long. Details for the member components will be provided throughout the example, as needed. Only members that carry a net tensile live load that exceeds any compressive dead load, in AASHTO's Strength Load Combination I, are required to be evaluated. Typically, for a flexural member this would include locations of maximum live load moment. Figure 3 provides the elevation view of the original design drawings where the field splices and haunched webs can be seen. For this example, four cross sections will be evaluated within the first two spans. Stress reversal zones are not evaluated here, although it would be recommended to do so in an actual bridge evaluation. The approximate four locations are shown with solid-colored lines at 0.4L of span A, center line of pier 1, 0.5L of span B, and center line of pier 2. These four locations represent the cross sections with the largest positive or negative live load moments in the first two spans.

3.2 *Summary of example bridge results*

The summary of results is provided in Table 1. These results were obtained by following the provisions of the IRM Guide Spec. It also contains the maximum special inspection interval for the cross section (or member) being evaluated. Guide Spec. Tables 3.1-1 and 3.1-2 provide guidance on determining the special inspection intervals. *XSec-1* was found to be a Case II member, having finite fatigue life in the unfaulted state and finite fatigue life in the faulted state. Thus, Table 3.1-2 from the IRM Guide Spec was used.

The total remaining fatigue life, N_f, was computed as 9.2 years. Being less than 20 years and greater than 5, the maximum permitted interval is calculated as $0.5N_f$, where the IRM Guide Spec allows for the result of $0.5N_f$ to be rounded up to the nearest next even-year interval. The user is referred to IRM Guide Spec article C3.1 for more information about rounding up to the next even-year interval.

Strength checks were made for the member cross-sections following the provisions of the IRM Guide Spec and recommended practices for flexural members, as described in Step 2 of Section 2.2 of the present paper. Two primary strength calculations are made, gross section yield on the faulted section (referring to the case where the outer-most cover plate is assumed to be failed), and net section fracture on the faulted section. Where "OK" is presented in Table 1, the cross-section was found to possess sufficient strength capacity in the faulted condition for both strength requirements.

Table 1. Summary of results for the example bridge IRM evaluation.

Cross Section	User Input Member ID	Faulted State Strength Check	IRM Special Inspection Interval Years
XSec-1	Span A, Positive Moment (0.4L)	OK	6
XSec-2	Negative Moment @ Pier 1	OK	8
XSec-3	Span B, Positive Moment (0.5L)	OK	6
XSec-4	Negative Moment @ Pier 2	OK	4

3.3 *Discussion of results and potential implementation*

Four cross sections were evaluated for the example bridge girder evaluation. Due to the symmetry of the spans, results can be extrapolated to cross sections of similar geometry and condition. It was found that all cross-sections met provisions of the IRM Guide Specifications resulting in Special Inspection intervals ranging from 4 to 8 years. Table 1 summarizes the results with the respective special inspection intervals. Keep in mind that these four cross sections represent the same continuous girder. They were selected as locations of highest live load, making them the likely most critical cross sections to evaluate. For continuous construction, stress reversal zones would also be recommended for evaluation. It would also be advisable to evaluate any location where cross-sectional properties change to ensure a critical demand-capacity ratio is not missed.

In this example, all cross sections passed the IRM evaluation requirements. Thus, the NSTM could be reclassified as an IRM. In the hypothetical case that a continuous girder has some cross sections that pass the IRM Guide Spec provisions and some that don't, it would fall upon the owner to decide how they wish to handle this. It could be that the continuous girder is divided into sections of positive and negative moment. Each section could be treated as a separate member with one or more cross sections evaluated for each member. Suggested cross sections to evaluate include those with maximum (or minimum for negative moment regions) live load moments, or those having abrupt section modulus changes, such as at the termination of a cover plate. (Only a single cross section was evaluated for each member in the example above to keep the example simple and brief.) Another possible solution, like the first, is to subdivide the girder some distance from the center line of the piers so that reversals zones are clearly included in a member, rather than falling on a dividing point. Consider that members need not be evaluated for internal redundancy at mechanically fastened splices (See IRM Guide Specifications 1.4), which will often be located at a stress reversal position on the continuous girder. A final strategy could be to implement a retrofit, such as strengthening, in areas that did not pass the IRM evaluation, making it so that the entire girder length does meet the IRM Guide Spec provisions and can be classified as IRM.

As is shown in this example, each cross section met the provisions of the IRM Guide Specifications. However, the analyses resulted in different special inspection intervals. This is a case where the owner would need to consider the options and decide if it makes sense to break out the sections of the girder and perform the special inspection for them on their different schedules or perhaps choose the section with the shortest inspection interval and perform the special inspection interval for the entire girder on that schedule such that the other special inspection interval requirements are exceeded. Suspending any unnecessary inspection of IRMs could save time, resources, and reduce lane closures and worker exposure to high-speed traffic helping to reduce risk. This aspect of implementation is not prescribed in the IRM Guide Specifications and therefore is incumbent upon the owner. There is ample flexibility built into the US Code of Federal Regulations for programming and conducting this type of inspection.

Development of the current AASHTO integrated fracture-control plan for steel bridges

R.J. Connor
Jack and Kay Hockema, Professor in Civil Engineering, Lyles School of Civil Engineering, Purdue University, West Lafayette, IN, USA

ABSTRACT: There has been considerable research and interest in the topic of fracture-critical members (FCMs) during the past decade. As a result, the entire concept of what constitutes a nonredundant steel tension member has been completely revised and many long-standing ideas and opinions related to this classification of members have been shown to be overly conservative. After years of research, two new stand-alone AASHTO Guide Specifications that give codified direction on how to perform 3D system analysis to verify system redundancy, as well as AASHTO Guide Specifications to evaluate internal member-level redundancy of mechanically-fastened built-up members, have now been developed and adopted by AASHTO. This paper will summarize the background to the current views of FCMs and suggestions about how this new integrated approach to redundancy, in particular as related to the fatigue and fracture limits states is being implemented in the US.

1 INTRODUCTION

In the United States, there is a special classification of steel bridge structures. To be placed into this classification, a few criteria must be met, specifically, 1) that are deemed to have non-redundant members that are, 2) fabricated from steel, and 3) these members must be in tension. Members placed in this category are subjected to additional design, fabrication, and in-service inspection requirements in the name of increasing reliability. The concept originated in the mid-1970s following a relatively small number of major failures associated with tension members, or the portion of a member in tension. While the initiating cause may vary, the final mode of failure of the member was brittle fracture. As a response to these failures, the added requirements mentioned above were developed and implemented over a period of about 10 to 15 years for these members. Historically these members have been referred to as Fracture Critical Members (FCMs) in the United States codes and specifications. Today, such members are referred to as Nonredundant Steel Tension Members (NSTMs) and henceforth, will be referred to as such in this paper. For all practical purposes, NSTMs should be viewed equivalent to FCMs.

Despite the perception surrounding bridges classified as having NSTMs, there is actually very little evidence that would suggest such bridges have been more unreliable than other types of steel bridges. In fact, the previous term "Fracture Critical" has conjured up thoughts that such members are doomed to failure in the form of brittle fracture. However, such a view when compared to the actual in-service performance of such members could not be further truth. In fact, while it is true that catastrophic failure of a tension member has critical consequences, truss bridges, which are classified as having NSTMs, also have what the author refers to as BCMs, or "buckling critical members". However, non-redundant compression members in trusses exist without any additional concern regarding their criticality nor do they require any special fabrication or in-service inspection.

DOI: 10.1201/9781003483755-264

Nevertheless, as an industry, there is little concern that non-redundant compression members will suddenly fail in an unstable buckling mode. The reason is simple: the bridge engineering community as a whole believe the results of many years of experimental research and analysis. Thus, such members are not treated differently in design or during in-service inspection whether they are redundant or not. For some reason, the same is not true for tension members. While isolated failures of tension members have occurred, the US bridge engineering community, more specifically regulatory agencies, have *in the past* been very reluctant to accept the decades of research and advancements that have been made in the understanding of fracture mechanics, the availability of steels with superior toughness, advances in fabrication methods and non-destructive testing. Fortunately, the culmination of multiple more recent research projects coupled with decades of earlier research has resulted in a sea change in how redundancy is viewed in steel bridge structures. This paper will present a summary of how redundancy in steel bridge members subjected to tension is viewed in the US today, and in particular as related to steel bridge members in tension.

2 PERFORMANCE OF THE "MODERN" STEEL BRIDGE

As stated, NSTMs have traditionally been subjected to more stringent material, design, fabrication, and in-service inspection requirements. In the context of NSTMs, "modern" NSTMs will generally possess the following characteristics:

1. Meet more stringent CVN requirements;
2. Be fabricated to the AASHTO/AWS D1.5 Fracture Control Plan (FCP)) (AWS 2020);
3. Be designed using the nominal stress range approach for fatigue, generally using an infinite life approach;
4. Unlikely to possess details susceptible to distortion induced fatigue cracking which is responsible for most cracking observed in highway bridges.

In general, bridges built after about 1985 meet all of the above. It is also worth noting that nearly two decades ago, research related to constraint induced fracture (CIF) led to the develop of design criteria and retrofit strategies that have effectively eliminated the likelihood of this type of fracture (FHWA 2021). For example, in 2012 the first requirements were added to the AASHTO LRFD Bridge Design Specifications (AASHTO 2021) to prevent the use of details susceptible to this form of fracture. Fortunately, most if not all nonredundant girder bridges in the US which possess CIF susceptible details on NSTMs designed prior to this date have been retrofit in order to prevent this form of fracture. Recent work funding by the Federal Highway Administration (FHWA) has also led to improved design and retrofit guidance that will be incorporated into the 10th Edition of the AASHTO LRFD Bridge Design Specifications.

History has shown that steel bridges which meet all of above criteria are extremely unlikely to be susceptible to brittle fracture. In fact, the author has not been able to identify any NSTMs which have met the above criteria (a period of over 45 years) in which a brittle fracture has occurred. Thus, the improvements made in the design and fabrication of NSTMs have resulted in steel members that are highly reliable in terms of the fatigue and fracture limit state. Thus, brittle fracture is a very unlikely mode of failure in modern steel bridges.

3 DEVELOPMENT OF AN INTEGRATED FRACTURE CONTROL PLAN

Considering the above, about 10-15 years ago, the steel bridge industry and owners partnered to begin to undertake research that would allow a more systematic approach to addressing redundancy in both new and old steel bridges. More specifically, identify, conduct and then implement research that would address the risk associated with brittle fracture in nonredundant members more holistically. Ideally, the final outcomes would link the reliability of in-service inspection, the strength or performance of the member following a defined level of

damage, and the interval of the inspection. The approach is referred to herein as an Integrated Fracture Control Plan. In such an approach, the desired reliability is achieved and deficiencies in one area is made up through exploiting the strength of a more reliable component of the plan. For example, if in-service inspection can't reliably detect small cracks, the member design is changed to ensure that the critical crack size is much larger thereby ensuring the inspection can detect important damage. Interestingly, this approach is commonly utilized in other industries such as oil and gas and aerospace and is a proven and effective strategy.

Early on when laying out the research efforts needed, several areas were identified in which further study was needed. Four broad areas were considered.

1. Probability of detection associated with in-service inspection;
2. Internal member redundancy;
3. System redundancy;
4. Improved performance through exploiting the superior toughness of modern steels and modern fatigue design.

Items one through three will be discussed in this paper as they have been implemented, either directly or indirectly into the current bridge design practices in the US. The fourth item has not been directly implemented to date, though further work is ongoing. Hence, the fourth topic will not be discussed further in this paper.

4 PROBABILITY OF DETECTION

In the US, members identified as NSTMs are subjected to detailed arms-length in-service inspections. Historically, these inspections are required at intervals of 24 months or less. Such inspections are conducted with the objective of finding and documented small defects such as fatigue cracks *BEFORE* they lead to brittle fracture or some other serious outcome. However, while this is a valid strategy, when performing any type of inspection, one should consider the concept of probability of detection (POD) and hence ask the question; "Can the inspection reliably detect a defect before it becomes critical?".

Probability of detection studies are used to determine the probability of detecting a defect in a specified component under the inspection conditions and procedures provided or commonly used. In the case of highway bridges, this is almost always performed through a visual inspection. POD is typically expressed as a function of a quantifiable target parameter associated with the given flaw (e.g., length). While the target parameter is the single most influential factor in determining the probability of detection, it is also a function of many other physical and operational factors including the material, geometry, flaw type, NDT method, testing conditions and the inspector, their certification, education and experience (Georgiou 2006).

Probability of detection data can be analyzed as discrete data, where the response is binary, either a hit or a miss, or as continuous data, which is a signal response, tracking how close the noted size of the defect is to the actual size. Hit/miss data produces qualitative information indicating whether a flaw is present or absent.

Having such knowledge, the owner can make informed decisions to minimize risk as related to the effectiveness of the inspection program. For example, the following approaches could be explored to minimize risk if the POD data suggests that at identify the critical defect is unlikely.

- The consequence associated with member failure must be kept low via other means.
- The inspection strategy must be changed to result in increased POD, such as using another form of NDT in contrast to basic visual inspection.
- The owner simply accepts the risk of member failure and a high-risk level is deemed tolerable.

One may believe that inspecting more frequently would be a valid approach. However, such a strategy will generally only increase the likelihood of finding the failed component sooner. In fact, in the majority of cases where brittle fractures occurred, the public identified and

reported the damage, not a bridge inspector. More frequent but *unreliable* inspections will only be marginally effective in preventing member failure.

To investigate the likelihood of detecting a fatigue crack in a steel member, a large-scale POD study was performed at Purdue University [Snyder et al, 2015]. This study, which is believed to be the first statistically significant study of its kind focused on fatigue cracks in bridge members, revealed that the 50-50 crack length (i.e., that length with a 50% probability of an inspector hitting or missing) is on the order of one inch (25 mm) using visual inspection. Further, to achieve a POD of 90% requires cracks to be in the range of five inches (125 mm) in length. Other studies have shown similar results in terms of the overall low POD associated with visual inspection [Moore et al, 2001, Washer et al, 2014]. This is essential data to have when developing an integrated fracture control plan. Ideally, if the crack size that has a detection rate of 90% is known, one could infer that a member should at least be able to tolerate such a crack before catastrophic member failure would be expected. On the other hand, if there is a low probability of detection associated with the critical defect size, the strategy should not be to find small cracks since it is known such an approach is pointless (i.e., there is a low probability that such a crack would ever be found in the first place). As will be discussed, this data was very useful when combined with research items two and three listed above.

5 INTERNAL MEMBER REDUNDANCY

Mechanically-fastened built-up steel members have long been *perceived* to be highly resistant to complete and sudden catastrophic failure due to brittle fracture. While this type of redundancy was generally known to be present through anecdotal evidence, no guidance existed on how to establish if *adequate and reliable* internal redundancy is present in a given mechanically-fastened built-up steel member. Due to a lack of experimental evidence or existing standards, the Federal Highway Administration (FHWA) was not previously able to recognize this form of redundancy (Lwin, 2012).

To gain the needed data, Transportation Pooled Fund Project TPF-5(253) "Evaluation of Member Level Redundancy in Built-up Steel Members" was conceived and completed (Hebdon et al., 2017a & b,; Lloyd, 2018).

The resistance to complete member failure following brittle fracture in an individual component is referred to as cross-boundary fracture resistance (CBFR). Through full-scale experimental testing performed in the research, it was shown that brittle fracture in one component does not propagate into the adjacent component if certain conditions are met. The member is then checked to establish if there is sufficient strength in the faulted condition under prescribed load combinations. The experimental work was furthered through fatigue testing to establish how long a member in the faulted state could survive in this damaged condition (i.e., with one component completed failed). Using this information, conservative estimates could then be made to set an appropriate inspection interval and scope to ensure a second component will not fail prior to the next inspection. The research showed that members meeting specific proportion and condition requirements can be designated as Internally Redundant Members (IRMs) that do not need to be subjected to the traditional arms-length inspection associated with NSTMs. The research was recently incorporated into the AASHTO Guide Specifications for Internal Redundancy of Mechanically-fastened Built-up Steel Members which was approved by the AASHTO Subcommittee on Bridges and Structures in June of 2018 (AASHTO 2018a w/ 2022 interims). These specifications are applicable to both new and old steel bridge structures. Since complete member fracture is not a plausible failure mode, the member is reclassified as an IRM that is to be inspected in a way that will reliably detect broken components at intervals of up to ten years (*normal safety inspection intervals and scope of the deck, piers, etc. remain unchanged*).

It is also important to note that the primary objective of the in-service special inspections of IRMs is to detect fully severed components and not to find very small fatigue cracks emanating from any one of thousands of fastener holes. The POD study cited earlier showed that it is unrealistic to assume that small cracks can be identified with a high level of reliability using traditional visual inspection techniques. In contrast, the likelihood of detecting a severed

component in a built-up member, on the order of 10 inches long or more, is obviously much higher. In this way, the fracture control plan is "integrated" in that the inspection interval and capability of the inspector is linked to the tolerance of the member as a function of time since the fatigue life in the damage state is also known based on the large-scale testing.

6 SYSTEM REDUNDANCY

Another form of redundancy can be exploited through the use of advanced analytical tools. In such an approach, analysis is performed in which entire NSTMs are assumed to have failed and the structure analyzed to establish the consequence of the failure. To develop and codify the procedures to evaluate the redundancy of bridges with members traditionally designated as NSTMs through 3D system analysis, NCHRP Project 12-87a was conducted (Connor et al, 2018) in which the following questions were studied.

- What is an acceptable target reliability for a damaged structure?
- What level of live load should a faulted structure be capable of carrying?
- How should live load be positioned on the bridge?
- What criteria (service and strength) should be used to define failure?
- What is the exposure period during which the bridge should be assumed to be in the faulted state and how does this tie into future inspection needs?

The research resulted in the AASHTO Guide Specifications for Analysis and Identification of Fracture Critical Members and System Redundant Members, which was approved by the AASHTO Subcommittee on Bridges and Structures in June of 2018 (AASHTO 2018b w/ 2022 interims). This Guide Specification provides owners and engineers with a robust benchmarked analysis methodology that can be used to increase the effectiveness and efficiency of inspection in steel bridges with members traditionally classified as NSTMs. These specifications are also applicable to both new and old steel bridge structures. since it is shown the failure of the entire member would not lead to collapse, the member by definition is not an NSTM. As a result the member is classified as a SRM and need only be inspected at an interval and scope as any other redundant steel member.

Similar to IRMs, the overall FCP is integrated as inspection is not required to find small cracks, but rather complete broken members since analyses have shown that complete member failure can be tolerated under established load combinations. Thus, an integrated approach is used as the FCP.

7 SUMMARY AND CONCLUSIONS

This paper has presented a number of significant advancements that have been made which can be used to more rationally treat members traditionally classified as NSTMs and lower the perceived and actual risk associated with such members. Strategies have been developed and codified where internal redundancy and system redundancy can be used to show the consequence associated with a partial or complete member fracture, though highly unlikely is also low. Explicitly considering the fracture limit state in such a way allows for the development of an integrated fracture control plan in which the inspection interval, scope and capability of the inspector are linked to the tolerance of the member or structure as a function of time. Moving forward with an integrated fracture control plan allows a more rational treatment of these members that is based on engineering principles rather than perception and feeling. Because of these advancements, the National Bridge Inspection Standards (NBIS) in the US were updated in June of 2022 to allow these new approaches to be implemented by owners. This is major change in how redundancy in steel members subjected to tension is viewed as compared to the historical views of the past. The new approaches allow a clearer understanding of actual redundancy allowing owners to put limited inspection resources where they are most needed thereby increasing the reliability of their gaining inventory.

Fabrication aspects of redundancy

R.D. Medlock
High Steel Structures, LLC, Lancaster, Pennsylvania, USA

ABSTRACT: There are special fabrication requirements for nonredundant steel bridges in the United States. As described in this paper, these include requirements for material, shop floor fabrication, and inspection.

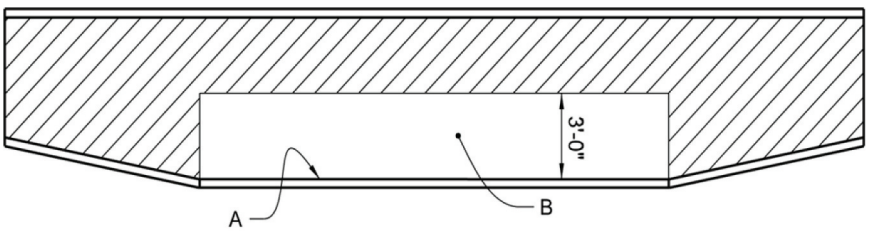
1 INTRODUCTION

The Fracture Control Plan of 1978 introduced fabrication and inspection practices and special materials requirements for non-redundant members in bridges. These special practices and materials are now called, "Fracture Control", as in, "fracture control practices" and "fracture control material requirements".

Non-redundant members were then called, "fracture critical members", but recently new types and classifications of nonredundant members have been adopted (1):

Table 1. Steel bridge member redundancy classifications.

Redundancy Form / Member Designation	Description	Fracture Control Practice Required	Previous Description
Load Path Redundancy (2) / Load Path Redundant Member (LPRM)	A redundancy exists based on the number of primary load-carrying members such that fracture of the cross section at one location of a member will not cause a portion or all of the bridge to collapse.	No	Non-Fracture Critical
Nonredundant Steel Tension Member (3) (NSTM)	A primary steel member fully or partially in tension, and without load path redundancy, whose failure may cause a portion of or the entire bridge to collapse.	Yes	Fracture Critical
System Redundant Member (2)/System Redundant Member (SRM)	A redundancy that exists in a bridge system without load path redundancy, such that fracture of the cross section at one location of a primary member will not cause a portion of or all of the bridge to collapse.	Yes	New
Internally Redundant Member (2)/Internally Redundant Member (IRM)	A redundancy that exists within a primary member cross-section without load path redundancy, such that fracture of one component will not propagate through the entire member, is discoverable by the applicable inspection procerus, and will not cause a portion of or the entire bridge to collapse.	Yes	New



DOI: 10.1201/9781003483755-265

As shown in Table 1, two types of redundant members are new: SRMs and IRMs. Before, these members would simply have been considered non-redundant and therefore fracture critical. There are two key things to note about these members. First, neither carry the same special, stringent in-service inspection requirements that NSTMs carry (2). However, SRMs and IRMs do carry the same fabrication, inspection (shop inspection), and material requirements as NSTMs (4,5). This is because it is possible for SRMs or IRMs to lose their conditions that provide special redundancy and thus revert to NSTM status.

2 IDENTIFICATION OF NONREDUNDANT MEMBERS

Given that fabricators must procure special materials and perform special fabrication and inspection practices for nonredundant members, such members must be identified in contract documents. It is dynamic tensile loading that is of concern for non-redundant bridge members, and only components in tension may be appropriately designated as NSTM, SRM, or IRM. Thus, when engineers use non-redundant members, they must indicate which members are non-redundant, and they must indicate the areas of these components which will be in tension. Further, the AASHTO LRFD Bridge Design Specifications (6) require that engineers do so.

Engineers have used a variety of ways to identify non-redundant members. Such variety often leads to confusion or incomplete information. When fabricators are not clear about this or not sure that the plans correctly identify non-redundant members are their tension zones, they issue requests for information (RFIs). To guide engineers and help unify practices, the FHWA provides recommendations in their Bridge Welding Reference Manual (7).

FRACTURE CRITICAL DESIGNATION

Note: Shaded area indicates areas that are FC.

Source: FHWA

Figure 1. Excerpt from Bridge Welding Reference Manual (7) showing how to designate tension zone of non-redundant members (i.e., FC zones).

3 FRACTURE CONTROL MATERIALS

Steels for bridges are defined in ASTM A709, "Standard Specification for Structural Steel for Bridges". Materials for non-redundant members are indicated with an "F" appended to the grade, i.e., "50F" instead of "50T". The steel materials used for non-redundant members are the same as those used for redundant members except for toughness properties and some practice requirements. Each of the following are requirements for materials for non-redundant materials:

- CVN requirements are higher. See examples in Table 1 for select grades. Note that the values shown are for service temperature 2.
- CVN testing is more frequent – testing is done per plate as opposed to per heat. These are known as "P" and "H" frequencies, respectively.
- There are restrictions on the welded repairs mills are allowed to perform.

Table 2. Sample material requirement comparisons for non-redundant members.

Grade	Test Temperature	Minimum Charpy CVN Value	Minimum Average Charpy CVN Value
	degrees F	foot-pounds	foot-pounds
36T, up to 4"	40	NA	15
36F, up to 4"	40	20	25
50WT, up to 2"	40	NA	15
50WF, up to 2"	40	20	25
50WT, 2" to 4"	40	NA	20
50WF, 2" to 4"	40	24	30
HPS 70WT, up to 4"	-10	NA	25
HPS 70WF, up to 4"	-10	24	35

Fabricators purchase materials appropriate for the redundancy condition indicated on the design plans. If components or parts of components are specified fracture critical, NSTM, SRM, or IRM, then "F" designated materials are procured for the components or component parts. Mills provide these materials, and the material test reports (MTRs) produced by the mill indicate the materials as "F", and document that "H" frequency sampling was done for toughness testing.

There are times when fabricators desire to use a non "F" designated plate for a nonredundant application. In such cases, the fabricator will take a coupon from the plate and test it at the "F" temperature. In practice, plates always pass this testing.

4 SHOP DRAWINGS

Fabricators produce shop drawings to provide instructions to the shop about how to fabricate the bridge. The instructions in the shop drawings are complete, including what materials to use where and what components or parts of components are non-redundant. It is essential that instructions regarding non-redundancy are complete, correct, and clear. Otherwise, incorrect material may be used, or incorrect practices may be used on nonredundant components.

Fabricators document the requirements of the materials for each component in the bill of materials for that component. For example, if a flange or web is nonredundant, this associated material requirements will be designated in the bill of materials on the shop drawings which feature this component. Further, the shop drawings will indicate which portion of the components are non-redundant. As is the case with designs, fabricators indicate non-redundant zones on components with sketches.

Under the fracture critical program, fabricators indicate fracture critical components and zone as "FC". Under the new program, there are now three types of nonredundant members: NSTMs, SRMs, and IRMs. With each of these three member types requiring the same special non-redundant materials and practices, the bridge community has decided to designate nonredundant zones as "FC", for "fracture control" (1). To properly align the shop drawings with the specific member types in the design, fabricators will use a note on the shop drawing general notes sheet to mentions the type of redundancy (i.e., NSTM, SRM, or IRM) and also state that nonredundant components and zone will be designated as "FC". Thus, the shop coworkers and material purchasers will only need to recognize one special designation, "FC". This practice will help provide clarity and avoid errors.

5 FABRICATION

Under the Bridge Welding Code (8), there are several special fabrication requirements intended as extra precautions against fatigue or fracture during performance of the bridges. These may be categorized as hydrogen controls, welding practices, non-destructive examination, repairs, qualifications, and material processing requirements.

Special hydrogen control practices are described in Table 3. Already, the Bridge Welding Code (8) has stringent and effective welding hydrogen controls for bridge welding. The special requirements for nonredundant members take these a step further. In welding, the presence of too much hydrogen can cause discontinuities such as porosity or, more seriously, cracking. Hydrogen is always present, including in base metals, welding consumables, and in the air. It is impossible to eliminate it completely. As weld metal cools, free hydrogen accumulates in the grain boundaries of the nearly solidified base metal. In the presence of stress, such as shrinkage constraints, and depending on the hardness of the base metals being joined, cracks can form. Welding practices such as preheating and consumable controls minimize the amount of hydrogen present at the start of welding. Other controls such as post heat can drive off undesirable hydrogen even after solidification. For nonredundant members, these controls are increased for extra caution. Since hydrogen cracks sometimes do not form immediately upon solidification, nondestructive examination (NDE) of welds in nonredundant members is delayed as an extra precaution to ensure that any cracking that might occur has time to form.

Table 3. Hydrogen controls for welding of non-redundant members.

- Diffusible hydrogen requirements for electrodes
- Special drying and storage for shielded metal arc welding (SMAW) electrodes
- Submerged arc welding (SAW) storage and baking requirements
- Mixing of recovered SAW fluxes
- Drying & storage requirements flux-cored arc welding (FCAW) and GMAW electrodes
- Higher preheat requirements
- Postheat requirements for repairs
- Waiting time for NDT
- Preheat for repairs

Further to hydrogen controls, there are other welding practice restrictions to provide an extra bit of conservatism for welding on nonredundant members. These are described in Table 4. Electroslag and electrogas welding are precluded because research conducted by the federal highway administration (FHWA) (9) did not demonstrate that the ESW practice required by the Bridge Welding Code (8) would be suitable for nonredundant members. Regarding gas metal arc welding (GMAW) electrodes, the original authors of the Bridge Welding Code (8) were concerned that GMAW would not be suitable for welding nonredundant members. However, GMAW is indeed suitable for nonredundant members; metal cored GMAW has since be adopted for nonredundant members, and solid wire GMAW needs to be so adopted (it is indeed permitted for redundant members).

There are extra, more stringent requirements for welder qualification and requalification. For welding procedure qualification, there is no extra testing for nonredundant members, but tests do expire every five years, unlike procedure for redundant members, which no longer expire under the Bridge Welding Code (8). Regarding tack welding, in addition to higher minimum preheat (noted in Table 3), there are also minimum length requirements.

Table 4. Welding practices (other than special Hydrogen Controls).

- Electroslag (ESW) and electrogas (EGW) not allowed
- Gas-Metal Arc Welding (GMAW) only allowed with metal-core wire (not solid wire)
- Special packaging for consumables
- Charpy V-notch requirements for welding procedures
- Prequalification not allowed for E9018 electrodes
- Expiry of welding procedures qualification tests
- Tack welding only allowed inside joint
- Tack welding restrictions in Table 12.3
- Both radiography and side bends required for welder qualifications
- Annual welder requalification

In addition to the time delay mandate described in Table 3, there are other NDE requirements intended to provide an extra measure of caution described in Table 5. A particularly noted requirement is that for butt splices, both RT and UT are required, doubling the NDE over that conducted for butt splices on redundant tension shop splices. For ultrasonic testing (UT) there are more stringent requirements for recordable indications. "Recordable indications" are indications that do pass requirements; hence the Code is mandated the documentation of indications that are acceptable as a means of providing a possible starting point of investigation of an in-service weld that happens to prove problematic. "Prod" type magnetic particle (MT) probes are not allowed because if prod type probes are not used properly, arc-strikes can occur. Arc-strikes are not uncommon in fabrication, and when they occur, fabricators remove them, but this extra bit of caution is in place for non-redundant members as an extra bit of caution. For RT, wire-type image quality indicators (IQIs) are not allowed because hole-type IQI reveal angular distortion if any were to occur due to placement of the source.

Table 5. Nondestructive examination practices.

- Extra recordables for ultrasonic testing
- Only yoke magnetic particle testing (MT) allowed, i.e., not prod MT
- NDT Level II vs. I
- Wait time requirement before performing NDE
- Both radiographic testing (RT) & ultrasonic testing (UT) required on butt joints
- Only hole-type IQI (not wire type) allowed for RT

The need for repairs is inherent in steel bridge fabrication. If not done properly, repairs can introduce conditions that may lead to performance concerns. However, many repairs are routine, and good practice for executing them is well known and understood. Therefore, for most repairs, the Bridge Welding Code (8) defines requirements for most repairs and does not require discrete engineer approval for such repairs; these are known as "prequalified repairs". In the case of nonredundant members, the Bridge Welding Code (8) introduces extra caution in requiring engineer approval and written documentation for repairs that would otherwise be prequalified. For nonredundant members, repairs are divided into two categories: "critical" and "noncritical". For noncritical repairs, engineers may give preapproval, hence giving the engineer additional control over repairs that are otherwise routine. However, critical repairs may not be handled with preapproval. As shown in Table 6, there are also some extra repair practice requirements to introduce more conservatism. Also note that under general rules for welding nonredundant members, the welding procedures used to conduct welded repairs must be approved for use on nonredundant members.

Table 6. Repair practices.

- Grind out an extra 1/8" of base metal when removing welds
- MT of 12" beyond required in repair of fillet welds
- Written documentation required for all repairs, including those that do not require a nonconformance report
- Prequalified repair procedures are not allowed for critical repairs
- Preheat requirements for gouging for repairs
- Mandatory MT of repair excavation

There are five additional requirements for nonredundant members in Table 7, including two qualification requirements and three material requirements. Under Clause 1 of the Bridge Welding Code (8), steel bridge fabricators must be certified by the American Institute of Steel Construction (AISC) (10). For fabrication of nonredundant members, fabricators must satisfy additional AISC qualification requirements and carry an AISC fracture critical (FC) endorsement. To earn this endorsement, fabricators must demonstrate knowledge of special

requirements associated with nonredundant member fabrication. Fabricators must also have a person with three years' bridge fabrication experience on their quality control staff.

Finally, there are some special control requirements for nonredundant base metals. Base metal must be inspected for discontinuities. Some level of initial discontinuities is allowed, and these are defined by ASTM A6, "Standard Specification for General Requirements for Rolled Structural Steel Bars, Plates, Shapes, and Sheet Piling" (11). The requirements are the same for materials for nonredundant members; however, this extra inspection is required as a precaution to ensure unallowed discontinuities were not overlooked. The Code requires removal of a bit of material for universal edges and for sheared edges because these edges are not as uniform as thermally cut edges and might provide initial stress risers or might mask unacceptable discontinuities that would otherwise be noted. Generally base metal laminations are innocuous; however, the Bridge Welding Code (8) has extra conditioning requirements for laminations as an extra precaution against the possibility of a lamination at a butt splice resulting in a crack.

Table 7. Special qualifications and special material requirements.

- Requirement for AISC FC endorsement
- Requirement for lead inspector; must have three years' experience
- Preinspection of base metal surfaces
- Remove 3/16" from sheared or universal mill edges
- Special acceptability and repair for base metal laminations

6 SUMMARY

Since 1978, there have been special material, fabrication, and inspection requirements in place for nonredundant tension members. Previously, nonredundant members were known as "fracture critical" members; these are now known as either nonredundant steel tension members (NSTMs) or members with special redundancy, including both system redundant members (SRMs) and internally redundant members (IRMs). Regardless of these labels, these requirements have remained the same.

For materials, the differences amount to addition material characteristic testing and Charpy V-notch (CVN) requirements that are slightly more stringent. In practice, fabricators observe that material which satisfy tension requirements typically also will satisfy the special nonredundant requirements when testing is done. For fabrications and inspection, there are a wide range of additional requirements intended to introduce extra conservatism in practice. Many are minor additional requirements which do not have a significant impact on shop practices, while others are more significant. The most significant practices are those which impact the project schedule. These include requirements for engineer approval, which can introduce waiting for answers, and extra practices associated with NDE, including use of both radiography and ultrasonic testing for butt splices and the waiting period before testing.

UHPC beam end encasement for the design of maintenance-free steel bridges

B. Lassy, A. Hain & S. Motaref
University of Connecticut, Storrs, Connecticut, USA

ABSTRACT: Repair of corroded steel girder ends is a costly and time-consuming issue in the maintenance of highway bridges. Through a collaboration between the Connecticut Department of Transportation and the University of Connecticut, a repair method using Ultra-High Performance Concrete (UHPC) beam end encasement has been developed and successfully implemented on in-service bridges. This study broadens the use of this UHPC repair method by applying it to new bridge construction. The proposed design replaces traditional steel bearing stiffeners with durable UHPC bearing columns, protecting the beam ends from corrosion that occurs beneath leaking deck joints. This paper presents the design of a beam end and novel end diaphragm connection for a sample bridge. By eliminating the need for maintenance and repair of bridges with deck joints, this research has the potential to contribute to longer-lasting, high-performance bridges that benefit the nation's transportation infrastructure.

1 INTRODUCTION

The maintenance and inspection of bridges in the US is costly and time intensive but is essential for the safety of the nation's transportation infrastructure (ASCE, 2021). Damage or deterioration of individual elements of a bridge can contribute to the deterioration of additional elements (Ault & Dolph, 2018; Kayser & Nowak, 1989). Once corrosion begins, it is difficult and expensive to a) inspect; b) conduct the load rating to determine the remaining strength; c) repaint, clean, or otherwise maintain; and d) rehabilitate or replace the entire corroded element (Kere & Huang, 2019; Kogler, 2015). There has been significant research on beam end encasement using ultra-high-performance concrete (UHPC) to provide both a structural replacement for a typical steel bearing stiffener as well as providing a protective enclosure (Zaghi et al., 2017). This paper aims to expand this method to new construction for the design of maintenance free beam ends.

In a multiphase, decade-long project, researchers at the University of Connecticut (UConn) and engineers at the Connecticut Department of Transportation (CTDOT) teamed up to develop a rehabilitation method for corroded steel bridge girders (Hain & Zaghi, 2022; Zaghi et al., 2015, 2017). In this method, headed shear studs are welded (Figure 1b) to intact surfaces of corroded steel beam ends (Figure 1a), then the beam end is encased in UHPC (Figure 1c) to provide an alternate load path for bearing forces (Zmetra, 2015). Phase I of the research project, beginning in 2013, began with proof of concept experiments on half scale girders that showed the repair was successful in restoring the bearing capacity of the beam end beyond the undamaged capacity (Zaghi et al., 2015).

Phase II of the project built on the knowledge from Phase I and focused on validating design choices, specifically the strength of steel headed shear studs embedded in UHPC (Kruszewski, 2018)(Hain, Zaghi, Kamali, et al., 2019)(Kruszewski, Wille, et al., 2018). For studs embedded in UHPC, the failure mode was primarily controlled by stud shear failure (Kruszewski, Zaghi, et al., 2018). Limitations on spacing, cover, and thickness of the underlying web were developed

DOI: 10.1201/9781003483755-266

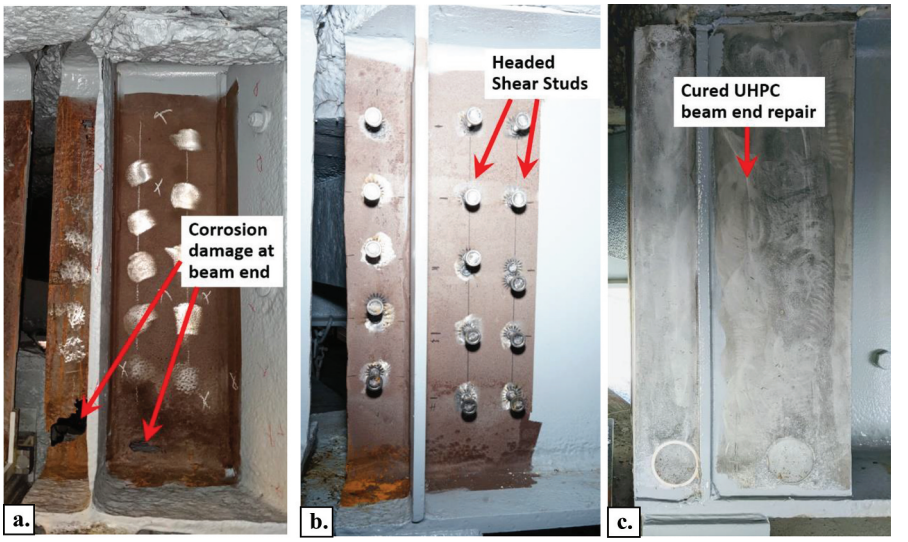

Figure 1. Beam end repair with uhpc encasement. a) corrosion damaged beam and bearing stiffener, b) headed shear studs are welded on to intact portions of the web, c) UHPC is poured over the corrosion and made integral with the beam end.

and validated with a series of push-off tests (Kruszewski & Zaghi, 2019)(Kruszewski & Zaghi, 2021). Phase II additionally included a full-scale girder test. The results showed that the repair restored the bearing capacity at the beam end and shifted the failure mode from web-crippling in the corroded region to web shear buckling in the first panel outside the extents of the UHPC repaired column (McMullen et al., 2018; McMullen & Zaghi, 2020).

Phase III focused on developing design guidelines for the repair to be used by practitioners and assisting CTDOT with the design and implementation of the repair on two highway bridges in Connecticut. The first bridge, repaired in 2019 in New Haven, CT, was a rolled steel girder bridge that carried highway traffic over rail lines (Hain, Zaghi, Fields, et al., 2019). While this presented a construction challenge, it showed the range of applicability for the repair. Due to the significant corrosion damage present, shear studs were laid out with consideration for the thickness of the underlying steel, leading to different layouts at different girders. The UHPC was poured overnight from the top of the deck through a core in the deck with PVC piping distributing it through the formwork (Hain & Zaghi, 2021). The second implementation in 2021 made use of partial height UHPC panels that extended from the bottom flange approximately one-third up the height of the web, allowing contractors to pour the UHPC into the top of the formwork without any distribution system (Lassy et al., 2023). The two beam end repairs the research team was involved with were fully instrumented and showed the successful force transfer through the studs into the bearing, findings which were back up through laboratory testing (Lassy et al., 2023). Due to the success of the multiphase research study, this repair was included in the Federal Highway Every Day Counts 6 Initiative (Haber & Ocel, 2020), and has begun gaining traction for projects around the country (CTDOT, 2020).

The main goal of this project is to extend the research from the beam end repair to new construction. The success of the beam end encasement method led to the concept of using a UHPC bearing column to replace a conventional steel bearing stiffener in new construction. This not only provides an alternative structural element for the bearing stiffener, but due to the proven durability and impenetrability of UHPC (Graybeal & Hartmann, 2003; Li et al., 2020), also acts as a maintenance-free protective coating to increase the service life of the bridge. The proposed design builds off the design guide produced for the beam end repair (CTDOT, 2020) with design options rooted in the AASHTO LRFD Bridge Design Specifications (AASHTO, 2020) and American Concrete Institute 318-19 Building Code Requirements

for Structural Concrete (ACI, 2019). The most significant challenge assessed for the UHPC bearing column detail is the connection between the UHPC and steel diaphragm. Several design options are documented in this paper to overcome this challenge.

2 DESIGN OF DIAPHRAGM CONNECTIONS

2.1 *Sample bridge*

A case study was conducted using the FHWA Design Example (Wilson et al., 2015) to generate a realistic example bridge. An important feature of the UHPC bearing column is the application on beam ends only. This feature has not been studied or designed for an intermediate bearing on a continuous span bridge, as there are significant structural differences. UHPC encasement aims to mitigate the leakage from deck joints, which can often be eliminated over a continuous bearing. However, the beam end encasement has been successfully implemented for the repair of the ends of continuous spans, where there is no negative moment. The end of a simple span beam has negligible moment to cause tension in the UHPC repair, while there is significant moment at the bearing of a continuous span. This should be avoided as such load effects have not been investigated and are not considered in the design guide.

Rather than performing a full bridge design for this project, the research team focused on the bearing column and diaphragm connections. The sample bridge selected for the study is a FHWA Example Steel Bridge, a continuous two span highway bridge designed to AASHTO LRFD specifications (AASHTO, 2020). The example bridge has five 1413 mm deep plate girders, a reinforced concrete integral deck, and standard steel bearing stiffeners and diaphragms. The diaphragm is a standard CTDOT k-frame diaphragm for steel girder bridges (Figure 2), which features a C channel and three angles welded to gusset plates attached to the diaphragm (CTDOT, 2003).

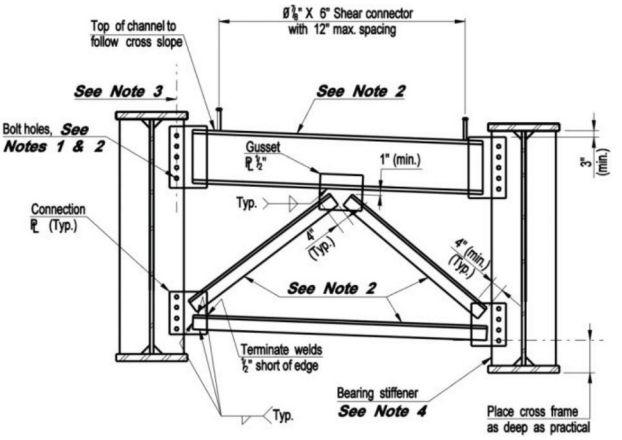

Figure 2. CTDOT standard K-frame diaphragm (CTDOT, 2003).

2.2 *Diaphragm design loads*

The FHWA example provides the loads on the bearing column (Wilson et al., 2015). However, it neglects the design for the diaphragm. To complete the design, the ASHTO LRFD specifications (AASHTO, 2020) were used to conduct a full design for both the bearing column and diaphragm connection. Horizontal loads are controlled by wind loading on the fascia girders, while vertical loading is controlled by the combination of dead and live loads from the bridge above. Seismic loading was not considered. The diaphragm is designed composite with the deck above, similar to the girders, with the top chord acting as a slab edge support. Based on AASHTO Article 9.7.1.4, "the edge beams may be designed as beams whose width may be taken as the effective width of

the deck specified in Article 4.6.2.1.4." For this design, the dead load was taken to be the weight of the haunch over the diaphragm only, with two calculations performed for live load. Based on AASHTO Article 4.6.2.1.4, the maximum live load moment is permitted to be found using AASHTO Table A4-1 and multiplying the moment per unit with by the corresponding full strip width of the edge beam. This was performed to find the total moment acting on the beam, and consequently, the reactions at the connections to the UHPC bearing columns. To check this method, the reactions were recalculated using principles from statics and a tandem wheel load over the diaphragm and found to be comparable to the values using Table A4-1. The controlling horizontal load was found to be 14.2 kN on the fascia girder from wind loading. The controlling vertical load was 206.4 kN at each connection point. For the design of the connection, both loads were considered.

2.3 *Bearing column design*

The bearing column was designed similar to a standard steel bearing stiffener, acting as a compression member at the beam end made up of the UHPC column and the steel web. Due to the high compressive strength of UHPC compared to conventional concrete, the UHPC column is only required to be approximately three times the width of an equivalent steel bearing stiffener. However, to attain the cover for the attachment studs and an appreciable level of protection for the beam end, the bearing column was increased in this design to 457 mm wide. Schematics of the beam end are shown below in Figure 3. Figure 3a and b show the detail of the stud spacing in CAD using a section and plan view, respectively. Figure 3c shows a final rendering with the cured UHPC. Currently, the CTDOT Bridge Design Manual Article 7.1.2.1c details a protective coating that extends (1.5×D) where D is the depth of the girder (CTDOT, 2003). Although the UHPC column does not extend a full 1.5D, the area of the bearing is the most critical structural component of the beam end, and this method can be combined with painting if necessary. The underlying stud pattern is centered over the centerline of the bearing, 229 mm from the edge of the beam. Due to the UHPC being placed prior to loading, the load path travels directly through the UHPC column between the flanges. The studs act primarily as an attachment mechanism, rather than the primary structural fuse in the beam end repair design. For this design, 16 studs were detailed on each side of the beam. The studs for each of the designs presented in this paper are 16 mm diameter by 76 mm length.

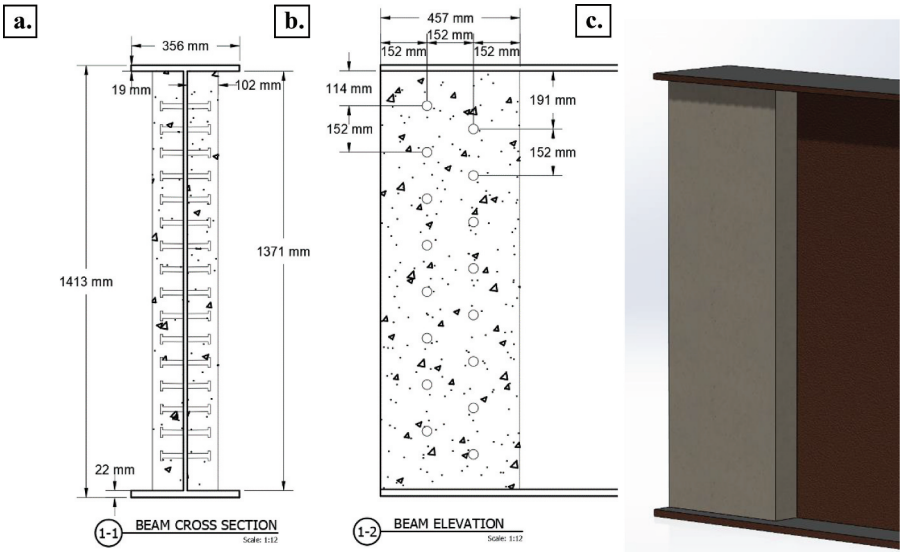

Figure 3. a) Cross sectional CAD schematic of UHPC bearing column, b) elevation view of UHPC bearing column, and c) 3D rendering of bearing column.

2.4 *WT-beam bolted connection option*

The first detail presented is a WT-beam connected to the front of the UHPC column with cast in place or post-installed anchors. This detail minimizes formwork complications when pouring the UHPC. For post-installed anchors, hammer drilling into UHPC permits the contractor to use standard anchor bolt installation methods with a high strength epoxy grout, and completely remove any interference with the formwork. Attaching the bolts to the formwork adds limited complexity to the formwork, but negates the need for any post installed anchors, which alleviates design concerns as the performance of bars embedded in UHPC is well studied (Choi et al., 2015; Kalthoff & Raupach, 2021). Using either anchor installation allows a WT beam to be bolted directly to the surface of the UHPC panel and the diaphragm welded to the WT-beam following a process well known to bridge contractors. It should be noted that in detailing this design, both anchors and shear studs must be arranged to comply with anchor spacing as defined in the ACI 318-19 Building Code Requirements for Structural Concrete (ACI, 2019) and shear stud requirements defined in the beam end repair guidelines (CTDOT, 2020).

A post-installed anchor bolt design using the Hilti PROFIS Engineering software (Hilti, 2023) was conducted to find a feasible anchor size and spacing for the required loading. Due to the short embedment depth permitted, the best working solution was two sets of eight anchor bolts for the top and bottom connections to the diaphragm. Figure 4a and b show the CAD layout of the WT-beams installed on the UHPC column, and Figure 4c shows a 3d rendering that includes the diaphragm connection. A significant challenge in the design is the limitation on concrete compressive strength for cast in place and post-installed anchors set by the ACI 318 committee and upheld in the ACI 318-19 Building Code and supported by research by Primevera. (ACI, 2019; Primavera et al., 1997). This research discovered that as the strength of the concrete increased past 55 MPa for post installed anchors and 69 MPa for cast in place anchors, the design equations became unconservative. However, the ACI Code notes that with tested verification, the limitation may be exceeded (ACI, 2019). While this is an area for further research, the research team continued with limited strength of the UHPC in the design of 55 MPa, as this will be conservative and allows designers to use standard concrete design software and ACI 318-19 formulas without conducting tests on each project.

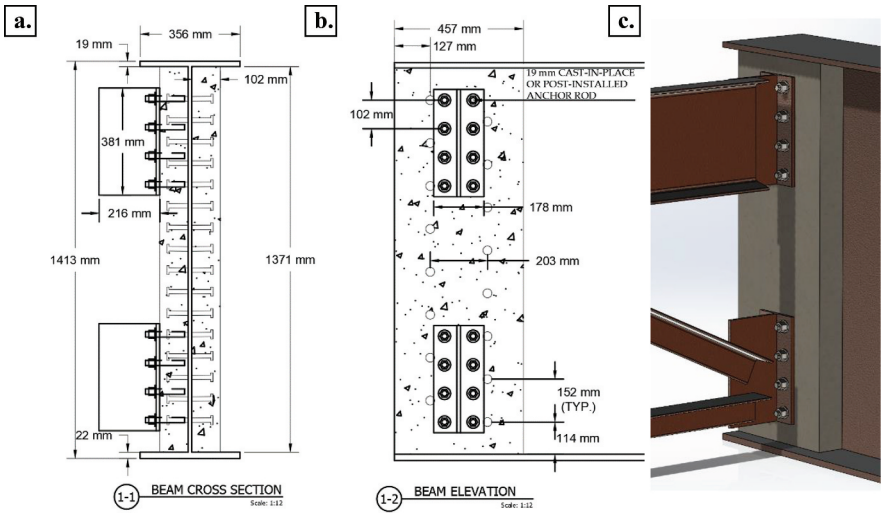

Figure 4. a) Cross sectional CAD schematic of WT-beam bolted option, b) elevation view of WT-beam bolted option, and c) 3D rendering of WT-beam bolted option.

2.5 *Embedded plate connection option*

The second set of connection options are embedded stiffener/gusset plates welded to the web with UHPC cast around them. Figure 5a and b show the CAD layout of the plate embedded in UHPC, and Figure 5c shows a 3d rendering including the diaphragm connection. These options provide a straightforward design and construction familiar to contractors with no additional design required for anchor bolts and no complications related to the design codes. One challenge is formwork construction around the gusset plates, requiring a tight fight for the formwork panel around the gusset plate. These designs require additional holes in the web and stiffener/ gusset plates to ensure one cohesive UHPC block. The sub-options include a bolted diaphragm connection and a welded connection. These options would be splitting the gusset plate into two separate gusset plates, once supporting the top channel and the second supporting the bottom chords of the diaphragm. The welded connections to the diaphragm chords could also be replaced with field-drilled bolted connections. As the UHPC acts as the main bearing column, and the stiffener/gusset plates do not span flanges, the design of the plates does not need to meet bearing requirements but does require design for diaphragm forces.

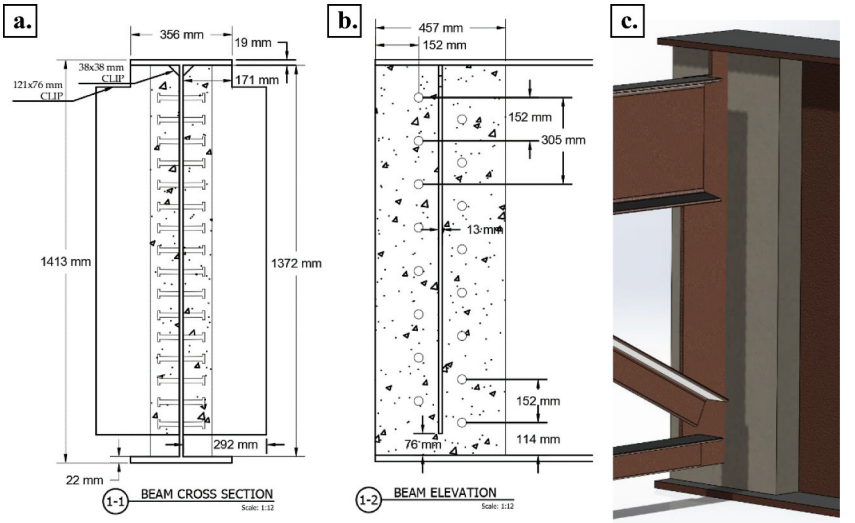

Figure 5. a) Cross sectional CAD schematic of embedded plate connection option, b) elevation view of embedded plate option, and c) 3D rendering of embedded plate option.

While this design primarily follows that of a gusset plate, several additional challenges are encountered. First, the UHPC bearing column is split into two sections with only small connection points. Additionally, each section of the UHPC column only has one row of studs and the minimal connection points may limit the studs on either side of the gusset/stiffener plates acting as a cohesive element. A second major complication is that the embedded plate cannot be easily replaced if it corrodes. Although the underlying web will remain intact, the diaphragm itself is still susceptible to corrosion and may require replacement. While the diaphragm cross members can be replaced, the embedded plate cannot be moved without removing the UHPC first.

3 FUTURE RESEARCH

The design of steel bridges with UHPC structural elements is a very new concept and has not been applied beyond rehabilitation. Significant research and development are required before bringing the proposed method to implementation. The current design and previous repair

have shown that it is viable to have a UHPC bearing column serve as a structural replacement for a steel bearing stiffener. In parallel, the research team is developing a life-cycle cost analysis comparing UHPC encasement, zinc metalizing, galvanizing, painting, and weathering steel. This analysis will provide valuable insight into the cost-effectiveness of UHPC as a protective method. Additionally, a forum with industry professionals was held and the data is being processed to evaluate the proposed diaphragm connection options in terms of cost effectiveness, design, and construction. Following analysis of this survey, the research team will take the best option and conduct a more in-depth design, including finite element analysis and performing full-scale tests on the diaphragm connection to the UHPC bearing column.

4 CONCLUSION

This work proposes a new design for a steel bridge bearing column by replacing the conventional steel bearing stiffener with a UHPC bearing column. While the majority of design for the beam can remain unchanged, the connection of a steel diaphragm to a UHPC bearing column presents a novel challenge to designers implementing this method. In this paper, two options are presented to overcome this challenge. The first option requires the embedment of steel anchor rods in UHPC, either cast in place or post-installed. The second option utilizes a modified steel stiffener and focuses on ease of design and construction. Both options are feasible but require significant further research before implementation can be considered. The designs presented in this paper provide multiple options for diaphragm connections to a UHPC bearing stiffener and identify several key areas where further research would benefit the existing literature on composite connections. The main learnings from this paper can be summarized below:

- UHPC beam end encasement is a promising method for eliminating corrosion under a deck joint in a steel bridge.
- A UHPC bearing stiffener can adequately sustain bearing loads at a beam end.
- Anchor bolts embedded in UHPC are a key area that further research is needed.
- Standard details for diaphragms can be integrated into a UHPC bearing column to minimize disruption to a steel bridge design process.

Identifying system redundant members in a steel arch bridge through advanced finite element analyses

A. Mosavi, H. Yuan, M. Tatarsky & M. Carter
Arup USA Inc.

ABSTRACT: The AASHTO LRFD Bridge Design Specifications define Non-Redundant Steel Tension Members (NSTM) as primary steel members subject to tension, whose failure could potentially lead to the collapse of a portion or the entire bridge. Bridges with NSTMs must adhere to special mandatory bi-annual hands-on inspections according to the National Bridge Inspection Standards (NBIS). These additional inspections, beyond routine checks, incur unnecessary costs for bridge owners.

Research indicates that bridges with traditionally designated NSTMs often retain significant strength reserves even after NSTM failure. AASHTO introduced a new guide specification in 2018 and outlined a detailed procedure for reclassifying NSTMs as System Redundant Members (SRMs). The procedure requires detailed nonlinear finite element analysis (FEA) to assess the available additional system redundancy.

This paper summarizes the FEA results for a newly designed steel arch bridge. AASHTO guideline procedure were directly followed to remove NSTM designation from the tension-tie members of this bridge.

1 INTRODUCTION

Non-load-path-redundant steel members were given a special designation of "Fracture Critical (FC)" following the collapse of the Silver Bridge in the US. This designation indicated that failure of these tension members could lead to collapse of the bridge. This term was first used in "AASHTO Guide Specification for Fracture Critical Non-Redundant Steel Bridge Members" in 1978 (AASHTO 1978). The most recent AASHTO LRFD Bridge Design Specifications (AASHTO 2017) define FCMs as "A steel primary member or portion thereof subject to tension whose failure would probably cause a portion of or the entire bridge to collapse". Special hands-on inspections have been mandatory for primary steel members designated as FCMs. These mandatory inspections impose additional costs for the owners. However, several studies have shown that bridges with traditionally designated FC Members (FCM) possess considerable strength reserves after the failure of these members. As the result, NBIS 2022 (FHWA 2022) has updated the terminology used for FCM to Non-Redundant Steel Tension Member (NSTM) to remove confusion around FCMs and failure criticality of these members. Also, a new AASHTO Guide Specification released in 2018 (AASHTO 2018) outlines a detailed procedure for reclassification of NSTMs as SRMs. The reclassified SRMs are not subjected to the same mandatory inspections as FCMs. As the result, bridge owners can save on their inspection costs and reallocate the saved budget to other priorities.

This paper summarizes the applied methodology and results of a study performed to reclassify NSTMs as SRMs in a new steel arch bridge. This bridge was a new design, and edge girders of the bridge were originally identified as NSTMs. A detailed nonlinear Finite Element Model (FEM) of the bridge was developed following the outlined procedure in the AASHTO Guide Specification. The critical bridge loading patterns are found, and detailed analyses are carried

DOI: 10.1201/9781003483755-267

out to assess the existing level of system redundancy in the bridge. The strength and serviceability requirements of the AASHTO Guide Specification are evaluated, and it is concluded that the edge girders in this bridge can be reclassified as SRMs. The outlined work established the methodology for adoption of the computationally intensive AASHTO procedure. The methodology will save a considerable amount of unnecessary inspection money for bridge owners during the bridge service life. In addition, it gives a better insight on the available redundancy within the structure and where the inspection effort should be better refocused.

2 METHODOLOGY FRAMEWORK

The AASHTO methodology starts with a screening process for the suitability of the candidate bridge. The full details of screening can be found in the AASHTO Guide Specification (AASHTO 2018). If the screening is satisfied, a detailed FEA is required to assess the available system redundancy for reclassification of the NSTMs within the candidate bridge.

The FEA methodology analyzes the structural responses of the candidate bridge at faulted states of the NSTM. FEA analyses shall be performed using a FE software capable of modelling the three-dimensional geometry, material and geometrical nonlinearity, kinematic constraints and a boundary conditions. Specific requirements set for the FEA software are outlined in the AASHTO Guide Specification (AASHTO 2018). This study has used LS-DYNA® which is a multi-purpose explicit and implicit finite element program capable of performing several types of nonlinear modeling.

Two failure locations at the middle and near the end of the tension tie member at its intersection with the arch are considered following the recommendations from the AASHTO Guide Specification (AASHTO 2018). The available system redundancy of the bridge is evaluated in these two failure scenarios assuming a full loss of steel beam cross-section.

Two redundancy load combinations are considered to investigate the performance of the bridge at its faulted state. The live loads are placed on the bridge deck maximize the demands in these load combinations for the remaining structure. The load combinations are:

1. Redundancy I: This load combination is designed to simulate the amplified dynamic effects during the free vibration immediately after the member failure. Only traffic lanes are considered for live loading of the bridge deck.
2. Redundancy II: This load combination assesses the performance of the faulted bridge under normal vehicular use after the failure event. Design lane loads are used to maximize the demands on the bridge.

The total factored load, *no*, for these redundancy load combinations are as following:

$$\gamma Q_n = (1 + DA_R)[\gamma_{DC} DC + \gamma_{DW} DW + \gamma_{LL}(LL + IM)] \tag{1}$$

Where DC is the dead load for structural and non-structural components, DW is the dead load of wearing surface and utilities, LL is the live load, DA_R is the dynamic load allowance, IM is the Impact factor. The load factors for these two load combinations are presented in Table 1.

Table 1. Load factors for the redundancy load combinations.

Load Combination	γ_{DC}	γ_{DW}	γ_{LL}	DA_R	IM
Redundancy I	1.05	1.05	0.85	0.4	0.0
Redundancy II	1.05	1.05	1.3	0	0.15

Both strength and serviceability requirements shall be met in these two redundancy load combinations in order to reclassify the NSTM to SRM. For the strength requirements, the following conditions shall be met in steel and concrete components:

– The average strain within the primary steel member shall remain smaller than five times the material yield strain. The average strain within the primary steel member shall also remain below 0.01. Also, the maximum strain anywhere within a primary steel member shall remain below 0.05.
– The compression strain within the concrete slab shall stay below 0.03.
– Also, both the foundation and substructure shall be able to support an additional 15 percent of the factored live load.

In addition, the following serviceability performance criteria shall be met to reclassify the NSTM to SRM:

– The maximum vertical deflection remains below L/50 for both the longitudinal primary member and floor beams, where L is the span length for the longitudinal primary member or distance between the remaining floor beams, respectively.

3 BRIDGE DESCRIPTION

This study is performed for a multiple tied-arch bridge, shown in Figure 1. The bridge has three arch spans. The two end spans are steel arch spans with hanger elements with an approximate span length of 260 ft. The middle span with the supporting steel arch below the deck is approximately 130 ft long. The total bridge length is over 650 ft. The bridge includes five traffic lanes, separated by a traffic median in the middle. Figure 2 shows the bridge deck typical cross-section with a total width of 101.5 ft.

The concrete column/abutments at the end spans and four foundation caps with drilled shafts in the middle support the steel arches at their ends. The arches are steel box girders. Tension tie members of the end spans are wide flange steel girders supported by the hanger

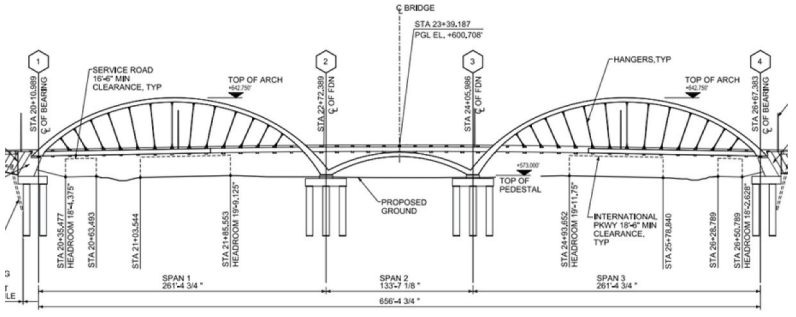

Figure 1. Steel arch bridge elevation view.

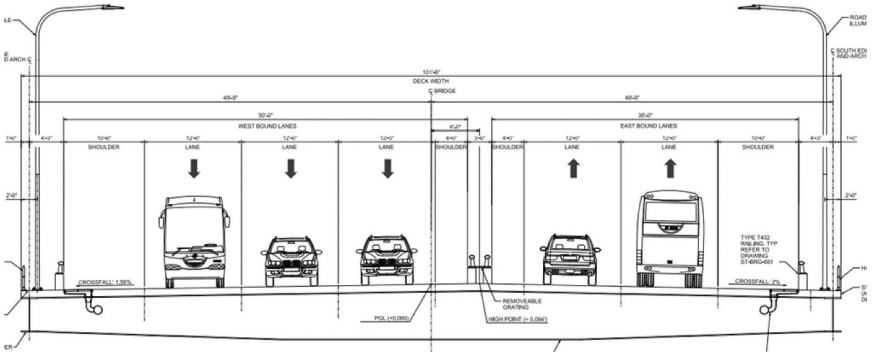

Figure 2. Bridge deck typical cross-section.

elements of the arch spans. The bridge deck is a 10.5" thick concrete slab compositely working with the floor beams and edge girders as shown in Figure 2. The floor beams running in transverse direction are placed at 15.5 ft spacings. The bridge is also designed with two sets of redundancy trusses as shown in Figure 3.

4 FINITE ELEMENT MODELING AND ANALYSES METHODOLOGY

AASHTO Guide Specification (AASHTO 2018) provides a guideline detailing the FEM requirements for the analyses. The outlined procedure intends to ensure the nonlinear behavior of the bridge at the fault state is properly captured by using the appropriate element type, size and properties for different material and component behavior. The FEM modeling in this study followed the provided guideline in great details. A 3-D detailed FEM of the bridge is developed is LS-DYNA as shown in Figure 3. A full description of the modeling approach for this study can be found in (Mosavi 2022).

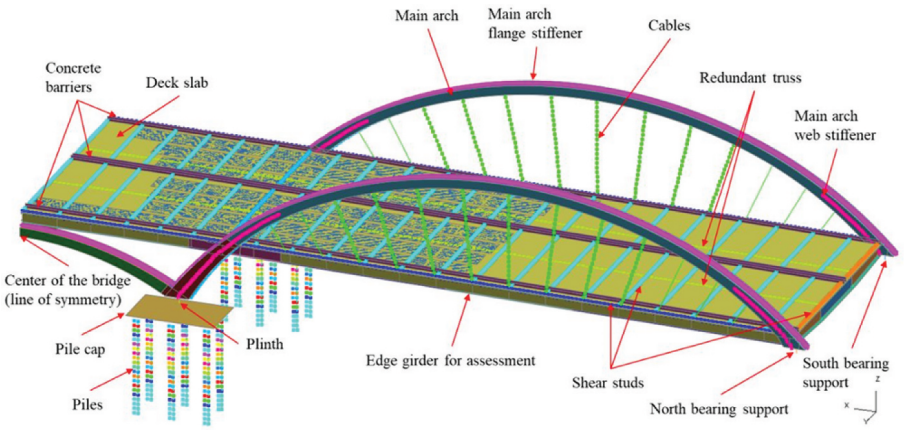

Figure 3. FE model of the candidate steel arch bridge.

Only half of the bridge is modelled with symmetrical boundary conditions at the line of symmetry to minimize the cost of analyses. This is shown still to be accurate as the location of the fault was within the end span and away from the line of symmetry.

All the primary steel members of the bridge are modelled using 4-noded linear Velichko-Lin -Tsay shell elements with reduced integration. These shell elements also have three integration points through thickness. All flanges and webs are modelled with a minimum of four shell as

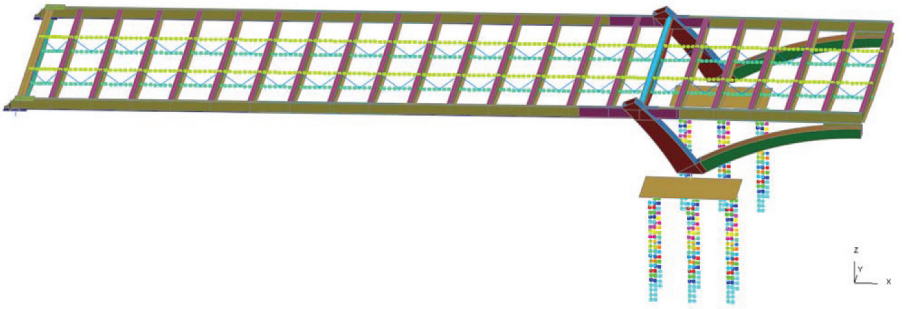

Figure 4. FE modeling of the redundancy trusses.

outlined per AASHTO Guide Specification (AASHTO 2018). The connections of the steel arch sections with the longitudinal tension tie edge girder and the transverse floor beam are modelled in full detail to ensure the true behavior of the connections. Also, both transverse and longitudinal stiffeners within the steel arch both girders are fully modelled to ensure analyzed strain values within the structure can be directly used without additional interpretations. Also, 2-noded nonlinear beam elements are used to model the secondary beam elements of the redundancy trusses as shown in Figure 4.

The foundation drilled shaft are modelled using linear beam elements. Also, linear spring elements are used in both transverse and longitudinal directions at every two feet along the length of the pile to model the force-displacement behavior of the soil around the piles. The pile cap was modeled using elastic linear shell elements. The pedestals on top of pile caps are modelled using linear beam elements, and nodes of the pedestal are connected to the nodes of the shell elements of the steel arch and pile cap using constraint equations. The abutment foundation at the end is not directly modelled since the abutment foundation is stiff and no major deformations are expected.

Nonlinear shell elements are used to simulate the concrete deck slab. This nonlinear composite shell element includes layers presenting cross-sectional properties of both top and bottom longitudinal and transverse reinforcements as shown in Figure 5. The thicknesses of these layers are calibrated to present the steel reinforcement cross-section correctly in both directions. The shell elements are modelled with representative nonlinear concrete and steel material curve as outlined per AASHTO Guide Specification (AASHTO 2018). The full details of the used nonlinear material curves can be found in (Mosavi 2022).

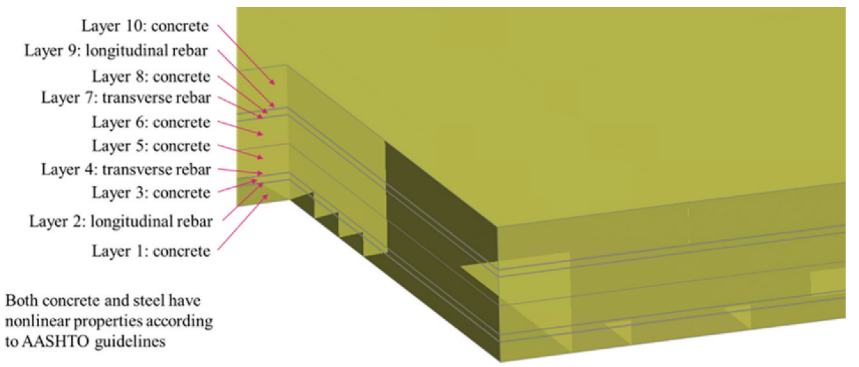

Figure 5. FE modeling of the concrete slab.

Shell studs are modelled using nonlinear beam elements. A set of nonlinear force-displacement curves are developed to model the full behavior of the shear studs in tensile and shear. These nonlinear curves are developed following the formulas outlined in AASHTO Guide Specification (AASHTO 2018). The full details of the developed tensile and shear properties of the shear studs can be found in (Mosavi 2022). The nonlinear beam elements of the shear studs are explicitly modeled with one node connecting to the top flange of the steel edge girders and floor beams and the other node connecting to the nodes of the shell elements of the concrete slab.

The hanger elements are modeled using tension-only cable elements. These elements did not possess any compression stiffness. Tensile failure force of the hanger elements is at 1044 kips and has an elastic modulus of 23000 kiss.

The material curves are used to simulate the nonlinear behavior of concrete slab with a 28-day compressive strength of 4000 psi. The steel nonlinear material curves are developed for ASTM A709 structural steel. Also, steel reinforcements are A706 Gr. 60.

Boundary conditions are simulated to represent the articulation plan presented in Figure 6. The boundary conditions at the median span foundations were modelled as discussed in the previous sections. The bridge had two expansion joints at its two ends. The boundary

conditions at the line of symmetry were modelled to simulate the symmetrical boundary conditions, and the bearings at the ends of the end span were modelled using beam elements to simulate the stiffness properties of the bearing.

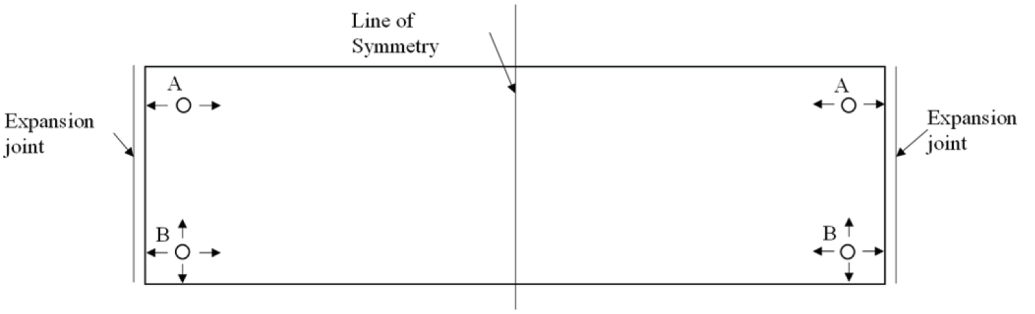

Figure 6. Articulation plan of the bridge.

Two damage scenarios are simulated. One is in the middle of the end span and the other one is at the end of edge girder close to its connection with the steel arch box girder. In both scenarios, the damages are assumed through the full height of the tension tie edge girder, and they are simulated by introducing two sets of nodes on either side of the simulated full height cracks.

Critical load patterns are identified to maximize the demand at the location of the simulated fault. Figure 7 shows the critical HL-93 vehicular live load pattern which maximizes the demand at the simulated fault location in the middle span for both redundancy I and II load combinations. Similarly, Figure 8 shows the critical HL-93 live load pattern for the fault location at the end of the end span for both of redundancy load combinations.

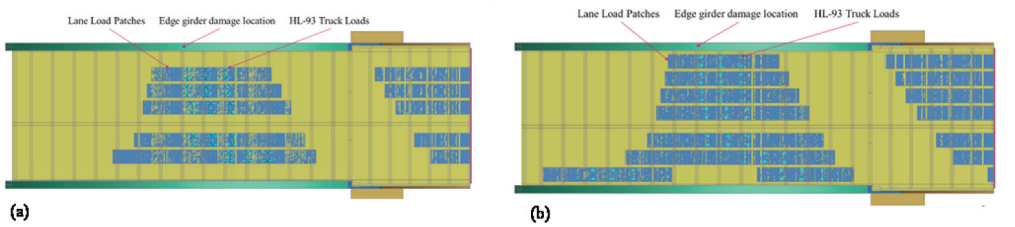

Figure 7. Vehicular live loads for (a) Redundancy I and (b) Redundancy II load combinations, Failure location in the middle span.

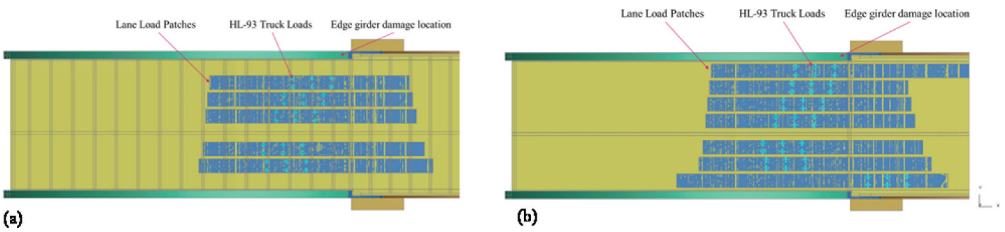

Figure 8. Vehicular live loads for (a) Redundancy I and (b) Redundancy II load combinations, Failure location in the end of the span.

5 DISCUSSION OF RESULTS

Strength performance requirements are checked by reviewing the strain values within the flange and web of the primary steel members. Figure 9 shows the von misses strains for both

redundancy I and II load combinations at the simulated fault scenario in the middle of the span, and Figure 10 shows the von misses strains in the primary steel members at the simulated fault state at the end of the end span. The average strain values within the primary steel members stayed below five time of the yield strain or 0.0086. The peak von misses strain is at 0.0014 for the midspan fault scenario and at 0.002 for the end span fault scenarios. These peak values are also comfortably lower than the maximum peak strain of 0.05. Additionally, the maximum compressive strains of the concrete are screened. The minimum principal strain within concrete slab remained comfortably below 0.0003. Only one single concrete shell element was found exceeding this strain limit, and this was considered a local numerical outlier. More details on the results of concrete strains and cracking can be found in (Mosavi 2022).

It is observed under both damage scenarios there were a few failing shear stud beams at the vicinity of the damage location. However, it did not result in a progressive failure and the area with the failed shear studs remained limited.

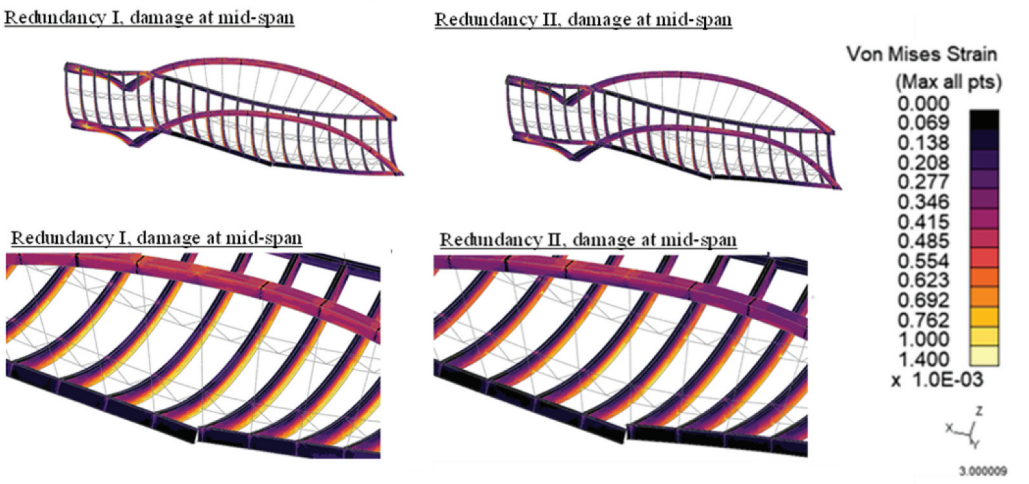

Figure 9. Von Misses strain plots of the primary steel members for the fault scenario in the middle of end span under redundancy I and II load combinations.

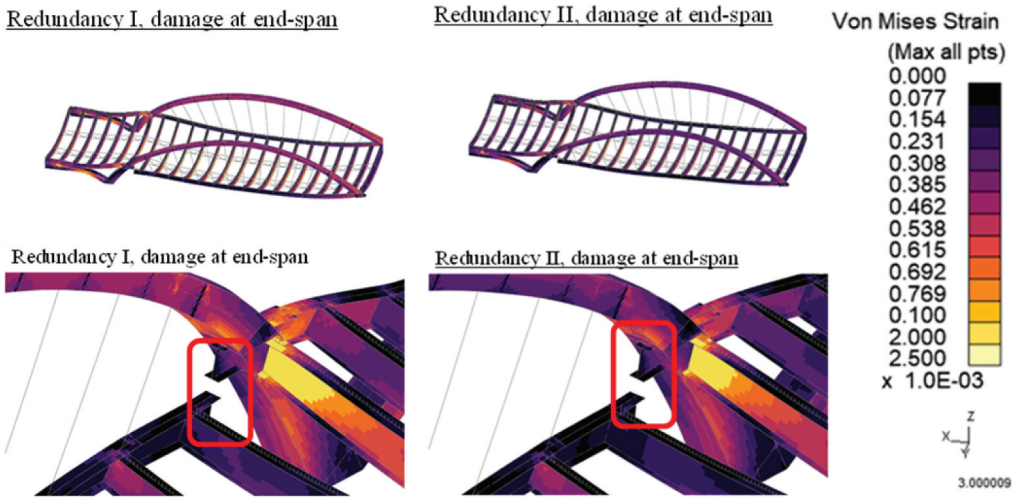

Figure 10. Von Misses strain plots of the primary steel members for the fault scenario at the end of end span under redundancy I and II load combinations.

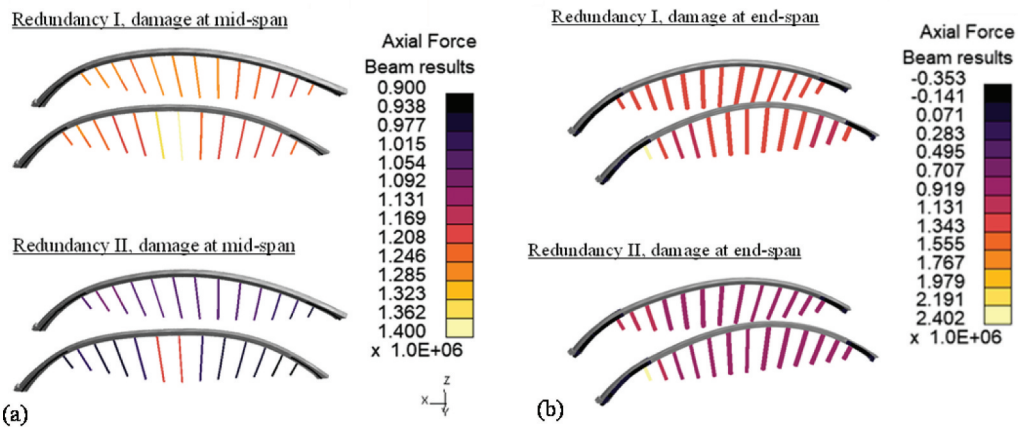

Figure 11. Hanger axial forces at both fault scenarios (a) middle of the span and (b) end of the end span under both redundancy I and II load combinations.

Overall, the deck loads previously carried by the edge girder redistributed either through the floor redundancy trusses to the other girders or to the steel arch box girders through the extra loads carried by the hanger elements. Figure 11 shows the distribution of the axial forces of the hanger elements under different redundancy load combinations at both fault scenarios. Also, all serviceability criteria were satisfied with deformations within the primary members remaining below L/50. More details on the results can be found in (Mosavi 2022).

6 CONCLUSIONS

This paper proposes reclassifying Non-Redundant Steel Tension Members (NSTMs) as System Redundant Members (SRMs) in a newly designed steel arch bridge, using a detailed procedure outlined in the AASHTO Guide Specification (AASHTO, 2017). The procedure involves detailed nonlinear FEA to assess the bridge's strength and serviceability performances under prescribed failure scenarios. The analysis of a new steel arch bridge, where edge girders were initially identified as NSTMs, revealed that strain levels in primary steel members and the concrete deck remained well below the prescribed AASHTO limits. Limited local cracking and shear stud failures were observed, confined to specific areas, with no progressive bridge failure. Maximum deflections also met serviceability requirements. Consequently, the study concludes that reclassifying edge girders as SRMs is safe, eliminating the need for bi-annual NSTMs inspections. This will potentially reduce the owner's operational maintenance cost of the newly designed bridge in a significant way.

Bridge condition and performance monitoring: An engineering approach

P.S. McCarten
Transport and Main Roads (Retired), Hawkes Bay, New Zealand

ABSTRACT: Historically bridge inspection was focused on defect reporting to record the 'health' of network bridge stock. The introduction of asset management principles and practices resulted in a change to condition reporting of network bridge health. Concerns with the current method are the Bridge Index has low sensitivity to criticality, Bridge Inspectors are using 'bias' to report perceived condition, and, the Bridge Index while suitable for high level reporting could not be used in 'day to day' bridge management. Currently an experienced and trained Bridge Management Team is accepted for bridge intervention but being based on visual inspection reporting it has high subjectivity on the hidden features. This paper outlines an engineering approach to ensure the bridge health is identified and defined for reporting. The paper hence is focused on the hidden features and considers risk and criticality. The paper presents various case studies to show the need for monitoring.

1 INTRODUCTION

Through contractual requirements and ethical obligations Bridge Managers have a responsibility to ensure bridge user safety and bridge stock is consistently within the condition and performance requirements set by the bridge owner, typically a Road Controlling Authority (RCA). The bridge management contractual requirements may be specifically scheduled or they may be bound within general 'stewardship' responsibilities. Bridge management contracts will usually allow the Bridge Management Team flexibility on the work processes to be used. In this paper the Bridge Management Team (BMT) is assumed to consist of three nominated positions, being:

- Bridge Manager: Responsible for overall BMT performance and outputs, and, liaison with the RCA
- Bridge Inspector: Responsible for undertaking and gathering the inspection information needed for the contract. This may involve several inspection teams and specialist personnel as required
- Bridge Engineer: Responsible for reviewing the inspection information and assessing risk and implications. This may involve specialist personnel as required

The RCA sets out the general management requirements in respect to inventory and inspection data collection, intervention programming requirements, and, bridge condition reporting requirements to meet short and long term network objectives. It is recognized that advanced asset management is a process consisting of predictive modelling, risk management and optimized decision making to develop the required life cycle treatment options to meet the strategic targets. Bush et al. (2011) highlighted the importance of collecting complete, comprehensive and reliable data to define and report the linkage between bridge management and the wider strategic vision to achieve a sustainable and economic network.

McCarten (2012, 2014, 2016 and 2018) respectively set out the basic risk requirements and performance measures for the bridge stock recognizing that each bridge is a complex

DOI: 10.1201/9781003483755-268

engineered system. The previous McCarten (2012, 2014, 2016 and 2018) papers have considered the network with a probabilistic perspective but with a move to an engineering approach to managing bridge networks (Austroads 2021) there is a need to consider the specific issues affecting each bridge within the network.

This paper focuses on condition and performance monitoring following an engineering approach underpinned by high quality evidence and generally follows a proactive preventive maintenance approach. By necessity the identification process needs to identify, quantify and assess risk and criticality issues.

2 BACKGROUND AND MOTIVATION

While this paper is focused on Condition and Performance monitoring it is useful to understand historic approaches to bridge inspection reporting. A core part of a mature asset management system is learning and updating systems and practices to ensure future practice is meaningful and targeted to meet outcomes required in a cost effective and efficient manner. A prime motivation for this paper is recording failures and incidents that can improve practice.

Historically bridge inspection was considered a safety inspection focused on defect reporting by identifying issues to be included in a bridge maintenance program. The principal outcomes were to ensure the bridges were safe for continued use, and, report on issues identified as not meeting RCA accepted condition. Initially non-complying issues were defined by an experienced Bridge Engineer familiar with RCA requirements.

Bridge inspection programming was formalized in the early 1970's following the tragic failure of the Silver Bridge caused by eyebolt stress corrosion cracking in a connection detail with low redundancy. It was recognized that under historic inspection requirements bridge inspection reporting had a degree of subjectivity. In order to ensure complete bridge inspection reporting and set up a sound asset management approach many RCA have implemented Condition reporting using a segmented component methodology reporting the specified Condition States for the full extent of the complete range of components on each bridge. In order to remove the historic subjectivity RCA's have produced a suite of photographs showing all components for the range of Condition States to be reported (these vary but typically between 3 and 10 Condition States).

There has been much research on the Condition States approach to bridge inspection reporting, Sanford et al. (2000), Frangopol et al. (2001) and Catbas & Aktan (2002). McCarten (2004) provided a method for using bridge inspection information in 3P (Public Private Partnership) concessions and McCarten (2006) showed how a bridge stock index could be used to correlate bridge condition to financial investment. This latter paper showed that an investment of 0.3% of the total bridge replacement cost was required to maintain the condition steady. While this research shows the Condition States approach gives transparency, enhances asset management reporting and strategic visions for bridge networks there are concerns it has limited use for 'day to day' bridge management and is deviating from the 'safety inspection' objective. These concerns are related to Bridge Indices reporting an 'average' condition which is not reflective of defect criticality, and, Bridge Inspectors using 'bias' to report critical defects. These practices impact the integrity of the bridge management systems and processes.

It is widely accepted that visual inspections alone provide limited reliability in reporting bridge condition. Bridges are an engineered system, Aktan et al. (2013) and defects can be built into a structure. FHWA (2021) has recognized the risks of defects and requires BMT to report them. The defects may be original construction related which may develop under service or they may develop under service and continue to change. With changes in bridge inspection programming the significance of developing defects may not be recognized. Monitoring offers the opportunity to better define the nature of the defect and the defect risk/criticality.

For more than 20 years there has been significant progress in developing instrumentation, data collection at remote sites and data analysis methodologies to improve the quality and reliability of evidence for bridge management decision making. These technologies along with Non-Destructive Testing (NDT) and visual inspection provide a range of tools for cost effective targeted monitoring for 'day to day' bridge management.

NZTA (2013) reported a Road Efficiency Group Case Study: Bridge Management Frameworks – Managing Risk and Ensuring Value for Money that recognized "...the majority (of failures) are preventable if we can embed a structured approach to assessing and acting on vulnerabilities and learning from our experiences...". It is for these bridge management concepts and recognizing the importance of bridge safety the industry is moving toward an engineering approach for bridge management, Austroads (2021). It is these concepts that provide the motivation for this paper and the concepts are further expanded below.

3 CONDITION/PERFORMANCE DEFINITION

In this paper bridge Condition and Performance are considered with the following definitions:

- Condition: is the state of a Component with regard to its appearance, quality or working order. The Condition is reported by the states defined by the RCA. A Defect or Issue is a Condition that is adversely affecting a Component
- Performance: is the action or process of the Bridge performing a task or function. Performance reporting is focused on the Bridge ability to meet the required demands. A Defect/Issue is reporting an influence causing the Bridge to not meet the required demands

In an engineering approach to bridge management the BMT must recognize the reserve of strength accepted by the RCA through allowing lower load factors when rating a bridge compared to those used for bridge design. The BMT must understand the effects of construction defects on this strength reserve to know what is available for in-service deterioration effects and/or increasing load effects on the bridge network.

Irrespective of the way the Condition or Performance is reported under stewardship any Defect/Issue must be assessed by the BMT for risk and criticality on each Component or Bridge, whether that be strength or function. It is recognized that a visual inspection may not give the information needed and it is considered monitoring will be required to improve the quality and reliability of the information for bridge management decision making. Bush et al. (2011) sets out a risk and criticality approach to inspection and data collection.

Many RCA are setting strategic plans requiring an increase in bridge network robustness and resilience. The BMT must know the limitations of the existing bridge stock and even if all the bridge components are in excellent condition whether the Performance demands will be met.

4 BRIDGE CONDITION MONITORING

In general Bridge Condition Monitoring (BCM) is well defined and embedded into Bridge Management practice and there are many guides, Austroads (2018) and Austroads (2021), that set out the processes to follow and the planning required for monitoring. It also needs to be recognized that monitoring may identify the response of 'unknown defects' if the monitoring is well planned and the known defect effects fully identified, any residual defective response may be attributed to an 'unknown defect'. Due to cost of monitoring a risk and criticality, Bush et al. (2011), approach is suggested for monitoring selection. As reported in McCarten (2018) bridge failures and significant incidents are still occurring and the following practice changes are suggested:

a. Enforce the need to better understand the nature and risk of Defects/Issues reported, FHWA (2021). Include monitoring in bridge management investment funding, include monitoring in Bridge Inspection forms and consider it as 'day to day' bridge management
b. Align BMT condition risk reporting with bridge design standards. McCarten (2012) showed that any bridge with 3% AEP (Annual Exceedance Probability) likelihood of failure could be justified for replacement and hence should be monitored until replacement occurs. It is recognized that FHWA (1991) requires BMT to confirm bridge foundation failure is unlikely under the 0.2% AEP event due to the high number of waterway bridge failures
c. Avoid confusion with monitoring terminology/jargon (NDT, NDE, SHM and SM should be defined) to ensure common understanding of requirements and outcomes

d. The academic, consulting, BMT and RCA staff, the wider bridge management industry, must liaise and work together with any monitoring work recognizing the skill sets and value added by each party

While BCM tends to be considered for the structure and materials parts of a bridge the opportunities for monitoring other bridge risk components should not be discounted. The following case studies for BCM provide further guidance on this and follow a proactive preventive focus with monitoring:

- BCM Case 1: Foundations: A two span (20m overall length) one lane bridge failure occurred in a remote location with the central pier settling 180mm during a 10% AEP event. A review was undertaken to assess whether monitoring could have avoided traffic disruption and the need for a temporary bypass. The review determined a borehole positioned immediately adjacent the central pier may have given sufficient notice of the impending failure but the geotechnical analysis would have been required to clearly quantify skin friction effects. General 30mm/year degradation of the river bed had been recorded and was determined to be due to softening of the argillite basement material
- BCM Case 2: Substructure: A 30year old four span (100m overall length) two lane bridge carrying approximately 25,000 vehicles per day was planned for replacement with a one lane bridge. The main reasons for bridge replacement included existing half joint hammer head pier caps (considered by the RCA as a low redundancy component), poor condition as evidenced by cracking at the base of the pier cap upstand/rear of the half joint corbel, and, an analysis showing 'theoretical deficiency' in the pier cap load carrying capacity. Durability testing was undertaken confirming corrosion was not significant from both carbonation and chloride ion, the bridge located approximately 5km from the coast, This first stage investigation included bridge inspection identifying possible bearing movement issues. Subsequent investigation of the pier cap cracking showed this effect only extended approximately 0.5m to 1m from the pier cap ends, with the extent considered to be limited by the large 1.8m diameter central pier columns. The cracks were assessed to be associated with load sharing with the designed pier cap reinforcing – consisting of stiffer diagonal reinforcing and normal corbel flexural reinforcement. This second stage investigation confirmed the bearings had not 'locked' and were still accommodating the determined movements. The original design calculations and designer sketches showed there was more reinforcing in the pier cap than considered in the structural analysis. Hence it was determined that all structural matters were met, especially with the proposal to shift the traffic to the central part of the cap with the single lane configuration, and it was recommended the end cracks be epoxy injected to maximize cap durability and enhance shear transfer. The monitoring and investigation cost of approximately $0.5M showed bridge replacement (assessed at $12M construction cost only) could be deferred at least another 30years achieving a cost effective and sustainable outcome
- BCM Case 3: Superstructure beams: This 90year old 20 span (245m overall length) two lane bridge carrying approximately 15,000 vehicles per day is located in an aggressive coastal environment. The bridge can accommodate a 1.5% AEP flood event without overtopping and to date there have been at least two bridge submergences. At approximately 25 years old a bitumastic coating was applied to the beams to enhance service life. Unfortunately, the coating limited visual inspection of the beams. When the bridge approximated 55 years old significant signs of deterioration were being observed through some parts of the coating and a comprehensive concrete condition survey was undertaken. This survey highlighted several 'hidden details' including:

  a. Chloride ion corrosion dominated beam deterioration and pitting corrosion was significant
  b. The concrete while generally good had parts with low compaction, these were evidenced by more than normal number of voids. The voids were such that stirrup reinforcing bars could corrode away completely with no cracking or rust staining exhibited at the beam surface, even if the coating was not present

c. The main reinforcing consisting of 32mm diameter plain bars was assessed to have reduced bond due to the bar surface corrosion. The bar strength is very reliant on the end 180degree hooks. The slippage from the bond loss could be expected to impact beam response
d. The report noted the concrete condition survey sampled a range of different parts of the bridge to get an indication of the range of defects, but the survey should not be considered comprehensive in extent of each defect over the 20 span bridge

When the bridge approximated 60years old a major concrete repair was undertaken, approximate cost $1.0M. The repair was risk targeted focusing on the beams closest to the coast and parts of the inner beams with a coating applied to the beams and spans over the main river channel. The repair work included reinstatement of many 10mm diameter stirrups that had completely corroded through. Comprehensive records of the work completed were taken so future bridge managers would be aware of the parts of the structure repaired and hence be able to assess the extent of bridge not opened up and that could still have the deterioration/defects recorded in the concrete condition survey. Due to the potentially significant extent of 'hidden deterioration/defects' with pitting corrosion and main reinforcing bond loss being of particular concern, Structural Health Monitoring (SHM) using a known load test was promoted as a reliable and cost effective method for supplementing visual inspection monitoring. The BMT compiled a bridge management plan for the bridge and the RCA initiated investigations into replacement bridge and road realignment options

- BCM Case 4: Superstructure deck: This case study expands on that included in McCarten (2022) providing more background on the subject bridge and BCM work undertaken. The bridge now almost 65years old of 5 spans (217m overall length with 3 steel truss spans of 57.6m, 82.3m and 57.6m, and, two short steel beam land spans) and two lanes carrying approximately 6,000 vehicles per day. The steel truss superstructure was made continuous following the development of steel truss fatigue issues. The continuous superstructure was lively but within the RCA requirements. The low level of deck shear connectivity (20mm diameter shear studs at 1.8m centres) is considered to contribute to the superstructure liveliness. Overall bridge expansion/contraction movement occurs at the north end of the bridge with a large steel plate expansion joint. Significant traffic impact effects occur with the expansion joint. Major industrial development south of the bridge has generated significant numbers of fully laden trucks travelling southward over the bridge and due to the road geometry some of these trucks had been recorded crossing the bridge at approximately 130km/hr. The Weigh-In-Motion site set up in 2010 data analysis has confirmed overloading to approximately 20% over the legal axle limit occurs. As reported in McCarten (2022) the 1980 cracking in the 150mm thick deck was significant and a speed limit imposed. The early cracking pattern reflected construction practice but there was negligible drying shrinkage or plastic settlement cracking. Subsequent cracking reflected traffic operations and loading effects compounded by plain round deck reinforcing and the superstructure liveliness. The bridge is located 30km from the coast and carbonation had not reached cover depth so durability deterioration was minimal. When it was agreed to remove the speed restriction in the early 1990's a BCM program was initiated. As international bridge deck fatigue experience was limited a 'first principles' approach was adopted using an NDT Test load versus Displacement methodology at 5 yearly intervals, refer McCarten (1991). Throughout the monitoring period crack width and extent of cracking, using "crack windows", was undertaken. It was expected that should the crack widths exceed 0.5mm then there was a high probability of losing compressive membrane effects and the grid like cracking pattern reflecting the slab bottom reinforcing could develop quickly. McCarten (2022) reported cracking that resulted in water leakage through the deck, it was determined these discreet cracks were associated with deteriorated water proofing leakage and low temperature effects and did not appear to significantly affect the general deck cracking observed. Approximately 15 years following the installation of the new water proofing system the general deck cracking had reached the stage for deck rehabilitation, McCarten (2022). The deck was rehabilitated using low viscosity epoxy crack injection, to reinstate original deck integrity, and the deck strength enhanced using carbon fibre strips to provide robustness for reinforcing bond loss and deck liveliness.

5 BRIDGE PERFORMANCE MONITORING

In general Bridge Performance Monitoring (BPM) is immature and Bridge Management guides, Austroads (2021), recognize that methods for monitoring Performance measures are required. Austraods (2021) presents seven Bridge Performance measures being:

a. Heavy vehicle loading – ability of the bridge network to accommodate the heavy vehicle configurations defined by the RCA
b. Bridge geometry – curvature, lateral clearance and vertical clearance to safely accommodate heavy vehicle passage with or without other traffic as required by the RCA
c. Bridge structural safety – recognizing inherent structural deficiency, collision damage, vehicle fire on/under the bridge and sabotage
d. Bridge safety under natural hazard
e. Resilience under natural hazard
f. Bridge condition
g. Value for money

The Performance of a bridge is principally set by the 'original bridge design' standards, unless retrofitted since original construction. As design codes change with time, generally becoming more demanding in requirements, the older bridges become more and more 'non-conforming' but they are still providing a useful function. As urban development/growth progresses the transport demands on the bridge network will increase. The integration of Bridge Asset Management requirements with the Network (Bridge) Planning requirements utilizes a Network Optimization process to generate a Bridge Management Strategy (BMS) for each bridge on the network, McCarten (2020). A comparison of the BMS Performance demand with the Performance provided by that bridge will show the "Performance deficiency" of the bridge. It is considered this Performance deficiency could be quantified and measured, and, by setting a target "Performance deficiency" bridge upgrading or replacement requirements could be prioritized in a transparent manner.

Many RCA are recognizing the requirement for Network Optimization process and identifying strategic objectives that provide high financial returns and are assessing the funding demands for those strategic objectives to confirm viability. Those strategic objectives provide an optimized preventive approach to managing the Performance deficiency. Some case studies on BPM providing further guidance on this are given below:

- BPM Case 1: Heavy haulage routes: The RCA will liaise with key stakeholders to identify appropriate routes and performance requirements required for those routes. The bridges on each route will be assessed for monitoring, upgrading or replacement. Route viability will be assessed by economic analysis and BPM requirements determined accordingly with Performance deficiency being fully addressed
- BPM Case 2: Natural hazard prioritization: Many RCA recognized that with the significant improvement in earthquake design requirements, developed through the 1970's and 1980's, there was a need to implement seismic prioritization in the 1990's/2000's to identify seismic performance deficiency in the bridge stock. Much work has been undertaken with retrofits of bridges to ensure acceptable seismic performance in the network. More recently resilience is recognized as a Performance measure, Austroads (2021). It is considered further assessments may be required to ensure emergency routes have the required seismic Performance. It is also considered bridge waterway risks should be subject to a similar prioritization process. This is because with increasing rain and river flow monitoring the reliability of flood discharge assessments is improving and with bridge site monitoring there is improved understanding of the hydrologic processes. With, say, an additional 10 or 20 years of river monitoring the bridge risks may be quite different from that originally predicted with bridge design. It has been observed that bridge site flood discharge assessments typically increase with longer flow monitoring periods. Some RCA have recognized the significant number of bridge failures over waterways and set specific Performance requirements, FHWA (1991), to identify Performance deficiency for monitoring or programming bridge retrofit

- BPM Case 3: Bridge access: Many RCA recognize the need to be proactive in providing bridge/road users with specific advice for "safe access" during flood events, DTMR (2022). Austroads (2021) recognizes that for bridges susceptible to high scour risk then consideration should be given to bridge closures under significant flood events. These initiatives require improved waterway analysis to ensure realistic closure triggers are adopted, an understanding of network operations (alternative route management), development of bridge monitoring/warning systems, and, implementing improved methods for communicating with the travelling public. The implementation of bridge site monitoring improves the reliability of the closure triggers and CCTV offers 'real time' bridge site response for communication purposes, especially where the network has limited road access

6 DISCUSSION

This study has found that most bridge defects/issues/failures are foreseeable and preventable if a structured approach to assessing and acting on vulnerabilities, and, learning from industry experience is embedded into bridge management practice. RCA's need to be confident inspections fully cover the extent of each bridge and all defects are reported. While a defect may have been identified the nature and risks of the defect need to be understood to ensure reliable and comprehensive information is used in bridge management decision making. Monitoring, whether visual, NDT or SHM, offers the opportunity to develop an improved understanding of any defect. The challenge for the BMT is identifying the type and extent of monitoring required and this decision needs to be undertaken with the RCA to confirm funding requirements. In some defect cases special consultants/academia may be required to assist with this process. Bush et al (2011) provide a risk and criticality approach to data collection prioritization to assist with funding investment requirements. BMT skill sets and contractual obligations may impact activity allocation.

There is a need to have a consistent approach to risk reporting with that appropriately aligned with bridge design and allowing for remaining bridge service life. McCarten (2012) suggests that if bridge failure is predicted under a 3%AEP event then that could provide a trigger for formal bridge monitoring. The study shows that embedding monitoring into Inspection Forms and 'day to day' bridge management puts in place a structured approach to assessing vulnerabilities.

This study has found Performance Monitoring to be immature in part due to the difficulties translating strategic objectives to the Performance management of specific bridges. The case studies presented show that many RCA are undertaking work to improve network bridge performance in an optimized manner, but this is only targeting parts of the network. Natural hazard prioritization has been used to improve network robustness and it is suggested resilience and development of emergency corridors offer a way to upgrade other parts of the network. "Safe Accessibility" is being pursued by some RCA to show good stewardship and proactiveness to the travelling public. It is suggested monitoring is required to improve reliability with safe access triggers.

Condition and Performance monitoring are core to an engineering approach to bridge management and with the limitations of visual inspections recognized monitoring using NDT, SHM and other techniques suggested in the Case Studies must be embedded into 'day to day' bridge management.

7 CONCLUSIONS

From this review of the Condition and Performance monitoring requirements for a network of bridges with bridge management following an engineering approach it is concluded:

- BMT needs to improve bridge risk reporting, aligned with bridge design risks
- BMT needs to be responsible for better quantifying defects/issues, to improve reporting and reliability for forecasting intervention investment
- RCA needs to include monitoring on Inspection Forms and encourage BMT to embed monitoring into 'day to day' bridge management

- RCA needs to be more proactive in setting Performance measures for accessibility, ensuring safety of bridge users, and, improving bridge resilience/robustness particularly under natural hazards
- RCA needs to define the Condition and Performance measures, aligned with strategic planning, to be monitored and reported by the BMT

Determination of precast concrete bridge slab connection stiffness by developing a digital twin

S. Ereiz, I. Duvnjak, J. Pajan, M. Bartolac, J. Košćak & D. Damjanović
Faculty of Civil Engineering, University of Zagreb, Zagreb, Croatia

ABSTRACT: The construction of bridges is usually a long-term task where the use of traditional concrete systems is challenging due to the installation of formwork, material falling from the scaffold and the disruption of traffic flow. Often, the use of such a system is limited due to the nature of the obstacle the bridge is spanning. As a solution to this problem, precast concrete slabs began to be produced and used in construction, which made construction easier but additionally caused problems for structural designers. One of the unknowns was how to interpret the connection between the slabs and how to describe the connection in the numerical model so that the global behavior of the structure matches the real behavior. This paper presents a determination of the precast concrete bridge connection stiffness by developing a digital twin. A pedestrian suspension bridge is selected as a case study. The digital twin of the precast slabs is developed by performing the numerical model and finite element model updating (FEMU). Based on the experimentally determined dynamic properties of the characteristic bridge slabs, the finite element model updating is performed. By updating the numerical model, the stiffness of the connection is determined.

1 INTRODUCTION

Among the various types of bridges, suspension bridges are increasingly used to span large spans and the richness of the architectural features and aesthetic aspects. However, their main cables and hangers may be subjected to corrosion and fatigue damage (Wickramasinghe & Wasanthi Ramyalatha, 2015). There is a need for a simple and reliable method to detect and locate this type of damage to subsequently make structural retrofitting and prevent further damage occurring (Zhang et al., 2019). SHM has emerged as an option that can meet this need (Heo & Jeon, 2016). Current SHM system are equipped with a variety of methods to detect damage of a local and global nature. The limitations of the local methods require non-destructive and global damage detection methods (Keshmiry et al., 2023). This has led to the continuous development of vibration-based damage detection (VBDD) methods in SHM systems (Chen, 2018). The basic principle of vibration based SHM is that damage changes the structural dynamic properties. Therefore, the change in structural dynamic properties can be used to detect damage. Due to the difficulty of detecting higher mode shapes in large structures such as suspension bridges, the applicability of existing damage estimates to this type of structure is limited (Comanducci et al., 2015). In addition, this type of structure oscillates in transversal, longitudinal, vertical, torsional, and combined mode shapes, making it difficult to identify the damage. According to the previous problem, a developing digital twin of the real structures and use it for the assessment of the structure is opened up (Hu et al., 2023). The advancement of the latest information technology and the widespread adoption of industrial information systems have spurred growing interest in the integration of cutting-edge technologies, including Digital Twins (DTs), into the civil engineering (Liu et al., 2020a). In this field, the finite element models are most commonly used for this purpose (Kaveh, 2014). To reflect the real structural behaviour, developed numerical mode is updated based on the experimentally determined

DOI: 10.1201/9781003483755-269

structural behaviour through the process of finite element model updating (FEMU) (Mottershead & Friswell, 2013). Utilizing DTs in engineering applications has the potential to greatly enhance the precision and intelligence of structural performance analysis. DT technology involves simulating the state and behavior of physical entities within a dynamic virtual model, offering high-fidelity representation (Liu et al., 2020b). Kessels et al. (Kessels et al., 2023) introduced different types of transient response features to update parameter values of nonlinear dynamic systems with increased computational efficiency and accuracy. In their work Ye et al. (S. Ye et al., 2020) they showed on the example of the freeway bridge in New Jersey that the operational monitoring of the bridge is sufficient for structural identification and that it enables the development of a 3D digital twin of the bridge that served in the formulation of meaningful interventions that can only be offered after model calibration. Jasiński et al. (Jasiński et al., 2023) presented the concept of DT development, its basic principles and features for its implementation in bridges where they highlighted the role of load testing in validating and updating the developed FEM model for further use in DTs. Jiménez Rios et al (Jiménez Rios et al., 2023) systematized information and knowledge on how information modelling of bridges, FEM and SHM can be combined and used to create DTs of bridges. Ghahari et al. (Ghahari et al., 2022) presented a Bayesian method technique for updating and developing a DT that includes the determination of various effects such as soil-structure interaction and the identification of measured structural responses. In their paper, Honghong et al. (Honghong et al., 2023) by reviewing, comparing and analysing 116 documents on Building Information Modelling (BIM) and DT concluded that the BIM framework can be significantly improved by DT to be implemented throughout the entire life cycle of a bridge. Ye et al. (C. Ye et al., 2022) made recommendations to encourage the adoption of bridge structure monitoring combined with the development of DTs in the form of numerical model development and their updating to realize industrial value. In this paper, the authors use DT to perform the FEMU of characteristic pedestrian suspension bridge slabs to solve problem of determination the stiffness of their connection. The following section provide some basics of the FEMU methodology used for the updating the DT of the characteristic slabs of the pedestrian suspension bridge. The section 3 provides the information about structure, initial numerical model of the characteristic slabs, experimental campaign, comparison between the predicted numerical model behaviour and the results of the experimental campaign while the last subsection describes the obtained results of the updating process. Section 4 discussed and evaluated the obtained results, since on the span slab the connection stiffness was determined through developing the DT and performing FEMU on span slab, while the obtained results are evaluated on the characteristic edge slab. The 5th section concluded the whole paper.

2 FINITE ELEMENT MODEL UPDATING - DIGITAL TWINS IN CIVIL ENGINEERING

For the practical engineering application, the updating process is usually performed considering the maximum likelihood method (MLM). According to this approach, the updating problem can be formulated as the combination of a bi objective optimization and a decision-making problem. The bi – objective optimization problem is defined in terms of the residuals between the experimentally obtained and numerically predicted structural dynamic properties. To optimize defined bi-objective function, nature inspired computational algorithms have been usually considered. According to the MLM the FEMU problem is transformed into an optimization problem. For this purpose, differences between the numerically predicted and experimentally obtained test results are defined in the form of the residuals. Using the structural dynamic properties natural frequencies residuals (r_t^f) are defined as relative differences, while the mode shape residuals (r_t^m) is most often defined in form of the modal assurance criterion and its derivates. General formulation of the FEMU problem under the multi objective approach can be defined as follow:

$$\min f(\theta) = (f_1(\theta)\, f_2(\theta)\,) = \; min\Big(\sum_{t=1}^{m_f} r_t^f(\theta)^2 \quad \sum_{t=1}^{m_m} r_t^m(\theta)^2 \Big) \tag{1}$$

where $f(\theta)$ represent the multi objective function, $f_1(\theta)$ and $f_2(\theta)$ is the first and second multi objective function residuals, m_f and m_m are the natural frequency and mode shape residual size; $r_t^f(\theta)$ and $r_t^m(\theta)$ are the residual vectors associated to the natural frequencies and normalized mode shapes. To guarantee that two types of residuals are well-balanced, they may be normalized as:

$$r_t^f(\theta) = \frac{f_{num,t}(\theta) - f_{exp,t}}{f_{exp,t}} \quad t = 1, 2, \cdots, m_f \tag{2}$$

$$r_t^m(\theta) = \sqrt{\left(\frac{\left(1 - \sqrt{MAC_t(\theta)}\right)^2}{MAC_t(\theta)}\right)} \quad t = 1, 2, \cdots, m_m \tag{3}$$

Optimizing defined objective function (Equation 1.), the optimal values of the parameters for which values the optimization is searching for are obtained. For the obtained values of parameters FE model the best represent the real structural behaviour and can serve for the other purpose such as structural maintenance, assessment, rehabilitation or defining the concept of the structural health monitoring.

3 FEMU OF PEDESTRIAN SUSPENSION BRIDGE

3.1 *Description of the structure*

Built in 1980, the suspension pedestrian bridge over the Drava River in Osijek is a testament to advanced engineering principles. With a span of 209,5 meters, the bridge has a statically prestressed catenary network, demonstrating precision in structural design to effectively connect opposite riverbanks. A parabolic suspension cable, securely anchored to blocks placed behind the bridge, spans 24-metre-high steel columns, highlighting the detailed engineering considerations. This integrates form and function, using precast concrete corridor panels suspended by inclined hangers on a parabolic suspension cable. The 5-meter-wide corridor itself contributes to the total width of the span, which is 6.12 meters. This architectural achievement exemplifies the merging of theoretical principles and practical application, establishing the suspension footbridge as a significant manifestation of scientific rigor and engineering excellence across the Drava River.

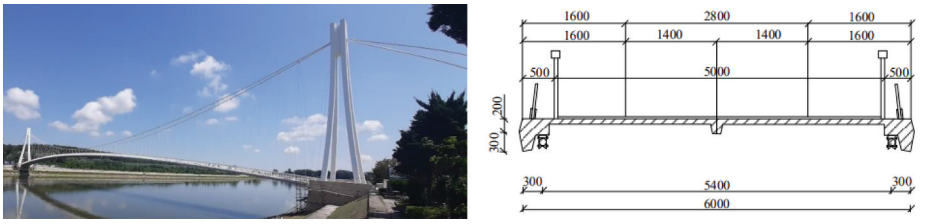

Figure 1. Pedestrian suspension bridge (a) view of the bridge (b) cross section of the bridge.

The span consists of prefabricated concrete slabs. There is a total of 50 of them, which can be divided into three types. The type 1 slabs are located at the beginning and end of the bridge (2 pieces). The type 3 slab is in the centre of the span (1 piece), while all other slabs are of type 2. These characteristic slabs have a dimension of 6 x 4 metres. The longitudinal and transverse ribs divide each slab into four parts. The lateral longitudinal ribs have a rectangular cross-section of 26 x 50 cm. The other ribs are 16 cm high, while their width varies: 12 x 18 cm for the longitudinal ribs in the centre, 12 x 15 cm for the outer transverse ribs and 16 x 22 cm for the central transverse ribs. The design value of the concrete cover thickness of the ribs is 2 cm, while the class of the concrete is MB 40. The slabs are 8 cm high, double-reinforced and have a design value for the concrete cover thickness of 1.5 cm. They are connected by a rigid, welded reinforcement in the lateral ribs. At one end, the slab is suspended from the hangers (ϕ21 mm),

while at its other end it is supported by a longitudinally movable mandrel (ϕ28 mm) that protrudes from the neighbouring slab. There are two tension cables under the slabs (Figure 1 (b)), which are anchored in the foundation of the pylon. The down main cable consists of (2 ϕ 61 mm) cables on each side of the bridge and forms a system of prestressing canaries that reduces the deformation of the deck and dampens vibrations. During the war the bridge (hangers) was damaged and two prefabricated slabs were broken through. The bridge was then rehabilitated to its original condition. In 2009, a new asphalt layer was installed, and the connection was repaired and rehabilitated. During the preparation of the concrete substructure for the installation of the asphalt, the concrete cover was removed in several lace by hydrodemolition of the concrete surface. In 2022, as part of the rehabilitation of the bridge, the connecting elements of the upper main cable were replaced, the asphalt layer was removed, beams of prefabricated slabs were reprofiled, the joints between prefabricated slabs were sealed, the corrosion protection of the steel elements was renewed, and the handrail was repaired. Based on the available drawings and documentation, the initial numerical model of the concrete slabs was developed to determine the connection stiffness between the concrete slabs.

3.2 *Initial numerical model*

Initial numerical modelling of the characteristic edge and span slab was performed using a commercial FE package ANSYS. FE model was developed using 3D linear BEAM 188, four node shell elements with six degree of freedom SHELL 181, uniaxial tension LINK 180 elements 1D longitudinal spring damper COMBIN14 elements with different degrees of freedom to define the connection between slabs and boundary conditions of edge slab. Material characteristics of steel was set as traditional (Bhadeshia & Honeycombe, 2017), while for the concrete it was set based on the information available in project documentation $E_{concrete}$ = 33 GPa, $c_{oncrete}$ =2548 kg/m^3, $\nu_{concrete}$=0,2. For cable elements E_{cable} = 160 GPa, ρ_{cable}=7850 kg/m^3, ν_{cable}=0,3. Properties of rigid elements was set as E_{rigid} = 210000 GPa, ρ_{cable}= 0,0001 kg/m^3, ν_{cable}=0,3. The stiffness of the connection elements between the slabs was set as k_{lon}=1x10^{10} N/m. On developed numerical model the modal analysis was performed to obtain the natural frequencies and mode shapes for considered mode t (Table 1.).

3.3 *Experimental investigation on characteristic edge and span slab*

To determine the boundary condition of the bridge, inspection of the bridge connection with the bank was performed and the dynamic parameters of the edge slab were determined. Since it was determined by visual inspection that the bridge is supported in the same way on both the left and the right bank (Figure 2. c) and d)), the measurement was performed only on one slab on the left bank. Determination of the structural dynamic parameters (natural frequencies and mode shapes) was proposed by Frequency Domain Decomposition (FDD) method.

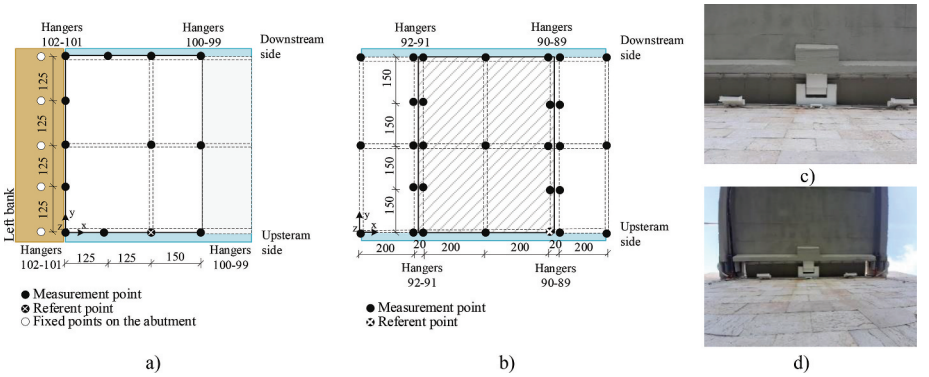

Figure 2. a) Arrangement of the measurement points (dimensions in cm) of the characteristic edge slab and b) characteristic slab in bridge span for which natural frequencies and mode shapes are determined c) boundary conditions on the left bank d) boundary condition on the right bank.

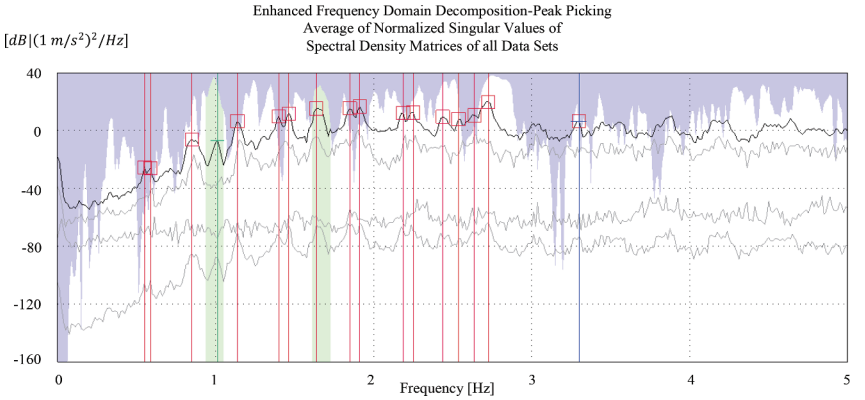

Figure 3. Characteristic record of Enhanced Frequency Domain Decomposition (EFDD) for the determination –average of the normalized singular values of spectral density matrices of all data sets for characteristic edge slab.

The slabs were vertically excited by pedestrian random walking for 2 minutes. Measurement of acceleration on the characteristic edge slab was performed in total 13 points (Figure 2. a)) while in the span slab it was performed in total 29 measuring points, for both in vertical direction. The natural frequencies were determined as the resonant peaks of the recorded singular values of the auto spectral densities (Figure 3.).

Based on determined natural frequencies values the mode shapes was also selected and assigned to the selected natural frequencies value. First mode characteristic for the edge, and second characteristic for the span slab are presented on the Figure 4.

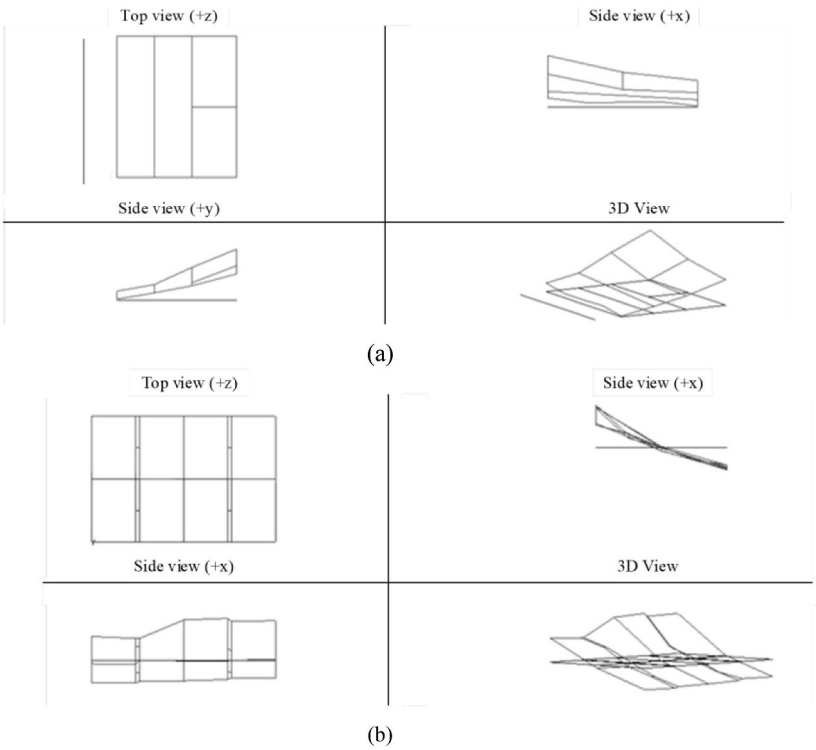

Figure 4. (a) First mode shape of edge slab (b) Second mode shape of span slab.

3.4 *Comparison between the experimental test results and initial model prediction*

The initial numerical model is tested based on comparative analysis (relative differences of the natural frequency and modal assurance criterion (MAC)) (Table 1.). The most relevant updating parameters were selected based on the sensitivity analysis (Sanayei et al., 2015). As a selection criterion, the ratio between the modal strain energy associated with physical parameters and the overall modal strain energy has been considered. The selected updating parameter include: the Young modulus of elasticity of concrete elements θ_1 [GPa]; (2) stiffness of the connection between the slabs elements - θ_2 [N/m]; (3) down main cable tension force - θ_3 [N]; (4) hangers tension force - θ_4 [N]; (5) Young modulus of elasticity of handrail elements – θ_5 [GPa]; (6) stiffness of the connection between the slabs and down main cables – θ_6 [N/m,]; (7) upper main cable tension force – θ_7 [N]. The vector of the initial values was set as follows: θ = [33 MPa $1x10^{10}$ N/m 1300 MPa 36,124 MPa 210 MPa 2.10 $x10^{11}$N/m^2 4760]. The constraints of the search domain are defined as: θ^l = [0,9 0,1 0,8 0,6 0,9 0,8 0,8] and θ^u = [1,1 2,0 1,2 1,1 1,1 1,2 1,2]

Table 1. The comparison of the numerically predicted and experimentally determined modal properties of the pedestrian suspension bridge edge and span slab.

	Edge				Span			
Mode t	f_t^{exp} [Hz]	f_t^{num} [Hz]	Δf_t [%]	MAC [/]	f_t^{exp} [Hz]	f_t^{num} [Hz]	Δf_t [%]	MAC [/]
1	0,587	0,568	3,2	0,967	0,587	0,567	3,4	0,934
2	0,850	0,863	-1,5	0,960	0,850	0,861	-1,3	0,972
3	1,013	1,172	-15,7	0,937	1,013	1,168	-15,3	0,794
4	1,462	1,145	21,7	0,870	1,400	1,146	18,1	0,712
5	1,850	1,795	3,0	0,802	1,650	1,695	-2,7	0,780
6	2,188	2,061	5,8	0,974	2,180	2,064	5,3	0,922
7	2,725	2,66	2,3	0,953	2,725	2,658	2,5	0,930
8	3,313	3,195	3,6	0,943	3,313	3,197	3,5	0,910

3.5 *Determination of the concrete slab connection stiffness*

The connection stiffness of the concrete slabs was determined using the approach described in the section 2 by determining the Pareto optimal front solution of the decision -making problem (determination of the knee point). For this purpose, the Harmony Search (HS) optimization algorithm has been considered (Manjarres et al., 2013) The updating process was performed by linking a FE analysis software, Ansys (*Ansys (2022)*), with mathematical software, Matlab (*Matlab (2022)*). The parameters of the HS algorithm were established as: population size PS=100; (ii) maximum number of iterations I_{max} =50; (iii) objective function tolerance $t_{of} = 1 \cdot 10^{-4}$; (iv) new population size $P_{s,\ new}$ = 40; (v) harmony memory pitch adjustment HMCR= 0.9 and (vi) pitch adjusting rate PAR=0.3. As a result of the FEMU the Pareto optimal front of considered residuals was determined. Based on the obtained set of optimal solutions, the best solution was select as knee point which correspond to the vector θ^*_{HS}= [0.9972, 0.8895, 1.0588, 1.0308, 1.0462, 0.8199, 1.0219]. The selected best optimal solution correspond to the numerical model properties: [32,908 $8{,}89 \cdot 10^9$ 1376,447 36,124 219,706 $1{,}721 \cdot 10^{11}$ 4864,130]. Based on the determined best optimal solution the stiffness connection between slabs was determined as k = $8{,}89 \cdot 10^9$ N/m.

4 DISCUSSION

Based on the connection stiffness value determined for the span slab, the edge slab was evaluated in a such way that the determined connection stiffness value was assigned to its one edge. The evaluation is performed based on the differences between the natural frequencies and the differences between the mode shapes expressed in the form of the MAC coefficient (Table 2).

Table 2. Correlation between experimental and updated natural frequencies and mode shapes on the edge and span slab.

	Edge				Span			
Mode t	f_t^{exp} [Hz]	f_t^{num} [Hz]	Δf_t [%]	MAC [/]	f_t^{exp} [Hz]	f_t^{num} [Hz]	Δf_t [%]	MAC [/]
1	0,587	0,596	-1,6	0,983	0,587	0,597	-1,6	0,999
2	0,850	0,841	1,0	0,976	0,850	0,843	0,9	0,967
3	1,013	1,027	-1,4	0,952	1,013	1,027	-1,3	0,940
4	1,462	1,500	-2,6	0,884	1,400	1,430	-2,2	0,903
5	1,850	1,839	0,6	0,815	1,650	1,659	-0,6	0,811
6	2,188	2,213	-1,2	0,990	2,180	2,203	-1,1	1,001
7	2,725	2,688	1,3	0,969	2,725	2,687	1,4	0,955
8	3,313	3,259	1,6	0,959	3,313	3,260	1,6	0,943

Based on the results presented in the Table 2 it can be concluded that the value of the stiffness of the panel connection determined on the basis of the dynamic parameters of the panel in the span corresponds to the stiffness of the connection between the edge panel and the rest of the bridge panels, which is visible not only from the difference in natural frequencies, but also from the value of the MAC factor.

5 CONCLUSION

To obtain a model of structure that corresponds as closely as possible to its actual behavior the digital twin models are developed. Developed models are combined with different known information from real structure to describe its behaviour as close as possible to correspond to actual behaviour. In this paper, for this purpose, the finite element model (digital twin) is combined with the finite element model updating process to determine the stiffness of connection between the slabs on the pedestrian suspension bridge. To update the developed numerical model the structural dynamic properties was determined on the one characteristic edge and one span slab. Based on the updating process of one span slab, the stiffness connection between slabs is determined and the obtained values are evaluated on the characteristic edge slab. Through described combination of digital twin and finite element model updating process it is possible to describe the structural behaviour to correspond to its actual and can be used for many other purposes such as structural maintenance, assessment, rehabilitation, conceptualization of the structural health monitoring concept, and many other. It is recommended for future research to perform the structural assessment based on the periodically performed measurement and updated the digital twin of structure.

Damage detection of riveted truss bridge using ANN-aided AMS optimization method

B. Šplíchal & D. Lehký
Brno University of Technology, Brno, Czechia

K. Lamperová
Slovak Technology University, Bratislava, Slovakia

ABSTRACT: Aging transport infrastructure brings increased economic burden and uncertainties regarding the reliability, durability and safe use of structures. Early damage detection to locate incipient damage provides an opportunity for early structural maintenance and can guarantee structural reliability and continuing serviceability. This paper describes the use of the hybrid identification method, which combines a metaheuristic optimization technique aimed multilevel sampling with an artificial neural network-based surrogate model to approximate the inverse relationship between structural response and structural parameters. The method is applied to identify damage in existing riveted truss bridge. The effect of the damage rate and location on the identification speed and the accuracy of the solution is investigated and discussed.

1 INTRODUCTION

The increasing frequency of bridge and footbridge collapses highlights the critical importance of early detection of damage to ageing structures through structural health monitoring data. This plays a key role in maintaining the reliability of structures and ensuring the safety of people and property. Various monitoring and detection approaches have been proposed for practical early warning of structural damage (Gomez et. al. 2019, Avci et al. 2021). Among them, vibration-based methods, which use the vibration response of the monitored structure to evaluate its condition and identify damage, have gained wide popularity.

Damage means a change in the geometric or physical properties of the structure. A damaged structure exhibits a different mechanical response compared to an intact structure, with response parameters directly affected by changes in physical properties such as mass and, in particular, stiffness. Damage identification involves a mathematical process known as finite element (FE) model updating. This process modifies the original intact model to accurately match the damaged structure. Once a match is achieved, local adjustments to the model pinpoint the presence of damage.

Minimizing the residuals between the static and dynamic characteristics of the FE model and the characteristics of the damaged structure is an optimization problem that can be solved either directly or in conjunction with a sensitivity-based method (Jung & Kim 2013, Mordini et al. 2015, Zheng et al. 2015). In the methods presented in this paper, sensitivity analysis is used to normalize the effect of response parameters with different sensitivities on the extent and location of damage. This increases the convergence and refinement of the results. Another group of methods directly addresses the inverse relationship between the static and dynamic characteristics of the FE model and its response parameters. This relationship is often represented by a surrogate model such as an artificial neural network, Kriging, etc. (Lehký & Novák 2009, Yin et al. 2019).

In this paper, three methods are used to detect structural damage. The first method uses a metaheuristic optimization technique called aimed multilevel sampling (AMS) to efficiently

DOI: 10.1201/9781003483755-270

explore the design parameter space, achieving the best match between the deformed structure and its model. This method is enhanced by involving an artificial neural network (ANN) in finding the best realizations during the optimization process. In this paper, the method is referred to as ANN-aided AMS. The second method is a modification of the first method where, in order to reduce the computational complexity, ANN is used in only a limited number of iterations and in the remaining iterations the selection of the best sample is driven by the minimum value of the objective function. The last method treats model updating as an inverse problem and utilizes an ANN metamodel to approximate the inverse relationship between structural response and parameters. All methods are employed to identify damage in single-span riveted steel truss bridge. The study investigates the effect of damage rate and location on the identification speed and solution accuracy.

2 DAMAGE IDENTIFICATION

2.1 *FE model updating*

The method for identifying damage operates through a computational model of the structure. Consequently, the initial step in the identification process involves creating a precise Finite Element model and performing static and dynamic analyses of the considered structure. To meet the required accuracy for damage localization, the structural model is segmented into multiple regions, with stiffness parameters varied during the optimization process. A probability distribution is assigned to these stiffness parameters to establish an initial design space.

Following this, the stiffness parameters for each region are randomly generated in FReET reliability software (Novák et al. 2014) using the Latin Hypercube Sampling method (LHS), (Stein 1987). Subsequently, modal analysis is performed to ascertain eigenfrequencies and mode shapes. This generates random input data in the form of stiffness values for each region and output data consisting of static and dynamic response parameters for each simulation. These data are then utilized to identify the location and extent of damage within the structure. In this paper, the identification process is carried out using a metaheuristic optimization algorithm coupled with inverse analysis employing artificial neural networks.

2.2 *Aimed multilevel sampling optimization method*

The AMS optimization technique employed in this paper was chosen for its capacity to significantly reduce computational complexity (Lehký 2018). The fundamental concept involves breaking down the simulation process into multiple levels. At each level, advanced LHS sampling is conducted within a predefined design vector **d**. The sample with the most favorable properties, addressing the optimization problem definition, is subsequently chosen.

Following this, the design space for generating samples is narrowed down around this best sample $\mathbf{d}_{i,\text{best}}$. The next LHS simulation is executed *within* this reduced space. This process facilitates a more detailed exploration in the vicinity of the best-performing samples for the extreme value function. The reduction of the sample space is executed based on heuristic assumptions, constituting a pivotal aspect influencing the accuracy and performance of the AMS method.

There are two approaches to obtaining the best realization for the given design vector, $\mathbf{d}_{i,\text{best}}$. The basic approach is, that it can be derived as the optimal realization generated at the ith level for the structural vector **d**, corresponding to the minimum of the objective function $\phi(\mathbf{d})$, defined as:

$$\phi(\mathbf{d}) = \sum_{j=1}^{n} w_i \left[\frac{e_j - m_j(\mathbf{d})}{e_j} \right] \tag{1}$$

where, the term e_j represents the jth experimental static or dynamic property, serving as a structural response parameter to be aligned. Meanwhile, $m_j(\mathbf{d})$ represents the equivalent response parameter generated by the FE model. The parameters w_i are weight coefficients associated with the response parameters. Their role is to offset the influence of response parameters with lower sensitivity, which is crucial for accurately identifying the location and

extent of damage. These parameters ensure that even though some response parameters may have lower sensitivity, their contribution is considered in the identification process, preventing their neglect in the presence of more dominant response parameters.

An alternative approach is to view the problem as an inverse problem, where the inputs are the eigenfrequencies and mode shapes and the outputs are the stiffness values. However, for complex structures, this inverse relationship is impossible to find and the FE model must be replaced by a surrogate model, in our case the ANN. The neural network is trained using input–output pairs and then the best realization of the vector $\mathbf{d}_{i,\text{best}}$ is predicted. The basic idea of this method is to perform a large number of simulations using LHS on the initial design space, map the inverse space using a robust ANN, and then use it to predict the best realization. This method is hereinafter called "pure ANN".

The flagship of this paper is a method using ANN at each level of AMS. This method is called the ANN-aided AMS method. This method is the most complex of all the methods in this paper because it requires creating, training and simulating an ANN at each AMS level. Due to the time-consuming nature of the method, there is an alternative approach called here as the "hybrid method" that combines two approaches to estimate the best realization, namely using an ANN at every third level and using the minimum of the objective function at the other levels (Eq. 1).

3 REVITED TRUSS BRIDGE

Figure 1. Sideview of a riveted truss bridge in Trnovec nad Váhom (Slovakia).

The methods were applied to a steel railway bridge over the Váh River in Trnovec nad Váhom (Slovakia) (Figure 1). The steel bridge consists of 28 simply supported bridge objects, 14 on each of the two tracks. One of the tracks consists of truss bridges and the other is a combination of truss and box bridges. The total span of the bridge is 455.8 m. Objects are placed on concrete pillars (four on each pillar). This paper will focus on one of the truss bridges. The span of the selected bridge object is 31.3 m.

3.1 *Measurement of the dynamic response of the bridge*

A large part of the bridge passes through an inundation area, so access to individual objects was relatively easy. The dynamic response of individual bridge objects was measured using several measuring devices. The measurements were made during full operation without traffic restrictions. The displacements of the structure caused by passing trains were measured using the IBIS-S interferometric radar. From the time records of the displacements, it was also possible to determine the natural frequencies of the structure. In addition, appropriately spaced

accelerometers were used to accurately determine the eigenfrequencies and mode shapes. The measured data were used to verify the correctness of the FE model.

3.2 *FEM model*

A detailed FEM model of the bridge was created (Figure 2). Almost all structural elements (except for the lateral and transverse bracing) were created using shell elements. To better capture the response of the bridge when trains pass by, non-load-bearing parts, such as wooden sleepers and steel rails, were also modelled. The bridge was supported by a fixed bearing on one side and a sliding hinged bearing on the other side.

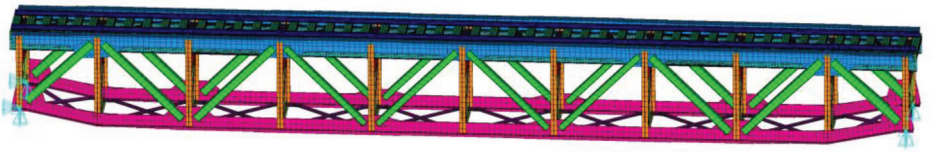

Figure 2. FEM model of the bridge.

The methods were applied to identify damage in three different cases – damage at one location, at three locations with the same and different levels of damage. The damage was modelled by reducing the Young's modulus of selected diagonal members. The original (undamaged) model was made of steel with a modulus of elasticity E = 210 GPa. A separate material model was created for each diagonal member, and the original modulus of elasticity E was multiplied by the coefficient k, which expressed how severe the damage to the member was. If the coefficient is equal to 1, the section was without damage (the coefficient less than 1 indicates damage). The coefficients k represent random variables for the FE model updating.

4 RESULTS

4.1 *Structure damaged in one location*

4.1.1 *Damage description*

The first analyzed case is the structure damaged in the fifth diagonal member, see Figure 3, where the damaged member is marked in red.

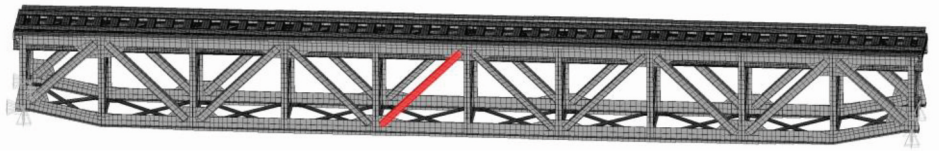

Figure 3. FEM model of the bridge with the damaged fifth diagonal member marked.

At the beginning of identification process, the initial design space was chosen in the range of 0.85-1.05 for all stiffnesses k. The total number of simulations was 1200, which for the AMS method was divided into 12 levels each of 100 simulations. The performance of each method is further compared in terms of error, which is calculated as:

$$Error = \sqrt{\sum_{i=1}^{n} \left(k_i^e - k_i^d\right)^2}, \tag{2}$$

where k_i^e is experimental stiffness of ith section, k_i^d is estimated stiffness of ith section, n is number of diagonals.

4.1.2 *ANN-aided AMS*

The first employed method is ANN-aided AMS method, where the best realization $\mathbf{d}_{i,\text{best}}$ at each AMS level is selected by an artificial neural network. The course of identification is shown in Figure 4, where on the left side is the evolution of the stiffness values during the optimization process and on the right side is the evolution of the error (Eq. 2).

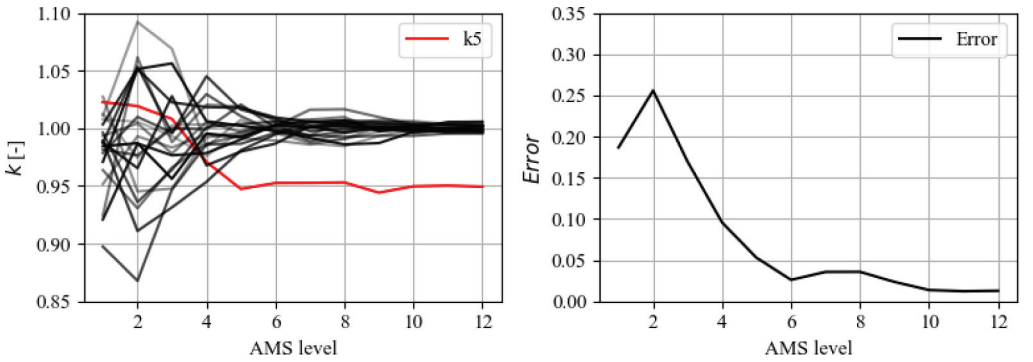

Figure 4. Case 1 optimization by the ANN-aided AMS: evolution of the stiffness values, with damaged segment k_5 in the red (left) and the evolution of the error (right).

4.1.3 *Hybrid method (ANN at every 3rd level)*

The second method is the hybrid method, which uses a combination of the objective function and artificial neural network. Compared to the first method, ANN is used only at every 3rd level, and the objective function is used at the other levels. The ANN helps to improve solution convergence while maintaining the speed of the classical AMS optimization method, see vertical changes in Figure 5.

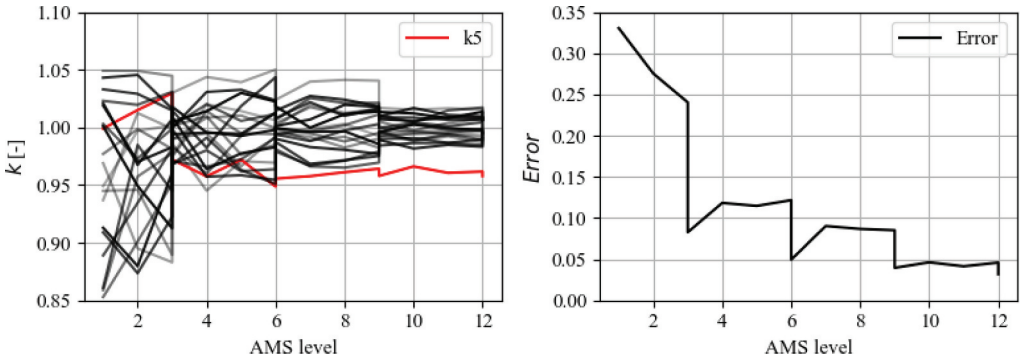

Figure 5. Case 1 optimization by the hybrid method: evolution of the stiffness values with damaged segment k_5 in the red (left), and the evolution of the error (right).

4.1.4 *Pure ANN*

The last method approaches optimization as an inverse analysis and uses ANN to replace the inverse relation. First, all 1200 simulations are calculated at once using the LHS method. The artificial neural network is then trained on all simulations and one prediction is provided. The method is not iterative and there is no sequential aiming. Figure 6 depicts the resulting stiffnesses of the diagonal members using a bar graph, with the damaged fifth member in red, and other undamaged members in shades of grey. The left side of the figure shows the best realization at the last AMS level (12th) provided by the ANN-aided AMS method, the middle is the

best realization at the last AMS level (12^{th}) calculated by the hybrid method, and the right-hand side is the damage prediction for the pure ANN. The results show that splitting the simulations into several levels using AMS brings better results than using ANN once for all available simulations.

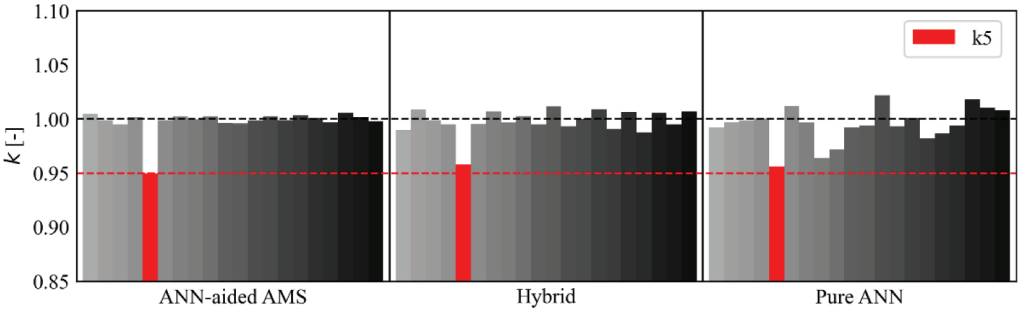

Figure 6. Comparison between ANN-aided AMS, Hybrid and Pure ANN methods.

A comparison of the errors for the first damage case for all methods is shown in Figure 7. The first column of the graph represents the ANN-aided AMS method, where the artificial neural network is used at each level, the error value is 0.0128. The second column represents the hybrid method, where ANN is used at every 3^{rd} level, the error value is 0.0319. The last column belongs to the pure ANN method, where only one ANN is used for all simulations, the error value is 0.0635.

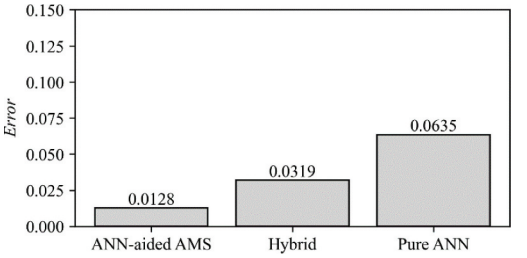

Figure 7. Comparison of the final optimization errors for the first damage case.

4.2 *Structure damaged in three locations with the same level of damage*

4.2.1 *Damage description*

The second case analyzed is the damage to the fifth, eighth and eighteenth diagonal members, as can be seen in Figure 8, where damaged members are marked in red. The damage magnitude is the same for all members and corresponds to a 5% reduction in stiffness.

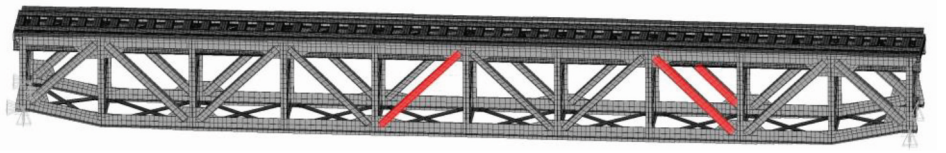

Figure 8. FEM model of the bridge with the damaged fifth, eighth and eighteenth diagonal member marked.

4.2.2 *ANN-aided AMS*

Given the best performance, only the ANN-aided AMS method was used, which uses an ANN to select the best realization at each AMS level. From the results depicted in Figure 9, it can be seen that all three damaged locations as well as the damage level were correctly identified.

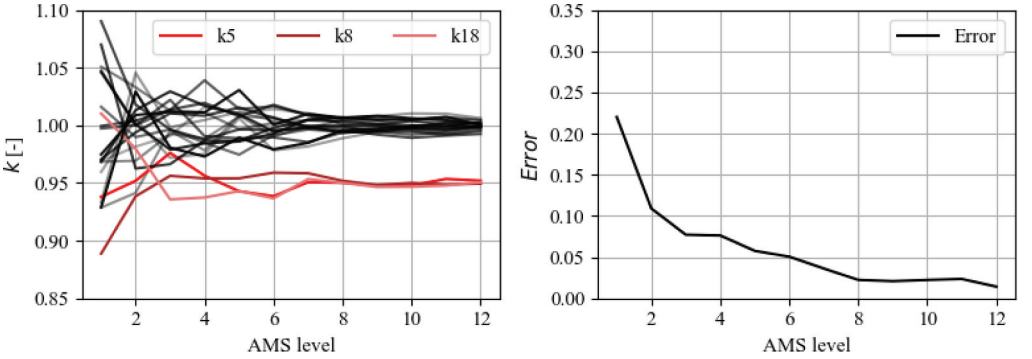

Figure 9. Case 2 optimization by the ANN-aided AMS: evolution of the stiffness values, with damaged segments in shades of red (left), and the evolution of the error (right).

4.3 *Structure damaged in three locations with different level of damage*

4.3.1 *Damage description*

The last case presented in this paper is a structure damaged in three different locations, each location having a different level of damage. The least damaged diagonal member is the eighth member (stiffness is reduced to 0.97), marked in light red, as shown in Figure 10. The most damaged member is the eighteenth member (stiffness is reduced to 0.93), the location is opposite to the eighth member, marked in dark red in the figure. In the fifth member, the stiffness is reduced still to 0.95, marked in red.

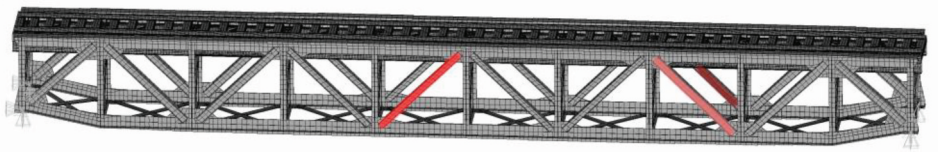

Figure 10. FEM model of the bridge with the damaged fifth, eighth and eighteenth diagonal member marked.

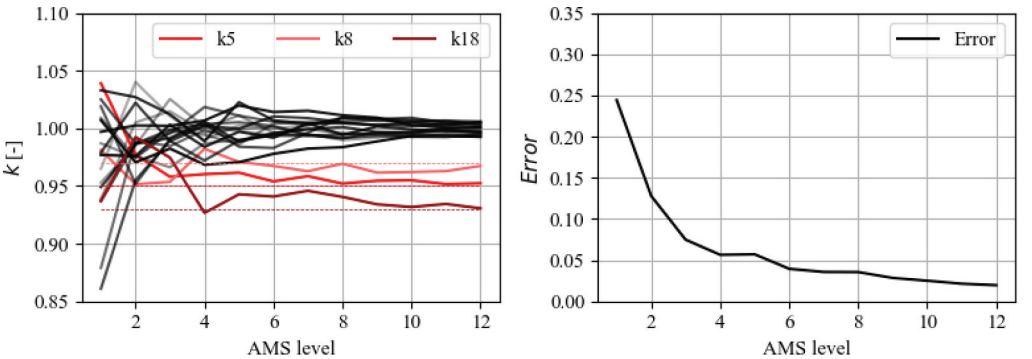

Figure 11. Case 3 optimization by the ANN-aided AMS: evolution of the stiffness values, with damaged segments in shades of red (left), and the evolution of the error (right).

4.3.2 *ANN-aided AMS*

As in the previous case, the ANN-aided AMS method was used. As can be seen in Figure 11, this method dealt with this problem really well. All damaged members were detected correctly, including an accurate estimation of the damage level.

5 CONCLUSION

The results of the analyzed damage cases show that the use of the AMS method in combination with an artificial neural network represents the most accurate approach to the task of damage identification. However, this method is the most time-consuming and computationally demanding of all the methods, since an ANN has to be created, trained, and simulated at each AMS level. An alternative is to use the classical AMS method, where the minimum of the objective function is used to select the best realization. This is a computationally relatively fast solution, but the disadvantages tend to be lower accuracy and slower convergence. A compromise between accuracy and time is the hybrid method, which combines the advantages of the classical AMS method and the use of ANNs at selected levels to improve convergence. When computational time is not an issue, the most efficient and accurate solution is the ANN-aided AMS method.

ABSTRACT: Structural health monitoring (SHM) applications are gaining increasing attention because they enable the early detection and characterization of damage during a prevention phase. Furthermore, SHM can also provide useful information associated with the condition and performance of a structure over time. SHM applications require a network of sensors to measure various structural parameters. However, the high cost of the required sensors is considered to be a limitation for their implementation in structures with limited monitoring budget. This paper presents an alternative low-cost solution to decrease the high cost of instrumentation. LARA (Low-Cost Adaptable Reliable Accelerometer) is a novel low-cost triaxial accelerometer based on Arduino and Raspberry Pi technologies. This system has a sampling frequency of 333 Hz and a noise density of 51μg/√Hz. This work presents an experimental campaign for the Operational Modal Analysis (OMA) of a footbridge using two types of sensors: a low-cost prototype LARA and a commercial one (HI-INC), in order to evaluate the reliability of the data acquired by LARA and to validate it as a low-cost accelerometer for SHM purposes.

1 INTRODUCTION

Since civil infrastructure and structures could be considered as the basis of contemporary civilization, it is crucial to prioritize the health of these systems (J. Lei et al., 2018). Evaluating structures along with their health-state assessment reduces repair and maintenance costs by detecting damage at the prevention stage and, eventually, for certifying infrastructure/structure safety (Peng et al., 2021b).

Structural health monitoring (SHM) applications provide statistics on the operating states of structures and their structural responses (Peng et al., 2021a) (X. Lei et al., 2022). To measure structural responses over time such as bending, deformation, rotation, temperature, humidity and accelerations, sensors are widely used in SHM systems (Komarizadehasl, Komary, et al., 2022). The information recorded by the sensors is used to estimate structural performance (Komarizadehasl, Lozano, et al., 2022). In fact, natural phenomena can be classified as static or quasi-static and dynamic (Atencio et al., 2022). On the one hand, some environmental parameters (such as temperature or humidity) change very slowly, so they can be considered to act in a quasi-static or static manner (Farré-Checa et al., 2022). On the other hand, some events (such as vibrations induced by traffic, environmental activities and waves from seismic events) are considered dynamic because their rate of change is significantly affected by time (Mobaraki et al., 2022).

DOI: 10.1201/9781003483755-271

According to the literature (see, e.g., (Komary et al., 2023)), the significant natural frequencies of most civil structures range from 0.2 to 100.0 Hz. It should also be noted that most of the environmental vibrations in civil structures are characterized by low amplitudes (Tran-Ngoc et al., 2018). The acceleration amplitude of these structures can be as low as 0.04 g. This characteristic shows the need to use accelerometers with low noise density and high sensitivity for SHM of bridges (Tran-Ngoc et al., 2018). Commercial MEMS accelerometers have a bandwidth of a few kHz. However, their design for higher frequencies has a lower noise density (Lee & Eun, 2022). It should be noted that the sensitivity of an accelerometer is indirectly proportional to the squared value of the resonance frequency. Therefore, the higher the sampling frequency of the accelerometer, the lower its sensitivity (Farrar et al., 2006). Because of this, many researchers have attempted to develop low-cost MEMS accelerometers with limited sampling frequency and vibration amplitude range for civil SHM (Shi et al., 2021).

The literature review shows a lack of works that include all the following points in a single approach for a low-cost accelerometer: (1) access to time information via the Internet for accurate sensor synchronization, (2) wireless control, (3) development of a synchronized data acquisition test, (4) measurement of ND and data resolution once the system is wired and, finally (5) performing experimental analysis of eigenfrequencies in real infrastructures.

Recently a Cost Hyper Efficient Arduino Product (CHEAP) was introduced by Komarizadehasl et al. (Komarizadehasl et al., 2021). Different laboratory tests were developed to validate CHEAP performance, and the results were compared with those of two commercial seismic accelerometers (PCB 393A03 and PCB 356B18).

The objective of this paper is to adapt CHEAP for solving all the detected problems and to develop a new reliable low-cost adaptive accelerometer (LARA). For this purpose, a laboratory test campaign was designed to validate the performance of LARA against its previous version. During the tests, frequencies between 0.1 Hz to 32 Hz and acceleration amplitudes in the range of [0.001- 9.806 m/s2] were tested. Further, another field test was developed on a short span footbridge in Barcelona. In this experiment, the eigenfrequencies measured by LARA were compared with those detected by a commercial dynamic sensor (HI-INC) (Komarizadehasl, Lozano, et al., 2022).

2 LOW-COST ADAPTABLE RELIABLE ACCELEROMETER (LARA) WITH POST-SYNCHRONIZATION CAPABILITY

Recently a Cost Hyper Efficient Arduino Product (CHEAP) was introduced by Komarizadehasl et al. (Komarizadehasl et al., 2021). LARA is an evolved version of CHEAP, it has a sampling frequency of 333 Hz, an acceleration range of ±2.0 g and an effective bandwidth of 165 Hz. LARA consists of two parts: (1) a sensing part: it contains the aligned accelerometers and the multiplexer, and (2) an acquisition part: composed of an Arduino and a Raspberry Pi (see Figure 1). LARA consists of five low-cost MEMS accelerometers aligned due to the fact that when averaging the results of a few accelerometers with unique inherent dynamic noises, the studied signal remains unchanged.

The advantages of LARA over CHEAP are the following: (1) higher bandwidth: it achieves a faster sampling rate (333 Hz) by efficiently rewriting all codes in the library, (2) independence: it does not need to be connected to a computer for data acquisition. LARA has a low-cost microprocessor that allows the acquired data to be saved on an SD card, a flash drive or portable hard disk, (3) triaxial data acquisition: having all LARA accelerometers aligned in the x, y, and z directions makes possible a triaxial data acquisition, and if it is necessary, it can operate as a uniaxial, biaxial accelerometer, (4) low Noise Density (ND), (5) time stamping and synchronization via the Internet: the Network Time Protocol (NTP) of LARA is activated, (6) experimental analysis: in this research, a short span was instrumented, and LARA eigenvalue analyses were compared with those of certified vibration detection devices, and (7) wireless accessibility: the user can access the stored data through the Internet. In this way, LARA can be controlled, updated via online commands and data can be recorded.

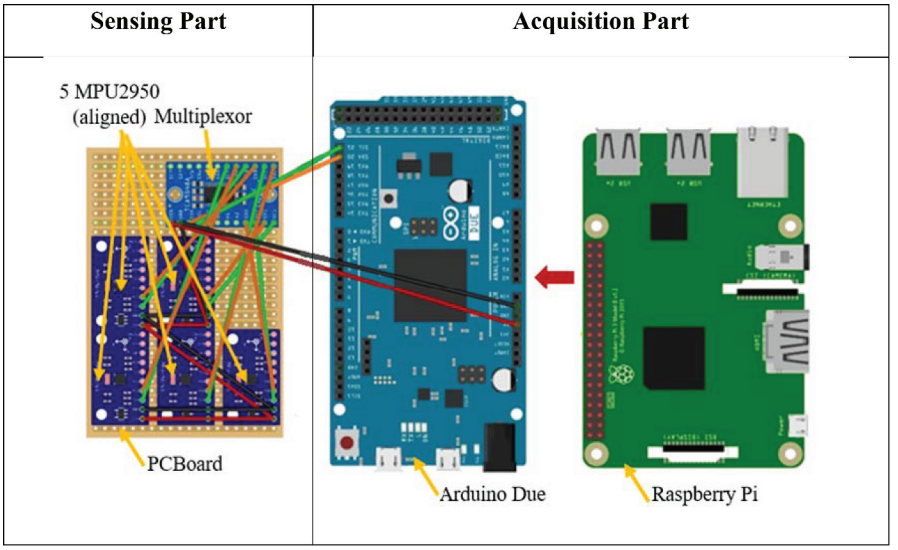

Figure 1. The sensing and acquisition part of LARA.

3 LABORATORY TESTS AND RESULTS

3.1 *Sensitivity, Noise Density (ND), and resolution evaluation*

This section compares the sensitivity, ND, and resolution results of a single accelerometer MPU9250 with CHEAP and LARA.

The sensitivity of accelerometers can be calculated as the ratio of the input (vibrations induced by the vibrating table) to the output (the information communicated by the accelerometer). This concept is measured differently for MEMS and analog sensors. While analog sensors report the sensitivity as V/g (voltage per gravitational acceleration), MEMS accelerometers report it as the Least Significant Bit per gravitational (LSB/g). The Analog to Digital Converter (ADC) formula for calculating the LSB is shown in equation (1) (Elhattab et al., 2019).

$$LSB = \frac{Input\ voltage}{2^{(number\ of\ bits)}} \tag{1}$$

Considering that MPU9250 accelerometers work with an input voltage of 2.5 volts and an ADC scale of 16 bits in equation (1), each LSB unit is equivalent to 0.03814 mV. Since datasheet of MPU9250 reports a sensitivity of 16 384 LSB/g for a range of ±2.0 g, the comparable sensitivity of MPU9250, CHEAP and LARA is calculated to be 625 mV/g.

A long-term test was performed to determine the ND and resolution of the devices. The ND values of the different accelerometers were calculated by applying equation (2) (Kwong, 2017).

$$ND = \sqrt{\frac{\sum_1^N (x_i - \mu)^2}{N * f}} \tag{2}$$

In Equation (2), the xi is the values read by the accelerometers in the time domain, μ is the average of all xi values, f is the sampling frequency of the accelerometer, and N is the number of used samples.

As a result, the calculated ND of MPU9250, CHEAP, and LARA for the z-directions were 390, 162, and 81 μg/√Hz, respectively. Additionally, the ND of LARA for both x and y directions was 51 μg/√Hz.

For a fair comparison between devices with different sampling frequencies, the same number of samples acquired was used in the test since the evaluation of the accelerometer resolution depends on the number of samples tested (*Data Acquisition Handbook*, n.d.). To illustrate the resolution of the accelerometers, the data was transformed from the time domain to the frequency domain by a Fast Fourier Transform (FFT).

Analyzing the frequency domain plots of the acquired LARA data for all axes, results show that the resolution of LARA for the x and y axes is 0.00005 m/s2. The resolution for the x and y directions is 44% better than for z-axis due to the absence of gravitational acceleration of the earth in those directions. As a result, the resolution of this accelerometer is evaluated to be 0.00005 m/s2.

After measuring the sensitivity, ND and resolution of LARA, it can be compared with other MEMS accelerometers. Several commercial applications of triaxial MEMS are presented in Table 1. The information shown in the table comes from data sheets provided by the manufacturers and from the measurements developed in this paper. The information is organized as follows: (1) number, (2) sensor's name, (3) sensitivity, (4) noise density, (5) acceleration range, (6) sampling frequency, (7) sensor cost (cost is based on data from 2021) (Komarizadehasl, Lozano, et al., 2022).

Table 1. Comparison of commercial triaxial MEMS accelerometers.

Nº	Name	Sensitivity (V/G)	Noise Density (μG/√ Hz)	Acceleration Range (G)	Sampling Frequency (Hz)	Cost (€)
1	IAC-Hires	2000	8	±2.0	800	1192
2	3713F112G	0.675	10	±2.0	500	2130
3	Unquake	0.400	25	±2.0	500	2500
4	Recovib Tiny	0.600	30	±2.0	500	1125
5	LARA	0.625	51	±2.0	333	140

Analyzing Table 1, indicates that LARA has a noise density very similar to commercial accelerometers and shows a wide range of prices of accelerometers solutions. Moreover, 3713F112G and IAC-Hires need extra data acquisition equipment for acquiring the vibrations which increases the cost. In the case of Unquake, Recovib Tiny, and LARA do not need any acquisition system for their data acquisition (Komarizadehasl, Lozano, et al., 2022).

3.2 *Frequency validation*

This section presents an experiment to validate the LARA frequency report. The vibration platform (INSTRON 8803) was programmed using Wave- Ma-trix2 Dynamic software. The jack can create several types of waveform with the frequency range from 0.1 to 100 Hz and its resonant frequency is 134 Hz. The direction of the vibration platform was in the z-direction.

To validate the accuracy of the accelerometers, 11 tests were performed with different frequency ranges (from 0.1 Hz to 32 Hz). To find the frequency report of the accelerometers, the raw data in the time domain of the accelerometers were transformed to the frequency domain using an FFT program written in MATLAB software.

The frequency error of the accelerometer was estimated by calculating the percentage error of the plot value compared to the reference value of the excitation device. Table 2 shows the comparison of the frequency errors of LARA, CHEAP and MPU9250 with the jack reference values.

Table 2 shows that a single MPU9250 reports the same frequency error as CHEAP from 2 Hz on. It also indicates that a single MPU9250 does not have enough resolution for

frequencies below 2 Hz. About CHEAP, it cannot display signals with a frequency lower than 0.4 Hz while LARA has a wider frequency range than MPU9250 and CHEAP and can detect signals down to 0.1 Hz with 0.5% error. In fact, LARA's frequency range is between 0.1 Hz and its bandwidth (165 Hz).

Table 2. Frequency validation of the accelerometers.

	PERCENTAGE OF ERROR PER SENSOR		
Frequency (Hz)	LARA	CHEAP	MPU9250
0.1	0.450 %		
0.2	0.295 %		
0.3	0.260 %		
0.4	0.050 %	0.470 %	
0.5	0.006 %	0.011 %	
2	0.005 %	0.025 %	0.025 %
4	0.000 %	0.000 %	0.000 %
8	0.003 %	0.003 %	0.003 %
10	0.004 %	0.004 %	0.004 %
16	0.001 %	0.001 %	0.001 %
32	0.003 %	0.003 %	0.003 %

4 REAL STRUCTURE TEST AND RESULTS

This section presents a field test performed on a short span footbridge to compare the measured eigenfrequencies of LARA with those of a high accuracy sensor (HI-INC). The footbridge under study is connected to an elevator box and, on the other side, is located on an abutment (see Figure 2). The commercial dynamic sensor (HI-INC) and LARA were mounted in the middle of the bridge span.

HI-INC is a dynamic inclinometer with a sampling frequency of 250 Hz, this sampling frequency is enough to acquire the main modal shapes of the footbridge. It should be noted that the reported noise density in its data sheet is 0.0004 deg/√Hz. This MEMS inclinometer was only used for comparing the eigenfrequency analysis of LARA.

Figure 2. A picture of the footbridge.

The process of installing the devices on the bridge consisted of manually connecting the sensors to the other monitoring components (power bank, 4G USB dongle, Arduino and Raspberry Pi). A Rasp- berry Pi was previously configured with a WiFi hotspot to enable the

communication of LARA over the Internet. In fact, after its on-site assembly, the Raspberry Pi was used to start the data acquisition process remotely via the Virtual Network Computing (VNC) software (Atencio et al., 2022).

Once the installation process was completed, LARA started working by following the next steps: first the acquired data were collected on the Raspberry Pi memory card and then the obtained data were transferred to a computer using VNC software.

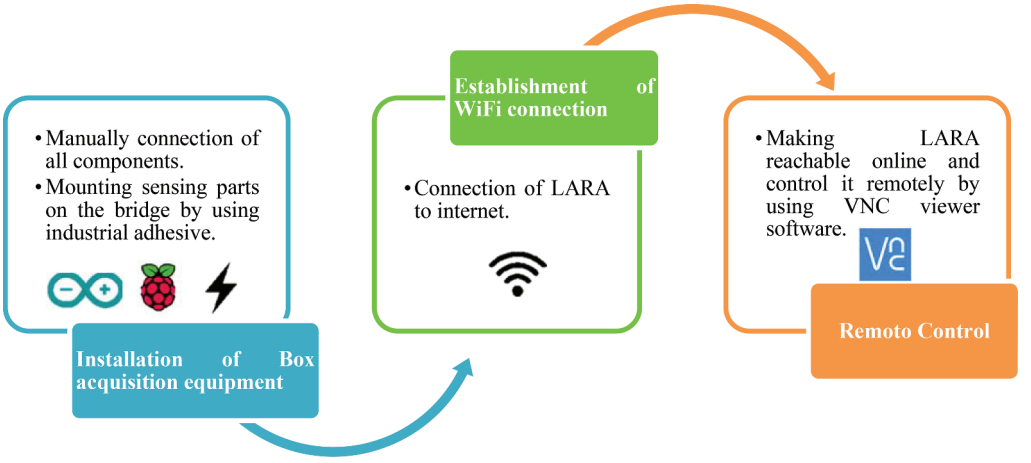

Figure 3. Mounting process of the sensors on the footbridge: LARA operation diagram.

The outputs of the eigenfrequency analysis of LARA are shown in Figure 4a–b for x and y axis, respectively.

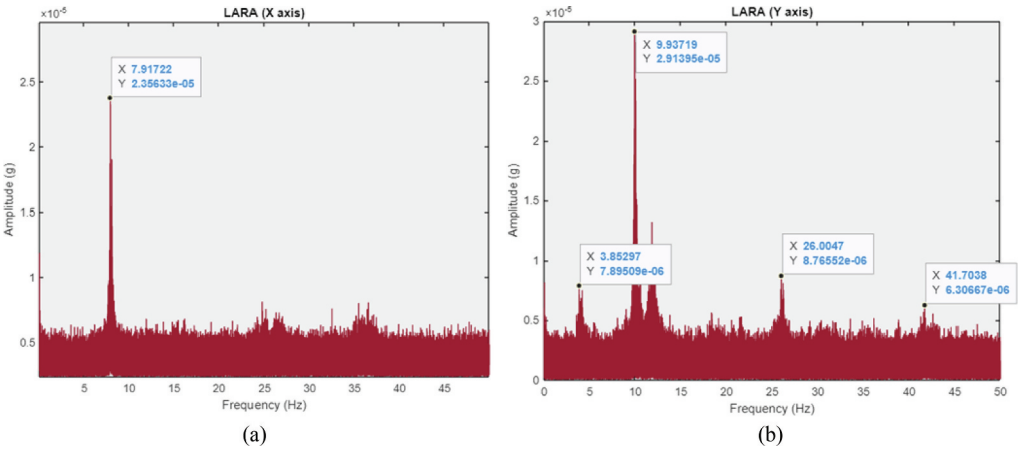

Figure 4. Eigenfrequency analysis of a footbridge using LARA for (a) longitudinal and (b) transversal directions of the footbridge.

As can be seen in the footbridge eigenfrequency diagrams, the structure does not show much excitation around its x-axis (longitudinal direction), while it shows a higher excitation around the other axis (y).

Table 3 presents the comparison of the results of the eigenfrequency analysis of LARA and the high accuracy dynamic inclinometer used (HI-INC).

Table 3. Comparison of the eigenfrequencies obtained between LARA and HI-INC.

	FREQUENCIES PER SENSOR		
Mode Shape	HI-INC	LARA	Difference (%)
1	3.90 Hz	3.85 Hz	1.28
2	7.91 Hz	7.91 Hz	0.20
3	9.94 Hz	9.93 Hz	0.88
4	26.25 Hz	26.01 Hz	0.91
5	42.81 Hz	41.70 Hz	0.27

Comparison of the measured eigenfrequencies of LARA with those of HI-INC shows a maximum error of 1.28%.

5 CONCLUSION

The development of low-cost sensors is essential for structural health monitoring (SHM) of structures with a low budget since these sensors can allow engineers to leave the equipment on the structure for monitoring. In previous work, a cost hyper-efficient Arduino product (CHEAP) was introduced, and its performance was validated in laboratory experiments. Improving both the hardware and software of CHEAP, a new Low Cost Triaxial Adaptive Reliable Adaptive Accelerometer (LARA) is introduced. The main advantages over its previous version are as follows:

(1) LARA achieved a faster sampling rate by rewriting the codes.
(2) LARA is independent of any connected computer for data sampling by using a Raspberry Pi connected to the Internet,
(3) LARA is a triaxial accelerometer.
(4) A reduced Noise Density.
(5) Having Internet time available is available for future data synchronization.
(6) LARA is a wireless accelerometer.

To evaluate the performance, resolution and ND of LARA, a set of laboratory experiments was performed. The results obtained show that LARA has lower ND ratio than MPU9250 and CHEAP for the same number of acquired data. In addition, comparison of MPU9250, CHEAP and LARA with shake table reports shows that LARA is more accurate in reporting frequency than MPU9250 and CHEAP in a laboratory experiment with the same time duration.

A field test has been performed over a 14m length footbridge located in Barcelona by using the LARA accelerometer. The frequencies obtained from the LARA eigenfrequency analysis have been validated by comparing its results with those obtained with a high-precision commercial sensor (HI-INC).

ABSTRACT: The need of a continuous re-qualification of infrastructures, faced with an increasing demand for mobility, requires the definition of reliable methods, from technical and economical points of view, to evaluate the current conditions of an asset and predict its future state when affected by damages. Advanced SHM solutions could be usefully implemented to gather relevant information about the behavior of bridges and tunnels, through industrial technological systems that must be reliable, cost effective and have suitable performances to assess structural conditions. However, several monitoring solutions are available today, with very different characteristics, performance and costs, so it is difficult both to evaluate how these systems, often tested only in laboratory, perform under operating conditions and to find the right tradeoff between technical and economic needs. The case study of an Italian highway viaduct is presented in this work with the aim to compare different SHM solutions.

1 INTRODUCTION

1.1 *Context*

Economic growth requires adequate infrastructure to meet its full potential. Infrastructure managers need to adopt sustainable methodologies that address both technical and economic aspects, especially in response to the increasing demand for mobility. The primary objective is to assess the present condition of an infrastructure and predict future state and potential damage. In this regard, the deployment of advanced Structural Health Monitoring (SHM) solutions proves beneficial for obtaining pertinent information about the performance of bridges and tunnels. These solutions rely on advanced technological systems that must meet strategic criteria, such as reliability, accuracy, cost-effectiveness, and performance suitability for assessing structural conditions.

The continuous evolution of technology facilitates the widespread integration of Internet of Things (IoT) systems, aligning seamlessly with the requirements of an effective SHM solution. Rather than investing in costly new projects, governments and private-sector infrastructure players may address some infrastructure needs by getting more out of existing capacity through: i) boosting asset utilization: intelligent transportation systems can foster the use of an asset, typically at a fraction of the cost of adding the equivalent in physical capacity; ii) optimizing maintenance planning, for instance through a Total Cost of Ownership (TCO) approach (Ellram, 1993), which considers costs over the complete life of an asset and finds the optimal balance between long-term renewal and short-term maintenance.

Properly, a TCO approach can be implemented with an efficient SHM application by calibrating the cost-benefit balance (Keller & Poblete, 2011).

DOI: 10.1201/9781003483755-272

1.2 *Manufact*

To compare the performances of different SHM solutions, a Proof of Concept (PoC) has been implemented on a real viaduct. The PoC started in August 2023 with a focus on technological solution comparison rather than long term structural monitoring. The structure consists of two independent lanes; the static scheme can be summarized in 7 simply supported reinforced concrete 32m-long spans. The deck consists of 5 parallel equally spaced beams and 4 transverse beams (Figure 1).

The reasons why it was decided to monitor the previously described structure are various. First, the structure dates to 1968 and is representative of Italian construction, as 70% of the structures in the network were built between 1960 and 1980. Moreover, also the static scheme of the beams (simply supported elements) and the construction technique (precast reinforced concrete) are representative of the Italian stock. In addition, the typology of the beams deck, in terms of number of beams and span length, is very common in the network. The fact that the structure is easily accessible without any limitations for its operativity is very helpful.

The structure has also undergone a preliminary structural vulnerability assessment. In a future work, it will then be possible to correlate monitoring measurements with the output of the numerical analysis.

Figure 1. View of the viaduct.

1.3 *Requirements*

The choice on the instrumentations to involve in the case study was motivated by the need to consider, at the state of the art, the most common type of sensors used to monitor bridges, viaducts and infrastructures, following a series of requirements briefly analyzed below.

The system must be able both to be broken down into smaller, independent components, or modules, that can be easily replaced or modified without affecting the operativity of the entire system and to handle an increasing number of signals or workload.

Both dynamic and static acquisition protocols are often used in SHM solution to provide a complete and reliable assessment of the performance of a structural system. Dynamic acquisition protocols involve measurements of the structural response connected to environmental vibrations and strong motion events (e.g. earthquakes), the static ones address long-term monitoring of the manufact under ordinary loads and evaluate the changes in deflection and deformation. For these reasons, it is desirable that the system is suitable for various measurement techniques and signals (e.g. voltage, current, digital, etc.) and it is able to detect faults or failures on sensors, data acquisition and processing components minimizing downtime, false alarms, outliers or missed detections of important events.

A suitable choice is to adopt an acquisition sampling ≥1kHz/sec/channels in simultaneous fashion to post-processing data in terms of amplitude and frequency as well as phase correlation for advanced operational modal analysis; in parallel, a resolution ≥18bit and a signal to noise ratio (SNR) ≥120dB are fully in line with the state of the art of the most common acquisition system available on the market and is suitable for ensuring accuracy and adequate precision to the output.

The buffering and local storage capacity are very important features, which are helpful in case the system turns offline and to accommodate the amount of data collected during an assigned monitoring period. In any case, the optimization of the data storage is usually managed also by triggering strategies, which initiate data gathering in case of occurrence of specific events. A good rule is to provide different strategies (e.g. time-based, event-based, threshold-based) as long as the system is not overcomplicated.

2 DESCRIPTION OF THE STRUCTURAL MONITORING SYSTEM

The layout of the structural monitoring system was designed with the purpose of tracking the structural response in static and dynamic conditions over time and to be compliant with the output of the numerical model implemented.

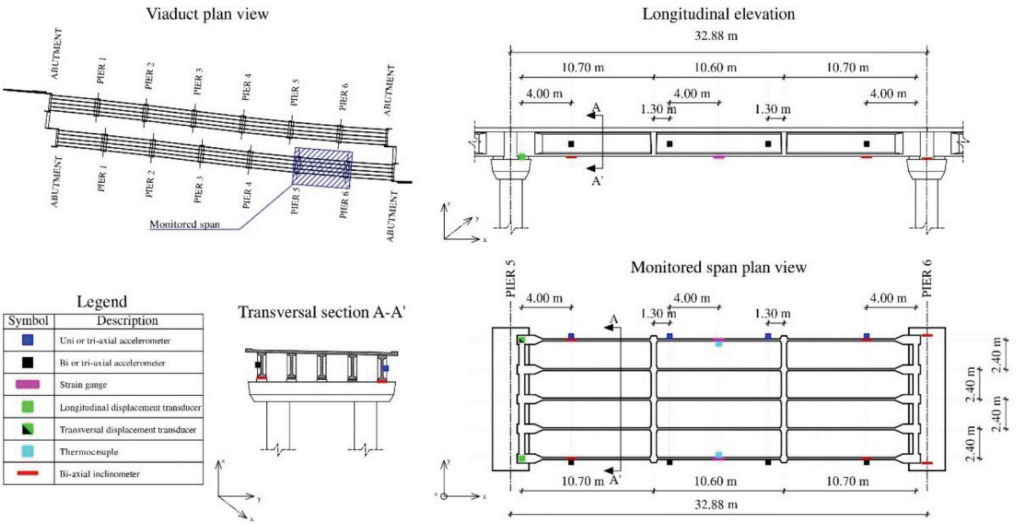

Figure 2. Sensor's installation layout.

The following types of sensors were included: accelerometers, inclinometers, displacement transducers, strain-gauges and thermocouples (Figure 2).

Integrated systems provided by four different suppliers were compared. The suppliers will hereafter be referred to as supplier A, B, C and D. Slightly different layouts were adopted for the installation of the sensors, whose specifications are listed in Table 1-Table 5.

Table 1. Accelerometers specifications.

	Supplier A	Supplier B	Supplier C	Supplier D
Quantity	12	8	12	8
Axis	1	3	1	1
Type	MEMS	MEMS	Piezoelectric	MEMS
Range	±2 g	±2 g	±5 g	±2 g
Sensitivity	4 V/g	-	1 V/g	4 V/g
Noise	7 μg/√Hz	25 μg/√Hz	2 μg/√Hz	7 μg/√Hz

Table 2. Inclinometers specifications.

	Supplier A	Supplier B	Supplier C	Supplier D
Quantity	6	6	6	4
Axis	2	2	2	2
Type	Analog	Analog	Analog	Analog
Range	±10°	±10°	±2°	±10°
Resolution	0.01°	0.01°	0.002°	0.01°
Accuracy	±0.15°	0.25°	-	±0.15°

Table 4. Displacement transducers specifications.

	Supplier A	Supplier B	Supplier C	Supplier D
Quantity	2	2	2	2
Range	0-100 mm	0-50 mm	0-200 mm	0-150 mm
Non-linearity	0.15% F.S.	0.1% F.S.	0.05% F.S.	0.15% F.S.

Table 5. Thermocouples specifications.

	Supplier A	Supplier B	Supplier C	Supplier D
Quantity	2	2	2	2
Range	±100 °C	-40/+80 °C	-	±100 °C

The sampling rate for dynamic sensors was imposed at 200 Hz for all suppliers except Supplier B, which has adopted a sampling of 100 Hz. The sampling rate of static sensors was set to 10 Hz for suppliers A and D, 1 Hz for supplier C and 1 sample every 5 minutes for supplier B. The system architecture adopted for all the suppliers is depicted in Figure 3.

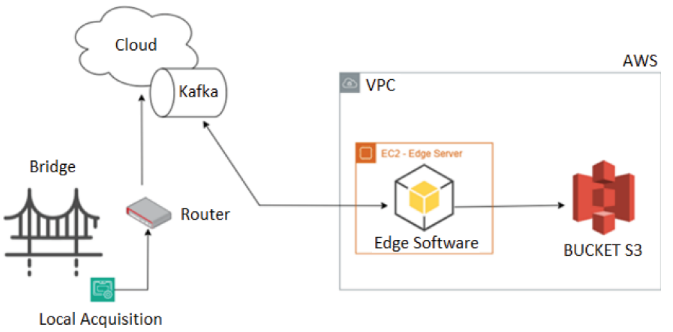

Figure 3. IoT system architecture.

The IoT system architecture idealization consists of:

- a local acquisition system for data sensors digitalization;
- a router for data transmission by mobile network;
- Kafka, message broker for robust management and to send the data flow;

- AWS, Virtual Private Cloud (VPC) composed by virtual machine (EC2-Edge Server) with an Edge Software ecosystem and Bucket S3 in order to manage data with object storage technology.

This IoT architecture is able to archive in cloud infrastructure data with a scalable potential.

3 STATIC MONITORING DATA ASSESSMENT AND COMPARISON

The static sensors of the monitoring installation include four inclinometers positioned on the external beams of the selected span, two sensors on each side (three suppliers installed two additional sensors on one of the piers), see Figure 2. Excluding a few tilt sensors, which exhibited electrical related malfunctions, the signals of the remaining inclinometers emphasize high amplitude peaks connected with traffic induced vibrations (Figure 4). This effect results more relevant on signals with a sampling rate of 10 Hz but it can be easily mitigated through a moving average to be adopted only in case the information on the dynamic content of the signal is not of interest.

Each supplier installed two strain gauges on the opposite sides of the external beams at the midspan. Strain gauges installation is a process which foresees a certain amount of expertise and that depends on a variety of factors including materials, geometry, surface conditions and more. Almost all the signals of the installed gauges are strongly affected by electrical noise. For this reason, the data related to the strain gauges are not shown.

Linear displacement transducers have been installed in both longitudinal and transversal direction, measuring the differential displacements between the external beams and a reference pier. These sensors appear to be slightly sensitive to electrical noise, see Figure 5.

Actually, the available data covered a period of four months (September to December 2023); if the displacements are observed on the longer period of time (Figure 6), it can be noted that the data coming from suppliers A, B and D are coherent between them, with differential displacement less than 3 mm. The static part of the systems also includes two thermocouples for each supplier installed on the external beams. The sensors were inserted into a drilled hole in the concrete to monitor its temperature drifts.

The available data of the thermocouples are shown in Figure 7 together with a longitudinal displacement transducer, as a comparison. In that figure it can be noticed the trend of the temperature, which decreases as a function of time, as expected. The three unexpected peaks arisen between the 90th and the 115th day correspond to real peaks of external temperature occurred exactly on December 1, 13 and 23, 2023, with values of about 20°C.

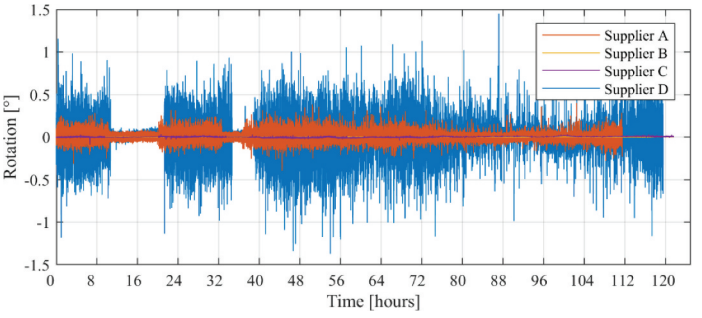

Figure 4. Signals of inclinometers.

The signal of the longitudinal displacement transducer seems to be coherent with te data coming from the thermocouples and since the nominal thermal coefficient of the displacement sensors is 5ppm/C° a variation of about 15°C between day 90 and 115 leads to a correlated expected drift in the displacement readings of 0.015mm due to environmental effects, consequently the remaining part of the displacement measured can be related to structural effects inducted by the temperature fluctuations.

More detailed analyzes and comparisons relating to long-term static monitoring will be performed when a greater amount of data will be available, at least 6 months (half of a seasonal cycle).

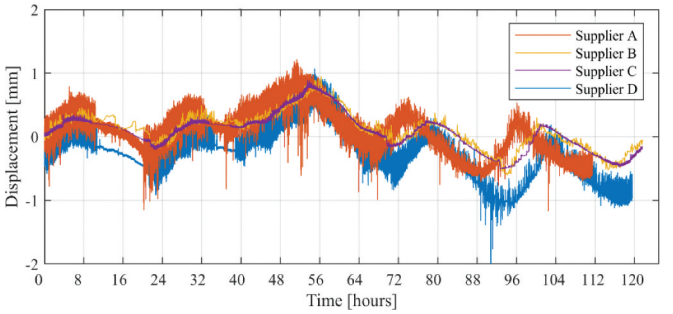

Figure 5. Signals of the longitudinal displacement transducers (limited time window, 120h).

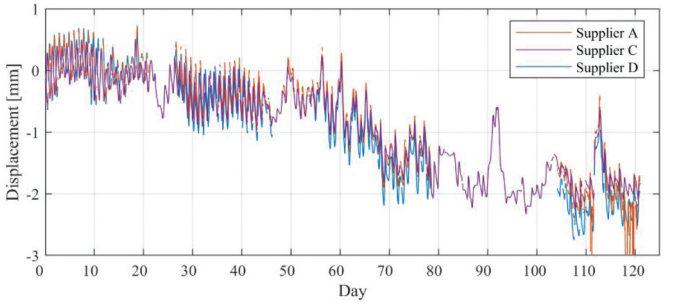

Figure 6. Signals of the longitudinal displacement transducers.

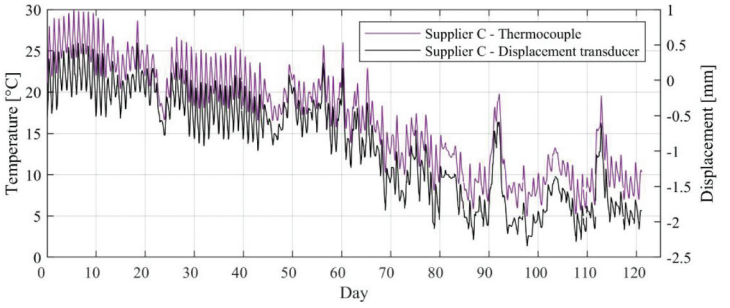

Figure 7. Signals comparison: thermocouple and longitudinal displacement transducer.

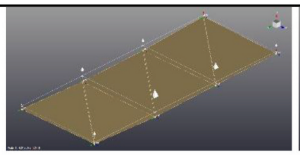
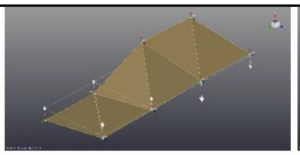
4 DYNAMIC MONITORING DATA ASSESSMENT AND COMPARISON

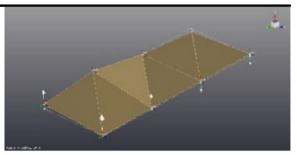
The dynamic acquisition in this context has been used to evaluate the main dynamic properties of the structure. All suppliers installed at least accelerometers to monitor accelerations in the vertical direction. Suppliers A and C added 4 more sensors, on one of the outer beams, to record accelerations in the transversal direction as well. Only Supplier B has exploited tri-axial sensors.

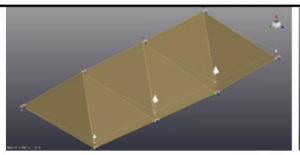
In this section the main results of operational modal analyses (OMAs), aimed to evaluate and compare modes and frequencies obtained from the different monitoring systems, are briefly summarized. In particular, the Operational Polymax Plus procedure has been used (Peeters B., 2012), (Siemens, 2023), since usually it has high computational efficiency and reliable stabilization diagrams even for highly damped systems and noisy signals.

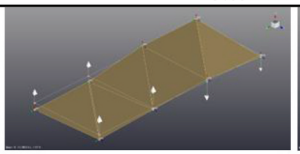
A 0.1 Hz ÷ 100 Hz or 0.1 Hz ÷ 50 Hz bandpass filter has been imposed to all input signals. The different values of the upper band did not affect the results, since the stabilization diagram has been evaluated in the range 0 ÷ 30 Hz. The analysis has been developed along three

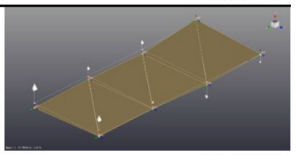


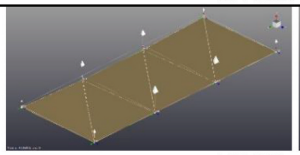


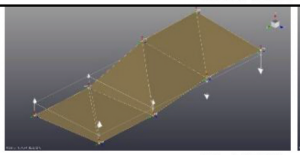


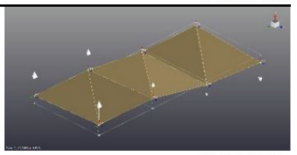


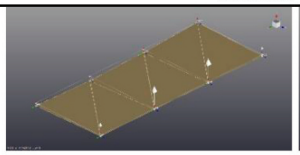


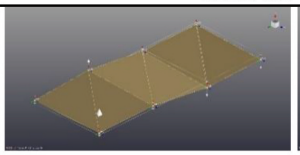


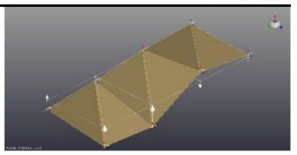












directions: vertical (Z), transversal (Y) and longitudinal (X). Only the configuration of accelerometric sensors of supplier B was suitable to analyze a 2D model of the bridge along all directions. Suppliers A and C refers to a 2D model along Z and a linear model in Y, with no data in X. Suppliers D considered only a 2D model in Z with no data along the other directions.

The most reliable results in Z direction have been provided by suppliers A, B and C (the last one identified the greater number of modes with a low scatter). Despite more scattered information, supplier D captured the values in common with the other systems. The common frequency values are 4.00-4.38 Hz, 13.30-13.80 Hz e 17.20-17.80 Hz (Table 6). The corresponding mode shapes, shown in Table 7, seem to be almost compatible between them. In Table 8 the frequencies for the transversal direction are shown.

Table 6. Frequency values along the vertical direction (the common frequencies are highlighted)..

	Supplier C	Supplier A	Supplier B	Supplier D
Mode 1	0.602 Hz	4.019 Hz	4.378 Hz	4.143 Hz
Mode 2	4.010 Hz	13.652 Hz	13.791 Hz	6.418 Hz
Mode 3	4.496 Hz	17.564 Hz	14.212 Hz	12.573 Hz
Mode 4	12.707 Hz	25.558 Hz	17.799 Hz	17.247 Hz
Mode 5	13.457 Hz	-	20.780 Hz	-
Mode 6	17.756 Hz	-	-	-

Table 7. Main mode shapes along the vertical direction.

Supplier	Mode 1	Mode 2	Mode 3
A	 4.019 Hz	 13.652 Hz	 17.564 Hz
B	 4.378 Hz	 13.791 Hz	 17.799 Hz
C	 4.010 Hz	 13.457 Hz	 17.756 Hz
D	 4.143 Hz	 12.573 Hz	 17.247 Hz

For what concerns the analysis in Y direction, an accelerometer of supplier A provided data with an amplitude significantly lower than the others. This issue clearly affected the results of supplier A.

The most reliable results were provided by supplier C, which was the only one able to capture the flexural mode shapes of the deck. From the monitoring systems of suppliers A and B incoherent mode shapes were obtained, in the sense that the deck expands and contracts as if it was not rigid in that direction or it is affected by movements at the ends (possible oscillations of the piers). Only supplier B provided results in the longitudinal (X) direction, which are characterized by a substantially high scatter. Four main frequency values have been obtained: 13.92 Hz, 15.87 Hz 22.49 Hz e 24.07 Hz. Nonetheless, only the first mode seems to be reliable.

Table 8. Frequency values along the transversal direction (the common frequencies are highlighted).

	Supplier C	Supplier A	Supplier B
Mode 1	4.119 Hz	7.082 Hz	7.190 Hz
Mode 2	12.762 Hz	12.893 Hz	12.981 Hz
Mode 3	17.692 Hz	17.688 Hz	17.701 Hz
Mode 4	20.579 Hz	20.640 Hz	24.076 Hz
Mode 5	22.348 Hz	21.409 Hz	26.353 Hz
Mode 6	-	22.458 Hz	-

5 CONCLUSIONS

In this paper a Proof of Concept based on four different monitoring systems installed on an Italian highway viaduct has been presented. The aim is to compare their functioning, the effectiveness of their results and essentially the technological solution. Each system consisted of several sensors to measure displacements, drifts, deformations, accelerations and temperature both in static and dynamic conditions.

During the period of the pilot test, the static part of the monitoring systems highlighted several issues inducted by electrical disturbances in terms of drift, spikes and broadband noise. Such phenomena could not be completely avoided. Disturbances from traffic, illumination system of a bridge or other electric sources is quite common and most of the time the monitoring system cannot be properly earthed to avoid such disturbances. These are the typical operational conditions on site. The software part of the system should include tools to identify such unwanted signals and attenuate the correlated negative effects. In most cases the characteristic of the signal was quite unique and could be detected by pattern recognition procedures. Electrical shocks are represented by extremely sharp rises, which means that the difference between two measurement points is orders of magnitude greater than normal signals.

The dynamic acquisition presented in some cases inaccuracies due to incomparable amplitudes of the accelerations of some sensor respect to the others. In any case it can be mentioned that system C provided reliable results in terms of frequencies and mode shapes.

Other results, particularly regarding the behaviour of the monitored structure, will be obtained only after a long-term observation period (i.e. at least one year).

ABSTRACT: This paper proposes a new prototype for the non-destructive testing of external post-tensioning tendons. The system is based on the dynamic response of the tendon from which a series of structural performance indicators are identified, allowing to assess them and to make maintenance or replacement decisions in case anomalies are detected. The prototype developed is economical, easy to use, scalable (more sensors or performance indicators can be included) and portable, since all the necessary equipment is placed on a trolley. The system has been used for the evaluation of the external post-tensioning tendons of a 12-span railway bridge, with a total of 202 tendon segments analyzed. For each test, the system generates a report summarizing the calculated indicators and pointing out any anomalies detected. Considering the results of all the segments, an unsupervised clustering technique is applied to create groups with similar patterns where the results obtained are classified and the presence of outliers, i.e. tendon sections with anomalous behavior, is checked.

1 INTRODUCTION

In the design of new bridges and their rehabilitation, the use of external post-tensioning tendons is common due to their ease of installation and replacement if necessary. The presence of defects (corrosion of the strands or cracks in the grout) can accelerate the breakage of the tendon leading, in the worst case scenario, to the collapse of the structure (Anania et al. 2019). Therefore, due to the importance of these structural elements, numerous works have been carried out in recent years for the monitoring and evaluation of their structural integrity. In this context, two general applications can be mentioned: continuous monitoring of their structural health (Cigada et al. 2020) and non-destructive testing (NDT) for the estimation of tension force (Abdel & Glisic 2019, Chen at al. 2016). Within this second application, techniques based on dynamic response, acoustic or strain measurements can be commonly found in practice.

Regarding the methods based on dynamic response, this is related to their dynamic properties, which may be altered due to damage, structural anomalies or by the modification of their support conditions. Lee & Kang (2019) demonstrated that both the natural frequencies and the tension force of tendons decrease as the strands damage progresses. In the case of adherent tendons (bonded), the loss of steel section is not proportional to either the reduction in frequencies or the reduction in tension due to self-anchorage. However, between the frequencies, higher frequencies are more sensitive to damage and the ratio between them and the fundamental should be greater than the modal order due to the non-negligible moment of inertia provided by the grout. The main objective of this work is to propose an NDT system for external tendons which is able to measure and analyze the experimental vibrations, extract their modal parameters and monitor them, detecting changes or obtaining mechanical parameters of interest.

External post-tensioning tendons can be modeled as a cable with bending stiffness and their dynamic behavior will depend on: the boundary conditions (usually different from simply

DOI: 10.1201/9781003483755-273

supported due to the effect of bending at diaphragms and deviators), the tension force at that moment, the mass distribution along its length and the bending stiffness which is not negligible in general, especially in the case of short tendons subjected to significant tension forces. By knowing these parameters, the structural behavior of the tendon can be accurately evaluated. Since the conditions of the tendons are not visible due to the sheath and grout, NDT based on dynamic response can be a useful tool in the overall assessment of tendon mechanical behavior.

Several continuous tendon monitoring applications based on the dynamic response of tendons can be found in the literature that track natural frequencies and, indirectly, tendon tension force (considering the equation of a string without bending stiffness and only the fundamental frequency which provides significant errors in the tension force estimation) (Cigada et al. 2020). However, there are no prototypes of NDT equipment that complement more classical techniques such as ultrasonic and that carry out the dynamic analysis of the tendon and the calibration of its digital model in an automated way. This article presents an efficient (in terms of test time), scalable and portable NDT system for the evaluation of tendon anomalies that can be used for maintenance on successive occasions. The system, once the measurement has been performed, generates a report with several performance indicators (PIs) that allow evaluating the tendon segment and, finally, to compare them with more segments for a more exhaustive analysis of the complete tendon.

Changes in the tendon's tension force affect its structural behavior and is a parameter of interest for maintenance and structural evaluations. In fact, a significant drop in the tension force with an increase in the tension force of adjacent tendons is a clear indicator of an anomaly. The effect of bending stiffness makes the ratio between the frequencies and the fundamental clearly greater than the modal order. Reductions in this ratio indicate deterioration of the grout. In addition, higher modes are more sensitive to local effects (local strains, wire breakage or loss of stiffness) and their estimation has a direct impact on the number of measurement points, the configuration of the acquisition equipment and the post-processing digital filters.

The NDTT system (Non-destructive Tendon Tester) performs a real-time calibration of the tendon model (digital twin) minimizing the error between analytical and experimental natural frequencies and modal shapes. For the estimation of the experimental frequencies, the problem of the double peak, known as doublets (Sagüés et al. 2006), in the PSD (Power Spectral Density) is solved with a procedure based on weighting the peaks involved to obtain an average. On the other hand, an Operational Modal Analysis (OMA) is performed to obtain the vibration modes.

2 DESCRIPTION OF THE SYSTEM

The developed system for the non-destructive testing of the external tendons is herein described. The device consists of four elements (Figure 1): a trolley with shelves, the sensors and acquisition system, a laptop and a power supplier.

PCB seismic accelerometers are used to measure the dynamic response of the tendons. In particular, the model that is employed is B12 with nominal sensitivity of 10 V/g, resolution of $8 \cdot 10^{-6}$ g rms and frequency range from 0.15 to 1000 Hz. The accelerometers are placed in the tendon by using a magnet which is attached to ad-hoc braces screwed to the sheath equipped with metal plates. The other sensor is a piezoelectric force sensor integrated in an impact hammer. All the sensors are connected to the acquisition system (NI-cDAQ) through BNC connections. Figure 2 shows these devices.

The laptop runs an app programmed in MATLAB developed by the authors. This app launches the test and executes the whole process: a) measure of accelerations using LABVIEW, b) analysis of the signals to extract the behavior of the tendon, and c) generation of an immediate report of the test. By default, the app is configured with a sampling frequency of 1651 Hz, a test duration of 480 s (including ambient vibration test and free vibration test). However, this values can be modified in the setting tab of the app.

The electric generator has a power of 600 W and guarantees at least 8 hours of continuous work of the system.

Figure 1. Experimental setup of the system: trolley with the laptop and electrical generator, accelerometers and visualization of the impact in the laptop.

Figure 2. Sensors, acquisition system and electrical power supplier.

3 WORKING OF THE SYSTEM

3.1 *Measurements and analysis*

The dynamic response of the tendon is obtained by means of two experimental tests. The first one is an ambient vibration test where only environmental loads are applied. Subsequently, an OMA is performed to extract the natural frequencies and mode shapes of the tendon. Initially, the app is configured to extract up to the fourth vibration mode.

The second one is a free vibration test. To do this, the tendon is excited three times with the impact hammer and the free response is assessed to estimate the damping applying the logarithmic decay method. The mean value of the three dampings is given as result.

3.2 *Performance indicators*

Several PIs are defined to assess the structural condition of the tendon. These PIs are calculated from the two previous analyses. Currently, the system calculates ten PIs.

The first four PIs are the first four natural frequencies of the tendon. According to the vibrating string theory, natural frequencies should be proportional (or higher due to bending stiffness) to the modal order. If this is not fulfilled, it is indicated a loss in both the tension

force or the bending stiffness. The following four PIs are associated to the symmetry of the mode shape and is called Symmetry Aspect Ratio (SAR). To define the symmetry, the Modal Assurance Criterion (MAC) parameter of the two sides of the tendon is calculated. A value of 1 reveals a perfect symmetry whereas lower values indicates loss of symmetry possibly due to an irregular distributions of the mass along the length of the tendon. The ninth PI is the damping ratio calculated from the free response test. Changes in the damping ratio may be associated to grout cracking. Finally, the last PI is the tension force of the tendon. This PI is estimated from the updating of an analytical model of the tendon. This process is explained in next section. Table 1 shows the PIs computed by the NDTT.

Table 1. Description of the PIs calculated by the system.

Indicator	Definition	Description
P1	f_1	Fundamental natural frequency [Hz]
P2	f_2/f_1	Ratio between second and first natural frequency
P3	f_3/f_1	Ratio between third and first natural frequency
P4	f_4/f_1	Ratio between fourth and first natural frequency
P5	SAR_1	Symmetry aspect ratio of first mode
P6	SAR_2	Symmetry aspect ratio of second mode
P7	SAR_3	Symmetry aspect ratio of third mode
P8	SAR_4	Symmetry aspect ratio of fourth mode
P9	ζ_1	Damping ratio of first mode
P10	T	Tension force [N]

The ten PIs are the results of a particular segment of the tendon, i.e. each tendon will have between 3 to 9 test results. When all the segments of a tendon have been tested, a behavior matrix P_{ij} of the tendon is defined. The size of this matrix will be $10 \times N$, N being the number of segments. Subsequently, an anomaly matrix is computed. This is defined as:

$$d_{ij} = \frac{\hat{P}_{ij} - P_{ij}}{\hat{P}_{ij}} \tag{1}$$

where $\hat{P}_{ij}$ is a prescribed threshold of the i-PI and segment j. When the anomaly is positive, it is considered that the behavior is not as expected. Finally, a cumulative value of anomaly for each tendon is calculated as:

$$D = \frac{1}{N}\sum_j^N \left[\sum_{i\in M} r_i^1 d_{ij}\right]; \text{ with } \sum_{i\in M} r_i^1 = 1 \tag{2}$$

M being the vector containing the indexes of the PIs at the segment j such that $d_{ij} > 0$, and r_i^1 is the weight associated with indicator i. The weights are obtained from the initial values of the indicator weights as a function of the number of PIs greater than 0 (M vector length):

$$\sum_i^{10} r_i^0 = 1;\ \sum_{i\in M} r_i^0 = A \le 1;\ r_i^1 = \frac{1}{A} r_i^0 \tag{3}$$

where r_i^0 are the initial weights that are defined according to the relevance assigned to each PI. In the case that M contains all the PIs, the weights will be equal to the initial ones, otherwise they will be scaled using Equation (3).

3.3 *Theoretical approach for tension force estimation*

The tension force of the measured tendon segment is estimated by calibrating its analytical dynamic model using the results extracted from the OMA. To define the tendon model, it is considered simply supported at both ends. To consider possible irregularities in the supports

that move it away from the ideal support, the concept of equivalent length is used (Chen et al. 2018). Under this hypothesis, it is assumed that the modal shape can be represented by a tendon with an equivalent length (smaller or equal to the real one). The main advantage is that this model has analytical solution, which significantly reduces the simulation time, making possible its use for in-line application.

The equation for the transverse displacement of the tendon is:

$$EI\frac{\partial^4 v(x,t)}{\partial x^4} - T\frac{\partial^2 v(x,t)}{\partial x^2} + \rho_l \frac{\partial^2 v(x,t)}{\partial t^2} = 0 \tag{4}$$

where EI is the bending stiffness, $v(x,t)$ is the transverse (vertical) displacement, T is the tension force and ρ_l is the linear density. The natural frequencies and modal shapes are calculated as (Morse & Ingard 1986):

$$f_i = \frac{i}{2L_{eq}}\sqrt{\frac{T}{\rho_l} + \frac{\pi^2 EIi^2}{L_{eq}^2 \rho_l}};\ \phi_i(x) = sen\left(\frac{i\pi x}{L_{eq}}\right) \text{with } i = 1,\ 2,\ 3,\ 4 \tag{5}$$

Equal equivalent length is assumed here for all modes. The calibration is carried out by solving a minimization problem whose objective is to minimize the differences between analytical and experimental modal properties by iteratively modifying the tendon parameters. These parameters are: $\boldsymbol{T}$, $\boldsymbol{EI}$ and $\boldsymbol{L_{eq}}$.

This process is run using the genetic algorithm programmed in MATLAB (function ***ga***). The population size is set to 100 individuals and the number of iterations equal to 300. The algorithm is executed 20 times with the aim of computing a weighted mean value of the 20 tension forces. The weights are obtained as the inverse value of the objective function, i.e. the result that reaches a lower value of objective function has a higher influence.

4 EXAMPLE OF APPLICATION

The system has been applied in the monitoring of all the tendons of a continuous double-track railroad viaduct with single-cell box section. The total length is 558 m distributed over 12 spans. The bridge has a first-stage straight launching prestressing and a second-stage prestressing. The latter is external to the section and has a polygonal layout inside the box, anchoring at the diaphragms and breaking at the deviators at a quarter of the span. Each tendon, in general, covers three spans with three segments in each span, giving a total of 9 segments, except for the tendons of the end spans which cover only one or two spans. This bridge has been analyzed due to the notable deterioration that the external tendons have suffered over the years, leading to advanced corrosion processes that have even led to the collapse of one of the tendons. Therefore, the NDTT system developed is intended to shed light on the uncertainty that exists about the actual structural condition of the remaining tendons. Figure 3 shows the analyzed bridge and the external tendons inside the box. As can be seen, the deterioration led to the tendons being sling-joined together to prevent damage. In addition to replacing the collapsed tendon, maintenance work was carried out on the rest of the tendons, replacing some of them.

The application of the proposed system in the bridge was performed at night when no trains were running. Each test analyzes only one segment and is saved with its name so that the analysis of complete tendons and the whole post-tensioning system can be performed later. As mentioned above, several tendons of the bridge were replaced before the tests, having a different technology than the previous ones. Specifically, these were tendons with strands encapsulated in individual sheaths with grease inside and all of them in an outer sheath. In addition, the number of strands was different from previous tendons. Therefore, for the whole analysis the tendons were classified into: Class 1 (C1) the old tendons (bonded) and Class 2 (C2) the new tendons (unbounded). Thus, Class 1 tendons show the phenomenon of self-anchoring (adherent tendons) while Class 2 tendons show non-adherent behavior.

Figure 3. View of the bridge and external post-tensioning tendons.

The behavior matrix (P_{ij}) and the anomaly matrix (d_{ij}) of a particular 9-segment tendon are shown in Tables 2 and 3. Considering these values, the cumulative anomaly for this example was $D = 0.026$ (Equation 2). From the analysis of the results of all the tendons in the structure it was possible to detect that there were 3 tendons with clearly anomalous behavior. Figure 4a shows the histogram of the cumulative anomaly D for all the tendons, where, in particular, one of them had a significantly higher value with respect to the others. These three anomalous tendons correspond to old tendons, for which a thorough inspection was proposed. Figure 4b shows the tendon sections identified as anomalous and therefore candidates for replacement. Tendons 2.1, 1.2 and 4.4 show clearly anomalous behavior, in addition, 4.2 and 2.5 (identified with a diamond in the figure) would also be candidates for replacement.

In addition to the calculation of cumulative damage indices, and given the large number of stretches analyzed, the use of an unsupervised machine learning technique has been proposed for the creation of groups (clusters) that have similar behaviors. With this technique, natural frequencies can be tracked and checked when one changes its behavior, i.e. it can be applied for

automated outlier detection. Furthermore, in the future, by applying transfer learning techniques, these classifiers can be used on similar bridges. In this study, the k-means technique has been used, which groups all the data into k groups characterized by their mean value. Due to the different types of segments (C1 and C2; inclined and horizontal; extreme spans and centered spans; etc.) there are a total of 8 groups. Therefore, the number of groups is $k = 8$. For the creation of the groups, an iterative process is performed and the results may vary between different calculations. To overcome this, 10 calculations (replicates) have been performed and the best of the 10 has been used based on the total sum of the distances between the points and the means. Figure 5 shows the graph with the groups obtained for the 4 natural frequencies. Each of the 8 colors represents a group and the repeated symbols indicate the frequency for which the analysis was performed (circles for the first frequency, squares for the second, pentagrams for the third and diamonds for the fourth). It should be noted that the groups with the same number for the 4 frequencies are not associated with each other, since the calculation has been made for each of the 4 frequencies independently. Clustering allows adding new values to previously created groups and verifying if it is in the right group. If not, it indicates that it does not have the expected behavior and proceeds to its detailed analysis. Using this clustering technique, outlier spans have been identified and it has been verified that these spans belonged to the tendons previously identified using the anomaly indicator.

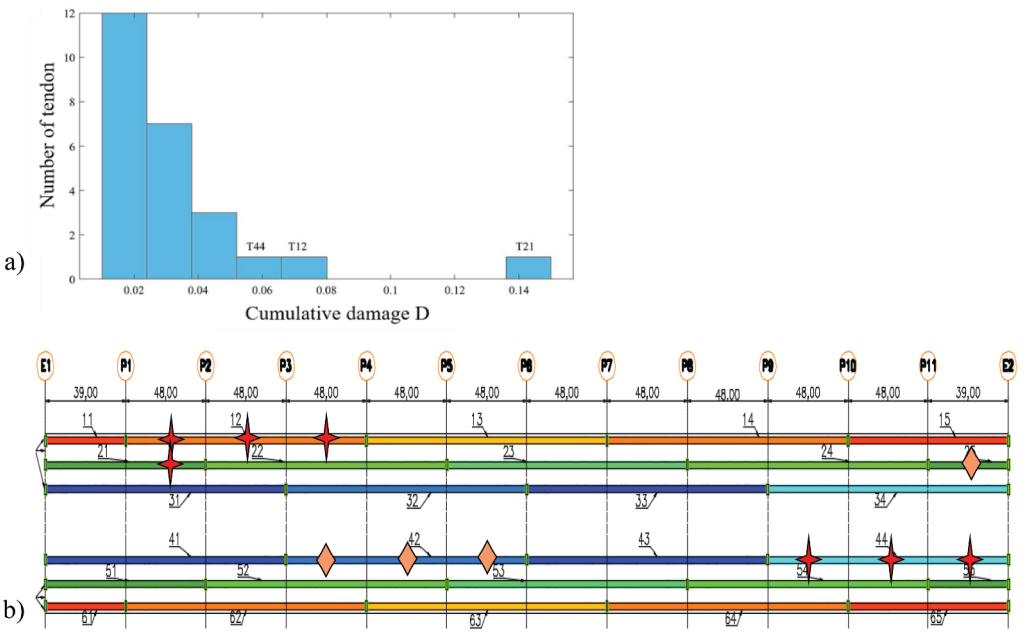

Figure 4. a) Histogram of the cumulative damage D and b) Segments with anomalous behavior.

5 CONCLUSIONS

In this paper, a new NDT system for external post-tensioning tendons has been presented and applied to a 12-span continuous bridge. The system calculates damage indicators on the one hand, and on the other hand, it performs an unsupervised clustering using machine learning techniques to identify tendon segment with abnormal behavior. By means of both procedures, some tendon sections with clearly anomalous behavior have been detected in the tested bridge. At the time of application of the system, new tendons had replaced the old ones and none of these were detected as anomalous. In conclusion, it was recommended to replace the anomalous ones or, if not, to strengthen the slinging and revise it periodically.

ABSTRACT: Vibration-based techniques for external post-tensioning tendons have been used as non-destructive technique to assess their mechanical behavior. Thus, the continuous monitoring allows to assess their deterioration process through the continuous tracking of their natural frequencies, which may be used as damage indicators and for continuous force estimation. Hence, temperature dependencies on the frequency spectra of natural frequencies may mask potential damage among other problems such as double peaks or the existence of bracing systems. In this sense, this paper presents a mixed-cascade clustering for the frequency tracking together with the application of regression models (including linear regression and nonlinear autoregressive with exogeneous input neural network) to the classified data for identification of temperature dependencies. The proposed methodology has been applied to a case of study corresponding to several monitored tendons on a railway continuous concrete bridge.

1 INTRODUCTION

As civil engineering structures become mature, some structural aging effects may appear due to environmental conditions such as corrosion or operational factors like fatigue. Evaluating the structural condition becomes imperative; however, depending on the structural design, employing destructive testing may not be a viable option. Among the non-destructive testing (NDT) alternatives, vibration-based structural health monitoring (SHM) allows to extract features from the dynamic response that can be used as indicators of the structural condition of the structure. In particular, stiffness reduction or tension force losses implies abnormal reduction of the natural frequencies. However, the natural frequencies are also affected by environmental and operational factors that may mask anomalies (Gharehbaghi et al., 2022; Middleton, Fidler & Vardanega, 2016).

In the specific context of bridges featuring external post-tensioning tendons, vibration-based SHM stands out as an optimal alternative, given the discernible correlation between damage and natural frequencies (Lee & Kang, 2019; Zhang et al., 2022). As illustrated in Figure 1, there is a notable frequency variation corresponding to the progression of damage: frequencies decrease with increasing damage, and higher modes exhibit more pronounced variations, thereby rendering damage more visible. This frequency decrease is accompanied by a tension force loss due to the release or fracture of prestress wire and/or of bending stiffness due to grout damage.

Despite the evident correlation between frequency and damage, certain considerations must be taken into account before embracing frequency as a definitive performance indicator. Two crucial effects require attention when a frequency tracking system is going to be implemented:

DOI: 10.1201/9781003483755-274

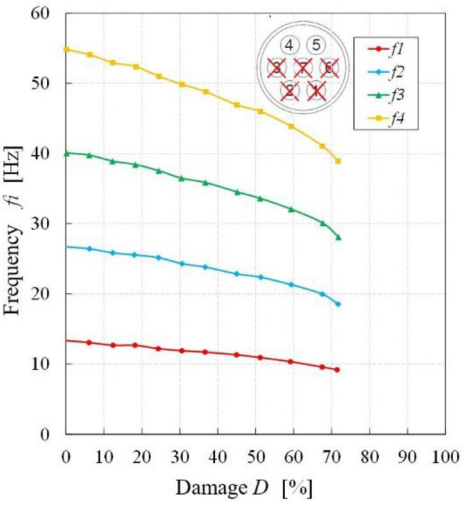

Figure 1. Damage – Frequency correlation adapted from (Lee & Kang, 2019).

I. Double peaks on Power Spectral Density (PSD).
   An important complication arises in experimental tests from the presence of peak doublets (Sagüés, Kranc & Eason, 2006). This may be due to the non-uniform strand arrangement inside the tendons and the different effective length due to different contact points at deviators.
II. Frequency variation attributable to temperature.
   In case of external posttensioning tendons, temperature variation affects importantly to the natural frequency estimation in such a way that NDT based on vibration measurement may not be as useful as expected.

To address the first effect, a cascade clustering process has been proposed. That is, two clustering processes are used to classify data before temperature dependency analysis. The first clustering process is utilized to identify daily and seasonal temperature cycles, as well as to detect coupling frequencies from adjacent tendon segments and outlier points. Subsequently, these outlier points are eliminated. The second clustering process serves to further filter out the outlier data, facilitating the creation of a robust and reliable regression model. This approach is specifically designed to mitigate the impact of the temperature variation on frequency and effectively address the challenges associated with the second effect.

When addressing the impact of temperature variation, the choice of regression methods becomes a pivotal consideration. Various techniques ranging from straightforward and explicit, exemplified by linear regression, to more complex and opaque approaches like neural networks, are available. The selection of an appropriate regression method depends on the specific characteristics of the dataset and the nuances of the relationship between temperature and the variable of interest. Simple and explicit methods, such as linear regression, offer interpretability and ease of implementation, making them suitable for scenarios where the underlying dynamics are relatively well-understood. On the other hand, black box methods like neural networks excel in capturing intricate patterns and non-linear relationships, providing a more flexible framework for modeling complex temperature effects. The decision to employ a particular regression method should align with the goals of the analysis, the nature of the data, and the desired balance between interpretability and predictive performance (Wang, Yang, Yi, Zhang & Han, 2022).

2 VIBRATION-BASED MONITORING OF EXTERNAL TENDONS

2.1 *Tendon description*

Tendons considered are of 2 types:

- Bonded:
  Bonded tendons, characterized by their sole protection through cement grout and a plastic tubing, often encounter corrosion issues, particularly in older instances. The corrosion problem is typically attributed to voids within the cement grout caused by inefficient filling techniques, creating spaces where water can accumulate around the steel strands. Notably, this category of tendons, particularly in aged conditions, does not exhibit a linear correlation between tendon damage and tension loss. This lack of linearity is attributed to the self-anchoring of the steel strands to the cement grout, posing challenges in accurately determining the extent of tendon damage. This fact makes frequencies less sensitive to damage than expected and makes the temperature-dependency removal crucial.
- Unbonded:
  Unbonded tendons distinguish themselves from bonded tendons through the inclusion of a second plastic enclosure filled with grease. This protective measure individually shields each cable, preventing water from reaching the steel strands. In contrast to bonded tendons, this type of tendon exhibits a much more linear correlation between tendon damage and tension loss since the tension loss is proportional to steel loss the absence of self-anchoring to the grease filling means that once a strand breaks, all tension along the strand is lost, contributing to the linear relationship observed in tension loss and tendon damage.

Figure 2 show an illustration of bonded and unbonded tendons.

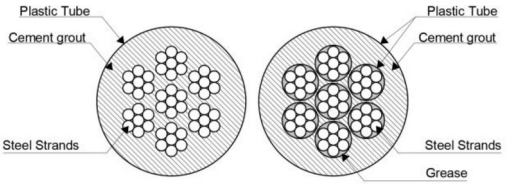

Figure 2. Bonded and unbonded tendons.

2.2 *Double peak on PSD*

As mentioned above, frequency doublets may appear due to:

- Non-homogeneous section
- Coupling frequencies from other segments
- Different contact points on boundaries
- Use of bracing systems

To show an example of this effect, the first frequency of a tendon with bracing is shown in Figure 3. As can be observed, the frequency estimates clearly jump into two different frequency groups, being one of them more persistent on time.

3 FREQUENCY TRACKING: CLUSTERING

3.1 *Mixed cascade clustering*

Due to the inherent characteristics of operational modal analysis, not every measurement yields a reliable value. This is attributed to the potential presence of coupling frequencies, and even when this issue is absent, measurements may be compromised due to insufficient excitation frequency, complicating the differentiation of the actual natural frequencies of the analysed tendon. To address these challenges, a clustering methodology has been proposed to filter

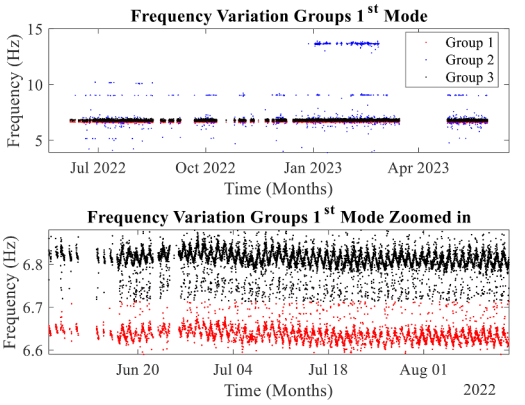

Figure 3. Clustering of coupling frequencies.

outlier data, detect trends, and separate coupling frequencies, facilitating the development of a robust regression model correlating temperature and frequency based on reliable data.

The method involves two clustering processes, with the first employing a Gaussian Mixture Model (GMM). GMM is a probabilistic model assuming data points originate from a mix of Gaussian distributions with unknown parameters (Bishop, 2006). This initial process identifies daily and seasonal temperature cycles, ideally resulting in two groups—one with outlier data and another with significant data. The latter is explored using a frequency vs temperature charts, often necessitating the removal of outlier data along this dimension. Two alternatives for this second classification are proposed hereof: the first involves using again GMM-based clustering process to separate outlier data from significant data, while the second employs Density-Based Spatial Clustering for Applications with Noise (DBSCAN). DBSCAN automatically creates clusters based on two parameters for each point: its border and the number of points inside that border (Ester, Kriegel, Sander & Xu, 1996). Although multiple clusters may be generated, the cluster numbered as -1 is crucial as it denotes outliers. Retaining the significant data obtained through either method results in a cleaner and reliable dataset, ready for applying regression methods. Figure 4 provides a flowchart of the proposed classification method which is illustrated by some plots.

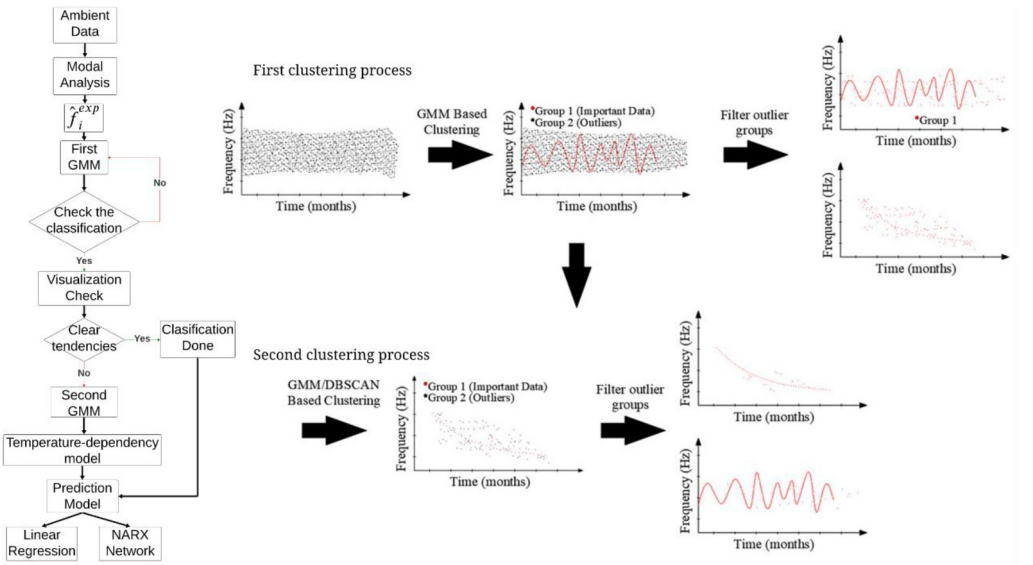

Figure 4. Cascade clustering process flowchart.

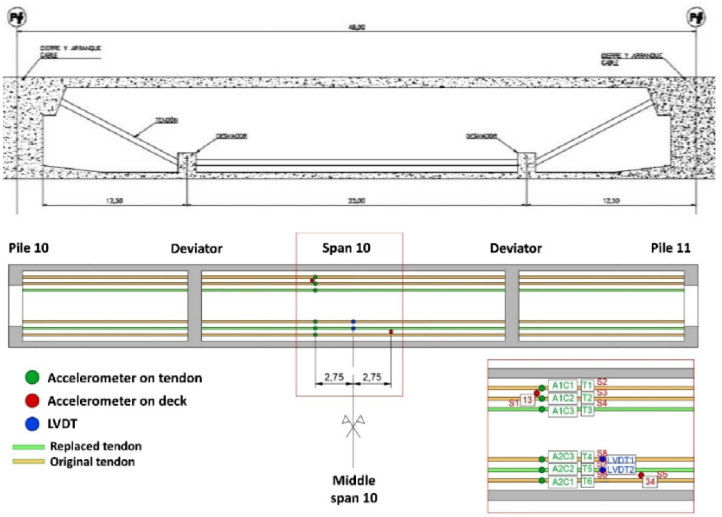
3.2 *Example of application*

The selected example involves one-year continuous monitoring initiative on a 12-span continuous concrete box-girder railway bridge featuring external post-tensioned tendons. The bridge initially incorporated six originally bonded tendons per span, which began exhibiting indications of stress-corrosion. For data acquisition, a monitoring system was deployed on the tenth span, comprising six accelerometers—one for each tendon—along with two accelerometers positioned on opposing borders, each located at a distance equivalent to one-tenth of the span from the center, and two displacement sensors (LVDTs) positioned at the midpoint of the horizontal section of the tendon. Additionally, an ambient temperature and humidity sensor was placed at the middle span inside the box-girder. Figure 5 illustrates the locations of these sensors and provides a visual representation of the tendon configuration at span 10.



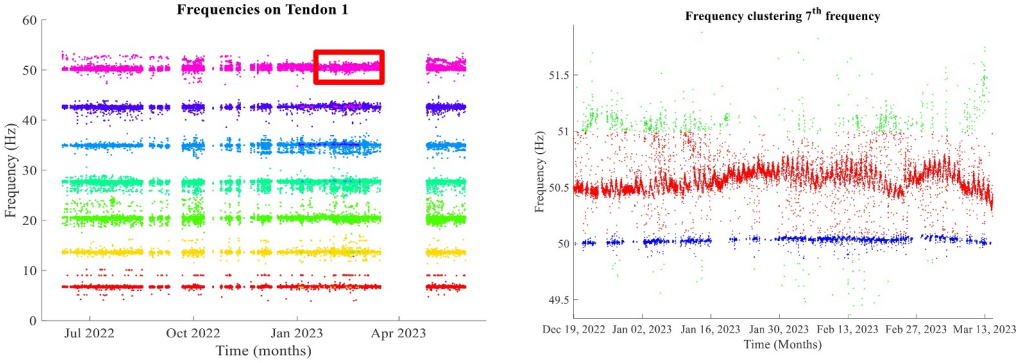


Figure 5. Sensor location.

The first 7 frequencies are obtained by peak picking on the PSD chart, this is done every 10 minutes over a one-yearperiod. These frequencies are illustrated in Figure 6. Initially, no discernible trend with temperature is evident in any of the seven frequencies. However, applying the cascade clustering process allows for the differentiation of day-night and seasonal cycles.

a) b)

Figure 6. a) First 7 natural frequencies of tendon 1. b) Zoom of resulting groups on the 7th frequency.

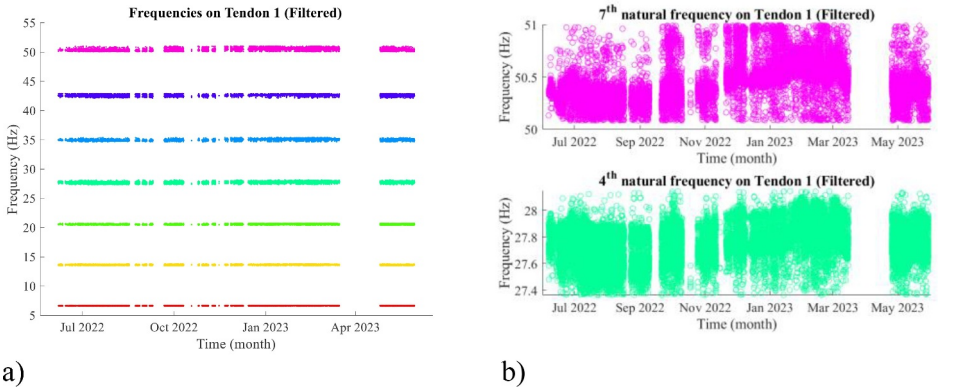

Figure 7. a) First 7 natural frequencies of tendon 1 after the first clustering process using GMM. b) Zoom of the 4th an 7th filtered natural frequencies.

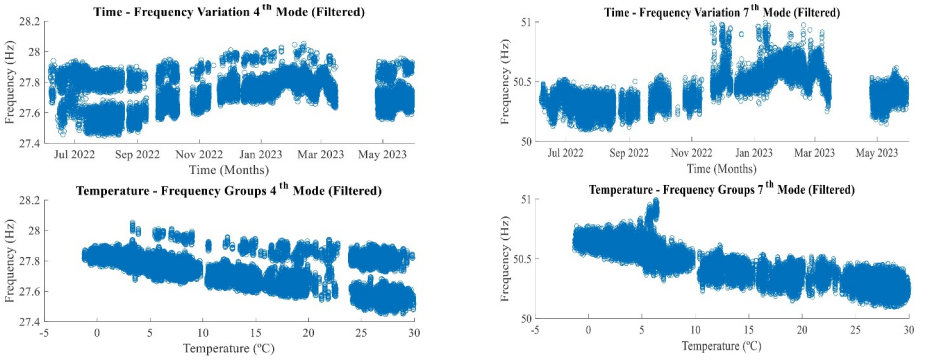
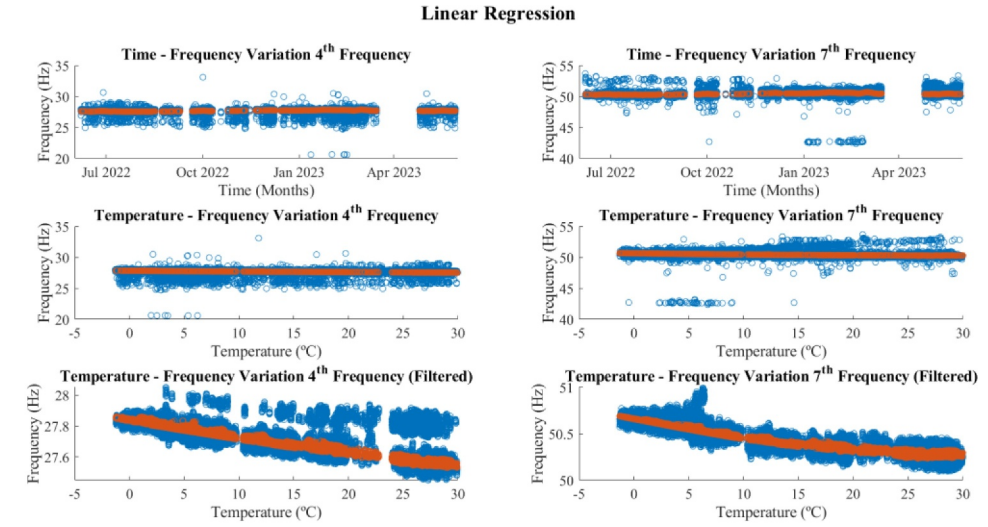
Figure 7 illustrates the frequency distribution of tendon 1 after the first clustering process using GMM searching for ideally 2 groups but because of coupling frequencies could be more.

A second clustering process is executed to further eliminate outlier points. Figure 8 presents, as an exaple, the filtered dataset of modes 4 and 7 both using DBSCAN in this case, illustrating both the effectiveness of the method and the issues that need resolution.





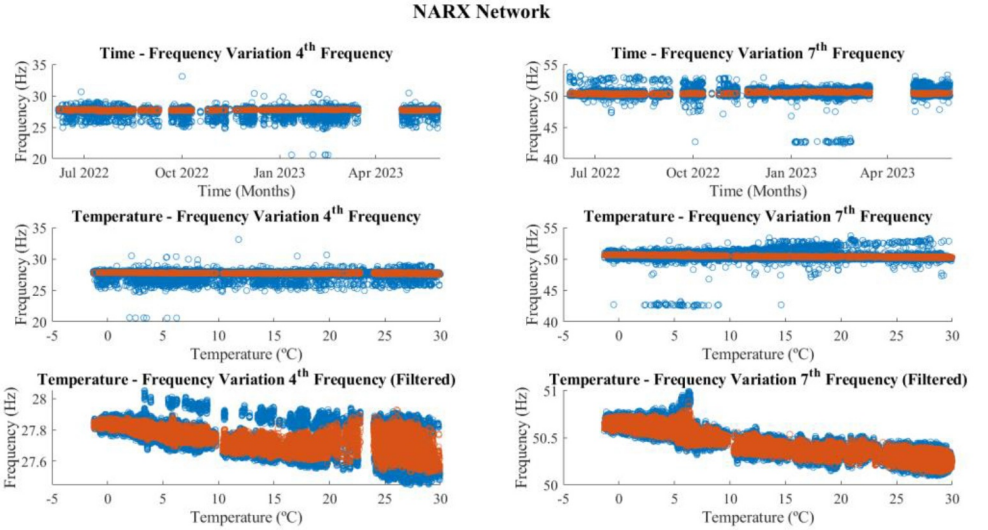


Figure 8. 4th and 7th filtered frequencies of the analysed tendon after the second clustering process using DBSCAN.

Following the acquisition of the classified dataset, two correlation methods were employed to establish a relationship between temperature and frequency. Among the numerous alternatives, linear regression and nonlinear autoregressive with exogeneous input neural network (NARX NN) were selected. The former was selected for its simplicity and fundamental nature in regression, while the latter, a specialized neural network for time-series analysis, was deemed ideal for this type of problem in which temperature changes take effect on frequencies after a period of time due to thermal inertia effect. Figure 9 illustrates the results obtained through the utilization of a linear regression and a NARX NN on the 4th and 7th natural frequencies.

It is evident that the NARX neural network can fit the majority of the data, but its consideration of coupling frequencies renders its predictions less reliable. Conversely, linear regression, although not as adept at describing the variation as the NARX NN, exhibits an advantage in its ability to disregard coupling frequencies that could not be filtered by the cascade clustering process.

a)

b)

Figure 9. Regression methods results a) Linear regression. b) NARX NN regression.

4 CONCLUSIONS

NDT of external tendons based on vibration data can be useful; however, some problems in the frequency estimates appear and make the use of natural frequencies as damage indicators awkward. Thus, methodology named as "cascade clustering process" comprising two successive clustering processes has been proposed. Two regression methods have been applied to the classified and compared: a basic method in the form of linear regression and a more complex approach using a NARX NN.

Linear regression demonstrates a notable capability to disregard coupled frequencies that may persist even after the cascade clustering process. This feature enhances its reliability in temperature effect elimination when coupled frequencies cannot be completely filtered.

Conversely, when there are no remaining coupling frequencies, the NARX neural network emerges as a superior alternative. Its capacity to effectively capture and describe the frequency variation surpasses that of linear regression.

As for future works, there is a keen interest in fully automating this process. Currently, the cascade clustering process involves numerous inputs that require manual configuration. Additionally, the differentiation between the analysed tendon's frequency and coupling frequencies, as well as the selection of GMM or DBSCAN for the second clustering process, relies on manual inputs that could benefit from automation. As depicted in Figure 8, coupling frequencies are not eliminated by the cascade clustering process in some modes. Consequently, there is a crucial necessity to enhance the clustering methods.

Integrating CWT and CNN for damage detection in high-speed railway bridges

ABSTRACT: High-speed railway bridges, reinforced by external post-tensioning systems, are prone to suffer from fatigue problems under corrosion environments. In order to perform the structural assessment of these structures, during their overall life-cycle, structural health monitoring strategies are currently being implemented. Among the different strategies, vibration-based ones are normally employed in civil engineering applications due to its ability to global damage detection. According to these strategies, the measured dynamic response of the structure is compared between two states (the current and the original one) in order to assess the performance level. Nowadays, deep learning, a machine-learning computational tool, has been used to assist in this comparison task. An artificial neural network is usually trained for this purpose. For this training process, two extreme states are normally considered: (i) undamaged state; and (ii) damaged state. As it is not normally possible to obtain data of the damaged state of the structural system, an updated physics-based model is usually considered for this purpose. Therefore, the dynamic response of the damaged structure is simulated based on this updated model. In this manuscript, the performance of a classifier is assessed when it is implemented for the damage detection of a high-speed railway bridge. As an original (undamaged) state, an updated Bayesian finite-element-model of the structure is considered. Different level of uncertainty has been considered (variation range of the updating parameters) for this updated model. As damaged state, different levels of numerical damage have been generated. The dynamic response of the structure (vertical accelerations) has been compared for the damage detection. For the feature extraction, the continuous wavelet transform has been considered. As deep learning technique, a pre-trained convolutional neuronal network has been taken into account. Thus, the performance of the proposed classifier has been assessed, for this particular case-study, via the determination of both the confusion matrix and the accuracy ratio. Finally, the variation of the accuracy ratio in terms of the uncertainty of the updated model and the damage level has been studied in detail.

1 INTRODUCTION

Structural health monitoring (SHM) is currently the most powerful tool for civil infrastructure management (Ghiasi et al., 2019). One of the main objectives of the SHM is to establish an autonomous damage identification (DI) strategy (Anastasia et al., 2023). DI can be broken down into three different areas (Ghiasi et al., 2021): (i) damage detection (DD), (ii) damage diagnosis; and (iii) damage prognosis. Additionally, damage diagnosis can be sub-divided in three sub-areas to better characterize the damage (location, type and severity).

A SHM strategy involves the long-term monitoring of a structure, the extraction of the damage-sensitive features from the monitoring data, and the statistical analysis of these

DOI: 10.1201/9781003483755-275

features to determine the actual structural condition (Figueiredo et al., 2019). There are commonly two main methods to establish a SHM strategy: (i) physics-based methods; and (ii) data-based methods. The first methods are based on the resolution of an inverse problem, the finite element (FE) model updating problem, and they attempt to perform the DI process via the comparison of the main physical parameters of a FE model of the structure (Ereiz et al., 2022). The value of these physical parameters is obtained by a calibration process based on the measurements of the long-term monitoring. The data-based methods attempt to cope with the DI problem via the direct processing of the data recorded during the monitoring process. Currently, this data processing is performed considering the machine learning (ML) field. ML algorithms learn the structural behavior from the experimental data and perform the pattern recognition for DI.

Two types of ML methods can be applied to solve the DI problem: (i) unsupervised learning, when training data are only available from the undamaged structure; and (ii) supervised learning, when training data are available from the undamaged and damaged structure. This manuscript is focused on the use of supervised learning algorithms, and in particular, DL methods. These supervised DL methods are based on the use of artificial neural networks (ANN) for time series analysis and image classification. Thus, the DI problem can be reformulated as a classification problem.

Several strategies have been proposed to cope with the DI problem using ANN. Among the different proposals, the use of a particular type of ANN, the so-called convolutional neural networks (CNN), has been recently proposed by several researchers (Talaei et al., 2023). A CNN is a type of ANN specially designed to classify images. A great effort has been performed in different research fields to cope with this image classification problem. Thus, a high number of architectures of CNN have been proposed. In order to reduce both the data set and simulation time needed to train these complex DL algorithms, it is a common practice, to take advantage of these previous architectures and try to adapt them to different engineering problems. Therefore, a pre-trained CNN is usually modified to solve the DI problem (Chen et al., 2023).

A key-point, for the good performance of the classification method, is the so-called feature extraction phase. In this sense, the analysis of the statistical properties of the response of the structure considering the time and frequency domain is considered. In this sense, the dynamic response of the structure subjected to operational conditions has been commonly employed. As the dynamic response of the structure is a transient signal, the time-frequency content of the signal can be remarkable data for the feature extraction. The continuous wavelet transform (CWT) has been recently proposed for this purpose (Amanollah et al, 2023).

Several recent researches have proposed the use of a CWT-CNN method, based on pre-trained DL architectures, to solve the DD problem of civil engineering structures (Figueiredo et al, 2023). Despite the detailed analysis performed in this line, all these studies present a clear drawback, they have been developed assuming deterministic conditions (Figueiredo et al, 2011).

In order to shed some light to this problem, this manuscript focuses on the analysis of the performance of the abovementioned CWT-CNN method when it is implemented for the DD of high-speed railway bridges subjected to uncertainty conditions. This uncertainty is associated with the variation of the operational and environmental conditions. In order to quantify the uncertainty, a stochastic FE model updating technique is taken into account. Thus, the updated model has been used to simulate numerically both the undamaged and damaged behavior of the structure. In this manner, the importance of the use of stochastic FE model updating for the solution of the DD problem considering uncertainty conditions has been highlighted herein.

2 MACHINE LEARNING STRATEGIES FOR DAMAGE DETECTION

The formulation of the SHM problem, according to the ML method, can be described as a four-step problem. These four-steps are (Avci et al., 2021): (i) the operational evaluation; (ii) the data acquisition; (iii) the feature extraction; and (iv) the statistical modeling for feature

classification. Thus, the main objective of the method is to recognize and distinguish between the statistical patterns of two states of the structure: (i) the undamaged structure under operational and environmental influences; and (ii) the damaged structure under the same conditions. The process starts with the measurement of the behavior of the structure via a long-term monitoring system and finishes with the assessment of current state of the structure.

As the key-point of the process is the feature extraction, currently the use of DL algorithms has prevailed over other ML techniques. DL allows the autonomous extraction of the features of the data. For this reason, a DL algorithm has been considered in this study.

3 BAYESIAN FINITE ELEMENT MODEL UPDATING

In order to quantify the uncertainty associated with the variation of the main physical parameters of a structure associated with the variation of the operational and environmental conditions, the stochastic finite element (FE) model updating can be employed (Kamariotis et al., 2022). In this manner, the data obtained for a long-term monitoring of the structure can be used to characterize numerically the variation of the main physical parameters of the structure.

An initial FE model of the structure is commonly updated based on the experimental and numerical modal properties of the structure. Due to the stochastic character of the problem, as estimator, Bayesian inference, is considered. In this manner, the probabilistic distribution of the main physical parameters of the structure, θ, is estimated via the Monte Carlo sampling (Lye et al., 2021) of the Bayes' rule:

$$P(\theta/D) = \frac{P(D/\theta) \cdot P(\theta)}{P(D)} \tag{1}$$

where D represents the vector of the measurements (or observations); $P(\theta)$ represents the prior distribution; $P(D/\theta)$ represents the likelihood function of the parameters, $P(D)$ represents the evidence; and $P(\theta/D)$ represents the posterior distribution (the target distribution from which sampling is done).

Figure 1 shows the flowchart of the Bayesian FE model updating of a civil engineering structure. According to this flowchart, the linking between a FE analysis package (Ansys, 2023) and a mathematical package (Matlab, 2022) is considered.

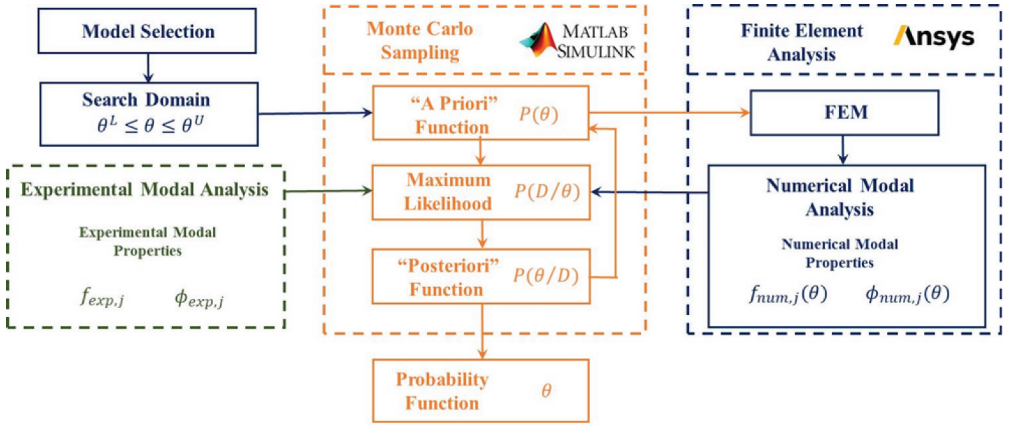

Figure 1. Flowchart for the Bayesian FE model updating of a civil engineering structure.

As a result of the Bayesian FE model updating process, a stochastic FE model of the structure is considered. According to this model, the main physical parameters that characterize

the behavior of the structure are defined as random variables. In this manner, this model can be used to simulate the abovementioned uncertainty conditions.

4 CONTINUOUS WAVELET TRANSFORM FOR FEATURE EXTRACTION

The dynamic response of bridges subjected to the crossing of a high-speed train is non-stationary in nature due to their frequency variation with time. Several researches have been performed to assess the deterioration state of these structures based on the data analysis of this response. Generally, the Fourier transform (FT) is used in these studies. FT breaks down a time series signal into its component frequencies. Therefore, FT is a mathematical decomposition of a signal in its discrete constituting components. Thus, FT allows transforming a signal from the time domain to the frequency domain.

For feature extraction, in signal processing, it is needed to transform the signal in time and frequency domains simultaneously. For this purpose, the FT is commonly used. However, this transform does not generate the actual time history of frequency variation when the frequency components are changing in the time domain. The FT of a time series signal, $x(t)$, is given below:

$$FT(w) = \int_{-\infty}^{\infty} x(t) \exp(-2\pi jft) dt \tag{2}$$

FT of a time series signal is the inner product between the given signal and the basis function, $\exp(-2\pi jft)$, in where t represents the time. FT is unable to detect any local variation in the time domain. Therefore, it is not ideal for non-stationary time signal analysis.

A partial solution to solve this problem, is the so-called the short-time Fourier transformation (STFT). In this transform a short-duration fixed window, $\mathbf{w}(\mathbf{t} - \tau)$, is used to extract all frequencies content in that time window. The STFT may be expressed as:

$$STFT(w, \tau) = \int_{-\infty}^{\infty} x(t)\mathbf{w}(\mathbf{t} - \tau) \exp(-2\pi jft) dt \tag{3}$$

However, the STFT presents a main problem, it has a fixed window (fixed frequency) which enables only short and fixed time–frequency resolution. In order to overcome this limitation, Wavelet transformation (WT) can be used.

WT is a computational tool that allows identifying local variations within a time series. This transform is a powerful technique to analyze random oscillation in a time series. As result of the WT a time-frequency spectrum is obtained. WT can be classified into two categories: (i) continuous Wavelet Transform (CWT); and (ii) discrete Wavelet Transform (DWT). The first category, CWT, is usually employed for feature extraction from time series. The idea of CWT was derived from short-time Fourier transform (STFT), where the time duration window is modified to extract all the frequencies within the window.

In this manner, the basic idea behind this transformation is the definition of the wavelet as a band-pass filter to the time series signal. This causes the translation and dilation of the mother wavelet. Therefore, this transform can expand a time series in the time and frequency domains at the same time. Therefore, CWT can examine and find a localized anomaly in time series analysis distributed at equal intervals. The CWT of a signal, $x(t)$, at scale, a, and time, b, can be defined as:

$$CWT(a, b) = \int_{-\infty}^{\infty} x(t) \frac{1}{\sqrt{a}} \psi^* \left(\frac{t - b}{a} \right) dt \tag{4}$$

where ψ is the mother wavelet; *is the complex conjugate; $CWT(a, b)$ are the CWT coefficients; a is the translation parameter; and b is the dilation parameter.

In this manner, small values of a cause the contraction of the mother wavelet producing high-frequency functions, while high values of a cause the stretching of the mother wavelet producing low-frequency.

In this study, the dynamic response of a high-speed railway is processed via a CWT. In this manner, the CWT coefficients are considered for the feature extraction. In particular, the scalogram, a frequency-time representation of these coefficients is considered for this purpose. Figure 2 shows the representation of the dynamic response of a high-speed railway bridge in the frequency-time domain.

5 PRE-TRAINED CONVOLUTION NEURAL NETWORKS FOR IMAGE CLASSIFICATION

As ML tool, a CNN has been considered in this study. A CNN is a special type of ANN which is specifically designed to classified images. One of the main advantages of using DL is that the algorithm extracts autonomously the features from the inputs (images).

As the design of this type of DL tool implies the determination of a high number of design parameters (associated with the parameters of the hidden layers of the ANN) a great data set together with a high simulation time is required to train the model. In order to overcome this limitation, the practical rule is to take advantage of a previously designed CNN and to adapt it to the new particular problem. This second approach, denominated as a pre-trained CNN, has been considered in this study. Among the different existing architecture, due to its good balance between complexity the accuracy of the results, the AlexNet CNN has been considered (Talaei et al, 2023).

In order to adapt this CNN to the DD problem, some layers of the CNN have been modified. In particular, the output layer has been modified to take into account the classification problem. Two classes have been considered for this purpose: (i) undamaged; and (ii) damaged state.

Finally, as data set of the pre-trained CNN a set of images must be generated. For this purpose, the CWT scalogram of the dynamic response of the bridges subjected to the crossing of a high-speed train has been considered. In this manner, the integration of the CWT and the pre-trained CNN allows designing an advanced classification model. Figure 2 shows a scheme of the CWT-CNN model.

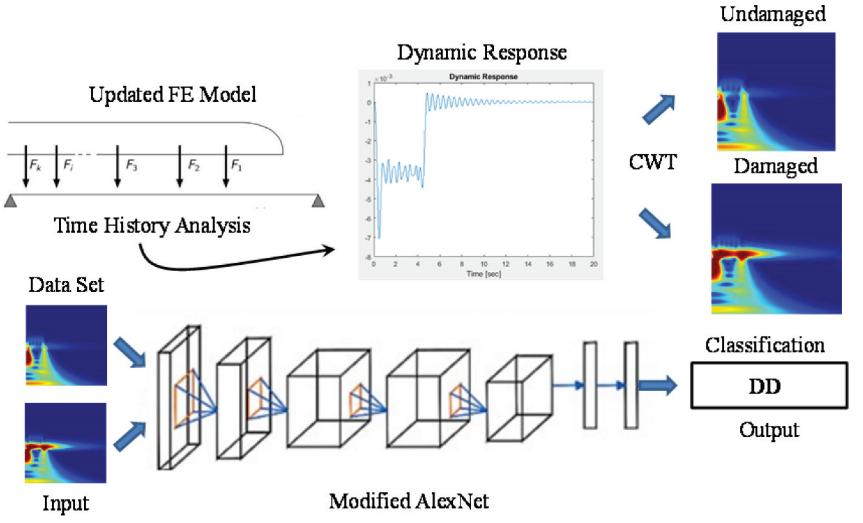

Figure 2. Flowchart of the CWT-CNN algorithm for DD.

6 VALIDATION EXAMPLE

As validation example, a single span high-speed railway bridge has been considered. The length of the span is about 58 m. The deck consists of a post-tensioned box-girder concrete structure. The depth of the deck is about 3.9 m. The following mechanical and material properties have been considered to model the structure: (i) cross-section area, 9.37 m^2; (ii) cross-section inertia, 19.59 m^4; (iii) concrete density, 2500 kg/m^3; (iv) concrete Young's modulus, 35000 MPa; (v) ballast mass, 13200 kg/m; and (vi) damping ratio, 2%.

A FE model of the structure is performed using a commercial FE package (Ansys, 2023). The dynamic response of the structure subjected to the crossing of a high-speed train is computed. The ICE2 train is considered for this purpose. As train velocity of 300 km/h has been taken into account. To compute the time history analysis a time increment of 0.01 sec and a total integration time of 20 secs have been considered. A full integration method has been considered. The damping matrix has been defined according to the Rayleigh method. The response of the structure is obtained considered undamaged and damaged conditions. The damage conditions have been simulated numerically reducing the stiffness of the structure. In order to take into account, the influence of the damage level in the performance of the classification method, a sensitivity analysis has been performed. Table 1 shows the damage level considered herein.

It is assumed that this FE model is updated, considering the Bayesian inference approach, based on the experiment modal properties identified from a long-term monitoring process. According to this, the FE model is re-defined according to a stochastic approach. Thus, three constitutive parameters have been updated as random normal variables (concrete density, concrete Young's modulus, ballast mass). As mean value of the normal distribution the aforementioned value has been considered. In order to taken into account, the influence of the variability of the operational and environmental conditions in the performance of the ML method, a sensitivity analysis has been performed. Table 1 shows the uncertainty level considered (range of variation of the random variables).

Subsequently, the dynamic response of the structure (times series), considering the two states (undamaged and damaged), has been transformed into an image using the CWT (scalogram). A data set, with 2000 images, has been considered to train (75% data set) and test (25 % data set) a pre-trained CNN (AlexNet) for each numerical simulation. In each simulation both a level of damage and uncertainty level have been taken into account. Ten epochs have been considered for the training process. The evolution of the accuracy of the pre-trained CNN in terms of the training together with the resulting confusion matrix are shown in Figure 3. The CWT-CNN model has been implemented in a mathematical package (Matlab, 2023).

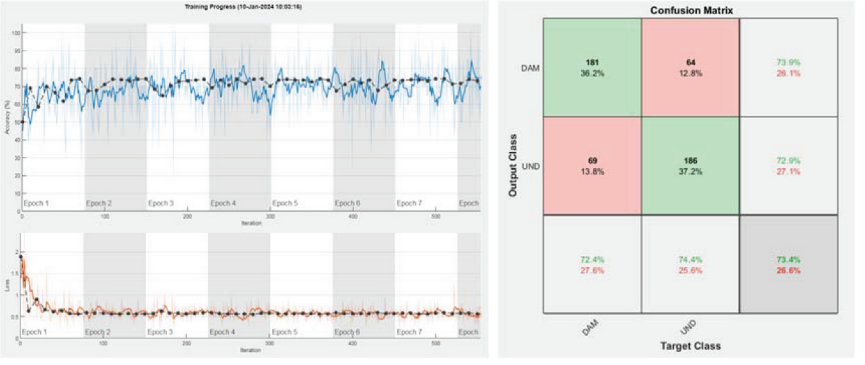

Figure 3. Training and testing process of the considered pre-trained AlexNet CNN.

As key-parameter to check the performance of the CWT-CNN method, the accuracy ratio is considered. The accuracy ratio is defined as the relation between the correct predictions of the model and the total predictions (based on the result of the confusion matrix). Finally, Table 1

shows the variation of the accuracy ratio of the neural network in terms of the uncertainty of the model and the damage level generated. As it is shown in Table 1, a clear reduction of the accuracy of the classification method is obtained when the uncertainty associated with the variability of the operational and environmental conditions masks a low damage level.

Table 1. Variation of the accuracy ratio of the pre-trained CWT-CNN in terms of the uncertainty of the model and the damage level generated.

	Damage level					
Uncertainty	0.05	0.10	0.15	0.20	0.25	0.30
0.05	0.984	1.000	1.000	1.000	1.000	1.000
0.10	0.884	0.988	1.000	1.000	1.000	1.000
0.15	0.790	0.938	0.990	1.000	1.000	1.000
0.20	0.734	0.892	0.968	0.992	1.000	1.000

7 CONCLUSIONS

In this manuscript, the performance of a CWT-CNN method is assessed when it is implemented for the DD of high-speed train bridges under uncertainty conditions. In particular, the influence of the uncertainty associated with the variability of the operational and environmental conditions is analyzed in detail. A stochastic method, a Bayesian inference technique has been considered for this purpose. Two possible states of the structure are considered (undamaged and damaged). The dynamic response of the structure subjected to the crossing of a high-speed train has been compared considering two scenarios undamaged and damaged structure. The damage state of the structure has been simulated numerically based on an updated Bayesian FE model of the bridge. The performance of a classification method, based on a ML algorithm, has been assessed herein. As method, the so-called CWT-CNN algorithm, has been considered. As input of the model, the CWT scalogram (image) of the dynamic response of the structure has been computed. As output, the damage state (undamaged or damaged) has been obtained. In order to reduce the training and complexity of the architecture of the DL algorithm, a pre-trained CNN has been taken into account, the AlexNet. As result of this study, a clear reduction of the performance of the proposal is achieved when the uncertainty conditions are high and the damage level is low. As consequence, further studies are needed to improve the performance of ML techniques when they are implemented to cope with the DI problem under uncertainty conditions.

ABSTRACT: This paper presents an automated methodology for data-driven damage detection (DD) based on feature extraction from the measured vibration responses of civil engineering structures subjected to ambient/operational conditions. To do so, after recording the dynamic response of the structure, feature extraction is performed in the time domain and then the best subset of measurement features that characterize the state of the structure is selected using Analysis of Variance (ANOVA) algorithm. Finally, DD is performed using a machine learning (ML) algorithm trained with selected features. To test the proposed framework, a dataset from a laboratory steel structure is used, and two supervised ML algorithms, K-nearest neighbor classification (KNN) and artificial neural network (ANN) were applied in order to classify damage states. The results showed that both classification techniques were able to successfully classify damage. In addition, the impact of using different feature extraction/selection methods on the accuracy of the proposed approach is studied in detail.

1 INTRODUCTION

Structural health monitoring (SHM) is one of the powerful tools for civil infrastructure management. The SHM process consists of permanent, continuous, periodic or periodically continuous acquisition of parameters by a sensor network, feature extraction and statistical modelling for feature classification to detect possible structural damages and to support the decision making (Ghiasi & Ghasemi, 2018; Avci et al., 2021). Damage is traditionally defined as changes in the material and/or geometric properties of the structures, including variations in the boundary conditions and system connectivity, which adversely affect the system's current or future performance. In contrast, normal condition refers to data acquired under different operational and environmental variability when the structure is known to be undamaged (Ghiasi et al., 2019; Ghasemi et al., 2018).

Significant efforts on SHM have been extensively undertaken (Avci et al., 2021). These studies could be mainly classified in two categories: a) physics-based approaches which are based on vibratory characteristics of structural systems including natural frequency, mode and curvature (Ghiasi et al., 2022), and b) data-driven approaches which extract sensitive features from sensor data to assess the structural conditions (Malekjafarian et al., 2022). In physics-based approaches, the captured sensor data are usually integrated in analytical models or simulations for calibration or interpretation to identify physical characteristics and assess the conditions of a structure. Although analytical models and simulation techniques are now well-established (Ereiz et al., 2022), rapid and accurate interpretation of large volumes of sensor data still lags

DOI: 10.1201/9781003483755-276

behind. Differently, by taking advantage of history sensor data, the data-driven models are robust to rapidly identify the key information from complex and heterogeneous sensor data, which may be no longer valid for the physics-based approaches (Ghiasi et al., 2019).

One of the important steps in data-driven approaches is extracting useful information from raw data which is called Feature Selection (FS) (Ghiasi et al., 2021). FS is generally used in machine learning (ML), especially when the learning task involves high-dimensional datasets. The primary purpose of feature selection is to choose a subset of available features, by eliminating features with little or no predictive information and also redundant features that are strongly correlated (Buckley et al., 2023). The availability of large amounts of data represents a challenge to classification analysis. For example, the use of many features may require the estimation of a considerable number of parameters during the classification process. Thus, the FS approaches is needed to tackle these problems.

The main focus of this research is facilitating the processing of datasets in SHM. Accordingly, the integrated system consisting of four blocks is proposed in this paper. After acquisition of acceleration response data of structure, statistical characteristics of structural response signals under ambient vibration are extracted, and feature vectors are obtained. Subsequently, the best feature subset is selected by the ANOVA analysis as FS algorithm based on importance score (Buckley et al., 2023). In the final step, selected features are employed to train a ML classification model based on the use of an ANN.

The proposed method's performance is evaluated on benchmark dataset of a steel laboratory structure (Jiménez Alonso et al., 2019). The structure has been excited by ambient vibration and the accelerations response of the structure in several characteristic points has been recorded.

Two comparative studies has been performed in order to evaluate the efficacy of the proposal: (i) the ANOVA approach has been compared to the Kruskal-Wallis (Bommert et al., 2020) criterion for FS; and (ii) the accuracy of the ANN classifier algorithm has been assessed in comparison to a conventional KNN classification model.

2 METHODOLOGY

The proposed data-driven approach for bridge health monitoring consists of four steps, which are shown in Figure 1, and the details of each of them are provided below.

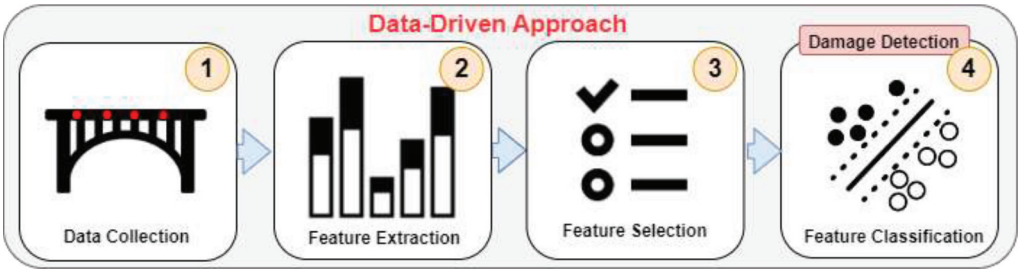

Figure 1. Proposed framework for direct monitoring of bridge.

In the first step, the acceleration response of the structure is recorded using accelerometer sensors on specific points of the structure. The response in the structure can be caused by different moving and static loads (Malekjafarian et al., 2022). In this paper ambient vibration is selected for structural excitation.

In the second step, the functions given in Table 1, are used to form the feature vectors from the data collected by sensors. These features are computed in time domain and provide a summary of the statistical characteristics of the signal over the feature extraction window. It should be mentioned that these features are selected based on the recommendations from previous works in this field (Buckley et al., 2023) and represent the energy, the time series distribution and the vibration amplitude of the signals in time-domain (Ghiasi & Malekjafarian, 2023).

In the third step, the best subset of extracted features will be selected using filter-based FS methods, which calculate the relevance of each feature with respect to the target classes. The features can then be sorted based on their individual relevance to the classes and a top percentage chosen for modelling. Filter methods are independent of classifiers and applied before any modelling is undertaken. A comparison of filter methods for high-dimensional data from different fields is provided in Ref. (Bommert et al., 2020). In this paper the 2 well-known filter-based approaches are used which are: ANOVA and Kruskal-Wallis (Bommert et al., 2020). In both algorithms, the Importance Scores (IS) is determined using F-statistic which compares the distribution variation between groups to the variation within the groups (Ghiasi et al., 2014).

Table 1. Time-domain features.

Feature	Function	Feature	Function
Root mean square	$rms = \sqrt{\frac{\sum_{n=1}^{N}(x(n))^2}{N}}$	Shape factor	$sf = \frac{rms}{\frac{1}{N}\sum_{n=1}^{N}\lvert x(n)\rvert}$
Variance	$var = \sigma^2 = \frac{\sum_{n=1}^{N}(x(n)-mean(x))^2}{(N-1)}$	Impulse factor	$cf = \frac{\max\lvert x(n)\rvert}{\left(\frac{1}{N}\sum_{n=1}^{N}\sqrt{\lvert x(n)\rvert}\right)^2}$
Skewness	$skewness = \frac{\sum_{n=1}^{N}(x(n)-mean(x))^3}{(N-1)\sigma^3}$	Crest factor	$crest = \frac{\max\lvert x(n)\rvert}{rms}$
Kurtosis	$kurtosis = \frac{\sum_{n=1}^{N}(x(n)-mean(x))^4}{(N-1)\sigma^4}$	Signal to noise and distortion ratio (SINAD)	Ratio of total signal power to total noise-plus-distortion power
Total harmonic distortion (THD)	Ratio of total harmonic component power to fundamental power	Signal-to-Noise Ratio (SNR)	Ratio of signal power to noise power

Finally, an ML classification model is used to classify various conditions of the laboratory steel structure. In this model, the input matrix includes the selected features of step 3, and the outputs are the corresponding damage conditions. In recent years, many ML approaches have been proposed or employed for various components of SHM in order to perform pattern classification, function approximation, and regression (Avci et al., 2021). In this paper, the performance of the ANN as a classification algorithm is compared with the kNN algorithm (with Euclidean distance and k = 5) (Gharehbaghi et al., 2023).

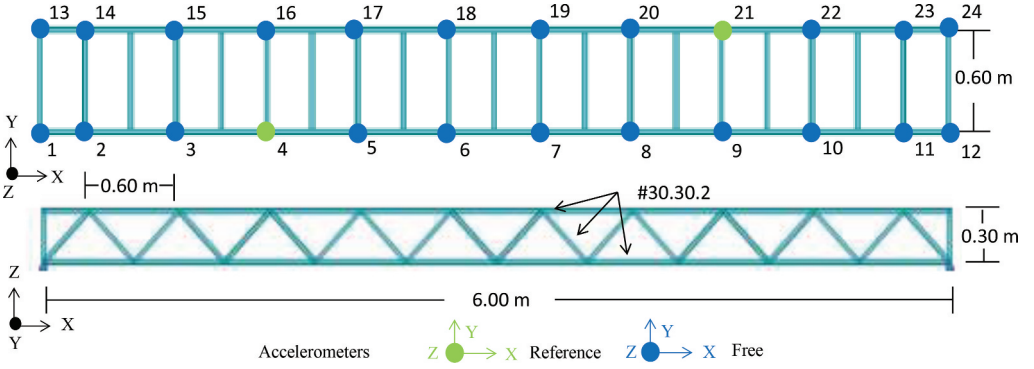
3 RESULTS: DAMAGE DETECTION OF A LABORATORY STEEL STRUCTURE

3.1 *Description of the benchmark structure and characterization of its modal properties*

As benchmark, a laboratory steel structure, that was designed and built in University of Almería (Universidad de Almería (UAL)) (Jiménez Alonso et al., 2019) is used to assess the performance of the data-driven based method. The structure consists of two parallel Warren trusses braced laterally by strut elements (Figure 2). The structure has a single span of 6 m in length. The depth of the structure is about 0.30 m. The two lateral Warren trusses are separated 0.60 m. All the elements of the structure are square tube profiles with dimensions 30x30x2 mm (Figure 3).

The stiffness of the upper chord at mid-span was reduced by severe damage (induced by a chainsaw). An ambient vibration test was performed experimentally to assess the dynamic behavior (modal properties) of the structure under the two considered states (healthy and damaged). The dynamic response (accelerations) of the nodes of the upper chords of the structure was recorded. Two points were considered as references. Each ambient vibration test was organized in 18 set-ups with a sampling frequency of 100 Hz and a duration of each step-up of 300 s. Three tri-axial force balanced accelerometers were used for the experimental ambient vibration tests. Figure 3 illustrates the gridline of the ambient vibration tests.

Figure 2. Laboratory footbridge at the Universidad de Almeria.



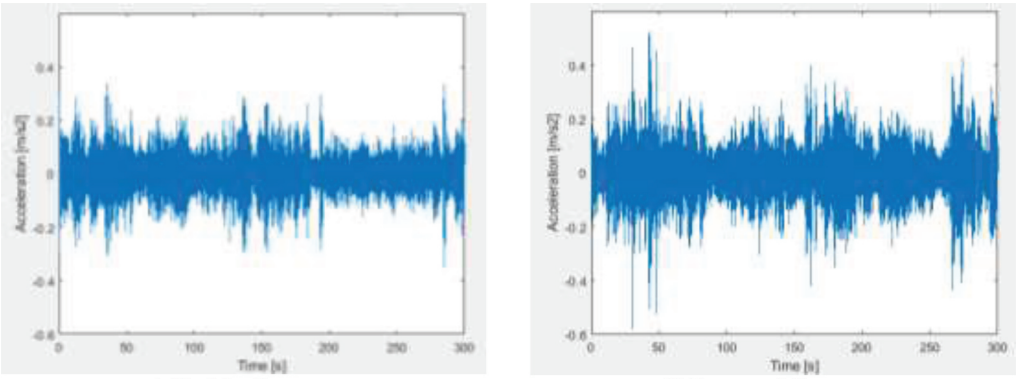


Figure 3. Gridline of the ambient vibration test.

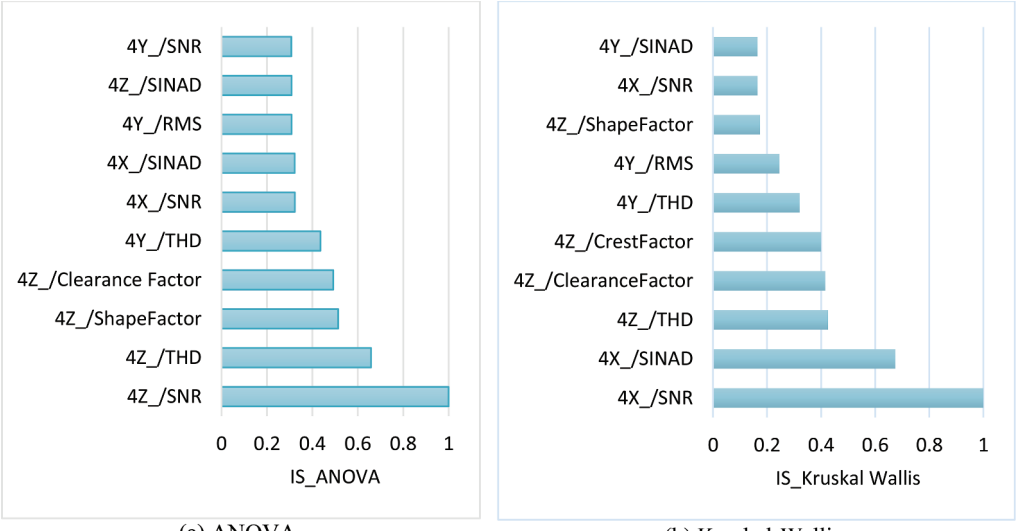
The signal recorded during the ambient vibration tests was processed by an operational modal analysis algorithm (Magalhães et al., 2012). A frequency domain algorithm, the so-called Enhanced Frequency Domain Decomposition method, was considered for this purpose. The algorithm has been implemented in the mathematical software MATLAB (Inc, n.d.). Table 2 shows the variation of the experimental modal properties of the laboratory structure (natural frequencies and vibration modes) associated with the two scenarios (healthy and damaged). In Table 2, f_{exp}^{hea} is the experimental natural frequency of the healthy structure, f_{exp}^{dam} is the experimental natural frequency of the damaged structure, Δf_{exp} is the relative difference of the natural frequencies between the healthy and damaged structure and MAC_{exp} is the experimental MAC ratio (Magalhães et al., 2012).

Table 2. Comparison between the modal properties of the structure corresponding to the two considered states (healthy and damaged).

Mode	Description	f_{exp}^{hea} [Hz]	f_{exp}^{dam} [Hz]	Δf_{exp} [%]	MAC_{exp}[%]
1	1st Lateral	9.75	9.23	-5.33	0.97
2	2nd Lateral	14.50	11.48	-20.83	0.85
3	3rd Lateral	16..17	14.40	-10.95	0.91
4	1st Vertical	20.14	16.55	-17.83	0.95
5	2nd Vertical	23.74	23.44	-1.26	0.91
6	1st Torsion	25.14	21.38	-14.96	0.95

In order to illustrate the response of the structure under ambient conditions, the vertical acceleration of the structure recorded during the ambient vibration test is illustrated in Figure 4. The two considered states, healthy and damaged, are taken into account.



a) Healthy Structure b) Damaged Structure

Figure 4. Recorded signal at point 4 (accelerations in Z direction) considering the two states: (a) healthy structure and (b) damaged structure.

3.2 *Feature extraction and features selection*

After recording the dynamic response of the structure, the static characteristic shown in Table 1 is extracted from the signal in the time domain. In this study, only the response of sensor at point 4 is used. Therefore, considering that the accelerometer sensor stores the response in three directions, the total number of extracted features is equal to 30.

Then, in the third step of the proposed framework, using the FS algorithms, 10 damage-sensitive features are extracted from the entire set of features. The results of FS using ANOVA algorithm are shown in Figure 5 (a). In addition, the effect of using another algorithm for FS on the arrangement of selected features is shown in Figure 5 (b). Both algorithms use the IS to select damage-sensitive features. As shown in Figure 5, most of the selected

(a) ANOVA (b) Kruskal-Wallis

Figure 5. FS based on IS using two filter-based methods (in where "4Y_/FEATURE.", 4 is the position of considered sensor, Y is the considered measurement direction and FEATURE the considered function for FS).

features are related to the vertical direction (Z), which shows its importance and high sensitivity to damage in this benchmark structure.

3.3 *Feature classification*

After extracting the sensitive features in the third step, the last step is the proposed framework is DD using the ANN algorithm. The feature set selected by ANOVA is utilized as input for the algorithm, and the output represents the state of the structure. In addition, a 5-fold cross-validation procedure (Shen et al., 2023) was conducted to assess the average classification performance measures for the classification problem. The result of using ANN algorithm is shown in Figure 6(a). Also, a similar approach has been implemented using the kNN algorithm and its results are shown in Figure 6(b). By comparison of confusion matrixes, it can be seen that both algorithms have a high accuracy in detecting damage in this laboratory structure. Therefore, their true positive rate (TPR) is above 95% and the positive predictive value (PPV) is above 93%, which indicates the optimal accuracy of the proposed framework. Additionally, as it is illustrated by Figure 6, the performance of the ANN model is upper than the kNN model with a higher value of the abovementioned ratios. On the other hand, selecting the Kruskal-Wallis as the FS algorithm resulted in an overall accuracy of 92% with the ANN algorithm and 90% with the kNN algorithm. This indicates that the ANOVA algorithm has identified features with greater sensitivity to damage.

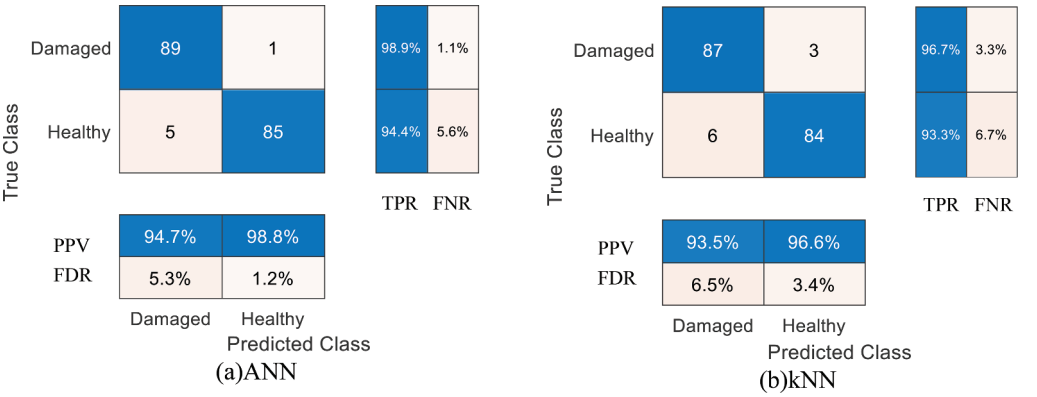


Figure 6. Confusion matrix for ML classifiers.

4 CONCLUSIONS

In this paper, a data-driven framework is presented for the feature selection in SHM problems. To evaluate the capabilities of the framework, the dynamic response of a laboratory steel structure subjected to ambient vibrations has been recorded for healthy and damaged conditions, and its time domain features have been used as input to ML classifiers. The results of this study show the sensitivity and effectiveness of the proposed method for detecting damage in bridges, and the classification accuracy of ANN and kNN is above 95%. A better performance of the ANN model is assessed when it is implemented for DD in this case study.

Moreover, the proposed framework can remove irrelevant and redundant information by choosing useful features as the input of the ML classifiers. These results highlight its potential to be used as a valuable tool for damage detection of civil engineering structures. Nevertheless, further studies are needed to characterize the performance of this proposal when it is implemented for DD in civil engineering structures subjected to environmental and operational conditions.

ABSTRACT: Currently a number of suspended swaying pedestrian bridges are constructed and planned in Korea by mainly local governments. However, the structural behavior of these bridges is not completely known or analyzed and maintenance system has not been implemented yet compared to other road and railway bridges. In this study, various monitoring sensors and systems are applied on a typical swaying pedestrian bridge and longterm monitoring data are collected to investigate the behavior and performance of the bridge. To find the displacement and location movements, GNSS system has been installed on the two locations of the bridge: one at the center of the bridge and the other at anchorage of the bridge. Since the swaying bridge has the shape of suspended cable, the sag is very important static characteristics of the bridge and it can be effectively measured using GNSS system. Dynamic vertical and lateral displacement can also be monitored using this system. To collect the vibration and other environmental data such as wind and temperature, IoT (Internet of Things) system are proposed and installed on the same swaying bridge together with GNSS system. IoT system can measure the accelerations and inclinations as well as strains, temperature and wind speed and direction using its digital and analog inputs. IoT system also has a capability of transmitting data into any data storage via Wifi or LTE connection. Acceleration data may be used to calculate the dynamic characteristics such as natural frequencies and damping ratios. Together with the temperature and wind data, the variance of the sag, static and dynamic characteristics of the bridge may be investigated effectively. The results of this study can be used to develop the comprehensive design and evaluation criteria for swaying bridges.

1 INTRODUCTION

Currently a number of swaying pedestrian bridges are constructed and planned in Korea by mainly local governments, as shown in Figure 1. Also the length of the bridge increases competitively as the years go by. However, the structural behavior of these bridges is not completely known or analyzed and maintenance system has not been implemented yet compared to other road and railway bridges. In this study, various monitoring sensors and systems are applied on a typical swaying pedestrian bridge and long-term monitoring data are collected to investigate the behavior and performance of the bridge. To find the displacement and location

DOI: 10.1201/9781003483755-277

movements, GNSS (Global Navigational Satellite System) has been installed on the two locations of the bridge: one at the center of the bridge and the other at anchorage of the bridge. This system can monitor the settlement and movement at the anchorage ground as well as can increase the accuracy of the location data. Since the swaying bridge has the shape of suspended cable, the sag is very important static characteristics of the bridge and it can be effectively calculated using GNSS system. Dynamic vertical and lateral displacement can also be monitored using this system. To collect the vibration and other environmental data such as wind and temperature, IoT (Internet of Things) system are proposed and installed on the same swaying bridge together with GNSS system. IoT system can measure the accelerations and inclinations as well as strains, temperature and wind speed and direction using its digital and analog inputs. IoT system also has a capability of transmitting data wirelessly into any data storage via Wifi or LTE connection. Acceleration data may be used to calculate the dynamic characteristics such as natural frequencies and damping ratios. Together with the temperature and wind data, the variance of the sag, static and dynamic characteristics of the bridge may be investigated effectively. Based on the results of this study, long-term monitoring system is proposed and the comprehensive design and evaluation criteria for swaying bridges can be developed and verified.

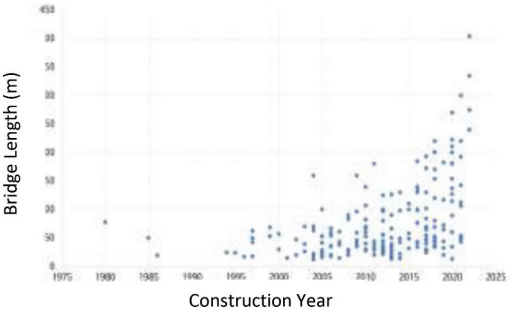

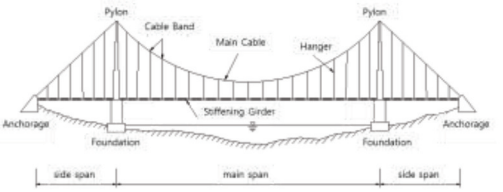

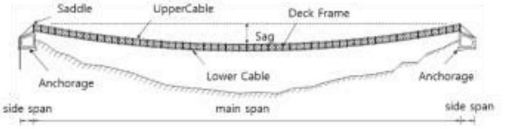

Figure 2. Increase of bridge length by construction year.

2 STRUCTURE OF SWAYING BRIDGES

There are generally two types of suspension swaying bridges; with or without pylons as shown in Figure 3. The swaying bridge with pylons has the similar shape with the conventional suspension bridges for roads or railways. To have swaying behavior, the deck frame or stiffening girder has segmental structure and no or minimum longitudinal stiffness. To design or evaluate swaying pedestrian bridges, several structural characteristics must be checked such as sag, static and dynamic displacement (vertical and lateral), deck accelerations, natural frequencies, damping, anchorage movement or inclination as well as wind and temperatures.

(b) Suspended swaying bridge without pylons

Figure 3. Types of suspended swaying bridges.

3 PROPOSED MONITORING SYSTEM FOR SWAYING BRIDGES

For general long span bridges such as cable-stayed or suspension bridges for roads and railways, comprehensive monitoring system has been installed as shown in Figure 4. It is equipped with many high-end and expensive sensors and data is monitored in real-time, displayed and stored. Also there is maintenance office near the bridge, some engineers and maintenance specialists. However, swaying pedestrian bridge usually have rather simple structural system and relatively small size in terms of bridge length and width. Consequently, construction cost and maintenance budget is low then it is impractical to have a large scale monitoring system. Furthermore, since the structural system is rather simple, there is a little space for installing sensors, electric cables. Therefore, low-cost, light, and wireless system is suitable for swaying pedestrian bridges.

To monitor the behavior of swaying bridges, several sensors should be used. Displacement data such as sag, static and dynamic displacement are measured by GNSS system. Sag is one of the most important characteristics of suspension-type structures and can be calculated as the distance between elevations of saddle and mid span of the cable. Settlement or movement of the anchorage also may be measured by GNSS. Accelerations and inclinations can be monitored by IoT sensor. It also has capability of transmitting data wirelessly by Wifi or LTE and connecting external sensors such as thermometer or wind gauge.

Figure 5 shows 1st version of the proposed monitoring system for swaying bridges. One GNSS includes two antennas (one in the midspan and one in the anchorage) and one receiver. Two IoT systems are installed on midspan and anchorage. Midspan IoT system is connected with wind sensor and thermometer measuring cable temperature. To verify the applicability of the long-term monitoring system, a test system with one GNSS and one IoT sensor was installed on a actual swaying bridge with main span length of 200 m as shown in Figure 6. It is also equipped with battery pack and solar charging panel for long-term monitoring. Data is transmitted via LTE to data server. Analysis of data measured by this monitoring system is explained in the next section.

After the successful application of the 1st version of monitoring system, it is upgraded to 2nd version to have more stable and reliable data collecting and easy installation. In the 1st version, GNSS data and IoT data are collected separately. But in the 2nd version, these are combined as one system so that the system becomes smaller and simpler and has more efficient data collection. The two combined systems are installed in midspan and anchorage, as shown in Figure 7.

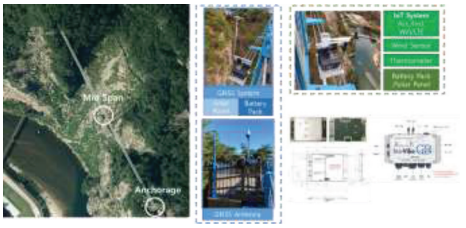

Figure 6. Installation of 1st version of proposed monitoring system on an actual swaying pedestrian bridge.

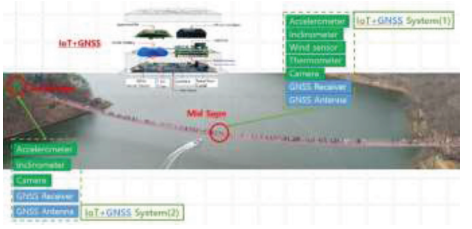

Figure 7. 2nd version of proposed monitoring system for swaying pedestrian bridges.

4 ANALYSIS OF MEASURED DATA

4.1 *Sag and vertical deflection*

The sag of the bridge can be calculated from altitudes of two antennas located at anchorage and midspan. Figure 8 shows the altitudes of two locations; anchorage (alt_val_x) and midspan (alt_val_y) during a day (from Dec. 29 9am to Dec. 30 9am, 2022). Even though the altitude of the anchorage is supposed to be constant, it shows some variations up to around 6.2 m due to the GNSS system error. However, since the same error also occurred on midspan altitude, sag can be accurately calculated from the relative altitudes of two points. Figure 9 shows the calculated sag of the same time period. It shows that sag varies as the temperature is increased or decreased. Figure 10 shows sag or vertical deflection during 1-minute time period. It shows the vertical dynamic deflection and some oscillations due to pedestrian walking.

To show the relationship between the sag and the temperature, 10-minutes' minimum, maximum and average value of the sag during a week (2022.12.29~2023.1.4) are calculated and shown in Figure 11 with the measured cable temperatures. It clearly shows that the sag and the temperature are in strong relationship. The sag in design document is 7.358 m based on the ambient temperature of 20 °C (Cable Bridge, 2017).

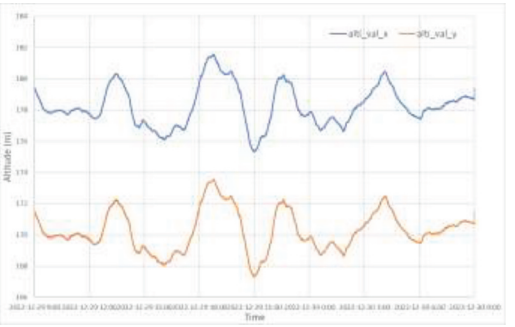

Figure 8. Altitudes of two GNSS antennas; anchorage (alt_val_x) and midspan (alt_val_y).

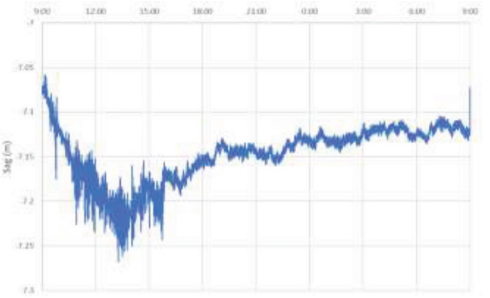

Figure 9. Measured sag during a day (2022.12.09~10).

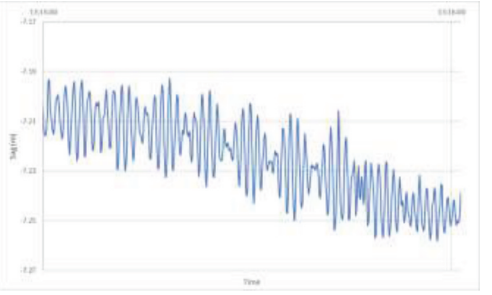

Figure 10. Measured dynamic deflection during 1 minute.

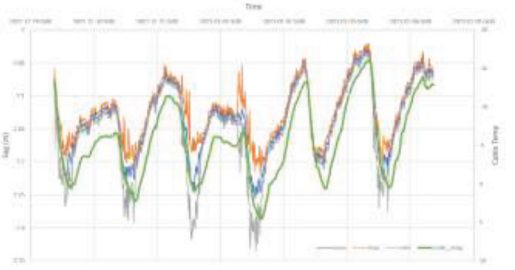

Figure 11. Measured sag and cable temperature during a week (2022.12.29~2023.1.4).

4.2 *Lateral displacement*

The lateral displacement is another characteristic of swaying bridges. To calculate the lateral displacement, the latitude and longitude from GNSS data is used. Figure 12 shows the variations of the latitude and longitude from two GNSS antennas. It shows larger lateral displacements during the opening hours of the bridge and less displacement during the night time without any pedestrian. The actual lateral displacement values should be calculated using geodetic considerations. There are a couple of methods to calculate the distance from latitude and longitude values. One is the relatively simpler method using the Haversine formula and the other is the method based on Vincenty formula. In this study, the Vincenty algorithm with inverse scheme is applied. Figure 13 shows the scatter plot during a day and maximum lateral displacement is about 92 mm and direction of lateral movement is perpendicular to the bridge axis.

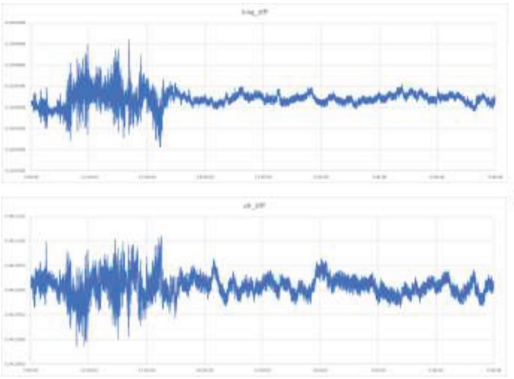

Figure 12. Variations of latitude and longitude of bridge midspan during a day (2022.12.09).

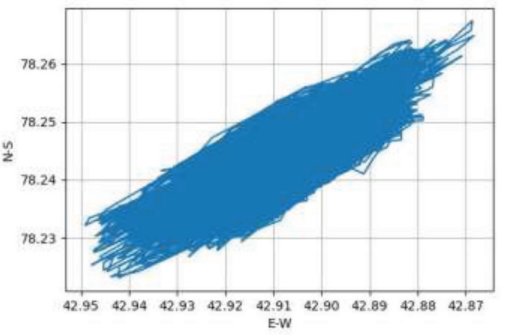

Figure 13. Lateral displacement of midspan GNSS antenna during a day (2022.12.09).

4.3 *Acceleration and natural frequencies*

Figure 14 shows accelerations in three directions during 10 minutes (2023.1.4 13:00:00~13:10:00). X-direction is longitudinal and accelerations are near zero. Y-direction is lateral and Z-direction is vertical. Vertical acceleration is larger than lateral acceleration. Figure 15 shows 10-minutes maximum and rms (root-mean-square) accelerations during a day (2023.1.6). The maximum vertical acceleration is about 0.4 m/s^2 and lateral acceleration is

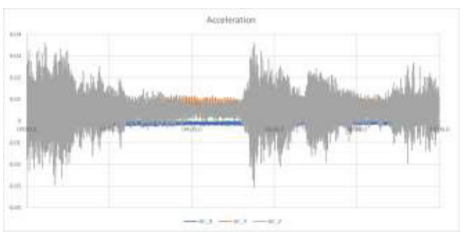

Figure 14. 10-minutes acceleration record in three directions (2023.1.4 13:00:00~13:10:00).

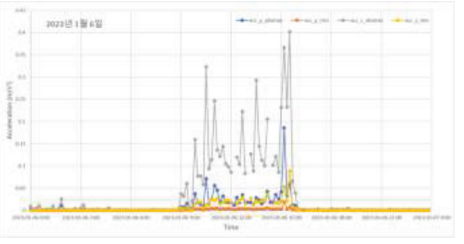

Figure 15. 10-minutes maximum and rms accelerations during a day (2023.1.6).

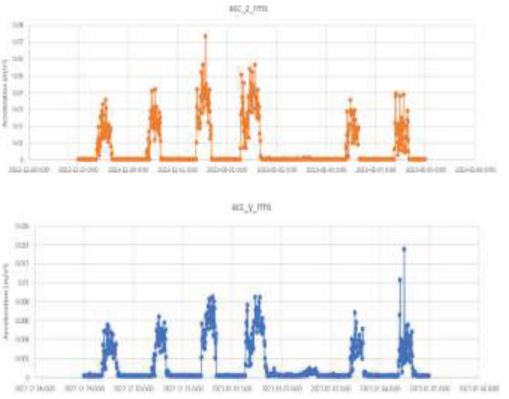
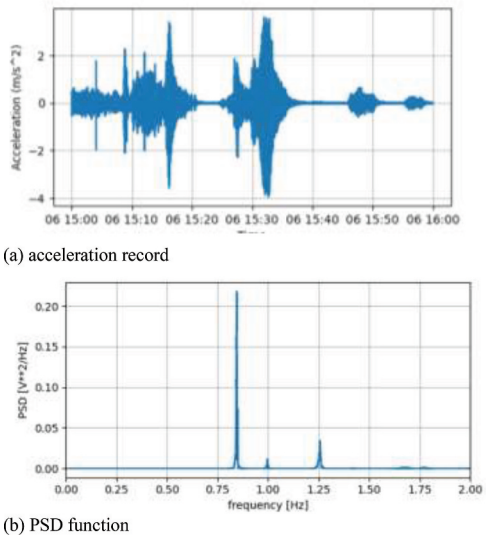
about 0.18 m/s^2, less than half of vertical acceleration. It also shows that the peak acceleration time is almost the same for vertical and lateral direction, which means that the torsional vibration may be dominant. In case of rms accelerations, the same trend is observed and maximum vertical and lateral rms accelerations are about 0.09 m/s^2 and 0.02 m/s^2, respectively.

Figure 16 shows 10-minutes vertical and lateral rms accelerations during a week (2022.12.29~2023.1.4). The tested swaying bridge is open to public usually from 9AM to 5PM during winter season and closed on every Monday. Since Jan. 2nd, 2023 is Monday, rms acceleration is nearly zero. Maximum rms vertical acceleration during this week is about 0.073 m/s^2 and maximum lateral acceleration is about 0.014 m/s^2.

Figure 17 and Figure 18 show 1-hour vertical acceleration records and corresponding PSD functions during opening hours (3pm~4pm) and closing hours (9pm~10pm), respectively. They show that the dominant natural frequencies are different. During the opening hours, dominant frequency is about 0.8 Hz, which is considered as one of the natural frequencies of the bridge. It also show a small peak at about 1 Hz, which is considered as the pedestrian walking frequency. However, during the closing hours, measured accelerations are about 0.01 m/s^2 and PSD function shows small peaks at 0.25 Hz, 0.54 Hz and 0.8 Hz, which are





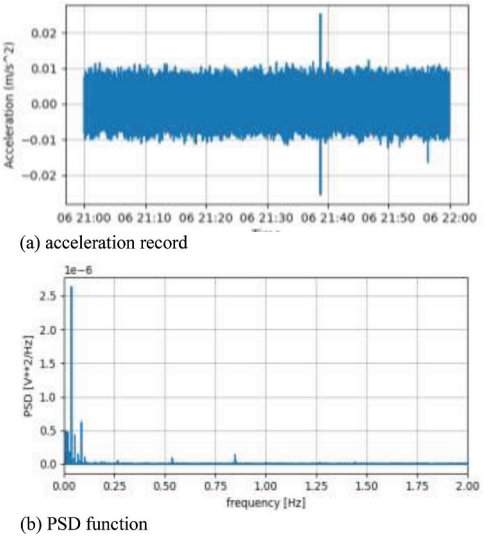


Figure 16. 10-minutes rms accelerations during a week (2022.12.29~2023.1.4).

(a) acceleration record

(b) PSD function

Figure 17. Acceleration records and corresponding PSD functions during opening hours.

(a) acceleration record

Figure 18. Acceleration records and corresponding PSD functions during closing hours (9pm ~ 10pm).

Table 1. Comparison of Natural Frequencies from Analysis and Tests.

		Natural frequencies (Hz)	
Mode No.	Mode shape	Analysis	Tests
1	1st lateral, sym.	0.255	0.239
2	1st vert., asym.	0.364	0.383
3	1st vert., sym.	0.491	0.503
4	1st lateral, asym.	0.541	0.525
5	2nd vert., sym.	0.601	0.682

natural frequencies of the bridge. In 2018, Korean Institute of Bridge and Structural Engineers test this pedestrian bridge and calculated natural frequencies by analysis and walking tests (KIBSE 2018). Results are shown in Table 1. It shows that the first natural frequency is

about 0.25 Hz (lateral symmetric mode). Since the IoT sensor is installed at midspan of the bridge, it can effectively show the first natural frequency in symmetrical vertical mode, which is about 0.5 Hz. More comprehensive analysis is required for analyzing vibration natural frequency and natural mode.

5 CONCLUSIONS

In this study, monitoring system using GNSS and IoT sensor for swaying pedestrian bridge is proposed and its applicability is analyzed using measurement data in real swaying bridge. Following conclusions can be made;

- Sag can be accurately measured by GNSS. It shows strong correlation with the temperature.
- Accelerations in three directions can be effectively monitored using IoT sensor.
- The proposed system can be effectively used as a long-term monitoring system.

More detailed analysis of long-term data is needed and results of this study are expected to be the basis for developing effective and economical monitoring system for swaying bridges as well as design and evaluation guidelines.

A framework for an integrated & digitally-supported bridge management

S. Moghtadernejad, Z. Lounis & J. Zhang
National Research Council Canada, Ottawa, ON, Canada

ABSTRACT: Presently, there is an increasing need to exploit digitalization in the construction industry due to its potential benefits in improving productivity and reducing the costs and negative environmental impacts of construction activities. This puts bridge managers in a perfect position to leverage the recent technological advancements and data availability to move beyond their existing prescriptive approaches that are iterative, lack the consideration of climate change impacts and risks, and suffer from cost overruns. This study proposes a framework for managers to digitalize bridge management activities. The framework generates a modular system using BrIM, a bridge version of BIM and incorporates methodologies for bridge deterioration and failure risk modelling in the context of a changing climate. Moreover, it systematically accounts for changes in future demand and capacity of bridges as well as the associated uncertainties. This framework will enable intelligent maintenance decisions with minimal life cycle costs and impacts while ensuring acceptable service levels.

1 INTRODUCTION

Transportation infrastructure, including highway bridges, play a vital role in driving economic growth and improving societal well-being. Presently, Canada's infrastructure deficit is estimated to range from $50 billion to $570 billion (Infrastructure Canada 2018). For Canada's highway bridges, this translates to 40% of bridges needing maintenance and rehabilitation as they are in fair, poor and very poor conditions, according to the 2019 Canadian Infrastructure Report Card (CIRC-Blue Plan 2019). The situation becomes more serious when considering that by 2030, annual passenger traffic is expected to increase by 50% compared to 2015 estimates, and global freight volumes are projected to rise by 70%. This surge in demand necessitates an increase in investment in the expansion and maintenance of transportation infrastructures, including highway bridges. Moreover, future climate changes can also lead to higher climatic loads on highway bridges and accelerate the rate of deterioration, which may further increase the rehabilitation and replacement needs. In the absence of transformative change towards sustainable transportation, this could mean rising GHG emissions, increasing air and noise pollution, and reducing bridge safety and functionality. There are, therefore, major challenges in the bridge management sector to meet this additional demand, ensuring adequate levels of functionality, reliability, and safety, without putting extra pressure on the natural environment.

Overcoming the challenges of meeting an increasing demand, safety and functionality requirements, and climate adaptation, however, can exacerbate global warming by producing more carbon footprint if bridge management does not consider sustainability. This is because a significant portion of GHG emissions associated with the transportation sector is attributed to the construction, operation, and maintenance of transportation infrastructure assets. Hence, intelligently designed, well-built and well-maintained transportation infrastructure are

DOI: 10.1201/9781003483755-278

key to reducing transportation GHG emissions (Churchill et al., 2021). For the transition towards sustainability in bridge management to become a reality, it is necessary to have robust decision support models and tools that promote sustainable development in the construction, operation and maintenance, as well as in the decommissioning stages in addition to the planning and design stages.

2 CURRENT SITUATION

Despite recent advances in technology, highway bridges are still managed using prescriptive approaches that are unproductive, lack consideration of the high environmental footprint related to construction and rehabilitation activities and suffer from cost overruns and significant users' costs. The reason is that decision-makers often lack comprehensive and user-friendly tools and frameworks that can fully integrate sustainability criteria into the decision-making processes and can make appropriate trade-offs between environmental, economic and social dimensions over long periods (Hu et al., 2019; Lepech, 2006; Wang et al., 2018). Existing approaches and frameworks only partially integrate sustainability criteria in the decision-making process. For example, they concentrate only on one part of the life cycle of bridges and ignore the requirements during other stages, or they evaluate the life cycle impacts concerning one or a few criteria (Li et al., 2019). Many fail to allow objective comparison of solutions since they do not include appropriate guidance for evaluating the environmental impacts and the associated risks on the provided services. Additionally, existing frameworks neglect decision-makers' ability to make new plans in the future if new information presents itself and new needs emerge. Hence, they do not explicitly consider the long-term dynamic and iterative process that is used to plan the development and maintenance of bridges, thereby resulting in unproductive processes and tools that lead to less-than-optimal integration of new solutions.

The literature suggests that digitalization is necessary for bridge life cycle management as it centralizes data, enables real-time monitoring, optimizes resource allocation, enhances collaboration, facilitates performance evaluation, improves safety, and promotes productivity and life cycle sustainability (Dmitriev et al., 2020). However, the construction industry has traditionally been slow to adopt new technologies and practices. This hesitancy is primarily attributed to several factors, including the costs and complexities associated with adopting advanced tools, limited expertise in implementing new technologies, the absence of common guidelines for seamless collaboration among different stakeholders, and occasional resistance to change.

This emphasizes the need for the development of decision-support tools using a shared digital platform for an ecosystem of solutions to minimize the costs and negative environmental impacts of bridges including reduction of GHG emissions throughout their whole life cycles. The platform should include solutions for: (a) novel and sustainable materials, design, and construction techniques; (b) sustainable operation and maintenance, and decommissioning plans considering the long-term uncertainties and the associated risks; and (c) increased circularity in construction materials. To guarantee the adoption of the developed platform in practice without much resistance, it is necessary to ensure that it is easy to use and provides guidelines and training to the users.

Although a holistic platform should tackle the whole life cycle of bridges; however, it's crucial to compartmentalize modules for various stages of the bridge life cycle. This separation is necessary because tasks such as design, operations and maintenance (O&M), and decommissioning are typically managed separately by different professionals with allocated individual budgets. Moreover, existing bridges are already in the O&M phase which does not require the implementation of these innovative solutions in their initial design and construction.

As a first step towards filling the existing gaps, this paper will present a framework for O&M of bridge infrastructure that can be integrated with other modules of the bridge life cycle in a shared digital platform using the concept of Building Information Modelling (BIM) for bridges, BrIM. The framework will integrate necessary tools and models to systematically develop intelligent maintenance and operational plans by assessing the environmental impacts of different decisions, adapting to future demands and climate change and their uncertainties,

and minimizing life cycle costs while ensuring acceptable safety and high service levels. It supports data-driven decision-making and results in more sustainable, productive and efficient bridge management. Successful implementation of the framework in practice can also contribute to the reduction of the negative environmental impacts, specifically, GHG emissions associated with bridge operation and maintenance tasks through:

(a) developing optimized maintenance plans to extend the remaining service life of existing bridges, thus leading to savings in material and energy consumption as well as in reduction of owner's and users' costs;
(b) comparing different sustainable materials and advanced maintenance, repair and rehabilitation technologies with lower environmental footprints and selecting the optimal solutions for each project;
(c) promoting recycling/reuse of construction waste; and
(d) improving the productivity and facilitating collaboration and communication among various stakeholders involved in bridge management, to reduce the time and resources required for management activities and, ultimately, reduce the GHG emissions associated with these activities.

3 DIGITAL PLATFORM FOR BRIDGE MANAGEMENT

3.1 *Bridge maintenance management*

Bridge Management Systems (BMSs) have been extensively developed to streamline the maintenance and management of bridges through digital solutions. Several countries have devised their own BMSs, such as America's Preservation, Optimization, and Network Information System (PONTIS) (Golabi et al., 1993). These systems comprehensively capture and document bridge information throughout their entire life cycle. However, most BMSs are only used for information recording and storage and lack a dynamic integration within the decision-making process. This is mainly due to limited expertise in using these systems and the absence of common guidelines for seamless collaboration among decision-makers and stakeholders. This limitation results in inefficiencies in bridge maintenance workflows.

Researchers have explored numerous approaches for overcoming this limitation. There's a particular focus on incorporating BIM into bridge management, increasingly known as BrIM, as it provides a digital representation of detailed information regarding each bridge component. BrIM can be integrated with a spectrum of modern technologies, including big data analytics, augmented reality, the Internet of Things (IoT), wireless monitoring, and cloud-based real-time collaboration. This empowers bridge managers to devise efficient maintenance strategies, forecast potential restoration or replacement needs for bridge assets, and allocate resources efficiently. Consequently, this leads to minimized downtime, prolonged asset service life, decreased operational costs and improved communications and productivity. Figure 1 illustrates the potential benefits of managing bridges using BrIM.

To integrate BrIM technology with BMS, researchers have focused on establishing structural analysis models and evaluation systems. For instance, Lee et al. (2020) created BrIM models encompassing bridge components and their structural parameters information. Shim et al. (2019) introduced a novel generation of BMSs employing the concept of a digital twin BrIM model, thereby enhancing the decision-making process. Xu et al. (2019) constructed a comprehensive evaluation framework for bridge structural conditions, drawing from visual detection data. Orcesi et al. (2011) incorporated a data evaluation BrIM model pertaining to structural health monitoring into the cost analysis of bridge construction, optimizing bridge maintenance methodologies. Li et al. (2022) developed a long-span bridge health condition monitoring system that integrates bridge sensor data with an environmental BrIM model.

However, the main focus of the previous studies has been the integration of BrIM into bridge management and they lack considerations related to life cycle sustainability management or changes in future climate conditions and demand patterns.

3.2 *Data requirements of an effective digital platform for bridge management*

BrIM relies on creating digital 3D models and continuous communication and improvement of these models with information from the users. One can perceive this as a network of integrated data exchange where different collaborators supply a common environment with relevant data that will be required for specific cases. Hence, it is important to note that the creation of geometric models will not always be mandatory since the impact and value of pure information models are also significant. A graphical 3D model can greatly enhance user experience and the comprehensibility of outputs. However, the absence of such models, particularly for existing bridges, would not diminish the significant improvement in the quality of decisions and process productivity through the digitalization of the O&M decision-making process.

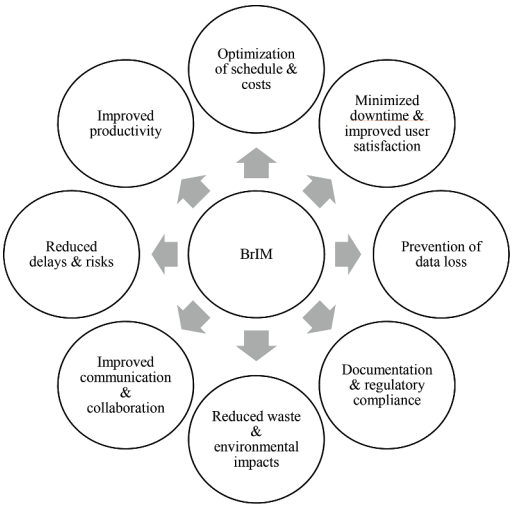

Figure 1. Potential benefits of managing bridges using BrIM.

Regardless of whether a 3D model is available or not, an effective digital platform for bridge management should encompass various features and functionalities to efficiently maintain bridges throughout their life cycle with minimal negative environmental impacts. Here are the key data requirements for such a platform:

- Structural design data or as-built models: This includes comprehensive information on the bridge's initial architectural and engineering designs. These details encompass blueprints, construction plans, material specifications, and structural configurations.
- Historical inspection and maintenance records: This includes detailed past inspection reports, maintenance schedules, and records of repairs or structural enhancements. These records provide a historical context regarding the bridge's maintenance history, identifying recurring issues, areas prone to damage, and the effectiveness of past maintenance strategies.
- Cost and resource data: This includes financial data related to maintenance, repairs, and replacement; which are associated with materials, labour, equipment, and any other resources utilized during these activities. Having such data is necessary for optimizing future budget allocations and assessing the cost-effectiveness of various maintenance strategies.
- Traffic data: This information helps in assessing the load, stress, and deterioration of bridges over time, considering that the deterioration rate and load carrying capacity are significantly influenced by the changes in traffic demand. The data includes information on traffic volume, vehicle classification, and traffic speed.
- Geographical Information Systems (GIS): Integrating geographical data such as maps, location-specific details, terrain information, and environmental factors that might impact

the bridge's condition. GIS data can provide insights into local weather patterns, nearby infrastructure, and geological aspects affecting the bridge's stability.

- Sensor or real-time data: This type of data is not mandatory but can significantly help with improving the bridge maintenance process. It includes data streams from various sensors installed on the bridge for real-time monitoring. These sensors capture critical structural health parameters like stress, strain, vibrations, temperature, and traffic load. Integrating this real-time data enables continuous monitoring of the bridge's condition and early detection of anomalies or potential hazards and the potential need for load posting of structurally deficient bridges.

3.3 *Models for effective bridge management*

Predictive analytics, life cycle sustainability analysis and optimization models are the core tools within effective bridge management. These tools leverage historical data, real-time monitoring, and advanced algorithms to predict potential bridge deterioration, assess risks, and estimate maintenance needs and select the most sustainable solution. Figure 2 provides an overview of the decision-making process and the models that should be embedded within the proposed digital platform.

Within the predictive analysis part, the bridge deterioration prediction models and failure risk estimations are incorporated. A comprehensive framework ought to take into account the impact of future changes in climate conditions and demand on the risks of failure, considering both gradual deterioration (such as accelerated deterioration due to climate change and alterations in traffic demand) and extreme events, such as heightened intensity and frequency of floods, scour, hurricanes, storms, and wildfire. This ensures that infrastructure managers are equipped with insights to proactively determine vulnerabilities and the maintenance needs of the bridge components. Using condition data and simulations during the predictive analysis stage, bridge managers can estimate the deterioration of bridge components over a defined time interval and assess the associated risks. This enables them to decide whether interventions will be necessary within that planning period or not.

If interventions are necessary, a list of potential solutions will be generated. These solutions will then be compared with regard to the Key Performance Indicators (KPIs) that define the life cycle sustainability of bridges. The life cycle sustainability model integrates the three pillars of sustainability, i.e., (a) environmental Life Cycle Assessment (LCA); (b) Life Cycle Costing (LCC); and (c) Social Life Cycle Assessment (S-LCA).

In LCA, the environmental impact of different intervention solutions is assessed across the entire life cycle of bridges (or bridge components). It quantifies various environmental aspects of interventions such as material and energy consumption, greenhouse gas emissions, recycling potential of materials, waste production, etc.

LCC evaluates the total direct and indirect costs of each solution throughout the life cycle of the bridge (or bridge component). It includes initial costs, impact on bridge durability and future intervention needs, users' costs and disposal costs.

S-LCA focuses on assessing the social and socio-economic aspects associated with different intervention solutions. It evaluates the social impacts throughout the life cycle, including factors like safety and user satisfaction. Presently, S-LCA has not reached the same level of maturity as the other two methods. This is due to the lack of clarity in the definition of S-LCA indicators, hence this area needs more research to reach broad application in practice. However, an initial step would be considering the effect of different intervention solutions on KPIs such as number of accidents and fatalities, traffic disruptions, and availability of the transportation network.

After a comparative analysis of various intervention solutions based on the defined KPIs, optimal intervention strategies for each bridge component will be identified. As a result, a compiled list of components requiring intervention during the upcoming planning period will be generated.

The next step would be the determination of optimal intervention programs that define optimal grouping and sequencing of interventions. The objective function is to maximize the net benefit; the benefit is defined as the reductions in failure risks and the net benefit is the benefit minus the overall costs of executing interventions.

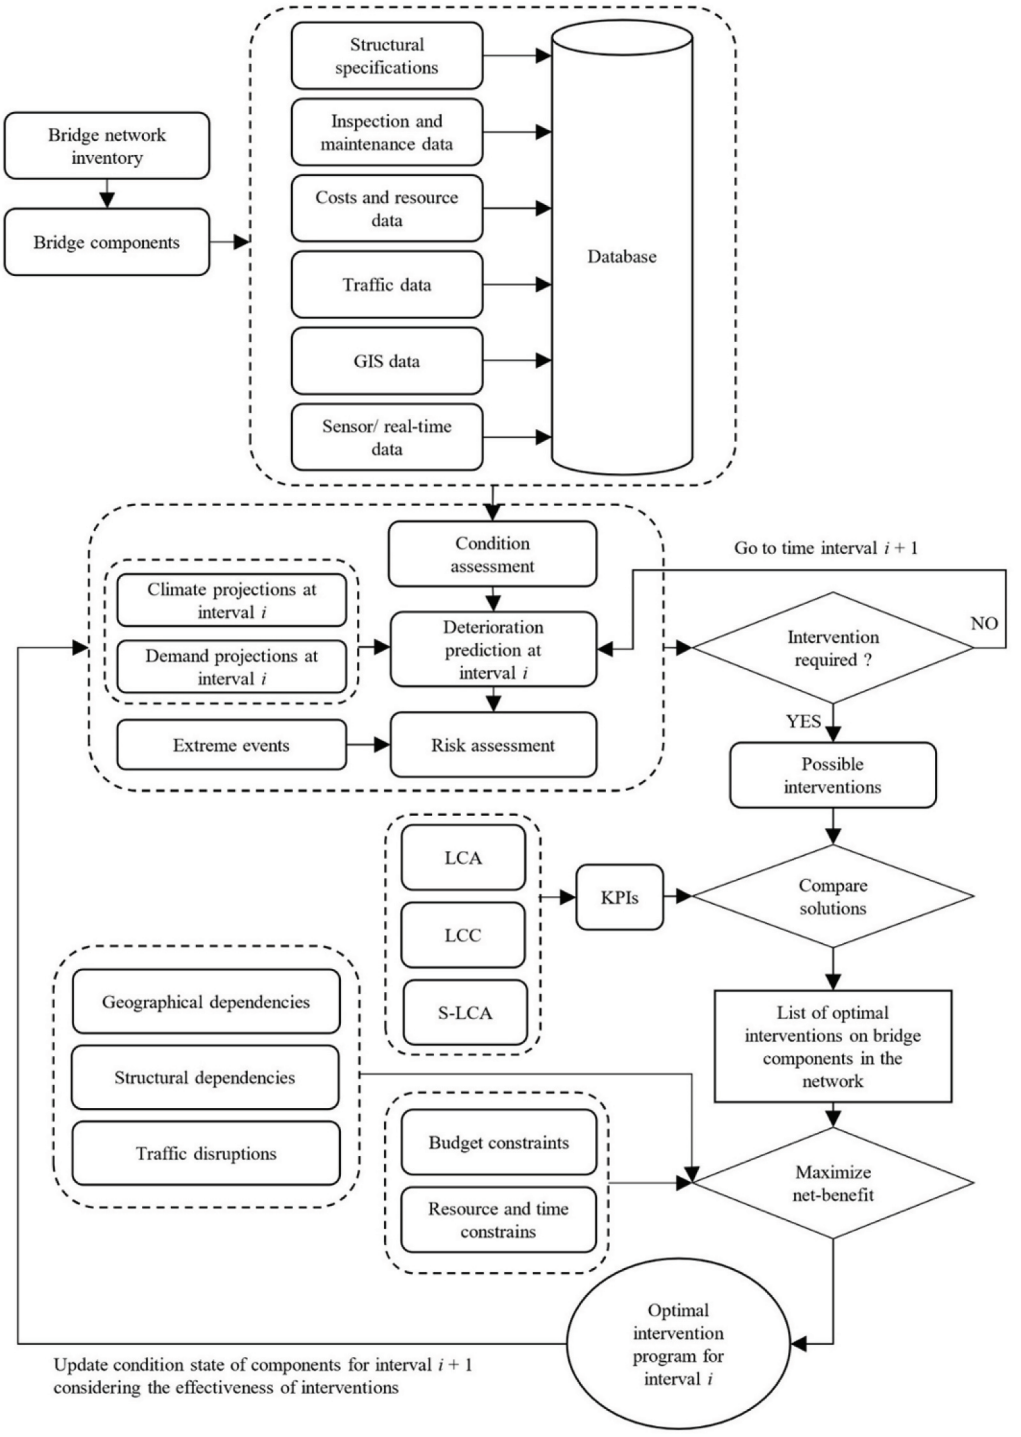

Figure 2. Framework for an integrated and digitally-supported bridge maintenance management.

It must be noted that optimizing the execution of network-level interventions within a defined planning period can be a very complex task. This objective demands a comprehensive approach that aligns various interconnected variables. When devising

intervention programs, it's essential to account for the synergies and interdependencies among structural components, the topological dependencies, and the impact of interventions on traffic flow. For instance, when undertaking interventions on different components of a bridge, consolidating these activities within the same planning period is more prudent than individual interventions across multiple planning periods.

The selection of the optimal execution timing for such interventions relies on the acceptable risk thresholds and evaluating the overall net benefit associated with executing interventions during each planning period.

Topological dependencies highlight the economic advantages gained from consolidating interventions on bridges situated in close proximity or within the same geographic area. By grouping interventions on interconnected or nearby assets, there's an opportunity to maximize economic benefits through efficient logistical operations, shared resources, and minimized disruptions to the surrounding environment. This approach allows for more efficient resource utilization and often results in cost savings, reduced downtime, and optimized workflows, ultimately contributing to enhanced overall project effectiveness. Minimizing traffic disruptions is a principal concern, as any intervention invariably affects transportation routes potentially leading to congestion, delays, and socioeconomic implications.

When developing the intervention programs, various constraints such as budget, time, or resource limitations, add another layer of complexity that cannot be overlooked in real-life practices and must be incorporated into the optimization model.

The output of this optimization would be an intervention program that illustrates the sequence, type and grouping of maintenance tasks in each planning period to maximize net benefit. Upon completion of the interventions, the digital platform will promptly update the condition state of the bridge components within the network. This update will reflect the efficacy of the executed interventions. These revised condition states will then be integrated into the analysis and predictive models for informing decisions during the subsequent planning period.

This platform is compatible with the long and dynamic nature of bridge maintenance management processes. This means that decisions will be initially made based on general and perhaps limited available data, years before their execution. As additional information becomes accessible, the planning process undergoes automatic updates, progressively becoming more comprehensive and refined. In the presence of 3D models or GIS mapping, interactive visualizations and reports should be generated to facilitate understanding of the data and the output intervention program.

4 NECESSARY CONSIDERATIONS

Achieving standardization across different phases is essential to leverage the benefits of digitalizing the bridge maintenance management process. When information is standardized, it can be efficiently preserved and used in a format that facilitates seamless integration and collaboration across various stages of a bridge life cycle, irrespective of the software being utilized. Consequently, the initial focus should be on exploring the requirements for developing information delivery specifications (IDS), BIM collaboration format (BCF), and a common data dictionary for bridge elements to be utilized by the O&M module of the integrated digital platform.

Data quality and accuracy are very crucial in digital asset management. If data integrity is endangered during storage or if updates are not consistently applied, the reliability of the digital bridge management systems can be undermined. This is because the accuracy of predictive maintenance models heavily relies on high-quality data. Moreover, particular attention should be directed towards addressing the uncertainty of the results, as forecast models (e.g., climatic data and loads and traffic demand projections) yield predictions that do not necessarily align with the real situation in the future.

Adherence to industry standards, codes, and regulations related to bridge management and safety is crucial. The platform should support compliance requirements and assist in regulatory reporting. Finally, robust security measures must be implemented to safeguard sensitive bridge data, ensure compliance with data privacy regulations and prevent cyber threats.

5 CONCLUSIONS

This paper proposed a framework for bridge managers to plan bridge maintenance activities using a shared digital platform. The framework generates a modular, interconnected system and incorporates methodologies for deterioration and failure risk modelling in a changing climate. This framework will develop intervention programs with minimal life cycle costs and impacts while ensuring acceptable safety and service levels. The platform is adaptable to changing future needs, increasing demands due to growth, climate change, extreme weather events, uncertainties, stakeholder demands, and new information. Using this platform, bridge managers can adjust their plans based on new information without going through unnecessary iterations. It also enables the tracking of the environmental and technical performance of various solutions for better future estimations.

While digitalizing the bridge management process, particularly in the context of maintenance management, presents several advantages, some limitations must be overcome for it to be efficiently implemented into existing workflows. One of the most prominent challenges is data integration and compatibility, as the existing systems often differ in formats and structures, necessitating intricate efforts to harmonize and synchronize diverse data sources. When implemented in practice, it is necessary to ensure that the platform is scalable to accommodate large bridge networks and capable of integrating with evolving technologies (e.g., automated structural health monitoring) and future upgrades.

PONTI: An open WebGL-based tool in support to defect analysis and 3D visualisation of bridges

R. Fascia, F. Barbieri, F. Gaspari, F. Ioli & L. Pinto
Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The importance of monitoring bridges has extensively emerged in the last decade, considering recent bridge collapses in Italy. With over half of the country's bridges in service for more than 50 years, ensuring their serviceability is crucial. This requires inspections that document the condition of infrastructures. In this context, the development of customised, reproducible, and user-friendly web platforms plays a crucial role for exploring georeferenced 3D models of bridges acquired through laser scanning and drone photogrammetry. This paper focused on implementing Potree WebGL, a JavaScript library for the exploration of point cloud, native and custom functionalities to support bridge geometry reconstruction and defect documentation, as required by the Guidelines for Risk Classification and Management established by Italian Ministry of Infrastructure and Transport. Catering the needs of administrators, a standardised web platform called PONTI (Potree platfOrm for iNfrasTructure Inspection) has been developed to aid decision-making in road infrastructure maintenance and monitoring.

1 INTRODUCTION

In light of the bridge structural health deterioration observed in Italy in recent years (Malerba 2022), there has been a surge in studies addressing the most effective ways for managing information and data in support of infrastructure management and decision making on routine inspections and maintenance operations. Literature has widely documented the adoption of Geographic Information Systems (GIS) (Gaspari et al. 2023), Computer-Aided Design (CAD) software (Tanaka et al. 2019) and Building Information Modelling approaches (Tanaka et al. 2016, Ciccone et al. 2022) for the management of road networks, civil construction, and infrastructures (Einizinab et al. 2023). However, most of these solutions consists of proprietary software that requires licences or case-study-driven applications with limited possibility of customisation according to different scenarios (Zhang & Hu 2018). Moreover, the implementation of web-based platforms fostering also remote collaborations within experts is often limited by the difficulties in integrating different format of data (Caldera et al. 2021). In the last decade, the rapid evolution of functionalities supported by Web Graphic Libraries (WebGL) however suggests possible lightweight and low-cost solutions for sharing and visualising large amounts of 2D and 3D data on web browsers, allowing users to compare and analyse different file formats in a georeferenced environment (La Guardia & Koeva 2023). For example, Potree is an open-source WebGL framework (Schuetz 2016) designed to explore large point clouds together with meshes, vector data, 3D annotations and oriented images. Such a solutions allows to easily disseminate online products generated by techniques like laser scanning and photogrammetry – widely used for bridge and building surveys - that previously were difficult to share with users because they required the transfer of large amounts of data and the installation of dedicated applications (Gaspari et al. 2022).

This work presents the development and the functionalities of PONTI (Potree platfOrm for iNfrasTructure Inspection), an easy-to-implement and replicate template based on Potree JS for the definition of a web platform designed to facilitate the sharing of bridge inspection 3D

DOI: 10.1201/9781003483755-279

georeferenced products such as point clouds and oriented UAV images. The effectiveness of its adoption is tested for a case study in the framework of the Italian bridge inspection guidelines (MIT 2020, MIT 2022) by using the products in the platform to identify and evaluate extension and intensity of defects through a posteriori visual inspection of collected images.

2 METHODOLOGY

The methodology proposes the development of a 3D web platform that aligns with the requirements of the Italian Guidelines for bridge management. The workflow consists of three main parts: data preparation and processing, 3D platform design and implementation and defect detection and evaluation with the support of the platform (Figure 1).

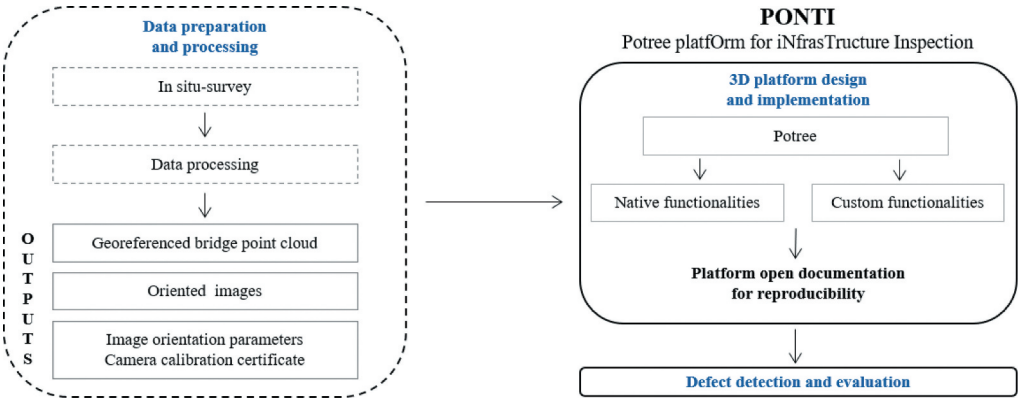

Figure 1. Workflow of the proposed methodology.

2.1 *Data preparation and processing*

Before defining the design of the platform, it is important to understand what type and format of products are required for it to function properly. The first requirement for the development of the web structure is the generation of a point cloud of the bridge, resulting for example from the processing of the data collected during the structure survey. This process involves the use of geomatics in-situ techniques such as traditional topography, photogrammetry and terrestrial laser scanning, followed by data processing in the laboratory to produce geo-referenced 3D products.

Once the point cloud of the bridge is obtained, it has to be classified according to the structural macro-components such as spans, piles, abutments and road surface. It is suggested to perform this step before the implementation of the platform, as it allows an immediate visualisation of the main parts of the structure. The classification of clouds can be done manually, for example using open-source software such as CloudCompare, or through advanced semantic segmentation methods (Xia et al. 2022). Another requirement for the platform to be efficient in sharing bridge point clouds is the presence of a terrestrial or UAV-photogrammetric survey and the insertion of oriented images into the visualisation of the 3D model. Such results are obtained through the reconstruction of the bridge 3D model, the orientation of the images and the georeferencing of the entire procedure in a global reference system. Once the photogrammetric processing is completed, the next step requires image files together with their exterior orientation parameters (i.e., the coordinates of the camera projection centres and the camera orientation angles in the world reference system at the time of each shot) and camera calibration certificate (i.e., the collection of the interior parameters of the cameras, including focal length, principal point coordinates and lens distortion parameters). These two pieces of information were derived from the photogrammetric processing aimed at reconstructing the 3D model.

2.2 *3D platform design and implementation*

The second step of the methodology initially consists in the design of the platform according to Potree WebGL native functionalities and custom needs for an effective user-friendly visual inspection of the digital 3D model of the structure. Potree offers flexible rendering of point clouds, the ability to perform measurements directly on the 3D model, and the ability to integrate oriented photos and georeferenced annotations without the need to install additional software packages. Its interface makes it easy to explore the 3D characteristics of the object, providing a better understanding of the model from both geometric and structural point of view. In addition, the ability to integrate and visualise oriented photographs of the object in a 3D context contributes to a higher level of detail and understanding, enriching the visual experience. Moreover, executing measurements on 2D objects like images and then automatically projecting them on the bridge point cloud avoids problem with the need of background in geomatics for managing a 3D object – the point cloud – that could require major efforts for non-familiar users.

To improve the visual inspection and facilitate the identification of defects in structures such as bridges, new functionalities have been implemented in the new PONTI platform. These include the visualisation of the point cloud with classified graphics, the management of chunk of images corresponding to the macro-components of the bridge to be inspected according to the Italian Guidelines, and the addition of geolocated annotations with media attachments as links.

In Potree's default configuration, the shared point cloud is generally displayed in RGB mode. The custom platform now offers a simplified classified view with its custom legend, which allows the 3D model of the bridge to be displayed in different colours according to the classification previously performed and also to be changed in visibility by hiding specific portions of it (Figure 2).

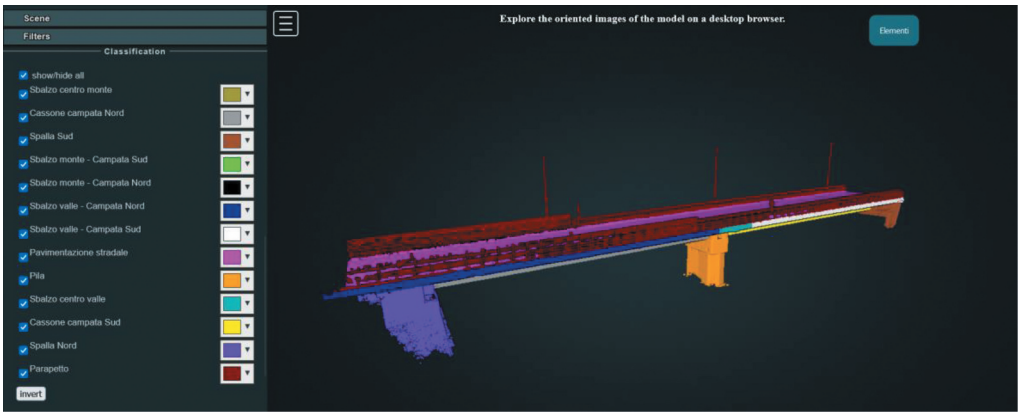

Figure 2. Classified view of the case study bridge in the PONTI template. The colours represent the structural macro-elements of the bridge: olive green - central cantilever; grey - north span caisson; brown - south abutment; green - south span mount cantilever; black - north span mount cantilever; blue - north span valley cantilever; white - south span valley cantilever; lilac - road surface; orange - pier; light blue - valley centre cantilever; yellow - south span caisson; violet - north abutment; red – parapet. It is possible to change the colours of each element according to user requirements.

The images can then be grouped into different folders/chunks according to the structural part of the bridge, together with the calibration certificates and images orientation parameters. In this way, the images are correctly geolocated and oriented in the 3D model viewer in relation to the structure according to the camera coordinates and the angle of view at the time of each shot. Indeed, in addition to reviewing the photos captured during the inspection and identify defects using the zoom and image measurement functions, it is also possible to get direct feedback on the location of the defect itself, as the photos are already organised

according to the structural elements of the bridge and spatially oriented on it in the 3D environment (Figure 3). The inclusion of a dedicated dropdown menu in the template provides users with the option to easily switch the view to a specific structural element of interest.

Figure 3. Oriented and geolocated image on the point cloud in the PONTI template. The image was taken during the drone survey and orientated using the calibration certificate and image orientation coordinates. Measurements can be made on the photographs. The photos are also divided into chunks/folders according to the structural element.

Geolocated annotations provide additional support in visualising and documenting defects found during visual inspection of bridges. Within the PONTI platform, each annotation is identified by a title and coordinates in the global reference system that defines the 3D scene. Each annotation is uniquely named, providing a direct link to the structural reference element (Figure 4).

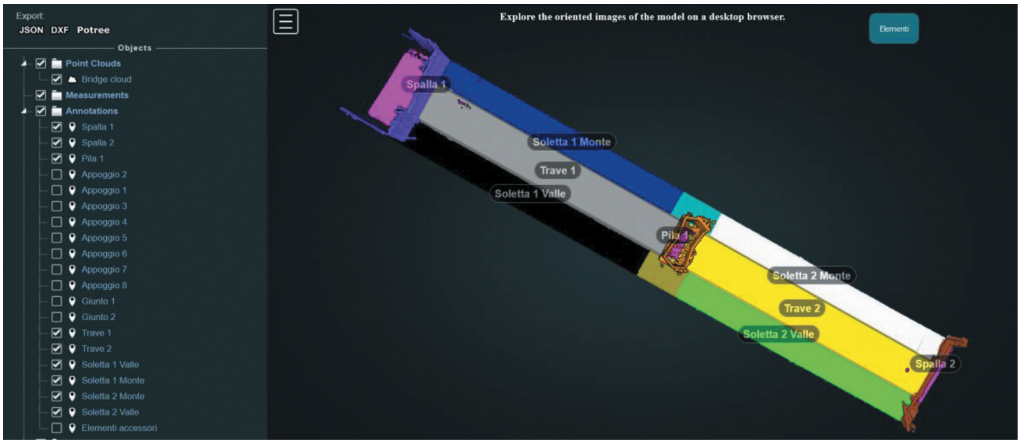

Figure 4. Visualisation of the classified point cloud in PONTI template with unique annotations associated with the bridge's structural macro-elements. It is possible to activate/deactivate the display of the tag. The image shows the following active: abutment 1, abutment 2, slab 1 mount, slab 2 mount, beam 1, beam 2, slab 1 valley, slab 2 valley.

2.2.1 *Platform open documentation for reproducibility*

Aiming at giving the possibility to researchers in the field to customise it, the template and the instructions for its adoption are freely accessible through a dedicated repository on GitHub, available at: https://github.com/labmgf-polimi/ponti.

The PONTI template indeed intends to guide users through the entire process of sharing bridge point clouds, providing instructions on how to get started, define the user interface (GUI), and integrate point clouds, oriented images, and annotations. The guide also explains how to customise the HTML and CSS to shape the appearance of the main page and sidebar, as well as specific details on how to integrate converted point clouds and oriented image files. It also provides detailed instructions on how to integrate oriented cameras, including details on how to load oriented images and camera parameters, and how to customise the dedicated script to correctly integrate them into the visualisation. The guide then explains how to add customised annotations to the point cloud, including steps for obtaining the coordinates of the desired points using Potree's measurement tool, editing the annotation file to correctly position and describe the annotations, and setting the camera view associated with each annotation.

2.3 *Defect detection and evaluation with the support of the platform*

In the final step of the workflow, the usability and effectiveness of the PONTI template is tested in support to the analysis of defects on structures. Currently, Level 1 of the Italian Guidelines requires a direct visual inspection and monitoring of the state of conservation of the structure through the compilation of reports documenting its condition. In order to facilitate the compilation of such document, defect sheets have also been created. These are reference documents that specify the description of the deterioration characteristics that should be identified during the inspection. The sheets are divided into five main groups according to element bridges material: steel, masonry, timber, reinforced/pre-stressed concrete and pre-stressed concrete. There are also additional sheets for abutments, footings, joints and accessories. Within each macro-group, there are several sheets that illustrate the various defects specific to the material considered with descriptions and images. In order to support objective observations on the structural defects, inspectors are also required to associate images to each defect detected and reported in each structural element sheet.

In this framework, PONTI is used to evaluate the effectiveness of its image data management in an a-posteriori visual inspection of survey pictures, with a particular focus on its ability to locate images on a 3D space, making measurement on them and connect them directly to the 3D reconstructed point cloud. Moreover, thanks to the classification of the bridge according to its macro-components and to the distinct annotations, it is easy to recognise the reference element on which the defect is manifested (Figure 5).

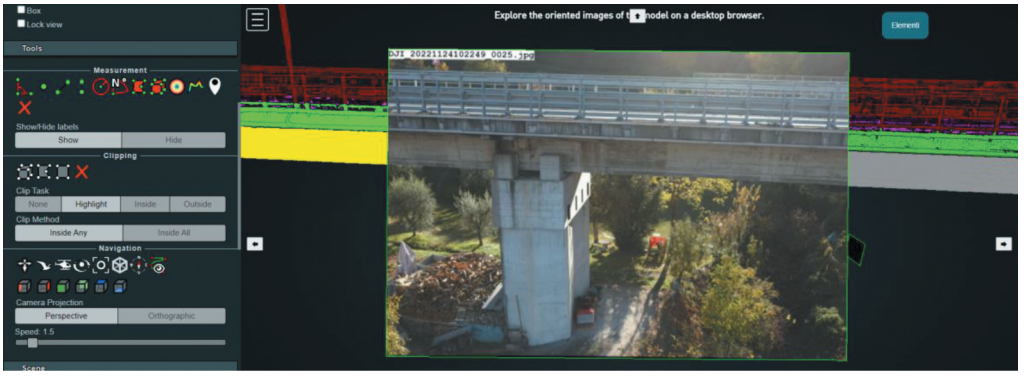

Figure 5. Oriented and geolocated image on the 3D model and displayed in the PONTI template. The image shows the presence of moisture spots on the structure. The image shows its nomenclature in the top left-hand corner.

3 CASE STUDY DATA COLLECTION

A bridge located in the municipality of Sulzano, in the province of Brescia, northern Italy, is analysed as a case study for the application of the described methodology. Its reinforced concrete structure consists of 2 spans (Figure 6).

Figure 6. Aerial view of the reinforced concrete bridge in Sulzano (Brescia) used as case study.

The process began with a preliminary visit to the sites to be surveyed in order to identify any obstacles or visual obstruction, such as vegetation or man-made objects. This was followed by the field survey phase. First, a topographic network was created for each structure in a local reference system using a total station (Leica Nova MS60) (Fagandini et al. 2017) to measure a series of targets placed on the structure and surrounding ground and used as Ground Control Points (GCPs), i.e., points with known coordinates both in the world reference system used to georeference and constrain the 3D model. Four of these targets were placed on the ground and measured with a GNSS antenna (Leica Viva GS14) for global georeferencing by roto-translation of the survey data processing products. The other targets were deploys directly on the structure and used as GCPs for the photogrammetric processing of nadiral (i.e., with the camera looking downwards) and oblique photographs taken during the UAV survey (DJI Matrice 300, RTK - DJI P1, DJI Mavic 2 Pro, DJI Phantom 4 RTK). Other images were taken manually with a handheld camera (Nikon D800). This integrated approach of aerial and ground photogrammetry was essential in areas close to vegetation, which could have compromised the efficiency of an UAV-photogrammetric approach. In parallel, point clouds were acquired by terrestrial laser scanning (Faro Focus M70). This combination of photogrammetry and laser scanning resulted in two point clouds, each derived from a different technique. The accuracy of the point clouds, assessed by error and residual analysis on targets not used as GCPs but used as check points (CPs, i.e., targets not used to georeferenced the 3D model, but to validate the model and ensure its accuracy), was compared to the required centimetre standards. To ensure accuracy, the results of the two techniques were checked during the post-processing phase on overlapping areas to identify any discrepancies. Once the accuracy requirements were met, the two separate point clouds were integrated and subsampled, incr. This process overcame the limitations of each technique, resulting in complete coverage of the structure. Following the data processing phase and before implementing the model in the PONTI template, the resulting point cloud was classified according to the structural macro-components of the bridge, such as piles, abutments, and spans. The images were processed and converted to .jpeg format to ensure lighter visualisation, with their orientation and associated camera parameters saved in separate text files. The PotreeConverter (Schuetz 2016) tool was used to convert the dense point cloud into a .json format compatible with Potree. The input data for the main functionalities and the basic structure of the 3D data exploration platform were created using a standard HTML structure, including the viewer and a sidebar with native tools for measurement and section extraction.

4 RESULTS AND DISCUSSION

The 3D point cloud represents the geometry of the bridge and provides a basis for understanding its structure, while the images and annotations allow immediate identification and anchor points for the visual analysis of the structural elements, together with their condition assessment and damage quantification. The classification of the point cloud according to structural macro-components facilitates the visual identification of the main parts of the structure. In fact, the introduction of this customisation makes it easier to recognise the different parts of the bridge like beams, abutments, piles and ancillary elements and contributes to a more effective overall understanding of the bridge. This rendering together with the dropdown menu for selecting the structural element to inspect also helps users to easily change the view in the scene according to the desired target element of the inspection as a simple shortcut that activate the corresponding oriented images chunk. By accessing each single image captured with UAV and compact cameras and loaded in the scene, users can conduct with simplicity an a posteriori visual inspection on the different reinforced concrete elements, comparing what they see in the picture with the references for defect quantification and evaluation provided by the Italian Guidelines. This approach revealed to be particularly effective in identifying qualitatively most of the standard defects such as passive and active moisture stains, detached concrete cover, cracks, exposure and/or corrosion of structural reinforcements as well as significant geometrical deformations.

However, some Guidelines-coded defects were difficult to identify as well as quantify due to visual obstructions, for example supports and portions of slabs. Such limitation is mainly connected anyway to the fact that most of the oriented images was captured by UAVs, not allowed to fly and stand less than a certain safe distance from the structure. A consequent problem hence regards the case of presence of thinner cracks that can be visually identified but whose severity and level on intensity can not be evaluated because their width is smaller than the geometrical resolution of the point cloud (around 1 cm). Regardless these limitations due to the surveying mode, the method was demonstrated valuable for evaluating the presence and the rough extension of the most severe defects, identifying their georeferenced position on a precise structural element, providing useful information for planning a subsequent more detailed in-situ investigation or for considering surveying technologies alternative to pure RGB cameras.

In addition, the inclusion of unique annotations has proved to be useful. This allowed the different structural parts of the bridge to be clearly identified with unique numbered labels such as ‘Beam 1’, ‘Beam 2’ and so on. Furthermore, the ability to integrate customised HTML content into the annotations facilitates the inclusion of multimedia attachments. For instance, for the case study, based on commissioners’ requests, in each structural element annotation it was included a direct link to a OneDrive space containing documents, files and additional images referring to the connected element. Indeed, PONTI’s open-source nature allows interested developers to implement the platform with new customisations even in contexts outside the Italian guidelines.

The custom features, together with the defect sheets, have proven to be effective tools for the rapid identification and association of bridge defects.

However, it is necessary to consider some aspects related to this method. The case study focuses on a reinforced concrete bridge, so the defect considerations are formulated using the Guidelines reference defect sheets specific to this material. As a result, the platform and defect detection considerations are different depending on the type of bridge examined, such as in the case of timber or masonry structures, which have different defect grades and defect maps to those of reinforced concrete structures. These considerations serve as a framework for improving and developing the PONTI template, testing also the integration of georeferenced data sourced from other type of instrumentations and surveying techniques.

5 CONCLUSION

The PONTI template presented in this work is an open-source resource for sharing and analysing bridge point clouds, providing a flexible and free approach to infrastructure

management, without the need for a licence. The practical application of the methodology on a bridge in Sulzano has demonstrated the efficiency of the platform in support of the a-posteriori visual inspection of a structure, making possible to identify the main defects standardised in the Italian Guidelines. The combination of georeferenced point clouds, images and annotations has indeed created an interactive environment that allows a comprehensive assessment of the geometrical state of the structure. It also has proven to be a flexible and accessible tool for different types of users, including administrators and non-expert users. The new implemented features, its open-source nature, the instructions for use and customisation and the intuitive interface make the platform user-friendly.

However, it is important to recognise some limitations, such as the possible presence of shaded areas in the 3D model and the challenge of visualising defects that are too small in the image, compromising the possibility of correctly quantifying. These aspects provide opportunities for further improvements by considering the integration in PONTI of compatible georeferenced data coming from other sources like for example thermal or multispectral cameras.

Future developments of the project aim to intensify the interaction between the platform and its users. Allowing users to download and upload annotations, adding comments and observations, could promote more collaborative work and a more comprehensive and up-to-date assessment of the bridge's conditions. A further step could be the introduction of coloured annotations that change according to the severity of the defect. For example, a colour could be associated with the weight G of the degradation in the defect sheets. This approach would allow an intuitive visualisation of defects. This functionality could also be associated to a database system that saves annotations made during an online session by the user and memorise them in the system when the viewing page of the platform is updated. This could be useful both in terms of a more collaborative approach between several users, and in terms of comparing the defects detected to provide a more accurate material pathology survey. In addition, the implementation of new functionalities is under study, such as the ability to compare the current state of the bridge with subsequent surveys over time, including different formats such as BIM representations, meshes, etc.

Advancing bridge asset management in Indonesia: Integrating scan-to-BIM for digital twin approach

H.T. Saksena & R.P.P. Sastrawiria
Directorate General of Highways, Ministry Public Works and Housing of Indonesia

ABSTRACT: Bridge asset management is pivotal for ensuring safety within transportation networks. Indonesia, amid rapid infrastructure growth driven by post-pandemic economic surges in 2023, faces distinct challenges in advancing asset management. This study focuses extensively on Ministry of Public Works and Public Housing of Indonesia policies, specifically integrating Building Information Modeling (BIM) to enhance bridge asset management. It meticulously compares these policies with global standards, dissecting disparities between Indonesia's practices and international benchmarks. The research delves deeply into the Scan-to-BIM approach, spotlighting its role in creating Digital Twins for Long-Span Bridge projects across Indonesia, currently under extensive construction. It assesses BIM implementation evidence, gauging data quality, quantity, and utilization in comparison to global practices. This evaluation aims to align Indonesia's practices with global norms and evaluate their efficacy. The study explores the gap between BIM use in different countries and Indonesia, identifying contributing factors and suggesting strategies to bridge this divergence. Additionally, it addresses prevalent challenges in BIM policies, human resources, and tool implementation, proposing solutions drawn from existing literature. Discussions encompass diverse BIM workflows globally, outlining strengths and weaknesses while contextualizing their impact within Indonesia's context. Furthermore, it emphasizes the need for standardized deviation between point cloud and 3D models for precision in constructing Digital Twins through Scan-to-BIM methods in bridge projects.

Keywords: BIM(Building Information Modeling), Digital asset management, Digital Twin, Laser Scanning, Point Cloud

1 INTRODUCTION

1.1 *Background*

Bridge infrastructure serves a crucial role in transportation networks, facilitating safe and efficient movement for vehicles and pedestrians while connecting regions and communities. Their significance goes beyond structure, supporting economic activities and societal well-being by ensuring uninterrupted connectivity for goods, services, and people. Effective bridge asset management involves collecting and analyzing data on bridge condition, risk, and performance to inform decision-making and prioritize actions (Bennetts et al., 2020). (Wei et al., 2021) suggest using emerging technologies like BIM, GIS, and artificial intelligence to enhance information management, visualization, and collaboration in bridge asset management. This proactive management aims to preserve and improve bridge condition and performance.

Building Information Modeling (BIM) involves creating digital data that visually represents infrastructure objects across their lifecycle stages. According to various sources, including (Ali et al., 2022) (Musarat et al., 2023), and (Saraireh & Haron, 2020), BIM enhances

DOI: 10.1201/9781003483755-280

collaboration among stakeholders, improves project efficiency, quality, and integrates new technologies in construction. BIM is crucial in providing accurate data and meeting project expectations.

Scan-to-BIM, utilizing Laser Scanning, transforms real-world assets into precise 3D models, forming the basis for Digital Twin creation. This process, outlined by (Kang, 2023), supports decision-making, project optimization, and provides accurate information on cost, schedule, and sustainability. These Digital Twins, created through Scan-to-BIM, offer comprehensive visualization for maintenance planning, decision-making, and simulations without physical interaction with the asset.

Scan-to-BIM's integration with BIM and other cutting-edge technologies, as highlighted by (Olanrewaju et al., 2021), significantly enhances project delivery efficiency and quality. By providing accurate Digital Twins, Scan-to-BIM revolutionizes bridge asset management, aiding in decision-making for maintenance, performance optimization, and lifecycle management, ultimately ensuring the safety, economic continuity, and connectivity of transportation networks.

1.2 *Objectives*

Global government efforts significantly influence BIM adoption, with governments wielding substantial authority to drive operational changes within the construction (Borrmann et al., 2018). In Indonesia, the government's evolving policies for BIM implementation in bridge asset management face specific challenges detailed in this study, drawing from prior research to harmonize existing issues and optimize BIM utilization among stakeholders.

Implementation hurdles, including cost barriers, limited awareness and skills, legal complexities, and resistance to change, hinder BIM adoption (Olanrewaju et al., 2021). Indonesia encounters similar obstacles, where inadequate stakeholder understanding limits the optimal use of BIM-generated processes and outputs.

The global landscape of BIM integration policies varies widely, ranging from the UK's mandatory BIM Level 2 for government projects to diverse approaches in countries like the US, European nations (Norway, Finland, Denmark), Singapore, and South Korea (Charef et al., 2019). Indonesia, notably through the Ministry of Public Works, showcases a significant initiative in implementing BIM, notably demonstrated in transformative projects like the new capital city's development, leveraging BIM methodologies for sustainability and smart city planning.

Furthermore, the application of Scan-to-BIM in bridge asset management illustrates the innovative use of technology to elevate infrastructure maintenance and planning, generating highly accurate Digital Twins for bridges. This research delves into three key objectives: highlighting Indonesia's BIM implementation efforts, aligning these with global standards, and introducing Scan-to-BIM's potential in long-span bridge projects. Together, these objectives illuminate Indonesia's strides in embracing BIM technology, aligning policies with international standards, and leveraging innovative methodologies for effective infrastructure asset management.

2 POLICY ANALYSIS AND COMPARATIVE STUDY

2.1 *Indonesia's policies on BIM*

In Indonesia, the implementation of BIM is governed by various regulations, encompassing Government Regulation 2021, which pertains to the Implementing Regulations of Law 2002 focusing on Buildings. Additionally, PUPR Ministerial Instruction Number 2022 outlines strategies to prevent deviations in the PUPR Ministry's Goods/Services Procurement Process from 2022 to 2024. Further regulations such as PUPR Ministerial Regulation 2021 on Construction Implementation Guidelines and PUPR Ministerial Regulation 2018 regarding State Building Construction contribute to the framework governing BIM usage.

Specifically for the road and bridge sector, Road and Bridge Sector Guidelines 2023 provide comprehensive guidelines for the application of BIM within the realm of road and bridge construction. These guidelines intricately regulate the implementation of BIM, highlighting its role in various aspects, notably in bridge asset management across Indonesia. Furthermore, circular letters from relevant authorities, like Circular Letter 2023 from the Director General of Water Resources and Circular Letter 2022 from the Director General of Housing, offer detailed technical instructions and guidelines for leveraging BIM in infrastructure construction and housing projects respectively.

Examining Indonesia's scan-to-BIM guidelines, notable deviations from global standards arise. While Indonesia uses diverse laser scanning technologies for surveying, discrepancies lie in standardized tool specifications and data processing protocols. Unlike international practices ensuring uniformity and precision, Indonesia's guidelines lack explicit specifications for tools and data integration into 3D models, impacting consistency and accuracy. Despite Indonesia's detailed information collection through laser scanning, gaps in standardized tool specifications and data processing protocols persist. Aligning these aspects with global standards could significantly enhance the accuracy and effectiveness of scan-to-BIM processes in Indonesian road and bridge construction.

2.2 *Scan-To-BIM implementation on Indonesian bridges*

The completed Scan-to-BIM projects managed by Indonesia's Directorate General of Highways encompass a range of specialized bridges across diverse regions, such as the Musi IV Bridge in South Sumatera, Barelang Bridge in Batam Island, Sigandul and Serayu Bridges in Central Java, Kretek II Bridge in Yogyakarta, Sembayat Baru II Bridge in East Java, Alalak Bridge in South Borneo, Pulau Balang Bentang Panjang Bridge in East Borneo, and Bahtera Emas Bridge in South Sulawesi. These projects were executed with strict adherence to technical specifications and unique requirements during their construction phase. However, while the visualization of these bridges may seem impressive, the lack of robust quality assurance mechanisms post-processing raises concerns about the final data's quality. Despite precision engineering during construction, the absence of stringent post-processing quality checks may undermine the overall reliability and accuracy of the data obtained. Consequently, while these bridges stand as symbols of enhanced infrastructure and connectivity across Indonesia's diverse landscape, ensuring the reliability and accuracy of the final data becomes imperative for their true effectiveness and long-term utility.

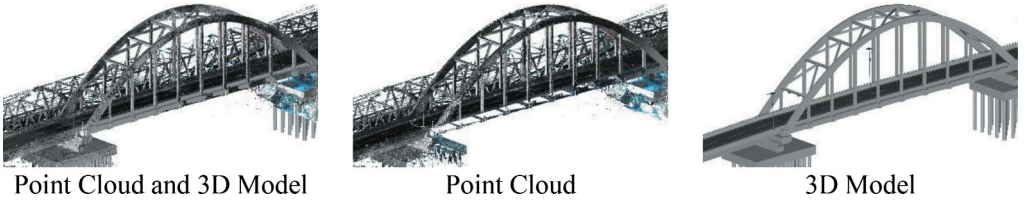

Figure 1. Sembayat Baru II Bridge digital asset from Scan-to-BIM approach.

3 ANALYSIS OF GAP AND FACTORS INFLUENCING BIM ADOPTION

3.1 *Bridging the gap: Comparative analysis*

The comparative analysis reveals Indonesia's progressive strides in BIM integration and Scan-to-BIM exploration but highlights significant disparities compared to global leaders like the UK, Norway, South Korea, and Singapore (Rocha & Mateus, 2021) While Indonesia's evolving policies show promise, they fall short compared to the UK's stringent BIM Level 2 mandates and Norway's comprehensive strategies, indicating a need for clearer directives and

standardized protocols. Moreover, Indonesia's moderate industry collaborations lag behind extensive partnerships seen in leading nations, demanding a faster pace of technological adoption to match Singapore and South Korea's advanced integration.

In Scan-to-BIM, Indonesia's exploration contrasts with established methodologies in the UK, Norway, and Singapore, signaling the need for adopting proven methodologies and advanced technology strategies (Saksena & Sastrawiria, 2023). Critical developmental areas emerge: explicit policy mandates, intensified industry collaborations, accelerated technological adoption, and focused adoption of established Scan-to-BIM methodologies from leading nations.

Table 1. Comparative analysis Indonesia's BIM framework and approach

Parameters	Policy Framework	Industry Collaboration	Technology Adoption	Standardization	Scan-to-BIM Approach
Indonesia	Ongoing integration efforts, emerging policies	Moderate collaborative initiatives	Emerging adoption, increasing awareness	Varied practices, limited standardization	Developing utilization, exploring potentials
Denmark	Extensive BIM initiatives	Industry-wide coordination	Advanced technology adoption	Uniform guidelines	Integrated in various projects
Finland	Emphasizes BIM	Active collaborations	Invests in technology	Standardized practices	Developing applications
Norway	Comprehensive BIM strategies	Unified industry practices	Innovative technology adoption	Established protocols	Proven application in projects
Singapore	BIM Excellence Program	Robust industry collaborations	Embraces digital innovation	Comprehensive standards	Implemented in major project
South Korea	Strong government support	Active industry partnerships	Cutting-edge tech integration	Unified standards	Advanced use in projects
UK	BIM Level 2 mandates	Extensive collaborations	Advanced technology integration	Unified protocols	Well-established methodologies
US	National BIM Standard	Collaborative approaches	Embraces BIM technologies	Standardized guidelines	Increasing use in projects

The table encapsulates diverse global approaches to Building Information Modeling (BIM) and Scan-to-BIM methodologies in infrastructure development. Denmark leads with extensive BIM initiatives, emphasizing coordination and technology adoption; Finland prioritizes BIM and collaboration while developing applications; Norway stands out for comprehensive strategies and proven application; Singapore excels with industry collaborations and real-world implementation; South Korea's government support drives cutting-edge tech integration; the UK mandates BIM Level 2 with advanced methodologies; the US steadily adopts BIM standards. Indonesia shows progress but faces challenges in standardization and collaboration, exploring Scan-to-BIM potentials and emerging policies, marking a developmental phase in BIM integration within infrastructure.

3.2 *Challenges in BIM implementation in Indonesia*

Embarking on Indonesia's journey towards seamless BIM integration exposes significant hurdles in policy, human resources, and tool implementation. Unlike the UK and Norway, Indonesia's evolving policies lack the granularity needed for standardized BIM adoption, posing challenges in uniform practices across projects. Digital twin creation, as highlighted by (Saksena & Sastrawiria, 2023), faces complexities due to diverse data, project dynamics, and multiple constraints, hindering recent BIM processes in Indonesia. Proficiency gaps in advanced BIM methodologies persist among professionals, limiting BIM's efficient use across project

phases, as noted in (Kineber et al., 2023), necessitating organizational and cultural readiness for embracing BIM in asset management. Furthermore, limited accessibility and familiarity with sophisticated BIM tools hinder their widespread adoption among professionals, restraining BIM's potential in transforming infrastructure development practices. Literature-based solutions suggest refining policies, upskilling the workforce, enhancing technological accessibility, and fostering collaborative efforts among stakeholders to advance BIM methodologies in Indonesian infrastructure projects.

Literature-based solutions suggest pivotal steps for enhancing BIM implementation in Indonesia. Clearer directives and stringent mandates within refined policies are crucial, fostering standardized BIM adoption across projects. Upskilling the workforce through comprehensive training programs can bridge proficiency gaps among professionals, while enhancing technological accessibility and affordability will ease BIM tool implementation. Collaborative efforts among stakeholders, facilitated by knowledge-sharing platforms, can create an ecosystem conducive to advancing BIM methodologies, driving Indonesia toward a more integrated BIM landscape in infrastructure projects.

4 COMPARATIVE WORKFLOWS AND IMPACTS

4.1 *Comparative analysis of BIM workflows*

The BIM delivery strategies across leading countries exhibit distinct advantages and disadvantages. For instance, the UK's stringent policy mandates foster standardized protocols and collaborative working, yet potential disadvantages might include initial implementation challenges and resource constraints. Conversely, while the US emphasizes national standards and industry collaboration, potential drawbacks could involve variations in state-level adoption and diverse stakeholder interests. Similarly, Norway's comprehensive BIM strategies showcase proven applications, but potential challenges may arise in scaling these strategies to match Indonesia's infrastructure diversity. Finland and Denmark's unified standards and innovative solutions present advantages in standardization and sustainability, yet challenges might surface in aligning these practices with Indonesia's developing infrastructure. South Korea's advanced technology integration and Singapore's comprehensive standards and digital innovation offer advantages in cutting-edge implementation; however, the potential challenge lies in adapting these high-tech approaches to Indonesia's varying technological landscape and resource availability. The impact within Indonesia's context hinges on leveraging these global practices to overcome challenges in policy refinement, skill development, technology accessibility, and fostering collaborative ecosystems suited to Indonesia's infrastructure complexities and developmental stages.

Leveraging these global BIM practices can offer valuable insights for Indonesia's infrastructure development. Indonesia can learn from stringent policy mandates like the UK's to foster collaboration, but should be mindful of initial challenges in implementation. Similarly, aligning strategies from Norway's comprehensive approaches with Indonesia's diverse infrastructure could pose challenges. Embracing collaborative models from the US while navigating state-level variations could provide a blueprint for Indonesia's industry cooperation. Further, lessons from high-tech integrations in South Korea and Singapore can inspire Indonesia's technological advancements but may require adaptation to suit local resource availability and infrastructure maturity. In essence, understanding these global practices' strengths and challenges empowers Indonesia to tailor BIM strategies to its developmental stages, focusing on refining policies, skill development, technology accessibility, and fostering collaborative ecosystems tailored to its infrastructure complexities and specific needs.

4.2 *Standardizing deviation point cloud vs 3D model in digital twin creation*

According to (Datta et al., 2023), common problems in BIM implementation include interoperability and standardization issues with software and data formats, leading to difficulties in data exchange across platforms and disciplines. Various BIM guidelines, like the US GSA BIM

guide and Finnish COBIM guidelines, show differences in defining tolerances and accuracy verification. While some, like the British PAS 1192 and Plowman Craven's BIM survey specification, suggest thresholds and verification methods, others lack explicit accuracy definitions. Existing standards from BuildingSMART International and ASTM International influence acceptable deviation ranges, aiding in tailored tolerance specifications. However, the absence of unified regulation points to the need for established maximum deviation standards between point clouds and 3D models in scan-to-BIM processes for bridges, crucial for data reliability, safety assessments, and predictive maintenance planning. Regulated deviations also enhance collaboration among stakeholders, streamline workflows, and ultimately optimize bridge asset management strategies. (Chen & Cho, 2018) highlight the importance of defined deviation standards and propose methods for measuring discrepancies between as-built conditions and BIM representations, contributing to data quality and integrity in bridge digital twins.

Moreover, regulated deviation standards foster interoperability and collaboration among stakeholders. With standardized tolerances, different entities involved in bridge projects can communicate effectively using common parameters, reducing misinterpretation and discrepancies. These standards also streamline the scan-to-BIM process, minimizing uncertainties and potential rework due to ambiguous accuracy requirements. This enhances efficiency in workflows, potentially reducing project costs and timeframes. Ultimately, regulated maximum deviations in scan-to-BIM creation for bridge assets optimize asset management by enabling better decision-making, predictive maintenance planning, and lifecycle management, thereby enhancing the overall effectiveness of bridge asset management strategies.

5 CONCLUSION

5.1 *Summary of findings*

The study delves into Indonesia's strides in BIM integration and Scan-to-BIM exploration, drawing comparisons with global leaders in the field. Indonesia shows progress in BIM implementation but lags behind nations like the UK, Norway, South Korea, and Singapore due to less stringent policies and differing methodologies in Scan-to-BIM approaches. This highlights the need for clearer frameworks and standardized protocols in Indonesia. Key influencers of this divergence include policy precision, industry collaborations, technological uptake, and standardization.

Recommendations advocate refining policies, bridging skill gaps, ensuring tech accessibility, fostering collaboration, and establishing standardized Scan-to-BIM protocols to address Indonesia's challenges in policy clarity, skill development, and technology accessibility.

In reviewing studies focused on BIM implementation and scan-to-BIM processes within bridge asset management, several critical insights have emerged. One key challenge identified across these studies lies in the lack of interoperability and standardization among various BIM software and data formats. This diversity poses significant difficulties in data exchange and integration across platforms and disciplines, leading to varying approaches to defining tolerances and accuracy verification within BIM guidelines.

Researchers advocate for the establishment of regulated maximum deviation standards between point clouds and 3D models in scan-to-BIM processes. This absence of a universal standard emphasizes the need to define tolerances, ensuring data quality and reliability for accurate digital representations of bridge assets. These regulated standards prove pivotal for safety assessments, informed decision-making, and predictive maintenance planning, aligning digital twins more closely with physical bridge structures.

Beyond ensuring data accuracy, regulated deviation standards foster better collaboration and interoperability among stakeholders. Common parameters help in effective communication, reducing misinterpretations and streamlining workflows. These standardized tolerances also promise increased efficiency, potentially cutting project costs and timeframes.

Ultimately, the application of regulated deviation standards within scan-to-BIM processes emerges as a linchpin for optimized asset management in bridge infrastructure. Their establishment facilitates improved decision-making, predictive maintenance planning, and overall

lifecycle management, thereby enhancing the effectiveness of bridge asset management strategies.

5.2 *Recommendations and future prospects*

The outlined roadmap for Indonesia's integration of BIM and Scan-to-BIM signifies both promise and challenges on the horizon. It highlights critical areas where significant progress is both necessary and achievable, demanding a holistic strategy to realign local practices with global benchmarks while addressing intrinsic developmental requirements.

Firstly, refining policy frameworks emerges as a cornerstone in Indonesia's journey. The need to revamp existing policies, mirroring the robust and stringent models observed in countries like the UK and Norway, becomes evident. This overhaul isn't solely about crafting stringent policies but ensuring their effective enforcement across the spectrum, fostering a consistent and regulated environment conducive to standardized BIM implementation in diverse infrastructure projects. This shift requires a harmonious blend of policy formulation and pragmatic enforcement mechanisms to ensure alignment with global benchmarks.

Secondly, the imperative for skill development among Indonesia's workforce looms large. Tailored training initiatives and certifications must be strategically introduced to bridge the prevailing skill gaps. These programs act as a catalyst, empowering professionals to proficiently wield sophisticated BIM methodologies and tools. The envisioned outcome is a workforce adept at harnessing these technologies effectively, thus fundamentally transforming their utility within Indonesia's infrastructure development landscape.

Thirdly, accessibility and affordability of cutting-edge BIM tools are pivotal. Promoting access to these tools and simplifying their user interfaces through strategic alliances or government-backed initiatives are essential catalysts for widespread adoption. This strategic move would democratize access to sophisticated BIM technologies, encouraging their utilization across diverse professional spectra within Indonesia's infrastructure development domain.

Furthermore, collaborative ecosystems are paramount. Encouraging the creation of platforms that facilitate knowledge exchange and interdisciplinary collaborations among stakeholders is crucial. These avenues are instrumental in fostering an environment conducive to embracing and propelling BIM methodologies forward. It's about forging synergistic alliances that transcend individual interests, emphasizing collective progress and innovation within Indonesia's infrastructure domain.

Finally, standardizing Scan-to-BIM methodologies is integral. Drawing lessons from successful global practices, particularly in laser scanning technologies and 3D model creation, will streamline and standardize protocols. This standardization ensures consistency, efficiency, and reliability in managing bridge assets within Indonesia's infrastructure landscape.

Overall, these recommendations collectively set the stage for Indonesia's ascendancy as a trailblazer in modern and efficient infrastructure development through BIM methodologies. They address intrinsic developmental requisites while aligning the nation with global standards, fostering a transformative trajectory in the realm of infrastructure development and management.

Material characterization for HBIM data structures on a masonry arch bridge

R. Chacón, C. Ramonell, H. Posada, L. Pelà, L. García-Ramonda, S. Gönen & A. Cabané
Universitat Politècnica de Catalunya, Barcelona, Spain

ABSTRACT: This paper presents a set of undertaken actions for characterizing masonry arch bridges using data structure suitable for proper embedment in Digital Twins and Heritage Building Information Modelling (HBM). Interfaces in bridge maintenance are relentlessly and increasingly sophisticated. For both new and existing bridges, these interfaces are tending towards their ability to deal with different sources of information. Comprehensive digital twins of heritage masonry arch bridges may include several sources of information gathered from the real asset. Measurements can be taken using many different techniques ranging from contact to contactless and from non-destructive to moderately destructive samples. In addition, these twins may base upon different numerical models aimed at predicting and anticipating the present and future behaviors of the asset, respectively. Masonry arch bridges are known for their complex material and structural characteristics. Digitizing these masonry properties is key for effective simulation and analysis, often involving homogenization of diverse material properties. The design of comprehensive information constructs able to store and federate multiple data layers within a single entity is still challenging. Layers must be connected using vast scoped solutions such as knowledge graphs, integrating measurements, simulations and other information sources. In this particular case study on a masonry arch bridge located in Catalonia, Spain, in-situ Non-Destructive Testing (NDT) data is conceptualized for proper infusion within HBIM schemas. This integration pursues a seamless information flow for analysis or predictive purposes.

1 INTRODUCTION

Masonry arch bridges can be found in numerous cities and landscapes across Europe and are renowned for their stunning and grand designs. Predominantly constructed from stone and/or brick, these bridges have exhibited excellent durability and structural integrity. They hold significant historical, scientific, and cultural values, with many being designated as world heritage sites. The resilient form of these bridges has been a key factor in their survival and continued functionality over centuries of service. However, most of these masonry structures are yet susceptible to varying degrees of irreversible damage due to natural disasters or the cumulative effects of environmental or serviceability exposure, with the materials being particularly vulnerable to such impacts. Consequently, it is crucial to forecast and anticipate potential collapses of those assets. Implementing strategic monitoring represents a crucial step in this endeavor.

Structural health monitoring (SHM) deployments includes the application of in-situ techniques for sensing and analyzing structural characteristics with the aim of diagnosing and detecting changes that could signify damage or degradation. The concept is decades old and it is nowadays benefiting from the use of more comprehensive information constructs within BIM (for organizational purposes), higher diagnosis capabilities with higher technological

DOI: 10.1201/9781003483755-281

readiness reached by characterization techniques (more varied and advanced ways of collecting data) and varied and sophisticated model-based or data-driven predictions for further prognosis. In the context of masonry bridges, one bottleneck is determined by the need of handling varied sources of collected data. The complexity and variety of characterization techniques and the non-standardized nature of their structural configurations pose challenges and thus, establishing threshold limits for anticipating collapse with data-informed warning indicators remains an intricate task.

For material characterization, an overall inspection of a masonry arch bridge traditionally encompasses different techniques. Non-destructive testing (NDT) and minor destructive testing (MDT) techniques, or a combination of both allow assessing the state of the components of the structure at a given episode (Cabané et al. 2023). Material characterization provides valuable insight related to the masonry components, i.e., mortars and units (fired clay or concrete bricks, cast or natural stones) and thus masonry as a homogenized continuum. In addition, static and dynamic proof load tests can shed light on the structural behavior at structural levels while geometrical surveys and visual identification of singularities contribute to the overall understanding of the behavior of the bridge.

BIM in civil engineering provides endless advantages for parametric modeling, 3D visualization, information management, and secondary development. It could also enhance efficiency and efficacy when handling information during construction phases. The operation and maintenance phase can also benefit from these information constructs. As a result, use of digital information of the asset encompasses design, construction and maintenance. In the particular case of heritage, HBIM stands for Heritage Building Information Modelling as an adaptation of the more widely known Building Information Modelling (BIM) technology, specifically tailored for historical and heritage buildings. HBIM focuses on digitally documenting, managing, and representing historic buildings and structures. Originally presented for characterizing geometric objects (Murphy et al. 2013), HBIM has permeated within many different types of heritage structures (López et al. 2018). In the specific field of masonry, BIM (and HBIM) schemas for masonry units and walls have been proposed in the literature (Gentry et al. 2016). In particular, these schemas are focused on new designs and designs using standard masonry units (MU). The field is active and advanced technologies, various types of software, and improved algorithms are under development to facilitate the automatic and rapid creation of structural HBIM models of heritage structures (Croce et al. 2022; Musella et al. 2021; Calvano et al. 2021).

SHM of masonry arch bridges can benefit from HBIM by leveraging frameworks in which information is retrievable and usable by different stakeholders (Wang et al. 2022). The synergy between SHM and HBIM provides vaster possibilities for encompassing information and better solutions for information integration, monitoring, and eventually, accurately anticipating the behavior of the asset. Recognizably, researchers have undertaken studies to develop Building Information Modeling (BIM) models for complex masonry arch bridges (Garozzo & Santagati, 2021). These efforts include parametric manual and AI-crafted modeling based on surveying and mapping data. The philosophy aims at integrating multi-source information such as history, geometry, material, detection, and repair data of heritage structures into BIM models. Researchers have proposed BIM parametric modelling for masonry vaults (Trovatelli et al. 2023). On an attempt of deploying comprehensive systems for anticipating the collapse of bridges, the Joncadella Viaduct, located in Catalonia, Spain is used systematically as an example of masonry bridge. The overall research project includes different types of measurements, simulations, surrogate models and analysis. All information legs are organized in the form of a multi-source information construct in the form of a digital twin. These actions belong to the Spanish National Research Project called PONT3 (www.pont3.es). In the particular case of actions deployed in this paper, the driving force of this research is underpinned by two primary research inquiries:

– What are the ontology structure for encapsulating the material characterization of masonry arch bridges?
– How can this domain of knowledge be leveraged for creating a Building Information Interoperable Model that emphasizes predicting potential collapses?

Advancing new ontologies or augmenting existing standards specifically for a thorough analysis of masonry bridges represents a significant stride that can contribute to assessing their health status. This endeavor necessitates a detailed examination of the available standards and ontologies. Developing a new data schema or an extension could additionally contribute to incorporating semantic layers into Heritage Building Information Modeling (HBIM) models. In this paper, advances on addressing this issue through a case study focusing on a specific masonry arch bridge located in Catalonia, Spain. This case study provides a practical application for initial examination of the theories and methodologies discussed, offering insights into their real-world implications and effectiveness in the context of the preservation and analysis of such historic structures.

2 THE CASE STUDY

2.1 *A brief history of the Joncadella Viaduct*

During the latter half of the 19th century, the expansion of railway networks in Europe spurred significant growth in the construction of stone and masonry arch bridges. While these bridges were generally built according to the 19th-century design standards for masonry arch structures, they also uniquely incorporated local construction techniques and materials. This blend of standardized design and local craftsmanship reflects the building practices of that era, serving as a historical testament to the architectural methods of the past. The Joncadella Viaduct is located in the Catalan region of "El Bages". It is part of the non-electrified "Manresa-Súria" railway line, primarily used for freight train traffic. Originally authorized as a mining railway to "Solvay & Cie" in 1918, the Joncadella Viaduct initially featured four masonry arches and a steel lattice girder deck with spans of varying lengths, all supported by masonry columns and abutments. Operational since 1924, it is currently operated by the *Ferrocarrils de la Generalitat de Catalunya* (FGC).. An exhaustive search of the documentation on the original structure has led researchers to several archives and museums of the area as well as documentation provided by historians. Reports date back to January 10th, 1919. The Manresa-Súria railway line, featuring a total of 6 viaducts, was undoubtedly built with the same technology, materials and construction processes. A historical photograph in Figure 1 illustrates the Manresa-Súria railway bridges under construction by "Construcciones y Ferrocarriles S.A." in 1920 and Figure 2 two photographs of the bridge with its initial design with a steel lattice girder deck during service.

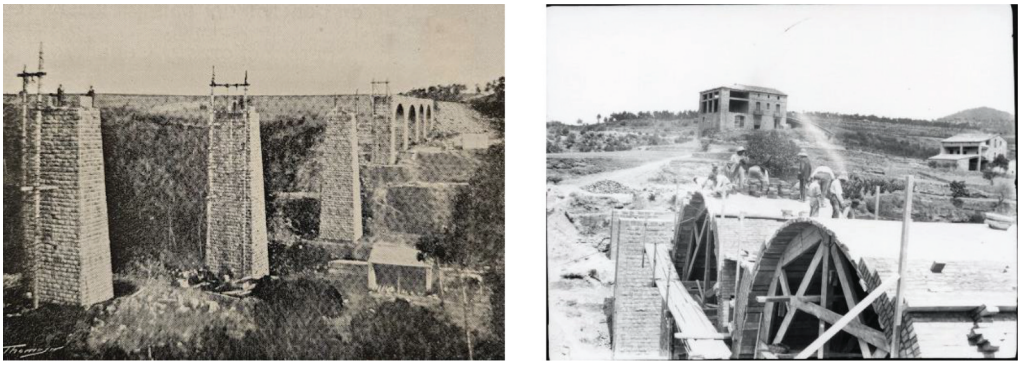

Figure 1. Left: The Joncadella Viaduct during early 20th century (Canet J. 1920). Right: The Cortes Viaduct (Fàbrega A. 2009). Both arch bridges under construction. Early 20th century.

Figure 2. The Joncadella Viaduct in November 1924 (Archive Comarcal del Bages, J.M. Rosal i d'Argullol collection, reference code ACBG30-154-N-1756 on the left and ACGB30-154-N-1764).

2.2 *The present of the Joncadella Viaduct*

Spanning roughly 169 meters in length and standing about 25 meters tall, the viaduct presently comprises thirteen spans. Initially, during the early 1920s construction phase, four of these spans were built as masonry arches. In a 1950 refurbishment project, the remaining nine spans were replaced with unreinforced concrete arches, taking the place of the original metallic truss that was heavily corroded and dismantled. The 1950s intervention and replacement works on the bridge were comprehensively documented, detailing the materials, structural elements, and construction process used. Figure 3 illustrate the concrete resulting arches that replaced the steel deck. Figure 4 provides both bird views and details of the viaduct in its present condition.

Figure 3. The Joncadella Viaduct during the second half of 20th century (Left: Roger (2008) Right: authors).

3 OBJECTIVES AND METHODOLOGY

The primary goal of this project is to proactively predict potential collapses across various bridge types. To achieve this, the methodology centers on creating an extensive information system that integrates diverse data sources, including measurements and numerical models. This system will not only assimilate various data inputs but also incorporate analytical and predictive tools. Central to this approach is the geometric model, which is grounded in

Figure 4. The Joncadella Viaduct bird view and detail of the masonry arch (Authors).

Heritage Building Information Modeling (HBIM) concepts. By combining HBIM with advanced data integration and analysis capabilities, the project aims to enhance bridge safety through early detection and prevention of structural failures. Figure 5 shows an overview of the encompassing techniques.

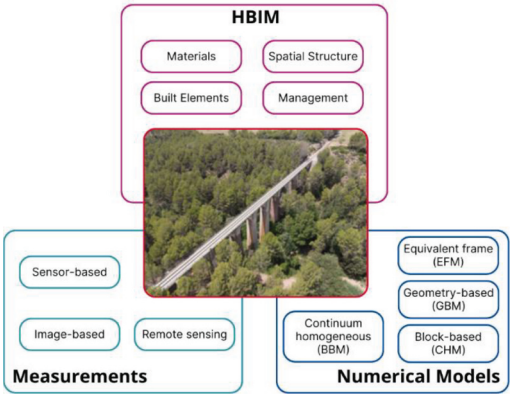

Figure 5. Different sources of information that must be encompassed together.

In this specific case study, it is crucial to highlight that the selected approach for numerical modeling relies on continuum models, which use homogenized material properties. This homogenization process combines both the properties of mortars and individual units to represent the masonry as a unified entity. To ensure accuracy and reliability, this methodology involves conducting specialized tests aimed at characterizing not just the mortars and individual units, but also the masonry as a whole. These specific characterization tests are integral to understanding the true nature and behavior of the materials in question. Additionally, the organization and management of the gathered information are heavily influenced by prior work in Heritage Building Information Modeling (HBIM). This approach in HBIM serves as a foundational framework for structuring and handling the diverse sets of data obtained from tests and analyses. By leveraging the principles and methods established in previous HBIM projects, the project can effectively organize and interpret the complex data. This structured approach not only enhances the accuracy of the numerical models but also ensures that the information is stored and managed in a way that is conducive to further analysis and application in the broader context of bridge maintenance and preservation.

4 NDT AND MATERIAL CHARACTERIZATION OF THE JONCADELLA VIADUCT

The Joncadella Viaduct is a protected cultural heritage, making it impossible to extract material or components that make up its structure for physical and mechanical characterization. For this reason, the characterization of its components requires the use of Minor Destructive Testing (MDT) and Non-Destructive Testing (NDT) Techniques. The MDT and NDT techniques used are increasingly recognized as valuable tools for characterizing and analyzing masonry. Concrete, stone, brick, and mortar, as individual components, can undergo assessment through penetration methods, pull-out tests, break-off tests, surface hardness tests, ultrasonic tests, and impact-echo tests. The research conducted on the Joncadella Viaduct focuses on utilizing the Pin Penetration Test (PPT), the Helix Screw Pull-out Test (HPT), the Torque Penetrometric Test (TPT), and the Rebound Hammer Test (RHT). The PPT involves measuring the depth of penetration of a steel pin to estimate compressive strength. Executed on concrete surfaces, stretcher brick faces, and mortar joints, a 3 mm diameter steel pin with a conical end is inserted into the Windsor Pin Instrument tool. The retraction nut is adjusted, ensuring the spring is in position, and the trigger is activated while maintaining firm contact between the device and the surface. A micrometer is then carefully inserted into the bottom of the hole to read the penetration. The HPT considers the pull-out load of a tie, inserted into a hole drilled into a brick or a mortar joint, as an indication of compressive strength. The mechanical tool and helices used are produced by Helifix Company UK. In the Joncadella Viaduct, the HPT is employed to test bricks and mortar joints. A 3 mm diameter pilot hole is made in the mortar, and a 4 mm one is made in the bricks, both with a depth of 35 mm. An helical tie with a diameter of 1/4 in. (6.3 mm) is embedded, and the Helifix mechanical tool is connected. Load is applied by turning a grip lever to progressively increase the load until failure. The TPT system measures the force required to twist the mortar using a notched tip inserted into the material with four protruding teeth. This test is conducted in mortar joints by inserting the notched tip into a 6 mm diameter pilot hole and subjecting the tip to torsion using a digital readout torque wrench until it reaches the maximum torque indicating material failure. The RHT measures the rebound of a spring-loaded mass impacting against the surface of a sample. The hammer test hits the concrete, stone, or brick at a defined energy, and its rebound is correlated with the material strength capacity. Figure 6 illustrates the MDT and NDT techniques described.

Figure 6. The MDT and NDT techniques. Left: PPT, centre: HPT, right: TPT.

5 NUMERICAL MODELLING STRATEGIES FOR MASONRY ARCHES

Masonry behavior is largely influenced by the mechanical properties of its blocks and mortar, and their interaction. For an accurate simulation of the mechanical behavior of an existing

masonry structure, it is essential to base the model on well-established mechanical properties, derived from experimental tests, and comprehensive geometrical and structural surveys (Lourenço 2002, Roca et al. 2010). The level of detail and accuracy needed for structural analysis dictates the choice of modeling strategies. These strategies differ in their approach to representing the notorious heterogeneity of masonry in numerical models. A recent classification provided by D'Altri et al. (2019) outlines the available strategies: a) continuum models; b) block-based models; c) macro-element models; and d) geometry-based models. Masonry also exhibits anisotropic characteristics, seen in its elastic properties, strength variations in different directions, and brittleness after peak stress. While regular brick masonry shows notable anisotropy, random stone masonry's lack of material regularity may result in less pronounced anisotropy in elasticity, strength, and brittleness. Defining the geometry of historic buildings, known for their intricate and irregular designs, is often complex and requires detailed surveys. Identifying the load-bearing elements within the building's geometry is a nuanced task dependent on the analyst's understanding of the structure. Furthermore, the applicability of this geometry in structural analysis poses its own challenges. While creating the structure's geometry in a CAD environment based on surveys is feasible, its integration into simplified structural analysis is more straightforward than in mesh-based analysis. The latter often encounters issues like mesh inaccuracies and compatibility problems, necessitating overly detailed meshes. Recent advances are directed towards utilizing 3D point clouds for automated mesh generation in historic buildings, aiming to overcome these difficulties. The refinement of these new methods is an active area of development, indicating the evolving nature of structural analysis in the context of historic buildings. Macro-modelling is one of the most popular and common numerical approaches due to its lesser computational demand when compared with other available strategies. Macro-modelling, which does not make any distinction between units and joints, may offer an adequate approach to characterize masonry structural response by considering the material as a fictitious homogeneous orthotropic continuum (Roca et al., 2010). Thus, an appropriate relationship between average masonry strain and stresses need to be established. To this end, the continuum parameters must be determined by means of experimental tests on specimens of sufficiently large size subjected to homogeneous states of stress. However, when it comes to existing masonry structures, such approach is not feasible. As an alternative, it is recommended the experimental assessment of the mechanical characteristic of the individual components of masonry by means of NDT or MDT (Pelà et al., 2016, 2018) and consider the obtained data as input parameters of a numerical homogenization technique. The homogenization procedure poses as a challenge due to the difficulties steaming from the accurate identification of mechanical properties and definition of reliable failure criteria for the homogenous equivalent material (Petracca et al., 2017). The proper definition and identification rely not only on the available empirical formulations provided by current standards, such as EC6 (European Standard, 2006), but also the heuristic-based criteria for the careful analysis of the experimental data, based on prior extensive experience.

6 MATERIAL DATA INTEGRATION

In the particular case of the case study, the integration of material data within a vaster information construct is presented in Figure 6. Site inspections include a series of material tests on several points of the masonry arches for both mortars and masonry units (MU). The data structure of the test program is prepared in a way it includes many samples together with crucial information about each sample. The measured value, an image, the exact location of the sample as well as open text are organized on reports for all tests. Information is sent to the geometrical model HBIM. Users of the HBIM can retrieve information of the testing program to infer structural properties of the masonry as an homogenized material. Numerical models can be based on processed information that can also be retrieved from the corresponding HBIM. A vaster information construct with decision-making capabilities such as

a comprehensive digital twin mustr be conceived in a way all information sources are seamlessly encompassed. Knowledge-graphs are used for integration purposes in this research (Ramonell et al. 2023).

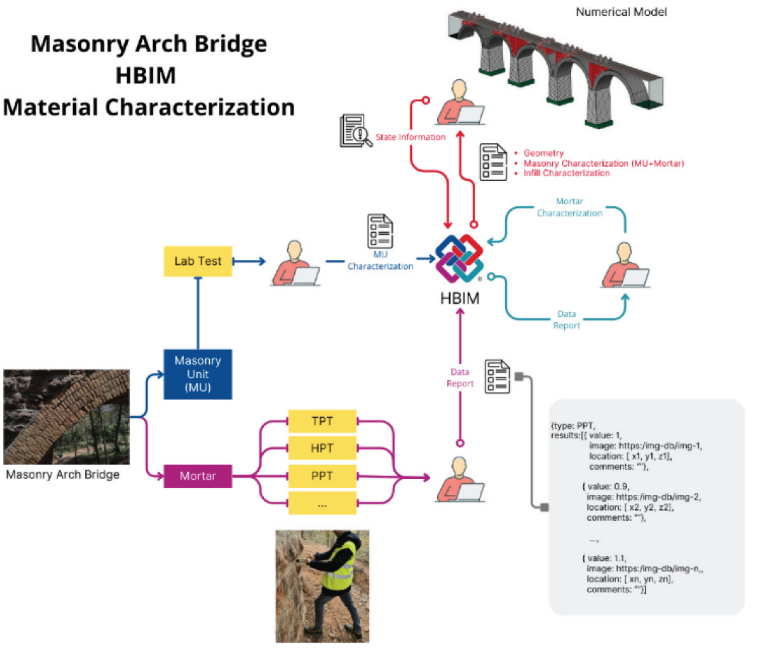

Figure 7. Schema for material characterization for the Joncadella Viaduct.

7 CONCLUSIONS AND FUTURE WORK

Anticipating collapse on masonry arch bridges implies encompassing information related to the physical condition of the bridge as well as related to accurate numerical predictions. A digital twin of a masonry arch bridges for decision-making processes can be used to organized all these data layers. This development necessitates meticulously designed material data structures. These structures should be crafted to seamlessly integrate information from in situ testing programs, ensuring a comprehensive representation of the bridge physical state. The key to successful digital twinning lies in the effective transmission of detailed, accurate data into Heritage Building Information Modeling (HBIM) constructs. This integration not only enhances the precision of the HBIM models but also ensures that every aspect of the bridge's material properties is accurately reflected and accessible for analysis, preservation, and maintenance planning.

ACKNOWLEDGEMENTS

The financial support from the Ministry of Science and Innovation (Spain), the State Agency of Research, and the European Regional Development Fund (ERDF) through the project PONT3 (PID2021-124236OB-C32). Authors also acknowledge the #KPI50 initiative of Ashvin, an H2020 project under agreement 958161 for the complementary support to the development of twinning techniques in new sites. ABSTRACT: Among the multicriteria decision-making (MCDM) methods, the Integrated Value Model for Sustainability Assessment (MIVES) stands out for its ability to quantitatively assess sustainability of civil and construction engineering projects. The integration of this method with building information modeling (BIM) offers a holistic approach to construction project management, this allowing promoting better decision-making, collaboration, and ultimately, more successful and efficient construction projects. While literature explores the link between BIM and MIVES, efforts often lack consistent sustainability assessment automation. Current approaches mainly define MIVES indicators within the BIM model, without achieving a comprehensive evaluation automation. To address this issue, a novel methodology that combines MIVES and BIM is presented to automate the sustainability assessment. The proposed methodology automates the sustainability analysis of BIM digital twin in Revit using quantity tables and internal operators. In addition, a parametric programming tool in Dynamo is developed for direct MIVES and BIM coupling. The approach is validated using a real viaduct to assess sustainability and perform a sensitivity analysis in order to identify those indicators with the most influence on sustainability performance. Critically, this methodology is not limited to the sustainability assessment of bridges as it can be readily adapted to other types of infrastructure. Moreover, it is worth noting that the capabilities of this approach can be significantly augmented by incorporating data from sensors and diverse sources. This inclusion of sensor-derived or alternative data sources enhances the depth and accuracy of the insights drawn from the integrated MCDM-BIM framework.

1 INTRODUCTION

In the context of the ongoing fourth industrial revolution, often referred as Industry 4.0 (Pereiro et al. (2023)), Architecture, Engineering, and Construction (AEC) industry is undergoing a profound shift driven by digitalization. One prominent methodology at the forefront of this transformation is the pivotal role played by Building Information Modeling (BIM) (Fernandez-Mora et al. (2022)), which enables the generation of virtual replicas of the assets, such as civil infrastructures and buildings (Bellido-Montesinos et al. (2019)). The benefits of BIM

DOI: 10.1201/9781003483755-282

include improved collaboration among project stakeholders, enhanced visualization of project details, reduced errors and rework, efficient resource allocation, and better decision-making throughout a construction project's lifecycle (Caglayan & Ozorhon (2023)). It is essential to remark that BIM virtual replicas extend beyond the three-dimensional geometry of their elements, these are also enriched with multidisciplinary databases. Indeed, the integration of these databases empowers stakeholders to access and share precise and up-to-date information, resulting in improved project outcomes and more efficient decision making.

Decision making is also enhanced with Multi-Criteria Decision-Making (MCDM) methods, which facilitate the evaluation between alternatives characterized by multiple, usually conflicting, criteria. These methods are crucial in fields where decisions are complex and involve various factors and stakeholders. The main goal of MCDM is to identify the best option or to rank the options in order of preference, based on the given criteria. Examples of MCDM methods in the Architectural Engineering and Construction AEC field include: Building Research Establishment Environmental Assessment Method (BREEAM) (BREAM (2022)), Leadership in Energy and Environmental Design (LEED) (LEED (2022)), German Sustainable Building Council (DGNB in German) (DGNB (2018)), Civil Engineering Environmental Quality Assessment and Awards Scheme (CEEQUAL) (CEEQUAL (2019)), and (5) Integrated Value Model for Sustainability Assessment (MIVES) (Viñolas et al. (2009)).

Most of these methods are based on economic, environmental, and social criteria. Nevertheless, it is important to highlight that contrary to many MCDM methods, MIVES is not limited to building analysis, as it is a versatile methodology that can be readily adapted to any engineering discipline (Pons et al. (2016)).

MCDM methods offer several advantages when integrated with BIM, including (1) *Database enrichment*: The information contained within a BIM model, including geometric dimensions and compliance data to existing documentation and expert insights, is instrumental in determining the values for parameters used in MCDM methods. (2) *Information processing*: BIM streamlines the collection, categorization, alteration, updating, and analysis of project information. (3) *Information management*: BIM facilitates efficient exchange of information across the various disciplines engaged in a project.

The synergy of Multi-Criteria Decision-Making (MCDM) methods with Building Information Modeling (BIM) has been the subject of extensive research. A recent literature review (Tan et al. (2021)), analyzed 45 papers to demonstrate the collaborative benefits of MCDM and BIM. However, despite the versatility of MIVES and the advantages of the BIM methodology, the literature lacks studies that directly couple MIVES with BIM. To address this gap, this paper introduces a methodology for integrating MIVES with BIM models. This methodology is particularized to study the sustainability assessment of viaducts.

This conference paper is organized as follows: Section 2 examines the proposed methodology, initially detailing the steps involved in applying the MIVES method and subsequently describing its integration with BIM, including the employment of parametric algorithms to automate the information extraction for sustainability assessment. Section 3 presents a case study, the Las Arenas Viaduct in Spain, to demonstrate the step-by-step application of the proposed methodology to an actual structure. Section 4 presents the conclusions derived from this study.

2 SUSTAINABILITY ASSESSMENT METHODOLOGY

In this section, the theoretical background of the MIVES methodology is first described. Then, the application of MIVES for the study of the sustainability assessment of viaducts is presented. Finally, a parametric methodology to integrate MIVES with BIM software is detailed.

2.1 *MIVES*

MIVES is a sustainability-based approach that aims to facilitate decision-making among various options through a multi-criteria analysis. It is based on the use of the Analytic Hierarchy Process (AHP) to manage the hierarchical relationships among different parameters and to set priorities within the decision framework.

To enable the assessment of an alternative from an economic, environmental, and social perspective, MIVES provides a Sustainability Index (SI) ranging between 0 and 1. The calculation and use of this index for the decision-making process is based on the following steps (Pons et al. (2016)):

1. Definition of the problem and the decision needed.
2. The decision model diagram is structured in a decision tree that hierarchically arranges the characteristics of the parameters across three following levels: requirements, criteria, and indicators.
3. Defining the value functions to add homogeneity to the variables by their transformation to common, non-dimensional units named value functions (V). The value function corresponding to each ith indicator (V_i) quantifies the preference for a specific alternative, ranging from minimum (P_{min}=0) to maximum (P_{max}=1) levels of satisfaction. The methodology for calculating V_i involves the following steps: (i) determining whether the value function should ascend or descend, (ii) establishing the minimum (P_{min}) and maximum (P_{max}) thresholds, (iii) deciding on the form of the value functions, with common shapes being concave, convex, linear, or S-shaped, and (iv) formulating the V_i using the following equation:

$$V_i = K_i \left[1 - e^{-m_i \left(\frac{\left| P_{i,x} - P_{i,min} \right|}{n_i} \right)^{A_i}} \right] \tag{1}$$

where n_i is the value used, mi the value of the ordinate n_i, A_i the shape factor of the i^{th} indicator value function (A_i<1 concave, A_i =1 linear, and A_i >1 convex or S-shape), $P_{i,\,min}$ and $P_{i,\,max}$ are the minimum and the maximum value of the i^{th} indicator, respectively, $P_{i,z}$ is the score of alternative z that is under assessment, with respect to the i^{th} indicator under study, and K_i is a factor used to assure that the value of V_i will be within the bounded between 0 and 1. This factor is obtained as follows:

$$K_i = \left[1 - e^{-m_i \left(\frac{\left| P_{i,max} - P_{i,min} \right|}{n_i} \right)^{A_i}} \right]^{-1} \tag{2}$$

where the parameters n_i, m_i, and A_i are fixed according to the preferences of the decision maker.
4. Establishing the significance of each distinct factor involved in the evaluation process. This importance is assigned by relative weights in each requirement (α_i), criterion (β_i), and indicator (γ_i) of the requirements tree. The assignment of these weights can be determined both directly, or by an Analytic Hierarchy Process (AHP) based on a pairwise comparison of all elements with each other.
5. Defining the different alternatives for the proposed problem.
6. Evaluating the assessment of the different alternatives by studying their Sustainability Index (SI). This parameter can be calculated as follows:

$$SI = V\ (P_x) = \sum_{i=1}^{i=n} \alpha_i \cdot \beta_i \cdot \gamma_i \cdot V_i(P_{i,x}) \tag{3}$$

where $V(P_x)$ measures the degree of sustainability (value) of each of the defined alternatives with respect to a set of criteria $P_{i,x}$, and parameters α_i, β_i, and γ_i refer to the weights of the requirements, criteria, and indicators.
7. The SI of the different alternatives are compared to identify the most appropriate one (the one with the highest SI).

2.2 *Sustainability assessment of viaducts*

The MIVES method has been tailored for assessing the sustainability of viaducts. Accordingly, the decision tree (see Table 1) has been structured into three requirements (R) (Economic, R_1, Environmental, R_2, and Social, R_3), six Criteria (C) (Cost, $C_{1.1}$, Time, $C_{1.2}$, Emissions, $C_{2.1}$, Resources, $C_{2.2}$, Social indexes, $C_{3.1}$, and Safety, $C_{3.2}$), and eleven indicators (Total cost, $I_{1.1.1}$, Indirect cost, $I_{1.1.2}$, Maintenance cost, $I_{1.1.3}$, Dismantling cost, $I_{1.1.4}$, Execution time, $I_{1.2.1}$, CO_2 emissions, $I_{2.1.1}$, Raw material consumption, $I_{2.2.1}$, Energy consumption, $I_{2.2.2}$, Affected area, $I_{3.1.1}$, General disturbances, $I_{3.1.2}$, and Health and safety during construction, $I_{3.2.1}$,). Table 1 also includes the values of the weights (α, β, and γ).

Table 1. MIVES decision-making tree for the case study.

Requirement	α_i	Criteria	β_i	Indicator	γ_i
R_1 Economic	55%	$C_{1.1}$ Cost	70%	$I_{1.1.1}$ Total cost	60%
				$I_{1.1.2}$ Indirect cost	10%
				$I_{1.1.3}$ Maintenance cost	20%
				$I_{1.1.4}$ Dismantling cost	10%
		$C_{1.2}$ Time	30%	$I_{1.2.1}$ Execution time	100%
R_2 Environmental	25%	$C_{2.1}$ Emissions	60%	$I_{2.1.1}$ CO_2 emissions	100%
		$C_{2.2}$ Resources	40%	$I_{2.2.1}$ Raw material consumption	50%
				$I_{2.2.2}$ Energy consumption	50%
R_3 Social	20%	$C_{3.1}$ Social indexes	40%	$I_{3.1.1}$ Affected area	40%
				$I_{3.1.2}$ General disturbances	60%
		$C_{3.2}$ Safety	60%	$I_{3.2.1}$ Health and safety	100%

A detailed definition of each of the considered indicators is detailed in Lozano-Galant et al. (Lozano et al. (2023)).

2.3 *Parametric integration between MIVES and BIM*

The following steps were implemented to automate the connection between MIVES and BIM:

1. Analysis of the problem: The information of the viaduct under study is reviewed together with the definition of the problem.
2. Decision framework for MIVES: The different requirements, criteria, and indicators defined in the previous section are defined together with their respective weights (α, β, and γ), and their value functions following the decision-making tree in Table 1. The weights are determined based on the stakeholders' needs, taking into account economic, social, and environmental considerations.
3. BIM modelling: A virtual model of the viaduct is generated with the BIM methodology. The sustainability indicators must be included into the BIM model as project parameters. This process is carried out with the help of a parametric programming in Dynamo to export the information from excel as showed in Figure 1.
4. Definition of the value functions: Both the parameters and coefficients of the value functions of the considered parameters are defined in Excel. The data used to shape the value functions is obtained from the knowledge of each specific variable.
5. Calculation of the sustainability indexes (SI): Equation 3 is used to calculate the sustainability index.

Figure 1. Flow chart of the information.

2.4 *Introduction of sensor information*

Integrating sensor information into a BIM model represents a key step towards enhancing the comprehensiveness and real-time relevance of digital representations of structures. This integration facilitates a dynamic and data-rich environment where real-world data and digital models seamlessly converge. In addition, the introduction of sensor data into the BIM model provides a comprehensive historical record of a structure's performance.

For example, in the case of the LARA (Low-Cost Adaptable Reliable Accelerometer-Anglemeter) (Komarizadehasl (2022)), the sensor measurements can be stored on the Internet of Things IoT web server, and the link to this site can be straightforwardly associated with the attributes of the monitored elements within the BIM model. The traditional protocol for integrating the LARA monitoring data is based on the following steps (Figure 2): (1) Importing LARA data into the Things Speak platform, (2) Visualizing and plotting the results obtained from LARA into the IoT platform, and (3) Adding the IoT site link to the attributes of the monitored BIM element. As a result, the historical measurements can be visualized and incorporated into the BIM model.

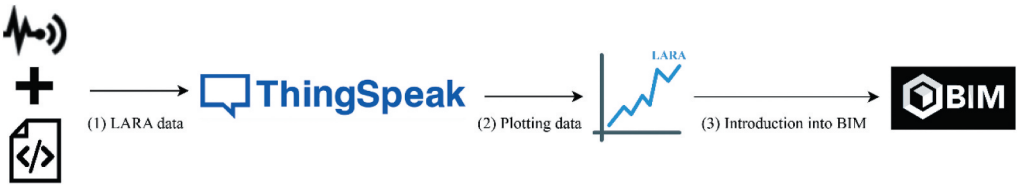

Figure 2. Flow of information to introduce LARA monitoring information in BIM.

In future works, information from actual sensors into the BIM model will be included into the MIVES analysis.

3 CASE OF STUDY

To validate the proposed methodology, the sustainability assessment was conducted on a case study, Las Arenas Viaduct. After describing the primary characteristics of the structure, the application of the proposed methodology is summarized, and the Sustainability Indexes for different scenarios are computed according to the method described in Section 2.1.

3.1 *Las Arenas Viaduct description*

Constructed in 2021, Las Arenas Viaduct stretches across the "Las Arenas" stream in Barcelona, Spain, and it is located on the C-58 road that liddinks Sabadell and Terrassa. The bridge extends over a total length of 128 meters and comprises four simply supported spans. Each span features a slab that rests on seven precast beams. A photography of the finished structure is presented in Figure 3.a.

The BIM model of the viaduct was constructed using Revit, based on the structural blueprints, achieving a Level of Detail (LOD) of 300. In this model, elements were organized into the following categories: (1) 'Columns' for the piles and piers, (2) 'Foundations' for the pile caps, (3) 'Walls' for the abutments, (4) 'Framing' for the deck beams, (5) 'Floor' for the deck slab, and (6) 'Structural Rebars' for the steel reinforcement embedded into the concrete elements. A capture of the model is presented in Figure 3.b.

A summary of the parameters and coefficients for the value function of the different indicators considered is presented the Table 2. This figure includes the shape of the value function (decreasing (D) or increasing (I) functions, these being linear (L_r), concave (C_e), convex (C_x) or S-shaped (S), the P_{max}, P_{min}, n_i, m_i, A_i, K_i, P_i, and V_i. For illustrative purposes the value functions of the indicators $I_{1.1.1}$ (Total cost) and $I_{2.1.1}$ (CO_2 emissions) are presented in Figure 4.

(b)

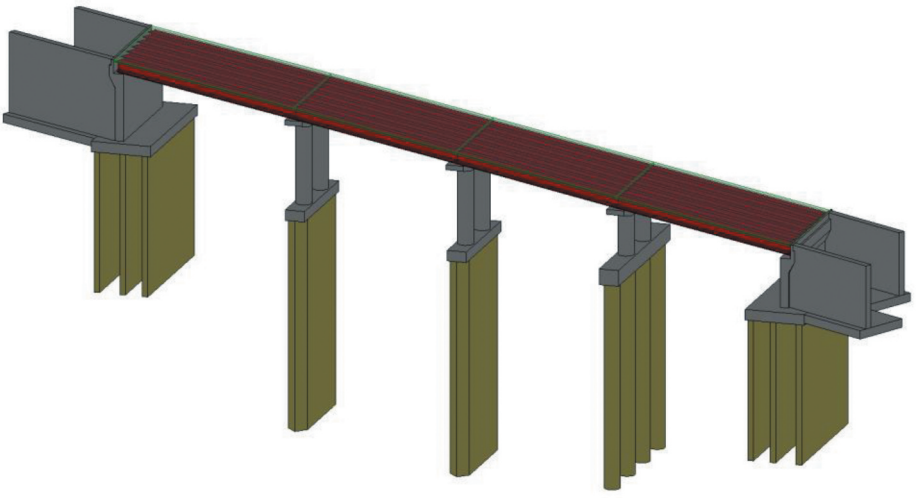

Figure 3. Las Arenas Viaduct: (a) Photography of the finished structure, and (b) BIM model.

Table 2. Parameters and coefficients for each indicator value function (Vi).

Indicator	Shape	P_{max}	P_{min}	n_i	m_i	A_i	K_i	P_i	V_i
$I_{1.1.1}$ Total cost	S-D	1036.18	414.47	625.00	10	1.90	1.00	828.94	0.707
$I_{1.1.2}$ Indirect cost	Cx-D	92.84	78.75	80.00	20	1.90	1.92	82.89	0.607
$I_{1.1.3}$ Maintenance cost	S-D	142.37	71.18	130.00	10	1.90	1.04	94.91	0.804
$I_{1.1.4}$ Dismantling cost	Cx-D	117.86	63.14	75.00	5	1.90	1.07	84.19	0.710
$I_{1.2.1}$ Execution time	S-D	98.00	52.00	160.00	20	2.00	1.24	65.00	0.709
$I_{2.1.1}$ CO_2 emissions	S-D	2682.91	1609.75	1500.00	3	1.45	1.19	2146.33	0.583
$I_{2.2.1}$ Raw material	S-D	12452.86	7471.72	12000.00	7	1.45	1.16	9962.29	0.596
$I_{2.2.2}$ Energy consumption	S-D	23914.29	14348.57	15000.00	4	1.45	1.14	19131.43	0.609
$I_{3.1.1}$ Affected area	Ce-D	6991.88	2913.29	5826.57	4	1.00	1.06	5826.57	0.568
$I_{3.1.2}$ General disturbances	Ce-I	0.00	10.00	3.00	1	1.00	1.04	3.40	0.703
$I_{3.2.1}$ Health and safety	Ce-D	1485.64	891.39	1000.00	3	1.00	1.20	1188.51	0.709

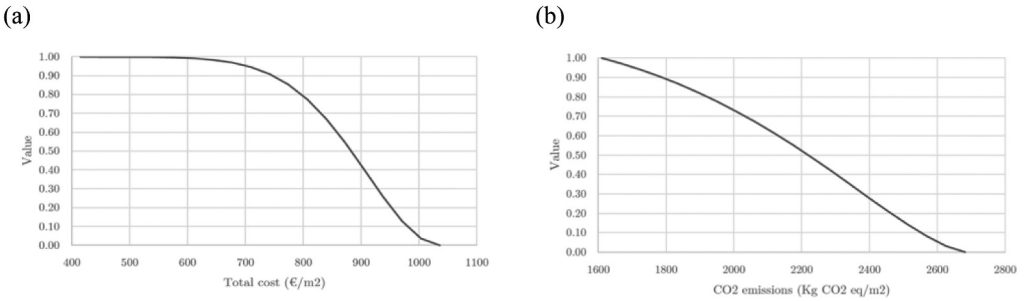

Figure 4. Value function of the indicators: (a) $I_{1.1.1}$: Total cost, and (b) $I_{2.1.1}$: CO_2 emissions.

3.2 *Results*

The sustainability index was examined across three scenarios, each characterized by distinct requirement weights (α). The initial scenario (SI_1) aligns with the reference case derived from the information outlined in Table 1. The second scenario (SI_2) reflects a sustainability balance scenario, where all requirement weights are uniformly set at $\alpha_1 = \alpha_2 = \alpha_3 = 33\%$. Lastly, the third scenario (SI_3) corresponds with a situation where the economic requirement's weight is highlighted, and environmental and social requirements are reduced in relation to the values established in SI_1 (specifically, $\alpha_1 = 75\%$, $\alpha_2 = 10\%$, and $\alpha_3 = 15\%$). It is important to note that both the criteria and indicator weights have remained constant across all three scenarios. Table 3 displays the resulting sustainability index values for each scenario, along with the respective weights assigned to each indicator. Additionally, the product of the different weights α_i, β_i, and γ_i is presented in the table.

Table 3. Sustainability indexes (SI) in the three analyzed scenarios.

Indicator	$[\alpha_1\beta_1\gamma_1]$	SI_1	$[\alpha_2\beta_2\gamma_2]$	SI_2	$[\alpha_3\beta_3\gamma_3]$	SI_3
$I_{1.1.1}$ Total cost	23.10%	0.163	14.00%	0.099	31.50%	0.223
$I_{1.1.2}$ Indirect cost	3.85%	0.023	2.33%	0.014	5.25%	0.032
$I_{1.1.3}$ Maintenance cost	7.70%	0.062	4.67%	0.038	10.50%	0.084
$I_{1.1.4}$ Dismantling cost	3.85%	0.027	2.33%	0.017	5.2%	0.037
$I_{1.2.1}$ Execution time	16.50%	0.116	10.00%	0.071	22.50%	0.159
$I_{2.1.1}$ CO_2 emissions	15.00%	0.087	20.00%	0.117	6.00%	0.035
$I_{2.2.1}$ Raw material	5.00%	0.030	6.67%	0.040	2.00%	0.012
$I_{2.2.2}$ Energy consumption	5.00%	0.030	6.67%	0.041	2.00%	0.012
$I_{3.1.1}$ Affected area	3.20%	0.019	5.33%	0.031	2.40%	0.014
$I_{3.1.2}$ General disturbances	4.80%	0.034	8.00%	0.056	3.60%	0.025
$I_{3.2.1}$ Health and safety	12.00%	0.085	20.00%	0.142	9.00%	0.064
	100.00%	0.678	100.00%	0.664	100.00%	0.698

The analysis of Table 3 shows that sustainability index of the reference scenario (SI_1) is 0.678. In this case, indicators such as total cost, execution time, CO_2 emissions, and health and safety during construction carry significant weight. This index displays slight fluctuations in the two alternative scenarios being considered. Remarkably, the scenario emphasizing the balanced requirements obtained a lower index with a value of SI_2=0.664. In contrast, the scenario focusing on the economic aspect demonstrates a slightly higher sustainability index (SI_3=0.698).

4 CONCLUSION

This paper proposes a new methodology for the evaluation of the sustainability assessment of viaducts. This approach is based on the integration of the MIVES method and the BIM

methodology using parametric programming tools. To illustrate the application of this method its step-by-step application to a real bridge (Las Arenas Viaduct) was studied for eleven economic, environmental, and social indicators.

The results obtained from the analyzed case study illustrate how the proposed methodology facilitates the automated analysis of diverse scenarios by considering both geometric and non-geometric information embedded in BIM databases. In the analyzed structure, a reference scenario was compared with two alternative scenarios- one emphasizing the sustainability balanced, and other simulating an economic crisis. The comparative analysis revealed that the sustainability index exhibited an increase when the significance of economic requirements was heightened, and conversely, it diminished when a balance among all requirements was maintained.

A new multi-source data fusion method for seismic identification of bridge

An Chang & Hongya Qu
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: In this study, a novel parameter identification method based on data fusion algorithm is proposed. A set of sparse matrix equations on state variables is obtained by establishing the state space system of bridge structure parameters. Data passed into the equation is multi-source and heterogeneous, which includes time-history measurements of acceleration and velocity, and displacement estimation acquired from digital image correlation. Bayesian inference with multi-process modification is applied to solve the equation. With the capability of eliminating ill-conditioned equation, method is verified through shake table test. Applying the method to a series of raw test data, results show that estimation error of the identified seismic excitation time history is at a very low level, which represents good effectiveness. Material parameters calculated from the excitation recognition results of the tested specimen are also in good agreement with estimated results, indicating feasibility in practice.

1 INTRODUCTION

Bridge seismic monitoring data serves as a crucial foundation for assessing the post-earthquake functionality of bridges. In structural health monitoring (SHM), various sensors continuously measure and collect relevant physical quantities at predetermined measuring points on the structure, storing the data for subsequent collation and analysis. Commonly used sensors in SHM include displacement sensors, strain gauges, accelerometers, and so on. As sensing technology advances and detection demands increase, new devices and technologies such as speckle interference imaging, digital cameras, structured light projection have been applied in SHM. While these new technologies provide more available data and information for bridge SHM research, they also present new challenges.

The key challenge lies in effectively integrating multi-source heterogeneous sensor data with different data dimensions to achieve parameter identification, damage diagnosis, maintenance decision-making, and operational decision-making. This problem is known as multisource heterogeneous data fusion (MHDF). Currently, traditional time-frequency domain methods, machine learning techniques, probability theory and statistics, as well as heuristic algorithms are being applied as common MHDF algorithms (Hall 1998; Zhang 2021).

For the sensor information processing of building structure, the current research mainly focuses on the calculation of mechanical parameters under small disturbance, component damage monitoring, vehicle load identification and other directions, which mostly focuses on the analysis and fusion of SHM data under normal use state (Kralovec 2020; Wu 2020), while the research of MHDF for bridge seismic response detection data is still blank. The effect of earthquake on bridge structure usually presents strong randomness and nonlinearity, which may lead to sensor failure and data loss and error. When using image sensors, the extraction of global image displacement and other features of image signals is more complex than that of displacement meter and accelerometer due to its large amount of data and large data dimension (Chen, J.G. 2018).

DOI: 10.1201/9781003483755-283

The change of dynamic parameters of bridges in earthquakes has a significant effect on the evaluation of bridge seismic performance, but the traditional single-source and homogeneous sensor data often have certain limitations in the evaluation of the change process of bridge dynamic parameters in earthquakes, such as single identification parameter and low accuracy (Zhu 2020). For this problem, some scholars have conducted certain theoretical research. For example, Feng et al. (2015) first proposed a new method to simultaneously identify the vehicle axle load of bridge structural parameters and vehicle-bridge interaction system from a limited number of responses. In this study, the vehicle-bridge interaction of simply supported girder bridge and continuous girder bridge was mechanically modeled, and the dynamic control equation in the form of state space and matrix was established. Based on this study, Sun et al. (2015) proposed a new heterogeneous data fusion method for the node excitation identification problem of truss bridge. This method combined the new regularization method based on time domain Bayesian inference to solve the problem of ill-conditioned state equation.

However, the application of MHDF in bridge SHM in existing literature primarily focuses on conventional scenarios where the excitation is small and time-varying parameters of the structure are not considered. Earthquakes, being strongly nonlinear, random, and causing large displacements, can significantly affect the mechanical parameters of a structure or even lead to structural damage. Bridge SHM systems typically incorporate various heterogeneous sensors such as displacement sensors, acceleration sensors, image sensors, etc., resulting in a substantial amount of long-term data generation (Xiong 2002). Considering the growing demand for bridge disaster prevention and structural strength assessment purposes, it becomes imperative to develop MHDF algorithms that are suitable for seismic excitations and enable accurate identification of structural parameters by effectively utilizing sensor data during earthquake events.

This paper proposes a novel approach for identifying the time history of seismic excitations and structural parameters. The method employs the extended Kalman filtering (EKF) algorithm to update the matrix of structural parameters and external loads. Additionally, it utilizes the regression shrinkage method based on first-order and second-order norms to address singularity issues in the parameter matrix and correct baseline drift in dynamic parameters (e.g., velocity and displacement) caused by integration. Furthermore, a heuristic search algorithm is employed to calculate optimal mechanical parameters at each time step.

2 METHODOLOGY FORMULATION

2.1 *Basic ideas*

The proposed MHDF algorithm is shown in Figure 1. It aims to estimate the complete process of seismic excitation by utilizing time series data collected from heterogeneous sensors and to determine the changing pattern of structural parameters (e.g., elastic modulu3) under loading conditions. Initially, the sensor data are acquired, cleaned, and filtered, followed by extracting

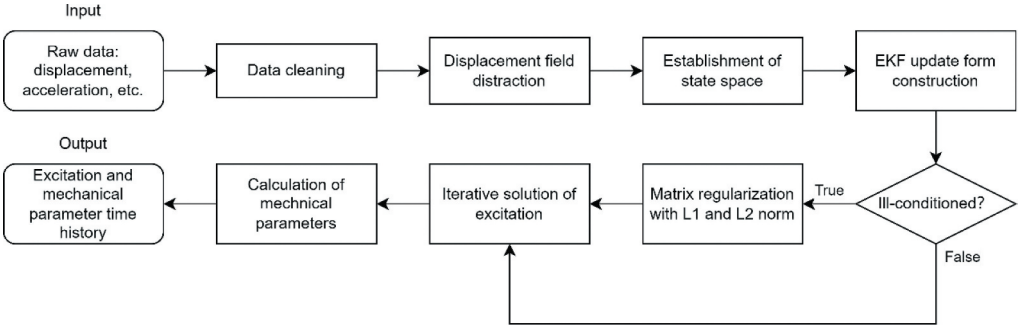

Figure 1. Flowchart of bridge parameter identification based on MHDF.

and modeling the displacement field of a specific section of the structure using digital image correlation (DIC) photography. By establishing a state space model and constructing an updated parameter matrix based on the EKF algorithm, the seismic excitation time history is iteratively solved. Subsequently, a search algorithm based on genetic algorithm is employed to update the model parameters, ultimately leading to acquirement of the relationship between structural parameters and loading condition.

2.2 *Data cleaning and extraction of displacement field*

Due to potential noise interference or sensor failure during data collection, it is necessary to perform basic cleaning and filtering on the original data. In this study, the noise is treated as a sparse vector representing differences throughout the entire process. By transforming the solution of the specific vector into a first-order norm minimization problem for estimating acceleration differences between time steps, hyperparameters can be approximated and adjusted to account for real acceleration drift errors. This approach is known as the first-order norm regression shrinkage method or LASSO method.

In the case of image sensors such as DIC, feature extraction is necessary to convert them into displacement fields within the shooting area. This is crucial for establishing the state equation and preventing potential singularity of parameter matrix in state equation. Figure 2 represents a frame selected from experimental DIC data of one pier from a simply supported beam bridge. The region can be modeled as the surface boundary of a columnar elastomer, and its mapping relationship with the node unit displacement of a multi-degree-of-freedom spring-damping model can be established through elastic theory.

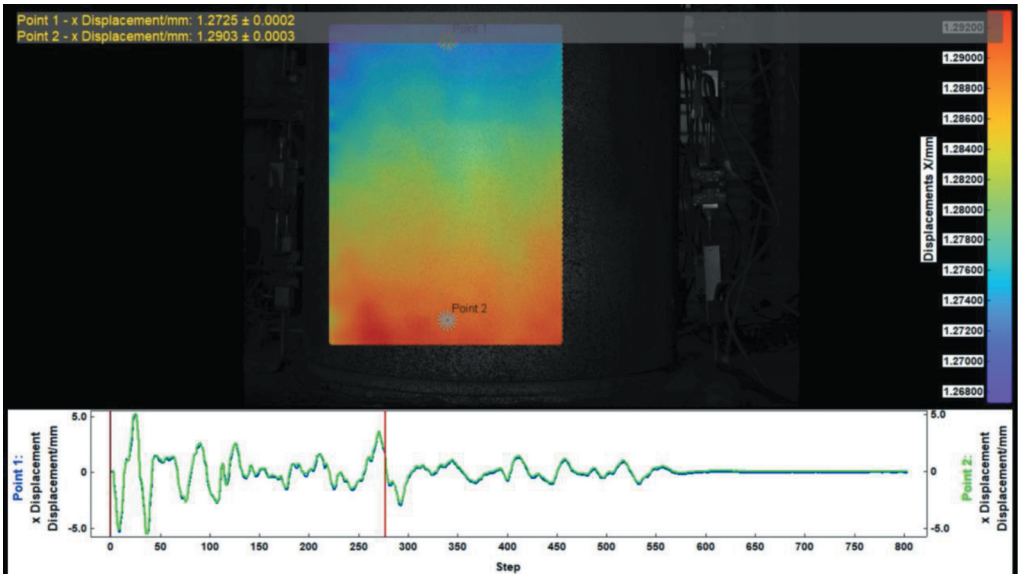

Figure 2. A frame selected from DIC displacement field data.

2.3 *State space construction and introduction of EKF*

The establishment of the state space in this study is based on the dynamic equations. The sensor data collected are primarily classified by dimensions such as displacement, acceleration, rotation angle, etc. Therefore, it is crucial to establish a correlation between the sensor data and structural parameters and external excitations. The studied structural parameters mainly include flexibility matrix, damping matrix, elastic modulus, etc., thus necessitating the

establishment of a mapping relationship between strain and displacement using geometric equations in elastic theory.

Subsequently, the dynamics differential equation is investigated. After processing each time step's state space with standardized matrices, seismic excitation can be solved using numerical methods such as Newmark-β. Given the inherent system nonlinearity in this study, EKF is employed for updating and predicting seismic excitation and parameter matrices. Since the mechanical parameters of the system itself may be time-varying, the use of EKF can better take into account the evolution of the system and avoid directly solving the coupling phenomenon of physical quantities that may exist (such as potential Duffing system), thereby improving the accuracy of recognition and the efficiency of denoising.

After establishing the state space, it becomes necessary to address the issue of ill-conditioning in the latent equation. The parameter matrix may become singular due to noise, potential collinearity, and other factors, rendering it unsolvable using ordinary least squares method. To overcome this challenge, regularization or regression shrinkage methods can be employed. Common regularization techniques include L1 regularization (LASSO regression) and L2 regularization (Ridge regression). In this study, we opt for utilizing the Elastic Net (EN) method which combines both L1 and L2 terms. EN offers sparsity through L1 regularization while effectively suppressing collinearity. By adjusting its hyperparameters, we can eliminate matrix singularity as well as enhancing computational efficiency. To clarify, the equation-solving problem is reformulated as a minimization problem involving a loss function comprising terms of first-order and second-order norms in every time step.

3 EXPERIMENTAL VERIFICATION

The effectiveness of the MHDF scheme was evaluated through shaking table test, as depicted in Figure 3. In this study, a scaled model of a simply supported girder bridge was subjected to shaking table experiments using amplitude modulation output of peak ground acceleration (PGA). Various parameters including the displacement and acceleration of the pier cap, displacement and acceleration of the bridge girder, and rotation of the girder were measured throughout the experiment. DIC monitoring was employed at the pier to obtain comprehensive displacement field data for fusion analysis.

Figure 3. The shaking table test of the double-column pier simply supported girder bridge.

The loading interval used in this study was set at 0.1 times the target PGA, gradually increasing with a step size of 0.1 times until reaching destructive deformation levels. The excitation source primarily relied on seismic records from the El Centro earthquake in the PEER seismic database. Additionally, white noise with an intensity level of 0.13g was applied between each load to ensure sufficient frequency domain coverage. The total loading time of the test was 52.55s, and the sensor monitoring step size was set to 0.0039s.

Through the aforementioned data fusion strategy, the drift vector of acceleration can be obtained as depicted in Figure 4. The state space is constructed by utilizing the modified acceleration and displacement information, and the update and prediction modes of EKF are iteratively solved to ultimately identify seismic excitation as the target recognition. Moreover, the identified seismic excitation's prediction results are evaluated using root mean square error, while residual autocorrelation testing is conducted. It is observed that the residual conforms to a random distribution with minimal error. The variation of pier elastic modulus obtained from material tests is compared with identified results, confirming accurate identification of elastic modulus under significant deformation and displacement conditions. An iterative process was conducted with an error threshold of 10^{-8}. It was verified that this method achieved convergence and yielded an average prediction error below 10%. Moreover, it demonstrates a relatively stable recognition outcome even under significant displacement conditions.

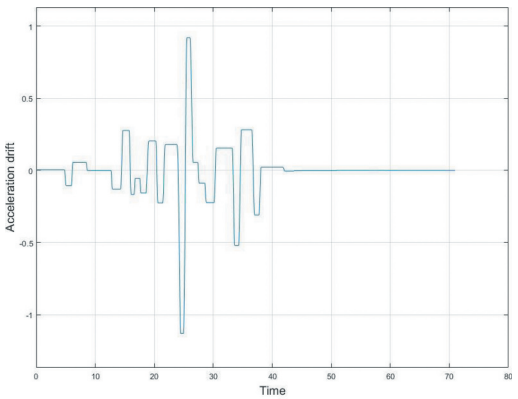

Figure 4. Identified acceleration drift vector.

4 CONCLUSIONS

In this paper, a new method is proposed for identifying bridge parameters and excitation time history in scenarios involving large displacement and strong nonlinear excitation. The method utilizes MHDF and primarily employs the extended Kalman filter to update and predict mechanical parameters and external excitation at each time step. To address potential ill-conditioned problems in the equations, L1 and L2 regularization techniques are employed. To validate the proposed method, numerical studies are conducted using ABAQUS to establish a finite element model, which is further verified through shaking table tests. The main findings of this study can be summarized as follows:

1. In the case of a single span simply supported beam model, displacement and acceleration parameters of the pier, cover beam, and main beam are considered. Despite strong earthquake scenarios, the proposed method effectively estimates the entire process of external load. When compared with actual test results, calculated results from our method exhibit smaller mean square error with residual errors conforming to random distribution patterns. This indicates that the data fusion approach is feasible in practical applications.

2. By standardizing procedures and employing first-order norm (L1) and second-order norm (L2) regularization techniques, we successfully eliminate ill-conditioned matrix problems while reducing computational complexity during EKF updating processes. Additionally, by establishing displacement-strain relationships through geometric equations, our proposed method enables obtaining time-varying processes of mechanical parameters for bridge structures.

G. Chen
Department of Civil, Architectural, and Environmental Engineering, Missouri University of Science and Technology, Rolla, Missouri, USA

ABSTRACT: Concrete bridges are vulnerable to both natural and man-made disasters, as well as aging and deterioration processes throughout their lifespan. Timely detection of defects in concrete structures is crucial for repair and decision-making purposes. However, traditional methods like visual inspection are time-consuming and expensive. Unmanned aerial vehicles (UAVs) equipped with infrared thermography (IRT) offer an efficient and cost-effective solution for detecting defects in concrete structures. This study presents passive and active IRT techniques for detecting common concrete defects, such as delamination and cracks. Principle and methods for quantifying these defects and evaluating the extent of damage are introduced. Experiments are conducted to validate the reliability of the algorithm. In conclusion, UAV-based IRT proves to be an effective method for detecting defects in concrete bridge structures.

1 INTRODUCTION

Bridges are the bottlenecks of infrastructure constitutes an essential component of the country's transportation network, which require sufficient maintenance to ensure their serviceability and safety. According to the report from American Road & Transportation Builders Association, more than one-third, or 220,000 of the nation's 618,000 bridges need structural repair, rehabilitation work or replacement (Black, 2022). Among all reinforced concrete bridge components, bridge decks have been the leading contributor to most deficient bridges in the United States (Maser et. al., 2012). Indeed, bridge decks have been identified as the most problematic, due to various forms of deterioration mechanisms.

Concrete delamination and cracking are the main reasons leading to bridge deck deteriation, which is attributed to many possible reasons, such as construction deficiencies, creep, temperature gradients, corrosion, and unforeseen over-load, etc. Once delamination and crack occurred, the path allows chloride ions, oxygen, and moisture more easily to penetrate adjacent concrete and rebar level, which will accelerate the process of rebar corrosion. The development of corrosion can cause delamination and concrete spalling, eventually reducing the load capacity of bridge deck and even threatening the safety of bridge when exposed to excessive external loads (Gucunski, 2010). Therefore, the localization and quantification of delamination and crack is critical importance to ensure the structural safety of concrete bridges and optimize maintenance and repair needs.

The evaluation of RC bridge decks is complex due to the heterogeneous nature of concrete. As a default bridge deck inspection methodology, visual inspection however has several limitations

DOI: 10.1201/9781003483755-284

including unavailable to inaccessible places, inability to detect hidden defects, and its operator sensitivity (Moore et. al., 2001). There are currently several Non-destructive Test (NDT) methods capable of reliable crack depth assessment for bridge decks based on acoustic, electric, electromagnetic, thermal, and other physical phenomena. Generally, such techniques utilize an approach to capture the characteristics of the medium from its response to an applied excitation (Gucunski, 2010 & ACI, 2013). However, it is difficult to access every concrete surface area located in the bottom of bridge deck with high altitude and other inaccessible places.

Infrared thermography (IRT) is a NDT technology that is often adopted for detecting characteristic thermal signatures related to RC bridge deck deterioration (Maser et. al., 2012 & Pozzer et. al., 2020). Such remote sensing technology provides data visualization in the form of real-time thermal images and does not require direct access to the surface under inspection. Currently, unmanned aerial vehicle (UAV) combined with IRT becomes more and more popular for bridge deck inspections, due to the advantages of no traffic block, fast, cost-effective, and reliable data collection. With the help of advanced artificial intelligent method, automatic bridge damage detection can be achieved more effectively and efficiently (Ding et. al., 2023). However, the delamination detection using UAV-based passive IRT method at the top of bridge deck in accordance with threshold defined by AASHTO has not been evaluated yet. In addition, the crack detection using UAV-based active IRT method in high resolution and fast way at the bottom of bridge deck has not been studied. Therefore, this study presents the case study of UAV-based passive and active IRT for delamination and crack detection, respectively, on the top and at the bottom of bridge decks.

2 PRINCIPLE

The principle of the passive and active IRT respectively for delamination and crack detection on the top and at the bottom of bridge deck is illustrated in the Figure 1. For passive IRT, solar is used for energy input. When a delamination layer initiated from the debonding between concrete and rebars, air occupies the space formed by the delamination. As a result, the thermal conductivity of the deteriorated region will be reduced. In the daylight, the delamination area will block the heat transfer from the top layer to bottom layer of concrete, and the heat will accumulate on the top of delamination area. This will result in a higher temperature difference between delamination and sound area. For active IRT, non-natural heat source should be adopted for crack detection at the bottom of the bridge deck. For example,

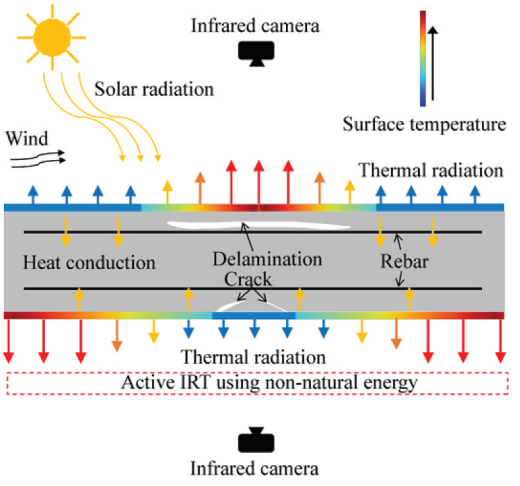

Figure 1. Schematic diagram of passive IRT and active IRT respectively on the top and at the bottom of bridge deck.

a thermal pulse is applied to a surface causing a non-stationary heat flow. The pulse heat conduction in the sound region is more efficient than cracking region, causing lower radiation heat and temperature at the bottom surface of the cracking region. These inhomogeneities in the near-surface region of the structural element, including delamination and crack, will result in measurable temperature differences in the local area of the surface.

3 PASSIVE IRT TEST

For passive IRT test, four specimens with artificial delamination were prepared. Each specimen was embedded with four large and eight delamination in different elevation. The dimension of the specimen is 114 cm in width, 183 cm in length, and 18 cm in height. The dimension and embedded depth of the delamination are presented in Table 1. The thermal properties of the materials used in this study is shown in Table 2.

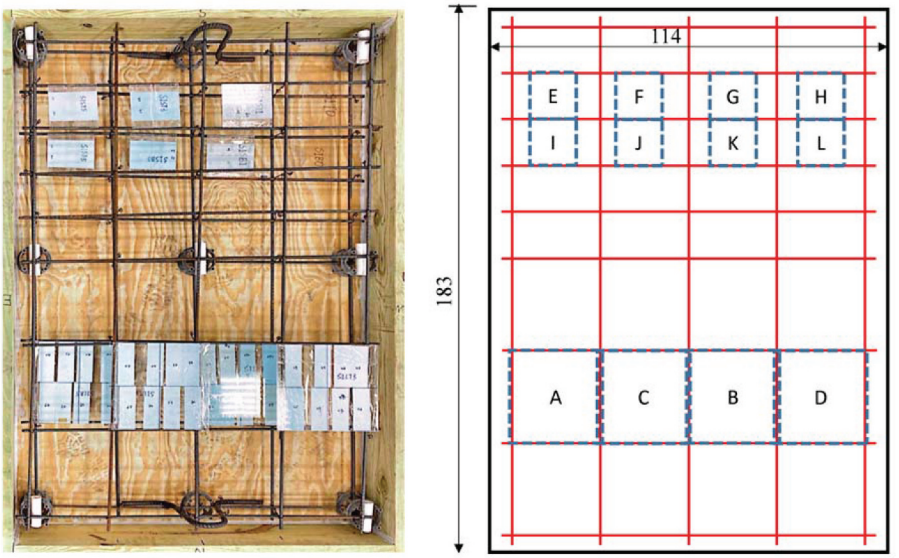

Figure 2. Specimen photo and schematic view for delamination detection of bridge deck. (Unit: cm).

Table 1. Dimension of delamination. (Unit: cm).

	A	B	C	D	E	F	G	H	I	J	K	L
length	30.5	30.5	30.5	30.5	15.2	15.2	15.2	15.2	15.2	15.2	15.2	15.2
Height	0.56	0.36	0.56	0.36	0.56	0.36	0.16	0.06	0.56	0.36	0.16	0.06
Depth	2.5	2.5	15.5	15.5	2.5	2.5	2.5	2.5	15.5	15.5	15.5	15.5

Table 2. Thermal properties of materials.

Material	k (W/m·K)	c (J/g·K)
Concrete	2.006	1.807
Steel rebar	45.000	3.500
Plastic board	0.213	1.274
Styrofoam board	0.024	0.025
Air	0.025	1.000

The four concrete bridge decks were placed side by side on a specially designed steel frame support to form a mock-up girder bridge, in order to mitigate the influence of the heat transfer from the ground. Ice block is used to provide an additional reference temperature to ensure the camera has been well calibrated in factory. An UAV (Model: DJI M600) equipped with a thermal camera was used to capture the thermal images at an altitude of 12 m above the bridge under sunlight. A weather station was set up on the Van to obtain weather information, such as wind speed, wind direction, ambient temperature, illumination intensity, etc. The tests were carried out at 14:00 as recommended by Washer et. al., 2010, when the temperature contrast between delamination and sound area is highest.

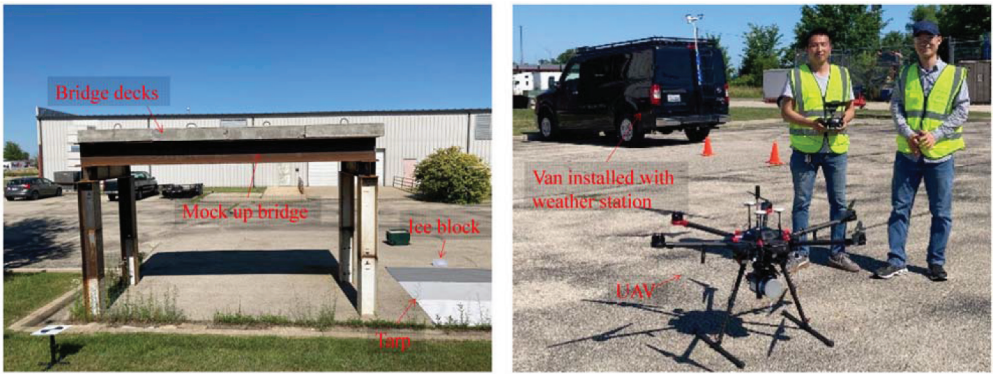

Figure 3. Test setup of passive IRT.

The thermal image of four bridge decks was transferred into binary image using gradient method, as shown in Figure 4. It can be found that all the shallow embedded large delamination and most of the shallow embedded small delamination can be detected through passive IRT method. However, some of the shallow embedded delamination with equivalent thickness of 0.06 cm cannot be distinguished due to the slight temperature difference. All the delamination with deep embedded of 15.5 cm cannot be detected. This test results satisfy the critical threshold levels in terms of size (15×15 cm) and embedded depth (2.5 cm) as defined by AASHTO.

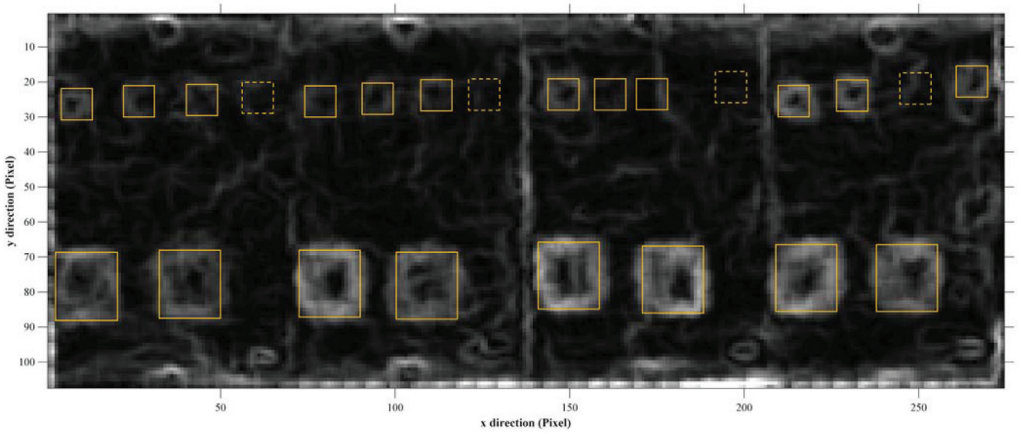

Figure 4. Delamination detection results for four concrete slabs.

4 ACTIVE IRT TEST

A concrete beam with artificial crack was prepared for active IRT test. Six cracks with the consistent width of 0.45 cm and depth of 1~6 cm at an interval of 1 cm were cut as shown in Figure 5. The ceiling drone that can fly against the bottom of bridge deck was designed and fabricated. The distance between the drone and the deck is only 18 cm, to get a best resolution of thermal and optical images. A laser generator is adopted as the non-natural heating source.

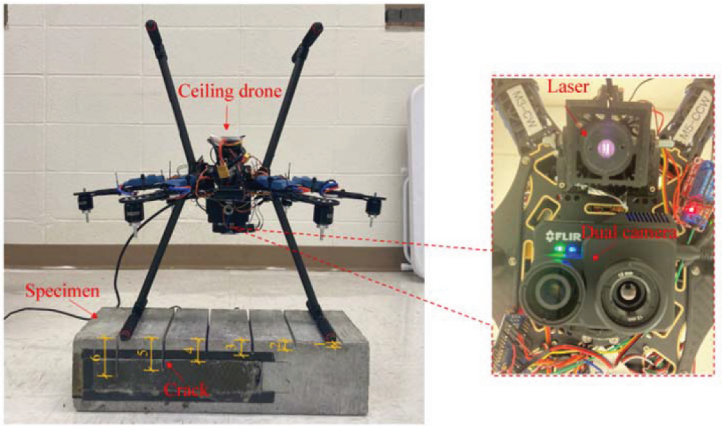

Figure 5. Test setup of active IRT. (Unit: cm).

The test results of thermal images of the crack detection with crack depth of 5 cm were presented in Figure 6. It can be found that the stable time of the thermal images at crack area is about 10 s. Similarly, other type of crack depth can be calculated as well, which was shown in Figure 7. It is shown that the relationship between stable time and crack depth is almost linear when the crack depth is larger than 1 cm. Therefore, utilizing the stable time of thermal image captured by active IRT, the crack depth at the bottom of concrete bridge deck can be obtained.

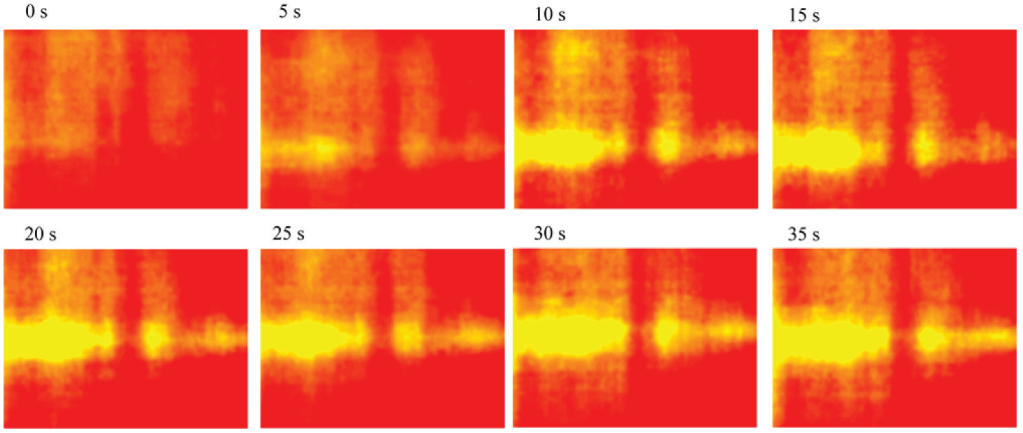

Figure 6. Test result for crack detection with crack depth of 5 cm using active IRT method.

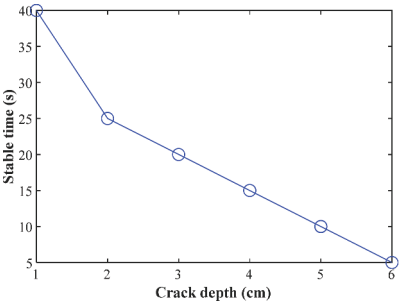

Figure 7. Relationship between crack depth and heating time.

5 CONCLUSION

This study presents case studies of UAV-based passive and active thermography for delamination and crack detection on the top and at the bottom of bridge deck, respectively. This method provides a fast and accurate way to quantify the deterioration of the bridge deck. The critical size and depth of the delamination as defined by AASHTO can be successfully detected. The relationship between stable time of thermal images and depth of the crack was established for ease of quantifying crack in practical application.

Senmos: A user-centered approach to structural health monitoring with applications on Lillebæltsbroen af 1935

Kasper Myrtue & Sandra D. Myrtue
KI Rådgivende Ingeniører, Denmark

Jakob Larsen & Pernille N.L. Sørensen
LIFA, Denmark

ABSTRACT: The increasing prevalence of Structural Health Monitoring (SHM) in recent years has led to a significant diversification of user profiles and a consequent demand for a more user-friendly approach in software and data exploration tools. Traditional SHM systems, tailored to large structures such as bridges and tunnels, often lack an intuitive interface and comprehensive data exploration facilities. In contrast, small-scale SHM systems frequently resort to a rudimentary file transfer protocol (FTP) server for data delivery. This research paper seeks to explore the prevailing usability issues associated with conventional SHM systems, focusing on two common use cases: alarm investigation and data correlation. Each use case is dissected to illuminate specific user experience components that often present challenges to users. Born out of the experience of developing Konmos[1], a structural health monitoring platform originally designed for the Great Belt Bridge in Denmark, Senmos represents an innovative departure from conventional SHM tools. Consciously designed with a user-centric approach, Senmos addresses usability concerns inherent in many traditional SHM platforms. The application of Senmos is then elaborated through a case study of its deployment on Lillebæltsbroen af 1935 in Denmark. By detailing how each user experience issue was resolved within the context of Lillebæltsbroen af 1935, we illustrate the effectiveness and adaptability of Senmos, providing evidence of its potential for broad scalability. The development of Senmos emphasizes the importance of considering the end-user experience in the design and implementation of SHM tools. As SHM practices continue to evolve, software solutions like Senmos that prioritize user experience, flexibility, and accessibility, will play an increasingly critical role in enabling efficient and effective monitoring for all types of structures.

1 INTRODUCTION

Structural Health Monitoring (SHM) has emerged as an indispensable tool for ensuring the longevity, safety, and optimal performance of infrastructure, especially structures such as bridges, tunnels, and skyscrapers. By employing a network of sensors, SHM systems constantly collect and analyze data to detect anomalies, assess damage, and predict the future health of structures. While the core objective of SHM is to provide real-time insights into the health of structures, the efficacy of this monitoring is closely tied to the tools and platforms that process, store, and present this data.

1. Kasper Myrtue & Nuno Martins (2021) SHM at the Great Belt Fixed Link in Denmark. SHMII 10 Conference.

DOI: 10.1201/9781003483755-285

Traditionally, the design of SHM platforms has been predominantly data-centric, focusing on the accurate collection and storage of sensor readings. Today, a broad spectrum of professionals, from field engineers to decision-makers, rely on SHM data. Yet, many of these individuals find themselves grappling with platforms that, while robust in data collection, often falter in user accessibility and intuitive data presentation.

Consider the conventional use of rudimentary file transfer protocols (FTP) for data delivery in smaller SHM systems. While FTPs are reliable, they are far from user-friendly, especially for those without technical backgrounds. Larger systems, tailored for monumental structures, often host vast troves of data but lack streamlined and intuitive interfaces for exploration. It's not uncommon for users to navigate through split systems or wrestle with hard-to-access data archives, leading to inefficiencies and potential oversights.

Senmos is a platform that seeks to reconcile the traditionally data-centered approach of SHM with the pressing need for user-centric design. Drawing inspiration from the principles of web platform usability, especially Nielsen's 10 heuristics[2], Senmos endeavors to transform how SHM data is accessed, visualized, and analyzed. But why is this shift towards user-centered design paramount for SHM's future? This article delves into the challenges of traditional SHM platforms, the paradigm shift introduced by Senmos, and the broader implications of aligning SHM tools with the evolving needs of its diverse user base.

In the development of Senmos, a user-centric design approach was selected from the beginning rather than the more traditional data-driven solutions. The 10 Usability Heuristics for User Interface Design by Jakob Nielsen were used for inspiration and to keep the right focus on the user's needs throughout the design of the user interface. While all 10 heuristics, or guidelines, are relevant, 3 in particular have had a huge impact on the user experience of the platform in comparison to traditional monitoring solutions:

1.1 *Visibility of system status*

Senmos very quickly lets the user know if sensors give errors or alarms, where the given sensors are located, and what caused the message. Furthermore, the overview dashboards quickly let the user get a live status of all sensors values in a logical and ordered format.

1.2 *Match between system and real world*

An important feature in Senmos, is the fact that rather than having to look through long lists of data and ID-numbers, the user can see live values and alarms depicted on images or drawings of their structure. This makes it easy and fast to pinpoint sensor type, location, and name and to see correlation between different sensors when looking at the data.

1.3 *Recognition rather than recall*

Throughout the platform the user is being presented with options rather than having to type in data themselves. This, for instance, is true for picking sensors through icons in menus, or clicking live values on dashboards to display data graphs. The sensors are easily sorted by type, location or status in several different ways, helping the user get to relevant data quickly without having to recall any ID's or names.

2. Molich, R., and Nielsen, J. (1990). Improving a human-computer dialogue, Communications of the ACM 33, 3 (March), 338-348.

2 COMMON USABILITY PROBLEMS IN TRADITIONAL STRUCTURAL HEALTH MONITORING

2.1 *Finding correlations in data*

The ability to discern correlations in structural health data is pivotal for understanding the dynamics of structures under various conditions, such as weather changes or load variations. Traditional SHM systems, however, often present a fragmented approach to data analysis, requiring civil engineers to manually plot and examine data files. This reliance on intuition and manual processes not only increases the likelihood of oversight but also restricts the depth of analysis, particularly when trying to distinguish between regular structural behavior and anomalies.

In contrast, Senmos revolutionizes this process by integrating data correlation tools directly within its platform. Unlike traditional or general-purpose cloud solutions, which may offer basic data plotting features without specialized focus, Senmos is tailored specifically for SHM. It provides an intuitive interface where users can effortlessly overlay various sensor data types to uncover hidden correlations. This feature is especially beneficial in cases like correlating strain gauge data with vehicular loads to assess road fatigue or analyzing weather impacts on structural behavior.

Senmos's correlation tools are designed for simplicity and effectiveness. Users can access a comprehensive data archive where any combination of sensors can be visualized together, making it straightforward to spot correlations, particularly with static sensors where movements occur over extended periods. For dynamic sensors, where detecting correlations can be more challenging due to rapid data fluctuations, Senmos offers a dedicated correlation plot feature. This tool allows plotting two sensors against each other, with the calculation of correlation coefficients, providing clear visual cues for positive or negative correlations.

Such advanced correlation capabilities in Senmos not only make it easier to discover meaningful connections between different data sets but also significantly reduce the time and effort required for data analysis. By lowering the barrier to data exploration, Senmos enables a broader range of users, from field engineers to decision-makers, to engage with SHM data more meaningfully. This approach contrasts sharply with older SHM methods or non-specialized cloud platforms, which often require more technical expertise and time-intensive procedures to achieve similar results.

2.2 *Investigating alarms*

In traditional SHM systems, when a sensor threshold is breached, the typical protocol is to dispatch an alarm email to the user, detailing the sensor's location and the value causing the alarm. However, this often leaves users at a crossroads, trying to determine the legitimacy of the alarm - is it a genuine structural issue requiring immediate attention, or merely a sensor malfunction?

Senmos seeks to revolutionize this process by enhancing user interaction and data accessibility. When an alarm is triggered, not only does the user receive the customary notification, but they're also presented with a clickable link. This link leads to a concise visualization of the past month's data for the sensor in question, displayed in an intuitive popup window.

This immediate access to relevant historical data facilitates rapid preliminary assessments. Sensor malfunctions often manifest as abrupt and large variations between data points, unrealistic for any real-world structural change. Such aberrations, caused potentially by a severed wire or a damaged sensor, can quickly be differentiated from genuine structural alarms.

Furthermore, noisy sensor outputs, which may send out alarms due to temporary spikes, can be discerned by analyzing the statistical mean of data over time. If this mean suggests that the actual structural movement is significantly less than the alarm value, it can be inferred that the alarm was possibly erroneous.

For those cases where a month's data isn't sufficiently illuminating, Senmos provides an expansive data archive. Here, users can juxtapose the data of the alarmed sensor with others, delve into tailored statistical views, or even isolate specific timespans for a more granular analysis.

The ability to swiftly and efficiently verify alarms not only instills confidence in the system but also empowers users to make informed decisions. When it comes to large infrastructure, where operational ramifications hinge on sensor outputs, such immediacy and clarity become paramount. Misinterpreting a sensor's alarm can lead to unnecessary interventions or, conversely, overlooking critical structural issues.

By simplifying and enhancing the alarm investigation process, Senmos ensures that users are no longer in the dark. Instead, they are equipped with the tools and insights necessary to discern genuine structural concerns from sensor anomalies, ensuring timely and appropriate responses.

3 CASE STUDY: LILLEBÆLTSBROEN AF 1935

Lillebæltsbroen af 1935 is owned and operated by Banedanmark, with sensor systems provided by the company LIFA for structural health monitoring. In 2023, the decision was made to implement Senmos as the data platform for monitoring this vital infrastructure. The primary objectives of deploying Senmos were to achieve real-time visualization of the bridge's condition, enable the extraction and analysis of historical data, and effectively manage sensor status and operation.

Figure 1. Lillebæltsbroen af 1935, senmos, overview dashboard.

3.1 *Sensor systems*

Lillebæltsbroen af 1935 features multiple sensor systems designed to monitor various aspects of the bridge's condition. These sensor systems are outlined in Table 1, with their respective functions described below:

1) Inclinometers on Pillars (8 units): Initially designed to monitor scour protection, these inclinometers served a critical role during a project aimed at safeguarding the bridge's pillars. Large rocks were strategically placed near the pillars to stabilize the soil around their foundations.

To ensure the pillars did not incline or tilt during the project, a monitoring system was devised. Initially, the system involved a steel wire threaded vertically through pillar 2 and 3, with a weight attached to its lower end. If any pillar exhibited angular movement, the steel wire would make contact with a small copper ring, completing an electrical circuit and triggering an alarm. However, this system had its limitations, including false alarms caused by birds nesting inside the pillars and a lack of detailed movement tracking.

To address these challenges and enhance monitoring precision, the steel wires and copper rings were replaced with inclinometers. These sensors provide real-time, precise measurements of the inclination of each pillar, allowing for continuous monitoring of pillar movement over time with high accuracy. This upgrade eliminated false alarms and enabled workers on the bridge to proactively track and respond to any subtle changes in pillar inclination.

2) and 3). Humidity and Air Temperature Sensors (16 units each): Positioned in the foundation of the pillars, these sensors track moisture and temperature levels to maintain sealed foundations and prevent moisture from continuously permeating the concrete by keeping the concrete and air on the inside fully humid.
3) Hydraulic System (1 unit): Monitored using a pressure sensor, this system tracks oil status and the condition of the enabling switch for the hydraulic buffer.
4) Total Stations (2 units): Located at land-adjacent pillars, total stations measure vertical displacements at the pillars.
5) Horizontal Displacement Sensors (11 units): These sensors monitor movement at expansion joints and rolling bearings.
6) Steel Temperature Sensors (4 units): Placed in one cross-section of the bridge, these sensors are used to correlate temperature changes with structural displacement to assess the impact of temperature variations.
7) Weather Station (1 unit): Positioned atop the bridge, this weather station includes an anemometer, rain gauge, air temperature, relative humidity, and air pressure sensors. It serves to analyze weather conditions and determine suitable conditions for bridge maintenance activities.

Table 1. List of sensors on Lillebæltsbroen af 1935.

Num.	Sensor type	Placement	Amount
1	Inclinometer	Inside pillars above sea level	8
2	Humidity	In pillar foundation below sea level	16
3	Air temperature	In pillar foundation below sea level	16
4	Hydraulics	In deck expansion joint	1
5	Total station	Externally on pillars	2
6	Displacement	In bridge deck	11
7	Steel temperature	Bridge deck	4
8	Weather station	Top of bridge	1

3.2 *Senmos on Lillebæltsbroen af 1935*

The implementation of Senmos on Lillebæltsbroen af 1935 aimed to achieve three key objectives in monitoring:

3.2.1 *Visualization of bridge conditions*

Each sensor system on the bridge is represented through a dedicated dashboard, simplifying real-time monitoring. As discussed in Section 3.1, these systems are configured to detect specific potential issues or to correlate data with other sensors. This arrangement allows for easy categorization by sensor type, facilitating straightforward value comparison and issue identification.

For instance, consider the inclinometers on pillars (see Figure 2). Live inclinometer data is displayed on a wire diagram of the bridge, offering a quick and clear overview of sensor

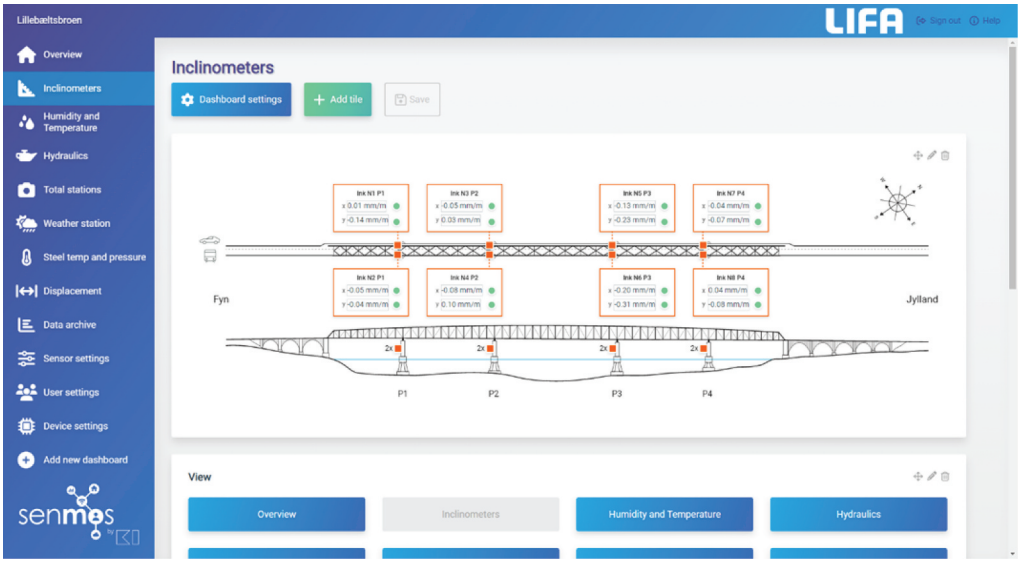

Figure 2. Inclinometers of pillars.

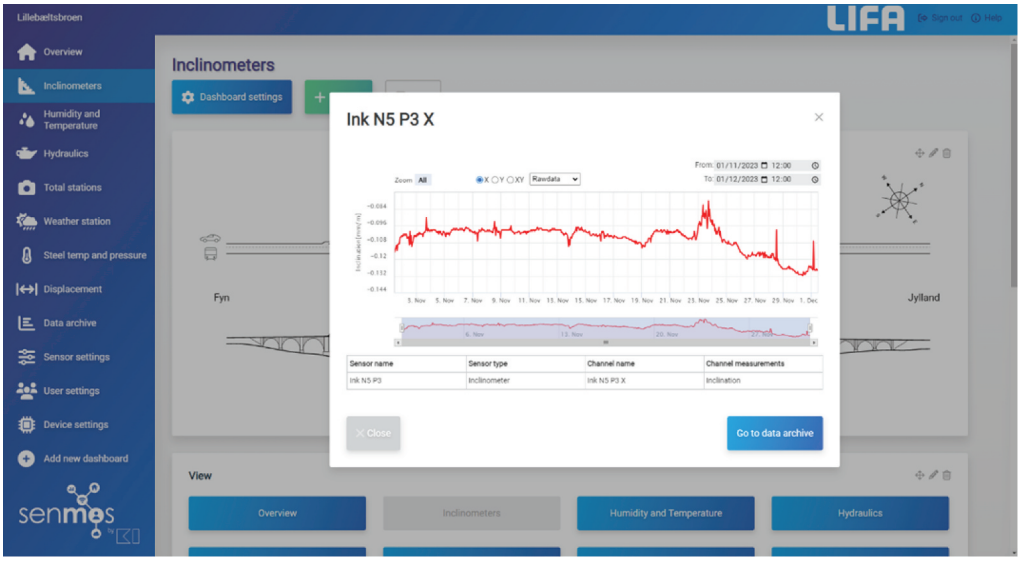

Figure 3. Pop-up with the last month of data from an inclinometer.

locations. Clicking on the live values in the white boxes (se Figure 2 the numbers inside the orange boxes) provides access to statistical information, with a pop-up window displaying the data from the past month (see Figure 3).

3.2.2 *Visualization of historical data*

Senmos offers access to a comprehensive data archive (see Figure 4) containing historical data from all sensors on the bridge. Users can plot various combinations of sensor data and, for instance, observe the correlation between steel temperature and pillar inclination, illustrating how temperature affects structural displacement (see Figure 4). All data is available for download and further analysis through the "generate data file" option in the menu to the right of the sensor graph.

Figure 4. Data archive displaying correlation between temperature and inclination of the pillar.

3.2.3 *Sensor status*

Structural health monitoring systems encompass a range of electrical components, including IoT devices, data loggers, and servers. Effective operation relies on service providers having up-to-date knowledge of the equipment. Senmos assists by displaying the date and time of the last received data from sensors, aiding in troubleshooting failure causes, and enabling email notifications if sensors cease sending data. These features collectively ensure ease of system maintenance and operational continuity.

4 CONCLUSION

In conclusion, Senmos represents a significant leap forward in the realm of Structural Health Monitoring (SHM) data platforms, driven by a steadfast commitment to user-centric design. As we've explored the challenges associated with conventional SHM systems and the paradigm shift introduced by Senmos, it becomes evident that this platform is not merely a technological advancement, but a fundamental transformation of how we approach structural health monitoring.

Senmos has successfully addressed some of the most pressing usability issues in traditional SHM platforms. Its adherence to Jakob Nielsen's usability heuristics has led to a platform that prioritizes user experience. The visibility of system status, the seamless matching of the platform with the real world, and the emphasis on recognition rather than recall have all contributed to Senmos's user-friendliness.

Moreover, the case study of Lillebæltsbroen af 1935 in Denmark exemplifies Senmos's real-world effectiveness. By providing intuitive dashboards for real-time monitoring, facilitating historical data visualization, and offering comprehensive sensor status management, Senmos has proven its adaptability and versatility in the monitoring of critical infrastructure.

The development and deployment of Senmos underscore the importance of considering the end-user experience in the design and implementation of SHM tools. In a world where the demand for efficient and effective monitoring of structures is ever-increasing, Senmos stands as a beacon of innovation and practicality. It not only enhances data accessibility and analysis but also empowers users to make informed decisions, ultimately contributing to the safety, longevity, and optimal performance of vital infrastructure.

As SHM practices continue to evolve, software solutions like Senmos that prioritize user experience, flexibility, and accessibility will play an increasingly critical role in ensuring the structural integrity of both large and small-scale structures.

ACKNOWLEDGEMENTS

Special thanks to Svend Erik Gaardmand and Banedanmark for allowing the use of the case "Lillebæltsbroen af 1935" for use in the article.

Investigation of the effect of surface condition variation on infrared imaging of concrete delamination

C. Cheng, D. Chen, H. Cai, S. Wang, R. Wang & X. Cheng
Chongqing Jiaotong University, Chongqing, China

ABSTRACT: Infrared thermography (IRT) has become an important non-destructive testing method for the layering of concrete bridge decks. One of the obstacles to making full use of infrared thermal imaging for detection in practice is the misjudgment of thermal images caused by the non-uniformity of bridge surface conditions (such as chromatic aberration) and the presence of foreign substances on the bridge deck surface. This "noise information" not only affects the data processing of infrared thermography detection but also changes the heat conduction process of the concrete deck under the solar heating cycle, which is a key factor in stimulating the thermal contrast of infrared thermography detection. In this paper, experimental studies are carried out to explore the effects of different surface conditions (bare concrete surface and painted surface of different colors) on the development of thermal contrast of concrete delamination in image inference. A simulated concrete platform with artificial delamination of the same buried depth was designed and constructed. The thermal image, heat flux and radiation intensity data of the solar natural loading environment are continuously recorded and analyzed, and the emissivity, absorption and reflectance of surface thermal radiation are revealed. The novelty of this study is that it captures two factors that influence the development of infrared thermography (IRT) sensing and delamination thermal contrast, which have rarely been reported in previous studies. On this basis, some suggestions are put forward to reduce noise and compensate for detection in thermal image processing.

1 INTRODUCTION

As an important transportation infrastructure connecting roads and highways, bridge plays a vital role in the operation of economic activities along roads and highways (Dabous et al., 2017). Bridges have a high-growing status in China's highway system, especially in the southwestern mountainous areas, and as of 2022, the number of bridges in China has reached 103,3200 (Transport, 2023). In addition, the bridge deck is an area where the wheels act directly, and the repeated heavy loads of vehicles will cause the bridge deck to crack (Koh et al., 1997), and rainwater will enter the cracks, which will then corrode the steel bars and gradually form delamination. Corrosion of steel bars is the most important factor that reduces the service life of reinforced concrete bridge decks, and it is also the culprit of the destruction of reinforced concrete bridge decks, which is in the form of cracking, delamination, and spalling (Oh et al., 2013, Tran et al., 2017). The degradation of the bridge deck not only affects the normal operation of traffic but in some cases can also threaten public safety (Oh et al., 2013, Raja et al., 2022). Therefore, the quality of the bridge deck directly affects the safety of the bridge and the comfort of driving. Regular inspection and long-term maintenance of the bridge deck is one of the most effective and indispensable means to ensure the normal operation of the bridge.

The current diagnostic methods based on infrared imaging for concrete deck delamination detection mainly focus on the criteria based on the surface temperature difference, that is, the

DOI: 10.1201/9781003483755-286

temperature difference (thermal contrast) between the defective area and the non-defective area. In 2013, Glenn Washer (Washer et al., 2013) discussed the effects of ambient temperature change rate and wind speed on the thermal contrast of soffit defects in the shadow of the bridge deck area. In 2015, Patricia Cotič (Cotič et al., 2015) also used thermal contrast evaluation techniques to study the applicability and limitations of cavities and delamination detection under concrete overburdens. A study in 2019 by Van Ha Mac (Mac et al., 2019) discussed the effects of different aspect ratios and different time windows of day on the thermal contrast of the specimen under passive excitation. In real bridges, there are differences in materials and different surface treatments (different colors of paint, different surface sanding methods, etc.) on the surface of the bridge deck, and the differences in these surface properties will affect infrared detection in terms of thermal contrast. In this paper, three artificial delamination with the same buried depth but with different surface properties (yellow paint, bare concrete, and white paint) were designed to explore the influence of the surface properties of the specimen under passive excitation on the thermal contrast.

2 EXPERIMENTAL WORK

2.1 *Specimen preparation*

As shown in Figure 1 (a), a concrete specimen CS20 with a size of 2100×900×100 mm^3 is designed as the testbed for deck simulation. Three polystyrene foams of the same size and shape with a thickness of 10 mm and a burial depth of 20 mm were embedded inside the specimen (as shown in Figure 1 b) to simulate the delamination inside the concrete bridge deck (see Table 1 for specific information). The polystyrene foam is selected to mimic the delamination with its thermal conductivity of k=0.027 w/m°C, which is similar to that of air k=0.024 w/m°C (Ta et al., 2023). For the concrete surface, 1.35m^2/kg of white paint and yellow paint were brushed on the top and bottom sides of the specimen surface to simulate the lane marking and the area of each color of paint is 900×800 mm^2. The middle part was bare concrete, which occupied an area of 900×500 mm^2 (as shown in Figure 1c). After the specimen is poured and cured, a heat flux sensor (XM269C, see details in Table 3) is attached to the center of each area surface correspondingly for data collection.

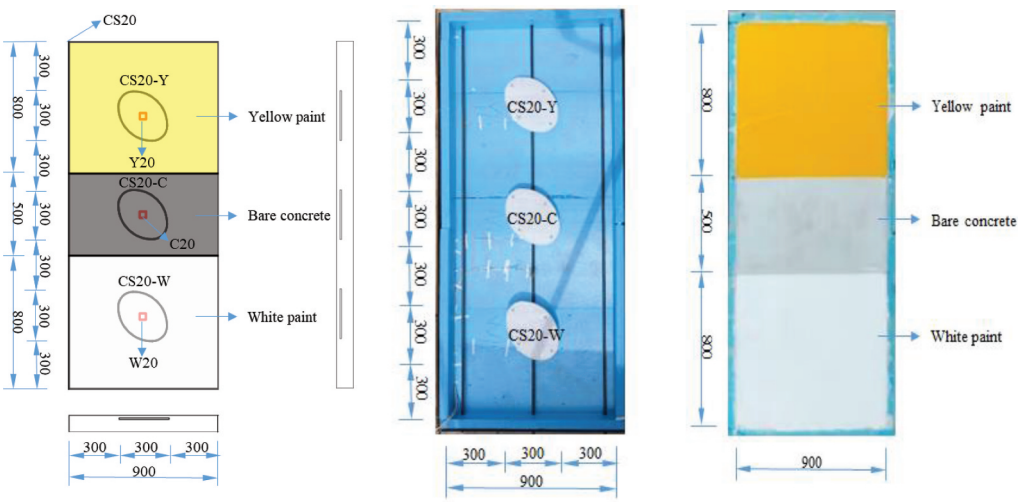

Figure 1. Specimen design and construction layout: (a) overall design and heat flux sensor layout; (b) artificial delamination arrangement; (b) Specimen after concrete pouring and surface painting.

Table 1. Detailed specification of the specimen CS20.

Delamination Annotation	The longest horizontal size (mm)	The longest vertical size (mm)	Area (mm^2)	Surface materials	Depth (mm)
CS20-Y	300	300	68508	Yellow paint	20
CS20-W	300	300	68508	White paint	20
CS20-C	300	300	68508	Bare concrete	20

2.2 *Experimental setup and equipment*

The experiment was carried out under the natural environmental conditions of the Science City Campus of Chongqing Jiaotong University in Chongqing, China as shown in Figure 2. To collect real-time meteorological data, a portable weather station (FT-BQX7) produced by Shandong Fengtu Internet of Things Technology Co., Ltd. was set up near the specimen to collect weather conditions, with a sampling frequency of every 15 minutes, and the measurement information included radiation intensity, atmospheric temperature, etc. (details are shown in Table 2). The heat flux sensor (XM269C) of Shanghai Anyi Scientific Instrument Co., Ltd., is used to measure the magnitude of the heat flux through the surface of the specimen (parameters are shown in Table 3), and the data is collected by the acquisition instrument DQ-100, which is collected every minute. In the natural environment, the MAG-F6 scientific thermal imaging camera of Shanghai Juge Technology Co., Ltd. was used to record a thermal image every minute (parameters shown in Table 4), with stability of ±0.3°C and an image resolution of 680×480 pixels (Ltd, 2022).

Spectral range	8~14μm
Field of view	25°×19°

2.3 *Surface emissivity and absorptivity measurements*

Emissivity is a quantity that represents the energy of an object's radiant energy (Vollmer & Möllmann, 2017). The emissivity is one of the factors that have the greatest impact on the temperature measurement of the target captured by the infrared camera, so the emissivity of concrete and paint is particularly important. Based on previous studies (Vollmer & Möllmann, 2017, Institute, 2013), the emissivity of a dry normal concrete surface was set at 0.95 in this study. For yellow paint and white paint, the emissivity was calculated by the double reference body method (Li & Zhen, 2012), which was 0.96 and 0.965, respectively. Absorption rate represents the ability of an object to absorb energy. Because the absorption rate of solar radiation by concrete directly relates to the temperature accumulation and temperature effect in the concrete structure, the heat balance equation can be established on the surface of the specimen by using the principles of heat transfer and energy balance, and the absorption rate of various materials on the surface of the specimen can be calculated approximately based on experimentation (Wenyan & Yaoming, 2004). The absorption rates of yellow paint, white paint, and concrete surfaces were 0.593, 0.135, and 0.658, respectively.

3 RESULTS & DISCUSSION

3.1 *The detection variation under the solar loading cycle*

In this study, we analyzed the degree of detectability by analyzing the temperature difference between the delamination and non-delamination regions. Delamination is considered detectable when it can be visually distinguished from the infrared image (qualitative) or when its thermal contrast (ΔT) is no less than 0.5°C (according to the relevant American standard ASTM D4788-03). The thermal contrast is calculated from Eq. (1) (Tran et al., 2017, Ahlborn & Brooks, 2015):

$$\Delta T = T_{\mathrm{d}} - T_{\mathrm{nd}} \tag{1}$$

In the formula, T_d, T_{nd}, and ΔT represent the average surface temperature of the delamination zone, the average surface temperature of the non-delamination zone, and the difference between the average surface temperature of the delamination zone and the non-delamination zone, respectively. When ΔT>0, it means that $T_d > T_{nd}$, that is, the temperature of the delamination region is higher than that of the non-delamination region (the so-called "heat island" region); Conversely, the temperature in the delamination zone is lower than in the non-delamination zone (the so-called "cold island" zone).

As shown in Figure 3, the temperature calculation of the delamination region T_d is based on the average temperature in the red solid box, while the temperature calculation of the non-delamination region T_{nd} is based on the average temperature in the black solid box.

Figure 4 shows the ΔT curve of the specimen's 20 mm depth simulation stratification with three days of data acquired under natural conditions. They can be used to evaluate the ability of infrared imaging for detection as well as the best time window when the thermal contrast is sufficient for detection. Based on the figure, the period of detection can be divided into three

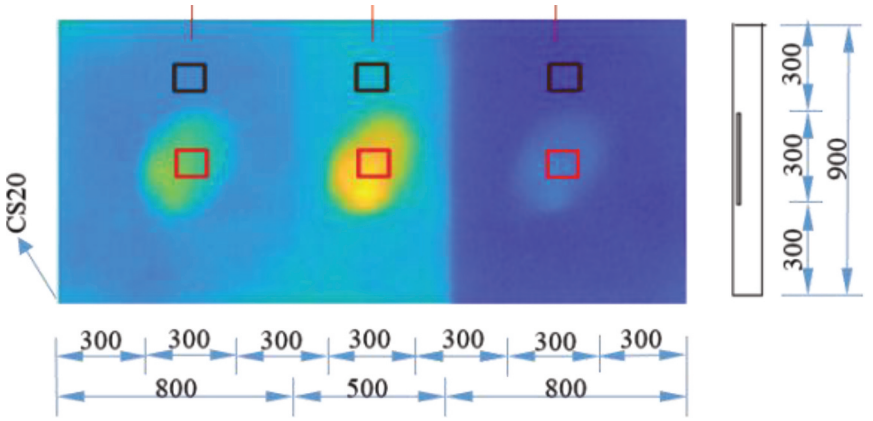

Figure 3. Temperature calculation of delamination and non-delamination areas.

phases. In phase I, the solar radiation is about to disappear and the only way to exchange heat is the convection heat exchange with the atmosphere and the radiation heat exchange of the environment. The temperature of the specimen is higher than the outside air temperature, and thus the specimen radiates heat to the outside. Due to the existence of the internal defect, the heat conduction rate in the delamination zone is different from the solid region, the ΔT is less than 0°C and the cold island area appears across all three regions. In addition, the defects with different surface conditions have developed different thermal contrasts meaning that the defects can be detected as cold regions with different temperature thresholds (maximum values of around 3.5, 3, and 20°C for concrete, yellow, and white surfaces). In phase II, the thermal contrasts in three surface regions become coincidental but still below 0°C meaning that the defects can be detected as cold regions with close temperature threshold (average contrast of -1.7 °C). In phase III, there is an inflection point at the intersection of II and III which may be majorly due to the start of solar radiation. After the solar loading, the thermal

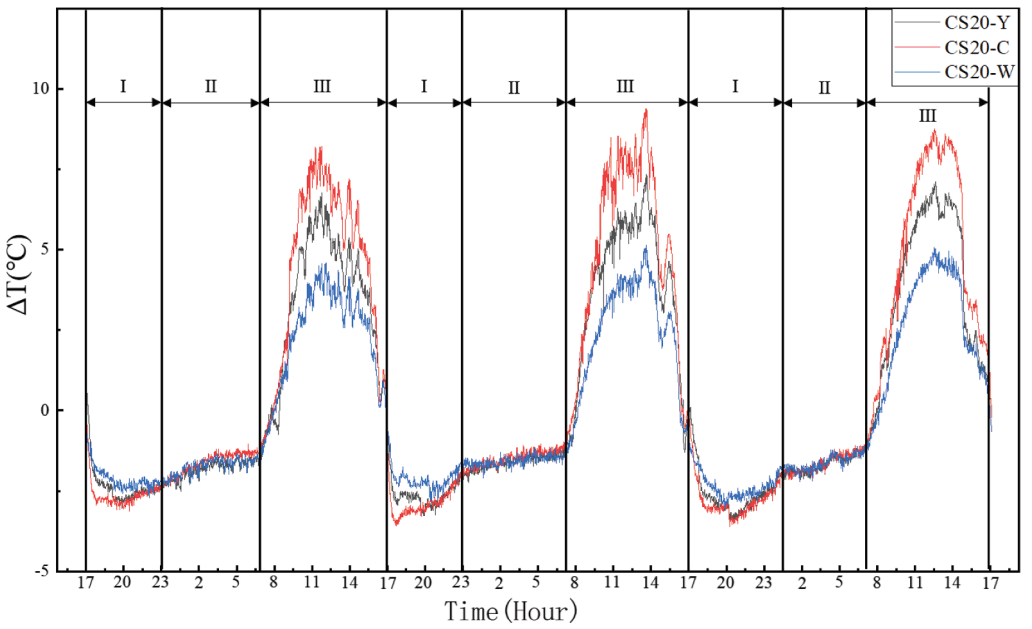

Figure 4. ΔT curves of heterogeneous materials on different surfaces under 20 mm deep delamination.

contrasts are developed dramatically and differently in three surface conditions. The maximum contrast can be reached at about 7, 5.7, and 4.5 °C for concrete, yellow, and white surfaces.

Figure 5 shows the heat flux curve attached to the center of the delamination regions. When the specimen emits heat to the environment, the sensor reads out positive values and vice versa. Between the time of 17:00 and 23:00 (phase I in Figure 4), the heat flux change is different for delamination under different surface conditions indicating the surface temperature may differ on each surface because of the consistent solar loading and air temperature during this period. During this period, the delamination area releases heat at different rates. Between the time of 23:00 and 7:00 (phase II in Figure 4), the heat flux for delamination under three surface conditions is almost the same around +25 w/m^2 indicating that the defect areas emit heat at the same rate. Between the time of 7:00 and 17:00 (phase III in Figure 4), the heat absorbed by the specimen increases dramatically, and the inside of the specimen gradually gains heat from the outside, making the value of heat flux less than 0. The delamination areas for all three regions share the same trend but with different magnitudes. The bare concrete, yellow, and white surface can reach a maximum rate of around -290, -260, and -120 w/m^2 which is correlated with the thermal contrast in Figure 4 respectively. It also found that during the day, at a certain point in time, the cloud obscures the sunshine which causes the curve to oscillate.

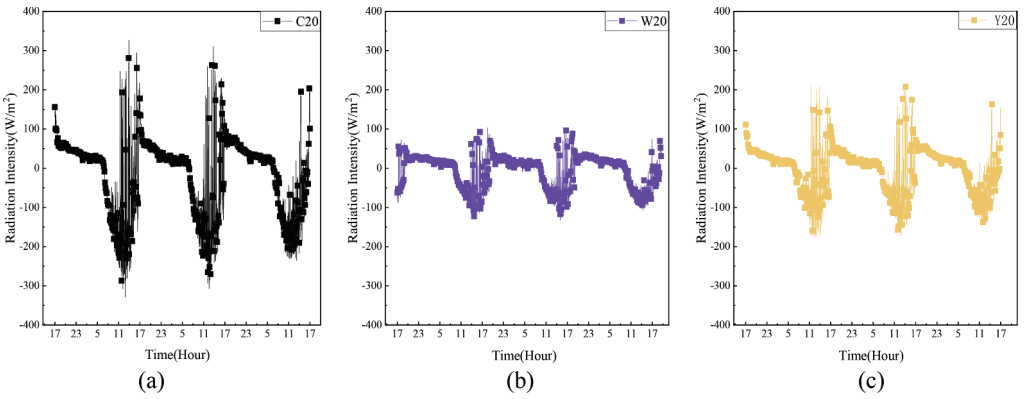

Figure 5. Surface heat flux curves of three surface conditions: (a) 20 mm depth delamination under bare concrete surface; (b) 20 mm depth delamination under white painting surface; (c) 20 mm depth delamination under yellow painting surface.

Figure 6 shows the solar radiant intensity plot during the experiment collected from the weather station. The solar loading starts around 6:30 and ends around 19:00. It can be used as an adjuvant analysis in addition to the ΔT curve and the heat flux curve. Between the time of 17:00 and 19:30, the intensity slowly decreases to zero showing the period of sunset. During this period, the thermal contrast is rapidly increasing for the delamination area in Figure 4 as well as heat flux in Figure 5. However, during the time between 16:30 and 17:30 the absolute value of thermal contrast is within ±0.5~1°C indicating the detectability of delamination remains low. Between the time of 19:30 and 6:00, the solar intensity is constantly zero showing the nighttime of the day. During this period, the thermal contrast and heat flux are relatively stable indicating the only influential factor of detection relates to the heat exchange between specimen and ambient. Between the time of 6:00 and 8:30, the intensity slowly increases showing the period of sunrise. During this period, the thermal contrast and heat flux increase rapidly. However, the absolute value of thermal contrast is within ±0.5~1°C indicating the detectability of delamination remains low. Between the time of 8:30 and 17:00, the radiant intensity rises first and then decreases rapidly, and the thermal contrast and heat flux curves follow the same trend.

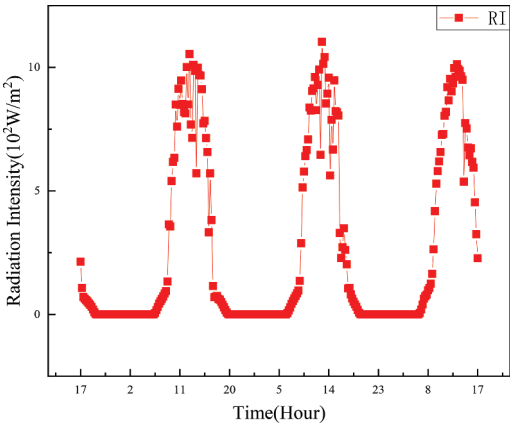

Figure 6. Solar radiation intensity.

3.2 *Effect of paint on the development of thermal contrast*

It found two time windows where the different surface conditions have a noticeable effect on the development of the thermal contrast. During the noon time when the solar radiation is relatively strong, the curve shows a hierarchical increase due to the different absorption rates of the surficial heterogeneous materials as shown in Figure 4. The ΔT of CS20-C is about 2°C larger than that of CS20-Y, and about 4°C larger than that of CS20-W. On the other hand, after about 2 hours of sunset, the ΔT of CS20-C is about 0.5°C larger than that of CS20-Y, and about 1°C larger than that of CS20-W. During the nighttime, there is no effect of solar radiation, and thus the curves coincide due to the same emissivity of the surface and similar heat exchange conditions. It also found that during phase II of Figure 4, the thermal contrast of delamination is constantly below zero (about -2 to -1.7 °C) indicating the potential time window for detection. Considering that the different surficial materials have different absorption rates but similar emissivity, the reason causing the difference in thermal contrast at daytime and sunset may be different. Further in-depth investigation is needed.

4 CONCLUSION

After three days under natural conditions, the delamination area can be detected under different surface conditions except for a period during sunrise and part of sunset whose developed thermal contrast is relatively low. In the daytime, the different surface conditions will have a major impact on the thermal contrast development of the delamination area due to the different absorption rates. The delamination under the bare concrete surface has a larger contrast than that under painted surfaces meaning higher detectability. In this period, the delamination can be detectable as hot regions in the thermal images. Right after the sunset, the different surface conditions also impact the thermal contrast development. The delamination area starts to become cold regions in the thermal images with different contrasts in terms of different surface conditions. During the nighttime, the surface condition has minimal impact on the thermal contrast, and the delamination area can be detected by using a similar threshold no matter what the surface conditions are. The above findings provide more insight and information for choosing the best time window and threshold for delamination detection when subjected to different surface conditions within the same bridge deck.

Structural health monitoring of the 1915Çanakkale Bridge in Turkey, the largest monitoring system for the longest suspension bridge in the world

S. Joye & M. De Witt
Sixense Monitoring, Nanterre, France

ABSTRACT: The 1915Çanakkale Bridge is outstanding and so is its Structural Health Monitoring. Designed and installed by Sixense upon the specification of the Client, the system will manage more than 1000 sensors. This monitoring architecture will allow to measure any external event happening on the Bridge such as strong wind, earthquakes, lightning, and heavy traffic. It will also record all the reaction behavior of the structure such as temperature, displacement, vibration, fatigue stresses. Amongst all the recorded data, dynamic records of such a slender structure is a key aspect. The acquisition system provided by Sixense will allow to record, compute, sample, and analyze a tremendous quantity of data related to the mechanical behavior of the structure. It will for instance allow rainflow counts of the stress cycles of the orthotropic slab in order to survey and prevent fatigue failure. But more than simply recording data for visualization and immediate maintenance, the system provided by Sixense will also allow predictive computations to model the future behavior of the infrastructure with regression analysis tools and will allow the owner of the bridge to anticipate the maintenance operations far in advance, out of critical service activity phases. This will increase the safety of the bridge, save money for the owner and allow this emblematic bridge to last for a very long time.

1 INTRODUCTION

The longest suspension bridge in the world is now open to traffic in Turkey with its 3563m length and a mid-span of 2023m. Located about 400km South West of Istanbul, the Bridge crosses the Çanakkale Strait (Dardanelles) to accelerate the traffic between Europe and Asia.

With more than 1000 sensors the SHM system implemented by Sixense allows to measure both environmental conditions and bridge mechanical response parameters. Besides the standard structural alert functionalities, the SHM system provides tools to anticipate the bridge performance in the long term.

2 THE BRIDGE

2.1 *Context an environment*

The Bridge is the fourth bridge linking Europe to Asia after the two well known Bosphorus bridges located in Istanbul and the 3rd Bosphorus Bridge Yavuz Sultan Selim located far North along the Black See. But this bridge in not over Bosphorus: located 500km South West it crosses the Çanakkale Strait just before the Agean Sea nearby the ancient city of Troy. Its purpose is to take into account the increase of traffic from Europe to Asia and to relieve some of the heavy traffic over the heavily congested Istanbul by derivating it south.

DOI: 10.1201/9781003483755-287

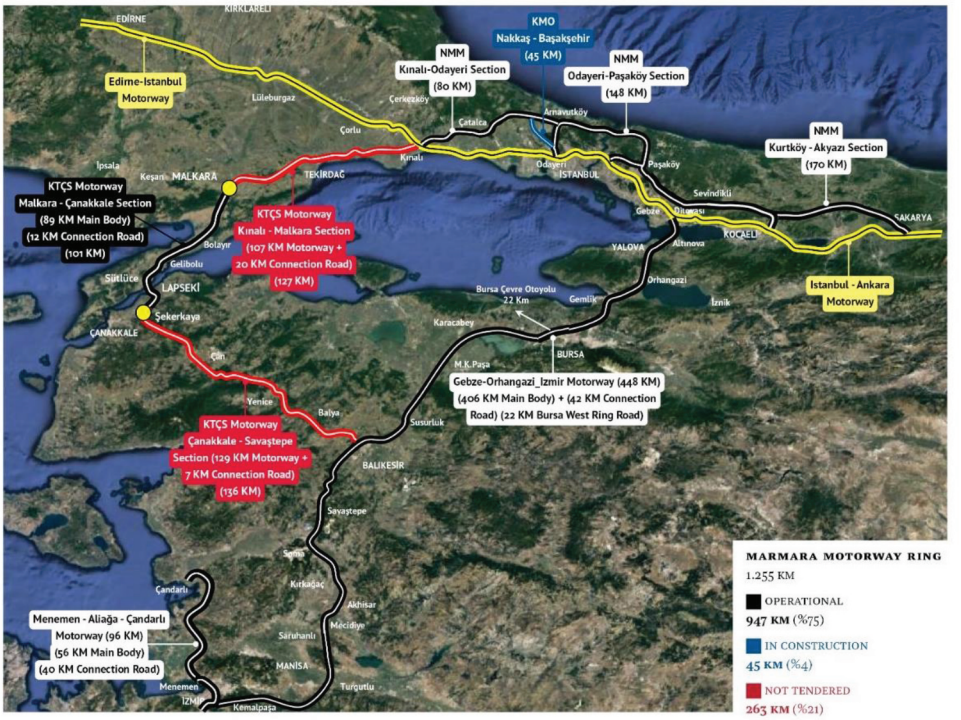

Figure 1. Routes between Europe and Asia.

2.2 *Bridge characteristics*

The Bridge has outstanding characteristics. Its mid span first with 2023m, it breaks the world record from the suspension bridge of Akashi Kaiko in Japan which has held the record since 1998 with 1991m mid span. The height of the tower is also a breakthrough. With a height of 318m it is higher than the Eiffel Tower in Paris.

Figure 2. 1915Çanakkale Bridge.

3 THE SHMS ARCHITECTURE

The SHMS architecture can be split between sensors and acquisition system. The sensors list may be split between environmental and traffic sensors and structural behaviour sensors.

3.1 *Environmental sensors*

The purpose of the environment and traffic sensors is to monitor the external loads that apply on the structures. This enable to alert on outstanding event that will raise alarm when predefined thresholds are overpassed. This can for instance allow to stop the traffic in case of wind or seismic events.

Monitoring of environmental loads can also enable to correlate the behaviour of the structure when submitted to specific environmental condition - for instance, wind against vibration - and verify the design calculation and hypothesis.

Table 1. Environmental sensors.

Sensor type	Quantity
Air temperature	3
Clearance - Laser distance sensor	2
Barometric Pressure	4
Humidity	4
Weather Station	6
Pyrometer	2
Seismic Station	2
Weight in Motion	2

3.2 *Structural sensors*

As environmental sensors, structural sensors enable to regulate the traffic in case of alarms raised by extreme vibrations for instance. But they are more particularly used to monitor the ageing of the structure or its long terms behaviour such as stress concentration, cumulative displacement, creep of the deck or even of corrosion of rebars inside the concrete deck.

Table 2. Structural sensors.

Sensor type	Quantity
Accelerometre	18
Asphalt Temperature	8
Steel Temperature	52
Cable temperature	4
Corrosion sensor	36
Displacement sensor	64
GPS	28
Inclinometer	74
Strain Gauge	508
Road Weather	4

3.3 *Integrated sensors*

The SHMS system is also designed to integrate data provided by external equipment such as dampers or buffers.

Table 3. Integrated sensors.

Sensor type	Quantity
Load Cell	16
Sensor in the Damper	4
Sensor in the Buffer	2

3.4 *Acquisition hardware units*

The acquisition hardware units are specifically design for the 1915Çanakkale Bridge. They enable the acquisition of either low frequency signal (ex. displacement) or high frequency signals (ex. accelerometers). They also enable the initial processing (summary statistics) and their transfer to data servers. Data acquisition units power supply is backed up by UPS (Uninterruptible Power Supply) to ensure they remain in service even in the unlikely event of a power failure.

4 THE SHM SOFTWARE

The Eversense SHM Software has been developed by Sixense for 15 years. However, the software has been specifically updated to include new functionalities requested by the specification of the Bridge.

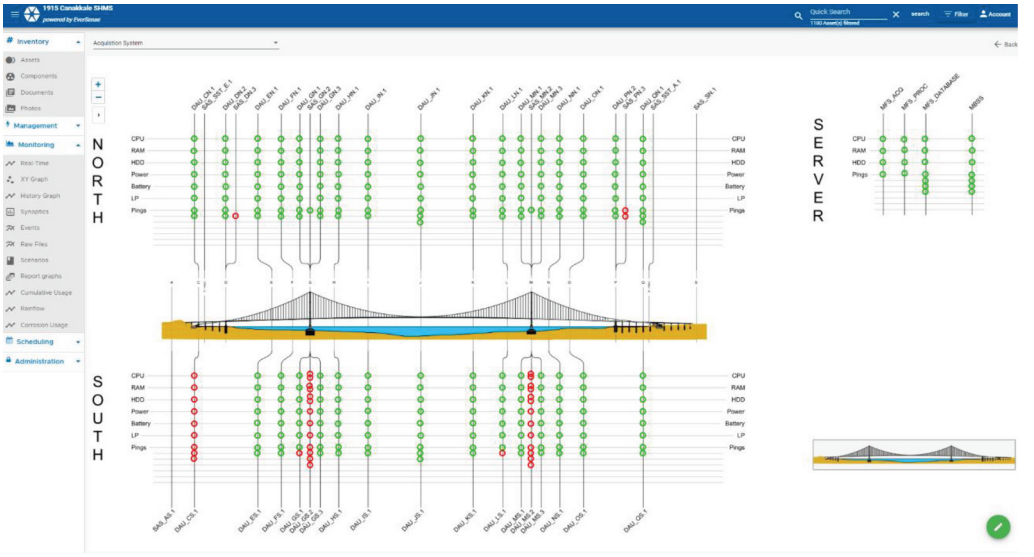

Figure 3. Eversense SHM software synoptic view.

It will enable to estimate the fatigue ageing of steel welds and component by a rainflow counting of the cumulated strains at specific locations. It will also enable predictive analysis of the behaviour of the Bridge by a comparison of bridge behaviour with environmental condition and application of specific predictive regression of the generated pattern. In this sense the software will act as a simplified but very useful full Digital Twin.

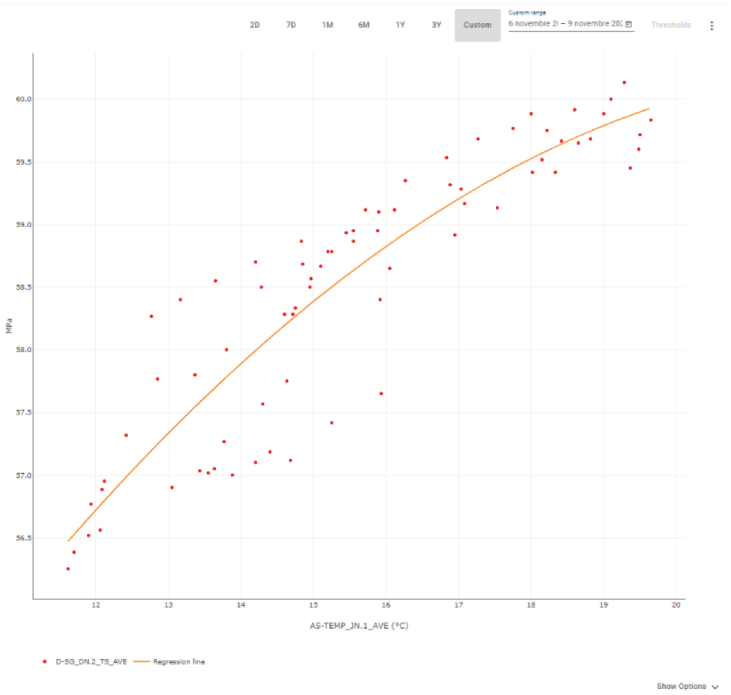

Figure 4. Stress measured by a differential strain gauge vs temperature and a trend curve obtained by regression plotted in Eversense software.

5 CONCLUSION

Worldwide increase of traffic is pushing civilisations to find new routes and new ways of reaching their destination always faster. Growing cities are desperately willing to deviate the traffic around to preserve their city centres form cars. Those goals are the sources for outstanding means or travelling when routes have no other choices that crossing sees.

The 1915Çanakkale Bridge is the result of such goals by outstandingly crossing the Çanakkale Strait over a main span of 2023m between towers becoming the new world record of the longest bridge main span.

Yet this Bridge is reaching such a great limit that is shall be backed by a significant and reliable structural health monitoring. Similarly, being designed and built to last more than 100 years this expectation cannot be reach without reliable information about the environment, the related structural response and an SHMS system allowing to correlate both in order to anticipate and advise about the maintenance of the structure. This is why Sixense SHM system has been chosen on this world record bridge.

ABSTRACT: Ageing infrastructure systems are easily prone to failure demanding frequent monitoring despite costs and risks. Digital twin offers an intelligent approach to overcome such limitations of traditional bridge monitoring. Current study focuses on implementing remotely connected real-time virtual models of bridges to visualize any induced stresses/strains of the actual bridge via the digital twin concept. It was first proposed to instrument a bridge with sensors and to follow an inverse approach to simulate the overall behavior using sensor measurements. A machine learning algorithm based finite element model has been suggested for this and three different algorithms were tested. All three machine learning algorithms accurately represented the behavior of the actual bridge in real-time. Overall, it was concluded that a combination of both physics-based and data-driven model development techniques is highly effective for real-time analyses and for the digital twining process. The proposed method can be extended to a large-scale bridge easily.

Keywords: Digital Twin, Machine Learning, Finite Element Method, Inverse Method, Structural Health Monitoring

1 INTRODUCTION

Civil infrastructure assets such as bridges, highways, and buildings are critical components of modern society. They provide essential services whilst supporting communities, industries, and economies as well. However, the aging infrastructure and the increasing frequency and severity of natural disasters have highlighted the need of having a systematic method of monitoring and maintenance of these assets (Mahmoodian, 2021). The traditional methods of inspection and maintenance are time-consuming, costly, and often reactive, leading to potential safety hazards and economic losses. According to cost estimates, Australia spends approximately $19 billion annually to maintain its road network (Austroads, 2016). Usually, bridges require between 0.4% and 2% of their construction cost for yearly maintenance activities (Mahmoodian et al., 2022). Consequently, for a bridge designed to last 100 years, its maintenance expenses could potentially reach twice the initial construction cost (Artus and Koch, 2020).

The emergence of digital twins offers a promising solution to address these challenges. Digital twins (DTs) are virtual replicas of physical assets that can be used for real-time monitoring,

DOI: 10.1201/9781003483755-288

analysis, and optimization (Callcut et al., 2021). The implementation procedure of digital twins initiates from the telemetry data collection from the operating asset and continue until the visualization of the real-time structural response via a digital model whilst accommodating a real-time connection in between. This allows to plan proper structural health monitoring (SHM) procedures based on the real-time behavior of bridges (Ye et al., 2019). Additionally, response-based acquisition units have become the prevailing choice, surpassing the popularity of image processing systems (Kaewunruen et al., 2021, Qiu et al., 2022). The digital replication can be accomplished either using a physics-based or data-driven methods (Mahmoodian et al., 2022) and also, a combination of them has demonstrated its ability to advance the functionality of a DT system (Ye et al., 2019). However, the majority of existing digital twins solely offer visualizations of the physical asset without depicting its structural integrity. Consequently, they are referred to as geometric digital twins and are primarily applicable during the structural design phase (Lu and Brilakis, 2019). Also, considering that the measured structural response serves as the input for the digital model, it is essential to adopt an inverse approach (Moi et al., 2020), which may often pose challenges due to its potential for ill-conditioning (Gupta, 2013, Wang et al., 2021). Recently, Artificial Intelligence (AI) techniques have been identified as potential algorithms for real-time FE modelling and for inverse structural analysis (Kononenko and Kononenko, 2018, Badarinath et al., 2021). Once trained, those algorithms will be able to do predictions for the given inputs immediately. However, they highly depend on the data availability.

In this light, the current study is proposing a novel methodology by aiming to demonstrate the feasibility of using digital twins and AI techniques for real-time structural analysis of bridges. It focuses on using Artificial Neural Networks (ANNs), Random Forest algorithms and Extreme Gradient (XG) boosting algorithms as surrogates for real-time inverse structural analysis via FEM. The sensor readings from IoT devices connected to the infrastructure will be fed into the trained model to perform real-time analysis and observe structural deformation.

The proposed methodology will enable the development of a system that can continuously monitor and analyze the structural health of civil infrastructure assets in real-time. This system can provide timely maintenance and intervention, reducing the risk of structural failure and ensuring the safety of the public and the environment. Also, this will contribute to the body of knowledge on AI-based surrogate models for structural analysis of civil infrastructure systems. It will demonstrate the potential of using digital twins and AI for real-time structural analysis and highlight the benefits of adopting these technologies for infrastructure monitoring and maintenance.

2 LITERATURE REVIEW

2.1 *Digital twins for bridges*

A digital twin of a bridge is anticipated to function as a dynamic digital representation, accurately reproducing and visually presenting every aspect of the bridge such as the geometry, materials, layout, inspections, and other pertinent details whilst facilitating a continuous data-flow with the actual bridge and providing stakeholders with the ability to respond promptly in emergency situations. (Ye et al., 2019). The commencement of the bridge digital twinning system involves gathering telemetry data. However, the crucial phase within this process is the implementation of the digital model. Researchers have utilized both physics-based and data-driven methods to construct virtual models (Shim et al., 2019, Ye et al., 2019, Lin et al., 2021, Febrianto et al., 2022). Each method comes with its own advantages and disadvantages that can have a substantial impact on the effectiveness of a digital twinning process. For instance, even though a physics-based method like FE modelling can detect damages, conducting real-time analysis is challenging due to its high computational cost. It is apparent that this kind of a method necessitates support from the other approach to boost its performance and produce results in real-time (Ye et al., 2019).

However, existing digital twins of bridges possess distinct limitations. The majority of existing digital twins showcase geometrical changes rather than considering the structural

performances (Lu and Brilakis, 2019). Also, they rarely incorporate real-time assessments of bridge structural integrity. Additionally, as sensors or image processing techniques document the performance of the real bridge, any faults in measurement instruments, environmental factors, or errors in storage devices may lead to the dispersion of measured data. Such dispersion has the potential to disrupt the entire digital twinning process (Ghahari et al., 2022). Hence, utilizing the technology to integrate actual environmental conditions with the generated models is crucial (Huang et al., 2015).

2.2 *Surrogates for real-time FE modelling*

Deemed as the widely used and powerful computational technique, FE analysis facilitates efficient structural analysis through advanced modeling and simulations (Marinkovic and Zehn, 2019). Also, FE modelling is the most popular physics-based technique for digital twins. However, in finite element (FE) modeling, a structure is divided into distinct elements (FE mesh) and these elements are analyzed individually rather than evaluating the entire structure as a whole (Logan, 2012). Consequently, it will produce highly accurate results albeit at a significant increase in computational costs. Thus, in response to these limitations, diverse surrogates have been introduced. Amongst, machine learning (ML) algorithms can be identified as one of the most promising approaches.

The application of machine learning algorithms has garnered significant attention, with numerous studies demonstrating its efficacy in real-time FE model analysis. Various machine learning algorithms have been employed to execute this specific task. Both FEM and ML algorithms individually hold significant predictive capabilities in various domains and their integration can be accomplished via three main distinct approaches: (i) Embedding ML algorithms directly into FEM architecture (Javadi et al., 2003, Tao et al., 2022), (ii) Developing empirical equations using generated data by FEM (Tohidi and Sharifi, 2016) and (iii) Conducting the entire FEM process to obtain desired outputs to given inputs after training via a dataset provided by FE analysis (Gudur and Dixit, 2008, Shahani et al., 2009). Amongst, the third approach is more suitable for an inverse approach of structural analysis as it allows to train an algorithm in between input and output values depending on the requirement (Kononenko and Kononenko, 2018).

Badarinath et al. (2021) assessed a one-dimensional beam, comparing three machine learning models: extreme gradient boosting trees, Random Forests, and Artificial Neural Networks (ANNs). Their findings highlighted ANNs as the most predictive method. Additionally, Vardhan and Sztipanovits (2022) also supported the effectiveness of deep learning by contrasting it with Random Forests and gradient boost regression models for sub-sea pressure vessel design via FEM. However, it is difficult to determine the best performing algorithm as all of these algorithms are highly relied on the dataset and the dataset will be completely different from one structure to another. Also, in terms of ANNs, the type of neural network also affects the performance of the trained model. Recent researches have focused on using Feedforward neural networks (Liu, 2019, Tran-Ngoc et al., 2021, Tao et al., 2023, Le-Duc et al., 2023), Recurrent neural networks (Ninić et al., 2017, Ghavamian and Simone, 2019), Convolutional neural Networks (Pizarro et al., 2021), Graph neural networks (Fu et al., 2023, Jiang and Chen, 2023), Radial basis functions (Lu et al., 2023) etc. Graph neural networks have attracted lots of interest for this specific application as it can indicate the FE mesh data in a graphical format and conduct the analysis in a more efficient way (Maurizi et al., 2022). It has been mentioned in most of the researchers a significant decrease in computational time when FEM replaced by ML algorithms. Also, the non-linearity in the structural behavior is not a problem for ML algorithms once trained by a proper dataset and these models are not highly sensitive for minor variations in the inputs.

3 METHODOLOGY: DEVELOPMENT OF THE DIGITAL TWIN

The methodology of this study has been proposed to develop the digital twin of a laboratory scaled bridge with the help of a machine learning approach for its real-time structural integrity

assessment. The methodology is twofold: Training the Artificial Neural Network, See Figure 1(a) and Real-time visualization of the structural response, See Figure 1(b).

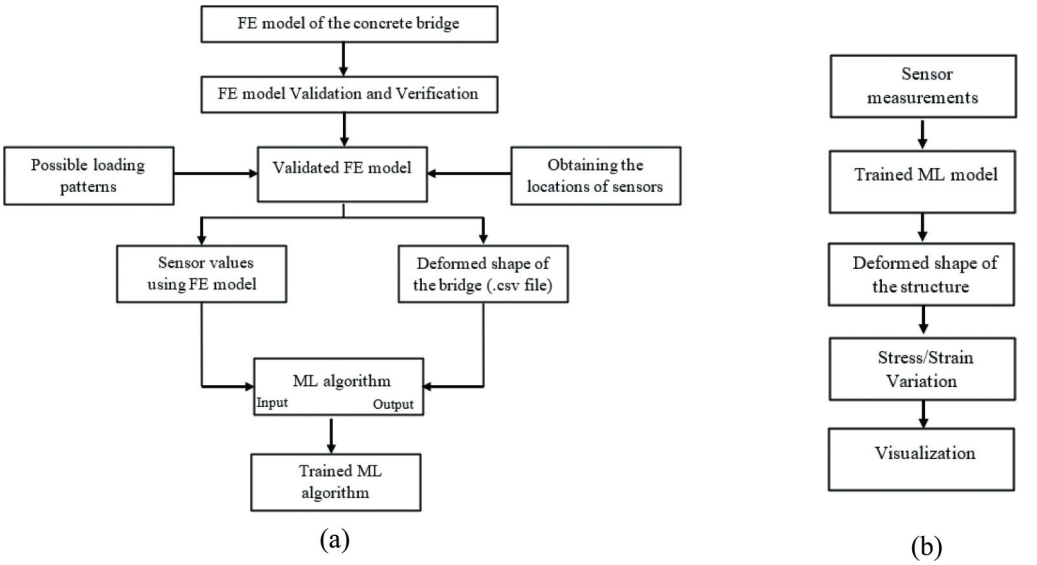

Figure 1. Methodology (a) Training of Neural Network (b) Real-time visualization.

3.1 *Experimental setup*

The selected bridge model, its geometry and sensor configurations are presented in Figure 2. SG refers to strain gauges. The model is a symmetrical roof truss with 13 circular cross-section members, each with a 6 mm diameter, made of stainless steel with a Young's modulus of 193 GPa. One end is a pin support, the other a roller support, and all joints are pin jointed. The truss, following manufacturer guidelines, can handle loads from -500N to 500N. Hence, all the possible loading patterns within that range were considered when generating the dataset and training the algorithm. The trained algorithm was used to feed randomly generated sensor data in real-time and allowed to visualize the stress variation in real-time.

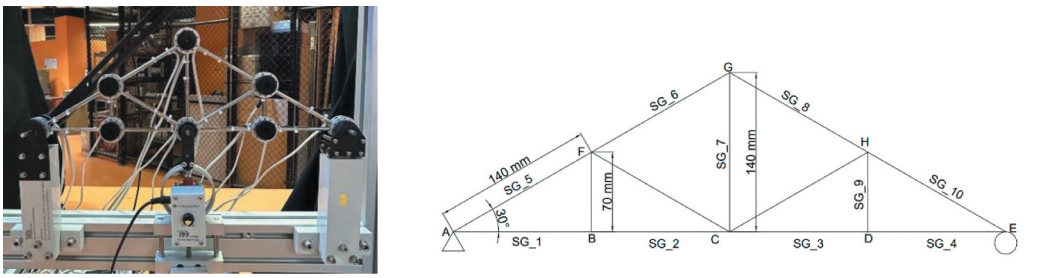

Figure 2. Structural setup and geometry of the laboratory model.

3.2 *Machine learning algorithms*

The FE model of the bridge was developed using python scripting and the analysis process was automated to generate a dataset as presented. Under the methodology three ML algorithms including the Random Forest (RF), Artificial neural networks (Multi-layer perceptron) and Extreme gradient (XG) boosting algorithms were followed to assess the predicting capacity of each of them towards the inverse structural modelling. Altogether 4000 records of strain values as the input and displacement of each node as the output were considered when

training the model. The data was split into 80% of training data, 20% of testing data and again 20% of testing data was considered for validation. Root mean square error (RMSE) value was used as the performance measure.

The RF algorithm stands out as a powerful ensemble technique that involves multiple independent decision trees with added randomness to obtain more accurate predictions (El Mrabet et al., 2022). Also, it has proved its effectiveness in different predicting tasks in the civil engineering domain (Huang et al., 2020, Liu et al., 2021). For the developed RF algorithm, 100 estimators were considered, and the cross-validation was also introduced to assess its performance.

Similarly, MLP based neural networks can be identified as the most popular neural network that includes a simple fully connected type of feedforward ANNs. It consists of three or more layers that includes an input layer, one or more hidden layers and an output layer. The nodes in each layer make relationships to conduct the prediction task effectively and MLPs show several successful attempts as a surrogate of FE modelling (Liu, 2019, Badarinath et al., 2021). For the developed MLP, min-max scaling was used to normalize the data to enhance the convergence of the training process. The feed forward neural network architecture was created using Keras, considering 4 layers with 2 hidden layers. A total of 10 inputs were fed to the model. Hidden layers consisted of 64 and 32 layers respectively and the size of the output layer was 13 as three nodes of the actual structure were constrained. The ReLU activation function and Adam optimizer were used whilst the RMSE was considered as the loss function. The model was trained for 100 epochs with the batch size of 32 with early stopping.

XG boost is also another powerful prediction algorithm that is based on the concept of gradient boosting and gained huge popularity due to its speed and performance. This also shows few successful attempts in predicting tasks in the civil engineering domain (de-Prado-Gil et al., 2022, Tuken et al., 2023). When developing the XG boost algorithm for the current study, initially the hyperparameters were tuned and the maximum depth of each individual tree was 15, min_child_weight was 9, learning rate was 0.1 and number of estimators were 100. Also, the tree-based models were obtained as the booster here. After training the ML algorithm, the best model was saved in order to use it when feeding the sensor data. The rest of the coding to visualize the stress variation was done using direct stiffness method and using the matplotlib library in python.

4 RESULTS AND DISCUSSION

4.1 *Machine learning models*

Three ML models including RF, ANN and XG boosting were trained using the developed dataset after conducting FE analysis of the truss structure for 4000 iterations. The data generation was automated. The obtained RMSE for both testing and validation are shown in Table 1.

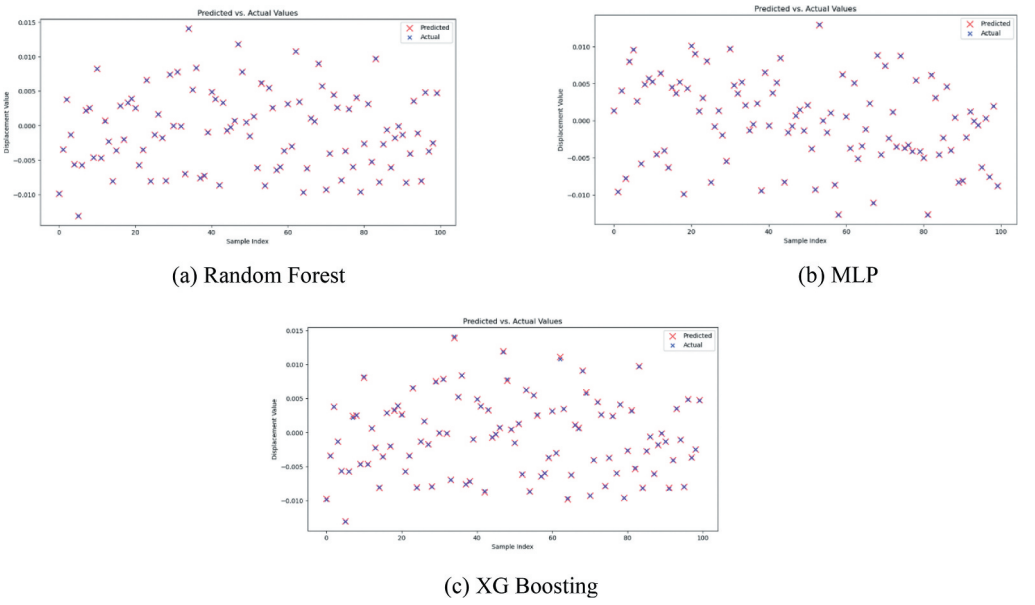

Table 1. RMSE of each tested algorithm.

Algorithm	Testing RMSE	Validation RMSE
Random Forest	0.000373	0.000341
MLP	0.000463	0.000473
XG Boosting	0.000470	0.000460

After training, 100 samples were randomly selected from the dataset to predict the output and a graph was created in between the actual output and predicted output for each model. Figure 3 depicts those graphs which compare the actual and predicted values. According to Table 1, the RMSE values were low for all three algorithms whilst the random forest algorithm shows the least RMSE values. Hence, the random forest showed the best performance regarding the inverse structural modelling whilst the feed forward architecture of ANNs and XG Boosting algorithm nearly similar RMSE values. Figure 3 also provides a similar observation.

4.2 *Real-time FE modelling*

The trained models were then fed with randomly generated sensor readings with a refresh rate of 1 second. All the three algorithms have the capability to generate the results in a time close to 20 milli seconds by proving its ability to conduct a real-time structural integrity assessment. As soon as the trained models provide an output, that output will be directly fed into a script that was written to visualize the stresses and deflected shape of a laboratory truss model. One output of that model is shown in Figure 4.

(a) Random Forest

(b) MLP

(c) XG Boosting

Figure 3. Comparison between predicted and actual outputs of each model.

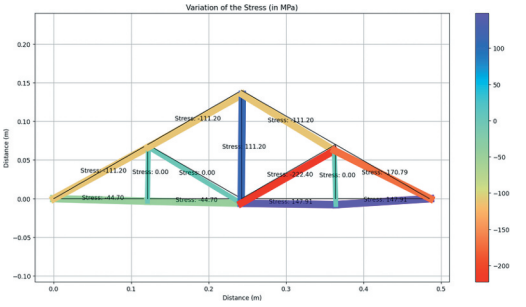

Figure 4. Real-time stress variation and deflected shape of the truss model.

The model indicates the elements with higher compression stresses in red color and higher tension stresses in blue color. Accordingly, it will provide the chance to decide which members carry out higher stresses and require a replacement.

5 CONCLUSION

This paper presents an implementation of a digital twin of a laboratory-scaled truss bridge. The bridge model was instrumented with ten strain gauges. Then, a dataset was

created including strain values and deformed coordinates of each node by conducting a finite element analysis for a series of loading patterns. Then, three machine learning algorithms including random forest, feedforward artificial neural network, and XG Boosting were developed and trained. The trained model was able to predict the real-time behavior of the bridge when actual strain gauge readings were fed into trained models. It was observed that all three models show relatively small error values when training whilst the random forest algorithm showed the best performance. All the three algorithms were able to predict the structural behavior of the bridge as soon as they receive a sensor reading and showed results immediately by proving their ability to conduct an inverse structural analysis in real-time. Also, it was noted that it is further possible to reduce the number of strain gauges of the truss model. However, to maintain the same accuracy, it is required to increase the size of the dataset. Overall, the proposed method was able to successfully visualize the stress variation of the bridge in real-time and it is clear that, this technique can be extended to a large-scale bridge.

ABSTRACT: Structural health monitoring (SHM) plays an increasingly significant role nowadays in ensuring the serviceability of large and complex bridge structures. Optimisation algorithms are employed to optimise the system settings, including the quality of the captured data and, hence, the SHM system's performance. This includes a selection of sensor types, numbers, and placement locations. Optimal sensor placement (OSP) aims to achieve cost-effective monitoring of bridges through minimal sensor adoptions. This study presents an application of the Effective Independence Method (EFI), one of the most adopted optimisation methods, to the case study bridge to derive an optimal solution. The generated sensor configurations are then evaluated in relation to their overall quality of sensor data collection, under predetermined project constraints, primarily the number of available sensor quantity and installation locations.

1 INTRODUCTION

In response to the rising demand for a more efficient, systematically consistent bridge integrity assurance approach, SHM was previously proposed in the field of civil infrastructure and mainly developed in bridge health monitoring (Aktan et al., 2001, Bui and De Roeck, 2012, Guidorzi et al., 2014, Bassoli et al., 2015, Saisi et al., 2018, Xin et al., 2022). The health monitoring of concrete bridges is commonly achieved through the employment of advanced sensors and intricate instrumentation for data acquisition to anticipate potential issues and detect structural damages. Being a source of instantaneous information on the structure, SHM allows bridge owners to access immediate structural assessments and timely responses when necessary. It allows for immediate maintenance responses with greater cost savings to be conducted before adverse changes in the structure. Ideally, to obtain information that is most representative of the dynamic characteristics of the bridge, the structure should be heavily populated with information-acquiring sensors to be able to extract as much data regarding the existing state of the structure. However, due to the costs and installation constraints for sensor technologies, the feasible number of sensors for installation on any single bridge for SHM is often limited (Li et al., 2012b, Pozo et al., 2021, Hassani and Dackermann, 2023). The typical installation of the wireless sensors was a result of the experience and knowledge of the installation team (Barthorpe and Worden, 2020). Nonetheless, as structures have grown in complexity, the problem of sensor placement has become a formalised one with the aim of achieving a balance between cost and the quality of information gathered by the sensors.

Sensor configuration, also known as sensor placement or deployment, constitutes the foundational process in establishing sensor networks for monitoring systems. OSP plays a critical role in elevating overall system performance, enabling optimal system utilisation, minimising downtime, and mitigating catastrophic failures. It is crucial to strategically position sensors to avoid incomplete information capture, such as inadequate modal data, which could compromise the precision of structural monitoring. Customising sensor configuration to suit the unique

DOI: 10.1201/9781003483755-289

requirements of each monitored system remains paramount. While engineering judgement often guides sensor placements, various computational methods have emerged to support OSP and streamline sensor deployments. The aim of OSP techniques is to achieve three key objectives: (i) minimise the number of sensors necessary, (ii) enhance system accuracy, and (iii) deliver a robust and optimal design. The overarching aim of OSP is to deliver precise data for potential issue and damage detection while simultaneously minimising sensor usage and ensuring comprehensive remote monitoring capabilities (Kralovec and Schagerl, 2020). Of the various research in OSP, the EFI is arguably the most adopted optimisation algorithms in the SHM of bridge structures (Friswell and Castro-Triguero, 2015, Demirlioglu et al., 2022, Hassani and Dackermann, 2023). The EFI method seeks the optimal set of degrees of freedom (DOFs) to place the sensors among all the candidate locations on the structure (Kammer, 1991). The user provides the candidate measurement locations. The optimal sensor configuration is determined based on the principle of linear independence of the mode shapes.

2 THEORETICAL BACKGROUND

The aim of EFI is to locate the most significant DOFs that accurately represent and communicate structural instability due to joint displacements. The determination of DOFs at joints is predicated on their potential for independent movements or rotations—essentially, the count of available directions in which these joints within a system can induce displacement. Consequently, these DOFs present favourable opportunities for the placement of sensors aimed at gathering data pertinent to structural damage detection. This is when the DOFs are deemed to provide the greatest amount of information about the structure. The linear independence of collected sensor data can be described as the minimisation of information redundancy and is an important quality indicator of EFI (Kim et al., 2018). Linear independence provides a concise set of unique displacements, which best represent the bridge's structural behavior. In structural dynamic applications, mode shapes refer to the characteristic patterns of vibration or deformation that a structure exhibits when subjected to dynamic loading. By iteratively deleting DOFs, which contributed the least linear independence from the mode shape matrix, EFI allows sensors at remaining candidate installation locations to collect the most significant structural responses. In other words, the errors between estimated mode shapes are minimised compared to the actual mode shapes (Kammer, 1991). This error is represented by the covariance matrix P and is displayed in E, q (1), where E is the expected value, q is the measure of modal displacement, andq' is the estimated modal displacement.

$$P = E\left[(q - q')(q - q')^T\right] = FIM^{-1} \tag{1}$$

The inverse of this covariance matrix P is the fisher information matrix (FIM), which is derived in E, q (5). FIM quantifies the amount of information that an observed set of data carries about the unknown parameters. In practice, Eghtesadi and McAuley (2016) identify the FIM as a summary of the potential impacts of model parameters on model predictions and have widely adopted it for the ranking of model parameters. Maximisation of FIM signifies greater information or precision about the parameters, indicating that slight changes in those parameters would significantly impact the likelihood of observing the given data. In other words, maximisation of FIM serves as a criterion for optimising sensor placement to ensure accurate parameter estimation or model identification. Hence, the determinant of the covariance matrix P can be minimised when the determinant of the FIM is maximised. The FIM is a product of the true mode shapes as shown in Φ_s and its transpose as shown in E, q (2).

$$FIM = \Phi_s^T \Phi_s \tag{2}$$

The EFI method begins with an initial placement of sensors determined by modal kinetic energy distribution at each candidate position towards the targeted mode shapes, as shown in E, q (3),

$$KE_{in} = \Phi_{in} \sum_j M_{ij} \Phi_{jn} \tag{3}$$

where for the n^{th} mode shape, KE_{in} is the kinetic energy for the i^{th} DOF, Φ_{in} and Φ_{jn} are the i^{th} and j^{th} coefficient of the mass matrix, and M_{ij} is the $i \times j$ term in the FE method mass matrix of the structure (Kammer, 1991). The mass matrix captures the distribution of mass within a structure or mechanical system and describes how this mass is related to the accelerations experienced by the system when subjected to external forces. It quantifies the inertia effects within the system, linking the accelerations of each DOF to the forces acting on those DOFs, considering the mass distribution and its influence on the dynamic behavior of the system. The contribution to kinetic energy at each location indicates the sensor's ability to retain structural dynamic information even where sensor noise is present (Heo et al., 1997). Thus, by initially ranking the candidate sensor location from the results of the kinetic energy distribution, the initial collection of sensor locations should yield greater resilience against sensor noise. The sensor output defined by is shown in E, q (4), where u_s is the sensor output and N is the Gaussian white noise vector with variance ${\Psi_0}^2$. The covariance matrix P can also be rewritten in the form of E, q (5) using the mode shape matrix and the white noise variance

$$u_s = \Phi_s q + N \tag{4}$$

$$P = [\Phi_S^T (\Psi_0^2)^{-1} \Phi_S]^{-1} = FIM^{-1} \tag{5}$$

In each iteration of the EFI, the independence distribution vector E_D is determined based on E, q (6), where Ψ_A and λ are the eigenvector and eigenvalue for the contribution of each DOF, respectively (Chai et al., 2022). The contribution of the i^{th} candidate sensor location to the FIM is determined by the i^{th} diagonal in E_D. The candidate sensor location with the least contribution to the EFI is removed. The process is continued until the target number of sensor locations is attained.

$$E_D = \Phi \Psi_A \lambda^{-1} (\Phi \Psi_A)^{-1} = \Phi [\Phi^T \Phi]^{-1} \Phi^T \tag{6}$$

The EFI method underwent validation through a trial conducted on a finite element (FE) model representing a space station (Kammer, 1991). Targeting the first 15 bending modes, the MATLAB implementation of the EFI process identified 70 sensor locations out of 187 candidates, achieving the desired mode shapes within 7 iterations. To ensure the validity of the EFI approach in this context, the FIM determinant was employed as a metric to assess the system's linear independence. Additionally, a comparative analysis was established, utilising sensor placement based solely on kinetic energy locations as a reference. Upon meticulous examination of the outcomes, it was observed that the EFI method yielded the largest determinant of the truncated FIM and demonstrated a condition number approaching 1, indicating a notably high level of linear independence. Moreover, the EFI approach exhibited superior computational efficiency compared to other sensor placement methods, primarily due to its ability to eliminate redundant sensors in each iteration, as highlighted by Kammer in 1991. Despite its initial design and verification within aerospace structures, this methodology has found widespread adoption in civil engineering applications, particularly in bridge infrastructure, owing to its demonstrated reliability (Li et al., 2012a, Sunca et al., 2021).

3 CASE STUDY IMPLEMENTATION

To provide a first glimpse into these questions, a numerical study has been carried out. For this purpose, Figure 1 shows a five-span SuperTee case study bridge situated over the water course located in Melbourne, Australia. A three-dimensional (3D) finite element model of the bridge was generated based on structural drawings and site observations using ANSYS. The employment of this modelling software is commonly accepted for FEM purposes (Lurie et al., 2018, Pachón et al., 2020, Hassani and Dackermann, 2023). The required modal information was extracted

from the numerical model to provide data for OSP analysis. The EFI method is adopted as the OSP algorithm and applied to determine 10 sensor locations with six target modes.

Figure 1. Five-span SuperTee bridge.

Figure 2 shows the typical cross-section details adopted for this study, which are verified according to available structural drawings.

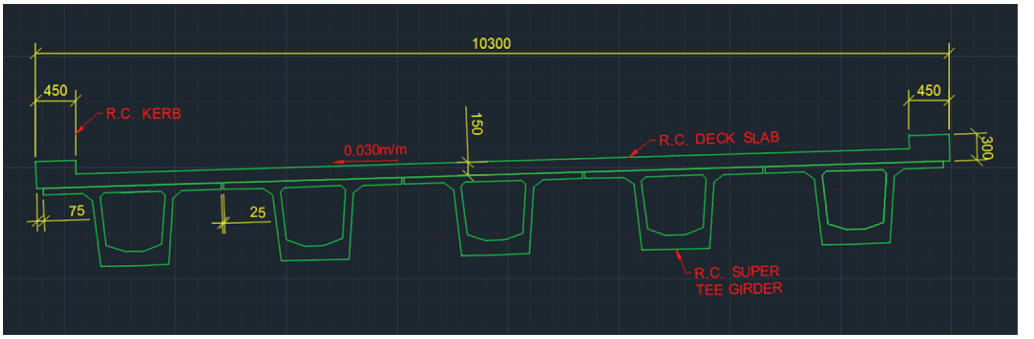

Figure 2. Typical bridge cross-section.

The bridge is accurately represented as a simply supported structure, with restraints positioned at the center edges of the super tee girders. The restraint configuration follows a pin-roller setup: specifically, the five nodes at the -x end are fixed in displacement across all three axes, while the five nodes at the +x end are constrained solely in displacement along the y- and z-axes. In its entirety, the adopted bridge model comprises 9,418 nodes and 5,258 elements. Each node encompasses three DOFs, enabling translation along the x-, y-, and z-axes, culminating in a total of 28,254 DOFs for the entire structure. The modal analysis is performed with the materials and geometry finalised, generating the first 4 mode shapes, shown in Figure 3. The displacements for each node in the x-, y- and z-directions are then compiled constructing the mode shape matrix φ, resulting in a 28,254x6 matrix. On the other hand, the 28,254x28,254 mass matrix M is determined by ANSYS based on the material and geometrical parameters given and could be only extracted through ANSYS scripting. The ANSYS model is also validated against the historical natural frequency measurements, the primary mode shape has been deemed to be mode 1, based on the participation factor solver embedded in ANSYS, the effective mass ratio is at 83% out of the total mass. This reflects the mass matrix is relevant to the field conditions.

The algorithm adopted in this study to implement the EFI on the bridge model follows E,q 2 and 6. The function of the initial EFI algorithm is outlined as follows: 1.import the mode shape matrix, 2.determine and record the initial independence distribution vector E_D using the complete mode shape matrix, 3. determine and record the initial determinant of the FIM using the complete mode shape matrix, and 4. perform the iterative process to delete candidate sensor locations. This iterative process includes: a. determine the lowest diagonal from the E_D, b. record, then delete the candidate sensor location with the lowest diagonal, and c. modify

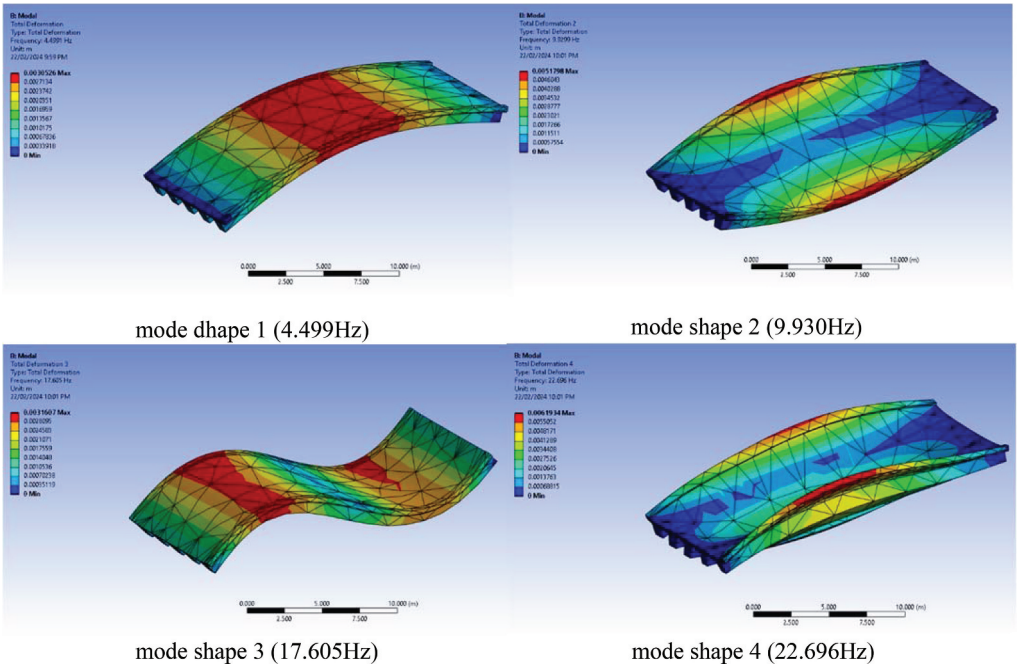

Figure 3. The first 4 mode shapes.

the mode shape matrix and calculate the new E_D and the new determinant of the FIM. The algorithm requires the mode shape matrix as input and returns the candidate sensor locations in order of deletion and the corresponding determinant of the FIM of the remaining sensor locations. Research on any existing EFI algorithm available for use prior to developing a novel MATLAB program. However, the search found that no EFI algorithm had been yet made available publicly and a new EFI algorithm was made specifically for this study. The algorithm executes its functions as intended and runs for about 4 hours for the 9,418 candidate sensor locations. Although there are 28,254 DOFs, in each iteration, the algorithm removes all the DOFs associated with the node to be deleted, reducing the number of iterations required.

4 RESULTS DISCUSSION

The developed EFI algorithm successfully truncating the list of candidate sensor locations until the desired 10 optimal locations are reached as shown in Figure 5, nine sensor locations are presented on the kerb and one at the bottom of the bridge girder.

Figure 4 displays a portion of the truncated list along with each DOF's corresponding contribution to the FIM determinant vector for the EFI. To simulate the feasibility of installation and operation on an actual bridge, only sensors located on the roadway of the bridge are selected for placement. Moreover, the faded circles indicate that the sensors are hidden from the view, located either under or on the side of the bridge deck. Additionally, the determinants of the FIM and the KE at each iteration for EFI arE Recorded And Then Plotted As Shown In Figure 6 and Figure 7 respectively. As shown in Figure 6, a comparison plot of FIM determinant derived from the case study EFI application is drawn against the original trend reported by Kammer (1991). As sensors are deleted, the FIM determinant trend follows the exponential decrease closely to the original study.

In addition, the graphical representation in Figure 7 exhibits the comparison between the kinetic energy (KE) derived from the EFI method alongside the original trend reported by

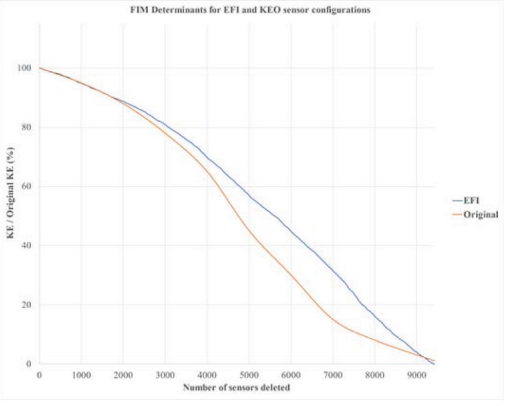

Figure 7. EFI KE retention.

(Heo et al., 1997). The original KE trend illustrates an almost linear correlation between the reduction in KE and the quantity of removed sensors. Despite a slight overall increase, the EFI case study application demonstrates a proportionate decrease in KE, mirroring the original linear trend while exhibiting a slight deviation over the entire plot. The EFI configuration shows a proportionate decrease in KE as a greater number of DOFs removed, suggesting its capability to retain sufficient KE along iterations. It is then practical to expect that adopting x% of considered sensor locations should retain at least x% of the total system kinetic energy. Likewise, to obtain the greatest KE in the system requires adopting as many sensors as possible. Yet, measuring KE could be argued as a better indicator of the accuracy of the adopted sensor configuration. Based on these findings, it can be argued that the implementation of the EFI method on the simplified reinforced concrete bridge model was successful as it follows the expectations listed in available studies.

5 CONCLUSIONS

In conclusion, the instrumentation of efficient and effective SHM systems on concrete bridges is crucial for ensuring the safety and longevity of these infrastructure assets. By adopting the EFI optimisation method, sensors can be strategically placed in key locations, ensuring the

accuracy of structural displacement measurements with a minimal number of sensors. This ensures bridge asset owners respond to sudden damages and potential failure in a timely manner though continuous bridge health monitoring. The development of a streamlined SHM system for concrete bridges, focusing on remote monitoring through optimal sensor placement and instrumentation methodologies, is of paramount importance. In this case-study, the adopted EFI method accurately predicted both the decreasing trend of FIM determinants and retained kinetic energy along with the iterative sensor deletion process, in close similarity to the previous studies. As the result, this system is expected to provide precise and reliable monitoring capabilities once sensors are correctly installed accordingly. In future, by leveraging advanced analytics and machine learning algorithms, the collected data could be analyzed to detect anomalies and deviations from expected behavior.

Overall, the development trial of an optimised SHM system with OSP for concrete bridges, supported by the successful implementation of the EFI method is a significant step towards ensuring the safety, longevity, and cost-effective maintenance of bridge infrastructure. By continuously monitoring the structural behavior of bridges, potential issues can be identified early on, leading to timely intervention. Ultimately, this will enhance the overall safety and performance of concrete bridges for the future.

ABSTRACT: This paper summarises the latest work carried out by the authors on the dynamic behaviour of various structures in Spain. After briefly reviewing the state-of-the-art on the subject, the description of the most relevant structures that are object of the study is included, a road and a railway bridge, as well as the installed monitoring and the dynamic analysis carried out. As most relevant results, the main conclusions for the road structure regarding the evolution over time of the dynamic parameters are presented, as well as the improvements in the calculation of the modal damping ratio. In this last case, the results obtained by applying different calculation methods are also shown, including an alternative methodology based on the reduction of the spectrum, whose main advantage is that it does not require the use of filters in multiple-degree-of-freedom systems, which contributes to reduce perturbations in the results.

1 INTRODUCTION

Technological evolution in recent years has made possible the extension of automatic structural health monitoring (SHM) systems for bridges, where dynamic parameters can be included as reference thresholds. However, given the singularities of bridges, the conclusions obtained in each case are not necessarily generalizable to similar cases. For this reason, academic studies carried out on real structures are of great interest, such as the two cases included in this communication: one road bridge, which is a long span metal arch, and another railway bridge, which is a continuous concrete girder.

Likewise, the studies carried out to date have shown the great dependence that exists in the case of the modal damping ratio on the calculation method. This paper summarises the new theoretical studies carried out in this regard, and proposes an alternative calculation method based on the reduction of the spectrum, thus minimizing the introduction of perturbations in the results. The results obtained in their application to one of the real structures are also included.

2 MAIN REFERENCES

Among the main references on the analysis of the dynamic behaviour of real structures, we can mention the studies carried out on the Europa Bridge (Austria), where the correlation between the first natural frequency and the ambient temperature was observed, as well as the

DOI: 10.1201/9781003483755-290

convenience to introduce corrections due to additional moving masses, which allowed the establishment of thresholds that could be used in an SHM system (Wenzel 2009); the work carried out by Magalhães, Cunha and Caetano in the monitoring of the Infante Don Enrique bridge in Porto (Portugal), which analysed the evolution over time of the dynamic parameters under the effect of environmental variables, such as temperature and recorded accelerations, which also made it possible to set thresholds for be used in an SHM system (Magalhães et al. 2008, 2009 and 2012); the analysis carried out by Gentile and Saisi on the evolution of the historic bridge of Paderno (Italy), where the relationship between the values of eigenfrequencies and changes in excitation (Gentile & Saisi 2010); the studies carried out by Soria, Díaz, García-Palacios and Ibán on a pedestrian walkway in Valladolid (Spain), which confirmed the great dependence of the modal parameters on temperature and that, once corrected, could be taken as a reference in a SHM system (Soria et al. 2016, Soria 2019); or the work carried out by Astiz on the dynamic behaviour of the cable stays of the Waterford Bridge (Ireland), in which it could be seen that the maximum accelerations in the cables were not due to traffic, but to the effect of wind (Astiz 2016).

Figure 1. Structures under study: E-1 (left) and E-2 (right) (Spanish Ministry for Transport and Sustainable Mobility, DGC and Adif).

Likewise, with regard to the possible identification of damage through variations in the dynamic behaviour of structures, the scale test carried out by Kölling, Reskin and Sargsyan can be mentioned, which demonstrated the appearance of new natural frequencies in the damaged structure, a reduction in the value of the main natural frequency and relevant modifications in the value of the modal damping factor (Kölling 2014); as well as the study carried out on the Regau Bridge (Austria), which showed a significant reduction in the frequency amplitude and a notable increase in the damping factor (Wenzel 2009).

Finally, in relation to the problem of the practical calculation of the modal damping ratio, the studies referenced by Wenzel on the Berlin Bridge in Halle (Germany) are of interest, where the disparity of results according to the calculation methods that were used (logarithmic decrement, adjustment to the theoretical curve and RDT) were revealed; as well as on the Regau Bridge (Austria), mentioned above, which also showed important differences both when the bandwidth method was used on the signal spectrum and depending on the type of filter.

3 STRUCTURES UNDER STUDY AND DYNAMIC ANALYSIS

3.1 *Description of the structures*

The objective of this study was the analysis of the experimental data recorded after the traffic opening of various structures, although this communication is exclusively focused on a road and a railway bridge, which are shown in Figure 1 (López Aragón & Astiz 2023).

The first of the structures is the road bridge known as "Arcos de Alconétar" (hereinafter, structure E-1). This viaduct is located on the A-66 highway, belonging to the State Highway Network in Spain, and allows it to cross the Tagus River.

This structure is composed of two twin structures 400 m in length, whose main spans are metal arches (spans of 220 m and 42.5 m rise) with an upper deck. Each of the arches is formed by two longitudinal pieces with a box section braced together. The deck, formed from a continuous section of composite steel–concrete structure, is simply supported on the metal pillars that rest on the arch and the reinforced concrete piers belonging to the access sections. The length of the spans, 26 m, is identical both in the access sections and in the main section. The steel used in the whole structure (arches, deck beams, and pillars on arches) is a weathering steel with improved resistance to atmospheric corrosion.

The second structure is the railway viaduct called "Arroyo del Valle" (hereinafter, structure E-2). This bridge is part of the Madrid – Segovia – Valladolid/Medina del Campo high-speed railway line, also in Spain.

The total length of the viaduct is 1755 m, divided into 2 extreme spans of 52.50 m and 25 intermediate spans of 66.00 m each. It is made up of a concrete box beam with a hollow box cross-section with a lower and upper slab and a variable depth between 3.30 m in the center of the span and 5.00 m in the pier support area. There are a total of 25 piers, with a hollow rectangular concrete box section. In addition, there is an ogival-type arch in the central area of the viaduct, formed by two semi-arches with a radius of curvature of 312.00 m and a hollow rectangular concrete box section so that the key of the arch materializes the fixed point of the structure, and both ends remain free.

3.2 *Monitoring*

In the case of structure E-1, the dynamic instrumentation was made up of 10 accelerometers (5 on each road), 2 anemometers and 2 vanes (on the left road). These accelerometers were located on each roadway as follows: three vertical accelerometers in the haunches of the arch (two in the south haunch and one in the north haunch) and two accelerometers in the key of the arch, one of them vertical and another transversal. The instrumentation was completed with a total of 37 thermometers and 2 laser distance meters to measure the movement of the expansion joints of the structure. The monitoring period in which there are dynamic records is between the months of March and September 2010.

In the case of structure E-2, the instrumentation that was implemented in the viaduct allowed the following variables to be controlled: pier movements, relative movements of pier/abutment– deck, accelerations due to centrifugal force and braking, vertical accelerations, wind speeds (gusts), train speeds, temperature and environmental conditions. For the study of dynamic behaviour, there were 15 accelerometers, 12 of which were vertical, 2 longitudinal and 1 transversal. The structure had this dynamic monitoring between the months of June 2008 and December 2009.

3.3 *Dynamic analysis*

Figure 2 shows an example of the type of dynamic analysis carried out in both structures. From the dynamic events recorded, the most representative ones during the monitoring period were selected (around 7% in both cases).

In each case, we started from the accelerograms of all the accelerometers (channels) corresponding to each event; sections of free vibrations were identified; analysis in the frequency domain was carried out, obtaining the eigenfrequencies; accelerograms corresponding to each natural frequency were filtered; and, finally, the modal damping factor associated with each natural frequency was obtained by applying different calculation methods. The whole obtained information was stored in a database.

Due to the typology of the E-2 structure, built mainly with concrete, accelerations were very reduced and the modal damping ratio was very high. This means that the entire structure was not excited by the passage of the moving load and gave rise to very short accelerograms, making it impossible to obtain precise values for both the natural frequencies and the modal damping ratios. Therefore, the rest of this communication will focus on the results obtained in the case of the E-1 structure.

4 EVOLUTION IN TIME OF THE DYNAMIC PARAMETERS

After the process indicated in the previous section, the study of the evolution of the dynamic parameters of the E-1 structure during the monitoring period was carried out (López-Aragón & Astiz 2014). In the case of the natural frequencies, a notable stability was observed, although certain variations occurred. In the case of the modal damping factor, although the results remained around certain values, greater variability was observed. In all cases, the possible relationship with other variables was studied: ambient temperature and arch

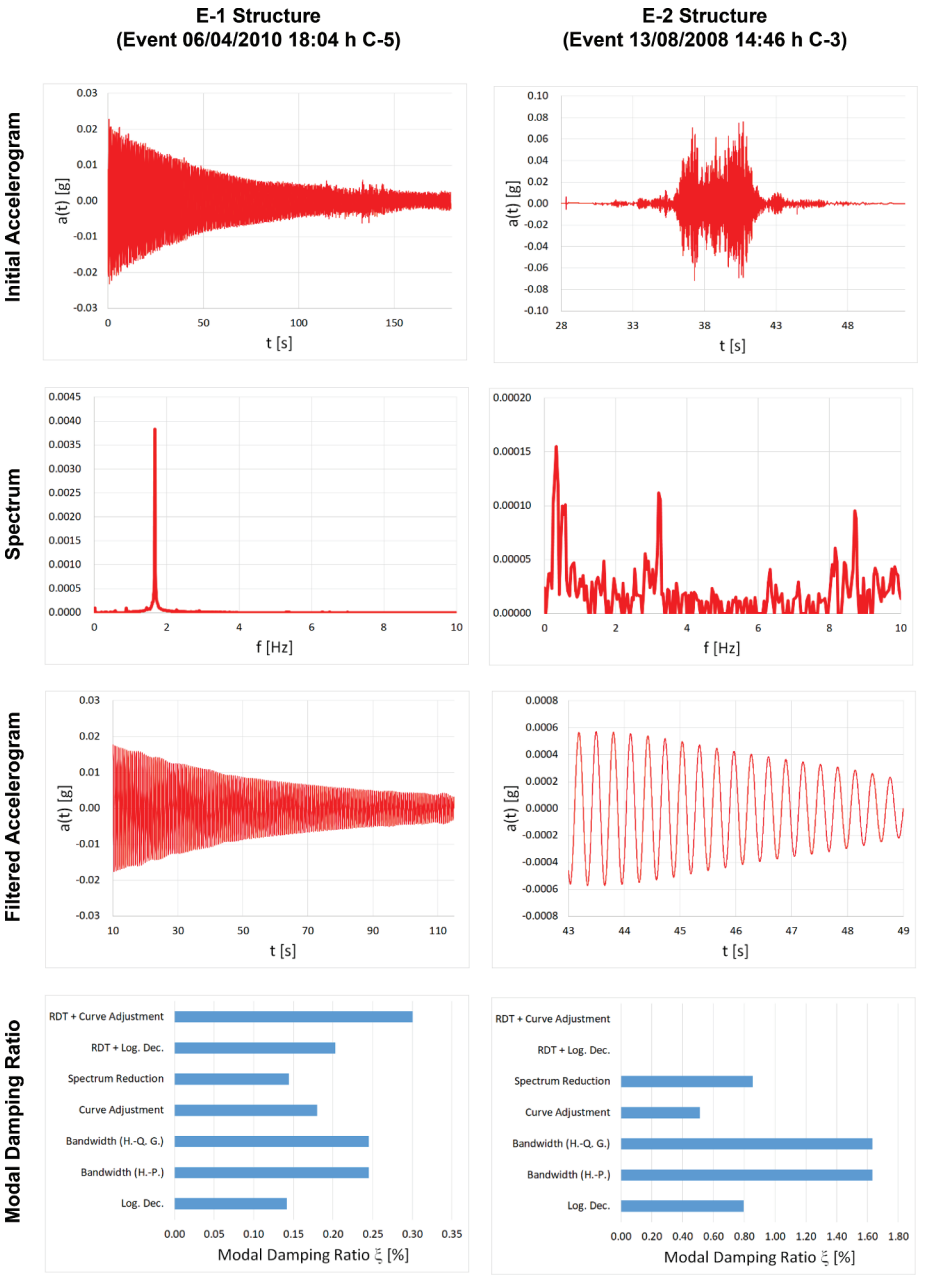

Figure 2. Example of the study of two accelerograms corresponding to structures E-1 and E-2.

temperature, average wind and maximum accelerations, both vertical and horizontal, since they represent the load to which the structure is subjected and, therefore, which resistant mechanisms are activated.

Table 1. E-1 Structure. Coefficients of determination for the mathematical models of the evolution of dynamic parameters.

	Coefficient of Determination (R^2)	
	Natural Frequency Model	Modal Damping Ratio Model
$f_{exp\ 1}$ = 0.396 Hz	0.66	0.30
$f_{exp\ 2}$ = 0.600 Hz	–	–
$f_{exp\ 3}$ = 0.878 Hz	0.58	0.04
$f_{exp\ 4}$ = 1.440 Hz	0.57	0.21
$f_{exp\ 5}$ = 1.674 Hz	0.24	0.30
$f_{exp\ 6}$ = 2.262 Hz	0.90	0.18
$f_{exp\ 7}$ = 3.018 Hz	–	–
$f_{exp\ 8}$ = 8.267 Hz	–	–

In the case of the natural frequencies, it was observed that there was an important relationship with the ambient temperature, which improved when the maximum accelerations were considered. However, practically no relationship with mean wind velocity was observed.

In the case of the modal damping ratio, the results –obtained using the logarithmic decrement method– showed a certain relationship with average wind velocity, which also improved when considering maximum accelerations. On the contrary, no relationship was observed with temperature, neither ambient nor arch.

For each natural frequency, when possible, a mathematical model was proposed that, taking into account these environmental variables, would allow correcting the values obtained for both the natural frequencies and the modal damping ratio. The results are summarised in Table 1. As it can be seen, the values of the coefficient of determination, R^2, are much higher in the case of the natural frequency models, even reaching 0.90. In them it was clearly seen that, when the temperature increases, a reduction in the value of the eigenfrequencies occurs. In the case of the modal damping ratio, the coefficients of determination are more reduced, and in some cases the behaviour is not clear, which may be due to the greater dispersion of the results.

In any case, the obtained results supported the possibility of incorporating dynamic parameters into a system for monitoring the structural health of this bridge, being able to set thresholds for them.

5 CALCULATION OF THE MODAL DAMPING RATIO

5.1 *General considerations*

As it was indicated in Section 2, several authors have warned about the variability of the damping factor ratios depending on the calculation method used. As an example, Table 2 shows the numerical results obtained for the accelerograms of the events shown in Figure 1. It can be seen that, in these specific examples, the damping values can even be doubled depending on the calculation method used. Therefore, it is important to know which calculation method for the modal damping factor is the one that is being used in SHM systems for bridges.

In addition, there are multiple variables that can influence the results, for example: in the logarithmic decrement method, the type of filter and the number of consecutive cycles that are considered; in the two formulations of the bandwidth method, it seems that the shape of the spectra has a lot of influence, especially if they show very sharp maxima; in the method of fitting to the theoretical curve, the discretization that is carried out to find the best fit; and in the random decrement technique (RDT), the duration set for the intervals and the threshold that is adopted. In conclusion, the used calculation methodology is a complex issue and has a great impact on the obtained results.

5.2 *Proposal for an alternative calculation method (Spectrum Reduction Method, SRM)*

To partially solve this problem, especially regarding to the disturbances introduced as a consequence of the application of the different filters, in the work carried out, it has been proposed an alternative method for the calculation of the modal damping ratio, based on the reduction of the signal spectrum (López-Aragón et al. 2024).

Table 2. E-1 and E-2 structures. Calculation of the modal damping ratio in two specific events applying various calculation methods.

	Modal Damping Ratio (%)	
Calculation Method	E-1 Structure (Event 06/04/2010 18:04 h C-5)	E-2 Structure (Event 13/08/2008 14:46 h C-3)
Logarithmic Decrement	0.142	0.795
Bandwidth (Half-Power)	0.245	1.631
Bandwidth (Half-Quadratic Gain)	0.245	1.630
Curve Adjustment	0.180	0.513
Spectrum Reduction	0.144	0.855
RDT + Log. Dec.	0.203	–
RDT + Curve Adjust.	0.300	–

As a summary, compared to the calculation of the modal damping ratio based on the study of the decrease in amplitude of the accelerogram in the time domain, this method is based on seeing how the Fourier transform of the original accelerogram decreases in the frequency domain, that is, its magnitude spectrum. To do this, the damping factor, ξ_k, for the desired natural frequency, f_k, is obtained from the following expression:

$$\xi_k = \frac{\ln\left(A_{k,q}/A_{k,q+n}\right)}{2\pi f_k \Delta t} \tag{1}$$

where $A_{k,q}$ y $A_{k,q+n}$ are the peak values of the spectrum for the k-th natural frequency in the initial spectrum section and in the last spectrum section, respectively; and Δt is the time distance between both spectrum sections.

The main advantage of this method is that it allows the study of multiple-degrees-of-freedom systems whose vibration modes are reasonably separated, which usually happens in bridges, without the need to apply filters to the initial signal to isolate each vibration mode.

As it can be seen in the reference where this method has been developed, the theoretical formulation does not restrict either the length of the spectrum sections or the number of separation cycles between them. However, the practical application suggests that, on the one hand, the sections must have sufficient length to adequately characterize the wave, that is, that the nature of the different excited natural frequencies is adequately manifested; and, on the other hand, the separation between the cycles must allow the damping of the structure to be appreciated in the free vibration regime. Likewise, to ensure that the vibration modes are reasonably separated, some prior knowledge of the structure is required.

Finally, it should be noted that, if damped free vibration does not predominate in the recorded accelerogram, this method would not be applicable, since the system would be excited by external forces and the formulation presented would not be applicable.

Both Figure 2 and Table 2 also include the values of the modal damping ratio obtained by applying the SRM methodology.

5.3 *Study on theoretical simulations*

To validate this method, the study was firstly carried out on several theoretical simulations, which modeled the behaviour of up to three superimposed waves, to which a random noise slightly higher than that expected from the measuring instruments was also added.

The average relative errors obtained through the study are shown in Table 3. It can be seen how the SRM method gave practically exact values (0.00%), followed by the logarithmic decrement (0.86%), the two formulations of the bandwidth (1.14% for half-power and 1.16% for half-quadratic), the two applications of the RDT method (2.15% combined with the logarithmic decrement and 3.06% combined with the curve adjustment) and, finally, the curve adjustment method (13.47%).

5.4 *Experimental analysis*

Likewise, the modal damping ratio of all the accelerograms corresponding to the dynamic events studied in the E-1 structure was recalculated by applying the same methods that were applied to the theoretical simulations.

Table 3. E-1 Structure. Average relative errors expected theoretically and recorded experimentally for the modal damping ratio.

Modal Damping Ratio Calculation Method	Averaged Relative Error (%)	
	Theoretical simulations	Registered Accelerograms
Logarithmic Decrement	0.86	–
Bandwidth (Half-Power)	1.14	428.38
Bandwidth (Half-Quadratic Gain)	1.16	336.71
Curve Adjustment	13.47	23.89
Spectrum Reduction	0.00	11.79
RDT + Log. Dec.	2.15	34.11
RDT + Curve Adjust.	3.06	81.52

In this case, those obtained using the logarithmic decrement method were adopted as reference values and the extent to which the results deviated by applying the rest of the methods was analysed. The results, which are shown in Table 3, show that the smallest differences were achieved with the SRM method proposed by the authors (11.79%), followed by the theoretical curve adjustment method (23.89%), RDT combined with logarithmic decrement (34.11%), RDT combined with curve adjustment (81.52%) and the two bandwidth formulations, the results of which were even several orders of magnitude higher (336.71% for half-quadratic gain and 428.38% for half-power).

It should be highlighted that the behaviour of the different calculation methods in the real accelerograms is quite different from when they were applied to the theoretical simulations, given that the variations are much higher, even of several orders of magnitude. This is especially relevant in the case of the two formulations based on the bandwidth method and, although more studies must be carried out in this regard, it seems to be related to the fact that the spectra are very sharply pointed in the case of this structure.

5.5 *Correlation between calculation methods*

In view of the clear dependence of the results on the calculation method adopted, another issue that was studied was the possibility of correlating the results obtained using two different calculation methods.

In that sense, it was noted that there was a great correlation between the results obtained through the SRM and the logarithmic decrement method (R^2=0.89) and, although smaller, also between the curve fitting method and the logarithmic decrement (R^2=0.65).

5.6 *Influence of the calculation methods in the damping predictive model*

Finally, another question that was studied is whether, as a consequence of the application of the other calculation methods, there was any significant change in the predictive model established for damping, the conclusions of which are summarized in Section 4. In this case,

although there could be some specific changes, both better and worse, in the study of the modal damping ratio corresponding to some of the eigenfrequencies, no significant changes were observed on average.

6 FUTURE STUDIES

As future studies, the following are proposed: the extension of the analysis of the behaviour of the dynamic parameters to the case of other real viaducts of different typologies; delve into the physical modelling of the correlations observed during the experimental analysis of the E-1 structure, especially between the eigenfrequencies and the temperature and the damping and the mean wind in the case of some of the eigenfrequencies; and, finally, carry out more studies on the variation of dynamic parameters as a consequence of the existence of damage to structures, both through the use of computational models, especially in the case of natural frequencies, and through use of scale tests, which would allow the study both in terms of the natural frequencies and the modal damping factor.

7 CONCLUSIONS

Throughout this paper some of the latest works carried out by the authors on the dynamic behaviour of various structures in Spain have been summarized, where the dynamic analysis of two real structures stands out, one road, which is a long span metal arch, and another railway, which is a continuous concrete girder.

From the point of view of the evolution over time of the dynamic parameters, it has been seen that, in the case of the road structure, it is possible to establish a model that considers several variables: temperature, the average wind and the maximum accelerations. In the case of the natural frequencies, very good correlations have been achieved taking into account the ambient temperature and the maximum accelerations, both vertical and transversal. In the case of the damping factor, although the correlations are smaller, a certain relationship with average wind velocity and maximum accelerations has also been observed.

Regarding the calculation of the modal damping ratio, the problems observed when applying the different calculation methods have been highlighted. As a consequence of this, an alternative calculation method proposed by the authors has been described, based on the reduction of the signal spectrum (Spectrum Reduction Method, SRM). The paper includes the most notable results of its application to both theoretical simulations and the experimental results recorded in the case of the road structure, which has given excellent results. Likewise, the possibility of correlating the results obtained between the logarithmic decrement and the SRM, as well as with the curve adjustment method, has been seen.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to the Spanish Ministry for Transport and Sustainable Mobility, particularly to the General Directorate of Roads (DGC) and the Administrator of Railway Infrastructures (ADIF), for facilitating access to the data of the monitored structures; to those responsible for Kinesia Data and IMC, for the necessary software for data processing; and to Ideam, for providing access to the computational model used during the construction of the E-1 structure.

Equivalent structural stress concentration factor for non-planar oblique butt joints

X. Wei & Q.L. Jia
The Department of Bridge Engineering, Southwest Jiaotong University, Chengdu, The PRC

ABSTRACT: Based on the finite element software ABAQUS, 135 non-planar oblique butt joint finite element models were established by considering different in-plane oblique angles and out-of-plane angles, aspect ratios, and stress ratios to investigate the equivalent structural stress concentration factor (ESSCF). The results show that the maximum ESSCF value only occurs at the obtuse angle point (hot point A1) of the weld toe on the concave side near the loading end and the obtuse angle point (hot point D1) on the convex side of the weld toe near the constraint end. As the out-of-plane angle increases, ESSCF at both points continues to grow at a nearly constant the in-plane oblique angle increases, the growth rate of ESSCF at hot point A1 gradually decreases, but the trend of ESSCF value change may increase or decrease; the change rate at hot point D1 remains almost constant, and the overall ESSCF decreases with an increase in in-plane inclination. As the stress ratio increases, ESSCF at hot point A1 continues to grow at a decreasing rate, while ESSCF at hot point D1 decreases at a decreasing rate. As the aspect ratio increases, ESSCF at hot point A1 continues to grow at an increasing rate, while ESSCF at hot point D1 decreases at an increasing rate. At the same time, the location of the maximum value tends to shift from hot point D1 to hot point A1 as the in-plane oblique angles, stress ratio, and aspect ratio increase but do not vary with changes in the out-of-plane angle. Finally, based on the ESSCF extraction results, formulas for calculating ESSCF at hot points A1 and D1 were obtained by LM-UGO fitting.

1 INSTRUCTIONS

With the innovative design of steel bridge structures, new and complex welded joints are being used in steel bridges, and their fatigue performance under long-term repeated loading deserves attention (Wei et al. 2017, 2018, Xiao et al. 2023). Non-planar oblique butt welded joints are commonly found in cable-girder anchorage structures of cable-stayed bridges, in which both oblique angle and out-of-plane angle exist between the two plates. The oblique angle can cause shear stresses at the weld toe, while the out-of-plane angles can cause bending stresses at the weld toe, both of which can affect the stress concentration at the weld toe, thereby affecting the fatigue life of the butt joint (Jie et al. 2017).

Including nominal stress method, hot spot stress method, notch stress method, and equivalent structural stress method, fatigue design and evaluation methods are recommended in the design standards, such as the International Institute of Welding (IIW 2000), the American Welding Society (AWS 2015), the American Petroleum Institute (API 2014), and the Eurocode 3 (CEN 2005). The equivalent structural stress method was proposed by Dong (2001) and used to predict the fatigue life of welded structures by constructing a master S-N curve based on structural stress. Unlike other stress methods, which rely on grid density for calculation (), the structural stress method is insensitive to the grid. It effectively converts the stress of complex three-dimensional regions of the structure into a two-dimensional crack problem (Kyuba et al. 2005). The equivalent structural stress is related to the structure's geometric

DOI: 10.1201/9781003483755-291

form, size, and weld toe position and is often obtained through finite element numerical simulation. The stress concentration degree of the structure can be quantified by the equivalent structural stress concentration factor (ESSCF).

Over the years, scholars have conducted much research on butt joints. Five types of specimens with different oblique butt-welding angles were used for the fatigue tests and subjected to fixed-directional loading to study the effect of oblique loading on the fatigue strength of butt-welded structures(Jen et al. 2008). Dong et al. (2019) evaluated the fatigue reliability of misaligned butt welded joints based on the structural hot spot stress method. Shen et al. (2019) derived the stress amplification factor considering the initial deformation effect of the thin plate based on the modified thick plate calculation formula. They compared the calculation results with traditional specifications. Su et al. (2020) studied the fatigue performance of the weathering steel Q345qNH butt welded joint without corrosion. The fatigue fracture mechanisms and the fatigue property evaluations of S355J2W steel butt-welded joints relieved welding residual stresses with and without welding reinforcement were systematically investigated by microstructure characterization and fatigue tests (Wang et al. 2023). At present, scholars have already done relatively complete research on butt joints, but there are still deficiencies in the study of non-planar oblique butt joints with both in-plane and out-of-plane angles.

This article establishes a finite element model of non-planar oblique butt joints using the ABAQUS software, analyzes the variation law of ESSCF at the weld toe with various parameters, and establishes a functional relationship for the ESSCF of non-planar oblique butt joints.

2 GEOMETRIC PARAMETERS

The geometric structure of a non-planar oblique butt joint is shown in Figure 1, where α is the oblique angle, γ is the out-of-plane angle, l is the distance from the obtuse-angle side weld toe to the edge of the test specimen, w is the plate width, and t is the plate thickness.

The oblique angle α and out-of-plane angle γ are the main research contents of this article. At the same time, the aspect ratio l/t and stress ratio σ/σ_0 are also the main factors affecting the ESSCF. This article takes the following values for each dimensionless parameter: α is taken as 30, 50, 70, γ is taken as 0, 4, 8, l/t is taken as 4, 6, 8, σ/σ_0 is taken as 0.5, 0.75, 1.0, 1.25, 1.5. The average stress σ_0 is taken as 100 MPa. A total of 135 models are established for parameterized research. In this study, the plate thickness t is 16 mm, and the plate width w is 50 mm.

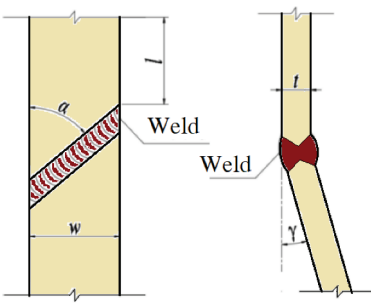

Figure 1. Non-planar oblique butt joint.

Many fatigue test results show that fatigue cracks in welded joints often start at the weld toe, and due to the relatively weak constraints at the structural boundary, cracks often originate at the intersection of the weld toe and the structural boundary. Therefore, this article focuses on solving and analyzing the eight hot spots at the weld toe, as shown in Figure 2. The

concave side of the loading end is the weld toe A, the convex side is the weld toe B, and the concave side of the constrained end is the weld toe C. The convex side is the weld toe D. Hot-point 1 is the location where the angle between the weld toe line and the plate edge is obtuse, and hot-point 2 is the location where the angle between the weld toe line and the plate edge is acute. Points A1 represent the hot spot at the obtuse angle of the weld toe A.

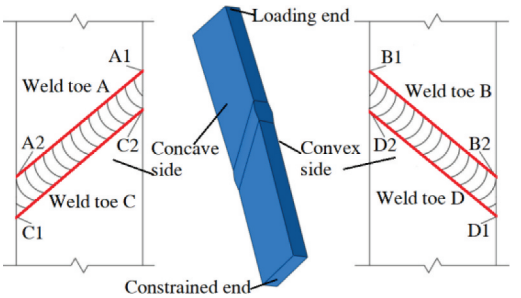

Figure 2. Hot-point in weld toe.

3 PARAMETRIC ANALYSIS OF ESSCF

3.1 *The definition of ESSCF*

According to the equivalent structural stress method, the stress in a welded joint can be decomposed into two parts, as shown in Figure 3. The first part of the stress is the structural stress that satisfies the equilibrium condition; the second part is called the notch stress.

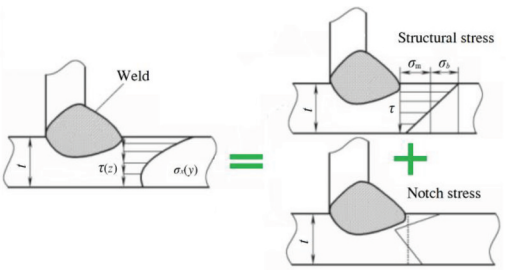

Figure 3. Structural stress and notch stress.

The structural stress, σ_s, is the sum of the membrane stress, σ_m, and the bending stress, σ_b. The membrane stress, σ_m, and bending stress, σ_b, within a section can be calculated using the following equations:

$$\sigma_m = \frac{1}{t}\int_{-t/2}^{t/2} \sigma_x(y)dy = \frac{f_y}{t} \tag{1}$$

$$\sigma_b = \frac{6}{t^2}\int_{-t/2}^{t/2} y\sigma_x(y)dy = \frac{6m_x}{t^2} \tag{2}$$

Where, t is the plate thickness; σ_x(y) is the distribution of structural stress along the plate thickness direction; f_y is the line force; m_x is the line moment.

After statistical analysis and fitting of a large number of experimental data, Dong defined the formula for equivalent structural stress range ΔS_s:

$$\Delta S_s = \frac{\Delta\sigma_s}{t^{(2-m)/2m} I(r)^{1/m}} \tag{3}$$

Where, m is the fatigue crack growth-related parameter obtained from experiments; $\Delta\sigma_s$ is the structural stress range; and I(r) is a dimensionless function of the load bending ratio r.

In this paper, the ESSCF is defined as the ratio of the equivalent structural stress S_s to the nominal stress σ_n.

$$ESCF = \frac{S_s}{\sigma_n} \tag{4}$$

Numerical analysis was conducted on non-planar oblique butt-welded joints, and the ESSCF for each hot spot at the weld toe were obtained according to Equation 4. The results showed that the maximum ESSCF occurred at points A1 or D1, which were located on the diagonal of the weld. As σ/σ_0, l/t, and α increased, the location of the maximum ESSCF shifted from point D1 to point A1. The location of the maximum ESSCF did not change with the change in γ. When γ=0, the ESSCF values at points A1 and D1 were the same.

3.2 *FE model of non-planar oblique butt joints*

Because the basis of structural stress is based on the equilibrium relationship, and the equilibrium relationship of force is insensitive to the number of nodes, the structural stress has the characteristic of grid insensitivity. The parameterized analysis model in this article adopts The C3D8R solid element in ABAQUS. In order to ensure the consistency of the number of structural stress samples extracted from each parametric model, the grid division is uniformly specified. The global element grid length is 5mm, the number of element divisions at the weld toe is 12, and the number of element divisions in the plate thickness direction is 4. The FE model of non-planar oblique butt joints is shown in Figure 4.

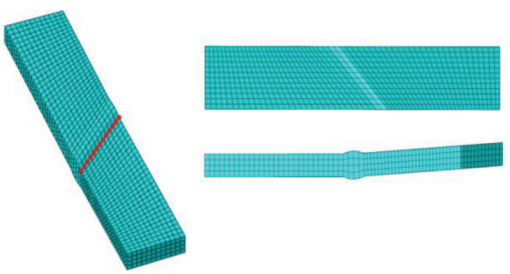

Figure 4. FE model of non-planar oblique butt joints.

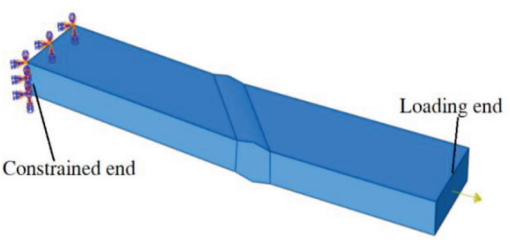

Figure 5. Loading and constrained condition.

One end of the model is the constrained end, and the other end is the loading end (Figure 5). The direction of the external load is consistent with the direction of the center line of the plate, acting on the center of the section. The degrees of freedom in all three directions of the constrained end are constrained.

3.3 *The influence of parameters on the ESSCF*

The variations in ESSCF at point A1 with different parameters are shown in Figure 6.

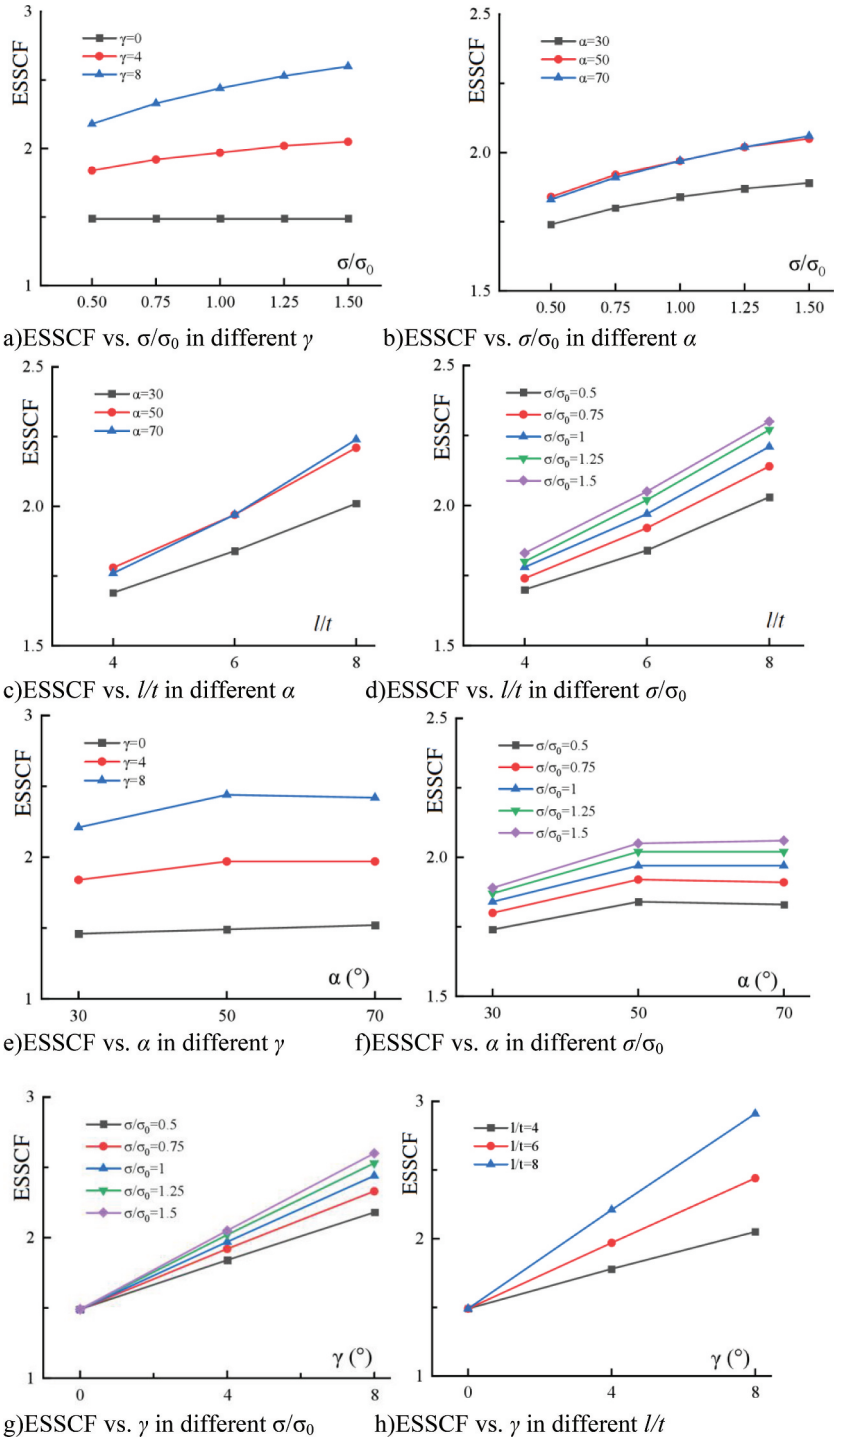
ESSCF at point A1 positively correlates with σ/σ_0, l/t, and γ. As σ/σ0 increases, the growth rate of ESSCF gradually decreases. With the increase of l/t, the growth rate of ESSCF gradually increases. As γ increases, ESSCF shows an approximately linear growth. As α increases, the growth rate of ESSCF gradually decreases. When α increases from 30 to 50, ESSCF increases accordingly; when α increases from 50 to 70, the change in ESSCF is relatively small and may slightly increase or decrease under different combinations of the other parameters.

The variations in ESSCF at point 4-1 with different parameters are shown in Figure 7.

It can be seen from Figure 7 that ESSCF at point D1 is positively correlated to γ. At the same time, the increase ratio of ESSCF increases with γ. ESSCF is negatively correlated to σ/σ_0 and l/t. With σ/σ_0 increasing, the rate of ESSCF decrease gradually slows down; with l/t increasing, the rate of ESSCF decreases gradually increases. As the increase of α, the rate of ESSCF change is almost constant, and ESSCF is approximately linearly changing. ESSCF decreases with the increase of α in different σ/σ_0 and l/t. When γ=0, ESSCF increases with the increase of α. When γ=4 or 8, ESSCF decreases with the increase of α.

4 CALCULATION FORMULAS OF ESSCF

4.1 *LM-UGO algorithm*



The most commonly used algorithms in nonlinear regression are the Marquardt method, Simplex algorithm, Simple surface climbing method, etc. However, regardless of the method, the user must provide appropriate initial parameter values. It is difficult to converge if the initial values are not set correctly. Providing appropriate initial parameter values in practical applications is pretty challenging, especially in cases with many parameters, and the difficulty increases sharply. However, the Levenberg-Marquardt algorithm and universal global optimization(LM-UGO) can solve this problem (Marquardt 1963). The most significant feature of this method is that it does not require users to provide initial values. With its robust optimization and error tolerance ability, in most cases, the correct results can be obtained starting with any random initial value, improving the solve rate and reducing the threshold for using it. Therefore, the LM-UGO algorithm was chosen to use in this article to calculate the function of ESSCF at points A1 and D1.

4.2 *Formula fitting at point A1*

In order to achieve high accuracy in fitting the formulas of non-planar oblique butt joints, this article uses polynomial functions for fitting. As described in section 3.2, ESSCF approximately linearly increases with the increase of γ. So γ was fitted linearly while fitting the other three parameters to the highest cubic term, considering all cross terms. Based on the fitting results, remove the coefficients with lower correlation. The final fitting formula is shown below, where the related coefficient R2=0.995.

$$ESSCF_{\mathrm{A1}} = 1.493 + \gamma\left(0.489\frac{l}{t}\frac{\sigma}{\sigma_0}\alpha - 0.541\frac{l}{t}\alpha^3 + 1.648\frac{l}{t}\alpha - 2.467\alpha\right) \tag{5}$$

The comparison between fit values and FEM values is shown in Figure 8a.

g)ESSCF vs. *γ* in different σ/σ0 h)ESSCF vs. *γ* in different *l*/*t*

Figure 7. ESSCF on point D1.

4.3 *Formula fitting at point D1*

Unlike point A1, all parameters at point D1 exhibit non-linearity. Therefore, all parameters are fitted to the highest cubic term, while all cross terms are considered. Based on the fitting results, remove the coefficients with lower correlation. The final fitting formula is shown below, where the related coefficient R2=0.992.

$$\begin{aligned} ESSCF_{\mathrm{D1}} = {} & 1.490 - 1.275\gamma^3\left(\frac{l}{t}\right)^3\left(\frac{\sigma}{\sigma_0}\right)^2 + 0.249\gamma^2\left(\frac{l}{t}\right)^3\left(\frac{\sigma}{\sigma_0}\right)^2 + 0.279\gamma^2\left(\frac{l}{t}\right)^2\frac{\sigma}{\sigma_0} \\ & + 0.0915\gamma\left(\frac{l}{t}\right)^3 - 0.311\gamma\left(\frac{l}{t}\right)^2\frac{\sigma}{\sigma_0} - 1.665\gamma\left(\frac{l}{t}\right)^2 + 9.813\gamma\frac{l}{t} - 6.218\gamma\alpha^2 \end{aligned} \tag{6}$$

The comparison between fit values and FEM values is shown in Figure 8b.

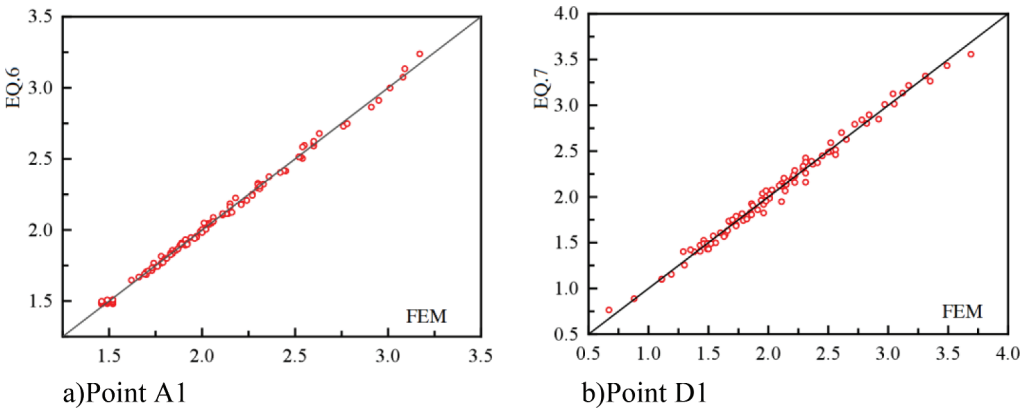

Figure 8. Comparison between fit values and FEM values.

5 CONCLUSION

(1) The maximum of ESSCF only appears at points A1 and D1, located at the obtuse side of the concave side of the load end and the obtuse side of the convex side of the constrained end. These two points are just at the diagonal positions of the structure relative to the weld seam.
(2) ESSCF is approximately linearly increasing with the increase of γ at points A1 and D1. The location of the maximum dose does not change with the change of γ.
(3) The increase rate of ESSCF decreases with the increase of α at point A1. At point D1, the change rate of ESSCF is almost unchanged. When γ=0, ESSCF increases with the increase of α. There is a trend that the location of the maximum of ESSCF shifts from point A1 to point D1 as α increases.
(4) ESSCF keeps on increasing with the increase of σ/σ_0 at point 1-1, and the increase rate gradually decreases. ESSCF keeps on decreasing with the increase of σ/σ_0 at point D1, and the change rate gradually decreases. The maximum ESSCF's location shifts from point D1 to point A1 as σ/σ_0 increases.
(5) at point A1, ESSCF increases with the increase of *l*/*t*, and the increase rate gradually increases; at point D1, ESSCF decreases with the increase of *l*/*t*, and the change rate gradually decreases. The maximum ESSCF's location shifts from point D1 to point A1 as *l*/*t* increases.
(6) Based on 135 non-planar oblique butt joint finite element models, ESSCF formulas at points A1 and D1 were fitted. The relative coefficient R^2 are 0.995 and 0.992. Two formulas reflect the relationship between ESSCF and various parameters at points A1 and D1 well.

Electrochemical-chemical-mechanical phase field model for corrosion-induced cracking

Xurui Fang, Zichao Pan & Airong Chen
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: Evaluating the degradation process of concrete under corrosion-induced concrete fracture is significant in prolonging the service life of structures. This paper presents an electrochemical-chemical-mechanical phase field model to study the processes of non-uniform corrosion, reactive transport and precipitation of $Fe(OH)_2$, rust-induced cracking. The non-uniform corrosion is described based on the electrochemical theory and the precipitation reactions of Fe^{2+} and OH^- in the concrete pore are considered. The eigenstrain caused by rust is related to the volume fraction of corrosion products. The phase field regularized cohesive zone model is calibrated for concrete cracking. The phenomenon of rust movement through cracks can be observed by relating the diffusion coefficient of rust and the phase field variable. The proposed model is validated with the experimental data and shows good agreement with the experimental data.

1 INTRODUCTION

Rebar corrosion can cause concrete cracking, which reduces the structural load carrying capacity and jeopardizes structural safety. In the marine environment, chloride will invade into the concrete. When the chloride concentration on the rebar surface reaches the critical chloride concentration, the surface of the rebar will be depassivated and corrosion will begin to occur(Fang et al., 2023). The rebar corrosion will produce iron ions, these iron ions will not only produce precipitation in the vicinity of the rebar, but also enter the pores and cracks and then form corrosion products. If such behavior is ignored, it is possible to underestimate the corrosion degree of the rebar and thus overestimate the structure safety.

Over the past few years, extensive research has been conducted to investigate the transport of corrosion products. Tran et al. (2011) assumed that corrosion products entering the voids and cracks do not generate strain. Ožbolt et al. (2014) and Sola et al. (2019) described the transport of corrosion products by a convective diffusion equation. Fahy et al. (2017) related the transport of corrosion products to the pressure gradient generated by the confined volumetric expansion. Zhang and Angst (2021) investigated the transport and precipitation of corrosion products in cementitious materials. Korec et al. (2023) presented a mechanistic framework for corrosion-induced cracking in concrete that considers the reactive transport and precipitation of dissolved $^{Fe2+}$ and $^{Fe3+}$.

In this paper, we proposed an electrochemical-chemical-mechanical phase field model. The non-uniform corrosion is described based on the electrochemical theory and the precipitation reactions of Fe^{2+} and OH^- in the concrete pore are considered. The eigenstrain caused by rust is related to the volume fraction of corrosion products. The cracking of concrete is described by the phase field regularized cohesive zone model. The model was verified by an experiment. Finally, the crack pattern and volume fraction of corrosion products were studied.

2 NUMERICAL MODEL

2.1 *Transport and chemical reactions*

Seven agents are considered in saturated concrete: Cl^-, Na^+, OH^-, K^+, Fe^{2+}, $Fe_{(OH)_2}$, O_2. The transport of these agents can be described by Nernst-Planck equation:

$$\frac{\partial C_i}{\partial t} = \nabla \cdot D_i \nabla C_i + \nabla \left(\frac{z_i F}{RT} D_i C_i \nabla \Phi \right) + S_i \tag{1}$$

where D_i, C_i, z_i and S_i are diffusion coefficient, concentration, charge number and reaction rate of i-th ions, respectively; t is the time; F, R and T are Faraday constant, ideal gas constant and absolute temperature, respectively; Φ is the electrostatic potential.

The chloride binding effect is considered based on Langmuir isotherm, and the governing equation for chloride transport is(Liu et al., 2022):

$$(1 + \lambda_{Cl}) \frac{\partial C_{Cl}}{\partial t} = \nabla \cdot D_{Cl} \nabla C_{Cl} + \nabla \left(\frac{z_{Cl} F}{RT} D_{Cl} C_{Cl} \nabla \Phi \right) \tag{2}$$

where $\lambda_{Cl} = \frac{aC_{Cl}}{w(1+bC_{Cl})}$, w = 0.3; a=0.42 and b = 0.8 mol/L.

The electroneutrality condition is used in this study:

$$\sum_{i=1}^{N} z_i C_i = 0 \tag{3}$$

where N is the total number of ion species.

The diffusion coefficient of various agents is calculated according to the following equation (Zhang and Angst, 2021):

$$D_i = D_i^0 \frac{\delta \varphi}{\tau^2} \tag{4}$$

where D_i^0 is the diffusion coefficient in bulk water; δ, φ and τ are constrictivity, porosity and tortuosity, respectively. The diffusion coefficient varies with porosity.

In concrete, $Fe_{(OH)_2}$ is formed when the concentration product of OH^- ions and Fe^{2+} ions exceed the solubility product, and the reaction rate $S_{Fe(OH)_2}$ is expressed as:

$$S_{Fe(OH)_2} = k_r \cdot \left(C_{OH^-}^2 \cdot C_{Fe^{2+}} - k_{sp} \right) \tag{5}$$

where k_r is the deposition rate constant, k_{sp} is the solubility product.

2.2 *Electrochemical corrosion of rebar*

During rebar corrosion, electrochemical reactions of metal dissolution and oxygen consumption occur simultaneously on the rebar surface. The dissolution rate of Fe^{2+} ions increase with the increase in anodic current density i_{Fe}.

The anodic current density i_{Fe} and the cathodic current density i_{O2} are obtained based on Tafel equation:

$$i_{Fe} = i_{0,Fe} \times 10^{\frac{\Phi - \Phi_{Fe}}{\beta_{Fe}}} \tag{6}$$

$$i_{O_2} = \frac{C_{O_2}}{C_{O_2,s}} i_{0,O_2} \times 10^{\frac{\Phi - \Phi_{O_2}}{\beta_{O_2}}} \tag{7}$$

where $i_{0,Fe}$ and i_{0,O_2} are the exchange current densities of the anodic and cathodic reactions, respectively; Φ_{Fe} and Φ_{O_2} are the equilibrium potentials of the anodic and cathodic reactions, respectively; β_{Fe} and β_{O_2} are the anodic and cathodic Tafel slopes, respectively; $C_{O_2,s}$ is the oxygen concentration on the concrete surface.

2.3 *Precipitation eigenstrain*

The corrosion products will fill the volume left by the corroded rebar and the pores, and exert stress on the surrounding concrete matrix. Thus, the eigenstrain can be calculated as:

$$\varepsilon = \frac{1}{3}\left(\frac{\rho_{Fe} M_{Fe(OH)_2}}{(1-r_0)\rho_{Fe(OH)_2} M_{Fe}} - 1\right) \tag{8}$$

where ρ_{Fe} and $\rho_{Fe(OH)_2}$ are the density of Fe and $Fe_{(OH)_2}$, respectively; M_{Fe} and $M_{Fe(OH)_2}$ are the molar mass of Fe and $Fe_{(OH)_2}$, respectively; r_0 is the porosity of the corrosion product $Fe_{(OH)_2}$. In this study, we assumed that the a fraction of the pore volume will be filled before strain starts to develop(Sarkar et al., 2010), we introduce a coefficient f_0 to describe this case, and the eigenstrain is:

$$\varepsilon = \frac{1}{3}\left(\frac{\rho_{Fe} M_{Fe(OH)_2}}{(1-r_0)\rho_{Fe(OH)_2} M_{Fe}} - 1\right) \cdot \left(\varphi_p - f_0 \cdot \varphi_0\right) \tag{9}$$

where φ_p is the volume fraction of corrosion product; φ_0 is the initial porosity. It should be mentioned that the porosity will change due to precipitation and crack.

2.4 *Cracking of concrete*

The cracking of concrete is described by the phase field regularized cohesive zone model(Wu, 2017). In the phase field model, the discrete crack is regularized over a localization band Γ. The phase field variable $\phi(x, t)$ is introduced to represent the damage level. $\phi(x, t) = 0$ and $\phi(x, t) = 1$ denote intact and completely failed material states, respectively. It uses the gradient of the order parameter to automatically track the interface evolution, and the evolution of the order parameter follows the energy minimization principle. The damage and mechanical behaviors are governed by the following equations:

$$\begin{cases} \nabla \cdot \sigma + \boldsymbol{b} = 0 & \Omega \\ \sigma \cdot \boldsymbol{n} - \boldsymbol{f} = 0 & \partial\Omega_f \\ g'(\phi)\boldsymbol{H} + \frac{G_c}{c_0}\left(\frac{\alpha'(\phi)}{l_f} - 2l_0\nabla\cdot\nabla\phi\right) = 0 & \Gamma \\ \frac{2G_c}{c_0} l_f \nabla\phi \cdot \boldsymbol{n}_\Gamma = 0 & \partial\Gamma \end{cases} \tag{10}$$

where σ is the stress; $\boldsymbol{b}$ is body force acted on the body Ω; $\boldsymbol{f}$ is the traction on the boundary $\partial\Omega_f$; $\boldsymbol{n}$ and $\boldsymbol{n}_\Gamma$ are the outward unit normal vector of external boundary of Ω and Γ; G_c is the critical energy release rate; l_f is the phase field length scale; $c_0 = \pi$ is a scaling constant; $g(\phi)$ and $\alpha(\phi)$ are the degradation function and crack geometric function, respectively. The equations of $g(\phi)$ and $\alpha(\phi)$ are expressed as

$$g(\phi) = \frac{(1-\phi)^p}{(1-\phi)^p + Q(\phi)}, \quad Q(\phi) = a_1\phi + a_1a_2\phi^2 + a_1a_2a_3\phi^3 + \ldots \tag{11}$$

$$\alpha(\phi) = 2\phi - \phi^2 \tag{12}$$

where p=2, a_2= 1.3868, and a_3 = 0.9106. $\boldsymbol{H}$ is the history variable, reads:

$$\boldsymbol{H} = \max\left(\frac{f_t^2}{2E_0}, Y_t\right) \tag{13}$$

where f_t is the failure strength; E_0 is the Young's modulus; $Y_t = \frac{\langle\bar{\sigma}_1\rangle^2}{2E_0}$, $\bar{\sigma}_1$ is the major principal value.

3 RESULTS

In this section, the proposed model is validated by the experimental results xx. In their work, the corrosion initiation of the rebar was triggered in a cyclic drying-wetting environment. The specimens were then placed in an environmental chamber at 80% relative humidity and 33 °C to accelerate the corrosion propagation. A non-uniform rust distribution was obtained during the test.

In the simulation, the geometry and boundary condition of the mesoscale model is shown in Figure 1. The gray, red, orange, grayish green and blue represent matrix, ITZ, fine aggregate, rebar and ITZ between rebar and matrix, respectively. The size of the model is 100 × 100 mm. The rebar diameter is 10 mm. The top and edge cover thickness are 10 mm and 25 mm, respectively. The displacements in the vertical and horizontal directions on the left surface of the model are fixed. The surface chloride content is 1 wt% of cement. The other parameters in the numerical model are in Tables 1 ~ 3.

Table 1. Material parameters for different phases.

Phase	Young's modulus (MPa)	Poisson's ratio	Failure strength (MPa)	Fracture energy (N/m)
Aggregate	70000	0.2	-	-
Matrix	25000	0.2	6	60
ITZ	15000	0.2	3	30
Rebar	210000	0.3	-	-

Table 2. Electrochemical parameters in the simulation.

parameters	values
β_{Fe} (V/dec)	0.09
β_{O_2} (V/dec)	-0.14
Φ_{Fe} (V)	-0.78
Φ_{O_2} (V)	0.16
$i_{0,Fe}$ (A/m^2)	3×10^{-4}
i_{0,O_2} (A/m^2)	1×10^{-5}

Table 3. Diffusion coefficient and concentration in the simulation.

Variables	Cl^-	Na^+	OH^-	K^+	Fe^{2+}	O_2
Charge number	-1	+1	-1	+1	+2	-
Diffusion coefficient ($\times10^{-9}$m^2/s)	1	1.33	5.27	1.96	0.7	100
Initial concentration (mol/m^3)	0	0	60	-60	0	0.268
Boundary concentration (mol/m^3)	105	105	0	0	0	0.268

Figure 2 demonstrates the crack patterns in concrete. It can be seen that there is one crack progressing from the concrete surface to the rebar surface, and three other cracks progressing from the rebar surface into the concrete, one to the upper left, one to the upper right, and one to the lower right.

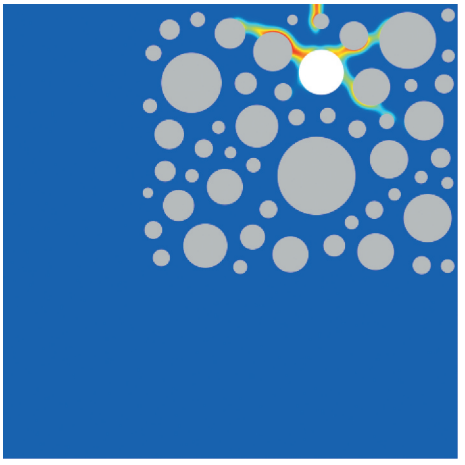

Figure 2. Crack patterns in concrete.

The comparisons of the experimental and numerical simulation results are illustrated in Figure 3. The black lines in the figure represent the numerical results, and the remaining three lines represent the experimental results. It can be seen that the trend of the simulated crack width with the corrosion degree is similar to that observed in the experimental results, indicating that the proposed model is efficient in addressing concrete cover cracking caused by rebar corrosion.

Figure 4 shows the damage level and concentration of $Fe_{(OH)_2}$ around the rebar. As can be seen from the figure, the concentration of $Fe_{(OH)_2}$ is smaller in the areas with more damage than in the areas with less damage. This is due to the fact that where the damage is large, the diffusion coefficient of Fe^{2+} is large and the Fe^{2+} ions are transported further away from the surface of the rebar and do not precipitate in the vicinity of the rebar surface.

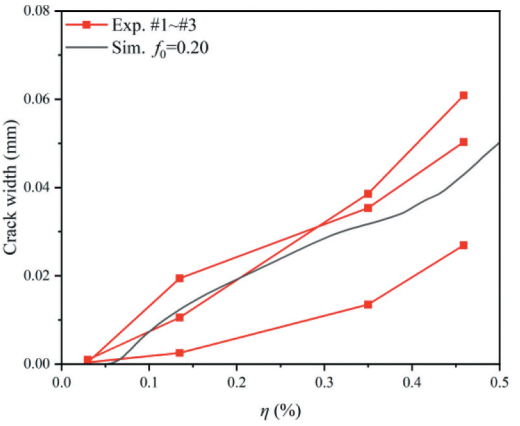

Figure 3. Comparisons of crack width between the experimental observations and numerical results.

Figure 5 shows the porosity in a radial direction from the rebar under different corrosion degree. It can be seen that because precipitation occurs first and faster near the rebar surface, the porosity near the rebar surface decreases. In the vicinity of 0.2 mm, the porosity decreases and then increases because the crack increases the porosity and the precipitation is not enough to

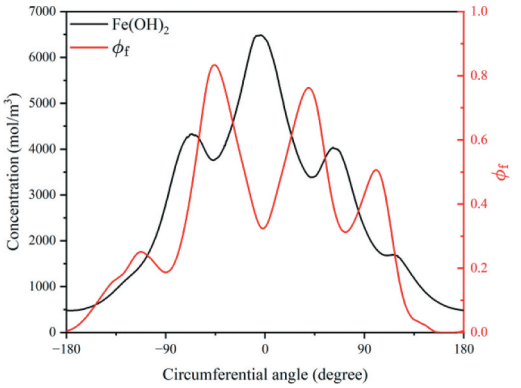

Figure 4. Damage level and concentration of $Fe_{(OH)_2}$ around the rebar.

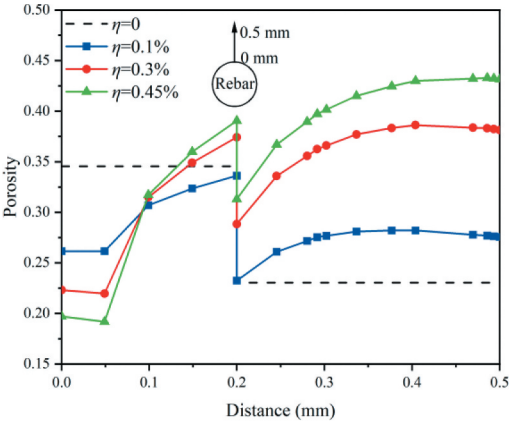

Figure 5. Porosity in a radial direction from the rebar.

offset the effect of the crack. In the matrix, there is less precipitation and the change in porosity is mainly affected by crack.

4 CONCLUSION

This paper presented a comprehensive electrochemical-chemical-mechanical phase field model to evaluate the degradation process of concrete subjected to rebar corrosion-induced fracture. The investigation encompassed non-uniform corrosion, reactive transport, $Fe(OH)_2$ precipitation, rust-induced cracking, and the movement of rust through cracks. The model considered precipitation reactions of Fe^{2+} and OH^- within the concrete pore space. The eigenstrain caused by rust is related to the volume fraction of corrosion products. The phase field regularized cohesive zone model is calibrated for concrete cracking. Validation against experimental data demonstrated the model's reliability, exhibiting a commendable agreement with the observed outcomes. The following conclusions can be drawn: (1) the concentration of $Fe_{(OH)_2}$ is smaller in the areas with more damage than in those with less damage; (2) damage leads to increased porosity, while precipitation decreases porosity, with the overall porosity variation pattern resulting from the interplay between these opposing factors.

ABSTRACT: Balanced cantilever method is one of the bridge construction methods, has the advantage that construction can be carried out regardless of the environment under the girder. In this method, it is important to measure the deformation of the bridge at each event such as concrete placement, tensioning, temperature change, and solar radiation. Currently, these deformations are measured by level surveying. However, level surveying for each event is time-consuming and labor-intensive, making it a challenge to improve efficiency and reduce manpower. In this study, temperature, strain, inclination, and position data were measured on PC bridges under construction as a basic study of bridge deformation measurement, and the data were analyzed in detail.

1 INTRODUCTION

Structural Health Monitoring (SHM) has been extensively studied in structural engineering (Tran-Ngoc et al., 2019) (Tran-Ngoc et al., 2022). However, research on bridge monitoring during construction is currently limited. For example, in the construction of prestressed concrete (PC) bridges using the cantilever construction method, managing vertical displacement due to events such as concrete casting, tensioning, and solar radiation is crucial for quality control. Currently, this management is carried out using leveling survey. However, there is a need to save manpower and reduce costs due to reduced working hours and costs. Therefore, in a previous study (Morichika et al. 2022), sensors such as inclinometers and strain gauges to monitor the construction of bridges. There, three-dimensional deformation diagrams were created. This study evaluates the displacement of bridges due to temperature variations in air temperature and discusses the measurement accuracy required for alternative methods of leveling survey.

The paper is structured as follows. Chapter 2 describes the structure, construction conditions, and measurement conditions, Chapter 3 compares the measurement data during concrete casting, temperature changes, and tensioning operations, and Chapter 4 provides a conclusion and prospects.

2 TARGET BRIDGE

This chapter describes the target bridge in this study. The target bridge structure is a PC 3-span continuous ramen box girder bridge (corrugated web), with a bridge length of

DOI: 10.1201/9781003483755-293

121 m. The construction of the test bridge was carried out by constructing the pillars and casting the concrete symmetrically in one block from the pillars. There are three main phases of construction: concrete casting, tensioning of the bridge, and work vehicle movement. It is desirable to measure the deformation of bridges due to temperature changes at any time, but this is time-consuming and labor-intensive, so a labor-saving solution is urgently needed. In this study, the period when the concrete was cast, and the PC member was tensed in Block 8 (8BL) and Block 9 (9BL) was investigated. The distance from the pier to the tip at the time the measurements were taken was 52.5 m. External photographs and cross-sections of the subject bridge are shown in Figures 1 and 2.

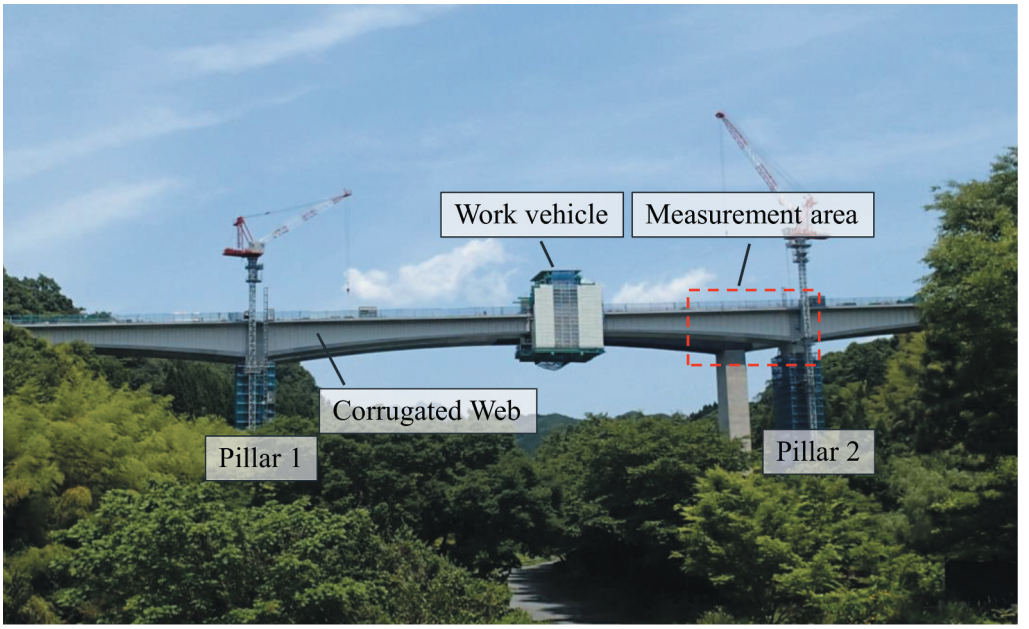

Figure 1. Appearance of the target bridge under construction.

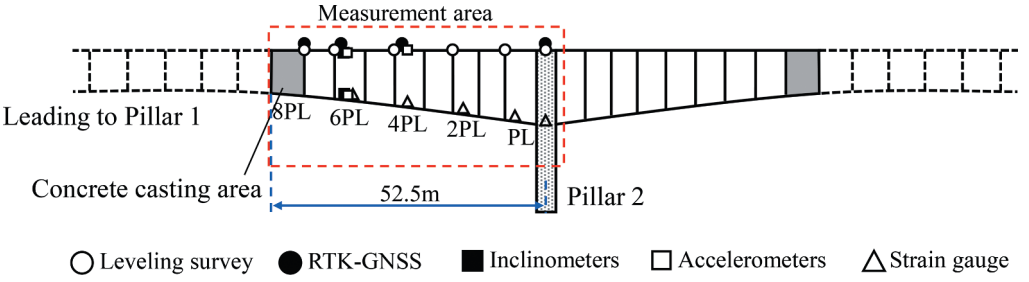

Figure 2. Details of the target bridge and measurement locations.

3 MEASUREMENT CONDITIONS

For the measurement of displacement, the Realtime Kinematic Global Navigation Satellite System (RTK-GNSS) was used in addition to the conventional method of leveling survey (Hussein et al. 2021) (Kubo et al. 2023). RTK-GNSS is a method that enables measurements on the order of centimeters by compensating for radio delays caused by the troposphere and

ionosphere. A wired inclinometer capable of measuring two axes and a three-axis Micro Electro Mechanical Systems (MEMS) accelerometer was used to measure the angle of inclination. The 3-axis MEMS accelerometers are easy to install because they can be installed with magnets (Sekiya et al. 2017) (Morichika et al. 2021). For strain measurements, a strain gauge with a gauge length of 67 mm, and a fiber-optic sensor were used. The survey positions and the locations of the various sensors are shown in Figure 2 and photographs of the installed sensors are shown in Figure 3.

Measurements were taken on both the upper and lower decks. For GNSS, the elevation angle must be open by about 15 degrees, so the GNSS is mounted on a pole and placed higher on the upper deck so that the measurement is not disturbed by worker traffic, etc. The strain gauge and fiber-optic sensors used for strain measurement were installed on both the upper and lower decks. Dummy gauges for temperature compensation were also installed for the strain gauges, as the analog signal output is particularly susceptible to temperature effects. In this study, however, only the data measured by strain gauges installed on the lower deck were treated.

4 MEASURED DATA RESULTS

4.1 *Relationship between vertical displacement and air temperature*

This chapter compares the measured data of the 8BL during concrete placement, temperature changes, and tensioning of the PC member. Figure 4 shows a plot of the vertical displacement results measured by level survey and GNSS for each event during the construction of 8BL and the outdoor temperature. However, the measurement positions are all at 8 BL at the tip and are based on 8:00 am, when the level survey was carried out at the beginning of the concrete placing day, and the differences from that point are shown.

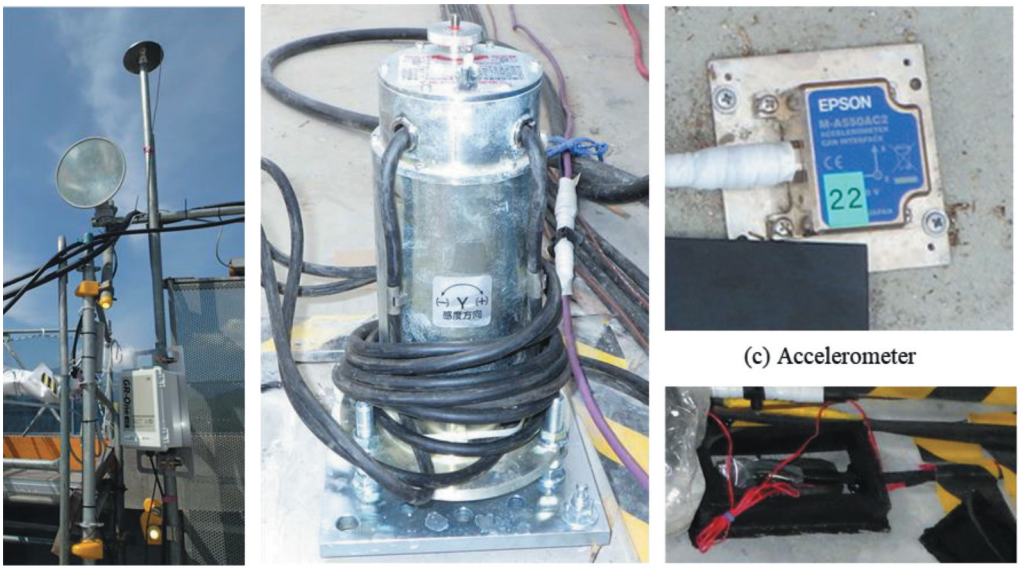

Figure 3. Measurement equipment used.

The black line in the diagram shows the vertical displacement measured by GNSS, the red dots show the vertical displacement measured by level surveying, a conventional method, and the blue line shows the air temperature around the target bridge as published by the JMA. Although the GNSS measurement data contained noise in centimeters, the behavior was

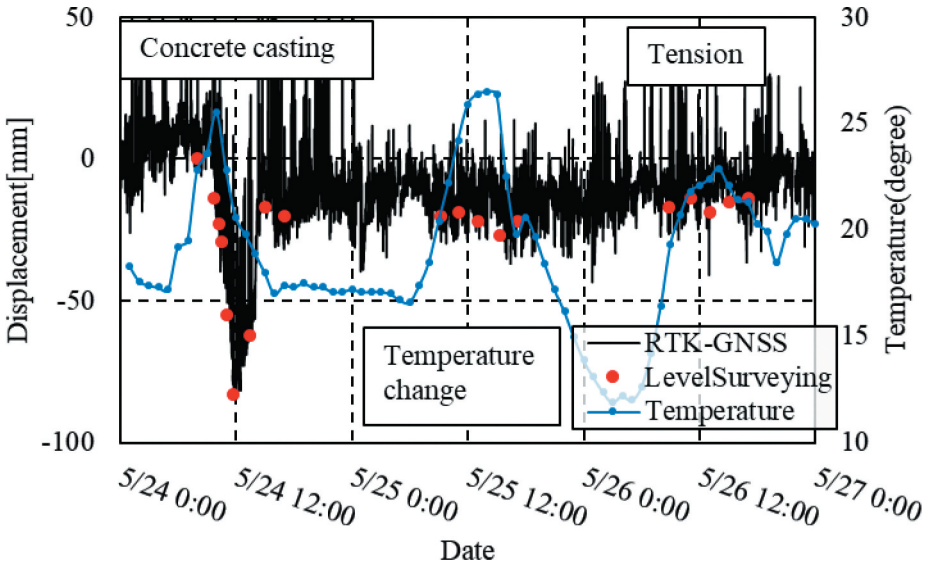

Figure 4. Relationship between vertical displacement and temperature during 8BL construction.

found to be consistent with the level survey results on the day of casting, when the vertical displacement was large throughout the day. However, for temperature changes with small vertical displacements and for days when tensioning operations were carried out, it was difficult to estimate the variables obtained by level surveying from the GNSS measurement data because the noise component was too large, and the results did not show sufficient measurement accuracy.

On the morning of 24 May, when the vertical displacement was greatest, 8 BLs of concrete were placed, with 12 m^3 of the lower deck completed at 10:30 and 20 m^3 of the upper deck placed at 11:45 for a total of 32 m^3 of concrete. The vertical displacement in this case is approximately 80 mm. In the afternoon of the same day, the pouring of the 8BL on the opposite side across P2 took place, with 12 m^3 of the lower deck being poured at 13:25 and 24 m^3 of the upper deck at 15:00, making a total of 68 m^3 of concrete poured since the morning. The vertical displacement returned by approximately 60 mm and the final vertical displacement of the bridge toe was approximately 20 mm. The following day, no major displacements occurred as there were no structural changes, but the temperature rose by approximately 10° C from early morning to midday, and this change caused displacements of up to 8 mm of vertical deflection downwards. The following day, the PC member was tensioned, but again no significant displacements occurred, with the maximum displacement being only 5 mm.

Displacements of more than 80 mm were observed at 8 BL at the tip during concrete placement, showing the potential of GNSS to replace conventional survey methods for such large displacements. However, the maximum displacement during temperature changes and when the PC member was under tension was approximately 8 mm, and the displacement response could not be captured by GNSS because the noise component was too large. Therefore, technology is required that can measure deformations on the order of mm. It was also found that the vertical displacement caused by a 10° C temperature change may be greater than the displacement caused by tensioning.

4.2 *Angle data*

The angle of inclination was measured using a wired inclinometer and a MEMS accelerometer. MEMS accelerometers output acceleration data in three axes, so conversion to an

inclination angle is necessary. The conceptual diagram and equation for calculating the inclination angle from the acceleration are shown in Figure 5 and Equation (1).

$$\theta = sin^{-1}\left(\frac{a_x}{g}\right) \tag{1}$$

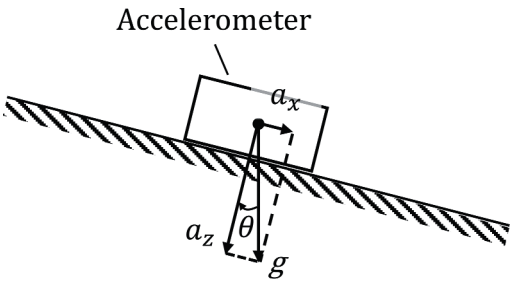

Figure 5. Relationship between measured acceleration and inclination angle.

The angles of inclination using the wired inclinometer and the acceleration data at the time of maximum displacement during concrete placement are shown in Figure 6. The angle of inclination is positive when the leading edge of the bridge is tilted vertically upwards when viewed from the column heads. As with the vertical displacements presented in the previous section, the differences are shown concerning 8.00 am, when the level survey was carried out at the beginning of the day of concrete placement.

The black line in Figure 6 shows the measured data from the inclinometer and the red line shows the angle of inclination calculated from the acceleration. A comparison of data from a wired inclinometer and an accelerometer installed at the same location shows that they have very equal inclination angles, indicating that the data from the accelerometer accurately measured the inclination angle.

A large inclination angle of -0.12° at the tip occurred at the time of casting, which was subsequently recovered to -0.04° by casting on the opposite side across P2. On the other hand, changes in inclination angle due to temperature changes and tensioning operations are small (about 0.02°) and therefore require highly accurate measurements.

4.3 *Strain data*

Strain measurements were carried out on the lower deck of the bridge. As in the previous sections, data on the strain during the construction of the 8BL are presented. However, the time is based on 8.00 a.m. on the day of casting and the difference is shown.

The measured data for strain showed that, compared to the inclination angle, the strain values were almost constant during concrete placement, irrespective of the installation location. The strain values at each location at 11:45 am, when the maximum displacement occurred, are shown in Figure 8 to confirm the response in more detail during the concrete placement. The strain gauge data for the lower deck showed values around -40 μ at all points, indicating that compressive forces were generated on the entire underside of the bridge and that the concrete placement deformed the bridge convexly upwards.

5 CONCLUSIONS

Various sensors were installed on bridges under construction and the measured data was analyzed in detail. The results show that a bridge of approximately 50 m in length deflects at its

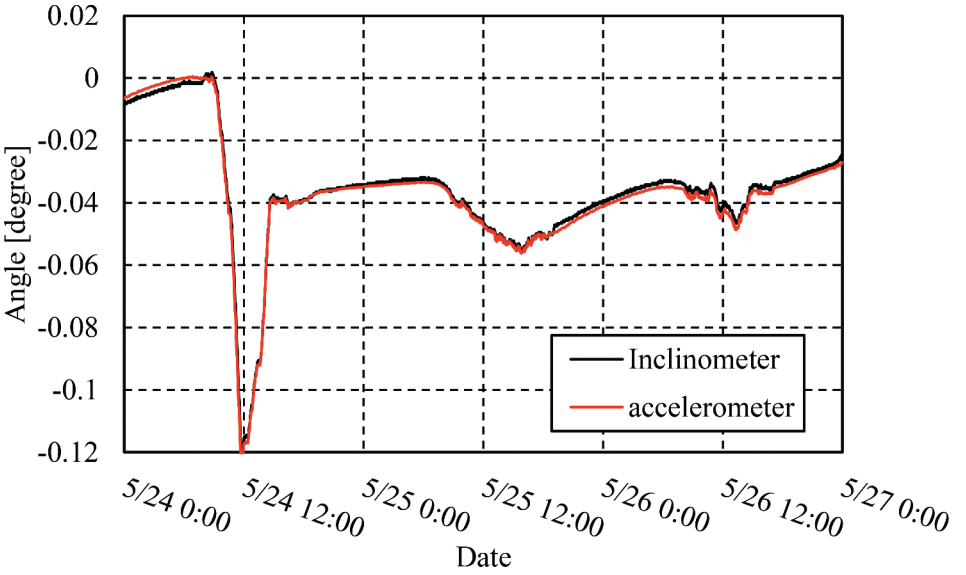

Figure 6. Inclination angle variation over time.

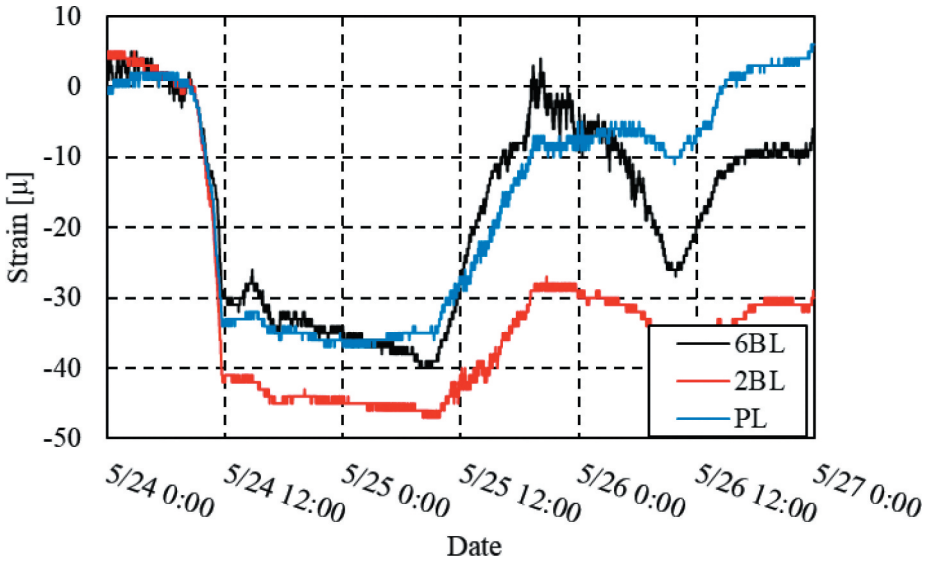

Figure 7. Time-series variation of strain.

leading edge by approximately 80 mm as a result of the concrete placement. For such large responses, the possibility of replacing conventional surveying with GNSS was demonstrated. The deformation of bridges due to temperature changes was found to be equal to or greater than that of PC member tensioning operations.

Prospects include the study and practical application of a method for estimating deformations on the order of millimeters in bridges under construction using measured strain, angle of inclination, and displacement data.

Piezo-Electric Dampers (PiDs) for energy harvesting purposes

J.F. Martins*, M. Francioli* & F. Petrini*
Sapienza University of Rome, Rome, Italy

ABSTRACT: Many modern bridges are able to sense their state in operational and emergency conditions through embedded sensors that constantly monitor structural damage conditions. However, the large amount of energy (supplied by the power grid or batteries) and wiring to operate the thousands of sensors required represents a concerning issue, entailing both a significant environmental impact (battery disposal) and disproportionate installation and maintenance costs (due to wiring and manual intervention). Energy Harvesting (EH) from induced vibrations has received emphasis allowing the development of efficient and reliable devices that convert into electrical energy the sensed perturbations occurred and piezoelectric materials have special attention given their natural capacity of converting mechanical into electrical energy. With the aim of Structural Health Monitoring (SHM), here is presented a device named PiD (piezoelectric damper) which, designed as an elastomeric bridge's bearing in which a piezoelectric fin is inserted, can harvest energy from induced vibrations.

1 INTRODUCTION

1.1 *Background*

Smart structures will facilitate the development of sustainable and resilient, modern/future European cities (Figure 1a) (Srinivasan et al 2001), (Rose 2011), sensing its own-status in operational and emergency conditions through embedded sensors (European Commission 2014) that constantly monitor the structural damage conditions (i.e., Structural Health Monitoring-SHM), often using wireless communication technology and allowing adaptive/rapid emergency response to different scenarios (e.g., accidental events) (Li 2016). However, a major challenge with current technology is the great amount of distributed energy (provided by the main sources or by batteries) and cables to operate the required thousands of sensors: this implies considerable environmental impact (batteries disposal) and disproportionate installation and maintenance costs (due to cabling, manual interventions). In this sense, Energy harvesting (EH) devices appear as a potential solution to sustain self-powered systems in alternative to batteries as well as to management operations; in accordance with an alternative to environmental impacting and cost-ineffective technologies, this work proposes a device named as Piezoelectric Dampers (PiDs), which represent an innovative type of device able to harvest energy from induced vibrations. They are battery and cable-free and they will embed piezoelectric materials and will be located in strategic joints providing power to wireless distributed sensors used for SHM. Piezoelectric (Pz) material receives a special look in engineering since it can convert the mechanical energy input into electrical energy. It can be said that PzEH technology is well-established at the micro- (Lu et al. 2011) and meso- (Tao et al. 2017) scale applications relevant to communication, space, and medical sectors where it is widely used for vibration or temperature gradient EH to power sensors and/or small actuators (Jung et al. 2011); however, no attempts were pursued to extend

DOI: 10.1201/9781003483755-294

PzEH usage in macro-scale civil engineering applications (such as in bridges), since specific properties of this material represented and still represent an obstacle for its diffusion in civil structural field. For example, Pz material has a limited stress resistance compared to structural material and it usually works well in a range of frequencies that doesn't belong to civil engineering field. Here are discussed the assumption made in order to avoid the aforementioned issues; however, there are still few literatures regarding this topic and the aim of the proposed study is to conceptualize a device that can be used for EH involving Pz material. Specifically, the idea is to design an innovative device that could replace a bridge's load bearing (Figure 2), guaranteeing both resistance and EH.

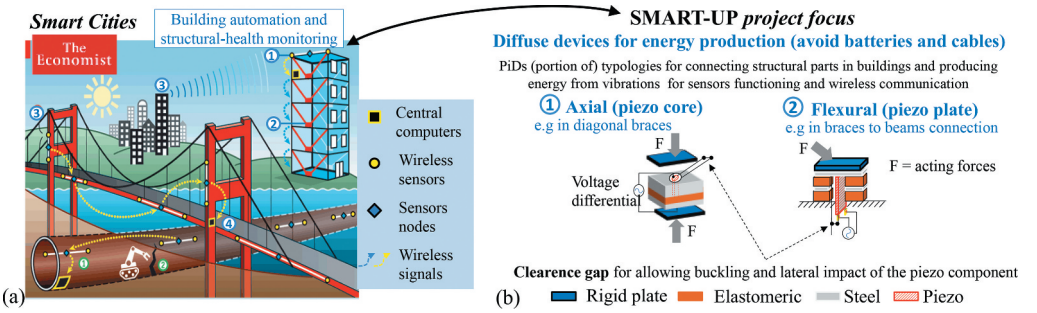

Figure 1. (a) smart structures operation in modern cities (The Economist Technology Quarterly); (b) position and schematic features of the PiDs.

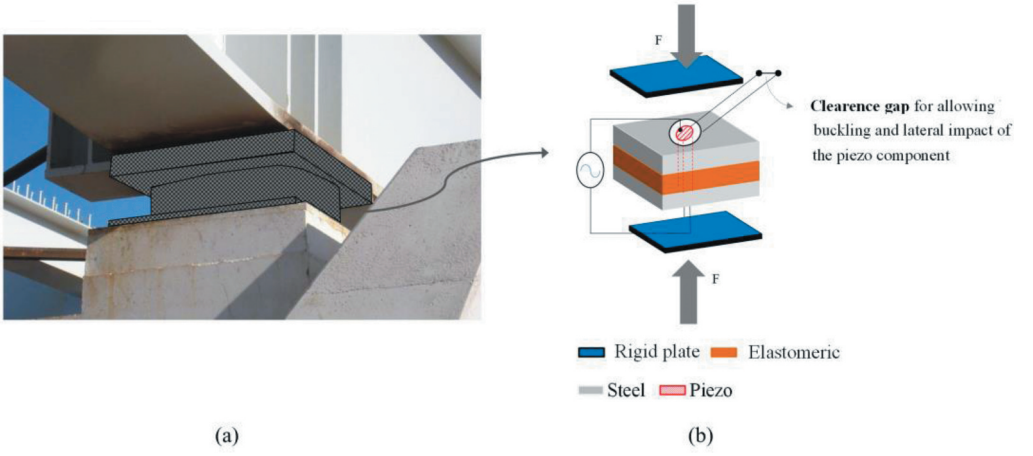

Figure 2. (a) Bridge's load bearing system; (b) concept of the proposed device (PiD).

2 METHODS

2.1 *Basic concepts regarding piezoelectricity and rubber bearings*

In accordance with the IEEE standard (ANSI 1988) the simplified piezoelectric constitutive equation is given by:

$$\begin{cases} S = sT + dE \\ D = dT + \varepsilon E \end{cases} \tag{1}$$

where S = strain; s = elastic compliance; T = stress; d = piezoelectric coefficient; E = electric field intensity; D = electrical displacement; and ε = permittivity.

Piezoelectric material operates in different modes depending on which direction the stress/strain occurs, as represented in Figure 3. Furthermore, there are two effects observed on those materials: direct and reverse. The direct effect is described as an electrical charge generated by mechanical stress, while the converse occurs when a strain is generated because of an applied electrical field. The piezoelectric material used on the d_{33} mode indicates that both voltage and stress occur in direction 3. When using d_{31} mode the piezoelectric will have the voltage acting in direction 3 (where the material is poled), and the mechanical stress/strain will occur in direction 1. In this last case, the use of thin bending elements is likely to occur, leading to a large strain in direction 1 developed due to bending. With that, d_{31} cases can be applied to a cantilever beam-type so larger strains can be produced with smaller input forces even if the electrical/mechanical coupling is lower than in the d_{33} modes. For the latter, more advanced structures configuration may be required as flex-tensional harvesters (Zhao et al. 2023).

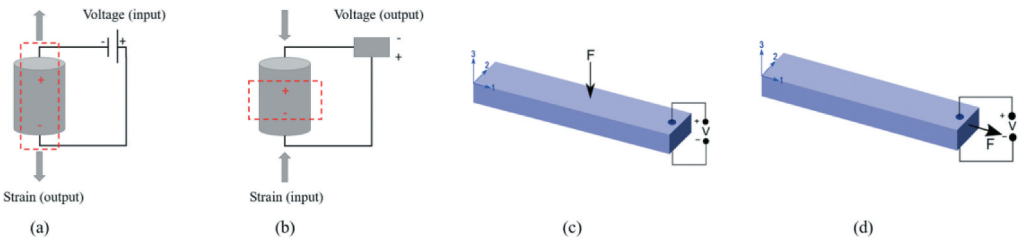

Figure 3. Effects of piezoelectric material direct (a) and converse (b) and operational modes piezo (c) d_{33} and (d) d_{31}.

One of the limitations that the PiD devices must surpass is the capability of supporting structural loads. Hence, to conceptualize the initial model it is taken in consideration the use of rubber bearings since it is a widely used equipment in civil engineering, and it is known for the capacity of working under high loads. Multilayer rubber bearings are devices that considerably decrease and/or dissipate the energy of a main structure to which it is attached, providing a damping mechanism. This type of device was used at first on structural elements of highways such as bridges or viaducts, then it started to be implemented on buildings to obtain seismic isolation. Conventionally, rubber bearings are laminated devices consisting of layers of different materials, as rubber (in order to provide period elongation and energy dissipation) and, usually, steel as reinforcing material which enhance the vertical bearing capacity. Moreover, the bearings are planned to sustain both the compressive load, given by the self-weight and live loads that act on the superstructures, and horizontal effects occurred by earthquakes or winds (Kelly et al. 2011), (Tubaldi et al. 2018). The use of such devices is mainly related to seismic isolations that works on minimizing or preventing structural damage in places such as buildings, bridges, and viaducts, providing a continuous operation by regulating the response of the structure (Ozkaya et al. 2011). Basically, rubber bearings can be subdivided into categories regarding the rubber material in low, natural, and high -damping rubber bearings (LDBR, NBR and HDRB, respectively); additional features may also be added to improve their performances, such as lead cores, reinforced fibers, and shape memory alloys (Ahmadipour et al. 2017). The efficiency of the bearings is related to their horizontal flexibility, vertical strength, and damping capacity: those functions are operated by rubber and steel layers. Since the PiDs concept lays on the idea of an element capable of supporting structural loads with a core denoted by a different material, few salient aspects are mentioned regarding the Lead Rubber Bearing (LRB, Figure 4), which is, among the others, the one with more similarities with the proposed device: LRB presents high damping capability due to the role of the lead core on shear displacements and in combination with the high damping rubber (Basshofi Habieb et al. 2019). It was introduced in New Zealand in the late 1970s, and presents elastomeric layers bonded to steel shim and fixing and

supporting plates at the top and bottom; the plus is that they are dotted with a lead core placed in the central part: the supporting steel plates confine the lead in the middle and restrain the whole isolator. LRBs bearings behave essentially as hysteretic damping devices since the lead goes inelastic; the lead core deforms plastically under shear deformation while energy dissipates through heat. It also provides an increase in vertical stiffness and energy absorption when compared to a low damping bearing (Ahmadipour et al. 2017). In this case, the stiffness of the structures may present a decrease because of the inelastic behavior of the lead, thus increasing structure's natural frequencies.

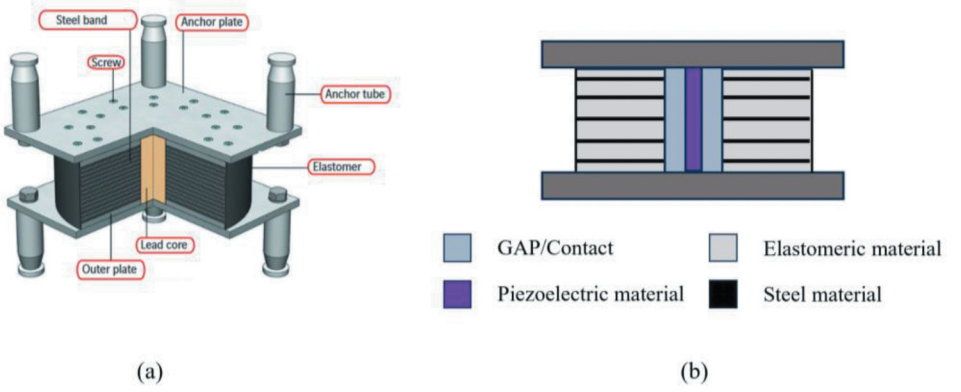

Figure 4. (a) Design of LRB (ISOSISM) and (b) section of the proposed device.

2.2 *Conceptual model for piezoelectric energy harvesters*

Despite the abilities of a piezoelectric material into convert energy, there are some limitations when such devices are implemented on civil structures, such as the load magnitude this material can support and its energy harvesting efficiency. Regarding the first aspect, it is possible to assume that the external part of PiD devices will be able to support the structural loads, while the internal core will be provided with piezoelectric energy harvesting. The choice of designing the PiD similarly as a rubber bearing guarantees every load's path, without compromising any possible structural function: they are thought as composite structural members comprising piezoelectric parts (in form of bars or fins), which resist loads either by axial or by flexural mode. A sufficient number of PiDs provided will constitute, as a whole, a self-powered parallel power system for sensors' energy needs, which is cable free (thanks to the wireless technology) and almost maintenance free (absence of batteries). However, PzEH from vibrations is proportional to the frequency of the dynamic loads and to the activated mass and here appears the other concern. In common (meso-, micro-scale) PzEH applications loading frequency is in the range of 0.1-10 kHz allowing for significant EH from small vibrating masses, while vibration frequencies in civil structures as bridges are orders of magnitude lower (within 1-25 Hz), reducing dramatically EH despite the larger masses involved. For this reason, the piezo components inside the PiDs will be designed to operate in two different kinds of nonlinear regimes: near-buckling conditions and impact dynamics. The first involves designing the piezo-bar inside the PiDs to buckle under the operating conditions, increasing both piezo strains and vibration frequencies with respect to the pre-buckling (linear) dynamic conditions (Friswell et al. 2012). The second regime allows impact of the vibrating piezo component, converting the low-frequency response to high frequency (Vijayan et al. 2015) and thus seeking a solution to maximize the energy production of piezoelectric harvesters when operating on civil structures: the maximum voltage and generated power from a vibrating mass are indeed mainly dependent on the frequency of vibration (the vibration mass is here the piezoelectric component). These two regimes (near-buckling and impact dynamics) will be enabled by the appropriate calibration of a "clearance gap" between the piezo fin and the other blocks being part of the PiDs, for allowing buckling and lateral impact of the piezo fin: those methods

receive the name frequency-up methods because they increase the frequency of vibration on the piezoelectric harvester and then their efficiency (Umeda et al. 1996), (Umeda et al. 1997).

In the proposed device configuration, as indicated in Figure 5, the impact phenomenon is likely to occur: the bar of piezoelectric material positioned in the core, as specified, is not in direct contact with the internal walls of the device but is detached from them by a certain gap (as represented by the back draw in the Figure 5b). When the PiD undergoes shortening due to the loads acting on the structure (PiDs are in fact designed to be positioned in the connection zones between structural elements), the bar can impact the aforementioned internal walls of the device, enabling the frequency-up conversion mechanism (the square dots in Figure 5b indicates the impact zone).

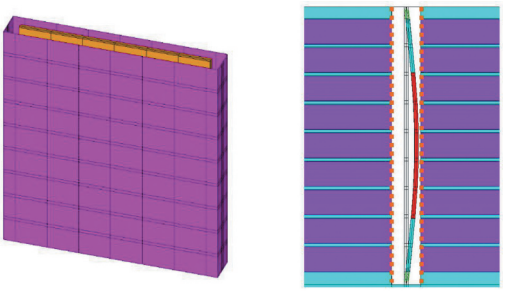

Figure 5. Contact (magenta) and target (orange) regions of the geometric model (a) and indication of the impact zones on a PiD device model (b).

3 APPLICATION

3.1 *Design of PiDs*

The materials used are steel, rubber and piezoelectric represented in blue, purple and red respectively (note that the steel shims in blue are also between purple – rubber – layers, Figure 6). The software used for the analysis is ANSYS® APDL: the element type chosen to represent the piezoelectric characteristics is the "SOLID5", which presents piezoelectric behavior, allowing the process of converting mechanical energy into electrical or vice-versa. The model used for further analyses is fully constrained at the bottom surface and horizontally constrained at top surface; vertical load is applied on the top plate and imperfections are taken into account by assuming a preferential buckling direction of the piezoelectric material component. Figures 6a and 6b presents the indication of the geometrical properties: W is the depth, L is the width (with W=L), Hi is the height of the internal core, t_{fix} is the thickness of the top and bottom plates, GAP is the gap between the piezo core and the lateral-internal walls that allows the buckling of the piezo-element (whose dimensions are named $PiezoW$ and $PiezoL$). Finally, t_r and t_s represent the height of the rubber and steel layers, respectively. The PiD dimensions (Table 1) are set by observing the maximum stress limit involved in the materials of the device: from literature (Usharani et al. 2017), (Anton et al. 2010) the maximum value for Pz material ranges around 45 MPa, which is the limit considered on this work, in order to secure the overall integrity. Besides the just mentioned values adopted for the geometric, Table 1 presents also the properties of the piezoelectric material: E is the young modulus, v Poisson constant, ε^T_{33} dielectric constant, d_{13} piezoelectric constant and ρ the material density. The clearance gap and the buckling of the piezo allow, as already stated, the PiDs to harvest significant energy even at the typical low-frequency range of vibration in civil structures; in order to catch in a correct way this phenomenon, the internal portion of the PiD is modeled using "contact" and "target" elements to have a simulation of an impact model during which the interaction among the surfaces is captured. One of the most challenging issues concerns the

simulation of the physical impact of the piezoelectric material core on the internal surfaces. In order to have a correct design, it is important to define i) which are the areas of impact and ii) what type of finite elements must be chosen to represent contact and sliding between 3-D target surfaces and a deformable surface. However, the region of contact is usually not known until the problem is run and, depending on loads, material, boundary conditions and other factors, surfaces can come into and go out of contact with each other in a largely unpredictable and abrupt manner. In the used model, element "CONTA174" is used to represent for deformable surfaces, while "TARGET170" is used for rigid bodies.

Table 1. The number of officially reported plague cases in the world.

$L = W$	$PiezoW$	$PiezoL$	GAP	Hi	t_s	t_r	t_{fix}	E	v	$\varepsilon^T{}_{33}$	d_{13}	r
800 mm	165mm	5mm	10mm	180mm	2.64mm	20mm	40mm	6.6E10Pa	0.2	1800	190e-12m/V	7800kg/m3

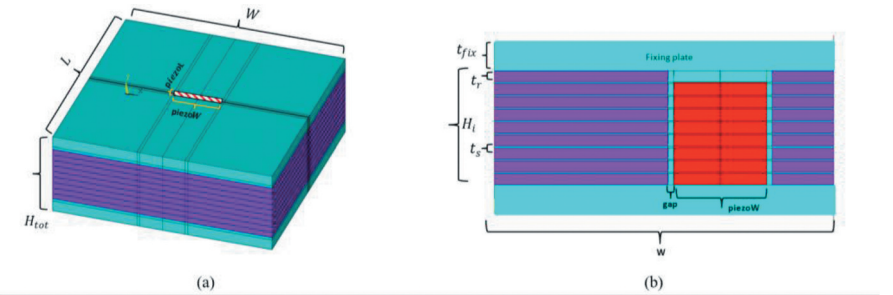

Figure 6. Geometry indication of the design parameters (a) and (b) section with indication of geometric parameters.

3.2 *Resistance's optimum value identification*

Given an eventual structural configuration in which PiDs can be inserted, it is possible to assume/reproduce a certain time-history for the relative displacement between the PiD nodes (Figure 7a) which will allow the evaluation of produced power. The time-history can be applied to the 3D PiD model/device as input on the top plate (the other one is assumed fully constrained for modeling purposes) and time-dependent analysis can be performed. Figure 7b represents a section of the device when the impact between the piezo core and the internal walls occurs, highlighting the clearance gap. The displacement of monitored core then is used in a subsequent analysis involving the piezoelectric energy harvester model: taking advantage of the possibility to combine structural and piezoelectric behavior in the same analysis, an electrical circuit element is added in order to obtain the power. The electric circuit is responsible for 'activating' the electrical part of the analysis which recognizes the piezoelectric behavior from mechanical to electrical energy or vice versa. Moreover, the addition of this element involves the appearance of a resistance (R) on the circuit, which influences the solution of the generated power. Since the solution obtained from the analysis is voltage (V) versus time, it is possible to obtain the root mean square (RMS) of the voltage by selecting two nodes on the different faces of the piezoelectric beam and then processing by the software tool. By Ohm's law, it can be presented that

$$P = V^2/R \tag{2}$$

where P is the power, V is voltage and R is the resistance applied on the circuit. Here the solution regards the Voltage (V) that is obtained by considering the RMS between the two nodes on opposite direction generated after performing the analysis, hence, by following the application of the Ohm's law, the parameter that may influence the obtained power is the Resistance

(R). In order to consider the optimum value for the resistance, different analyses were performed, varying the maximum displacement applied on the 3D PiD model and the frequency of vibration by introducing a generic sinusoidal signal. The results determined as optimum value a resistance of 2.5 KΩ (Figure 8). The presented methodology divided into levels appears to be a way of simplifying the performance of the PiD's device conception.

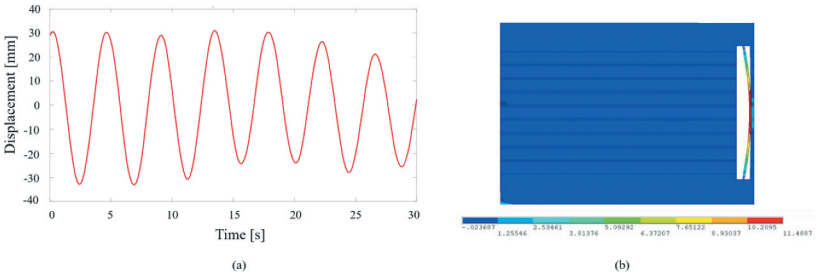

Figure 7. Time-History of the relative displacement (a) and section of PiD device with piezoelectric core impacting on lateral wall (mm).

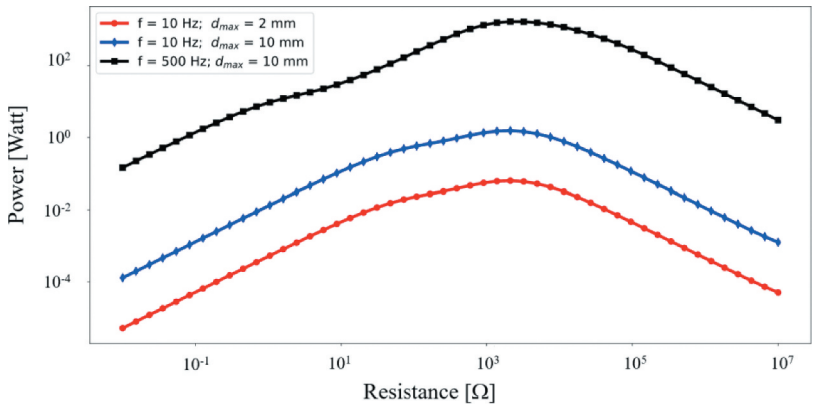

Figure 8. Optimum resistance observation in respect to different scenarios of frequency and maximum displacement.

4 CONCLUSION

A novel conception of a PiD device is here presented, showing the possibility of harvesting energy from vibration (as traffic induced vibration in case of bridges). This particular device is conceptualized as embedded in a structural member: the name, PiDs, stands for Piezoelectric Dampers. The importance for such devices results from the necessity of providing an infinitesimal amount of power to sensors and the novelty of this work is represented by the possibility of providing a solution to one of the main problems of sensors, power availability. PiDs are idealized to be energy harvesters by using piezoelectric materials, which produce electrical energy by converting the collected mechanical energy. In order to avoid some common problems that have made difficult the diffusion of piezo-material in civil engineering as the limited stress resistance (compared to structural material which doesn't allow to carry typical structural loads) and the different range of frequencies in which it usually works well (its behavior is at its best in a range that does not belong to civil engineering field), a design assumption was made: the PiD design started from a typical Lead Rubber Bearing device (LRB) in which the lead is replaced with a fin of piezoelectric material (in order to guarantee sufficient strength to resist structural loads) that does not occupy the whole core and that can buckle and impact on lateral walls,

increasing the vibration frequency and thus the harvested energy. However, it is necessary to be aware of the conditions of the materials if too much impact start happening; in this sense, the entity of the operational gap between the components and the size of the core are important aspects to consider among the design criteria. It is clear that further and in-depth research is still necessary on this topic, but the application has highlighted the feasibility of an innovative device that simultaneously guarantees structural support and energy harvesting from induced vibrations. Future developments, already partially under development, will concern both the implementation of experimental tests and finite element modeling that allows evaluating the behavior of PiDs in real situations (for example considering the loads induced by traffic passing on the deck of a bridge).

Infrastructure structural health monitoring of bridge with polarimetric radar sensor

Lilong Zou
School of Computing and Engineering, University of West London, London, UK

Amir M. Alani
Faculty of Engineering, Computing and the Environment, University of Kingston, London, UK

ABSTRACT: The implementation of infrastructure structural health monitoring for bridges is crucial in thoroughly evaluating their condition and maintaining their structural robustness. Recently, novel technologies have been introduced for both static and dynamic evaluation, opening up exceptional opportunities in the fields of risk management and structural assessment. Notably, microwave radar sensors have been effectively utilized for the continuous surveillance of dynamic and static displacements in bridges via aerial deformation measurement techniques. However, a primary challenge for microwave interferometry arises from its inherent linear measurement nature, making it challenging to precisely locate damage and derive accurate displacement time-series for bridges. Furthermore, it is worth noting that vertical displacements typically hold more significance than horizontal displacements in the dynamic monitoring of bridges. Regrettably, microwave radar interferometry can yield only the line-of-sight (LOS) displacement of a monitored bridge. In this study, our primary objective is the remote surveillance of dynamic displacement responses in bridges using a polarimetric radar system. To achieve this, we employ various methodologies to surmount the inherent limitations of this technique. Further, we discuss the results obtained from our monitoring of a long-span metallic railway bridge and a reinforced concrete Shinkansen bridge. The ultimate goal of this research is to generate more comprehensive and precise data for bridge health monitoring through the use of a polarimetric sensor. As part of our approach, we conducted a polarimetric analysis to detect reflections from the deck of the bridges. Furthermore, details relating to the polarization orientation angle and the local incidence angle were processed under the acquisition geometry to compute the radar look angle. As a result, we were able to easily convert the bridge deformation fields in the vertical direction using the slant range distances. The maximum transient vertical deformation corresponding to the LOS deformation was also transformed while a train traversed the bridge

1 INTRODUCTION

As a key element in our infrastructure, bridges are pivotal for both economic growth and transportation efficiency. The maintenance and repair of aging bridge structures has become an increasingly critical issue worldwide. Traditional monitoring methods, such as on-site visual inspection, have significant limitations, often failing to detect non-visible problems. This has led to the rise of infrastructure health monitoring techniques, which are more effective in early problem identification and assessing the overall health of bridges. These techniques include vibration-based monitoring and innovative radar systems, such as Synthetic Aperture Radar (SAR) and Ground-Based Real Aperture Radar (GB-RAR), which have been advancing in recent years. Current research focuses on enhancing these technologies for more precise monitoring and assessment, including methods for dynamic deformation measurement and 3D imaging, to better manage and maintain bridge integrity (Zou et al., 2024).

DOI: 10.1201/9781003483755-295

In the last few decades, the field of infrastructure health monitoring, particularly for bridges, has seen significant advancements, becoming a critical tool in the maintenance and longevity of these essential structures. The evolution of this field owes much to the decreased costs associated with data collection, making comprehensive monitoring systems more feasible and widespread. The core objective of these systems is to detect potential issues at the earliest stage possible, thereby extending the lifespan of the infrastructure. Infrastructure health monitoring focuses not only on identifying damage but also on understanding the current state and load-bearing capacity of bridges (Tran-Ngoc et al., 2019). Damage, in this context, refers to any alterations in the material properties, boundary condition or overall integrity of the structure, caused by various factors including natural disasters, man-made events or gradual deterioration due to aging and environmental factors. The capability of these monitoring systems to provide an objective and continuous assessment of a bridge's condition is invaluable, especially in detecting issues before they escalate into major problems (Tran-Ngoc et al., 2021).

One of the most prominent methods in this field is vibration-based health monitoring. This approach is based on the principle that structural damage can be identified through dynamic testing, which evaluates the mechanical response of a structure to various stresses. Most vibration-based methods use fiber optic sensors and piezoelectric accelerometers, which are adept at capturing dynamic deformations over time. However, installing these systems can be challenging and potentially damaging, especially to historical bridges. In addition to vibration-based methods, microwave interferometric radar systems – particularly Synthetic Aperture Radar (SAR) and Ground-Based Real Aperture Radar (GB-RAR) – have become integral in bridge health monitoring. These systems use phase information from reflected microwave signals to detect displacements. Space-borne SAR offers wide-area monitoring, providing high-resolution data that can detect minute changes in a structure (Lazecky et al., 2016). On the other hand, GB-RAR is primarily used for the dynamic deformation monitoring of bridges, offering high accuracy and a non-invasive approach.

Despite their effectiveness, these radar systems have limitations, especially in providing comprehensive 2D or 3D images of a structure, which is crucial for a detailed assessment (Monserrat et al., 2014; Alani et al., 2014). Recent advancements have aimed to overcome these limitations. For instance, the introduction of polarimetric GB-RAR sensors has allowed a more detailed monitoring of bridge deformation. These sensors enhance the signal-to-noise ratio and can discern different structural properties of a bridge, allowing a more targeted and effective monitoring approach. Furthermore, recent research has explored methods by which to improve these radar systems. Techniques for obtaining 2D and 3D imaging have been proposed, enhancing the ability to monitor vertical and torsional movements. The use of multi-static GB-RAR systems and the integration of other technologies, such as terrestrial laser scanning, have furthered the capability to gather detailed structural information. In conclusion, the field of infrastructure health monitoring has evolved significantly, offering more precise and comprehensive methods for assessing the health of bridges. This evolution is crucial for ensuring the safety and longevity of these vital structures, and continued research and development in this area promise even more effective monitoring solutions in the future.

2 METHODOLOGY

2.1 *Microwave radar interferometry*

In the realm of microwave interferometric radar applications, a diversification of systems tailored to fulfill distinct objectives has occurred in recent years. These systems can be broadly categorized (based on the radar system's platform) into two principal classes: (1) space-borne Synthetic Aperture Radar (SAR) Systems and (2) ground-based Synthetic Aperture Radar Systems. Space-borne Interferometry SAR is adept at conducting efficient wide-area monitoring with a semi-continuous operation. It is proficient in detecting alterations in track geometry with commendable precision, measured in millimeters. These changes are ascertained through weekly measurement updates, complemented by superior spatial resolution. In instances

where infrastructural deformation predominantly occurs in the vertical and horizontal transversal directions, it is feasible to deduce the two-dimensional deformation vector utilizing multi-track radar data. However, it should be noted that the sensitivity of this deduction is contingent upon the track's directional orientation.

Deformation monitoring with InSAR requires phase observations from coherent scatterers, which can be double-different to phase differences between two locations and two epochs. From this, differential displacements can be derived by the multiplication of the phase differences with the radar wavelength (typically in the order of cms) and correcting for the two-way travel of the radar pulse. Coherent scatterers are primarily reflected from targets with stable phase values in time, such as buildings, bare rock and rails (Shao et al., 2018).

In satellite SAR interferometry, the differential interferometric phase is a combination of contributions from the systematic phase from the flat term $\Delta\phi_{flat}$, the topographic phase term $\Delta\phi_{topo}$, the deformation phase term $\Delta\phi_{def}$ and ionospheric $\Delta\phi_{ion}$, as well as the phase noise term $\Delta\phi_{noise}$. Hence, the interferometry phase in satellite SAR can be written as:

$$\Delta\phi = \Delta\phi_{flat} + \Delta\phi_{topo} + \Delta\phi_{def} + \Delta\phi_{ion} + \Delta\phi_{noise} + 2n\pi \tag{1}$$

where $2n\pi$ indicates the phase wrapping term. Following elimination of the non-deformation induced phase terms from the interferogram, the displacement phase in the radar line-of-sight (LOS) direction can be extracted. Radar measurements are only sensitive to the projection of the (3D) deformation phase $\Delta\phi$ onto the radar LOS. In practice, a local geodetic coordinate system is used for the projection containing the deformation components in the East, North and Up directions, respectively. With one satellite and single viewing geometry, estimation of the 3D deformation components based on the line-of-sight measurements is ill-posed, with three unknowns against one measurement. Therefore, it is impossible to determine 3D deformation from one satellite unless additional constraints can be introduced.

2.2 *Ground-based radar interferometry*

Ground and satellite-based radar interferometers follow the same basic principles. The only difference relates to viewing the geometry. As a kind of sensor, the ground interferometric radar can detect the displacement of the target in the target cone by using the phase information of the back-reflected microwave signal. If only a single-point scattering of monochromatic wave impact is considered, the phase difference of the backward reflected wave depends on the distance between the radar and the target. However, this phase information cannot be directly used for distance measurement because the phase must be affected by an ambiguity phase equal to half a wavelength. It is also affected by the nature of the air at the moment and the changes in the position of the sensor. Therefore, the interference phase $\Delta\varphi_{21}$ obtained at two moments can be expressed as (Zhang et al., 2018):

$$\Delta\phi_{21} = \Delta\phi_{def} + \Delta\phi_{atmo} + \Delta\phi_{geo} + \Delta\phi_{noise} + 2n\pi \tag{2}$$

where $\Delta\phi_{def}$ is the component related to the displacement; $\Delta\phi_{atmo}$ is the phase component due to the atmospheric effects during image acquisition; $\Delta\phi_{geo}$ contains the geometric phase component due to repositioning errors between the two acquisitions; and $\Delta\phi_{noise}$ is the phase noise component. Finally, the term $2n\pi$ relates to the phase wrapping corresponding to the ambiguity phase equal to half a wavelength. Interferometry phase accuracy depends not only on the ability of the electronic device to appreciate small phase rotation but also on the subsequent signal processing. In an ideal situation, using electromagnetic waves in the Ku band can achieve an accuracy of 0.1 mm, which is significantly higher than SAR interferometry observations.

In the case of the real aperture, the radar transmits a modulated signal that gives the sensor the capability to detect the displacement of targets that are more widely spaced than the resolution of the radar. In many applications, only-range resolution monitoring could be inadequate. In order to also provide angular resolution, it is necessary to rotate or move the microwave radar system. This makes it possible to obtain a 2D image in which the responses

of targets at the same distance from the radar can be discriminated in azimuth. In other words, moving the microwave radar system allows the obtaining of a 2D image of the displacement pattern and not simply a plot of its projection in the view direction. Although this is an important capability, it does result in the sensor becoming slower, heavier and bulkier; as such, it is an option not commonly implemented.

3 METHODOLOGY AND MONITORING RESULTS

3.1 *Monitoring of long-span metallic railway bridge*

The outstanding performance of the FastGBSAR-R (Zou et al., 2019) Interferometry radar sensor was implemented to investigate the dynamic behavior of the long-span metallic railway bridge. The sensor is a full polarimetric radar system featuring four horn antennas, two of which are used to transmit horizontal and vertical polarimetric electromagnetic waves while the remaining two are used to receive horizontal and vertical polarimetric reflective waves. The sensor was positioned on a tripod 10 m from the bridge, with the antennas pointed alongside the structure, as shown in Figure 1 (left). The measurements were taken during normal train traffic conditions. The aim of this study is to provide the dynamical monitoring of the bridge during a train crossing. The health condition of the bridge can be detected by judging the vertical deformation scale. The radar system can provide a radar profile within an extremely short sampling time. In this study, the pulse repetition frequency (PRF) was set to 500 Hz. The acquisition lasted approximately 300s. Under this monitoring condition, no movement occurred along the azimuth direction using a high PRF rate but the cost of this is a lack of azimuth resolution. All targets inside the antenna beam with the same slant range were recorded together, making it difficult to identify the corresponding target from the radar diagram. The Radar Cross Section (RCS) profiles of each polarimetric response of this bridge are presented in Figure 1 (right). Due to the scattering properties of the bridge and the acquisition geometry, the RCS decreases regularly as the distance increases. Identification of the bridge response commences at a 40 m range. The corresponding temporal profiles of the LOS deformation of each polarimetric component being passed by a train are shown in Figure 2 (left). It can be observed that, between 180s and 240s, deformation is measured in all the range profiles corresponding to the targets on the bridge.

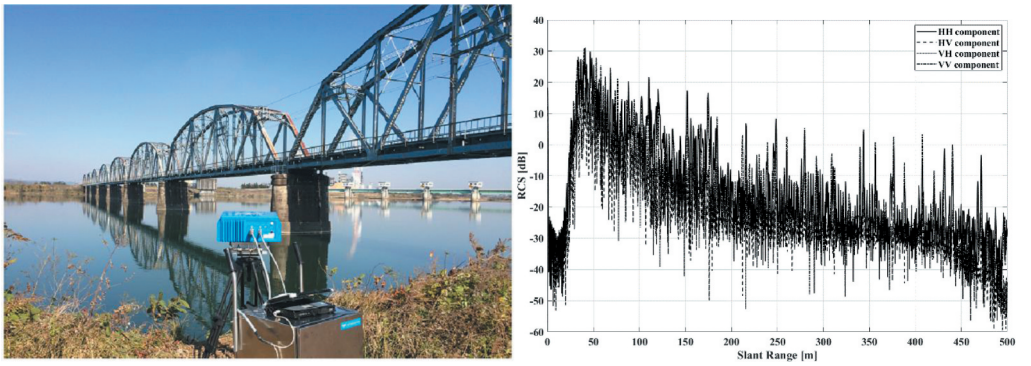

Figure 1. Polarimetric FastGBSAR-R system beside metallic railway bridge and RCS profile of HH, HV, VH and VV components.

Since radar has only a 1D range profile with distance resolution, the radar is able to distinguish objects on a distance basis only. In order to capture the overall bridge desk vertical vibration, an advanced methodology was proposed based on polarimetric analysis and acquisition geometry. The polarimetric responses hold all the information from the scatterers and all the polarimetric information can be written into a scattering matrix. Many current approaches that decompose the polarimetric scattering matrix are applied to more

meaningful, phenomenological parameter spaces. Based on these approaches, polarimetric information can be applied in our specialized case to target identification and classification. The proposed method can not only distinguish the resolution cell from the bridge desk, but also can provide vertical deformation information.

Due to the submeter-level spatial resolution of GB-RAR observations, a scatterer contains various noises. The total coherence can be modeled as:

$$\chi_{total} = \chi_{SNR} \cdot \chi_{vol} \cdot \chi_{add} \tag{3}$$

The loss of coherence caused by SNR decorrelation effects is represented by χ_{SNR}. The loss of coherence brought about by volume decorrelation effects is represented by χ_{vol}. The coherence loss resulting from extra residual sources, such as ambiguities and quantization mistakes, is represented by χ_{add}. The interaction between a radar wave and the target is characterized by total coherence, making the comparison of interferograms more straightforward. The precision of the determined signal phase difference $\Delta\phi$ error is correlated with the attained outcomes of the calculated deformations. It is possible to evaluate the signal phase difference based on the relationship between the total coherence value χ_{total} of the target and the GB-RAR observation using:

$$\Delta\phi^2 = \frac{1 - \chi_{total}^2}{2\chi_{total}^2} \tag{4}$$

Researchers have established that the SNR of scatterers plays a critical role in determining the accuracy of deformation monitoring in real-world measurements. In addition to considering the SNR value, the distance between scatterers within the scene must also be considered. Given that the obtained SNR values appear to be significantly overestimated, it is logical to establish a correlation between deformation and total coherence based on the preceding discussion, to enhance the real-world accuracy of deformation measurements under field conditions. In this paper, we implement an approach that combines the co-polarization deformation of scatterers according to coherence, to improve the estimation of the deformation time series. More specifically, the associated deformation of scatterers in the HH and VV channels is denoted as Def_{HH} and Def_{VV}, respectively. Employing the improved deformation method, their weighted average value was calculated (Chang et al., 2021):

$$Def_{LOS} = \frac{W_{VV} * Def_{VV} + W_{HH} * Def_{HH}}{W_{VV} + W_{HH}} \tag{5}$$

The designated weights for deformation in the HH and VV channels are represented by W_{HH} and W_{VV}, respectively. These weights can be influenced by the coherence of scatterers. In scenarios where coherence is elevated, scatterers are assigned significant weight. The precision of GB-RAR observational uncertainty and time series processing errors impacts considerably on the quality of the Def_{HH} and Def_{VV} deformation estimations.

H/Alpha analysis was then conducted, based on the full polarimetric responses of the RCS profiles. Entropy arises as a natural measure of the inherent reversibility of the scattering data and the alpha angle can be used to identify the underlying average scattering mechanisms. The H/Alpha plane can be subdivided into nine basic zones by considering different scattering behavior, to separate the data into basic scattering mechanisms. Each of these zones independently represents the pixel indexes corresponding to dominant scattering mechanisms identified by a backscattered signal (Lee et al., 2006). From the results of the H/Alpha analysis, we could see that most reflections emanated from a region with low entropy values. Regions in which entropy varies from 0 to 0.5 and alpha angle varies from 0° to 42.5° represent scattering from the Bragg Surface. Regions in which entropy varies from 0 to 0.5 and alpha angle varies from 42.5° to 47.5° represent the scattering from a target such as an isolated dipole (Lee et al., 2018). The reflections from these two regions mainly arose from the side surface of the metallic bridge. At this stage, the reflection from the side surface of the metallic bridge was selected from the RCS profiles, based on its polarimetric property.

We next focused on the reflections from these two regions and calculated the vertical deformation based on the acquisition geometry and radar polarimetry. The azimuth direction and ground range direction were determined by the radar H-pol and V-pol, respectively.

Polarization orientation angle (POA) is the angle of rotation about the radar line of sight (Lee et al., 2018). POA can be estimated from PolSAR data by the angle of the correlation between LL and RR circular polarizations (Lee et al., 2006), and can be expressed as:

$$\tan(-4\eta) = \frac{-4Re\left(\left\langle (S_{HH} - S_{VV})S_{HV}^{*}\right\rangle\right)}{-\left\langle |S_{HH} - S_{VV}|^{2}\right\rangle + 4\left\langle |S_{HV}|^{2}\right\rangle} \tag{6}$$

where ξ indicates POA. POA can also be obtained from the azimuth slope angle ω, ground range slope angle γ and radar look angle ϕ, based on the imaging geometry using the following equation (Moreira et al., 2013):

$$\tan(\xi) = \frac{tan\omega}{-tan\gamma cos\phi + sin\phi} \tag{7}$$

Since the sensor was positioned on a tripod 10 m distant from the bridge, the local incidence angle θ can be calculated by the following relationship:

$$\cos\theta = \frac{10}{R} \tag{8}$$

where R indicates the slant range distance from the radar sensor to the target, which can be obtained from the RCS profiles. The local incidence angle can also be derived in terms of the local slopes and radar look angle, and can be expressed as:

$$\cos\theta = \frac{tan\gamma sin\phi + cos\phi}{\sqrt{1 + tan^{2}\gamma + tan^{2}\omega}} \tag{9}$$

Hence, the radar look angle θ can be solved with the above equations. For deformation caused by passing trains, planar displacements contribute only minimally to the radar derived LOS deformation in most cases. Thus, it is recommended that planar deformation components are neglected when monitoring railway induced deformation on bridges regarded as having no planar deformations. With the known radar look angle ϕ, the bridge deformation fields in the vertical direction were easily converted with the slant range distances, as shown in Figure 2 (right).

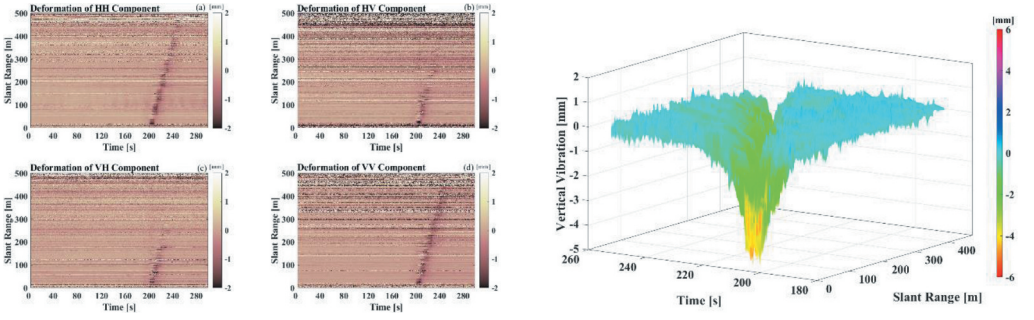

Figure 2. LOS deformation profiles and vertical deformation measured at metallic railway bridge while a train passes.

3.2 *Monitoring of reinforced concrete Shinkansen bridge*

The FastGBSAR-R Interferometry radar sensor was also implemented to investigate the dynamic behavior of the reinforced concrete Shinkansen bridge. The sensor was positioned on

a tripod under the edge of the bridge and the antennas were pointed along the structure, shown in Figure 3 (left). Measurements were carried out during the normal traffic conditions of the bridge. An aim of this study is to provide the dynamical monitoring of the bridge while being crossed by a Shinkansen train. The health condition of the bridge can be detected by judging the vertical deformation scale. In this study, the pulse repetition frequency (PRF) was set to 1000 Hz and acquisition lasted 300s. The Radar Cross Section (RCS) profiles of each polarimetric response of the bridge are presented in Figure 3 (right). The corresponding temporal profiles of the LOS deformation of HH and VV, while being passed over by a Shinkansen train, are set out in Figure 4 (left). It can be observed that, between 10s and 40s, displacement was measured in all the range profiles corresponding to targets on the bridge. The displacement is clear for targets located within 250 m of HH components but unclear for the VV component.

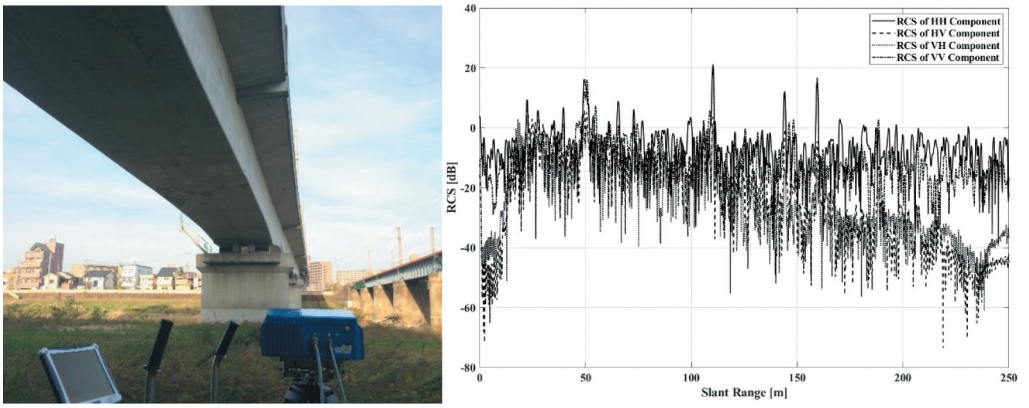

Figure 3. Polarimetric FastGBSAR-R system beside reinforced concrete bridge and RCS profile of HH, HV, VH and VV components.

Since the bridge deck surface is relatively smooth, the back reflected signals of each polarimetric component are very weak. The lower the signal to noise ratio (SNR), the lower the phase quality of the interferometry will be. It is not recommended that the interferometry phases of all reflections from the bridge deck are monitored, since just a small number of reflection points at the structure can retrieve an accurate displacement time series. From Figure 3 (right), three high RCS reflection points could be observed at approximately 50 m, 110 m and 160 m. H/Alpha analysis was carried out based on the polarimetric responses of the reflections. From the result of the H/Alpha analysis, we see that most of the coherent scatterers came from a region with low entropy and alpha values varying from 20° to 70°. This is

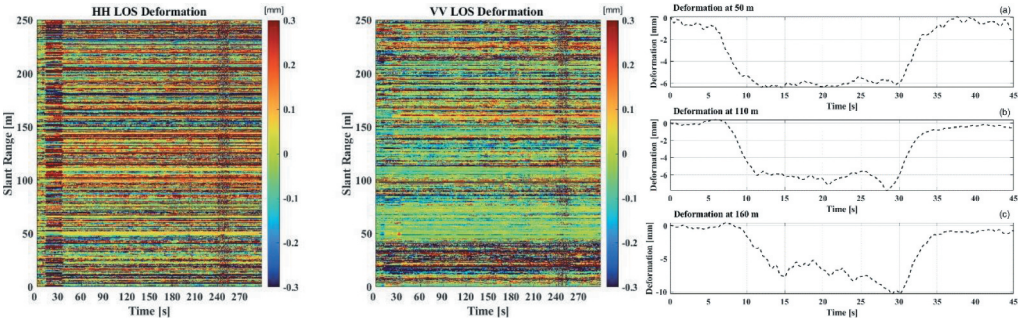

Figure 4. LOS deformation profiles and vertical deformation measured at reinforced concrete bridge while a Shinkansen train passes.

likely to mean that these reflections not only emanate from similar dihedral reflectors and dipole targets, but also similar Bragg surface targets.

It is clear that the reflections of the three points emanate from targets such as the dihedral reflector. Due to the acquisition geometry, we conclude that these reflections come from the horizontal desk with a vertical edge, which is similar to a dihedral corner reflector. The altitude difference between the sensor and the bridge desk is 2.5 m. Deformation of the three points in the vertical direction was easily converted with the slant range distances, as shown in Figure 4 (right). The maximum vertical deformation of the reinforced concrete Shinkansen bridge is around 10 mm. Each saw tooth of the deformation curve corresponds to a Shinkansen carriage.

4 CONCLUSION

Within the sphere of the structural health monitoring of infrastructure, Ground-based Real Aperture Radar (GB-RAR) interferometry has emerged as an innovative measurement technique. Its principal advantage is its capacity to generate comprehensive insights into the integrity of scrutinized structures. Nevertheless, technology is not without its limitations; specifically, the accurate localization of deformations within a structure represents a significant challenge, given that any point within a resolution cell can influence measurement. This paper introduces a suite of methodologies designed to counterbalance the inherent constraints associated with GB-RAR interferometry, particularly in the context of bridge monitoring applications. The investigation delves into the vertical deformation patterns of bridges, employing a polarimetric GB-RAR system augmented by sophisticated signal processing algorithms. Furthermore, the study explores the correlation between the modal parameters of a bridge and its structural properties. The signal processing strategies proposed herein are multifaceted, including the categorization of scattering characteristics via polarization analysis, the refinement of deformation forecasting by leveraging dual-polarization channels, and the estimation of radar look angles to compute vertical deformations. These methodologies collectively aim to enhance the precision of structural localization and vertical deformation measurements in bridge monitoring. Empirical findings presented in this research detail the dynamic behaviors of two distinct bridge types under varying load conditions, encompassing scenarios such as the transit of low-speed trains and the passage of high-velocity Shinkansen bullet trains. The outcomes underscore the efficacy of polarimetric GB-RAR, in concert with the advanced algorithms proposed, as a potent approach for the surveillance of bridge structures. This technique significantly enriches the quality and veracity of dynamic deformation monitoring, underscoring its utility in the domain of infrastructure health assessment.

ABSTRACT: Ground penetrating radar (GPR) is a non-destructive technology widely used for the structural mapping of bridge deck pavements. However, since traditional numerical simulation models have limitations in accuracy – inevitably resulting in dissatisfaction with current research – our study develops a refined three-dimensional GPR simulation model for enhanced imaging applications and fine structure inversion. The model comprises a mechanical construction, using a discrete element method (DEM) to accurately simulate coarse aggregate positioning. MATLAB is then employed for domain discretization and the integration of fine aggregate and asphalt binder. Subsequently, the study undertakes GPR numerical simulations using the finite-difference time-domain (FDTD) method with gprMax software. The results show a level of error between simulation results and empirical values below 2%, and a discrepancy between simulation results and measured data below 3%, demonstrating the high accuracy of the proposed method in simulating GPR responses in bridge deck pavements.

1 INTRODUCTION

Bridge structures play a vital role in economic development, cultural exchange and transportation within human society (Abouhamad et al., 2017). Affected by continuous repeated vehicle loading and other severe service conditions, such as high humidity in the natural environment and dramatic day/night temperature variations, bridge deck pavements typically suffer from distresses such as moisture damage, rutting, cracking and debonding (Alani et al., 2013). These issues are mainly caused by the mechanism of asphalt-aggregate debonding, which leads to a loss in pavement strength and stiffness and consequently shortens the service life of bridges (Zhang et al., 2020). Therefore, condition assessment and maintenance activities are essential for estimating the remaining service life of bridges that are structurally deficient or functionally obsolete. GPR stands out as one of the most effective Non-Destructive Evaluation (NDE) technologies for assessing bridge deck pavement deterioration due to its efficient data collection, rapid detection capabilities and high-resolution imaging. It has long been recognized as an exceptionally promising tool for capturing and quantifying the progression of deterioration in bridge decks, detecting debonding distribution and measuring the thickness of concrete cover, among other applications (Asadi et al., 2020).

GPR operates by transmitting high-frequency radio waves into the ground. As these waves encounter different subsurface materials, they are reflected back at varying intensities, depending on the material's electrical properties. The radar's receiving antenna captures these reflected signals while the remaining energy propagates further and gradually diminishes over

DOI: 10.1201/9781003483755-296

time (Varnavina et al., 2015). Therefore, the GPR application is based on electromagnetic wave propagation, indicating that numerical simulation using GPR can be realized by solving Maxwell equations, which mathematically express the relationship between fundamental electromagnetic (EM) field quantities and their dependence on their sources (Alani et al., 2014). GPR simulations enable the visualization of EM phenomena that are otherwise difficult to detect, significantly enhancing the accuracy of GPR interpretation. However, traditional modeling methods – which often simplify bridge pavement structures to homogeneous media – are becoming increasingly inadequate for contemporary complex research, such as the inversion study of the fine structure of bridge pavements. These simplified models can even lead to conflicting results between field test measurements and simulation outcomes. For example, research by Mezgeen et al. into the characteristics of GPR signals in response to varying crack widths in rigid pavements revealed a notable difference: cracks as narrow as 2mm (barely detectable in experimental measurements) were clearly observable in simulations (Zou et al., 2020). In reality, the material of bridge deck pavements, including asphalt concrete, is a multiphase, heterogeneous mixture composed of various substances. When high-frequency EM waves traverse through such a medium, a substantial amount of scattering wave occurs. This scattering leads to random features in the received signals, which is a primary reason for the significant discrepancies observed between the results of homogeneous model simulations and actual measurements. Therefore, it is essential for improving the accuracy of GPR numerical simulation to develop a multiphase random discrete medium model which more accurately reflects the actual conditions of bridge deck materials. However, methodologies for building numerical simulation models of composite media using GPR are scarce. Li et al. enhanced simulation accuracy by incorporating surface roughness, which increased heterogeneous scattering waves at interfaces (Zeng et al., 2023). However, irregular interfaces cannot accurately represent the random scattering waves occurring within the medium. Solla et al. combined image processing techniques (IPT) with the FDTD algorithm to achieve 2D GPR simulations of bridges (Solla et al., 2016). However, this method is heavily dependent on the quality of the input images and is not an automated process. Certainly, the integration of Computed Tomography (CT) technology with IPT can significantly enhance the efficiency of modeling, potentially achieving a one-to-one replication of the actual scenario in a three-dimensional model (Özkap et al., 2020). However, obtaining CT scan results for large-scale bridge deck pavements is impractical.

Considering the research discussed previously, this study introduces a Realistic Composite Medium Modelling (RCMM) approach tailored for actual composite mediums, with the aim of enhancing the precision of GPR numerical simulations on bridge deck pavements. The structure of this paper is as follows: a comprehensive description of the RCMM method is given in Section 2, followed by details of the validation process in Section 3. The final section offers a summary of our findings.

2 METHODOLOGY

In this paper, the bridge deck pavement is modelled as an asphalt concrete (AC) mixture. Aggregates, asphalt binder and air voids compose the three-phase heterogeneous media, excluding water, reinforcement mesh and other intricate structural elements typically found in bridge pavements. Given a specific designed air void content, the volume fractions of the other two phases are calculated as follows:

$$V_a = \frac{(1 - P_b) \times G_{mb}}{G_s} = \frac{(1 - P_b) \times (1 - V_{air}) \times G_{mm}}{G_s} \quad (1)$$

$$V_b = 1 - V_{air} - V_a \quad (2)$$

where V_{air} is the designed air void content; G_{mb} and G_s are the bulk density of asphalt mixture and aggregates, respectively; G_{mm} represents the maximum theoretical density of the asphalt mixture; and P_b signifies the asphalt content (Liang et al., 2022). The specific values of these

parameters can be derived from the design documents of AC mixtures. Compared with methods that depend on IPT, the RCMM method is independent of the need for high-definition images or the microstructure of real-world specimens, making it more adaptable for extensive modeling and precise parameter management. In this study, EDEM (a commercial DEM software) was employed as a promising tool to simulate both the location and orientation of coarse aggregate particles. To accurately simulate a realistic road model, we carried out two key simulations sequentially – settlement and compaction – based on the constitutive mechanical model of asphalt mixtures. Additionally, it is noteworthy that the irregularity of particles was achieved by importing various stone templates, each differing in angularity index and dimensional value. Considering the application of Yee's algorithm in the Finite-Difference Time-Domain (FDTD) method, the simulation domain was subsequently discretized into uniform cubic cells. The dimensions of these cells are designed to match the spatial resolution of the FDTD method, ensuring coherence between the simulation elements and the method's inherent structure. The three-phase pavement generation algorithm is summarized as follows:

1. Calculate V_s and V_b using Equation (1) and Equation (2).
2. Generate coarse aggregates with sizes larger than 2.36mm using EDEM, based on aggregate gradation data and Vs.
3. Discretize the simulation domain into a three-dimensional array using unit cubes and verify the aggregate gradation, noting that the dimensions of each cube should be smaller than 2mm to achieve the desired level of accuracy. After discretization, areas within the sample boundary that are not occupied by aggregates are designated as free space.
4. Complement the fine aggregates and asphalt binder by randomly substituting the free space elements within the sample boundary. This arrangement is accomplished by utilizing two distinct types of cube: aggregate-asphalt cubes and asphalt-void cubes. The former type represents elements where fine aggregates are mixed with asphalt binder at a specific ratio, whereas the latter represents elements combining asphalt binder and air voids in a certain proportion.

The dielectric properties of the materials were assigned following the completion of the FDTD model. In this study, all materials are considered non-lossy, implying that the imagery elements of their dielectric constants are not taken into account. In this work, the dielectric constants of free space and asphalt binder are set to 1 and 3, respectively (Leng et al., 2011). Subsequently, a two-phase Rayleigh model is employed to determine the dielectric constants for the aggregate-asphalt cube and the asphalt-void cube (Sihvola, 2000). Meanwhile, the ALL model is utilized to calculate the empirical values of the dielectric constant for asphalt concrete (AC) mixtures (Abufares et al., 2023).

3 LABORATORY TESTING AND NUMERICAL SIMULATION

In this section, we conducted laboratory experiments on GPR measurements for AC mixtures. The design parameters of the experimental specimens were utilized for two primary purposes: firstly, they were input into the ALL model to calculate the empirical values of the specimens' dielectric constants and, secondly, they served as input parameters for numerical modeling. To further underscore the accuracy of our proposed method, we also established a simulation model with identical parameters using the Random Sequential Adsorption (RSA) algorithm (Cao and Al-Qadi, 2021). Consequently, we compared the simulation outcomes from both methods with actual measurements and empirical values.

The thickness of the pavement layer of bridge deck pavements varies, as its design must incorporate factors such as the construction environment and vehicle density. In this research, thickness exceeding 10 cm significantly increases the experimental workload, while thickness below 5 cm causes the radar signals from the top and bottom surfaces to overlap, complicating the calculation of the dielectric constant using the two-way travel time (TWTT) algorithm. Consequently, three AC samples, each 10 cm thick, were designed and fabricated. Details of the designed parameters are summarized in Table 1 and the gradation curve is depicted in Figure 1.

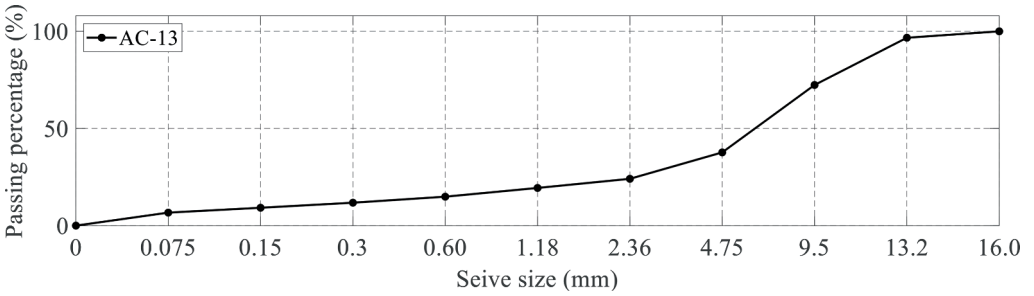

Figure 1. Aggregate gradation data of AC-13 mixture.

Table 1. Asphalt mixture information for specimens.

Characteristics	V_{air} (%)	G_{mm}(-)	G_s(-)	G_{mb}(-)	P_b(%)
AC-13*	6.00	2.69	2.93	2.53	5.00

*With a nominal maximum aggregate size of 13mm.

The laboratory GPR static tests were conducted using an IDS radar system, equipped with a palm antenna operating at a central frequency of 2 GHz. As depicted in Figure 2, a palm radar system was mounted at the center of each specimen for data collection. Due to the limited footprint of the antenna, individual data sets were obtained from each specimen. The time window for a single GPR A-scan was established at 20 ns, with a sampling rate of 2048 to ensure sufficient time-domain resolution for the TWTT method (0.0098 ns/sample). To prevent subsurface reflections from the floor decks (which are outside the scope of this study), a steel plate was placed beneath each specimen. Data collection involved eight measurements per specimen: four on the front side and four on the back side. Post-measurement processing included DC removal, bandpass filtering and time-window cutting for the received signals. Figure 3 illustrates a representative set of A-scan data, in which the reflection times of the upper and lower surfaces are extracted using the Hilbert transform. Figure 4 displays the experimental results for each plate, with average results being 8.34, 8.17 and 8.06, respectively.

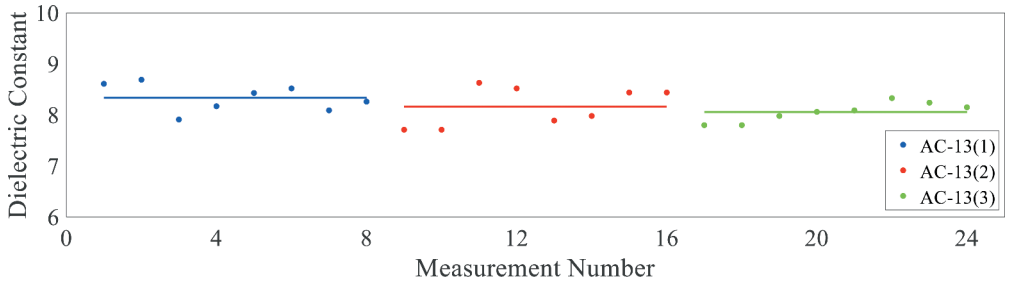

Figure 4. Dielectric constants for each AC mixture.

The numerical models were developed incorporating the same air voids, aggregate type, asphalt binder contents and aggregate gradations as depicted in Table 1 and Figure 1. Figure 5 presents a visualization of two simulated geometric models. It is noteworthy that, despite its theoretical capability, the RSA method encounters significant spatial configuration constraints in actual three-dimensional modeling. This limitation, characterized by increasing difficulty in avoiding overlaps between spheres as their number grows, makes effective spatial arrangement challenging within a limited area. Such constraints prevent the RSA method from effectively realizing a high-density, three-dimensional AC model. Therefore, we established the RSA-based AC model as a two-dimensional model with the dimensions 0.3m × 0.1m.

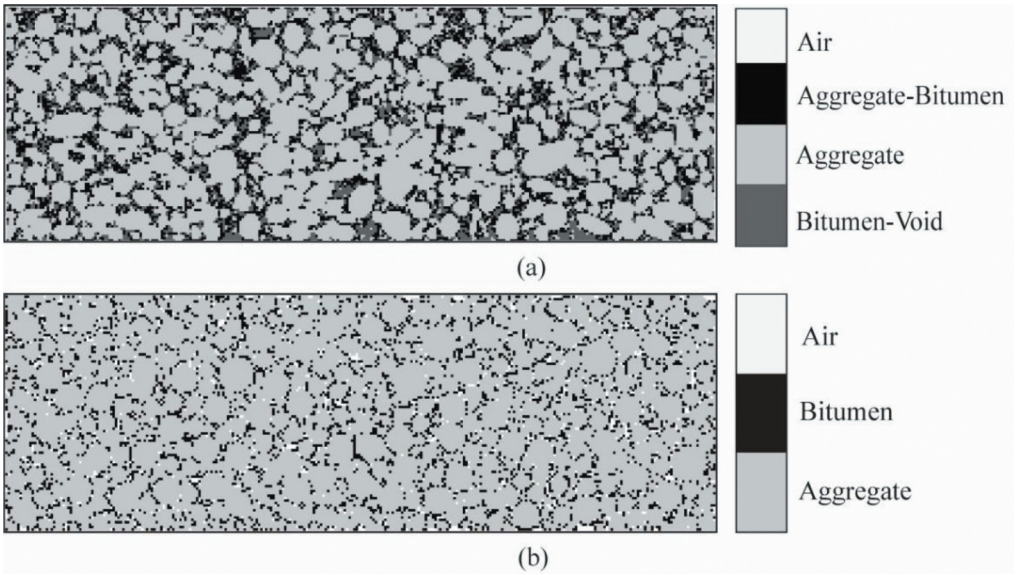

Figure 5. Visualization of (a) RCMM-based AC model and (b) RSA based AC model.

We continued to build the numerical simulation model based on FDTD using gprMax software. As depicted in Figure 6, the schematic of the FDTD model consists of two layers. The top layer was developed utilizing the generated heterogeneous models. The other was set as a Perfect Electric Conductor (PEC) due to its capability to strengthen the reflected waveform, which aids in the identification of TWTT. 'Tx' denotes the transmitting antenna and 'Rx' represents the receiving antenna. The Perfectly Matched Layer (PML) was employed to simulate EM wave propagation in an infinite space, effectively weakening EM waves at the boundary without generating any reflections. Additional model parameters are listed in Table 2.

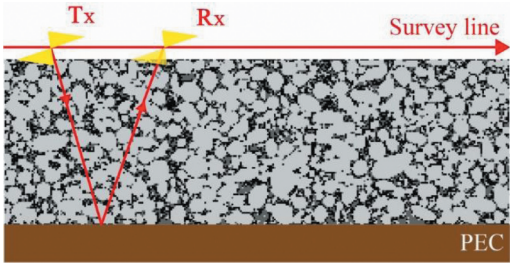

Figure 6. FDTD simulation model in gprMax.

Table 2. Asphalt mixture information for specimens.

Characteristics	Time window (ns)	Central frequency (GHz)	Function of excitation source (-)	Spatial resolution (m)	Antenna spacing (m)	Movement step (m)
Value	10	2	Ricker	0.001	0.06	0.01

The dielectric constant of the aggregates was found to be 10.5 (Parkhomenko, 1967). Subsequently, we calculated the dielectric constants for the aggregate-asphalt cubes and the asphalt-void cubes as 7.66 and 2.29, respectively. In the case of all materials, except for PEC, conductivity was set to 1e-5, indicating that the materials were assumed to be non-lossy.

After completing the simulations, Figure 7 showcases an example of the subtracted GPR A-scan signals, where the direct wave is removed. Consequently, Table 3 presents a comprehensive summary of various data types: average values from the simulations, empirical values derived from the ALL model, field experiment measurements, and discrepancies between both the simulated and empirical values as well as the simulated and measured

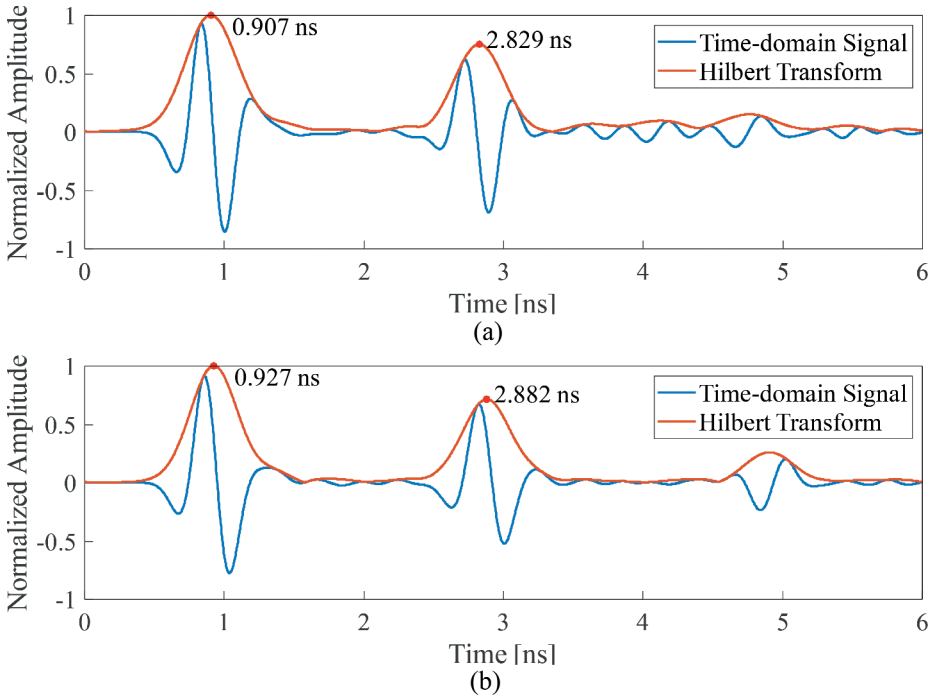

Figure 7. A-scan signals from (a) RCMM and (b) RSA Forward Simulations.

Table 3. Asphalt mixture information for specimens.

Characteristics	Values (-)	RCMM model result (-)	RSA model result (-)	Error with RCMM models (%)	Error with RSA-based (%)
AC-13(1)	8.34	8.30	8.60	0.5	3.1
AC-13(2)	8.17			1.6	5.3

AC-13(ALL)*	8.25			0.6	4.2

*Empirical value calculated by ALL model.

values. The data in Table 3 clearly indicates that, regardless of whether empirical values or measured results are considered, the refined model's simulation results significantly surpass those obtained from the RSA model.

4 CONCLUSION

In this study, we introduced the RCMM method – a novel approach in numerical modeling for simulations of bridge deck pavements using GPR. We began by constructing a three-dimensional structure with coarse aggregates as the skeleton, emphasizing the predominant volume fraction of aggregates relative to the other components. DEM was employed to position the coarse aggregates, incorporating irregular aggregate templates and an asphalt mechanical model for enhanced accuracy. Subsequently, we utilized MATLAB to discretize the simulation domain into Yee's grids. Innovatively, we introduced two types of grid element as aggregate-asphalt and asphalt-void elements during this phase to optimize the model's adaptability in the Yee grid. Finally, the model was encoded into a three-dimensional matrix and introduced into gprMax for GPR wave propagation. To validate our model's effectiveness, we conducted a comparative analysis against the RSA method, using identical parameters This comparison, backed by empirical data and actual measurements, revealed that our RCMM method significantly reduces simulation errors – less than 2% in comparison to empirical values and under 3% against measured data. These findings underscore the RCMM method's superior precision in simulating GPR responses for bridge pavement layers.

New trends and possibilities of GPR in bridge inspection

M. Solla, A. Elseicy & A. Alonso-Díaz
CINTECX, Universidade de Vigo, Geotech research group, Spain

ABSTRACT: This contribution presents an overview of the GPR technique applied to bridge inspection, covering all the information that can be detected from both structural (layering, cover depth, etc.) and diagnosis (cracking, voids, corrosion, etc.) points of view. The use of Artificial Intelligence on GPR data will be also addressed, such as the use of Deep Learning methods to extract rebars or distresses like cracks or delamination. Moreover, data digitalization will be considered, with a special attention on GPR data formats to be integrated into GIS and BIM models, and other digital innovations like augmented reality and digital twins. Finally, a review of other non-destructive emerging methods commonly used with the GPR technique will be considered.

1 INTRODUCTION

Bridges are essential structures within the transportation infrastructure domain. They connect lands, and human communities in general, thus facilitating the movement of people and goods and representing a key factor in the economic, industrial, and social development. However, regular maintenance is required to ensure their safety and functionality. Bridges are exposed to several adverse aspects, such as aging, extreme weather conditions, changes in traffic loads, physical and chemical agents, and construction defects. Neglected maintenance can lead to deterioration, and in the worst case in collapse, and costly repairs.

The use of Non-Destructive Testing (NDT) evaluation is highly recommended for more complete inspections while preserving the integrity of these structures, particularly when they suffer from structural deterioration. There are various NDT methods that have been successfully applied for bridge monitoring. Among the different non-destructive methods, mechanical and electromagnetic technologies are especially important for structural imaging.

Conventionally, bridge inspection is based on visual inspection, instead of monitoring the real subsurface condition. Internal damage detection can prevent unpredictable and premature collapse of structures. Within the electromagnetic methods, the Ground-Penetrating Radar (GPR) is a geophysical and non-intrusive imaging technique widely used for routine subsurface inspections, due to its high-resolution and continuous imaging, in addition to its easy portability (compared to other techniques). GPR allows for data acquisition at high speed, continuously, using mobile acquisition units and in a non-contact mode. It enables to keep the bridge in-service during the GPR surveys, thus reducing costs and discomfort to users (Solla et al. 2021).

This work presents an overview of the applicability of the GPR method to bridge monitoring, including the information (findings) than can be detected, and the main limitations. Moreover, a case study is included showing the capabilities of the method for the documentation and evaluation of an ancient masonry arch bridge. A reflection on the use of emerging processing techniques based on artificial intelligence is also included. Another case study is also presented focusing on the use of deep learning (YOLOv8) for automatic rebar detection in concrete bridges. Finally, there is a brief discussion of complementary NDT methods that

DOI: 10.1201/9781003483755-297

have been commonly combined with GPR in the assessment of bridge structures, including the use of emerging techniques (such as Interferometric Synthetic Aperture Radar (InSAR) and drones or unmanned aerial vehicles (UAV) equipped with GPR). Further trends in the application are also commented.

2 GPR APPLIED TO BRIDGE INSPECTION

In bridge inspection, the GPR method has been successfully employed for a great variety of applications and different types of structures (masonry and concrete bridges).

Regarding masonry bridges (brick or stone), the GPR method has been demonstrated its capabilities in detecting:

- Thicknesses in ashlars (spandrel walls, ring arch, etc.) (Solla et al. 2014, Arêde et al. 2017).
- Filling distribution (probable material characterization) (Bergamo et al. 2015, Stavroulaki et al. 2016).
- Bridge foundations (Sánchez-Aparicio et al. 2019).
- Damages such as cracking, voids or cavities in stonework (Solla et al. 2011a).
- Moisture content (Kalogeropoulos & Brühwiler 2011).
- Evidence of restorations/reconstructions (Solla et al. 2016, Alani et al. 2017).
- Hidden structural elements such as arches or ancient geometries of the structure (Solla et al. 2010, Solla et al. 2011b).

With respect to concrete bridges, GPR has been successfully used in:

- Estimation of cover depth (Hugenschmidt & Mastrangelo 2006).
- Detecting and mapping reinforcing bars (Alani et al. 2013, Rathod et al. 2019).
- Moisture detection and water content estimation (Simi et al. 2012, Agred et al. 2018).
- Damage detection such as corrosion, cracking, delamination, etc. (Benedetto 2013, Abouhamad et al. 2017, Diamanti et al. 2017).
- Location of hidden elements and utilities (cable ducts, deck joints, etc.) (Sławski et al. 2016, Dinh et al. 2019).

It should be mentioned that the GPR method has been more widely used for the inspection of concrete bridge. Surveying masonry or concrete bridges differs in the GPR equipment and in data acquisition methods used. Ground-coupled antennas, usually single antennas mounted on a trolley or manually on a survey cart, are most generally used in masonry bridge surveying, while both ground-coupled and air-coupled antenna systems can be used in inspecting concrete bridges. For small survey areas and vertical surfaces (punctual areas), when more image resolution is required, ground-coupled antennas are most used. On the other hand, air-coupled antennas are generally mounted on a van or a vehicle (suspended) to conduct whole length of the bridge measurements, which allow operating at a higher speed (with lower resolution measurements) thus avoiding traffic disruption. Moreover, for large survey areas, and particularly to map utilities and reinforcement, the use of multi-channel systems is highly recommended. Array multi-channel systems are preferred because they cover wider width measurements (increasing the productivity and benefiting 3D visualization). Both air-coupled and array multi-channel systems are normally mounted on vehicles connected to a differential RTK GPS and an encoder-based distance measuring instrument (DMI) for real-time positioning.

The analysis and interpretation of GPR data in masonry bridges is often difficult due to the complexity of these structures and the heterogeneity of masonry and filling. Therefore, for these bridges, it is recommended to conduct more than one profile line to improve data quality and to prevent inappropriate data interpretation.

In the case of concrete bridges, the presentation of GPR data is usually carried out in the form of 3D maps, or time-slices, at different depths (amplitude/attenuation maps and deterioration/delamination maps). This way, it is possible to estimate the extent of deterioration. Nevertheless, some limitations can occur. In reinforced concrete bridges, the detection of

rebar is generally easy because the steel is a quasi-perfect reflector of the GPR waves, but deeper targets of interest can be masked. To overcome this limitation, collecting data in both polarizations is recommended. The reflections produced by metallic targets perpendicular to the data collection direction are weakly seen in data collected with dipoles parallel to the scanning direction, so that other potential targets below them can be more easily detected. In this regard, array multi-channel systems may use antennas arranged with different polarizations. Negatively, these systems have an excessive cost and decrease the survey speed (higher sampling rates are required). The later could result in higher survey costs and, more importantly, could interrupt the traffic flow.

Finally, for bridge structures in general, it is important to mention the technical difficulties experienced during data acquisition to access some parts of the structure (e.g., piers and spandrel walls). Further developments should therefore include the design of innovative devices for the automatic data collection such as drones or robots (Howlader et al. 2016, Gibb et al. 2018).

2.1 *Case study No. 1: Surveying the Arnuide Masonry Arch Bridge (Spain)*

The Arnuide Bridge is a medieval bridge located in the municipality of Vilar de Barrio, in the northwest region of Galicia, Spain. It has a gothic arch with a span of 11.65 m and presents a double slope profile, with a length of about 35 m and 3.50 m wide (Figure 1). In the construction of the bridge, granite ashlars were used as masonry with a regular morphology and without mortar in the joints (at least to the naked eye).

Figure 1. General view of the Arnuide Bridge.

The GPR survey was conducted using a ground-coupled pulsed system manufactured by Malå Geoscience, composed of a Proex control unit with a 500 MHz frequency antenna. The setting parameters used for data acquisition were trace-interval distance of 0.02 s and total time window of 75 ns composed of 512 samples per trace. To guarantee positioning, while measuring the profile lengths, marks were recorded during data acquisition at the joints between ashlars.

Figure 2 presents the GPR images collected along the pathway through the longitudinal direction of the bridge. Figure 2-a corresponds to the profile line close to the upstream side, while Figure 2-b corresponds to the profile line close to the downstream side. Both radargrams are shown from the upstream side, with the starting point (trace 0 in the x-axis) at the right margin upstream. The following characteristics and pathologies are interpreted:

(i) The reflections produced by the pavement/filling interface (orange line) and infill distribution in the form of layering (yellow lines).
(ii) Both the reflections produced by the filling/voussoirs interface (pink line) and voussoirs/air interface (red line), indicating the arch-ring thickness.
(iii) Different signal behavior at the right and left walls of the vault. In the right side (Zone 3), it is possible to observe the signal scattering produced by the existence of lateral

cracking through the extrados. Conversely, in the left side (Zone 2) signal attenuation occurs, which is most probably due to internal moisture.

(iv) Zone 1 highlights the presence of displacement (bulging) in ashlars. This area in the radargrams is likely associated with a more homogenous area, which could be related to a loss of filling by water infiltration. This agrees with the interpretation of signal attenuation due to moisture (iii). Moreover, observing the reflection produced by the voussoirs/air interface below this "empty" area, there is a jump in the beginning of the hyperbola showing lower travelled time distances.

(v) Zone 4, showing signal attenuation, corresponds to the area of the stonework having different masonry with presence of clay material.

(vi) The reflections produced by the air/water interface (blue lines), indicating the water level.

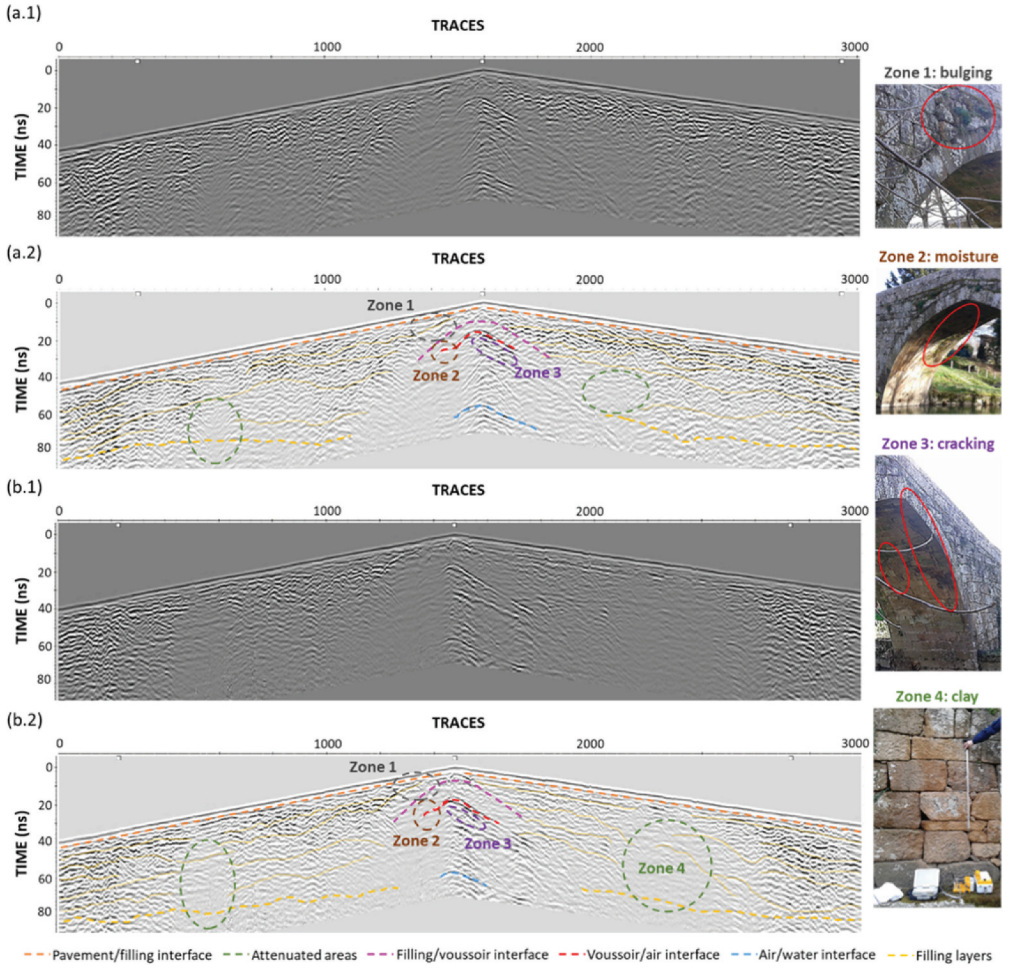

Figure 2. 500 MHz data obtained through the longitudinal direction of the bridge structure (1) and interpretation (2): a) profile line close to the upstream side and b) profile line close to the downstream side.

Figure 3 presents the radargram obtained in the transverse direction at the keystone, which allows to determine the pavement and keystone thicknesses. The pavement has a regular thickness of ~8 ns, whereas the arch-ring thickness at the keystone shows a variable depth, from lower thickness at the downstream (~5 ns) to higher thickness at the upstream side (~8 ns).

Using a pre-calibrated velocity of 0.12 m/ns for granite, the following thicknesses were computed: 0.5 m for pavement and 0.3 to 0.5 m for the granite ashlars at the keystone.

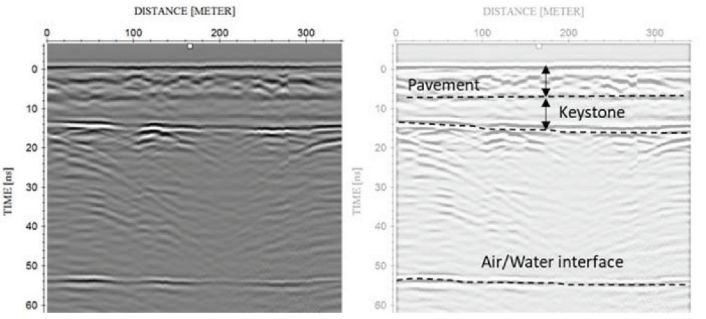

Figure 3. 500 MHz data obtained in the transverse direction at the keystone showing the interpretation of the pavement and keystone thicknesses.

3 INTELLIGENT DATA PROCESSING BASED ON DEEP LEARNING

GPR data collection can be fast and efficient when surveying concrete bridges, but a large amount of data are produced and extensive manual processing is required, which is time-consuming and labor-intensive. Moreover, the interpretation of the GPR data highly depends on the interpretational abilities of the operator to provide accurate information and reliable results, which is somewhat subjective. The introduction of Artificial Intelligence (AI) and cloud-based systems in condition monitoring, particularly in Structural Health Monitoring (SHM), has emerged as the top priorities for practicing engineers and researchers. AI is now an emerging technology to process GPR data and real-time analysis. Adapting state-of-the-art (SoA), AI technologies led to eliminating analysis subjectivity, saving processing time, and reducing the overall operation cost compared to traditional methods.

Recently, Deep Learning (DL) techniques and their application in signal processing and object detection became SoA thanks to their detection speed and accuracy compared to conventional image processing techniques. Several architectures can be applied to GPR data as 1D, 2D and 3D. DL applications help to eliminate analysis subjectivity by detecting hidden patterns between target features. Convolutional Neural Networks (CNN) is one of the DL architectures that has emerged to solve the complex data classification problem. CNN-based models can be used to detect the concrete cover depth (Wickramanayake et al. 2022). Moreover, object detection algorithms such as single-shot multibox detector (SSD) is used to detect corrosive environments (Zhang et al. 2022). The You Only Look Once (YOLO) method can also detect and localize steel bars and combine them with 1D CNN to estimate rebar diameters (Park et al. 2021). It should be highlighted that even though DL algorithms are widely used in computer vision tasks, they still need to be adequately explored with GPR data.

3.1 *Case study No. 2: Automatic rebar detection in concrete bridges using YOLOv8*

Manual rebar picking from GPR profiles of concrete bridge decks is a repetitive task that is time-intensive and labor-intensive. Analyzing the identified rebar reflections provides valuable data, enabling the extraction of peak amplitudes to generate bridge deck condition maps or estimate rebar dimensions. In this section, we present a case study leveraging the recent UltralyticsYOLOv8 object detection model to automate the localization and detection of rebar in concrete bridge decks.

A total of 1772 images were utilized for the experiment. The dataset was prepared by combining a subset the DECKGPRH1.0 dataset (Asadi et al. 2019) with profiles from a concrete bridge deck scanned using a 2.6 GHz antenna from SDNET2021 dataset (Eberichi et al.

2021), ensuring a diverse range of rebar scales within individual images. The influence of scale on the shape of rebar reflections is crucial for training a robust object detection model. According to the plotting scale, the rebar hyperbolic reflection can vary or overlap between adjacent rebars. To account for data variability, the training dataset incorporated multiple visualization scales, ranging from individual rebar reflections to longitudinal representations extending up to 3 meters. To standardize the input, all images were converted to grayscale and resized to uniform 256x256 pixel dimensions. Subsequently, the dataset was partitioned into train, validation, and test subsets, following a ratio of 7:2:1. A data augmentation technique was applied during training to increase the training data's size to enhance the model's robustness. The augmentation involved the random application of transformations, such as adjustments in image brightness, blur, noise, and exposure. Additionally, a random image mosaic was introduced to improve the detectability of rebar reflections. The size of the training data set was 6,205 after applying the augmentation.

The YOLOv8x model was trained from scratch for 210 epochs with a batch size of 16. The SGD optimizer was used with an initial learning rate of 0.02 and momentum of 0.9. The test dataset mAP50 was 0.992, while the mAP50-95 was 0.825. Figure 4 shows an example of prediction results on an unseen bridge deck.

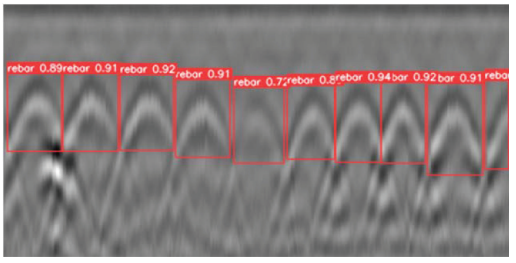

Figure 4. An example of the prediction results for a 2-meter profile.

4 COMPLEMENTARY NDT AND EMERGING TECHNOLOGY

The combination of GPR with complementary geophysical techniques is highly recommended. Each method provides different information owing to the physical properties of the construction materials, which allows for a more detailed investigation in the diagnosis of bridge stability. As discussed in Solla et al. (2021), the geophysical techniques that have been generally combined with GPR for the inspection of masonry bridges are sonic testing, ambient seismic noise, ultrasonic pulse echo and impact-echo, half-cell potential (HCP), hammer sounding resistivity, electromagnetic pulse induction (profoscope), infrared tomography and electrical resistivity.

The use of a multi-temporal InSAR (interferometric synthetic aperture radar) for bridge inspection has also been significantly increasing during the last few years. Studies undertaken on bridges have demonstrated the potential of the InSAR, together with GPR, to monitor subsidence at the transition zones of railway bridges (D'Amico et al. 2020). At network level, the InSAR allowed to detect differential settlements in transition zones and subsidence due to soil consolidation in high embankments; whereas, at project level, the GPR enabled to identify the possible causes of the displacements detected. Other authors (Alani et al. 2020) have combined GPR and InSAR technologies to investigate both the subsurface geometry and the structural displacements of masonry arch bridges certainly caused by water floods and the riverbed soil expansions. The work by Alonso-Díaz et al. (2023) has combined InSAR, GPR and FWD techniques for the assessment of road pavements, including the investigation of differential settlements in the transition zones of a concrete bridge.

The use of GPR mounted on drones or UAV (Unmanned Aerial Vehicle) has been also tested in experimental research, with some prototypes (García-Fernández et al. 2019,

Vergnano et al. 2022). This approach requires the design of novel portable antennas (Wu et al. 2019). Further progress could be focused on the development of antennas and UAV systems for surveying structural elements with poor accessibility (Esposito et al. 2023).

5 REMARKS AND FURTHER TRENDS

Transport infrastructure digitization is gaining popularity for monitoring and maintenance strategies, as reliable and effective information exchange is crucial to any industry. Misinterpretations or delays directly translate into increased cost and time requirements. Bridges are long-lasting investments that shall be functional for many decades and must deal with different domains and large amount of data that needs a collaborative environment to work together. This requires a framework for semantic integration of data sources that must deal with different types of data exchange standards. The arrival of Geographic Information Systems (GIS), Building Information Modelling (BIM) and Digital Twins (DT) to the transport infrastructure domain gives insights into latest developments in open standards for interoperability. The data from SHM inspection and monitoring can be used to create more confident information models, such as the GIS or BIM models (data), to support decision-making (Solla et al. 2020). There are different SHM studies using GPR data to create structural models for more detailed assessment of the bridge's structural load capacity and safety. The knowledge of the internal geometry and material characterization of the bridge allows engineers to perform more accurate numerical simulations (Alani et al. 2014, Bouzas et al. 2023). Nevertheless, GPR provides a subsurface representation which is rarely part of a geometric model. Thus, the representation of detailed geometries from standards still poses an open problem, as the SHM information to be added to the model may require of custom extensions of the standard or distributing semantic information points with custom SHM-related data.

Øresund Bridge: Case study of a monitoring system for movement of bridge bearings

A. Paciacconi & T. Richli
Mageba SA, Bülach, Switzerland

ABSTRACT: Assessment of infrastructure conditions is currently a topic of great importance, but also a challenging one. Many significant pieces of infrastructure were built decades ago and have, since then been exposed to load cycles, weather, special events, and all other design scenarios. During this time period, a structure will experience structural degradation and reduction in remaining service life. In addition, over such a long time span, service conditions are likely to change and other phenomena can occur with unknown effects on the structures, which may not have been taken into consideration during original design. This spontaneously raises questions about the structure's condition and real time performance. Such questions are typically driven by a limited confidence in performance, directly stemming from limited information available. A monitoring system provides comprehensive information about the structures status and provides vital support for Engineers and Asset Managers involved in decision-making processes.

1 INTRODUCTION

This paper presents the case study of the Øresund Bridge, an outstanding stay cable bridge, carrying highway traffic and a rail system. Here, a system is installed to monitor bearings movements. The owner aimed to have accurate and clear data to clear the lack of information about bearings performances in the various scenarios of operation, for example seasonal changes of temperatures or passing trains. The system design and implementation has relied on special care and attention to the fine details, from ensuring long durability in harsh environment to undertaking accurate measurements in order to generate easy-to-use data. It consists of 28 sensors and 9 Data Acquisition Units (DAU) installed at the main bridge sections, for the whole bridge length from Sweden to Denmark. Excellent results have been achieved thanks to a pilot test performed prior to system development. Installation was first performed at only 2 bearings, simulating the real case. This enabled the engineers to gain more confidence and knowledge about the specific application, being able to fine tune the system design to better meet the end user needs and expectations. Data is being used to better understand bearing movements due to temperature, wind and passing trains. A catalogue of informative data will support in design of future refurbishment works, most of all bearing replacements upon end of service life.

2 ØRESUND BRIDGE

The Øresund Bridge is an outstanding piece of major infrastructure, the longest in Europe with both roadway and railway combined in a single structure, to provide connectivity across the Øresund strait between Denmark and Sweden. It runs approximately 8 kilometres (5.0 miles) from Sweden to the artificial island Peberholm in the middle of the strait, and from there onwards via the 4-kilometre Drogden Tunnel to complete the crossing to Denmark. Deck carries 4 lanes of highway traffic on the upper section and two railways tracks on the lower section. West and East approach viaducts consist of 23 and 28 spans respectively, each 140m in length. The cable-stayed span is 1090m in total, with the central section of 490m and clear height approx. 55 m above sea level to allow passage of vessel traffic beneath.

DOI: 10.1201/9781003483755-298

Figure 1. Øresund Bridge, aerial view of stayed cable span and artificial Peberholm island.

3 SYSTEM LAYOUT

The SHM system (Structural Health Monitoring system) is composed of 19 displacement sensors and 9 temperature sensors installed at the 9 bridge sections with expansion joints, from East Abutment to West Abutment. Sensors have been selected with specific features for this application, with high- performance under quasi-dynamic application, sufficient robustness to withstand a harsh marine environment, and very precise measurements of movements up to 0.1mm. In addition, sensor installation has been tailored to allow co-ordination below the weather protection skirt currently in place at the bearings which protects the sliding surface and sliding material. As a result, and to ensure longevity, sensors are not exposed to direct weathering.

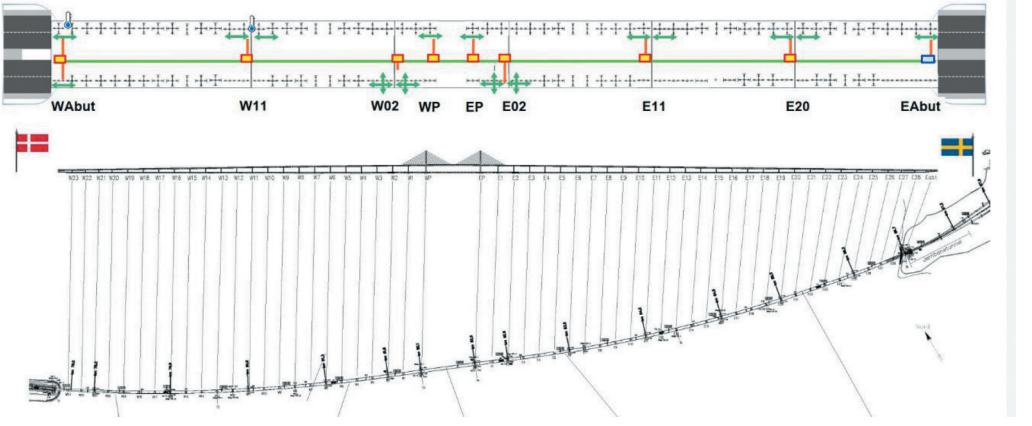

Figure 2. System layout: sensors and data acquisition units locations.

At each section being monitored, a Data Acquisition Unit (DAU) is also installed to collect the data from the sensors. DAUs are robust electronic cabinets used for industrial applications, highly resistant to corrosive agents and provided with internal heater and diagnostic sensors to prevent malfunctioning.

The DAUs feed the sensors, acquiring measurements and gathering data 24/7 at high frequency, but storage nor data processing is performed at the DAUs. Instead these are connected via the technical network to the Master Station located at the East Abutment.

Figure 3. Bearing being monitored and DAU.

The Master Station is the main unit equipped with an industrial computer where the monitoring software runs to, among other functions, gather data 24/7 displaying them in real time. Measurements undertaken by the sensors are calibrated to provide the bearings movements with respect to the middle position on the sliding plate. During commissioning, before hand over of the system to the bridge operator, such calibration has been double checked physically on site in order to confirm that the operator and the bridge owner can rely on accurate data.

Once stored at the Master Station, data is made available for the SCADA system, the supervisory and control system of the bridge owner for importing, further processing and reporting.

To ensure smooth operation, the bridge operator can remotely access the Master Station at any time, facilitating full control of the system to upgrade system configuration, measurement settings (sampling frequency, storage, etc.), perform troubleshooting in case of technical issues or control possible anomalies e.g. communication issues among the DAUs or internal temperatures not optimal for operation of such cabinets. The system is also equipped with self-diagnostic features to identify issues and in some cases restore the full functionalities. In any case, the operator is notified and informed.

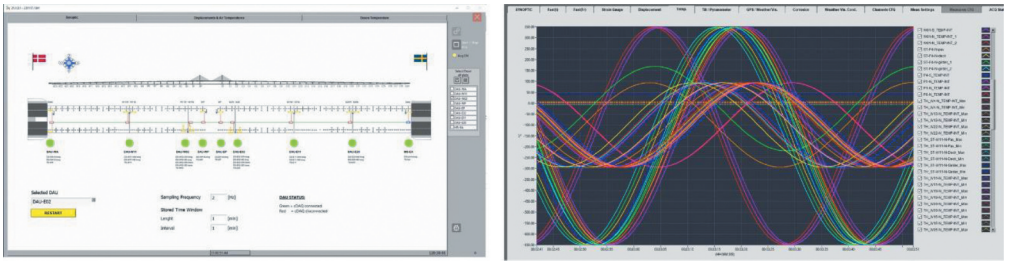

Figure 4. Interface of monitoring software, synoptic panel (left) and real time data visualization during simulation tests (right). For illustrative purpose only.

4 OPERATION, USAGE AND BENEFITS

The monitoring system has been carefully designed, paying special attention to detail, for example, precision in mechanical installation of sensors and software development to

provide data reliable, easy to use and suitable for direct interpretation. Therefore, the operator receives clear insight and information about the bearings directly from the system, without any further conversion steps, processing or analysis required. Other than saving time and efforts, this avoids possible misinterpretation of data.

One of the most important benefits is that, in general, the monitoring system allows continuous and automatic measurements, without the need for someone to go physically on site for an inspection. Visual inspections also have their importance but provide sparse information with isolated measurement and can only indicate the condition of the structure at that specific time in point, but do not give a detailed long-term overview of the behaviour.

The monitoring system operates 24/7, providing comprehensive information to understand behaviours, trends and performances over long time periods, for different weather conditions or traffic scenarios.

In addition, the quality and accuracy of information is far better with a proper monitoring system than with visual inspections referring to rapid movements, dynamic behaviour or the effects of live loads such as wind, road traffic and passing trains.

Current values and trends on the long term are obtained with sampling frequency of 2 Hz. The sampling frequency adopted has been chosen from the outcome of the pilot project, it results enough to capture the dynamic responses of interest but without generating an exaggerated amount of data. Thus, effects of wind and traffic on the bridge, which affect the bearing movements, are properly described.

First, data can be correlated to the temperature to cross check whether bearing movements meet expectations and understand possible deviations from expected values. Comparison of movements at different locations, either at corresponding locations in the northern & southern section or at different cross sections, enables a check on overall consistency of bearings movements.

Finally, trends show whether the bearings experience smooth or sudden movements, which can provide further insight as to the status of sliding material and possible friction transferred to the substructure.

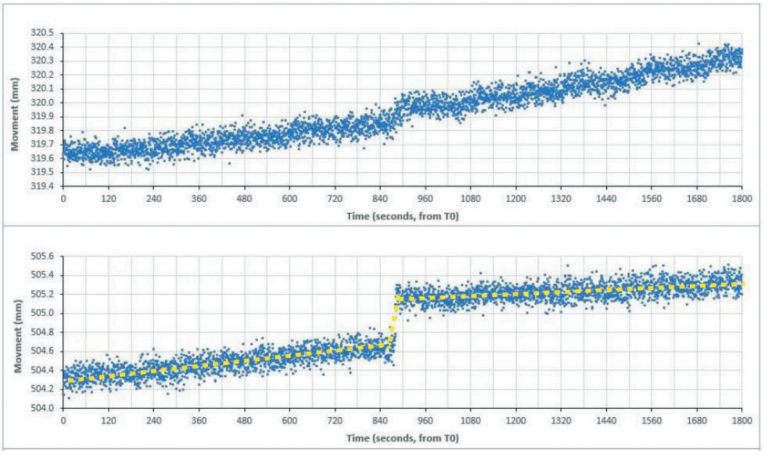

Figure 5. Example of data provided, movement vs time. For illustrative purpose only.

5 CONCLUSION

The SHM field is constantly developing thanks to active scientific research, and thanks to the development of new and upgrading technologies being developed to better support engineers and market needs. This project is a good example of how new technologies together with a well-thought detailed design of the monitoring system, often bespoke for the specific application, offer added value to the bridge maintenance, operation and assessment processes.

Thermal response prediction of the MX3D bridge's operational dataset

T. Glashier & C. Buchanan
Department of Civil and Environmental Engineering, Imperial College London, London, UK

R. Kromanis
Department of Civil Engineering and Management, University of Twente, Enschede, The Netherlands

ABSTRACT: Environmental and operational variations (*eov*) remain a major obstacle for the successful transfer of structural health monitoring (*shm*) techniques from laboratory experiments, such as cracked beam experiments, to full-scale structures, such as long-span bridges. With evidence that timely interventions significantly increase the service-life and reduce the overall life-cycle cost of ageing infrastructure, carrying out *shm* in the presence of *eov*, such as temperature, is therefore of high priority within the bridge maintenance community. An iterative regression-based thermal response prediction (*irbtrp*) methodology is utilised within the temperature-based measurement interpretation (*tb-mi*) approach and is trained on the healthy condition of the bridge to predict its undamaged response to temperature fluctuations. The *tb-mi* approach and the irbtrp methodology are applied to the *mx3d* bridge in this study, demonstrating that their use enables earlier and more widespread damage detection amongst multiple sensor groups, compared to when no temperature effects are considered.

1 INTRODUCTION

Current infrastructure maintenance practices primarily involve routine visual inspection of structural surfaces (Aktan *et al.*, 1996), particularly for bridges where subjective assessments are often used to gauge the severity and extent of visible defects (Helmerich *et al.*, 2008), which results in data that tends to focus on individual structural components rather than offering a comprehensive view of the asset (Kong and Frangopol, 2003). In contrast, structural health monitoring (SHM) promotes condition-based maintenance, whereby interventions occur when specific real-time performance indicators surpass predefined thresholds (Brownjohn, 2007; Farrar and Worden, 2012). The field of SHM has garnered substantial momentum in recent decades, thanks to advancements in computing power, data handling capabilities, and storage, along with breakthroughs in deep learning research (Xu and Brownjohn, 2018; Ye, Tao and Yun, 2019; Zhao *et al.*, 2019; Azimi, Eslamlou and Pekcan, 2020), showcasing significant potential in supporting the maintenance of civil infrastructure.

SHM has proven its effectiveness in specific real-world infrastructure applications, such as conducting health assessments for bridges (De Roeck, 2003; Brownjohn *et al.*, 2015; Peiris, Sun and Harik, 2020; Turrisi, Zappa and Cigada, 2022) and damage detection using data-driven methodologies (Catbas, Gokce and Gul, 2012) as well as combinations with model-based techniques (Martín-Sanz *et al.*, 2020). Nonetheless, limitations remain that have affected its transition from controlled laboratory experiments to practical, real-world implementations (Brownjohn *et al.*, 2011; Masciotta *et al.*, 2016; Cawley, 2018). Figueiredo and Brownjohn (2022) have highlighted the primary challenges for SHM that include characterising the normal variations induced by environmental and operational variability (EOV) (Sohn,

DOI: 10.1201/9781003483755-299

2007) and shifting the focus towards real damage, away from cracked beam experiments. Overcoming these current limitations will help SHM research demonstrate successful infrastructure applications, and consequently positive return on investment (Figueiredo and Brownjohn, 2022).

This study focuses on minimising the influence that EOV has on the collected structural response of full-scale structures in operation. A temperature-based measurement interpretation (TB-MI) approach (Kromanis and Kripakaran, 2016; Glashier, Kromanis and Buchanan, 2023b) is adopted to analyse structural measurements following the removal of the thermal response. An iterative regression-based thermal response prediction (IRBTRP) methodology (Glashier, Kromanis and Buchanan, 2023a) learns and predicts the response of instrumented infrastructure to temperature variations and has been shown to be effective for a Laboratory Truss and the MX3D Bridge. In this study, the IRBTRP methodology is applied to the 2-year operational dataset of the MX3D Bridge (see Figure 1). This work evaluates the performance of the IRBTRP methodology to real-life structures and datasets.

Figure 1. The MX3D Bridge over the Oudezijds Achterburgwal canal in Amsterdam, the Netherlands, during the A) day and B) evening.

2 TEMPERATURE-BASED MEASUREMENT INTERPRETATION

The temperature-driven structural response is removed from the measured response prior to its interpretation within the TB-MI approach. This approach can be applied to infrastructure instrumented with sensors that measure its distributed temperature profile, using thermistors or thermocouples for example, and uses regression methodologies to characterise the thermal behaviour, such as an IRBTRP methodology that is outlined herein.

2.1 *Iterative regression based thermal response prediction methodology*

The structural response to static and dynamic loads has been shown to be masked by EOV, as well concealing damage-related features in the measured structural response. Damage detection techniques are hence less effective in the presence of EOV (Sohn, 2007; Figueiredo and Brownjohn, 2022). The IRBTRP methodology (Glashier, Kromanis and Buchanan, 2023a), described in Figure 2, was developed to accurately predict the normal response of a structure to temperature variations, to enable both a detailed understanding of its environmental response and a temperature-corrected and improved application of damage detection techniques. The healthy state of the structure is used as a reference period to understand its typical thermal response. This reference dataset is divided into training, validation, and testing periods. These segments are used for generating, selecting, and evaluating the regression model, respectively.

The initial stage of the methodology is data preparation (see Step 1 in Figure 2) to remove the influence of traffic loading and high-frequency noise in the input reference period signals. This is achieved, respectively, through a traffic load removal (TLR) algorithm (Glashier, Kromanis and Buchanan, 2023a), which uses load cell signals to detect the presence of traffic, and a moving average filter (MAF) to produce a dataset with only the distributed temperature and thermal response. The inputs to the model generation phase are therefore the distributed temperature and a single measured response signal (e.g., from a displacement gauge, inclinometer, or strain gauge).

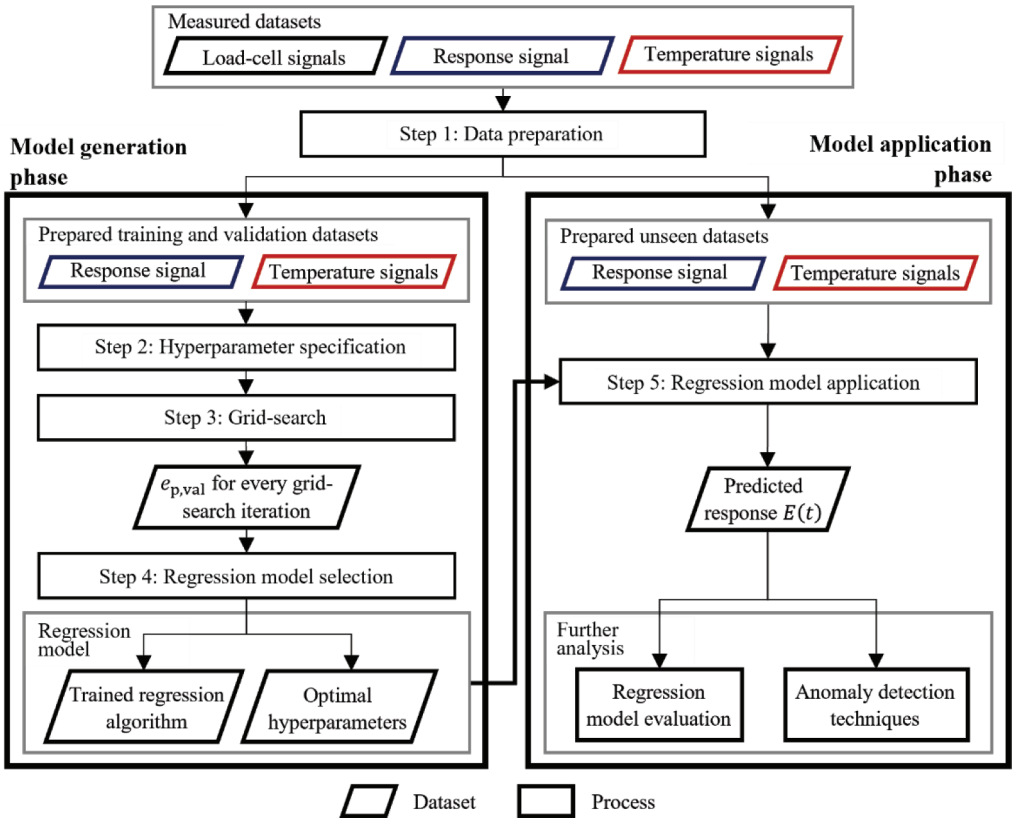

Figure 2. Flowchart of the IRBTRP methodology (Glashier, Kromanis and Buchanan, 2023a).

The IRBTRP methodology employs customisable parameters relating to measurement pre-processing, regression algorithms and post-processing, named hyperparameters, and regression algorithms to adapt and optimise itself to its application. A hyperparameter specification step identifies values that can simultaneously reduce computation time and minimize prediction errors. A grid-search is employed to optimise both hyperparameters and regression algorithms, with the regression model providing the lowest validation dataset error being selected. The models are then evaluated based on their performance on the unseen testing period, avoiding a biased assessment. Their prediction error is computed using the root mean squared error parameter e_p, defined as

$$e_p = \frac{\sqrt{\frac{1}{N}\sum_{i=1}^{N} E(t_i)^2}}{r_{\text{ref}}} \tag{1}$$

for N recorded data points, where $E(t_i)$ is the error signal (i.e., the difference between measured and subtracted signals) and r_{ref} is the signal's reference period range. The prediction error for the validation and testing subperiods are symbolised as $e_{\text{p,val}}$ and $e_{\text{p,test}}$.

3 THE MX3D BRIDGE

The MX3D Bridge is the world's first structure produced using metal additive manufacturing (AM), and is show in its Amsterdam location in Figure 1. The bridge's printed

components (i.e., the hollow handrails, substructure, and decorative end swirls) were separately printed by MX3D, and then hand welded along with the conventionally formed deck plate and two rectangular hollow section end beams. The bridge is fitted with a comprehensive sensor network that includes accelerometers (denoted by the notation A*XX*, where *XX* is the sensor number), displacement gauges (D*XX*), inclinometers (I*XX*), load cells (LC*XX*}), strain gauges (SG*XX*) and thermistors (T*XX*). The locations of the sensors used in this study are displayed in Figure 3. Additional information on the MX3D Bridge manufacturing process and dimensions can be found in (Glashier, Kromanis and Buchanan, 2023b).

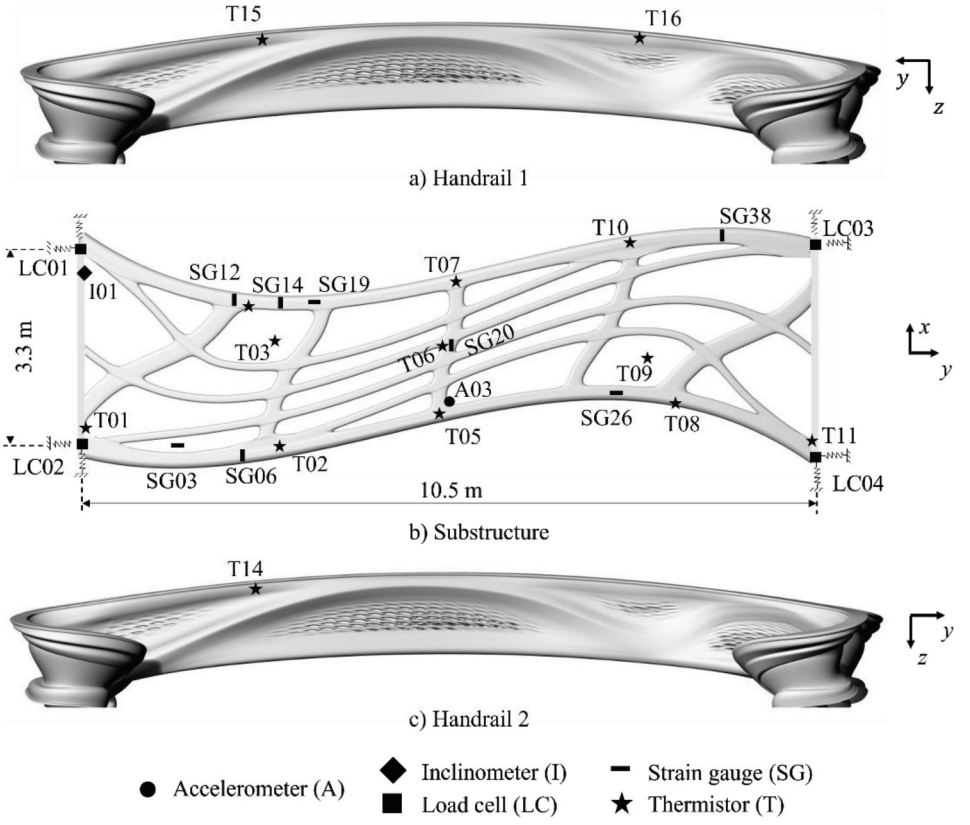

Figure 3. Locations of the MX3D Bridge sensors on the a) Handrail 1, b) Substructure, and c) Handrail 2 used in this study.

Following the bridge's installation in central Amsterdam in July 2021, a 2-year operational dataset was collected for research purposes into its long-term behaviour. Temperature and pedestrian loadings are the dominant sources of environmental and operational variations, respectively, for the MX3D Bridge. Typical measured operational responses from a load cell, strain gauge and a thermistor are provided in Figure 4 for a 48-hour period. The baseline of the LC03 load cell and SG10 strain measurements show a daily variation that correlates with thermistor T01's output. The change in the baseline of the load signal is caused by variations in the structure's self-weight distribution over its supports.

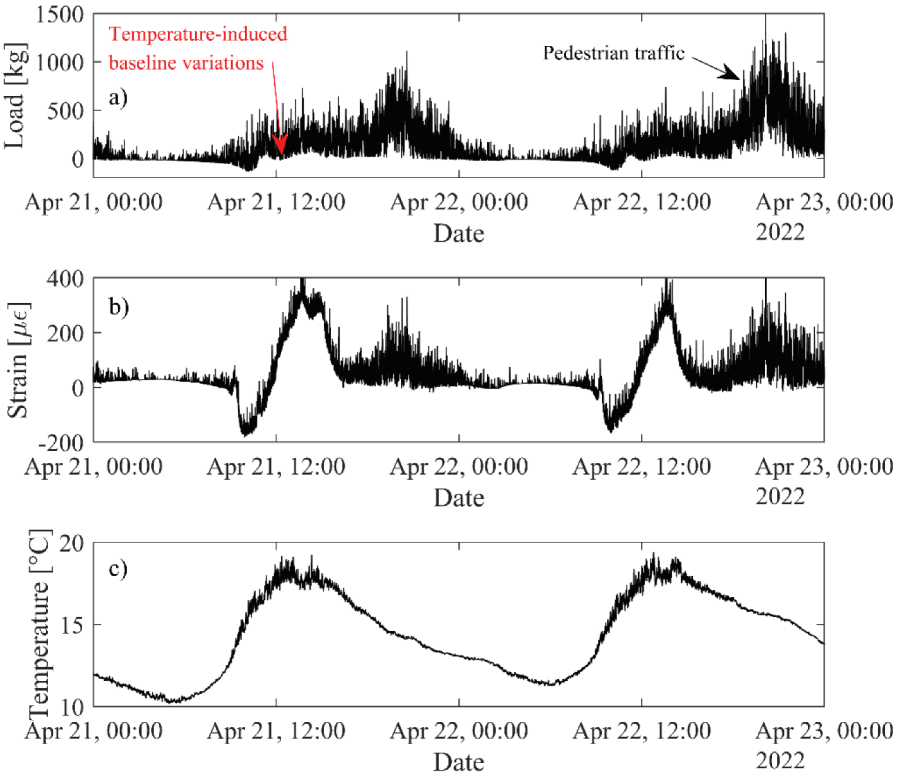

Figure 4. Typical measured response for a) LC03 load cell, b) SG10 strain gauge, and c) T01 thermistor over two days of the operational dataset.

4 APPLICATION TO THE MX3D BRIDGE

The TB-MI approach is applied to the MX3D Bridge operational dataset with the IRBTRP methodology being used to provide thermal response predictions. The first step of the methodology involves data preparation of the input signals that include the distributed thermistor and structural response signals. Traffic loading and measurement noise are removed through the application of the TLR algorithm (Glashier, Kromanis and Buchanan, 2023a) and a moving average filter, providing structural response signals free from operational variations. The specification of hyperparameters for the grid-search, and the consequent performance of the thermal response predictions are described in Sections 0 and 4.2, respectively.

4.1 *Hyperparameter specification*

The specification process determines the regions for each hyperparameter that can minimise both computation time and the prediction error. The selection process is carried out for all hyperparameters, but only illustrated using one pre-processing hyperparameter in this study. Figure 5 demonstrates the effect that the sampling rate of the training data has on accuracy and the computation time. Prediction errors are seen to rise with increasing sampling periods but are steady for < 10 minutes, whilst for sampling periods < 10 s, computing times grow rapidly. The values selected for computation within the grid-search are therefore 10 s, 1, and 10 minutes.

The outcome of the hyperparameter specification stage is summarised in Table 1, listing all the hyperparameter values along with the three regression algorithms investigated in this study: multiple linear regression (MLR) and robust regression (RR) as well as artificial neural

networks (ANN). The total number of hyperparameter combinations that are to be computed in the grid-search are 43,200 for MLR and RR, and 432,000 for ANN.

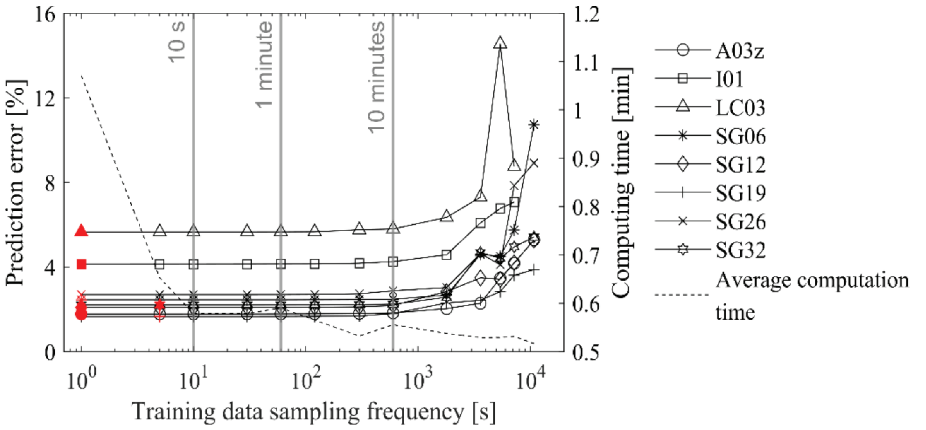

Figure 5. The effect of the training data sampling rate on prediction error and computing time (minima in red, and selected hyperparameters shown as solid grey lines).

Table 1. Summary of the IRBTRP methodology hyperparameters selected for modelling the MX3D Bridge.

Step	Hyperparameter	Grid-search value
Pre-processing	Inter-quartile range analysis (IQRA) window size	0 and 10 minutes
	Moving average filter (MAF) window size	0 and 2 minutes
	Training data sampling period	10 seconds, 1 and 10 minutes
	Number of principal components	5, 10, and 14
	Thermal inertia n°1 (TI_1)	0 to 11.5 hours in 30-minute steps for $TI_1 < TI_2$
	Thermal inertia n°2 (TI_2)	1 to 12 hours in 1-hour steps
Regression	N° ANN hidden layers (HL)	1 to 4
	N° ANN neurons per layer	1 5, 10 and 15 (HL = 1); 5, 10 and 15 (HL = 2); 10 and 15(HL = 3); and 15 (HL = 4)
	N° of networks in ANN ensemble	3
	N° cross-validation groups	20
Post-processing	IQRA window size	0 and 2 minutes
	MAF window size	0 and 2 minutes

4.2 *Thermal response predictions*

For the response signals measured on the MX3D Bridge by the sensors displayed in Figure 3, all hyperparameter and regression algorithms were computed in a grid search. The combination yielding the smallest validation error was selected as optimal and used to predict the structure's response for the testing period. The validation and testing prediction errors of the optimal regression models are reported in Table 2. The validation and testing errors of the optimal MX3D Bridge thermal response predictions. for a subset of the bridge's sensors. The measured and predicted signal of SG03 and SG20 strain gauges are displayed in Figure 6.

The overall thermal responses are accurately predicted for the training and the unseen testing sets, with average $e_{p,val}$ and $e_{p,test}$ of 2.0% and 2.1%. The predicted signals are compared to the measured signals (post data preparation), demonstrating a very good modelling of the structure's baseline response induced by temperature fluctuations (see Figure 6). Minimal increases between the validation and testing errors are observed, which confirms the accuracy of the regression models provided by the IRBTRP methodology. Previous work by the authors (Glashier, Kromanis and Buchanan, 2023a) had found significant increases in the testing errors however they were linked to non-negligible differences in the environmental conditions between the training and testing datasets.

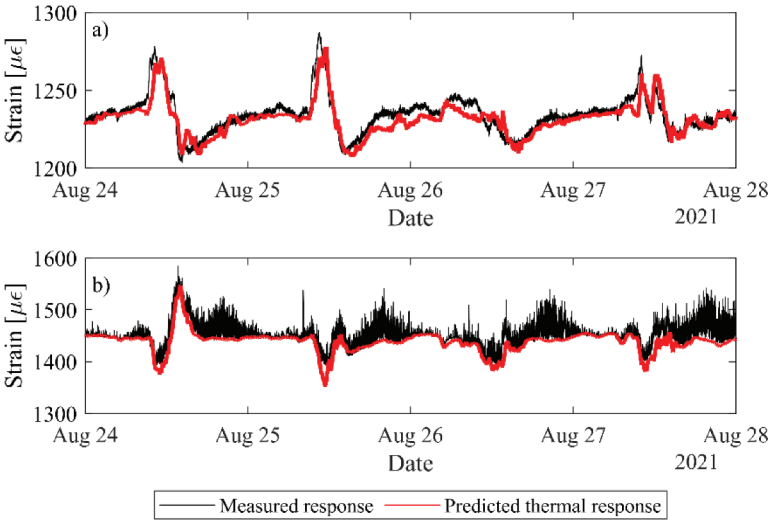

Figure 6. The measured response, and predicted thermal response of a) SG03 and b) SG20 strain gauges.

Table 2. The validation and testing errors of the optimal MX3D Bridge thermal response predictions.

	Optimal regression models			
Sensor	Regression algorithm	$e_{p,val}$	$e_{p,test}$	r_{ref}
A03z	MLR	3.0%	3.0%	0.029 m/s^2
I01	ANN	4.9%	4.9%	0.94 °
LC03	ANN	5.0%	4.4%	3.98 kN
SG03	ANN	1.6%	1.9%	225 $\mu \in$
SG06	ANN	0.9%	1.1%	490 $\mu \in$
SG12	ANN	0.6%	0.7%	370$\mu \in$
SG14	ANN	1.0%	2.3%	196 $\mu \in$
SG19	ANN	0.8%	0.8%	213$\mu \in$
SG20	ANN	0.6%	0.5%	551 $\mu \in$
SG26	ANN	1.3%	1.3%	124 $\mu \in$
SG38	ANN	1.8%	1.8%	3528 $\mu \in$
Average	–	2.0%	2.1%	–

As the bridge's structural response is driven by traffic as well as temperature (see Figure 4) and the regression models account for temperature variations, prediction errors cannot be evaluated for times of applied loading (e.g., pedestrians). For short-span structures, the response to applied loading makes up a larger part of the measured signal, whereas the response of long-span bridges is largely temperature-induced, encouraging the availability of

thermal response predictions at all times. For temperature-based measurement interpretation, it is recommended to minimise the variations in the operational conditions (e.g., minimally loaded or even unloaded).

Other than for A03*z,* artificial neural networks yielded the most accurate regression models for all sensors investigated in this work, indicating that simple regression techniques such as MLR and RR are not optimal for capturing the nonlinear relationship between a structure's distributed temperature and its response.

5 CONCLUSIONS

Temperature-based approaches for measurement interpretation of SHM datasets rely on accurate thermal response predictions to remove the effect of temperature variations from the measured structural response. So far, predictions for thermal response have been predominantly obtained for laboratory-set-ups, whilst the challenge remains to demonstrate that SHM techniques can be successfully applied to full-scale structures that are subject to environmental and operational variability (EOV).

Data preparation was applied to ready a 2-year operational dataset collected from the MX3D Bridge, including a step to detect the applied loading from pedestrians on the bridge, hence removing operational variations. The prepared dataset was then used in an iterative regression based thermal response prediction (IRBTRP) methodology to learn and predict the bridge's response to environmental changes in temperature. The structure's surface temperature measured by 14 thermistors suffices to provide accurate thermal response predictions of the MX3D Bridge for testing periods unseen during training, with average $e_{p,test}$ of 2.1%.

Further work will involve the application of anomaly detection techniques to the prediction error signals for the detection of structural change that may have occurred later on the bridge's structural dataset.

Identification of main cable shape of suspension bridge based on 3D point cloud

R. Pan, D. Dan & Y. Li
Tongji University, Shanghai, China

ABSTRACT: The main cable of the suspension bridge is the main and most important component of the structure. The main cable shape is mainly determined by the horizontal tension of the main cable, the suspension cable force, and its own load concentration. In the completed bridge state, the main cable shape can reflect the cable force of the suspension cable and also reflect its own internal force distribution. Therefore, the true shape of the main cable of the completed bridge is the key to study the stress state of the cable structure of the suspension bridge, which is of great significance to the long-term monitoring of the suspension bridge. In this paper, a method to identify the main cable shape of the suspension bridge based on a 3D point cloud is proposed, and the method is verified against the background of Honghe Bridge in Yunnan Province. The raw point cloud data of main cable was obtained through LiDAR. After noise reduction and registration of the raw data, the main cable point cloud is obtained through clustering algorithm. Then, using the circular tube axis algorithm, the measured central axis of the main cable is obtained. The construction phase of Suspension bridge is analyzed and the main cable model is obtained in the finite element software. Then, the finite element model is exported and registered with the measured point cloud to obtain the theoretical central axis. Finally, the theoretical central axis is compared with the measured central axis to obtain the main cable shape deviation result.

1 INTRODUCTION

The cable system of a suspension bridge is the key to bearing the full bridge load. For suspension bridges, precise construction quality control is particularly important. The identification and control of the main cable shape is a major project in suspension bridge construction monitoring. However, the identification of the main cable line of suspension bridges faces the following challenges: traditional methods for identifying the main cable line mainly rely on traditional measurement tools such as total stations and levels to measure some characteristic points of the main cable discretely. The results are not rigorous enough, and there are shortcomings such as low efficiency, large workload, and low data reliability. On the other hand, the geometric state of the suspension bridge structural system is more sensitive to temperature changes, and if the measurement time is too long, accurate main cable shape cannot be obtained. Therefore, an accurate and fast method for identifying the main cable shape of suspension bridges is needed.

3D laser scanning technology can accurately and efficiently measure the geometric information of objects (Tang, et al., 2010). The main principle of 3D laser scanning technology is to obtain the distance between the scanner and the measured point through a ranging system, and then obtain the horizontal and vertical angles from the scanner to the measured point through an angle measurement system to calculate the 3D coordinates of the measured point. After continuously scanning the measured object at a certain sample density, corresponding point cloud data can be obtained, thereby achieving a high-quality and comprehensive measurement of the object. This is something that conventional measuring instruments and methods cannot achieve.

DOI: 10.1201/9781003483755-300

Considering the shortcomings of traditional cable line recognition methods and the advantages of 3D laser scanning, this paper proposes a suspension bridge cable line recognition method based on 3D scanning. The point cloud data of the suspension bridge was obtained through LiDAR. The main cable point cloud was obtained through clustering algorithm. Obtain the measurement center axis of the main cable through the circular tube axis algorithm. Furthermore, the theoretical central axis is compared with the measured central axis to obtain the deviation results of the main cable line identification. The results indicate that the accuracy of the main cable line shape identified by this method is high, which has certain reference significance for practical engineering.

2 A METHOD FOR IDENTIFYING THE MAIN CABLE LINE SHAPE OF SUSPENSION BRIDGES USING 3D SCANNING TECHNOLOGY

The emergence of 3D scanning technology provides a new way to measure the continuous geometric shape of structures in space. This technology can comprehensively measure structures under complex environmental conditions and provide stronger support for the acquisition of position and appearance information of the tested object based on its large amount of data acquisition. At the same time, this technology greatly improves measurement efficiency and quality, and has good application prospects in structural detection. This section provides an introduction to the application methods of 3D scanning technology in identifying the main cable line shape of suspension bridges.

2.1 *3D scanning technology*

3D scanning technology transforms the traditional single point acquisition method into a new automatic and continuous way to obtain a large amount of point cloud data, which has the advantages of speed, high accuracy, and comprehensiveness, providing a new approach for measuring structures. Therefore, 3D scanning technology establishes a high-precision 3D point cloud model by obtaining actual spatial position information data such as points, lines, surfaces, volumes, and spaces of the target structure.

In the field of structural deformation monitoring, Stuart Gordon et al. (2001) used a 3D scanner to perform multi-site scanning of aged wooden bridge piers and analyze the coordinate differences between each station to complete deformation monitoring of the bridge piers in 2001. H S. Park et al. (2007) conducted deformation tests on simply supported steel beams using 3D scanning technology. Armasto J et al. (2010) applied 3D scanning technology to monitor the deformation of ancient stone arch bridges. Shi et al. (2014) attempted to apply 3D scanning technology to the monitoring of bridge pier shield excavation and proposed a 3D holographic modeling method based on triangular grid point cloud encapsulation. Matsumoto et al. (2018) proposed a spatial measurement method based on 3D ground laser scanning to capture the overall deformation of bridges. Through 3D scanning technology, the deformation of the pylon of the Twantay Bridge in Myanmar caused by anchor sliding was monitored. Yoon et al. (2018) proposed a method that minimizes the mismatch between shear grooves and shear connectors on bridge decks through 3D laser scanning and signal processing technology, and automatically identifies the optimal installation position of precast bridge decks on precast beams. Kwiatkowski et al. (2020) used FARO Focus 3D and Trimble TX8 scanners to scan and measure the main beams and cables of conveyor belt bridges, and the results showed that this method can be applied to deformation monitoring of bridge structures. Zhou et al. (2021) used 3D scanning technology to scan the main cables of suspension bridges and developed a method for inferring the force of suspension bridge suspension rods through the relationship between adjacent intersection points.

2.2 *Point cloud data preprocessing*

A point cloud is a collection of points with coordinates, vectors, and color information arranged in actual spatial positions, expressed in billions. The distance between points in

the point cloud obtained by a 3D scanner is very small, and various methods can be used to form patches and package them into a 3D model. When using a scanner to obtain point cloud data, the surrounding environment and the target structure itself may obstruct some components of the structure. This requires the use of multi-site scanning to collect multi-site clouds and obtain complete information of the target. Due to the need to move the scanner for multi-site scanning, the coordinate origin changes, resulting in the obtained point cloud data not being in the same coordinate system. This requires in-house personnel to register multi-site data. In addition, the point cloud data obtained by scanning generally includes some information about the surrounding environment. In order to present a better point cloud model and reduce the amount of data, data deletion and reduction are required. The point cloud model processed above still has a large number of noise points, which cannot meet the requirements of later analysis. Therefore, point cloud denoising is still needed (Tian F, et al., 2019).

The so-called "noise reduction" refers to the influence of on-site environmental factors such as human and machine vibration, which causes some noise points unrelated to the measured object to appear in the collected point cloud data. At this time, some filtering algorithms are used to filter out the point cloud data of occluded objects and some discrete points, retain the point cloud data of the target object, and use the "noise reduction" function to achieve structural noise reduction. Delete all point clouds unrelated to the curved tube structure (including all secondary components unrelated to the tube structure) in preparation for extracting the tube shape.

2.3 *Identification method for main cable line type*

The key to identifying the main cable line type is to extract the central axis of the main cable. This article proposes an algorithm for extracting the central axis of the main cable, and its main calculation process is as follows: the point cloud of the main cable is generally presented in spatial posture. To simplify the algorithm for extracting the central axis of the main cable and improve its computational efficiency, it can be segmented first, then the segmented main cable is projected onto a plane and linearly fitted. After segmentation, each microelement segment is fitted with a plane circle to obtain the plane coordinates of its center. Finally, the corresponding center space coordinates are found, and the spatial posture of each center is restored to complete the extraction of the axis. Set the collection of main cable point clouds as $P_{n\times 3} \in \{(x_i, y_i, z_i), i = 1, 2, 3, \cdots n\}$ and perform linear fitting on it, that is

$$\min \|\delta\|^2 = \sum [kx_i + b - y_i] \tag{1}$$

Calculate the slope of the linear fitting of the point cloud on the x-y plane according to formula (1), and then calculate the angle θ between the fitted line and the x-axis, where $\theta = \arctan k$. Rotate the point cloud clockwise around the z-axis with θ to obtain the point cloud in the x-z plane coordinate system. In computer graphics, the mathematical expression for this rotation process is to multiply $P_{n\times 3} \in \{(x_i, y_i, z_i), i = 1, 2, 3, \cdots n\}$ by equation A. The formula for A is as follows

$$A = \begin{bmatrix} \cos\theta & \sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{2}$$

Rotate and project each element segment onto the x-z plane using the above method, then fit the plane circle to obtain the center coordinates, and finally use the inverse matrix of formula (2) to restore the spatial orientation of the center. Finally, interpolate the centers of all microelement segments using a cubic spline curve to obtain the centerline of the main cable. All the above processes can be implemented by programming languages. The algorithm flow for identifying the main cable line type is shown in Figure 1.

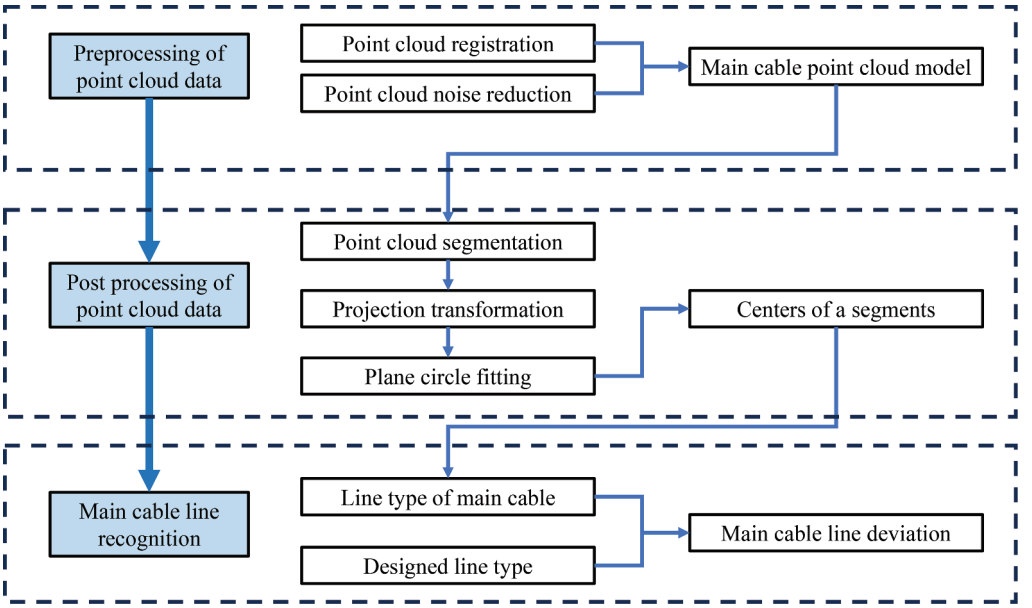

Figure 1. Algorithm flow for identifying the main cable line type.

3 CASE STUDY

3.1 *Case introduction*

This study uses the main cable point cloud data of the Honghe Bridge in Yunnan Province, China. The Honghe Bridge is a two-tower suspension bridge. The bridge is composed of cable towers, anchorages, suspension cables, suspension cables, and a deck system, with a total length of 1366 meters. The north approach bridge is 580 meters long, the south approach bridge is 80 meters long, and the main span is 700 meters long. The water surface is as high as 184 meters from the bridge deck, with the north main tower at a height of 181.29 meters and the south main tower at a height of 122.5 meters.

Figure 2. Honghe Bridge.

3.2 *Data acquisition*

This study used Livox Mid-70 LiDAR to collect point cloud data of the main cable of the bridge. Some parameters of the LiDAR are shown in the table below. LiDAR is shown in Figure 3.

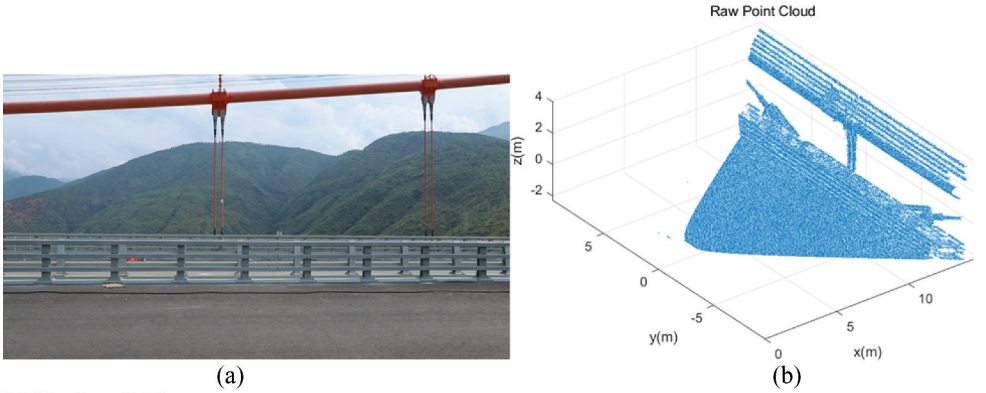

Table 1. LiDAR parameters.

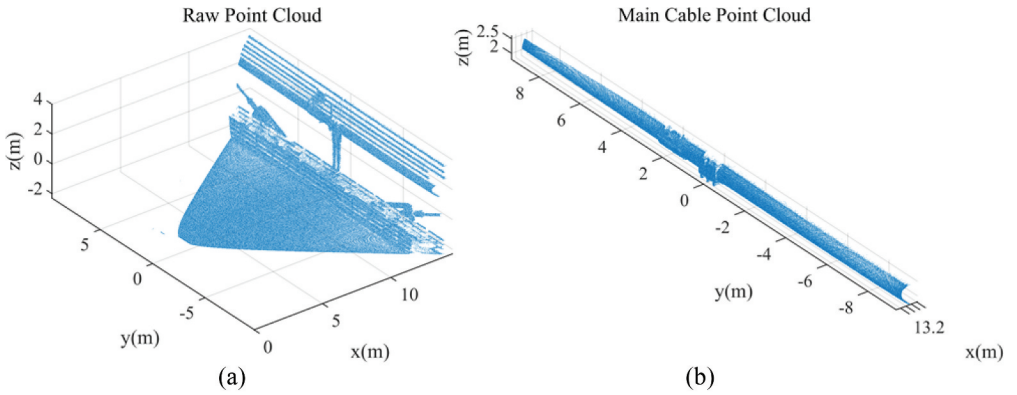
Type	Livox Mid70
Size	97×64×62.7 mm
Weight	580g
Laser wavelength	905nm
Range	260m
FOV	70.4°
Distance measurement error	≤2cm
Angle measurement error	<0.1°

Figure 3. Livox Mid-70.

The testing field and the obtained main cable point cloud data are shown in the following figure.

(a) Testing field
(b) Raw point cloud data of main cable

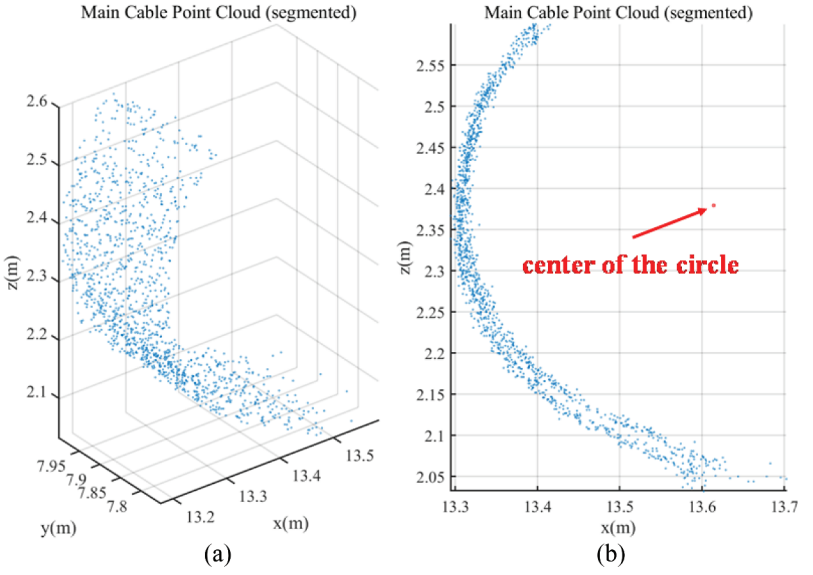
Figure 4. Experimental data and source.



3.3 *Identification result*

Firstly, preprocess the original point cloud data to remove noise and unnecessary point cloud data, while preserving the point cloud data of the target object as much as possible. The results of data preprocessing are shown in the following figure.

Segment the preprocessed point cloud data, in order to balance computational efficiency and accuracy, the length of the microsegment is taken as 0.25m. One of the segmented main cable point cloud is shown in Figure 6(a).



According to the method in section 2.3, rotate and project the point cloud of the segment, and find the center of the segment through the method of plane circle fitting. The result is shown in Figure 6(b).

After obtaining the centers of all segments, interpolate all control points through a cubic spline curve to obtain the centerline of the main cable. The results are shown in Figure 7.

(a) Raw cloud data
(b) Pre-processed point cloud data

Figure 5. Point cloud data of main cable.

(a) Segmented main cable point cloud
(b) Point cloud after projection transformation

Figure 6. Segmented main cable point cloud.

In Figure 7, the red curve represents the central axis of the main cable. From Figure 7, it can be seen that the central axis of the main cable identified by the above method is located at the center of the main cable point cloud. The accuracy of identification will be verified in the next section.

3.4 *Result verification*

In order to verify the accuracy of the main cable line identified by this method, the center axis identified is subtracted from the theoretical axis, and the vertical coordinate difference of each control point near the mid span is calculated to determine the recognition effect.

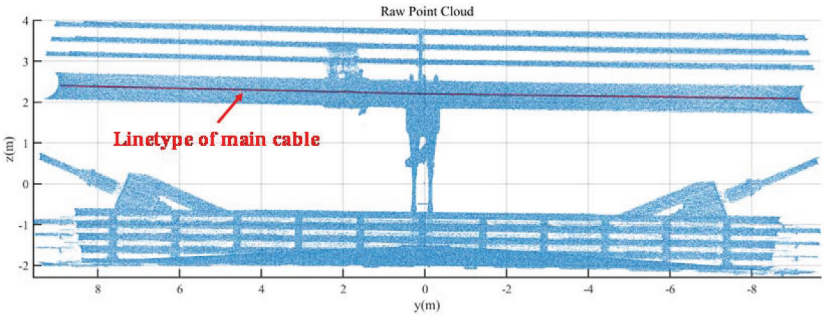


Figure 7. Line type of main cable.

Table 2. Result comparison.

Horizontal ordinate of control point (m)	Vertical coordinate of designed line type (m)	Vertical coordinate of identified line type (m)	D-value (m)
-8	2.093	2.096	-0.003
-6	2.120	2.123	-0.003
-4	2.144	2.147	-0.003
-2	2.169	2.172	-0.003
0	2.219	2.226	-0.007
2	2.234	2.259	-0.024
4	2.284	2.291	-0.006
6	2.328	2.333	-0.005
8	2.380	2.386	-0.006

From Table 2, it can be seen that the difference in vertical coordinates between the designed line type and the identified line type at the same control point is relatively small, indicating that the identified central axis of the main cable has high accuracy.

4 CONCLUSION

Research has shown that applying 3D scanning technology to the identification of the main cable line shape of suspension bridges is effective, and the following conclusions have been obtained.

(1) The three-dimensional LiDAR was used to quickly and comprehensively obtain rich data for the main cable of the suspension bridge. Combined with the influence of the micro segment point cloud projection circle, algorithm programming was used to automatically and efficiently extract the centerline shape of the structure. By comparing the reconstructed circular tube with the point cloud three-dimensional analysis given the centerline radius, the results show that the overall accuracy of the linear shape is high, the effect is stable, and it can meet the requirements of engineering measurement.
(2) The deviation between the detection method and the theoretical line shape of the suspension bridge was compared, and the results showed that the overall trend of the deviation between the two was basically consistent, and the deviation results of adjacent control points were close. The overall linear accuracy is high, which has certain significance for guiding the subsequent construction of the structure and ensuring on-site construction.

The proposal of this detection method has certain reference significance for the overall linear extraction of circular tube structures.

A framework for bridge condition assessment using graph neural network

G. Marasco, S. Sadeghi Eshkevari, I. Dabbaghchian & S.N. Pakzad
Lehigh University, Bethlehem, PA, USA

D. Sen
Southern Illinois University, Carbondale, IL, USA

ABSTRACT: A heuristic approach based on visual inspections cannot provide an adequate and unbiased evaluation of bridges' structural state. Fatigue assessment methods, based on the structural dynamic response, turn out to be crucial to consider the current structural conditions. Conventionally, strain data under traffic loading are collected for fatigue assessment. Although direct measurements of strain signals allow effective structural health monitoring strategies, they would induce a considerable rise in costs and errors, specifically where an extensive sensor network is needed. To pursue higher reliability of the monitoring system, a machine learning approach to convert acceleration to strain signals is proposed from a life cycle assessment perspective. Graph neural networks (GNNs), a class of machine learning models recently emerging in the civil engineering field, are employed to achieve this task. The GNN enables the encoding of structural information to describe the relationship between its nodes, representing the structural joints, and creating a geometry-based architecture in this application. The approach has been validated on a numerical simulation and promising results have been obtained.

1 INTRODUCTION

Monitoring the health of structures such as bridges, subjected to dynamic loads and material aging, is essential for ensuring their structural integrity (Gulgec 2017). Bridge management systems (BMSs) are currently used for the management of bridge information and maintenance cost mitigation. They rely on periodical visual inspections presenting significant limitations due to constraints in both time and space.

Over the years, Structural Health Monitoring (SHM) strategies have been proposing to overcome such limitations, offering timely assessments of structural condition (Chiaia 2020a) saving time and costs as well as enhancing safety significantly. When assessing structural condition, methods related to damage condition and evaluation of remaining useful life are employed.

Damage detection techniques often revolve around either vibration-based (Magalhães 2011, Cronin 2021) or static-based approaches (Nguyen 2016). Vibration-based methods can reveal damage through shifts in modal parameters. However, factors like data volume, monitoring time, and environmental conditions (Chiaia 2020b) can impede accurately estimating these parameters, hindering early damage detection. Consequently, these methods are better suited for updating structural models rather than promptly detecting early deterioration. Static-based methods more readily achieve the second level of the hierarchical structure in damage identification, specifically targeting damage localization (Farrar 2012, Marasco 2022a). However, their application tends to incur greater expenses overall.

DOI: 10.1201/9781003483755-301

The evaluation of the remaining useful life is traditionally performed by collecting strain or stress data; they allow to evaluate the fatigue behavior of the structure by constructing rainflow diagrams (Fatemi 1998). Obtaining strain responses poses challenges due to limited access to critical areas, high associated costs, and labor-intensive nature of the process (Kim 2007, Childers 2001).

While recent studies have shown highly promising results in utilizing deep learning techniques to convert acceleration signals into strain signals, further investigations are required to determine the most suitable architecture for tackling this intricate task effectively. In (Gulgec 2019b), a long short-term memory (LSTM) architecture demonstrates effective performance in the task at hand. However, there remains a need for further exploration regarding LSTM computational cost and suitability, as indicated in (Gulgec 2020). Moreover, while LSTM excels in sequence prediction tasks, it may not be the optimal choice for simulating nonlinear models. Recent advancements in machine learning have illustrated notable performance improvements for time-series data compared to LSTM-centric approaches. Integrating different architectures, as demonstrated in (Le-Xuang 2024) where 1D Convolutional Neural Networks (1DCNN), LSTM, and Residual Networks (ResNet) are combined, can enhance overall performance. Additionally, cutting-edge algorithms such as Transformers and GNNs emerge as promising solutions worth considering.

This study aims at providing a deep learning framework for strain estimation by exploiting graph networks, one of the most recent emerging architecture in the civil engineering field. Graph-based data structuring, originating from fields like biology, recommender systems, traffic prediction, and computer vision, holds significant promise when applied to structural analysis. By representing a structure as a graph, the model captures spatial properties and element connections, thereby improving the model's understanding of structural responses. Currently, studies in the civil engineering field utilizing graph architecture are centered on two tasks: classifying damage and predicting static structural responses. Following are some of the main contributions. Dan et al. (Dang 2022) introduced a graph convolutional framework that directly utilizes vibration data for damage classification. Node features incorporate both node coordinates and the time-evolving patterns of recorded accelerations. Kim and Song developed a damage identification approach (Kim 2023) exploiting the structural response during an earthquake event. Whalen and Mueller (Whalen 2022) introduced a graph-oriented method tailored for trusses. Their approach encodes the structural geometry, supports, and applied loads within a graph framework to forecast displacement field resulting from static loads. Similarly, Song et al. proposed the utilization of graph neural networks in a self-supervised learning setup for elastic structural analysis (Song 2022).

Starting from the encouraging outcomes of a previous study (Marasco 2023), the present research aims at bridging the literature gap in addressing dynamic problems and the associated challenges with GNNs. It investigates the performance of a graph convolution neural network (GCN) architecture converting acceleration signal to strain signal at each structural node, evaluating what is the impact of physics information within this architecture. The method has been validated using synthetic data, showing promising results.

2 GRAPH NEURAL NETWORKS

GNNs are recent deep learning architectures that enhance the functionality of conventional neural networks such as CNNs (Gulgec 2019a), Recurrent Neural Networks (RNNs) (Eshkevari 2021, Eshkevari 2022), and Multi-Layer Perceptron (MLP) (Marasco 2022b) enabling them to process non-Euclidean input. In the conventional notation, a graph is typically represented as $G = (V, E)$, where V stands for the set of nodes (vertices) and E denotes the set of edges. Within structural contexts, nodes represent structural joints, while edges stand for the connecting structural elements that link these joints (Scarselli 2008)Two key matrices define a graph: the feature matrix and the adjacency matrix. The first one, $X \in R^{N \times D}$, contains the attributes of the nodes. The second one, $A \in R^{N \times N}$, contains information about the node connection. Here, N is the number of nodes and D is the attributes dimension. In this study,

sensor locations serve as nodes of an undirect graph, and vibration data along with physics information are their multidimensional attributes. Due to its nature, the present study addresses a regression problem at the node level. Among the various types of GNNs, this study specifically concentrates on GCNs. This architecture aggregates node information from neighboring nodes using convolutional techniques leveraging the graph's structure. GCNs have demonstrated success across diverse tasks and possess a strong ability to learn representations of graphs (Zhang 2019).

The key difference between CNNs and GCNs lies in how they merge vibration signals from multiple sensors. When CNN's kernel combines signals, it doesn't retain information about which sensor each time series corresponds to. Conversely, after the GCN operation, a revised set of node features is generated, combining signals exclusively from directly linked nodes. Therefore, it becomes possible to discern the data from each sensor following a GCN layer. In contrast to CNNs which combine considering their organization, GCNs leverage real mechanical interactions. They are designed to consider that adjacent data might not have direct mechanical interactions.

The GCN layer usually calculates, X^{l+1}, the node representation at layer $(l+1)$ based on, X^l, the representation at level l, by Equation 1:

$$X^{l+1} = \hat{D}^{-1/2}\hat{A}\hat{D}^{-1/2}X^l W + b \tag{1}$$

where, $\hat{A} = A + I$ represents the adjacency matrix with self-loops, $\hat{D}$ stands for its degree matrix, I is the identity matrix, and W denotes a weight matrix. Notably, this study does not apply the graph filter using the degree matrix to normalize the input adjacency matrix.

3 CASE STUDY AND GCN IMPLEMENTATION

In evaluating the graph architecture for the fatigue assessment task, a case study involving a two-span beam subjected to traveling loads, simulating vehicle weights on a bridge using Finite Element Software SAP2000, has been employed. The beam has two spans, each spanning 7.3 meters and divided into 8 equal-length elements. Figure 1a illustrates the geometry with sensor locations marked by blue rectangles for capturing the structural response in terms of accelerations and strains. To closely resemble a bridge dataset, adjustments were made to the natural frequencies, damping, and repetition of moving loads for the vibration dataset. Specifically, the first three mode frequencies are set at 1.9, 3, and 7.5 Hz.

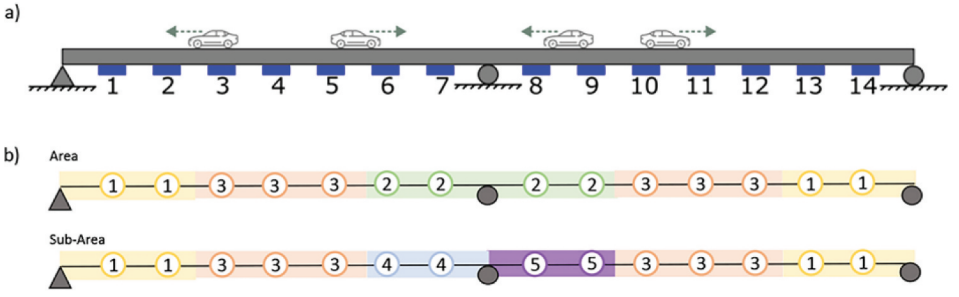

Figure 1. a) Two-span simulated beam b) Structural area and subarea.

Recordings of acceleration and strain time series were taken during a 4-minute period of vehicle movement, with data sampled at a frequency of 0.01 seconds. Subsequently, noise with an SNR of 15 was introduced. Normalization was performed by subtracting the average value and dividing by the standard deviation for each node individually. The signals were segmented into 4-second segments, each containing 400 samples with a step of 20 samples. Consequently, a dataset comprising 1181 signals, each containing 400 data points, was generated for each of the 14 nodes representing the graph's sensor locations.

The GCN architecture consists of several key components: GCN, normalization, dense, dropout, and dense layers. Initially, it employs convolutional and normalization layers to compress the input size from the attribute nodes' dimension (403 or more) down to 200. This reduction is aimed at capturing the most crucial features within the acceleration signal. Following this, the dimension remains fixed at 400 to make predictions for the strain signals. The dataset was split into training (70%), validation (20%), and testing (10%) subsets. Model training utilized the Adam optimizer with a learning rate set at 0.0001. However, the primary focus of this study was not on optimizing the model but rather on demonstrating the technique's applicability and highlighting the influence of physics-based information on performance. The network was implemented in Python, leveraging the Spektral library for coding, as detailed in (Grattarola 2021).

4 IMPACT OF PHYSICS INFORMATION

Evaluating the Graph Neural Network architecture's capacity to harness physics-based information involved investigating different approaches to incorporate this crucial data, acknowledging its fundamental importance in the process. To achieve this goal, both the feature and adjacency matrices have been used. The Time–Response Assurance Criterion (TRAC) has served as a metric to assess and compare the models' capability in accurately predicting the strain signals from the acceleration ones. Equation 2 shows its formulation, where X_t and $\overline{X_t}$ are the measured strain signal and the predicted strain signal, respectively.

$$TRAC = \frac{\left[X_t^T \bar{X}_t^T\right]^2}{\left[X_t^T X_t^T\right]\left[\bar{X}_t^T \bar{X}_t^T\right]} \tag{2}$$

Starting from an adjacency matrix composed of elements A_{ij} that are set to 1 if nodes i and j ae connected, including cases where i equals j, and are 0 otherwise, this study investigated how the results are influenced by the introduction of physics information into both the feature matrix and the adjacency matrix.

4.1 *Feature matrix*

As mentioned in Section *Graph Neural Networks*, the attributes of the nodes are represented by the feature matrix. In the first scenario S_1, apart from the raw signals, node coordinates and the normalized values of the first mode shape are also incorporated in the feature matrix by means of concatenation for each node. In the second scenario S_2, additional information specifying the structural area of each node is included. This was achieved by appending a vector that encodes this area information to each row of the feature matrix, essentially expanding the attribute vector of every node. This vector comprises ten repetitions of the index related to the structural area, concatenated with ten repetitions of the index linked to

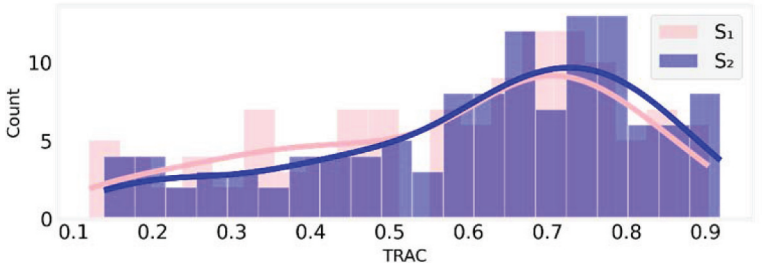

Figure 2. TRAC distribution for test dataset from case S_1 and S_2.

the sub-area. Figure 1b shows the splitting of the structure into distinct areas and subareas, each labeled with their respective associated indexes. Incorporating the structural area to which each node belongs provided a method to incorporate information regarding the influence of supports on the recorded signals.

Figure 2 illustrates the distributions of TRAC within the test datasets for scenarios S_1 and S_2. Table 1 summarizes the main statistical parameters (P) of such distributions. As can be observed, introducing additional physics-related information has yielded a positive effect on the overall performance. The mean, the mode, the minimum, and the maximum value of the TRAC distribution increase, as shown in the last column of Table 1.

Table 1. Statistical parameters for TRAC distributions for S_1 and S_2 scenarios.

Parameter (P)	S_1	S_2	$\Delta PS_2,S_1/PS_1$
Mean	0.58	0.62	6.9%
Mode	0.71	0.73	2.8%
Min	0.11	0.14	27.3%
Max	0.90	0.92	2.2%
Range	0.79	0.78	-1.3%
Skewness	-0.52	-0.71	36.5%
Kurtosis	-0.80	-0.41	49.5%

4.2 *Adjacency matrix*

Each structural system can be described using the eigenvalue decomposition approach by use of mode shapes and corresponding natural frequencies. Therefore, the structural properties can be represented by the mode shapes. The higher the difference in mode shape across nodes, the lower the spatial correlation (Kim 2023). The values of the elements, A_{ij}, within the modal-based weighted adjacency matrix, were calculated by:

$$A_{ij} = \sum_{i=1}^{n} T_i^2 e^{-\left|\bar{\phi}_{m,i} - \bar{\phi}_{m,j}\right|} \tag{3}$$

where T_i is the period of the m-th mode and $\bar{\phi}_{m,i}$ is the normalized mode shape of m-th mode at node i. The modes considered in this study are the first three. For research sake, such formulation has been used when node i and j are connected (S_3) and when node i and j are connected and equal (S_4). As shown in Table 2, S_4 has a narrower range then S_3 due to a greater minimum. Therefore, the use of this adjacency matrix allows to eliminate outliers.

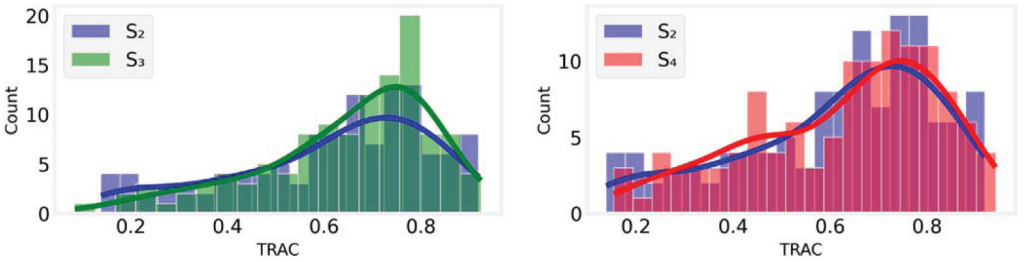

Figure 3. TRAC distribution for test dataset from case S_1 and S_2.

In S_3, an outlier is noticeable, yet the overall trend demonstrates improvement. In Figure 3, the green line portraying the S_3 distribution is situated below the blue line (representing S_2) on the left side and above it on the right side. The positive kurtosis value in S_3 indicates a distribution characterized by a distinct peak. S_4 shows an improvement in all the parameters

Table 2. Statistical parameters for TRAC distributions for S_3 and S_4 scenarios.

Parameter (P)	S_3	S_4	$\Delta PS_3,S_2/PS_2$	$\Delta PS_4,S_2/PS_2$
Mean	0.65	0.63	4.8%	1.6%
Mode	0.75	0.75	2.7%	2.7%
Min	0.08	0.15	-42.8%	7.1%
Max	0.92	0.94	0.0%	2.1%
Range	0.84	0.78	7.7%	0.0%
Skewness	-0.95	-0.61	33.8%	-14.0%
Kurtosis	0.34	-0.56	-183.0%	36.5%

with respect to S_2. The mean, mode, minimum, and maximum values of distribution S_4 are indeed greater of the ones of distribution S_2. The skewness shows a value slightly greater indicating a lower presence of outliers but the smaller value of kurtosis highlights a flatter shape of the distribution. In conclusion, both approaches showcase the positive influence of integrating physics-related structural mode information.

Alongside structural modes, another significant physical parameter affecting signal similarity between nodes is the distance separating them. As the distance increases, the weight assigned in the adjacency matrix decreases correspondingly. Figure 4 shows TRAC distributions associated with different values of n in Equation 4.

$$A_{ij} = \frac{\sum_{i=1}^{n} T_i^2 e^{-\left|\bar{\phi}_{m,i} - \bar{\phi}_{m,j}\right|}}{\left(d_{i,j}\right)^n} \tag{4}$$

The three curves corresponding to the three different values of n show a narrowing of the distribution with respect to S_2 and S_3 further deleting outliers. Equation 5 is proposed in the case in which the values on diagonal are not equal to zero.

$$A_{ij} = \sum_{i=1}^{n} T_i^2 e^{-\left|\bar{\phi}_{m,i} - \bar{\phi}_{m,j}\right|} \left(e^{-d_{i,j}}\right)^k \tag{5}$$

At varying of k, variations in the statistical parameters describing the distribution appear to show negligible impact.

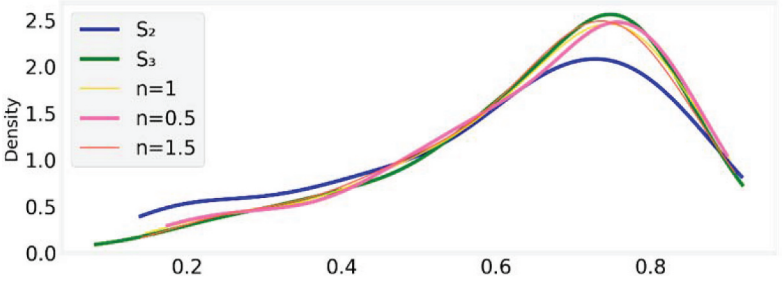

Figure 4. TRAC distribution for test dataset for different values of n.

5 CONCLUDING REMARKS

This study delved into utilizing graph convolutional neural networks to convert acceleration into strain signals for life-cycle assessment purposes. To validate the approach, a numerical case study was employed. The investigation aimed to discern the impact of integrating physics information within this framework. Despite the architecture's simplicity, with limited depth,

the accuracy of predictions was notably satisfactory and enhanced upon the inclusion of physics information. These promising outcomes serve as a foundation for future studies. Our forthcoming research endeavors involve developing more sophisticated methodologies and formulations to incorporate and leverage this invaluable information further.

An innovative approach for a sustainable monitoring of large infrastructures networks

M. Longo, S. Cirelli, D. La Mazza, I. Alovisi, P. Darò & G. Mancini
SACERTIS Ingegneria S.r.l., Roma, Italy

ABSTRACT: The progress made in the field of Structural Health Monitoring (SHM) has led monitoring systems to become an essential support tool for infrastructures management. The application of these systems on large infrastructures networks allows administrators to assess the remaining safety levels of managed bridges and, if necessary, helps in prioritizing and planning maintenance interventions. The need to implement a widespread monitoring system on a large scale clearly incurs costs that are often not compatible with the resources available. This problem gives rise to the need to optimize the use of monitoring systems. Sacertis Ingegneria, a leading company in the field of structural monitoring with over 150 continuously monitored structures, has responded to this need by offering various monitoring services, ranging in complexity. These services are evaluated and applied based on the characteristics and monitoring requirements of the structure under examination. This paper details distinct monitoring approaches proposed by Sacertis Ingegneria, differentiated by the adopted analysis method, which can be Model Driven, Data Driven, or a combination of both, and by the extension of the system (sensors layout) on the monitored elements (Local vs Global monitoring). Algorithms and Key Performance Indicators (KPIs) are so differentiated, as well as the scope of the analysis changes based on the chosen approach, ranging from an anomaly to a damage detection aim (Model Driven vs Data Driven approach). The choice of the approach depends on the structure itself, and the paper describes all the aspects to consider in this decision, including the health status of the structure, its strategic importance, its robustness, the consequences associated with potential closure or structural collapse, etc. Furthermore, the paper provides an illustrative example of the proposed monitoring approaches, comparing them and highlighting their advantages and limitations in a practical case study.

1 INTRODUCTION

Structural Health Monitoring (SHM) is a comprehensive solution designed to monitor various civil infrastructures, including bridges, tunnels, and monuments, assessing the impact of environmental factors, external actions, and damage processes on their structural response (Catbas 2009). The field of SHM has experienced significant advancements, establishing monitoring systems as indispensable tools for managing infrastructures effectively (Alovisi et al. 2022). Despite these developments, a crucial scientific gap persists - the optimization of structural monitoring to enable widespread implementation on a large scale without incurring prohibitively high costs. Overall, deterioration, material aging, widespread corrosion of steel reinforcing bars, corrosion of steel structures and components, increasing traffic volume and overloading, accidental damage combined with defects of design and construction, can cause a progressive loss of the infrastructures load carrying capacity (Fib Bulletin No. 109 2022). The application of these systems within extensive infrastructure networks plays a pivotal role in evaluating the ongoing safety levels of managed bridges. However, in order to have widespread monitoring systems on a large scale, it's necessary to invest costs that are often too high compared to the resources available, as highlighted in recent funded EU research projects

DOI: 10.1201/9781003483755-302

such as IM-SAFE (H2020 CSA IM-SAFE, 2020-2022), (Darò et al. 2022a), presenting Road Operators and Engineers with the challenging task of optimizing the use of monitoring systems across the network. In the following sections, a solution to this issue is proposed, also providing a practical application on a real case study.

2 METHODOLOGY

In response to this challenge, Sacertis Ingegneria, a leader company in structural monitoring, with over 150 structures (predominantly road bridges) under continuous monitoring, has developed a range of monitoring services with varying complexities (Darò et al. 2023). These services are meticulously assessed and applied, considering the monitoring requisites of the structure under scrutiny. The design of SHM systems, including the type and positioning of sensors, can be fine-tuned, ranging from a broad approach to a localized one. The diagnostic approach may vary not only between different structures but also within different spans of the same bridge. This variation is based on monitoring requirements or the state of conservation, blending more sophisticated Model-Driven (MD) analysis with Data-Driven (DD) approaches (Barthorpe 2011). Model-Driven diagnostic approaches are backed by detailed non-linear Finite Element Method (FEM) models updated based on the ongoing structural response, offering a profound understanding of the asset and supporting damage identification objectives. Conversely, Data-Driven approaches incorporate anomaly detection techniques to quickly pinpoint deviations from the standard behavior in structures, without providing correlations with safety levels. The instrumental equipment selected to reach the monitoring purpose are a series of sensors, like wired pre-assembled chains of MEMS accelerometers and inclinometers, temperature sensors and crackmeters, installed on the bridges key structural components to measure the identified Key Performance Indicators (Strauss et al. 2022a). An IoT smart gateway collects and pre-processes data in near-real time and sends them to the Cloud for further long-term analysis. These monitoring systems help optimizing the maintenance strategies, avoiding disasters, assessing risks according to the current safety methodologies and moving from a corrective to a preventive approach based on data analytics (Darò et al. 2022b), (Strauss et al. 2022b).

Ensuring the safety, performance, and long-term sustainability of assets relies significantly on the effective maintenance of infrastructure. This paper delves into the optimized approaches employed by Sacertis Ingegneria, integrating Model-Driven and Data-Driven solutions in practical applications across its network of continuously monitored bridges using MEMS sensors. It explores the extent of system deployment (sensor layout) on the monitored elements, differentiating between Local and Global monitoring strategies. Additionally, the paper discusses the selection of algorithms and KPIs tailor-fitted to the structural problem, offering a varied scope of analysis approaches, from anomaly detection to damage assessment (Data-Driven versus Model-Driven approach).

The selection of the most appropriate approach depends on various considerations, including the structural health, strategic significance, robustness, and potential consequences associated with shutdown or structural failure. This paper provides a comprehensive exploration of the factors influencing this decision-making process, highlighting the respective strengths and limitations of the diagnostic approaches through a practical case study analyzed using all the proposed approaches.

3 CASE STUDY

To highlight the potential of each specific approach, a structure has been identified as a case study (Cigada et al. 2021). It is a prestressed reinforced concrete slab bridge with two independent carriageways; each of them has a statically determined deck with a full-depth section with constant height in the longitudinal direction. For each of the two carriageways, the viaduct consists of n.9 spans, each with a total length of 35.0 meters, and a clear span between supports of 33.90 meters. This bridge, built in northern Italy in the early 1960s, is reflective of many Italian highway infrastructures in terms of its geometric and design features. It has been

chosen as a case study because it has several characteristics that make it suitable for the purpose: it is possible to identify one or more units (spans) that are repeated within the viaduct; the spans have the same features in terms of geometry, materials, reinforcements, loads, boundary conditions, etc..; further, in each carriageway, there is a span that, over the years, has experienced a performance loss due to the corrosion of prestressing reinforcements and has subsequently undergone structural strengthening interventions. In more detail, these two spans correspond to span number 4 in the south carriageway and span number 6 in the north carriageway. For the latter, the monitoring system was installed before the retrofitting intervention, and experimental data were collected in both the damaged and undamaged conditions (Cigada et al. 2021). A structural health monitoring system, consisting of 90 biaxial tiltmeters and 90 triaxial accelerometers, has been installed on the bottom surface of the decks. Specifically, each of the nine spans is equipped with a chain comprising 10 sensors (5 tiltmeters + 5 accelerometers). The sensors are interconnected using powerline communication technology. Two gateways, one per each carriageway, have been used to collect the data from the sensors and to send them to a cloud system.

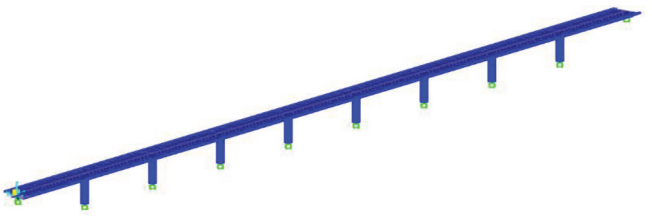

Figure 1. 3D view of the FEM model of a carriageway.

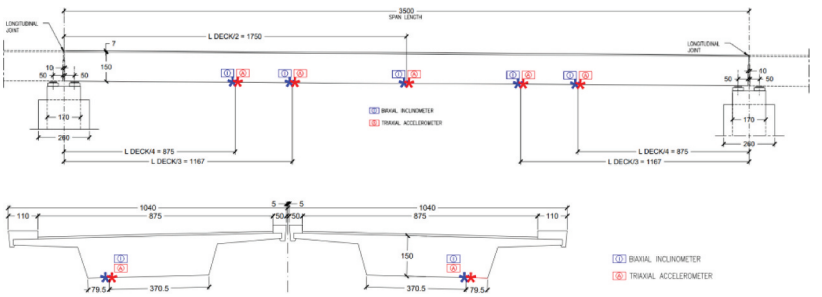

Figure 2. Longitudinal view of a span (top) and transversal cross section of both carriageways (bottom).

4 REAL APPLICATIONS OF DIFFERENT MONITORING APPROACHES

The case study presented in the previous section has been used as a mean to show with practical applications the possible implementation of the available approaches, such as Model Driven, Data Driven or a combination of both, with the aim to optimize the monitoring systems based on the diagnostics objective whilst highlighting the cost-benefits aspects of the selected monitoring strategy. In all approaches, the primary goal is to ensure the safety and durability of the infrastructure, based on the specific needs and the characteristics of the monitored structures with a decreasing Level of Approximations (LoA) of the analysis moving from a Model-Driven towards a Data-driven approach. In chapter 4.1 the attention is focused on the advantages of applying a Model-Driven damage detection diagnostics to the entire structure, with a detailed knowledge of the structural response based on the updated nonlinear FE model in face of a greater technical and economical effort. A mix of Model-Driven and Data-Driven analysis is also explored as a hypothetical solution, taking advantage of the bridge modularity. In chapter 4.2 the bridge is analyzed using the same dense sensing

monitoring system (same sensors number and positioning) however applying a Data-Driven approach only, assuming not to have the updated Digital Twin: in this second case the data analytics on similar spans supports an anomaly detection approach based on the comparisons of the clusters of homogeneous simply supported spans. Finally, in chapter 4.3 the analysis is restricted to a selection of sensors assuming a monitoring strategy that requires a minimal number of sensors installed on local positions, exploring the level of information available when choosing a Data-Driven approach with a light sensing scheme.

4.1 *Application 1: An optimized combination of model and data driven approach*

In the Model-Driven approach, the diagnostic service relies on a sophisticated numerical model using a Finite Element Model. This model is updated through calibrations, such as static and dynamic load tests, to accurately calibrate the initial condition of the monitored structure with the actual state. This allows for the establishment of a standard reference condition against which threshold levels can be assessed. These threshold levels are determined, based on predefined damage scenarios, on all the KPIs (static and dynamic) defined for the structure continuous monitoring. The instrumental equipment used in this approach consists of sensors of different type, well distributed along each key structural element, ensuring a comprehensive static and dynamic characterization and monitoring of the structure. This approach is particularly suitable for critical or strategic structures and requires a detailed numerical model that corresponds to the digital twin of the real structure. Referring to the highway viaduct outlined in paragraph 0, an illustration of the advantages of a Model-Driven approach can be observed by examining the monitoring data from span number 6 in the north carriageway. Figure 3 shows the results obtained from the static load test conducted on the span in 2019.

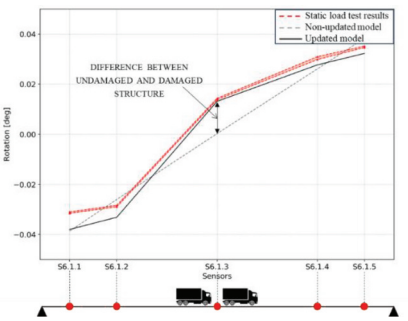

Figure 3. Static load test results on span number 6 of the north carriageway. Comparison between experimental data (red curves) and FEM results with both non-updated (grey curve) and updated (black curve) model.

The analysis of its deformation under a known load clearly indicates that the span exhibited significantly higher deformability than expected. The updating of the model, based on experimental data collected during tests, revealed the existence of damages that compromised the safety levels of the structure, necessitating a strengthening intervention (Cigada et al. 2021).

In some cases, the Model-Driven approach may also be used in conjunction with the Data-Driven approach, particularly when identifiable modularity exists in the structural static scheme. For instance, in the case of a multi-span bridge where spans share similarities in geometry, reinforcements, etc., a Model-Driven approach can be applied to the most critical span or to a typical span, and its threshold values, assessed on selected parameters, can then be transferred to all spans with similar characteristics.

In the context of the paper case study, an example of a monitoring system that combines Model-Driven (MD) and Data-Driven (DD) services can be illustrated. Let's assume two identical spans of the viaduct, theoretically indistinguishable, are monitored: one using the MD approach and the other using the DD approach. For example, consider spans number 6 on

both the north and south carriageways (i.e., spans with the same geometry, bearings condition, and location along the deck). In this example, span 6 of the south carriageway was modeled, and both static and dynamic load tests were conducted. Based on the results, an updated numerical model was obtained. Various damage scenarios were simulated on the updated FEM model, evaluating sensitive KPIs and establishing threshold levels corresponding to increasing degrees of damage (Warning and Alarm levels). These thresholds were then applied to the same KPIs calculated on the analogous DD span (span number 6 of the north carriageway).

In Figure 4 an application of this approach is illustrated: the selected KPI is the natural flexural frequency of the two spans. The south MD span (green curve) exhibits frequency values around 2.7Hz, with modeled warning and alarm thresholds represented by yellow and orange horizontal lines. The initial data collected in 2019 for this KPI on the south DD span (red curve) were below the warning level, suggesting the presence of potential damage. This would prompt a more in-depth analysis of this span, possibly upgrading the monitoring service to an MD one.

Notice, instead, how values collected after the retrofitting intervention on the span lie above both alarm and threshold levels, even though the frequencies consistently indicate its reduced stiffness compared to the MD span.

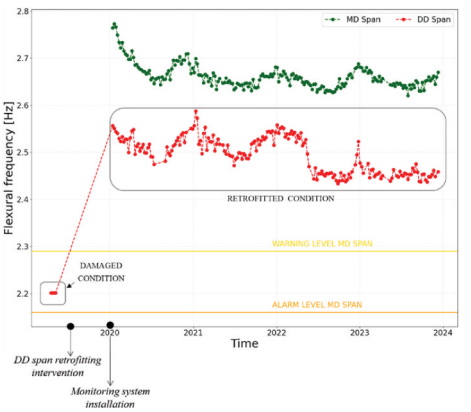

Figure 4. Example of combination of MD and DD services in the paper's case study. Evolution in time of the natural flexural frequencies of span number 6 on both the north (DD) and the south (MD) carriageways.

4.2 *Application 2: Data driven SHM*

A Data-Driven SHM solution is suitable for situations where comprehensive structural diagnostics may not be necessary or practical. It is often used for cases with lower criticality, non-strategic structures, or limited levels of degradation. The Data-Driven approach does not rely on the typical numerical structural modeling used in the Model-Driven approach; instead, it employs techniques for anomaly detection, such as machine learning, artificial intelligence, or statistical methods, to highlight any unfavorable trends in control parameters: the goal is to identify deviations from the standard behavior of the structure. Several Data-Driven techniques applied to the SHM field can be found in literature, such as those proposed by (H. Tran-Ngoc et al. 2019) or (Hung V. Dang et al. 2020 & Thang Le-Xuan et al. 2023).

The accuracy and robustness of the thresholds improve with the accumulation of a comprehensive history of recordings. Defining thresholds requires a history of data collected during the regular operation of the structure to capture seasonal variations and external influences. Any exceedance of thresholds requires on-site inspections to confirm the nature of the detected event. Thresholds defined with the Data-Driven approach can indicate an alert condition, signaling the need to monitor the evolution of the phenomenon without necessarily compromising the safety of the structure.

Typically, this solution involves an initial observation period (training period) covering the first months acquired by the structural health monitoring (SHM) system. This reference

period is crucial for establishing the standard behavior of all key performance indicators (KPIs) designated for monitoring. It is used to train data-based algorithms and consequently set thresholds capable of detecting anomalies. When opting for a Data-Driven solution, it is advisable to design a thorough sensor layout, encompassing various sensor types and locations. This facilitates an easy transition to a Model-Driven solution if anomalies in the structure intensify. A comprehensive sensor layout allows for a complete characterization of the monitoring object. Utilizing a well-designed network of accelerometers, operational modal analysis (OMA) algorithms can be applied to extract modal parameters such as frequency, damping, and mode shape. Vibrational analysis can also be conducted to study the vibrational behavior of each structural element, identifying both short and long-term anomalies through their vibrations under traffic. In static characterization, a similar depth of information can be achieved by correctly installing sensors like clinometers and crackmeters distributed on each span or near known defects (e.g., cracks).

Additional advantages of a Data-Driven solution emerge when modular elements are identifiable within the monitored structure. Comparative analyses can reveal anomalies when theoretically identical elements exhibit different responses. The paper proposed case study illustrates this point. The two carriageways are identical from a design standpoint, and repetitive modules can be identified between the 9 spans based on their bearings and geometry.

Continuous monitoring revealed an increase in vibrational levels in some spans in the longitudinal direction. Comparative analyses indicated that this increase in Y-axis (longitudinal) vibrations was concentrated in spans over the expansion joint. Initially attributed to the "normal" movement of spans due to thermal variations, this aspect became clearer a year later when a complete seasonal cycle was closed, highlighting variations in the vibrational indicator due to thermal factors. Figure 5 illustrates the behavior of the chosen KPI monitoring the vibrational levels of spans longitudinally over a year and a half of monitoring. Noticeable differences are observed between spans near and far from the expansion joint. While spans 4 and 5 exhibit significant oscillations in vibrations (increasing in winter and decreasing in summer), end spans (1 and 9) remain relatively stable over the reference period. In this instance, a comparative analysis facilitated the understanding that the rise in the vibrational indicator was not indicative of an anomaly but rather associated with the expansion joint. It underscored the importance of considering the joint as a critical element when studying the dynamic response of the viaduct. Moreover, this example highlighted and confirmed that a uniform treatment and a single training model for all spans may not be appropriate. A differentiation into at least three span categories is essential: the first category represents spans situated near the expansion joint, the second pertains to end spans, and the third encompasses central spans. In summary, a DD approach offers several advantages, such as the cost of the service, which is certainly lower than a Model-Driven approach, and the possibility, due to a complete instrumentation, of a comprehensive characterization of the viaduct from both a static and dynamic point of view. The drawback, however, lies in the lack of safety control, without the ability to detect structural damage, but this does not preclude the possibility of easily extending the service from DD to MD in case of anomalies.

Figure 5. Data driven approach application in the case study. Comparison of spans vibrational levels with respect to their distance from the structural joint.

4.3 *Application 3: Advantages and disadvantages of a light monitoring solution*

In case a light monitoring solution is opted for, the number and type of sensors installed on the structure is limited to key structural components and key positions to collect a set of data that aims to be representative of potential structural anomalies, acting as a 'sentinel' sensor that triggers further detailed analysis. In this case, no FE updated model nor diagnostics load test is available, therefore the attention is given primarily to the optimization of the cost implications in case of limited resources or in such cases where a structural preliminary analysis has confirmed that the state of conservation of the asset fully respects the reliability requirements with limited or absent signs of degradation. This approach implies that there is sufficient time to detect potential anomalies and time to intervene with either more detailed inspections/investigations, detailed analysis or proactive maintenance. The SHM objective changes from damage detection to anomaly detection. In the specific case under analysis, the hypothesis is to reduce the sensors to a minimum of n.1 MEMS triaxial accelerometer and biaxial clinometer at mid-span and concentrate on fewer Key Performance Indicators (Figure 6 (b)). As illustrated in Figure 6 (a), focusing on the natural frequencies as an example, clustering the response of similar spans allows to identify by comparison the damaged span as it stands out as a clear outlier from the standard values. This is a particularly representative case in which the first flexural mode is highly affected by the presence of the damage to the slab deck prestressing. However, as this approach allows to minimize the sensing technologies spreading the control over an increased number of assets, the absence of an updated FEM model impedes to directly correlate the damage entity/location and severity with the acquired data. In order to classify the identified anomaly, further inspections or analysis are required to inform the decision-making in terms of future corrective interventions. The clear advantage of optimizing the cost of information, favoring a diffused approach on a high number of assets with less sensors, is conversely accompanied by the drawback of losing redundancy in the measurements, limiting the analysis to local structural sections missing the global response (eg. impossibility to perform a full modal analysis) and decreasing the potentiality to identify anomalies or effects of damages due to the spatial distance between adjacent sensors. The thermal response correlate to the presence of the joints, as described in 4.2, would not be seen choosing a light sensing monitoring system.

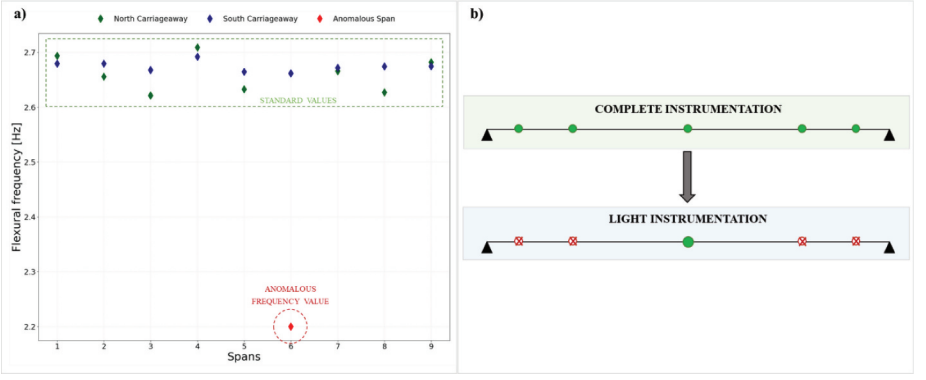

Figure 6. a) Comparison between spans flexural frequencies, when opting for a light monitoring solution. b) An example of sensors layout in a light monitoring approach.

5 CONCLUSIONS

As SHM solutions proved to be essential tools in infrastructure management, the deployment of these systems across extensive infrastructure networks enables administrators to evaluate the remaining safety levels of managed bridges and assists in prioritizing and planning maintenance interventions when necessary. However, implementing a widespread monitoring

system on a large scale often necessitates the optimization of monitoring system utilization. In response to this challenge, Sacertis Ingegneria has introduced various monitoring services of varying complexity. These services are assessed and applied based on the characteristics and monitoring requirements of the structure under examination. This paper delineates distinct monitoring approaches, distinguished by the adopted analysis method—whether Model Driven, Data Driven, or a combination of both—and by the extension of the system (sensor layout) on the monitored elements (Local vs Global monitoring). A case study of a modular prestressed reinforced concrete slab bridge with two independent carriageways has been analyzed, focusing on the differences and analogies between the n.18 spans. Algorithms and Key Performance Indicators (KPIs) are tailored accordingly, and the scope of the analysis varies based on the chosen approach, ranging from anomaly detection to damage identification goals (Model Driven vs Data Driven approach). The selection of the approach is contingent on the structure itself, and the paper thoroughly describes all considerations in this decision-making process, highlighting pros and cons of the monitoring and diagnostics options explored.

Field monitoring of bridge link slab performance under long-term and live load effects

A.M. Okeil
Department of Civil and Environmental Engineering, Louisiana State University, Baton Rouge, LA, USA

M. Canales
Universidad Tecnológica Centroamericana, Tegucigalpa, Honduras

ABSTRACT: Several details to eliminate bridge expansion joints have been proposed, and employed, in bridge construction. Expansion joints are known to require regular maintenance and are the cause of a host of problems including damage to girder ends and substructure components in the vicinity of the joints. The link slab detail is one of these alternatives that eliminates bridge expansion joints without introducing full bridge girder continuity. It has been gaining wide acceptance in North America and is becoming a standard construction detail. A bridge over the Ouachita River in Louisiana, US, employed the link slab detail to connect prestressed concrete bridge girder spans and was instrumented by six types of sensors, namely embedded sensors (sisterbars, strandmeters, and strain gages) and surface-mounted sensors (gapmeters and titlmeters). A total of 134 sensors were installed in three phases following construction sequence. The monitoring system recorded strains, girder end movements and rotations, and temperatures for the project, which employed different link slab details and segment lengths. The data was collected over a period of more than three years to study long-term effects as well as during a static live load test. Results show that cracking, which is mainly due to thermal effects, affects the performance of the link slab. The monitoring data also shows that jointless segments up to a length of 164.6 m (540 ft) performed well without excessive support movement.

1 INTRODUCTION

Precast prestressed concrete (PPC) girder bridges are considered one of the more efficient designs, which is reflected by the statistics in the National Bridge Inventory (NBI) (Federal Highway Administration 2016). They offer many advantages over traditional designs, such as ease of construction and durability. Prestressed concrete girders are usually precast offsite and transported for erection before pouring composite decks on site. As a result, full continuity between the girders has generally been sacrificed for the sake of ease of construction. As can be seen in Figure 1a, bridge deck joints traditionally have gaps of 1-3 inches under operating conditions (LA DOTD 2005). These gaps within the joints have the disadvantages of causing ride discomfort, debris accumulation, the need for maintenance to avoid leakage on the bridge substructure as a result of wear and tear caused by traveling vehicles and environmental exposure, which can cause corrosion of the substructure (Canales 2019). The direct costs associated with deck joints include construction, installation and maintenance. When deck drainage water is contaminated with chemicals such as deicing salts leaks through joints, it can damage the bridge superstructure and the pier caps below. This can lead to the damage of vital bridge parts, such as internal reinforcement, girder ends, caps and bearings. Accumulated debris in the joints may restrain deck expansion, causing increased pressures in bridge decks.

DOI: 10.1201/9781003483755-303

According to Lam (2011), expansion joints have not performed up to design expectations, in particular, during winter operations which has compromised the durability of many of these structures. Joints also make span unseating more likely for multiple-simple-span bridges in the event of earthquakes or floods and water surges during hurricanes (Okeil and Cai 2008). Therefore, there is need for reducing or eliminating expansion joints in bridge decks that are constructed as simple spans by developing continuity details that cover the gaps between adjacent spans. Several projects have looked into different continuity details (e.g. NCHRP Report 322 (Oesterle et al. 1989) and NCHRP Report 519 (Miller et al. 2004)). Several field investigations have also monitored the behavior of jointless bridge decks (Wing and Kowalsky 2005; Okeil et al. 2013). In Louisiana, the new John James Audubon Bridge was designed with a positive moment continuity detail (Hossain et al. 2014). It was observed that hairpin bars cause stress concentrations at girder ends that is likely to cause cracking in the bottom flanges (Okeil et al. 2013; Hossain and Okeil 2014). Conversely, the link slab detail, where continuity is only achieved in the deck slab (see Figure 1-b), does not establish full continuity as it allows girder ends to translate almost freely with respect to each other.

Analysis of this simple link slab detail has been the focus of many studies. Caner and Zia (1998) assumed that the contribution of the link slab is limited to additional flexural rigidity, which is small compared to the girder's. They also recommended debonding 5% of the span length for the link slab. Ignoring the restraining of girder rotations by the link slab will yield greater rotations than could actually be expected (Zhao et al. 2012). Therefore, Okeil and El-Safty (2005) proposed a simple design method for link slabs based on the three-moment equation method for analyzing continuous beams where the contribution of the deck was limited to its axial stiffness at the top of the girders. In another study, El-Safty and Okeil (2008) demonstrated that link-slabs may reduce the live-load stress range by 4.7% to 19.9% in comparison to simple span bridges. Au and Lam (2011) revised the flexural design approach to account for the compatibility between the deck and the girder displacements within the debonded length.

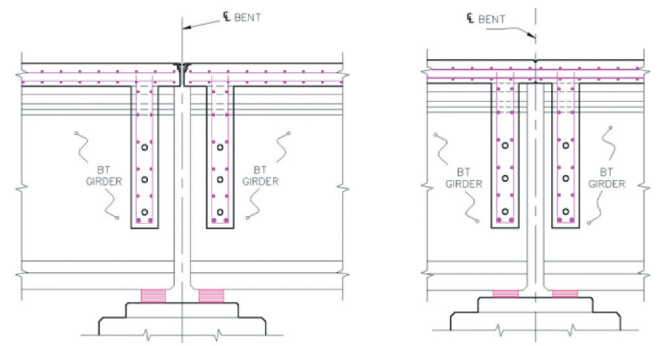

Figure 1. Typical details at bridge bents: (a) expansion joints, (b) link slab joints).

As can be seen, the link slab detail offers advantages over full continuity details such as ease of construction and elimination of stress concentrations. There is no consensus, however, on how this simple detail should be designed. This led to the initiation of another project to monitor the performance of a newly constructed bridge in Louisiana with the link slab details (Okeil and Canales 2020). In this study, details of a structural health monitoring system that was installed in the Ouachita River Bridge in Louisiana that is constructed with link slabs will be described. The bridge was selected to be a testbed for evaluating the performance of several link slab details. Data was collected over a period of more than three years to study long-term effects as well as during a static live load test. Results show that cracking, which is mainly due to thermal effects, affects the performance of the link slab.

2 MOTIVATION

Debris accumulation, deicing chemicals, improper selection of materials, or improper installation can cause the deterioration of expansion joints in bridges (Chang and Lee 2002), which in turn could lead to corrosion due to contaminated water leakage causing girder and pier deterioration. The cost of maintaining deteriorated expansion joints and the possible need for strengthening damaged substructure components has led to the call for reducing the amount of necessary expansion joints, or eliminating them altogether. The construction of fully continuous bridge decks can produce behavior similar to "blowups" in adjacent pavement through the compounding of the longitudinal pressures generated by thermal expansion (Burke 2004). Jointless bridge decks over simple span bridges reduces the need for expansion joints, and thus have a positive impact to bridge economics when properly implemented (Russell and Gerken 1994). Deck-only integration, or link slab, is the less intrusive alternative compared to full girder integration which may lead to girder end cracking (Hossain and Okeil 2014). This project was motivated by the lack of consensus on how link slabs should be designed. A field monitoring study was deemed important to understand the complex structural behavior of the simple link slabs detail.

3 METHODOLOGY

A structural health monitoring (SHM) approach was adopted to better understand the field behavior of link slabs. The Ouachita River Bridge was selected for this purpose and the long bridge, 3,275 ft (998.22 m) divided into 20 spans was constructed with different link slab details to study the best detail for future bridge construction projects. Sensors were embedded in the PPC girders as well as in the link slab. Additionally, sensors were also surface mounted to complete the SHM system.

3.1 *The Ouachita River Bridge*

The main bridge span over the river is a continuous steel girder segment with a total length of 980 ft (298.70 m). The rest of the bridge was divided into 17×135-ft (41.15 m) spans divided into a western approach (6 spans) and an eastern approach (9 spans). Figure 2-a and b shows the span length configurations for the western and eastern approaches. Figure 2-c shows the cross section of the bridge in these approaches, which consists of 7 standard AASHTO Bulb-T (BT-72) PPC girder spaced at 6′-8″ (1.69 m). The eastern approach consisted of one 4-span segment and 2 2-span continuous segments, while the eastern approach consisted of 4×2-span continuous segments in addition to one simple span.

3.2 *SHM system*

The SHM system was designed to capture the following: (1) force in the top and bottom link slab reinforcement, (2) differential displacements between adjacent girders at link slab locations, (3) displacement of the girder with respect to its supporting bent, (4) rotation of girder ends, (5) corresponding temperature for each of the recorded readings. Sensor placement was selected in order to obtain the necessary data at key locations within the structure and be able to effectively characterize link slab performance. Five types of sensors were employed in the designed monitoring system, namely embedded sensors (sisterbars, strandmeters, and straingages) and surface-mounted sensors (gapmeters and titlmeters). All of the selected gages are the vibrating wire gages, which is suitable for long-term monitoring as their readings do not drift with age (Bordes and DeBreuille 1985; Choquet et al. 1999). Table 1 lists the type and number of each of the employed sensors. A total of 134 sensors were installed in three phases. The sensors were installed at various locations as shown in Figure 3.

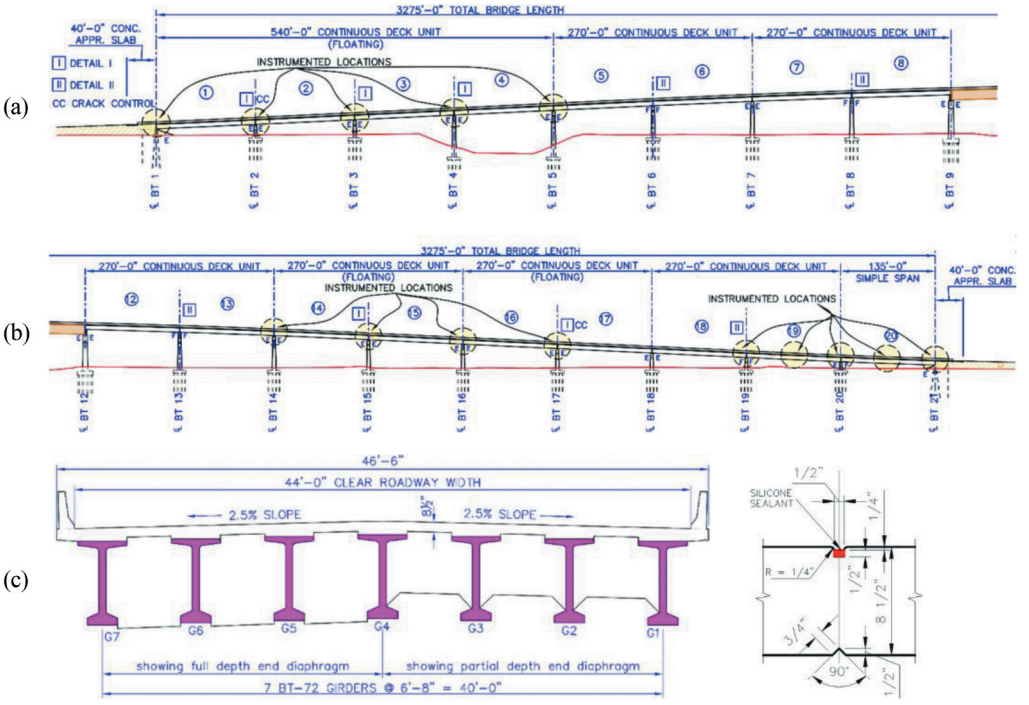

Figure 2. Ouachita River Bridge details: (a) western approach, (b) cross section, (c) eastern approach (1 ft= 0.3048 m; 1 in.=25.4 mm).

Table 1. Summary of sensors used in the Ouachita River Bridge.

Sensor Type	Measurement	Location	Number
Sisterbars	Strain in reinforcing steel	Embedded	18
Strandmeters	Strain in reinforcing steel	Embedded	36
Strain Gages	Strain in reinforcing steel	Embedded	2
Gapmeters	Displacement	Surface mounted	64
Tiltmeters	Rotation	Surface mounted	12
Weather Stations	Temperature and humidity	Surface mounted	2
Total:			134

Data from the SHM system was collected for a period of approximately 3 years and during one live load test where trucks were placed in 23 load cases were executed (11 positive moment and 12 negative moment). More details about the SHM system can be found elsewhere (Okeil and Canales 2020).

4 RESULTS

The SHM system provided a lot of data on many aspect of the behavior of continuous bridges with link slabs. In this section, a select few aspects of the behavior are presented.

4.1 *Girder end movement*

Figure 4 show plots of the relative girder end displacements based on from the gapmeters installed at the beginning and end of each segment. It should be noted that the plotted deformations are the cumulative deformation recorded at both ends of each segment.

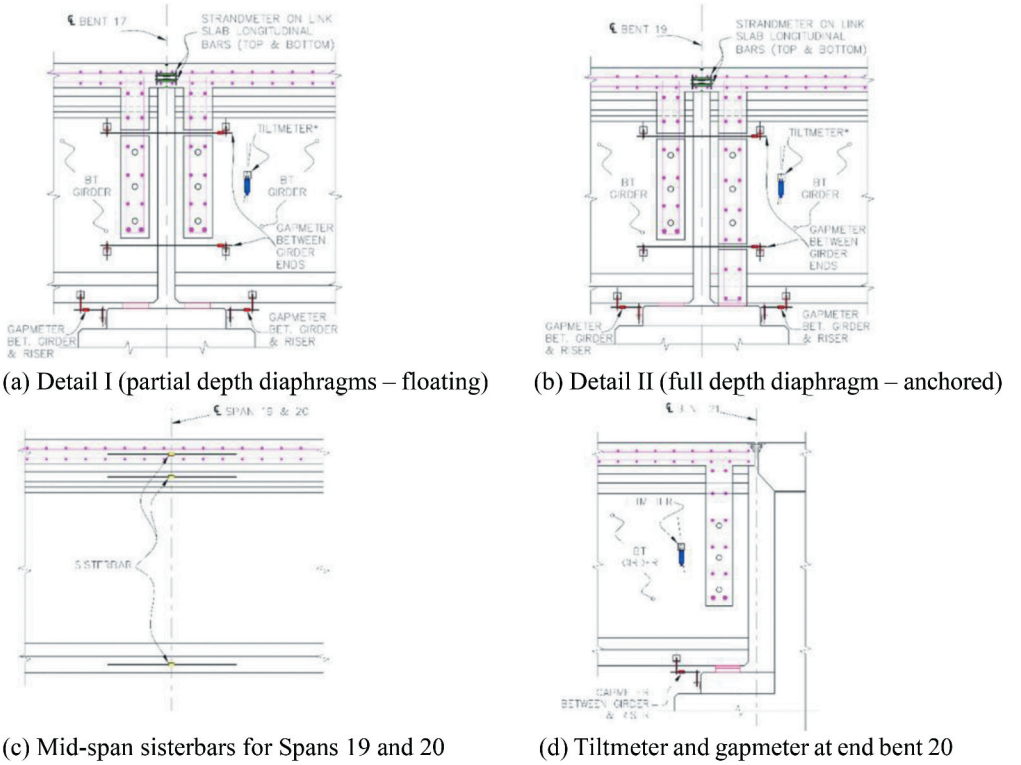

Figure 3. Placement of selected sensors at various locations.

$$\Delta = \Delta_{end} + \Delta_{beg} \tag{1}$$

The plotted results are for a period of about two years from March 2017 to February 2019. It can be seen that seasonal and daily temperature changes are directly correlated to the plotted relative girder end movements. This is expected as seasonal changes cause a uniform elongation, or shortening, of the entire bridge segment, while daily temperature changes are more affected by the temperature gradient, which causes girder camber leading to end rotations. In all cases, the girder end movements did not exceed 0.5 in (12.5 mm). The plots also show that floating segments experience smaller girder end movements (~ 0.2 in. [~5 mm]) compared to anchored segments. This implies that anchoring diaphragms, whether by design or due to unforeseen locking mechanisms, leads to more demands on the bearings.

4.2 *Relative angle between girder ends*

The relative angle between girder ends was extracted at locations where gapmeters were installed. Figure 5 shows the relative angle between girder end of Girder G7 at Bent 2 which is within the 4-span floating segment (see Figure 2-a). Like with girder end displacement, the observed relative angles are correlated with ambient temperature (not shown). It can be seen that the maximum relative angle between girder ends did not exceed 0.1°, which is small. However, given the large depth of the girders (81.5 in. (2.07 m)), this rotation imposes an extension on the link slab that causes tensile stresses that need to be addressed in design. Tensile force in the link slab of about 100 kip (445 kN) per girder were estimated at some locations (Canales 2019).

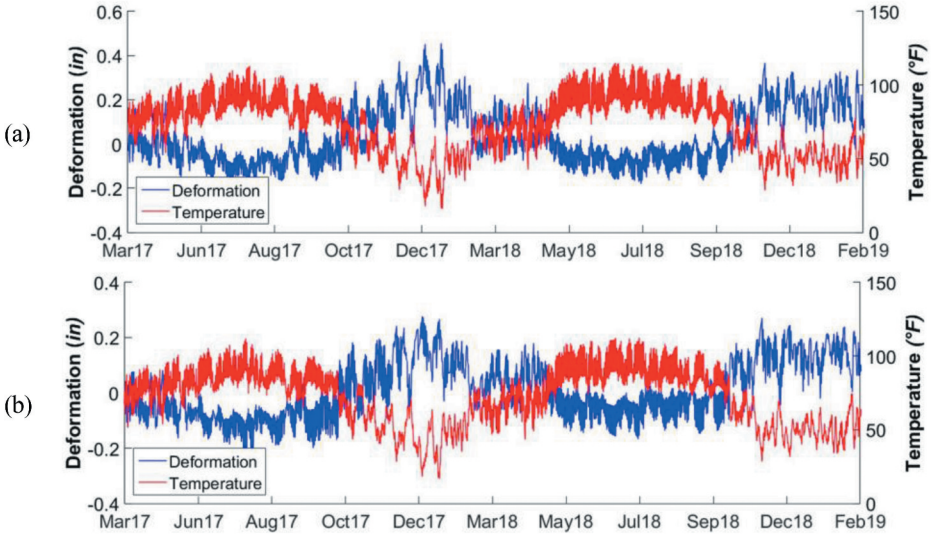

Figure 4. Girder G7 end displacement: (a) Span 2 (4-span floating segment), (b) Span 19 (2-span fixed segment).

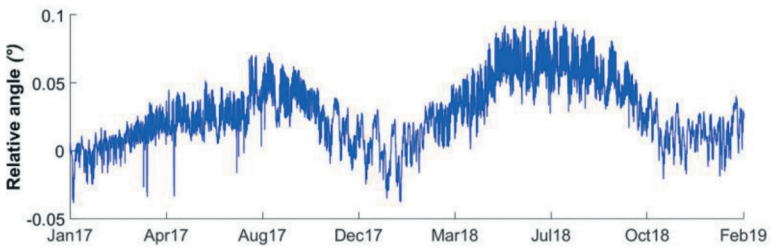

Figure 5. Relative angle between girder ends (Girder G7 at bent 2 (4-span floating segment)).

4.3 *Live load data*

As stated earlier, a load test was conducted to study the performance of link slabs under live loads. The trucks were position side by side for positive moment cases and in a truck train configuration (one on each span) for negative moment cases (see Figure 6). Figure 7 shows the link slab force in the link slab over Girder G7 at Bent 3. This plot shows that forces developed in the link slab for positive moment position P2 (side-by-side trucks over Span 2) and negative moment position N5 (truck train on Spans 2 and 3 over G7). In both cases, the link slab force is 20-40 kip (89 kN-178 kN) less than what was observed due to temperature changes. This implies that link slabs allow girder ends to rotate more freely under live loads and provide more release to restraint forces.

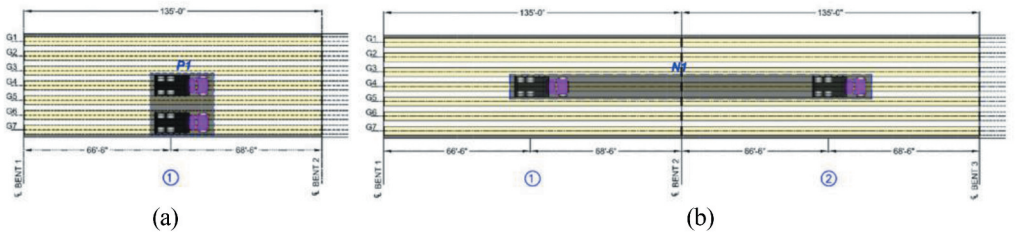

Figure 6. Positioning of trucks for load test: (a) positive moment case, (b) negative moment case.

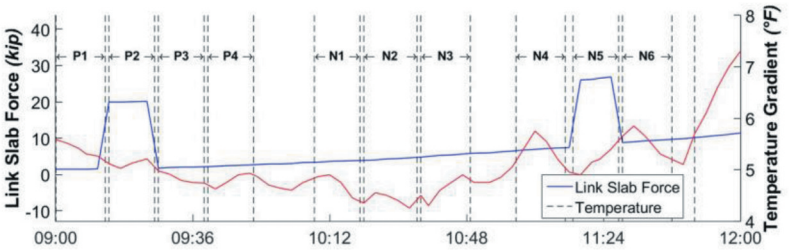

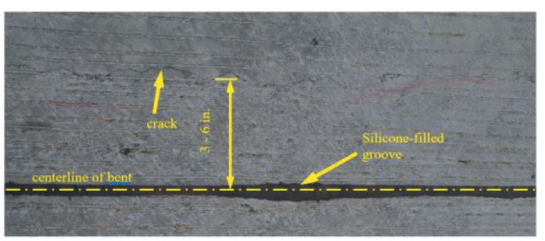

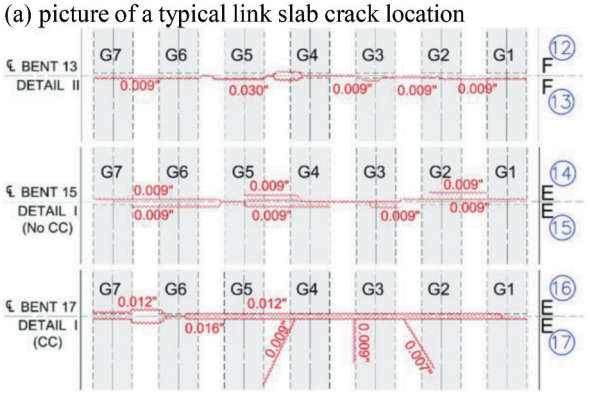

Figure 7. Live load forces in the link sab at Bent 3 for Girder G7 (4-span floating segment).

4.4 *Link slab transverse cracking*

Cast-in-place (CIP) reinforced concrete (RC) decks are known to crack in the transverse direction due to several reasons. Similarly, cracks were observed at all link slab locations even though certain crack mitigation strategies were employed at different bents such as saw-cut silicone filled groove to arrest cracks (see Figure 2-c). Cracks would disappear into the saw-cut groove intermittently but would reappear as transverse cracks running parallel to the groove approximately 3 to 6 in away from the groove. In other words, the crack control detail was not efficient in arresting the cracks. Figure 8 shows the crack pattern at Bent 13 (fixed bearings and anchored diaphragm) and Bent 15 (expansion bearings with partial diaphragm and no crack control) and 17 (expansion bearings with partial diaphragm with crack control detail). It can be seen that transverse cracks did not take place within the crack control groove as was intended. Cracks propagated away from the groove for most of the bridge width. Even though the observed crack width were not alarming, it is prudent to study ways for eliminating them such as by using Ultra-High Performance Concrete (UHPC) for link slab construction.

Figure 8. Transverse deck link slab cracking at bents 13, 15, and 17.

5 SUMMARY AND CONCLUSION

The Louisiana Department of Transportation and Development selected the Ouachita River Bridge to study the performance of link slab continuity detail, as well as quantify the influence of support conditions on its behavior. A SHM system consisting of various sensor types (sisterbars, strandmeters, straingages, gapmeters, tiltmeters and weather stations) with a total of 134 sensors was installed for long-term monitoring. A live load test was also conducted to test the instrumented spans under positive moment as well as negative moment. Data was collected over a period of more than 3 years, and sensor data was processed and corrected as per manufacturer instructions. Several analyses were performed to obtain different results including girder end displacement, relative angle between girder ends, and force in the link slab.

Continuous span segments up to 540 ft (164.6 m) in length performed well and did not show any signs of distress due to excessive expansions or contractions. Girder end rotations were affected by uniform temperature changes and temperature gradient changes. The small girder end rotations still caused notable link slab forces that need to be considered in design. It was found that the temperature gradient was found to generate larger link slab forces than live loads. With regards to link slab cracking, it was found that crack mitigation measure employed in the Ouachita River bridge did not perform as expected. Crack width formation is directly affected by temperature gradient variations throughout the day and seems to be unavoidable using reinforced concrete for the construction of link slabs. Therefore, it is recommended that the use of Ultra-High Performance Concrete (UHPC) for link slab construction be investigated.

ABSTRACT: Conventional deep-learning-based methods for bridge structural health diagnosis require complicated network structures and verbose from-scratch training with hyperparameter tuning. Because the pre-trained vision-language big model perceives fundamental knowledge of large-scale image and linguistic datasets, it should be of great potential to perform structural health diagnosis with full use of image and text datasets. This study performs a feasibility study towards establishing a big model for structural health diagnosis based on vision-language cross-modal learning. Specifically, an overall pipeline is proposed using a pre-trained vision-language big model of OFA (one for all, established by DAMO Academy in 2022). A series of Transformer modules based on the self-attention mechanism are stacked to unify pre-training tasks and downstream tasks in pure vision modality, pure language modality, and vision-language cross-modality learning. The results preliminarily demonstrate the feasibility and effectiveness of the vision-language cross-modal learning paradigm using OFA big model for structural health diagnosis.

1 INTRODUCTION

During the service period for decades, bridge structures are inevitably affected by various complex factors (including environmental erosion, material aging, fatigue load, and disaster events such as typhoons, earthquakes, and other emergencies), leading to the irreversible appearance and accumulation of structural damage. Various types of structural damage would occur, including concrete cracks, steel fatigue cracks, concrete spalling, and steel corrosion.

Timely identification of the location, morphology and geometrical characteristics of surface damage to ensure the resistance and service performance of structures is a crucial problem to be urgently solved in engineering practice. In recent years, with the development of artificial intelligence and collectible large-scale datasets, machine learning and deep learning have shown prominent potential in multiple application fields for structural health diagnosis (Xu et al., 2022a; Xu et al., 2022b). Bao and Li (2021) proposed a machine learning-based paradigm of structural health diagnosis using mathematical algorithms to process various monitoring data and predict the structural performance and state in high-dimensional feature space.

In deep learning-based methods, convolutional neural networks (CNNs) have been extensively utilized to extract the multi-level features of input images to map the damage annotations for various damage classification, localization, and change segmentation tasks (Xu et al., 2018; Xu et al., 2019; Qiao et al., 2021). In addition to image-based structural damage

DOI: 10.1201/9781003483755-304

recognition, plenty of machine learning algorithms and deep learning models have been applied to crack propogation modeling(Xu et al., 2022c), fatigue reliability analysis (Chen et al., 2021), mechanical property prediction (Xu et al., 2023c), and multi-task modeling of structural component segmentation, damage segmentation, and condition assessment (Xu et al., 2023d).

Conventional deep-learning-based CNN models for bridge structural health diagnosis require complicated network structures and verbose from-scratch training with hyperparameter tuning. To reduce the dependency on data quantity and diversity, a model-agnostic meta-learning (MAML) with an attribute transferring method was proposed for structural damage identification based on the initial parameter optimization. Recently, meta-learning has been further developed in bridge damage recognition (Xu et al., 2021), and a task-significance-aware meta-learning paradigm has been established for structural damage segmentation (Xu et al., 2023b).

Besides CNNs, transformer is another type of widely-used deep learning model consisting of an encoder-decoder structure, in which the attention mechanism helps the model to remember longer sequential information (Vaswani et al., 2017). Initially, transformers were proposed to solve problems in natural language processing; later, vision transformers utilized superb contextual memorization and achieved outstanding performance in computer vision (Bi et al., 2021). Novel attention modules have been designed to merge into deep learning models and enhance the feature extraction of multi-type structural damage (Zhao et al., 2022; Xu et al., 2023a).

The success of pre-trained large-scale language models demonstrates that scaling-up models significantly improve task-agnostic few-shot performance and even surpass prior state-of-the-art fine-tuning approaches. By consistently increasing model parameters, researchers are trying to explore the performance-improving limitations of big models. In recent years, the conventional model design pattern of "different models for different tasks" is gradually transformed into the new trend, "one large-scale pre-trained model for various tasks". In this new pattern, researchers collect massive amounts of data, design advanced algorithms, and train big models for users with different demands. Among these big models, big multi-modal models can fuse different modal information and process them like human brains by training with large-scale multi-modal data. The goal of big multi-modal models is to align data from different modalities and acquire the ability to transfer their learned knowledge to various downstream tasks, ultimately approaching robust artificial general intelligence (AGI).

Large-scale pre-training models have led to revolutionary performance improvement in the natural language processing (NLP) community. The advent of BERT (Devlin et al., 2019) and GPT-4 (OpenAI, 2023) indicates the power of pre-training. After witnessing the great success of pre-training, many large-scale transformer-based vision models have also been proposed in recent years. The masked image modeling (MIM) method was proposed for pre-training methods to learn rich visual representations via masked part prediction conditioning on visible context. MIM also provides another direction for exploring the large-scale pre-training visual model.

Multi-modal pre-training big models are usually trained in an unsupervised way on a massive training dataset without annotations. Due to the enormous parameters and massive multi-modal data, the support of computing power is essential. Multi-modal data collection is significantly more challenging than unimodal data due to the scarcity of multi-modal data alignment. Most of the current multi-modal pre-trained large-scale models are vision-language models because of the easy access to image and text data pairs from the Internet.

The network modules for feature encoding of multiple input modalities are worthy of carefully tailoring, as different modalities may have unique characteristics, and thus, specific network structures are required. In general, current research on multi-modal models mainly focuses on video, image, speech, and language. Vision-language pre-training models, which take a large proportion in current research, extract image and text representation and learn to fuse image and text with pre-training tasks (Lu et al., 2019; Chen et al., 2020). These pre-trained models can easily accommodate several vision-language integration downstream tasks, mainly including comprehension tasks and generation tasks. For example, visual

grounding (VG), one of the most mainly investigated downstream tasks, aims to locate the most relevant object or region in an image based on a natural language query. The query can be a phrase, a sentence, or multi-round dialogue.

The remainder of this study is organized as follows. Section 2 describes the proposed overall framework for a big model of structural health diagnosis by cross-modal learning. Section 3 shows some validation results and discussion to verify the feasibility of the proposed method. Section 4 concludes the paper.

2 METHODOLOGY

In this study, we explore the viability of utilizing OFA (Wang et al., 2022), a unified big visual language model, for bridge structural health diagnosis. OFA is a task-agnostic and modality-agnostic framework that supports task comprehensiveness and unifies a diverse set of cross-modal and unimodal tasks, including image generation, visual grounding, and image caption, in a universal end-to-end sequence-to-sequence learning framework with no need for task-specific layers for downstream tasks. Pre-trained on only 20M image-text pairs, OFA have achieved great performance in a series of cross-modal tasks and uni-modal tasks.

The overall framework of the big model for structural health diagnosis based on vision-language cross-modal learning is shown in Figure 1. Firstly, single-modal pre-training tasks, including image infilling, masked image modeling, and masked language modeling, individually perform vision and language representation learning. Secondly, cross-modal pre-training tasks align visual and language features, including visual grounding, grounded captioning, image-text matching, image captioning, and visual question answering. Then, the pre-trained OFA model is fine-tuned on different downstream tasks with specified prompts following the prompt learning paradigm to transfer the well-learned knowledge based on frequently-used public deep learning datasets of Conceptual Caption 12M(CC12M), Conceptual Captions (CC3M), SBU, MSCOCO image captions (COCO) and Visual Genome Captions (VG Captions). Afterward, a fine-tuned OFA big model is utilized to generate text descriptions from structural images based on the universal tokenization of each image and the language description, which uses ResNet101 and BERT as the image encoder and text encoder, respectively.

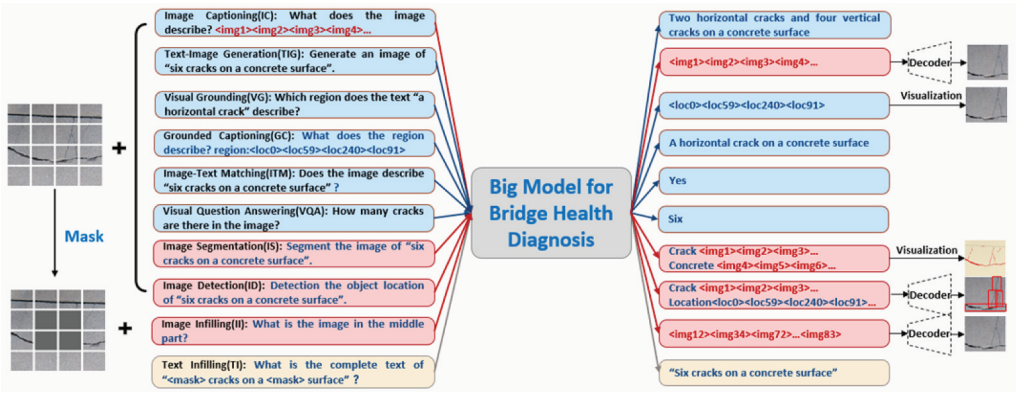

Figure 1. Overall framework of big model for structural health diagnosis by vision-language cross-modal learning.

The input data from different modalities undergo separate feature extraction and embedding representation processes. Subsequently, positional encoding is applied to the multi-modal data, enabling the corresponding token mapping to a unified representation space. This universal representation module establishes an integrated alignment framework for

multi-modal data, which is then fed into a pre-trained large-scale Transformer-based model for sequence modeling. Figure 2 shows the schematics of multi-modal feature representation and token alignment. Computational modules are designed with high-efficiency frozen-and-adaption strategy on visual-language pre-training tasks, as shown in Figure 3.

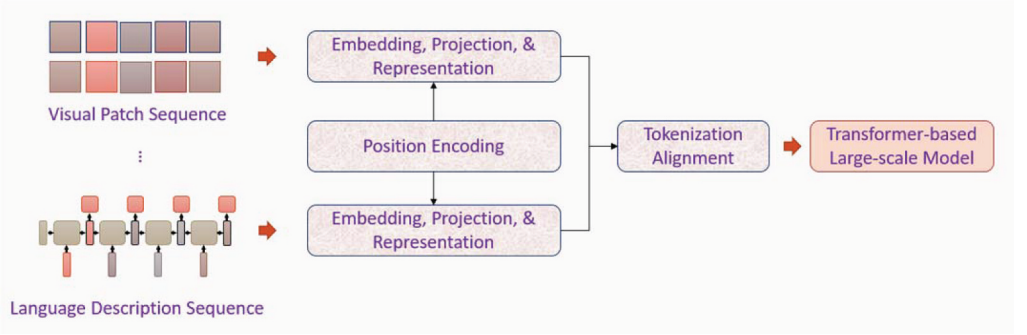

Figure 2. Schematics of multi-modal feature representation and token alignment.

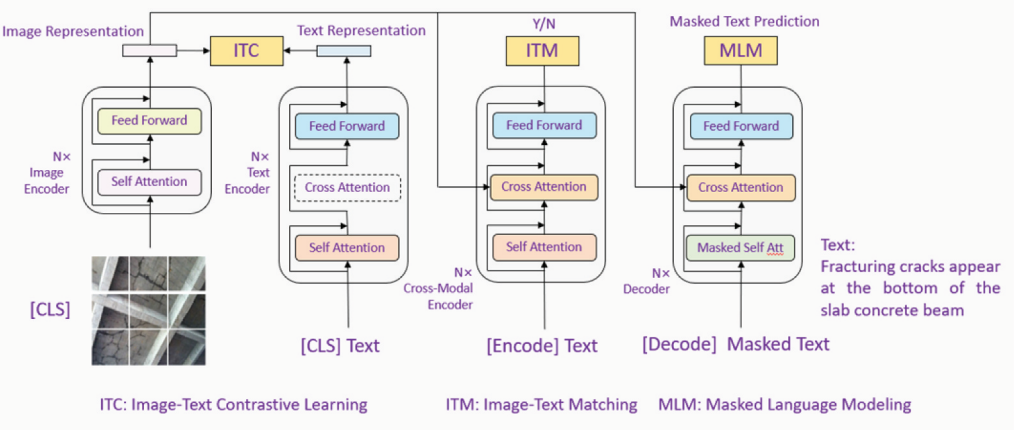

Figure 3. High-efficiency frozen-and-adaption strategy on visual-language pre-training tasks.

To identify the cross-modal features of multi-type structural components, material, and damage, the proposed big model utilizes different feature extraction modules to obtain the embedding feature vectors of damage images and texts, respectively. This setup enables that the model can possess the ability to merge the damage features in different modes through uni-modal feature extraction and cross-modal feature alignment. In addition, the model uses an additional decoding module to analyze the damage features extracted by the encoder to obtain the optimal text generation ability. Specifically, the calculation modules for uni-modal feature extraction of image and text are similar by stacking multiple self-attention layers. The visual-language cross-modal feature extraction module uses an additional cross-attention layer for feature fusion. The cross-attention layer accepts outputs of the image feature vector and text feature vector output from the image and text uni-modal encoder as inputs. The mask self-attention layer is added to the feature decoding module to keep the calculation of the training process consistent with the inference process of text generation for damage description. In the pre-training phase, three types of losses for image-text contrastive learning,

image-text matching, and mask language modeling are utilized to optimize the model on the collected bridge damage dataset of image-text pairs as

$$
\begin{aligned}
p_i^{i2t}(I) &= \frac{\mathrm{Exp}[\mathrm{Sim}(I, T_i)/\tau]}{\sum_T \mathrm{Exp}[\mathrm{Sim}(I, T)/\tau]} \\
p_j^{t2i}(T) &= \frac{\mathrm{Exp}\left[\mathrm{Sim}(T, I_j)/\tau\right]}{\sum_I \mathrm{Exp}[\mathrm{Sim}(T, I)/\tau]} \\
L^{ITC} &= \frac{1}{2}\sum_T \sum_I \left\{H\left[y^{i2t}(I), p^{i2t}(I)\right] + H\left[y^{t2i}(T), p^{t2i}(T)\right]\right)\}
\end{aligned}
\tag{1}
$$

where L^{ITC} denotes the image-text contrastive learning loss, I denotes image representation, T denotes text representation, Sim denotes cosine similarity, τ denotes annealing coefficient, H denotes the cross-entropy loss, y denotes the ground-truth one-hot vector.

$$
p^{itm}(I, T) = \mathrm{soft\,max}[\mathrm{MLP}(c)], L^{ITM} = H[y^{itm}, p^{itm}(I, T)] \tag{2}
$$

where L^{ITM} denotes the image-text matching loss, c denotes the image-text cross representation.

$$
L^{MLM} = H\left[y^{mask}, p^{mask}\left(I, \hat{T}\right)\right] \tag{3}
$$

where L^{MLM} denotes the mask language modeling loss, $\hat{T}$ denotes the masked text representation.

3 RESULTS AND DISCUSSION

Figure 4 shows some representative results of description generation for structural damage images. It can be found that the proposed method can successfully identify structural components (column, window, pavement, beam), materials (concrete, reinforced concrete, masonry, asphalt, protective layer), structural damage (crack, peal, corrosion, exposure, rusted, sink, broken, shear failure), location directions (bottom, surface, longitudinal, main reinforcement direction, middle, horizontal), and geometrical morphology (crisscross, X-shaped).

Figure 4. Validation results of description generation for structural damage images.

Figure 5 shows some representative results of attention map visualization for prompt-following logicality verification. It can be found that the generated phrase description could capture the semantic information and align image features of structural components, materials, structural damage, location directions, and geometrical morphology.

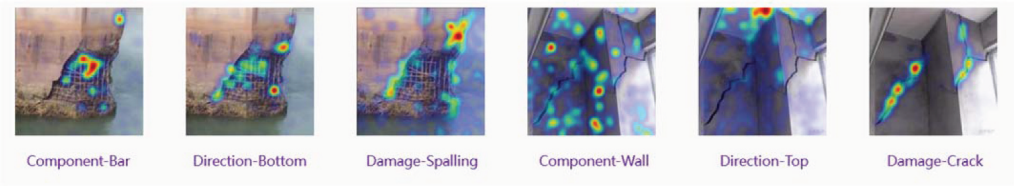

Figure 5. Attention map visualization for prompt-following logicality verification.

4 CONCLUSIONS

This study establishes a big model for structural health diagnosis based on vision-language cross-modal learning. The main conclusions are obtained as follows:

(1) An overall pipeline is proposed using a pre-trained vision-language big model of OFA with a series of Transformer modules. The image-self-attention, text-self-attention, image-text-cross -attention, and text-masked-attention mechanisms are stacked to unify pre-training tasks and downstream tasks in pure vision, pure language, and vision-language cross-modality learning.
(2) The proposed method can successfully identify structural components (column, window, pavement, beam), materials (concrete, reinforced concrete, masonry, asphalt, protective layer), structural damage (crack, peal, corrosion, exposure, rusted, sink, broken, shear failure), location directions (bottom, surface, longitudinal, main reinforcement direction, middle, horizontal), and geometrical morphology (crisscross, X-shaped).
(3) The results preliminarily demonstrate the feasibility and effectiveness of using a visionlanguage cross-modal learning framework based on the OFA big model for structural health diagnosis.

Large vision model-based crack segmentation under limited supervision

Yapeng Guo & Shunlong Li

Yang Xu
School of Civil Engineering, Harbin Institute of Technology, Harbin, China

ABSTRACT: Crack segmentation is an important basis for automatic evaluation of the apparent state of bridge structures. The emergence of large vision models has revolutionized the basic process of object segmentation and demonstrated strong generalization ability. In this paper, a novel large vision model-based crack automatic segmentation method under limited supervision is proposed. By adding a crack segmentation head, the segmentation generalization ability of the large vision model is retained, and the automatic segmentation of cracks is realized. The effectiveness and accuracy of the proposed method are illustrated by comparing with the state-of-the-art crack segmentation methods on eight commonly used crack datasets.

1 INTRODUCTION

Crack identification is of great significance for obtaining and analyzing the appearance state of bridge structure, evaluating its service performance and making maintenance decisions (Adhikari et al., 2014, Koch et al., 2015, Yeum and Dyke, 2015, Cha et al., 2017). In view of the shortcomings of current manual inspection, such as strong subjectivity and low efficiency, researchers have begun to use computer vision to simulate the function of the human eye, and use mobile phones, drones and other devices equipped with cameras to collect crack images. A variety of crack automatic identification algorithms based on traditional digital image processing, machine learning and deep learning have been developed. Among them, the pixel-level crack segmentation method based on deep learning is more active and practical.

The current crack pixel-level segmentation methods take fully supervised learning as the main-stream. These methods involve training state-of-the-art object segmentation frameworks using crack image and pixel-level annotation data pairs. Innovative research in this field has focused on dataset construction, deep learning network optimization, loss function combination, and post-processing enhancement, leading to improved accuracy and algorithm efficiency in crack pixel-level segmentation (Li et al., 2019, Liu et al., 2019, Chen and Jahanshahi, 2020, Huyan et al., 2020, Kang et al., 2020, Zhang et al., 2021, Asadi Shamsabadi et al., 2022, Zhong et al., 2022, Guo et al., 2023, Xu et al., 2023, Zhang et al., 2023). However, the current crack segmentation models still have limited generalization ability due to constraints such as data size and segmentation framework efficiency, leaving ample room for improvement.

The advent of Segment Anything Model (SAM) has been likened to the GPT-3 moment in computer vision (Kirillov et al., 2023). SAM has been trained using over one billion masks on 11 million images and is designed as an interactive model that incorporates prompts during training. As a result, SAM can be applied to new image distributions and tasks through zero-shot learning, showcasing remarkable generalization ability. It can effectively segment unfamiliar scenes or objects. This large vision model has revolutionized the generalization ability of segmentation models in common object segmentation domains. Although SAM successfully captures some features of the crack image, two issues arise: (1) the segmentation

DOI: 10.1201/9781003483755-305

result lacks semantic information and does not conform to the requirements of the crack segmentation task, and (2) the accuracy needs improvement. Consequently, there is an urgent need to leverage the features learned by SAM and automate the crack segmentation task more effectively.

This paper focuses on the efficient application of large visual model in the task of automatic crack segmentation, aiming to provide a simple and accurate way to use the generalization ability of large visual model to improve the accuracy of crack segmentation under limited supervision. The remaining content of this article is arranged as follows. Section 2 introduces the architecture and objective function of the proposed method. Section 3 explains the dataset and implementation details. Section 4 shows the testing results. Section 5 summarizes the whole article.

2 METHODOLOGY

The proposed crack segmentation method based on fine-tuning SAM is mainly composed of crack image encoder and crack segmentation head, as shown in Figure 1. When training, all the parameters of the crack image encoder are frozen and not updated, only the parameters of the crack segmentation head are updated. The initial upsampling layer is to unify the crack image size to the input size of SAM. The crack image embedding refers to the high-dimensional features generated by the crack image after passing through the encoder.

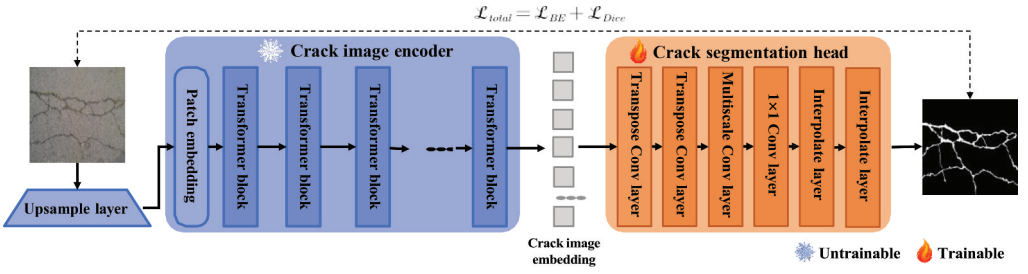

Figure 1. Framework of the proposed large vision model-based crack segmentation method.

2.1 *Crack image encoder*

The SAM architecture consists of three parts: image encoder, prompt encoder and mask decoder. Because the crack segmentation task does not require prompt input, this paper only uses the trained image encoder in SAM, because the encoder contains the general multi-level features of various objects.

The image encoder of SAM employs the pre-trained ViT-Base model. The original crack image is first upsampled to 1024 × 1024, and then the convolution with kernel size of 16 and stride of 16 is used to discretize the image into a vector of 64 × 64 × 768. The vector is flattened in order in length and width to 4096 × 768 with positional encoding, that is, 4096 tokens with a length of 768, so that the visual problem is transformed into a sequence to sequence problem. After the above patch embedding, the crack image will be sent to the transformer block. Each block consists of a normalization layer, a multi-head attention layer, another normalization layer, and a multi-layer perceptron (MLP).

2.2 *Crack segmentation head*

SAM uses prompts to assist object segmentation, that is, adding a prompt encoder and a mask decoder to process image embedding, prompt embedding, and output tokens after the

image encoder. Because the crack segmentation task referred to in this study is automatic and does not require prompt input, the second half of the SAM needs to be modified. This paper adds a crack segmentation head to achieve the required functions.

Specifically, the crack segmentation head consists of two transposed convolution layers, a multi-scale convolution layer, a 1 × 1 convolution layer and two interpolation layers (Zhang et al., 2022). The role of the transposed convolution layer is to perform 2 times upsampling on the encoded crack image embedding to restore spatial information. The multi-scale convolution layer is employed to obtain gain from feature fusion at different scales, that is, to learn information in different ranges around key pixels through back propagation gradient. The 1 × 1 convolutional layer is used to fuse the information of different channels and adjust the output dimension. The function of the interpolation layer is to further upsample to adjust the output dimension.

The objective function of the proposed method is the joint loss ($\mathcal{L}_{total}$) of binary entropy ($\mathcal{L}_{BE}$) and Dice ($\mathcal{L}_{dice}$), as shown in Equations (1)-(3). Where N represents the number of all pixels in an image, y_i and p_i are the ground truth label and prediction of the i^{th} pixel, and Y and $\hat{Y}$ are the ground truth and predicted crack masks, respectively.

$$\mathcal{L}_{total} = \mathcal{L}_{BE} + \mathcal{L}_{dice} \tag{1}$$

$$\mathcal{L}_{BE} = -\frac{1}{N}\sum_{i=1}^{N} y_i log(p_i) \tag{2}$$

$$\mathcal{L}_{dice} = 1 - \frac{2\left|\hat{Y} \cap Y\right| + 1}{\left|\hat{Y}\right| + |Y| + 1} \tag{3}$$

3 DATASETS AND IMPLEMENTATION DETAILS

This paper selected eight influential datasets to evaluate the proposed method, which were CFD (Shi et al., 2016), Crack500 (Yang et al., 2020), Cracktree200 (Zou et al., 2012), DeepCrack (Liu et al., 2019), EugenMiller (Yang et al., 2020), GAPs (Eisenbach et al., 2017), Rissbilder (Yang et al., 2020) and Volker (Yang et al., 2020) (Datasets 1-8). These datasets have large differences in the structural materials, structural parts, image quality, and image quantity, so they can effectively evaluate the generalization ability of crack segmentation models. All the training images (7754 in total) were divided into the training subset (90%) and validation subset (10%). All the testing images (the testing subset) were employed to evaluate segmentation methods in this paper.

The initial learning rate of fine-tuning the proposed crack segmentation model was set to 1e-5, the total number of training iterations was 24000, and the change of learning rate was multi-step, which became 0.1 times of the previous one at the 16000th and 20000th respectively. The fine-tuning process adopts the early stopping strategy, batch size was set to 2, r in LoRA was set to 4. The hardware platform employed for fine-tuning and testing the proposed method included: an Intel Xeon(R) E5-2620 v4 (CPU), an Nvidia RTX 3090 graphics processing unit (GPU) with 24GB memory and 128 GB of memory.

4 TESTING RESULTS UNDER KIMITED SUPERVISION

In this paper, the state-of-the art CNN-based crack segmentation model Deeplab v3p (Chen et al., 2018) and transformer-based crack segmentation model Segformer (Xie et al., 2021) are selected as the comparison methods. For fairness, these two methods used the weights trained on the large-scale segmentation dataset CityScapes (Cordts et al., 2016) as the basis for fine-tuning in this paper.

The trained weight parameters in SAM map the general features of object segmentation, so using the features in SAM and performing full-supervised fine-tuning has achieved significant accuracy improvement. The powerful generalization ability of SAM is also reflected in the few-shot task under limited supervision conditions, that is, using as few annotations as possible can also achieve acceptable segmentation results on new data distributions. In this section, the crack segmentation ability of the proposed method under limited supervision is explored by taking 1%-shot and one-shot cases as examples.

The 1%-shot case means that the data used to train the proposed method is randomly sampled from the training subset under the fully supervised condition at a ratio of 1%, and the 1%-shot training subset has a total of 77 images. The one-shot case means that an image is randomly selected from the training subset of each dataset as the one-shot training subset, that is, a total of 8 images. Table 1 illustrates the Dice scores of three methods on the test set under limited supervision.

Consistent with the theoretical analysis, when the size of training subset is sharply reduced, the segmentation accuracy of the proposed method on the eight datasets is reduced. Compared with the fully supervision, the average Dice scores of 1%-shot and one-shot decreased by 7.1 and 23.5, respectively. However, it is worth noting that compared with Deeplab v3p and Segformer, the accuracy of the proposed method has a Dice score improvement of 13.4, 9.5 and 3.8, 5.6 under two cases, respectively. More importantly, using only 1% of the training subset, the accuracy of the proposed method significantly exceeds that of Deeplab v3p trained under full supervision, which illustrates the strong generalization ability of the proposed method.

Table 1. Testing Dice scores (×100%) on eight datasets under limited-supervision.

		Dataset								
Data size	Method	1	2	3	4	5	6	7	8	Average
1%-shot	Deeplab v3p	31.4	54.0	21.9	69.4	33.6	13.5	30.6	60.1	42.9
	Segformer	47.2	60.0	17.3	65.6	44.8	23.0	47.0	64.2	52.5
	Proposed	54.2	65.8	21.1	70.5	48.1	32.9	48.3	66.8	**56.3**

5 CONCLUSIONS

This paper proposes a SAM-based crack segmentation framework, realizing the significant improvement on segmentation accuracy. The proposed method achieves significant accuracy improvement on eight widely used datasets under full supervision and limited supervision conditions, and the average Dice scores reach 56.3 (1%-shot) and 39.9 (one-shot), indicating the excellent fitting ability and generalization ability. The proposed crack segmentation method based on SAM provides a feasible way for the application of large vision model in the field of crack recognition. However, limited by the computational hardware resources of the authors, this study is carried out on the SAM with ViT-Base as the backbone. Future research will focus on light-weight work such as distillation of SAM model, making the application of large vision model under limited hardware conditions more feasible.

ABSTRACT: Cable monitoring and safety evaluation are crucial for cable-supported bridges in service. Due to its cost-effectiveness and convenience, vibration-based methods are widely used in cable monitoring. The fatigue assessment and damage detection of the cable using vibration monitoring data are developed in this paper. For the fatigue assessment of cables, a real-time monitoring and sensing scheme based on the amplitude and phase estimation method and the Miner's linear fatigue damage accumulation theory is proposed. It considers both the real stress amplitude spectrum as well as the changes in the mechanical properties of cables simultaneously. For cable damage detection, a method using the cable dynamic stiffness theory and time-varying frequency to detect damage in operational cables is proposed. In this method, empirical mode decomposition and moving average methods are used to remove the effects of traffic and temperature on cable frequency. K-means clustering method is used for identifying cable damage.

1 INTRODUCTION

Cables, as crucial load-bearing components of cable-stayed bridges, play a paramount role in determining the operational performance of the bridge. However, due to the coupling effect of harsh environment, complex live load, and insufficient maintenance, cables are prone to corrosion and fatigue damage, posing a serious threat to the safety of the bridge structure (Feng *et al.* 2022).

In cable fatigue analysis, simulation methods for obtaining cable load spectra usually involve statistical analysis of traffic loads over a period of time based on weigh in motion (WIM data), applying the obtained traffic load model to the bridge model (Jiang *et al.* 2020). The main problem addressed by this method is the accuracy of the vehicle load and finite element models. It is an ideal method to obtain fatigue load spectrum based on long-term actual cable data (Mao *et al.* 2019). However, the accuracy and durability of existing direct cable force measurement sensors cannot meet the requirements of fatigue stress.

In cable damage detection, early identification of the cable damage is essential for the assessment of the current condition, potential future life, maintenance and safety assessment of the cable (Li *et al.* 2019). In cable dynamic monitoring, although the collected data include responses to a combination of known and unknown loads, the obtained frequencies can characterize the

DOI: 10.1201/9781003483755-306

response of the structure to a constant static load by eliminating the effect of external dynamic actions. Therefore, cable damage can be identified by the processed frequency (Huang *et al.* 2018).

Cable dynamic monitoring is an essential part of the cable-stayed bridge health monitoring system. Applying cable dynamic parameters to the evaluation of cables is convenient and economical. Therefore, based on cable vibration monitoring data, this paper proposes a fatigue assessment method that considers the real fatigue load spectrum of the cable over entire lifespan and a cable damage identification method that considers the influence of external dynamic actions during operation.

2 BACKGROUND OF THE METHOD

Figure 1 establishes a simplified mechanical model of a taut cable without lateral forces, extensively used in cable-stayed bridges. This model assumes that the cable is continuous and nonextensible. It integrates essential cable parameters, including cable force H, cable length l_0, bending stiffness EI, sag d, and inclination angle θ. Such integration is crucial for accurately analyzing the dynamic characteristics of the cable. In the analysis, the cable is divided into two segments with chord length l_1 and l_2. To simplify the analysis, chord coordinate systems are established for each cable segment.

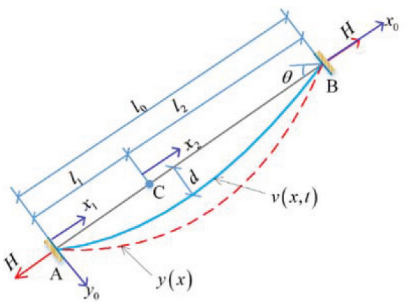

Figure 1. Cable mechanical model.

The cable illustrated in Figure 1 without considering internal damping and shear forces adheres to the motion differential equation presented in Eq.(1) under free vibration condition.

$$EI\frac{\partial^4 v(x_j,t)}{\partial {x_j}^4} - H\frac{\partial^2 v(x_j,t)}{\partial {x_j}^2} - h_j(t)\frac{d^2 y(x_0)}{d{x_0}^2} + m\frac{\partial^2 v(x_j,t)}{\partial t^2} = 0 \tag{1}$$

where, $v(x_j, t)$ is the dynamic configuration of the *jth* cable segment, $y(x_0)$ is the static configuration of the cable, which is approximated as a quadratic parabola, m is the mass per unit length, $h_j(t)$ is the vibration-induced additional cable force.

By employing the separation of variables and considering the boundary conditions of cable forces and displacements, the dynamic equilibrium equation Eq.(2) is derived (Dan *et al.* 2016).

$$\boldsymbol{Ka} = 0 \tag{2}$$

where, $\boldsymbol{K}$ is the cable dynamic stiffness matrix; $\boldsymbol{a}$ is the vector of boundary dynamic displacement amplitudes.

Based on Eq.(2), a cable frequency equation as indicated in Eq.(3) is derived (Xu *et al.* 2019). It is effective for accurately calculating cable frequencies when cable parameters are known.

$$det(\boldsymbol{K}) = 0 \tag{3}$$

3 FATIGUE ASSESSMENT OF THE CABLE

3.1 *Identification of fatigue load spectrum*

3.1.1 *Identification of time-varying cable force*

Since the variation amplitude of the time-varying cable force accounts for a small proportion of the total cable force, the sensing method must have sufficient accuracy. Therefore, this paper combines the BRAPES method and the exact formula fitting method, which can realize the accurate time-varying cable force sensing method with smaller cable force variation(Xu *et al.* 2022). In this way, the time-varying cable forces and frequencies can be identified based on the acceleration response of the cable.

3.1.2 *Cable bending stress sensing method*

The perception of bending stress is achieved by retrieving the joint load from the joint displacement and calculating the internal force of the section. According to the dynamic stiffness balance equation and Leung's theory, the equivalent joint external load and inertia force are obtained when the two ends of cables are consolidated. The bending moment and stress along time are as shown in Eq.(4) and Eq.(5) (Xu & Dan 2022).

$$M(t) = \sum_{j=1}^{j=n} \beta M(\omega_j) e^{i\left(\omega_j t + \phi_j\right)} \tag{4}$$

$$\sigma_C(t) = \frac{M(t)y}{I_z} \tag{5}$$

where, $M(\omega_j)$ represents the bending moment in the frequency domain, $\beta = k_B/(k_B + k_H)$ is the reduction coefficient, k_B is the bending stiffness of the cable section, k_H is the geometric stiffness provided by cable tension, y is the distance of the calculated point from the neutral axis of the cable section.

3.2 *Cable fatigue damage assessment method*

The calculation of fatigue damage adopts Miner's linear fatigue damage accumulation theory, and the expression is:

$$D = \sum D_i = \sum \frac{n_i}{N_i} (i = 1, 2..., k) \tag{6}$$

where, D_i is the damage experienced by n_i cycles under the action of the ith level stress level; n_i is the number of cycles of the ith level stress; N_i is the number of cycles to fatigue failure under constant ith level stress.

In the fatigue assessment, the S-N curve of the non-corroding and corroded steel strand under the average stress amplitude and the S-N curve of the cable considering the influence of the clamping effect and the anchoring effect are used (Birkenmaier 1980, Li *et al.* 2007).

$$\text{No corrosion}: \ lg(N) = 15.21 + 3.5\, lg\left(\frac{S_b - S_m}{S_b}\right) - 3.5\, lg(S_a) \tag{7}$$

$$\text{Corrosion}: lg(N) = 14.73 + 3.5\, lg\left(\frac{a(S_b - S_m)}{S_b}\right) - 3.5\, lg(S_a) \tag{8}$$

$$\text{Cable}: \ lg(N) = lg(C) - 3.5\ lg(1.6 S_{\text{ca}}) \tag{9}$$

where, S_b is the tensile strength of the material, S_m is the average stress, S_a is the corrected fatigue stress amplitude, a reflects the corrosion state of the section, S_{ca} is the fatigue stress

amplitude of the cable, N is the number of cycles, and C is the parameter of the S-N curve of the cable.

The schematic of the dynamic cable fatigue damage assessment method is shown in Figure 2.

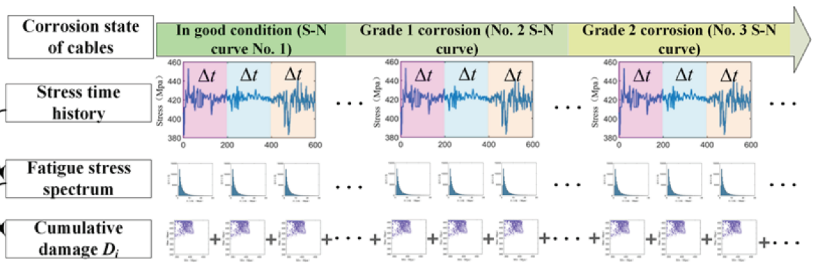

Figure 2. Schematic diagram of dynamic assessment of cable fatigue damage.

4 DAMAGE DETECTION

4.1 *Simulation of time-varying cable frequency considering traffic and temperature*

4.1.1 *Simulation of cable forces caused by traffic loads*

The traffic acts directly on the beam-deck and is transmitted to the cable through the anchoring points. The simulation of the static action of traffic loads on the cable is described by Eq. (10).

$$\Delta H_1(t) = \sum_{i=1}^{N} \alpha_i(t) W_i cos\theta \tag{10}$$

where, M_i is the weight of vehicle i; α_i is the load transfer coefficient, with a range of [0,1].

The simulation of the dynamic action of traffic loads on the cable is described by Eq. (11).

$$\Delta H_2(t) = M_{bi} a(t) cos\theta \tag{11}$$

where, M_{bi} is the mass of the beam segment supported by the cable, and $a(t)$ is the vibration acceleration of the beam at the location of the cable.

4.1.2 *Simulation of cable forces caused by temperature*

The cable tension caused by temperature can be calculated by Eq. (12)(Lepidi & Gattulli 2012).

$$\Delta H_3(t) = -EA\alpha_c \Delta T(t) \tag{12}$$

where, E is the elastic modulus of steel, A *is* cross-sectional area, α_c is the thermal expansion coefficient of steel; $\Delta T(t)$ is the temperature variation.

4.1.3 *Simulation of time-varying cable frequency*

Considering the influence of traffic loads and temperature on cable force, the time-varying force of an in-service cable can be expressed by Eq.(13).

$$H(t) = H_0 + \Delta H_1(t) + \Delta H_2(t) + \Delta H_3(t) \tag{13}$$

where, H_0 is the cable force under permanent load.

Once the time-varying cable force is determined, the corresponding time-varying cable frequency can be calculated using Eq.(3).

4.2 *Eliminating the influence of traffic loads and temperature on time-varying frequencies*

Moving average (MA) is used to eliminate the effect of traffic, while empirical mode decomposition (EMD) is used to eliminate the effect of temperature. Considering the order and number of applications of the two methods, the following two cases are analyzed: Method1 (MA-EMD-MA) and Method2 (EMD-MA) were compared in a previous study (Xu *et al.* 2023). To examine the effectiveness of these two methods, six types of trend data are selected from 24-hour time-varying force and frequency of the cable: (a) Upward trend; (b) Downward trend; (c) Convex curve; (d) Concave curve; (e) Outlier data; (f) Periodic curve. According to the results, comparing Method1 with Method2, it was found that the fluctuation of Method1 is less than Method2, and the results obtained by Method1 are all less than the cable frequency deviation when the cable moment of inertia damage reaches 5% for long cables with dense frequencies. This indicates that Method1 has better robustness. Therefore, this paper adopts Method1 for analysis.

4.3 *Qualitative identification of cable damage*

Although there is a significant shift in frequency when the cable has damage, the processed frequencies of different damage levels still overlap. Especially with longer cables, the frequencies are denser and the frequency changes caused by damage are smaller, making damage detection more challenging. The question of whether a cable has sustained damage can be regarded as a classification problem. This article uses the K-Means clustering method to achieve qualitative identification. The K-Means Clustering algorithm classifies data by minimizing the sum of squared distances between data points and the centroids within each cluster (Guo *et al.* 2022).

5 CASE STUDY

5.1 *Background of Yongjiang Bridge*

The A02 and A11 cables (Figure 3) of Yongjiang Bridge were used for verification. The bridge is a 105+97 m prestressed concrete single-tower cable-stayed bridge with 11 groups of 4 cables arranged in a harp shape with a spacing of 8 m. The cable parameters are shown in Table 1. The accelerometers are mounted on cables, and the vertical accelerometers are mounted in the middle span of the main beam. The bridge layout and sensor locations are shown in Figure 4.

Table 1. Cable parameters of Yongjiang Bridge.

Cable number	E/Pa	l_0/m	m/(kg m^{-1})	A/m^2	θ/ °	I/m^4	H_0/kN
A02	1.95E+11	102.436	40.846	8.825E-03	26.565	6.197E-06	2496
A11	1.95E+11	31.011	32.522	6.940E-03	26.565	3.832E-06	2060

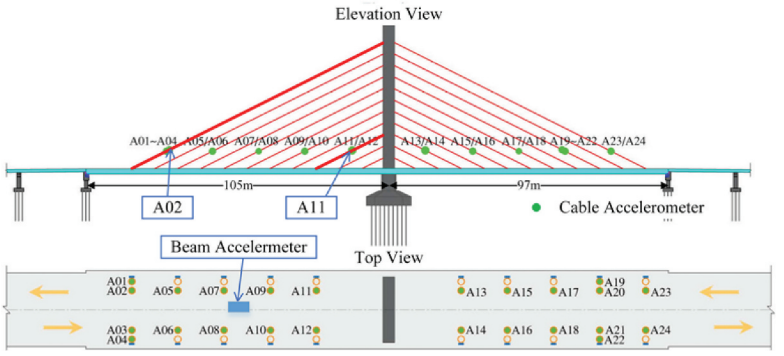

Figure 3. Cable sensor layout of Yongjiang Bridge.

5.2 *Fatigue assessment*

5.2.1 *Calculation of stress spectrum*

According to the aforementioned method, the time-varying cable force and the time-varying cross-section bending moment are calculated respectively. The 28-days of the acceleration data of the A02 and A11 cables were collected, and the time-varying cross-section bending moment was used to calculate the stress time history in the point at 0.1 l_0 along the cable length. Figure 4 is the stress time history of the A02 cable for 10 minutes.

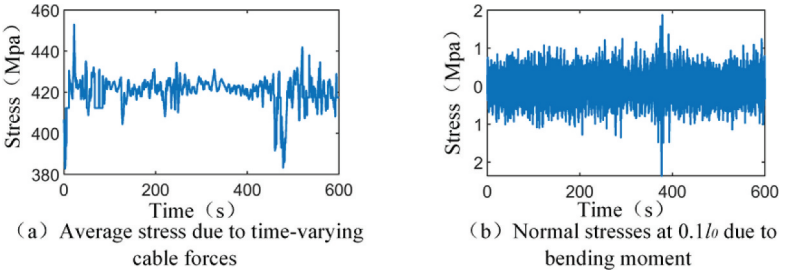

Figure 4. Stress history (10 minutes) of cable A02 due to axial force (a) and bending moment (b).

5.2.2 *Prediction of cable's fatigue*

Before estimating fatigue damage, the damage degree matrix is first calculated through the rainflow counting method. The accumulation of fatigue damage is the real fatigue damage of the cable. Figure 5 shows the fatigue damage matrix cloud diagram of the two cables.

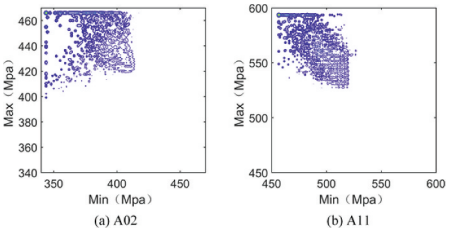

Figure 5. Nephogram of fatigue damage degree matrix of cables.

Table 2 gives the fatigue life estimated by different equations. Among them, Estimation 1 represents Eq. (7) or Eq. (8), and the stress amplitude adopts the average stress amplitude. Estimation 2 represents Eq. (9), and the stress amplitude adopts 1.6 times the average stress amplitude. When considering corrosion fatigue, the value of a is approximately 0.7.

Table 2. The fatigue life of cables (Unit: year).

	No consideration of corrosion		Consider corrosion	
Cable	Estimation 1	Estimation 2	Estimation 1	Estimation 2
A02	41368	7984	3905	754
A11	8324	1607	784	151

Table 2 shows that the fatigue life calculated by the stress amplitude of different formulas is quite different. Method 1 does not consider the interaction between the finished anchorage and the steel strand, and overestimates the fatigue life of the wire rope. The fatigue life calculated by method 2 is more reasonable. After considering the corrosion of the cable, the fatigue life of the

cable will be significantly reduced. For a bridge in operation, its cable is more susceptible to corrosion, and its service life will be significantly shortened under the combined effect of fatigue.

5.3 *Damage detection*

Since it is extremely difficult to get data from damaged real cables, the effectiveness of the method to remove the effect of external dynamic actions, as traffic and temperature, is verified by using real bridge cable data, but the damage detection can only be verified by numerical simulation.

5.3.1 *Eliminating the effects of traffic and temperature*

Based on the 24-hour acceleration data of the cable, the real time-varying frequency of cable A02 obtained through BRAPES is shown in Figure 6a. For the simulation of time-varying frequency, the method in reference (Ge *et al.* 2022) is used to simulate the traffic flow of Yongjiang Bridge, and $\Delta H_1(t)$, $\Delta H_2(t)$ and $\Delta H_3(t)$ of cable A02 are calculated by Eq.(10)-(12) also taking into account the temperature change along the day in the bridge location. The simulated time-varying frequency is shown in Figure 6b.

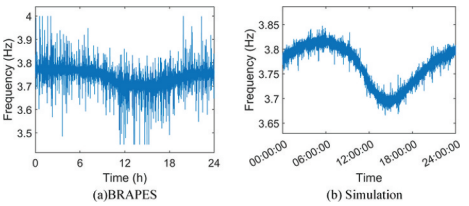

Figure 6. Time-Varying Frequency of Cable A02. a) From real acceleration data gathered with accelerometer in the cable. b) From simulation.

The time-varying frequency of the cable after removing the effects of traffic loads and temperature is shown in Figure 7.

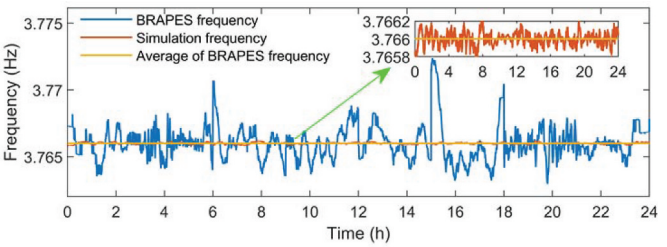

Figure 7. Time-varying frequencies processed by Method1.

From Figure 7, it can be seen that the post-processed simulated frequency has less variability, while the pots-processed measured frequency fluctuates more. However, by taking the average value of processed measured frequency as the representative value, it can be seen that the two coincide very well, with the maximum deviation less than 0.0002Hz. This indicates that the proposed simulation method is applicable for real cables.

5.3.2 *Simulation of cable damage*

The cable damage is simulated through the loss of the cable moment of inertia. For cable A11, five levels of damage: 0%, 5%, 10%, 15%, and 20% are considered. The corresponding calculated time-varying frequencies are shown in Figure 8.

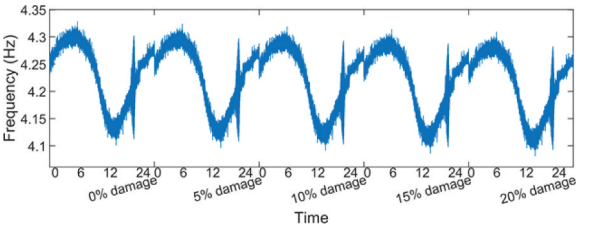

Figure 8. 24-hour of simulated time-varying frequencies of cable A11 for different levels of damage.

Method 1 (MA-EMD-MA) is used to remove the traffic load and temperature effects in the time-varying frequency, and the results are shown in Figure 9. As can be seen from Figure 9, it is feasible to evaluate whether cable damage has occurred based on changes in frequency.

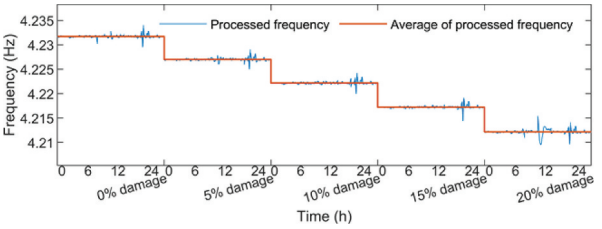

Figure 9. Processed time-varying frequency of cable A11 for different levels of damage.

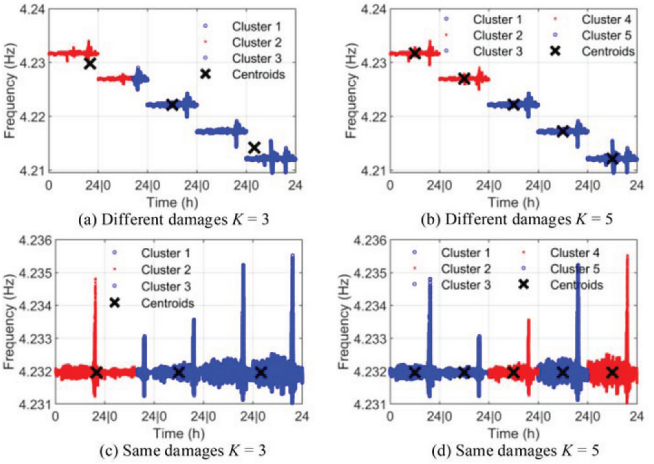

Figure 10. Results of time-varying frequency of cable A11 processed by K-means clustering.

5.3.3 *Qualitative identification of damage*

Figure 10 shows the application of the K-means clustering algorithm to cable A11 for the case of 5 levels of damage (a, b) and no damage (c, d) and different values of K. It can be seen that the accurate damage identification is only possible when K is equal to the number of damage levels, while when the data contains only one state, the centroids are the same, regardless of whether the K is correct or not. For real cables, the total damage levels of the cable are unknown, but they evolve gradually. Therefore, once the cable is damaged, the data will contain only two states. Therefore, the value of K=2 is recommended. If the clustering results are consistent, it is judged that no damage has occurred; if the clustering results are different, it is determined that the cable has sustained damage.

6 CONCLUSION

This article uses cable vibration as monitoring technique, and based on the vibration data, proposes two methods for cable fatigue assessment and damage detection. In the assessment of cable fatigue, a real-time stress perception method is first proposed, which includes time-varying cable tension and sectional bending stress. On this basis, a real-time monitoring and perception scheme for the fatigue state of service cables is established. In the cable damage detection, a qualitative assessment method for service cable damage based on time-varying frequencies is proposed. First, the MA-EMD-MA method is introduced to eliminate the operational and environmental variability from the cable frequency, and then K-means clustering method is used to qualitatively identify damage based on the offset of time-varying frequencies.

Monitoring to secure the Ile-de-Ré viaduct France

S. Joye & M.De Witt
Sixense Monitoring, Nanterre, France

ABSTRACT: The Ile de Ré viaduct is a cantilever bridge made of 6 independent viaducts to link the Ré island to the city of La Rochelle in France. Built in 1988, it is 2926m long. Unfortunately, the viaduct experienced a failure of one of its external post tensioning tendon in 2018. The Department de la Charente-Maritime, owner of the bridge asked Sixense and Freyssinet to secure the structure for the replacement of the broken tendon. This securing operation consisted in 3 phases: ultrasonic inspection of the cable anchorage zone, installation of acoustic monitoring and finally, strapping of the group of cables together. The objective of the ultrasonic inspection was to qualify the current state of degradation of the anchorage. Indeed, the cause and location of cable failure was known to be within a short distance (within 2 m at the most) behind the anchorage. Failure was attributed to a corrosion phenomenon associated with a poor injection of cement grout inside the cable duct. Once the cable condition was qualified at the anchorage, the acoustic monitoring allowed to remotely detect any subsequent failure of wire inside the tendons. Any overpassing of the maximum allowed number of broken wires or any acceleration of failing wires would trigger an alert, and put the work in progress on hold. Finally, as an additional safety measure to secure the works within the bridge, the external post tensioning cables were strapped by group in order to prevent any whipping effect that would hurt the operator in case of cables failure. The quantity, strength, and location of straps has been carefully calculated with dynamic load cases. Thanks to this monitoring, the broken cable, 6 cables in poor state and more cable at risks were replaced between 2019 and 2023, allowing to secure the whole viaduct.

1 THE BRIDGE

The Ile de Ré viaduct is located on the Atlantic coast of France 500km south west from Paris. Built in 1988 it links the Ré Island to the main land. The 2962m of ocean water is crossed by a balanced cantilever bridge made of 6 independent viaducts.

Figure 1. View of the Ile de Ré viaduct.

DOI: 10.1201/9781003483755-307

2 AN EMERGENCY SITUATION

In september 2018, a broken cable from the post tensioning cable network was found broken down, laying on the floor. The tension released was sufficient to expulse the two anchorage heads out of their concrete blocks. The failure of the cable occurred within the massive anchorage concrete block at about 1m far from the anchorage head.

A preliminary inspection revealed that the anchorage head was lacking cement grout injection and this lack was compensated by polyurethane foam during the injection process.

The Charente Maritime Department, owner of the bridge, immediately organised a response to this unexpecting event with the help of specialised civil engineer experts. This response was structured in several stages:

- initial assessment of the stability of the bridge without the failed cables
- securing of the future operations by assessment of the condition of the other cable anchorages
- monitoring in time by installation of acoustic sensors the sound emitted by a broken wire makes it possible to detect any subsequent wire failure, following the principles of acoustic emission techniques),
- replacement of the broken cables
- identification of the 4 worst condition cables thank to the results of the ultrasonic inspection (Uscan technique) for later replacement,
- replacement of 2 additional critical cables.

Figure 2. Broken tendon inside the deck.

3 THE RESPONSE

3.1 *Securing*

3.1.1 *Ultrasonic reflectometry*

Ultrasonic reflectometry applied to prestressing cables (Uscan) has been developed by Gustave Eiffel University (UGE) and Sixense. It has been applied for 10 years on the stay cables of the Normandie Bridge. The principle of this non-destructive technique relies on the propagation of ultrasonic waves along the steel wires constituting the tendons and their reflection upon a broken wire.

Figure 3. Uscan measurement on strand extremity (anonymous project).

The ultrasonic sensor both acts as an emitter and receiver and the reflected signal are recorded for every single wire inspected for later analysis, and a possible defects identification. Typical defects involve generalised corrosion, fatigue cracks (for stay cables) and/or ultimately, wire breaks. The ultrasonic frequency is tuned according to the type of tendons: individually sheathed strands, strands poured in cement grout or individual parallel wires. The results are classified in 3 different levels: green, orange or red depending on the shape of the reflected signal.

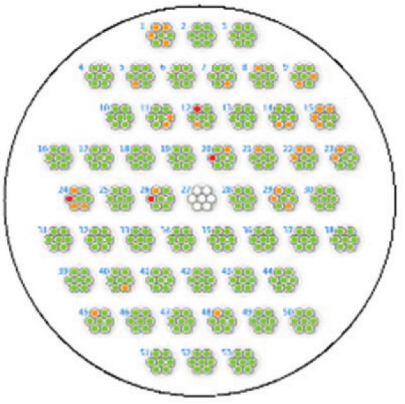

Figure 4. Uscan typical resulting pattern on anchorage head (anonymous project).

For the Ile de Ré viaduct, 85 anchorages were initially inspected during a campaign iniated just after the uncover of the broken tendon. A larger campaign was initiated in 2023 to assess the conditions of all anchorages in the bridge with the inspection of over 300 anchorages. In total this corresponds to over 50,000 wires, each individually inspected. The results of Uscan inspection allow the client to identify the cables with the worst condition that have to be replaced in priority.

After the removal of the first cables, visual inspections were carried on to confirm the reliability of the technique. With severe corrosion conditions, the wire break detection rates was found to drop significantly, but the technique was deemed to yield a sufficiently accurate assessment of the cable conditions to prioritize the replacement operations.

Figure 5. Uscan measurement in Ile de Ré viaduct.

3.1.2 *Acoustic monitoring*

After the condition of the cables was assessed by Uscan, an acoustic monitoring system was installed to detect any subsequent wire failure. The principle of the acoustic monitoring is to install acoustic sensors around and along external post-tensioning cable. Then any wire break occurring in a post tension cables is detected by the sensors and recorded by the associated data acquisition unit. Detection of the wire break generates an alert and the signal is analysed for confirmation of the wire break event. An Artificial Intelligence algorithm was trained to automatically filter false alarms generated by traffic noise or other external works.

Figure 6. Picture showing some acoustic sensors (in blue) located close to cable anchors in Ile de Ré viaduct.

The system was implemented during the operations in 2019 over a limited length of the bridge (where the broken tendon was uncovered). In 2023, the installation was completed to equip the entire bridge with an acoustic system. Over the past years, the system has detected about 30 wire break allowing the client to identify the cables at risk and in some cases led to cable replacements.

Figure 7. Data acquisition unit for acoustic monitoring.

4 THE FOLLOW UP

The acoustic monitoring system is still continuously monitoring the wire breaks that can occur during the service life of the structure. This system has been running since 2019 and is regularly detecting wire break. The Charente Maritime Department has commissioned a new work phase on the bridge in 2023, with an extended acoustic monitoring system, and additional works to ensure the structural stability of the bridge for the next decades. On specific periods with critical phases (cables dismantling), a dedicated specialist also helps identifying in quasi real-time potential acoustic events after the AI filter, to ensure the security of the working personnel.

5 EXPERIENCE

Sixense has performed many projects using Uscan ultrasonic reflectometry. The following table is giving the characteristic of our two major projects.

Table 1. Main work references for Sixense Uscan.

Project	Client	Type of anchorage	Number of Wire measured
Normandie	CCISE	Stay cable	109 000
Ile de Ré	CD 17	Prestressing	>50 000

Uscan technology has also be implemented on several infrastructures in France such as Bidouze Viaduc, Iroise bridge, Pont d'Isere, Chavanon viaduct or viaduct El Castro in Spain.

6 CONCLUSIONS

Uscan ultrasonic reflectometry is a patented method to assess the conditions of the structural cables in their anchorage zone. It applied for both stay cables or post tensioning cables giving a general assessment of the ageing at their anchorage area. It is particularly interesting to classify the state of the anchorages compare to others on order to prioritize the replacement of worst cables.

The Eversense Acoustics monitoring system allows to follow wire break during the lifetime of the bridge. It is a complex field requiring expertise in multiple domain such as sensors, analogical signal processing, advanced computer processing, acoustic skills and civil engineering

knowledge. Recent implementation of artificial intelligence program is securing the process by improving the filtering strategy and the outcome for the data analyst.

Uscan is giving a screen shot of the state of the cables whereas Acoustic monitoring allows to follow up the ageing through time. When combined together these technologies are complementary to assess the condition of structural cables and monitor their aging over time.

ABSTRACT: The inspection of the condition of prestressing steel in post-tensioned structures is a challenging issue because of the potential presence of corrosion in the tendons not warned by any other visible degradation condition. The economic unfeasibility and technical difficulty of performing a large number of semi-destructive tests (endoscopies) require the identification and practical application feasibility of non-destructive testing techniques to optimize the inspection procedure and enhance its accuracy. Many real-world examples have evidenced that ineffective grouting, or even the lack of it, triggers the corrosion mechanism that, if not detected early, can lead to the brittle failure of the bridge. Therefore, failure of post-tensioned structures is normally associated with ineffective grouting. For this reason, it becomes of interest to localize and quantify grouting defects and voids in the tendons. Some non-destructive techniques are currently available; one of these being the Ultrasonic Tomography.

This paper presents the results of the combined application of Ultrasonic Tomography and endoscopies in the detection of un-grouted regions in a real bridge. The reliability of the Ultrasonic Tomography results is then obtained through the Probability of Detection (PoD) curves which are checked against the results given by the endoscopic testing campaign.

1 INTRODUCTION

Prestressed concrete bridges with bonded internal post-tensioning, in the following PT bridges, are difficult to investigate and assess. The high-strength steel cables are protected from dangerous conditions triggering corrosion by the grout, the metallic or plastic sheet of the ducts, and the concrete cover. Many protective layers are, therefore, provided, and for this reason, especially for the first constructions, there were no worries about their durability (Godart 2001). One of the serious and sudden events occurred in the UK in 1985 when a single-span PT bridge collapsed without any warning (Woodward 2001; Woodward and Williams 1988). The events led to the Department of Transport's (DoT) decision to ban the PT bridges with internal tendons until the design and construction standard could be reviewed, in September 1992. At the same time, DoT announced that all the PT Trunk bridges would be systematically inspected over a five years period. The moratorium was lifted for cast-in-place posttensioned concrete bridges in 1996 since the results of the Special Inspections revealed that the majority of structures have a good record of durability. Anyway, this fact focused the

DOI: 10.1201/9781003483755-308

attention on the methodologies to apply to inspect these structures, in particular in identifying not visible defects.

Regarding Italy, the triggering event was the collapse of the Polcevera viaduct, in August 2018. After that, many efforts were made to organize and standardize the inspection and assessment of bridges and viaducts of any typology. The publication of the Guidelines for Risk Classification and Management, Safety Assessment and Monitoring of Existing Bridges (MIT CSLP 2020) in 2020 stated a set of actions to be completed to inspect the structures depending on the level of knowledge to reach. In this context, PT bridges are presented as a "particular case", to be dealt with by executing the so-called Special Inspection. The main problem is that, even if some indications are given, there is a gap regarding the testing methodologies to apply and the definition of the number of samples. Some proposals have been made during the very last years to cover this lack (Mazzatura, Caprili, et al. 2023; Mazzatura, Salvatore, et al. 2023), and the research here presented is part of these wider topics.

The focus is on the possible non-destructive methodologies to apply in searching for defects in PT tendons. Since searching for corrosion is difficult, and since corrosion is often associated with the lack of grouting (i.e. voids within the ducts), a way to search for defects can be searching for voids. The underlying and main assumption is that the void sections are associated with the defective ones. Even if this assumption is conservative, detecting voids is easier through Non-Destructive Technologies (NDTs). Many NDTs are proposed in the state of the arts. In the present research, the choice is to apply the proposed method to a real bridge and investigate the reliability of the result provided by UT.

2 METHODOLOGY

A 14-span viaduct located on a Highway in the North of Italy was investigated. The followed methodology was the one explained in (Mazzatura, Caprili, et al. 2023). Even if the present paper will focus only on the individuation of ungrouted areas within the PT ducts, a few words will be spent in the following to explain the determination and the location of the samples to investigate. Starting from the consideration given by the Italian Guidelines (MIT CSLP 2020), and by the study of the available state of the art (in particular of (FHWA 2013; Highways England 2020)), a multiphase methodology is proposed. It works on subsequent levels of analysis, meaning that only for the most degraded structures is necessary to go through all the phases. The first two phases are mandatory for all the bridges: *phase 0* provides the knowledge of the structure and the determination of the number of samples to investigate, *phase 1* provides the overall assessment conditions through both non-destructive (ND) and semi-destructive (SD) technologies, *phase 2* consists in the deep analysis of the defectiveness individuated at the end of the previous one, and *phase 3* is optional and contains suggestions for the global analysis of the bridge. For the present structure, the first two phases are executed.

Once the number of samples was determined, the choice was to employ as NDT the Ultrasonic Tomography. On the basis of a laboratory testing campaign previously executed and presented both in (Mazzatura, Salvatore, et al. 2023), and in (Mazzatura et al. n.d.), the way of employing the instrumentation and some considerations useful for the critical elaboration of data had been determined. In particular, the main results are about the reliability of the NDT given in terms of Probability of Detection (PoD). The PoD model is an evaluation often carried out for Non-Destructive methodologies, widely employed in the context of aerospace and nuclear engineering, and standardized by ASTM (ASTM International 2015, 2018). Stated a certain confidence and for a given probability, by the PoD curve it is possible to determine the largest flaw that a system can miss.

The tests' campaign will be described, and the focus will be on the tests for the location of the grouting defects. Finally, a critical analysis of the results is given, considering the main outputs deriving from the PoD analysis.

3 EXPERIMENTAL CAMPAIGN

3.1 *Description of the structure*

The studied viaduct is located on a highway in the North of Italy. It has 14 spans of variable length for a total length of 600 m. Each span is either 45, 40, or 34 m; but the very large part (11) is 45 m. The deck has 4 posttensioned beams and 4 reinforced concrete cross members. The subject of the investigation campaign were the beams belonging to the large population, i.e. the ones of 45 m.

From the design documentation, it is known that each beam is posttensioned by 6 cables (Figure 1), each composed of 42 wires of 7 mm diameter. The longitudinal design layout of the cables is known as well (Figure 1), and also the design mechanical characteristics of both the concrete and the high-strength steel. The initial prestress is not known. The main information about the viaduct is summarized in Table 1.

Table 1. Main information.

Year	N_{spans}	L (m)	L_s (m)	N_{beams}/span	N_{cables} /beam	Cables' typology	f_t (MPa)	Initial prestress
1976	14	600	34-40-45	4	4-5-6	Parallel wires	1′600	Unknown

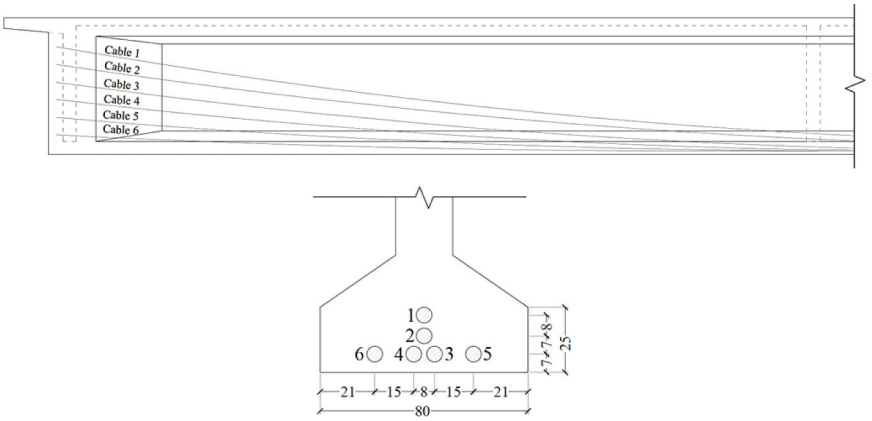

Figure 1. The upper figure shows the cables' trace, the lower one the middle-span cross-section.

3.2 *Number of samples and localization*

Many tests were performed on the structure. In the following, the focus will be only on the ones necessary to investigate the grouting defects within the ducts. First, a revision of the design documentation and the execution of a visual inspection is completed. This allows reaching a satisfying level of knowledge for the definition of the number of samples.

The basic assumption is that a sample corresponds to a cable and that a cable can be considered fully investigated if all the sites where voids are most likely to occur are tested. For more details, please refer to (Mazzatura, Caprili, et al. 2023).

In the present case, 14 samples resulted, therefore, 14 cables were chosen. A maximum of two tendons per beam are selected, to reasonably spread the testing campaign. Thus, 7 beams are chosen belonging to 3 different spans. The NDTs for the preliminary investigation aiming to define the layout of the cables (i.e. Ground Penetrating Radar), and the ones for the localization of voids (i.e. Ultrasonic Tomography), can be executed only in the areas shown in Figure 1, which corresponds to the ones in which the cables lies in the web of the beam and not in the lower part. The other locations (mainly the mid-span regions) were investigated through SDTs, i.e. endoscopies.

Figure 2. Inspected areas by GPR and UTs.

Endoscopies were also executed on the cables' trace in the web of the beam, both in areas warned by the Ultrasonic Tomography and in random areas.

3.3 *Preliminary investigation*

Before performing the investigations to locate grouting defects, it is necessary to collect some pieces of information about the structure. A revision of the design documentation was carried out, to identify potential conditions promoting damage, such as inadequate waterproofing and drainage system. The visual inspection is also fundamental to preliminary state the conservation status of the structure and to identify defects that can warn of possible deficiencies in the PT system. Particular attention must be given to cracks, whose presence could mean excessive losses in the precompression, and to defects showing the penetration of water/moisture inside the concrete section. Anyway, no worrying conditions were identified.

Once the overall condition of the structure is stated, and the number of samples to investigate is computed, it is possible to proceed with the preliminary in situ tests, mainly devoted to the location of the cables' layout. All the subsequent tests are concentrated on the cables, then it is important to exactly know their trace. In the present research, the Ground Penetrating Radar (GPR) was employed to locate the ducts.

GPR is a radar imaging technique using electromagnetic pulses transmitted to the element at very high frequencies. It was widely used (Terzioglu et al. 2018a) for achieving information about reinforcements' layout (Beben, Mordak, and Anigacz 2012; Kohl and Streicher 2006; Pasculli et al. 2018; dos Santos et al. 2014; Shaw et al. 2005; Soldovieri et al. 2006), the position of prestressing strands and metallic ducts (Clem, Schumacher, and Deshon 2015; Kohl and Streicher 2006; dos Santos et al. 2014; Terzioglu et al. 2018b), and the presence of voids in the concrete. From a practical perspective, the tests were executed by doing vertical scans (i.e. the 0, 1, … 10 sections in Figure 2) on the beam web each 100 cm. In each section, the location of each cable is identified. Finally, the single locations are joined to obtain the actual trace. As previously mentioned, the GPR test was executed in the areas of the beam where the cables lie in the web. These areas correspond to around the first 10 m from the beam heads. Indeed, it is not possible to execute the tests in other areas, such as the bulb of the beam, because the investigation surface is inclined. The trace of the cable represents the fundamental base for the execution of posterior tests.

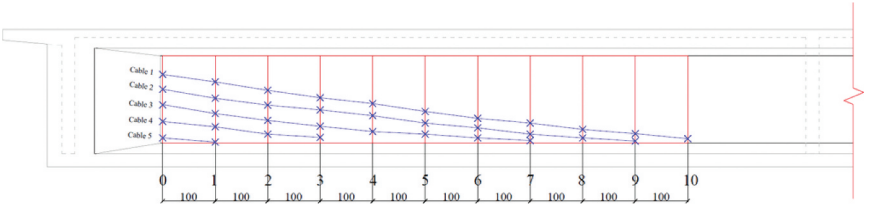

Figure 3. Operating modality for tracing cables.

3.4 *Investigations for the localization of voids*

The localization of voids was performed through Ultrasonic Tomography and endoscopies. Two cables per beam were inspected, and in detail cables 3 and 4. These are the cables that present largest areas on the web for feasible investigation. For instance, cable 1 and cable 2 are more visible in correspondence of the web, being the higher ones, but it is not possible to investigate them in the midspan region because they are located in the second order of PT reinforcements, having both a very large concrete cover, and the cables from 3 to 6 and the

ordinary reinforcements in the first order, making difficult the execution of any other kind of test (endoscopies and UTs), considering to execute them on the intrados of the beam (Figure 1 in the lower part shows the mid-span cross-section of the beam).

UTs were performed in all areas of the cables that could be tested, while endoscopies were performed in areas in which UTs gave no information (i.e. midspan region), in random areas (i.e. locations investigated but not warned by UT), and in critical areas (i.e. locations warned by UTs).

3.4.1 *Ultrasonic tomography*

UT was selected because of its quick and easy in-situ application. The in-situ conditions are often very adverse, mainly because of the height of the bridge, and therefore the uncomfortable work areas, and of the limited time available to complete the tests (it is often necessary to stop the traffic, or at least to limit it).

UT is reliable in estimating the thickness of elements/layers and in locating voids in PT ducts, especially when coupled with other testing methodologies (Martin et al. 2001; Muldoon et al. 2007). In the present campaign, the MIRA A10403d instrument, employing shear waves and dry point contact sensors was used. A stress pulse is generated through a mechanical impact of the sensors, even working as receivers. Part of the pulse propagates through the body, and part is reflected. Changes in the acoustic impedance are then captured. Through time-of-flight measurements, it is possible to locate discontinuities and therefore reinforcements, tendons, voids (cracks, honeycomb, delamination), or water defects (Muldoon et al. 2007). The testing apparatus gives images as results, elaborated through the SAFT algorithm (Schickert, Krause, and Mü Ller 2003; Stepinski and Lingvall 2010). Figure 4 shows the elaborated results of the UTs on one of the beams.

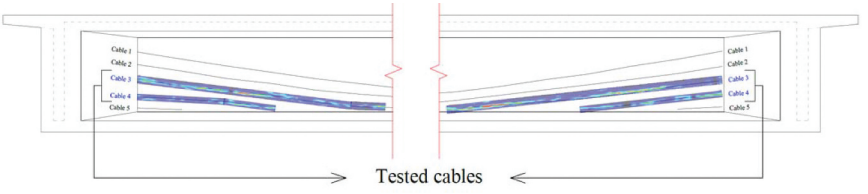

Figure 4. Results from UTs after postprocessing.

3.4.2 *Endoscopies*

To execute endoscopic investigations is necessary to locate the cable. In fact, a tiny spot (usually no more than 20 mm in diameter) is investigated. The endoscopies were executed firstly by performing a hole of a bigger diameter (20 mm), and then proceeding with a smaller one (10 mm); this methodology avoids smashing the metallic sheet of the duct on the tendon (Figure 5a.) and thus avoids performing a non-informative test.

Understanding the conservation status of the tendons through endoscopic investigations could be challenging, but it is a balanced compromise between an NDT and a full destructive investigation (i.e. the removal of the concrete cover, the metallic duct, and the grout).

a. *b.*

Figure 5. A. The mashed duct does not allow a correct evaluation; b. correct endoscopy with no evidence of grout.

4 RESULTS AND DISCUSSION

Starting from the results of a laboratory campaign for the definition of the Probability of Detection (PoD) curve for the UT investigating voids in PT metallic duct, the results of the in-situ testing campaign are elaborated. A critical discussion of the results is given with consideration about the overall observed state of conservation of the structure.

4.1 *Probability of detection*

The Probability of Detection is a methodology to evaluate the reliability of an NDT by furnishing as main information the largest flaw that the system can miss (given a certain probability and stated level of confidence). This piece of information is obtained by establishing a relationship between the probability of detecting a defect with its size, under representative application conditions. Since the main assumption is that the PoD depends only on the flaw size, it is very important to understand the other potential influencing parameters, that can be related to the geometry of the investigated body, environmental conditions, the testing set-up, and so on. Some details about the PoD construction are contained in (Mazzatura et al. n.d.); here the results of the PoD analysis are used to analyse the ones derived from the in-situ testing campaign.

The PoD useful for the present work is the one given in Figure 6, from (Mazzatura et al. n.d.). The displayed values are PoD(50%), i.e. the size of the void that the system can miss with a 50% probability and a 50% confidence level; PoD(90%), i.e. the size of the void that the system can miss with a 90% probability and a 50% confidence level; and PoD(90/95), i.e. the size of the void that the system can miss with a 90% probability and a 95% confidence level.

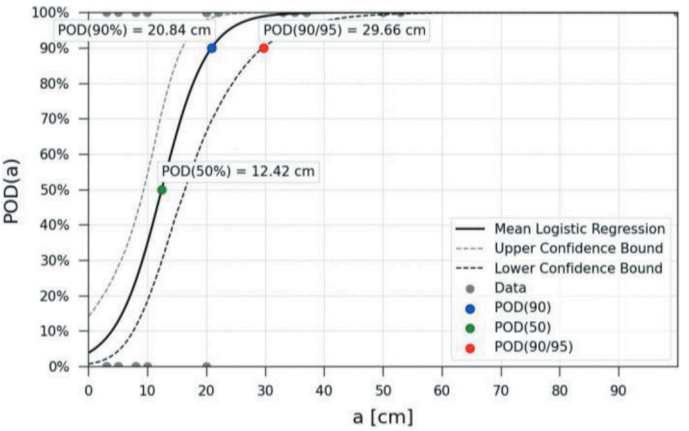

Figure 6. PoD curve for PT duct located at 15 cm from the investigation surface.

The last value, i.e. POD(90/95) is the interesting one, as the ASTM requires. The shown curve is obtained for defects located in cables lying 15 cm from the investigation surface and employing the same instrumentation calibration. This case represents the most similar one to the present testing campaign since the cables lie 11 cm from the concrete surface and all the tests were performed employing the same calibration.

4.2 *Critical analysis*

The results of the UTs and endoscopies were reported and compared as shown in Figure 7. Being the POD(90/95)= 25.66 cm (Figure 6), only the UTs showing a warn wider than 30 cm are considered as defective areas, i.e. voids inside ducts. In 4 out of 14 investigated cables, resulted in no defects at all.

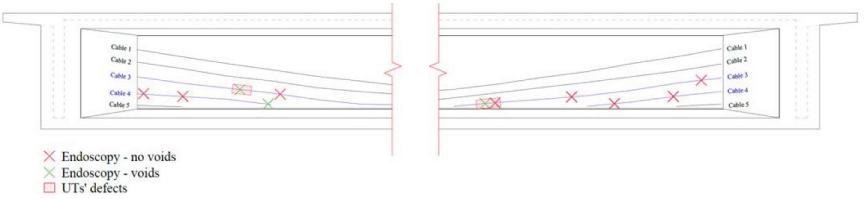

Figure 7. UTs defects and output of the endoscopic investigations.

In the other cables, some defects were signaled by the UTs. Table 2 gives a summary of the analysis. The last column represents the percentage of defective areas (L_{war}= warned length) on the total investigated length (L_{inv}= investigated length).

Table 2. Results of the UTs.

Span	Beam	Cable	UTs defective percentage ($L_{war}/L_{inv} \cdot 100$)
3	1	3	10%
3	1	4	30%
4	1	3	9%
6	1	3	8%
8	1	3	16%
8	1	4	43%
6	2	4	31%
8	2	4	6%
3	3	3	49%
3	3	4	55%

On a total of 56 endoscopies, 26 were executed in random areas of the cables and 30 in the areas warned by UTs. 63% of the tests in the warned areas reported the presence of voids; however, some of these voids are not located inside the duct but outside of it. The tests in random areas reported voids in 23% of the cases. No oxidized or corroded wires were found.

Table 3. Number of false positives and true positives.

	30 cm≤d<50 cm	50 cm≤ d <100 cm	100 cm≤ d <150 cm
Number of false positives	4	3	2
Number of true positives	4	7	7

By combining the output of the endoscopies and the UTs, it is possible to obtain the results summarized in Table 3. The assumptions are that if endoscopies are executed in correspondence of areas warned by UTs, and no evidence of voids is found, then false positives are identified; otherwise, if the endoscopies are not executed, or if the endoscopies are executed and voids evidence is found, then true positives are identified. It can be observed that the quote of false positives decreases with the length of the defects.

5 CONCLUSIONS

The present research deals with the inspection of PT bridges, with particular attention to the execution of tests for the location of voids. The focus is on Ultrasonic Tomography, employed on a 14-span bridge located in the North of Italy to investigate the status of grouting of 14 cables. The results of the investigations are elaborated in view of the reliability evaluation of the technique obtained thanks to a previous laboratory testing campaign. Some endoscopic investigations were conducted to check the reliability of the detection technique.

This case study shows that the PoD curves obtained in laboratory under controlled conditions and where only the flaw size is the variable, may have to be considered cautiously when applied to real bridges under uncertainties not encountered in the laboratory, related to the inspectors' ability to work in difficult environments, the variability due to in situ conditions, and others. The number of false positives encountered in real conditions, even for large voids has to be taken into account in further applications to real bridges.

However, by considering both the results of the NDT and of the SDT, mainly since no evidence of corrosion was found in any case, it is possible to affirm that the structure is in a good state of conservation, even if some voids within the ducts were found.

ABSTRACT: The paper explores Greece's Polyfytos viaduct, the nation's second-longest bridge spanning 1,372 meters, renowned also for providing access to key power plants in South-East Europe. A resilience analysis of different retrofitting scenarios was conducted, including both transitability and structural capacity aspects, employing visual inspections, digital data collection, and advanced modeling techniques. The viaduct, conceptualized by Prof Riccardo Morandi and built in 1972-1975, displays typical degradation seen in pre-stressed and reinforced concrete bridges. Unlike previous research focused solely on retrofitting with LCA and LCC assessments, this study integrates resilience assessment, marking a pioneering holistic approach to viaducts refurbishment.

1 INTRODUCTION

1.1 *Summary*

Over the last five decades, the balanced cantilever method has become increasingly popular in constructing bridges with medium spans, typically ranging between 100 to 200 meters (Concrete Bridge Development Group, 2017). However, issues related to long-term material effects such as concrete creep, steel tendon corrosion, and others have been noted since the 1990s, resulting in excessive vertical deflections (Bažant and Chern 1984, Bažant and Kim 1991, Bažant and Panula 1980). These problems have led to instances of bridge deterioration, even partial collapse, primarily exacerbated by heightened traffic loads up to 5-6 times the original ones (Morgese et al. 2020) and potential construction complications (Lucko and De La Garza 2003). Despite multiple research efforts (Gu et al. 2011, Wang and Fu 2015, Domaneschi et al. 2020), a comprehensive mechanism to predict and calculate these faults remains elusive.

The lack of a standardized solution suggests to propose an alternative approach, moving away from traditional on-site inspections and extensive sampling. This paper suggests formerly a method for evaluating vulnerable assets with uncertain structural integrity, where destructive testing or extensive sample collection is not feasible. Drawing on digitalization and monitoring trends in the construction sector, the recommended approach relies on computer analysis and innovative tools like drone-based photogrammetry (Varbla et al. 2021). Emphasizing cost-effectiveness and environmental friendliness, this method aligns with the growing popularity of laser scanning technology (Lõhmus et al. 2018), capable of providing detailed results within limited time frames (Witcher 2017).

DOI: 10.1201/9781003483755-309

Furthermore, this study serves as a complement to prior research that focused on assessing various retrofit solutions for this bridge type, particularly concerning environmental sustainability and cost impacts. It aims to evaluate these solutions by quantifying their resilience considering both transitability and structural capacity issues in the resilience computation. Therefore, the result is to promote a holistic approach to the reinforcement and maintenance of existing viaducts, considering not only the classical technical aspects of structural engineering but also environmental impact, cost, and resilience in identifying the most suitable solution. The Polyfytos Bridge in Western Macedonia, Greece, has been chosen as the case study for this multi-step research effort.

1.2 *The Polyfytos Bridge*

The Polyfytos Bridge, constructed in 1975 within the Municipality of Western Macedonia, Kozani, Greece, stretches over the artificial Polyfytos lake, playing a crucial role in connecting local and national road networks. One section of the bridge, spanning 260 meters between piers 22, 23, and 24 (Figure 1), was built using the balanced cantilever method, contributing to the bridge's overall length of 1372 meters. Recent inspections, carried out by multiple inspectors, including one of the authors of this paper, revealed excessive deflections at the free ends of the cantilevers, a common issue in aging bridges constructed using this method (Markogiannaki et al. 2022). Initial evaluations highlighted corrosion and localized concrete damage, raising significant concerns about the bridge's structural soundness. Consequently, traffic restrictions, such as weight limitations for heavy vehicles and reduced speed limits, were imposed to minimize dynamic impacts.

Typically, extensive material sampling, destructive testing, and vibration/loading assessments are utilized to evaluate material conditions. However, due to concerns about critical points on the deck's capacity, the owners did not authorize these methods (Markogiannaki et al. 2022). Furthermore, because of the bridge's importance in the bustling national road network (part of the E65 Central Greece Highway), conducting tests that could disrupt traffic necessitates considerable challenges.

Figure 1. The Polyfytos bridge and the three piers under evaluation.

1.3 *Digital technologies toward bridge inspection*

A proposed method for digital damage assessment is introduced, employing sophisticated computational tools adaptable to diverse structural assets. While several monitoring systems utilizing sensor technology have been recommended in previous studies (Li et al. 2022, Zhou et al. 2021), none have achieved universal optimization due to varying levels of accuracy. The proposed innovative approach aims to minimize intrusion, time, cost, and environmental impact.

The suggested process starts with a report on the necessity for on-site inspections. High-tech surveying tools, such as drone-based photogrammetry, provide valuable data on deflections, rotations, and visible cracks without requiring physical access to the structure (Li et al. 2022). These measurements generate deflection curves for mathematical comparison with other datasets. Additionally, information sourced from design reports and literature complements this analysis, contributing to an advanced structural model.

Acknowledging existing knowledge gaps (Bažant and Jirásek 2018), the advanced model considers potential factors such as creep and shrinkage observed in similar structures.

Scenario-based analyses explore the impact of various parameters on the structure. By comparing the deflection curves from these scenarios with measured results, potential causes are identified, guiding further investigation without providing definitive conclusions.

While this approach may not offer conclusive findings, it provides engineers and asset stakeholders with reliable information, offering a digitally streamlined, cost-effective, time-efficient, and environmentally friendly solution with minimal structural intervention.

1.4 *Some remarks on corrosion issues*

The corrosion of tendons in prestressed concrete bridges poses a significant threat to their structural integrity, as seen in incidents such as the catastrophic failure of the Ynys-y-Gwas bridge in the UK in 1985 (Podolny 1992). Even early in a bridge's lifespan, events like the replacement of post-tensioned tendons in Florida's Mid-Bay bridge after eight years due to corrosion-related concerns emphasize the importance of this issue (Hartt and Venugopalan 2002).

This study primarily focuses on corrosion as the primary cause of the investigated bridge's deterioration, largely disregarding potential additional failure mechanisms such as scouring or spalling of the reinforced concrete. Exposure to moisture makes the exposed interface of a strand highly vulnerable to corrosion-induced damage. The concept of "localized corrosion" raises significant concerns as it could lead to substantial reductions in the strand's cross-section, resulting in severe decreases in its tension capacity. Variations may exist within a strut, with differences between corroded and uncorroded wires in the same section and corroded and uncorroded segments along its length (Bartolozzi et al. 2022, De Gaetano et al. 2020).

2 BRIDGE CONDITION

A more detailed description of the bridge, focusing on the segment examined in this research (piers #22, #23, #24 with cantilever and precast beams connected by half-joints), is presented in the study by Domaneschi et al. (2023), along with the utilization of prestressed concrete technique in construction. Additionally, specifics regarding geometry, constituent materials, conducted analyses, and degradation assessment are provided.

According to Domaneschi et al. (2023), an in-depth detailing of the current state of the bridge is presented utilizing a point cloud. This visualization offers insights into particular aspects of both the cantilever and the half-joint of the bridge.

The report also addresses the deflection of the most critical cantilever, noting a significant variance between the expected and measured elevations. The measured position reveals a considerable discrepancy, measuring 133mm and 207mm lower than the anticipated elevation.

These differences specifically highlight downward displacements at the tip or end of the most critical cantilever. Such considerable deviations from the expected positions may indicate potential structural concerns within this specific component of the bridge. Further investigation and analysis are crucial to determine the underlying causes and implement necessary measures to maintain the bridge's structural integrity and safety.

3 FRAMEWORK FOR THE ASSESSMENT

The comprehensive approach involves assessing the structure's condition, proposing various technical solutions, evaluating costs, analyzing environmental effects, and gauging resilience against diverse challenges. The ultimate selection of the retrofitting solution integrates these aspects, ensuring a balance between structural improvement, economic viability, sustainability, and long-term resilience. This framework aims to guide decision-making and implementation, aiming for a safer, more durable, and environmentally conscious infrastructure.

4 PRELIMINARY BRIDGE RETROFITTING MEASURE

The initial design for retrofitting the analyzed piers aims to improve the structural performance and safety of the bridge in accordance with standard regulations. As discussed earlier,

significant damage to the bridge is primarily attributed to inadequate maintenance, potential issues during construction, increased traffic, high loads during service, and exposure to harsh environmental conditions. The critical reduction in prestressing stress at the cantilever supports severely impacts the bridge's functionality. Thus, two viable retrofitting scenarios have been identified to restore its original functionality (Domaneschi et al. 2023).

- Scenario #1: Demolition and reconstruction involve demolishing the current continuous deck, comprising six tapered box girder cantilevers and three girder bridges, while retaining the existing piers. Reconstruction maintains the same structural configuration, materials, and behaviors due to the widespread use of the bridge's design.
- Scenario #2: Local interventions and replacement of the girder bridge sections incorporate installing external prestressing cables to restore proper compression stresses in the six cantilevers, enhancing the bridge's functionality. Additionally, it considers replacing three girder bridges with steel box girder sections to prevent cable corrosion. This solution results in improved slenderness and reduced load on the cantilevers.

For Scenario #1, the interventions include:

a) Disassembling the defective balanced cantilever segment of the deck and the reinforced concrete girder bridge using non-explosive agents that rely on chemical action instead of explosive charges.
b) Recreating the original structural design of the bridge by reconstructing the decks. Calculations for construction expenses cover both the concrete deck and steel reinforcement, encompassing the steel reinforcement within the deck and the necessary attachments to secure the new cantilever to the existing piers' head.
c) Installing elastomeric bearings at the cantilever's extremity.
d) Introducing expansion joints at the girder bridge deck level to prevent thermal constraints or damage to the traffic pavement.
e) Building the road surface, incorporating layers such as surfacing layers, an asphalt bond coat, protective layers, epoxy bonding, waterproofing, and a reinforced concrete deck.
f) Installing all requisite functional amenities, including road signs, safety barriers, and others

For Scenario #2, the interventions involve:

a) Removing only the Gerber bridge sections using a controlled approach.
b) Installing a steel box deck designed to minimize overall weight. This encompasses procedures related to creating the reinforced concrete slab utilizing the predalles system.
c) Employing hot-dip galvanization on all steel surfaces of the deck to apply a passivating treatment.
d) Substituting girder deck bearings with the FPS system to prevent any slippage between the deck and its supports.
e) Introducing expansion joints at the girder bridge deck level to avert thermal impacts or harm to the traffic pavement.
f) Constructing the road surface, which includes surfacing layers, an asphalt bond coat, protective layers, epoxy bonding, waterproofing, and a reinforced concrete deck.
g) Implementing all necessary functional amenities such as road signs, safety barriers, etc.
h) Introducing an external prestressing system by adding four cables along each cantilever to reinstate the original deflection. The design considerations involve utilizing cables of the same section as those depicted in the technical drawings and introducing compression stress to prevent any cracking.

5 EFFECTS OF THE RETROFITTING MEASURES

5.1 *Costs*

The financial assessments for each scenario were conducted utilizing the price catalogs provided by ANAS (2022) from Italy, with the exception of the evaluation for the cost of the

prestressing system, where the authors adopted the parametric cost outlined in Devitofranceschi (2018). Acknowledging potential variations in price lists across countries, the analysis primarily focused on comparing diverse retrofitting scenarios, noting that within the European community, discrepancies, while existent, are not considered significant.

For comparative purposes, a specific segment of the bridge was selected, encompassing all operations within an economic framework (one pier coupled with its associated cantilevers and one Gerber beam). The projected cost estimates for each scenario were derived from this slice, simplifying the extrapolation of the comprehensive intervention expenses. Table 1 provides a comprehensive overview of each intervention to facilitate the assessment of the total cost for individual scenarios. Ultimately, the final costs for each scenario clarify the higher financial impact associated with the first one (Domaneschi et al., 2023).

Table 1. Costs for each scenario.

Scenario #1 Phase	[k€]	Scenario #2 Phase	[k€]
(a)	80	(a)	25
(b)	2000	(b)	1100
(c)	11.2	(c)	9.5
(d)	13.5	(d)	11.2
(e)	106	(e)	13.5
(f)	133	(f)	76
		(g)	53
		(h)	35

5.2 *Environmental quality*

A Life Cycle Assessment (LCA) analysis, in parallel with the prior cost analysis, has been carried out for a comparative evaluation between the two scenarios and comprehend their collective environmental potential (Domaneschi et al., 2023). The selected functional unit for comparative assessment and benchmarking is the bridge's individual surface area (km² bridge). The analysis has predominantly centered on the Global Warming Potential impact category (GWP 100ys, CML 2001 calculated in ton CO_2 eq.), utilizing environmental data developed from GENERIS® software (Fraunhofer 2023). These data stem from available product-specific information (Environmental Product Declarations, EPD) and average datasets for common construction materials (Federal Ministry for Housing, Urban Development and Building 2023). For products lacking specific environmental information, like expansion joints and bridge support systems, average datasets have been employed for initial environmental assessments. For example, both bearing systems has been modelled as a double steel plate and an elastomeric intermediate element.

It is crucial to note that in the LCA, functional amenities such as facilities, electrical and drainage systems, as well as safety barriers, have been intentionally omitted from the analysis.

Table 2. Environmental impact for each scenario.

Scenario #1 Phase	[ton CO_2 eq]	Scenario #2 Phase	[ton CO_2 eq]
(a)	171	(a)	54
(b)	165	(b)	189
(c)	30	(c)	3.8
(d)	385	(d)	30
(e)	23	(e)	385
(f)	out of scope	(f)	26
		(g)	out of scope
		(h)	out of scope
Total	778	Total	690
Ton CO_2 eq./km²	0.6	Ton CO_2 eq./km²	0.5

These elements have been deemed beyond the scope, as the primary focus was exclusively on the restoration scenarios themselves.

Parallel to the cost analysis, GWP calculations are tabulated and consolidated within interventions in Table 2. The ultimate environmental impact for each scenario emphasizes a reasonable similarity between them (Domaneschi et al., 2023).

6 RESILIENCE ASSESSMENT

6.1 *Transit capability*

This section discusses the functionality curves of the system for both retrofitting scenarios under consideration. While interventions encompass the entire viaduct, the primary focus of this work is on analyzing the three main piers from #22 to #24, which feature the largest spans consisting of cantilevers connected by Gerber beams. Expert bridge engineering specialists, involved in designing, executing, reinforcing, and rehabilitating similar bridge structures have been consulted to establish reasonable and realistic parameters for plotting functionality curves for each intervention type.

The initial phases, such as selecting the intervention designer, assessing technical-economic feasibility, finalizing executive designs, and administration, are estimated to take 6-8 months before the bridge closes for interventions. Safety concerns identified in inspections starting in 2020 have led to traffic limitations and reduced load intensity. This includes traffic restrictions, lowering vehicle weight limits to 500 kN and speed limits to 40 km/h.

Both scenarios aim to utilize existing piers and related foundational structures. Additionally, both scenarios account for the bridge's closure due to its single-carriageway design, preventing reconstruction partitioning.

Figure 2 illustrates the functionality curves for the proposed solutions, starting at time 0 when either the whole deck or Gerber beams only are demolished, resulting in a complete bridge closure. In Scenario #1, demolition using explosives is estimated to take around 10 days, while for Scenario #2, controlled demolition of the Gerber beams will take approximately 20 days.

For the solution involving deck replacement or a portion of it, it is assumed that before demolition starts, the replacement structure is prepared nearby for swift replacement. Specifically, installing the new deck is estimated to take 3 months for Solution #1. Scenario #2, involving new Gerber beams and external prestressing cables for the cantilevers, is estimated to take 5 months.

Upon construction completion, the estimated timeline for testing, processing (technical-administrative approval), and full bridge reopening is set at 90 days. Post this period, it is assumed that the bridge's transit capability will be restored to 100%. Resilience values for the different scenarios considering a maximum closure period of 360 days are tabulated in Table 3.

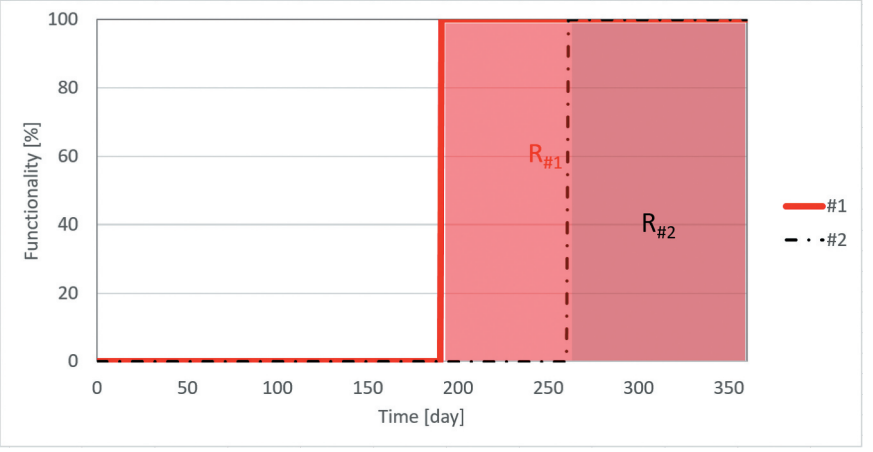

Figure 2. Functionality curves and resilience (transitability).

Table 3. Resilience values computed through transit capability.

Scenario	#1	#2
Resilience	0.47	0.28

6.2 *Capacity*

It is interesting to analyze the problem of assumed interventions by considering structural capacity and its restoration instead of transit capability. Consequently, for capacity analysis, purely administrative aspects are neglected. Obviously, it is necessary to introduce some assumptions, for example, it is assumed the linear pattern of the recovery curves, which in real conditions are associated with high uncertainty, including pauses, accelerations, and so on.

Shows the trends of the capacity curves for the various assumed scenarios, while Table 4 reports the resilience values computed concerning capacity.

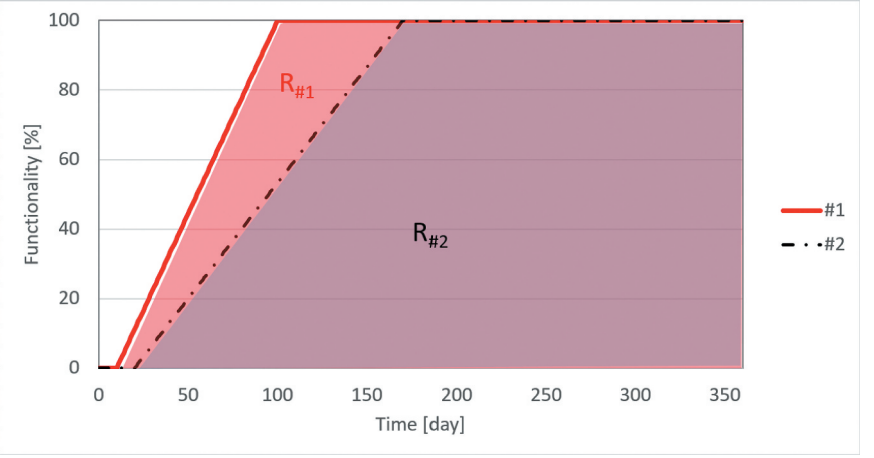

Figure 3. Functionality curves and resilience (capacity).

Table 4. Resilience values computed through capacity.

Scenario	#1	#2
Resilience	0.85	0.73

7 CONCLUSIVE REMARKS

This investigation assesses retrofit for the deteriorating Polyfytos Bridge using advanced surveying tools. A couple of different interventions are evaluated in terms of cost, sustainability, and resilience, aiming for a comprehensive (holistic) retrofit approach. Initial findings highlight cost disparities and interesting differences in resilience when transit capability is considered among interventions. On the other hand, the environmental impact, and the resilience values in terms of capacity results are reasonably equivalent.

Differences in resilience calculations, whether focused on transit capability instead of capacity, indicate how bureaucratic and administrative components might impact the process and, consequently, resilience by extending downtime. This underscores the significance of administrative efficiency in mitigating delays during retrofitting or maintenance processes for bridges. Streamlining bureaucratic procedures and administrative tasks can significantly minimize the downtime experienced during these critical infrastructure projects. Efficient

administrative processes contribute to shorter project timelines, reducing disruptions to the bridge's functionality and overall resilience of transport infrastructure.

Deterioration rate diagnosis to global climatic change: The case of Dnipro Dam in Ukraine

N.S. Kopiika & J. Ninic
University of Birmingham, Birmingham, UK

R. Cucuzza
Politecnico di Torino, Turin, Italy

S.A. Mitoulis
University of Birmingham, Birmingham, UK

ABSTRACT: Global climate change and increase of CO_2 emissions have dramatically influenced the deterioration processes in concrete structures worldwide. Thus, increased rate of carbonisation-induced corrosion for long-operated concrete structures has become one of the most critical durability issues in recent years. Although significant research has been conducted on the development of comprehensive approaches for evaluating the carbonisation effect on remaining resource, the application of existing models to particular case studies and bridging the gap between theory and practice is still underexplored, which is the main motivation for this study. Existing carbonisation-induced numerical models are investigated and applied to this case study. Results demonstrate the criticality of structural deterioration in conditions of global climatic change and this highlights the need to account for environmental changes in design and practice.

1 INTRODUCTION

In recent decades, an alarming change of climate was witnessed, the most important signs of which are relentless temperature increase and enhanced carbon dioxide emissions. According to Mauna Loa Observatory (MLO) measurements, the atmospheric CO_2 emissions increased by 100 ppm during last 60 years, which induced an increase in global air temperature by about 1° during last century (Bastidas-Arteaga et al, 2022; Talukdar et al, 2012). Recent patterns in climate change, including temperature and pollutant concentrations increment, changes in relative humidity and precipitation are widely recognized as one of the most pressing global challenges of our time. The consequences of these intertwined phenomena extend far beyond mere scientific curiosity; they encompass a complex web of ecological, economic, and societal ramifications. Within the scope of various influences, the phenomenon of global warming, characterized by an elevated CO_2 concentration, and the subsequent changes in temperature and relative humidity under specific circumstances, have the potential to expedite carbonation-induced corrosion. This, in turn, has the capacity to exert an impact on the longevity and operational capability of reinforced concrete (RC) structures (Saura-Gómez, et al, 2022; Coronelli, 2007; Anand et al, 2021; Lahdensivu et al, 2019). Given the predominant role of RC as construction type used in infrastructural assets and substantial direct and indirect expenses associated with their corrosion, even a minor acceleration of the corrosion process due to climate change can lead to substantial annual rises in maintenance and repair costs (Stewart et al, 2012). Considering that decreasing service life s in the context of a changing climate is among the most important research issues of interest, the development of approach to assess the level of deterioration of RC assets has reached its topicality during recent decades

DOI: 10.1201/9781003483755-310

(Ekolu, 2020; Inam et al, 2021). Most of existing studies in the literature provide the description of carbonization models, considering various influential factors. However, there is still insignificant amount of research, which would provide comprehensive illustration of application of such models on particular case studies- e.g. RC assets. Such demonstrative case study would provide valuable representation of the critical impact of structural deterioration in conditions of global climatic change and emphasize necessity to account environmental trends in design practice.

2 CLIMATE CHANGE AND CARBONATION-INDUCED CORROSION MODEL

Climate changes, reflected in various environmental factors (CO_2 concentration, temperature, humidity) have considerable impact on rate of deterioration especially in urban areas. In particular, corrosion damages in RC massive structures, operated during long time is a common problem for efficient exploitation of infrastructural systems. Initiation and propagation of corrosion damages, thus, could differ depending on structural type, loading schemes and aggressive environment, but in most cases include common stages: corrosion initiation, crack initiation and crack propagation. In this work damage due to carbonation induced corrosion will be considered, as one of the most common reasons of aged RC structures deterioration or even failure (Saura-Gómez, et al, 2022; Coronelli, 2007; Anand et al, 2021; Lahdensivu et al, 2019).

The point of carbonation -induced corrosion initiation (T_{init}) could be considered as the time when the carbonation depth reaches the surface of the rebar. Models for evaluation of carbonation depth, presented in the literature are based on Fick`s 1st low, and, according to Yoon et al. (2007) could be described by following Equation 1:

$$X_C = \sqrt{\frac{2D_{CO_2}}{\alpha} C_{CO_2} t} \tag{1}$$

where X_c = carbonation depth; C_{CO2} =atmospheric CO_2 concentration; D_{CO2} =CO_2 diffusion coefficient concentration. Further modification of this model was assumed by Stewart et al (2010) and Peng & Stewart (2014), by considering the time (t) dependent change in diffusion coefficient due to temperature ($f_T(t)$) and humidity ($f_{RH}(t)$) changes, as well as increased CO_2 levels in urban environment (k_{urb}), which could be expressed by Equations 2-3:

$$X_C(t) \approx \sqrt{\frac{2f_T(t)f_{RH}(t)D_{CO_2}(t)}{\alpha} k_{urb} \int_{to}^{t} C_{CO_2}(t)dt \left(\frac{1}{t-t_0}\right)^{n_m}} \tag{2}$$

$$D_{CO_2}(t) = D_1(t-t_0)^{-n_d} \tag{3}$$

where D_1 =diffusion coefficient after one year of operation of structure, which is assumed to increase in rate of age factor n_d; t_0 =time of beginning of exploitation; n_m = age factor for microclimatic conditions; k_{urb} =urban environment factor.

Increase of diffusion rate at high temperatures could be described according to Arrhenius Law:

$$f_T(t) = \exp\left(\frac{E}{R}\left(\frac{1}{293} - \frac{1}{273+T(t)}\right)\right) \tag{4}$$

In which the reference temperature of 20°C is considered; E= activation energy of the diffusion process; R =gas constant; $T(t)$=temperature change within the time (t) range.

According to Model Code for Service Life Design (fib, 2006), the impact of humidity changes ($RH(t)$) on the carbonation rate is taken into account by Equation 5:

$$f_{RH}(t) = \begin{cases} 0 & RH(t) \le 25\% \\ \left[\frac{1-(RH(t)/100)^{fe}}{1-(RH_{ref}/100)^{fe}}\right]^{g_e} & RH(t) > 25\% \end{cases} \tag{5}$$

where RH_{ref}= the reference humidity value (which in most cases is 65%); f_e and g_e=constant coefficients, equal to 5 and 2.5, respectively. Equation (5) reflects general trends of increase of diffusion rate up to RH=65%, while 100% humidity corresponds to f_{RH}=0. It is considered, the if RH is lower than the bottom level (25 %) carbonation would not begin due to small amount of water.

The degree of hydration (α) can be defined via Equation 6:

$$\alpha = 0.75 C_e C_{CaO} \alpha_H \frac{M_{CO_2}}{M_{CaO}} \tag{6}$$

where C_e=cement content; C_{CaO}=content of CaO in Portland cement; M_{CaO} and M_{CO2}= molar mass of CaO and CO_2, respectively; α_H= degree of hydration after more than 400 days, depending on water-cement ratio of concrete (w/c):

$$\alpha_H = 1 - e^{-3.38 w/c} \tag{7}$$

It could be assumed, that the stage of 1st crack initiation corresponds to time, when the 1st crack of 0.05 mm width is formed (T_{1st}), which is further followed by crack propagation and development, until the limit crack width is reached. (Stewart et al (2010))

Thus, further propagation of crack could be defined with the use of following model, which is obtained by reformulation of Stewart et al (2010):

$$\omega = \frac{i_{corr_20}(T - T_{init}) k_c ME(r_{crack}) r_{crack}}{0.0114 k_R} \tag{8}$$

where i_{corr_20}=corrosion current density at reference temperature (T_{ref}=20°C); ME(r_{crack})=error of the model, used for evaluation of crack propagation, which considers variabilities between model prediction and experimental data (assumed values of mean and COV are 1.04 and 0.09, respectively (Stewart et al (2010)). Also, ω=crack width; k_c=confinement factor, which is important for rebars, allocated at edges of RC structures, due to increased rate of crack growth at zones with insufficient concrete confinement. Other parameters in model are defined by Equations 9-11.

$$\psi_{cp} = \frac{Cov}{\varnothing f_t} \in [0.1 \ldots 1] \tag{9}$$

$$r_{crack} = 0.0008 e^{-1.7 \psi_{cp}} \tag{10}$$

$$k_r \approx 0.95 \left[\exp\left(-\frac{0.3 i_{corr(\exp)}}{i_{corr_20}} \right) - \frac{i_{corr(\exp)}}{2500 i_{corr_20}} + 0.3 \right] \tag{11}$$

where f_t=tensile strength of the concrete; $\varnothing$=diameter of the rebar; Cov=cover of concrete; r_{crack}=the rate of crack development, which is exponentially dependent on depends on the Cov, f_t, $\varnothing$. In order to consider accelerated corrosion rate ($i_{corr_20(exp)}$), required for enhancing crack development rate, loading rate correction factor k_r is introduced.

Equations listed above can be used for description of crack propagation within the time frame for RC structures, subjected to carbonation-induced corrosion. In particular the stage of corrosion damage (T_{sp}) corresponds to time when cracks in concrete cover reach the limit width (w_{lim} =1 mm). After the limit width of crack is reached, the corrosion of rebar is initiated, resulting in loss of steel bar cross-section, which, according to Stewart et al (2010) can be defined as:

$$\Delta\varnothing(t) = 2 \cdot 0.0116 \int_{T_{sp}}^{t} i_{corr}(t) dt \tag{12}$$

where temperature-dependent corrosion rate ($i_{corr}(t)$) is defined by equation, which is close correlation to Arrhenius equation:

$$i_{corr}(t) = i_{corr_20}[1 + K(T(t) - 20)] \tag{13}$$

Additionally, it is important to consider the effect of corrosion processes on material behavior. Cracking and spalling in the compressed concrete lead to more brittle behavior. Thus, enhanced transverse strains and longitudinal microcracking cause reduction of the compressive concrete, which is, according to model of Vecchio & Collins (1986) can be defined by (Coronelli & Gambarova (2004)):

$$f'_c = \frac{f_c}{1 + K\varepsilon_1/\varepsilon_{co}} \tag{14}$$

where ε_{co} =strain at the peak compressive stress f_c; ε_1 =average tensile strain:

$$\varepsilon_1 = \frac{n_{bars}\omega_{cr}}{b_o} \tag{15}$$

where b_0= initial width of the concrete cross-section; n_{bars}=number of bars in concrete cover; ω_{cr}=total crack width for a given corrosion level X_c:

$$\omega_{cr} = 2\pi(\upsilon_{rs} - 1)X_c \tag{16}$$

where ν_{rs}=ratio of volumetric expansion of the oxides.

The general scheme for the time margins of each stage of corrosion degradation, according to utilized carbonation model is given in Figure 1.

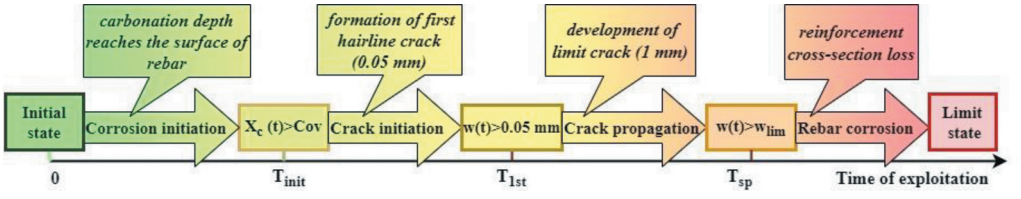

Figure 1. Main stages of degradation model.

3 CASE STUDY: RESULTS AND DISCUSSION

3.1 *Description of the case study -Dnipro HPP Dam-Bridge complex*

The Dnipro Hydroelectric Station (Dnipro HPPS) is the largest hydroelectric power station on the Dnipro River (Ukraine) and one of the most important network nodes, serving for both electric power provision for the most important industrial regions of country and enabling connection between two banks and communication within the country. As the part of transport infrastructure of Ukraine, the bridge of Dnipro HPP complex enables connection of the most important geopolitical centers and districts of the country, efficient operation of transport and logistic routes.

The Dnipro HPP consists of 49 supports that are connected from above by a monolithic reinforced concrete overpass. Its length is 760 meters, and its height is 60 meters (see Figure 2).

Dnipro HPPs complex is the oldest hydro-power station in the territory of Ukraine, which is the reason of increasing attention to its technical state and reliable operation regime. Its construction commenced in 1927, with the first hydro-unit being put into operation in 1932, while the design capacity of 560 MW was reached in 1939. Considering such long-term of operation of the

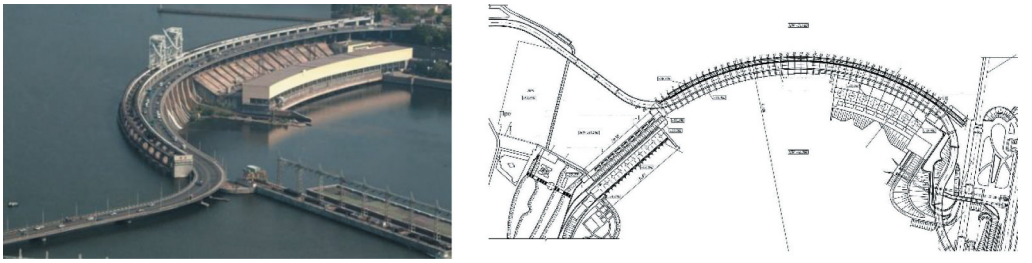

Figure 2. General view of the case study (Dnipro HPPS, Zaporizha, Ukraine).

structure in aggressive environment it is obvious, that its technical state and remaining resource requires specific attention: remote monitoring of deformations and structural state, on-site inspections of signs of deterioration, tracking damages growth. The HPP complex, in particular its bridge part is subjected to ageing, physical wear, intensive impact of humidity, etc. The strengthening measures, introduced during the last years enabled to slow down the process of destruction of structures. However, as was stated by Head of Ukrhydroenergo, based on trends of worsening of damages, the risk of destruction of the damn is increasingly reaching the emergency level (Press Service of Dnipro HPP in Politeks; Forpost). However, the ongoing military situation in Ukraine makes it impossible to conduct reconstruction works on this structure. Thus, the assessment of remaining capacity and corrosion-induced deterioration level is of prevalent importance.

3.2 *Climate changes in Ukraine and globally: Anthropological impacts*

Ukraine, as many other parts of the world has faced considerable climate changes during recent decades, which has become a growing concern, raising the public attention to necessity of adaptation measures and more precise assessment of structural deterioration parameters. In particular, a consistent increase in temperatures has been recorded, which is especially urgent for urban areas due to urban heat island effect (which is relevant for the case study in this research). Thus, according to the information of World Bank Group, temperature patterns for the examined period of time (period of exploitation of the case study, - 1932-2023) reveal the rise of annual mean average temperature by approximately 1.7 °C, while the August temperature anomalies show the increase by 2.54 °C per decade, according to NOAA National Centers for Environmental information (see Figure 3, a).

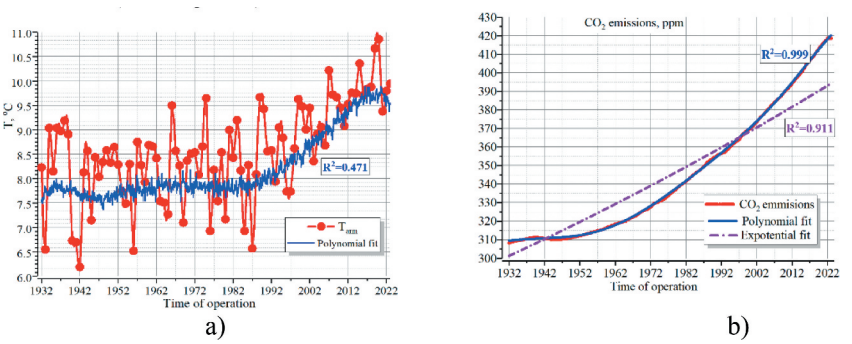

Figure 3. Patterns of climate changes in Ukraine for studied period of time (in the area of interest-Zaporizha, Ukraine): a) annual mean average temperature; b) The increase of CO_2 concentration.

The increase of CO_2 emissions and the rise in temperature are closely interlinked aspects of climate change, as increased levels of CO_2 in the atmosphere enhance the greenhouse effect, leading to a gradual rise in global temperatures. This issue has reached its topicality during recent years, as the concentration of CO_2 has ben steadily increasing after during last century

(see Figure 3, b) up to warning level, resulting in more frequent and severe heatwaves, changing precipitation patterns, and a rise in sea levels, among other effects.

3.3 *Assessment of deterioration due to carbonation induced corrosion*

Carbonation induced corrosion damage has critical impact on RC structures, subjected to long-term operation in aggressive environments, which is demonstrated with the use of case study. Deterioration model described above was used for assessment of level of corrosion damage to Dnipro HPP complex (Zaporizha, Ukraine). Values of initial parameters, used for the case study with reference sources are given in Table 1.

Table 1. Initial parameters for assessment of damage level of case study.

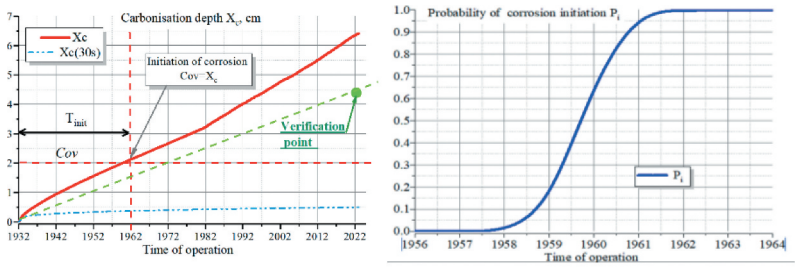
T_{ref}	20	°C	RH_{ref}	0.65	%	Peng & Stewart, 2016

Parameters and coefficients of empirical model of corrosion propagation were taken from the studied literature (see Section 2). In order to consider structural parameters of the particular case study, archive materials of experimental testing of the concrete samples from Dnipro HPP in 1930 were thoroughly studied.

Thus, with the use of equations and assumptions, described in previous section, the corrosion initiation and propagation in the particular case study was assessed and its effect on remaining capacity was evaluated.



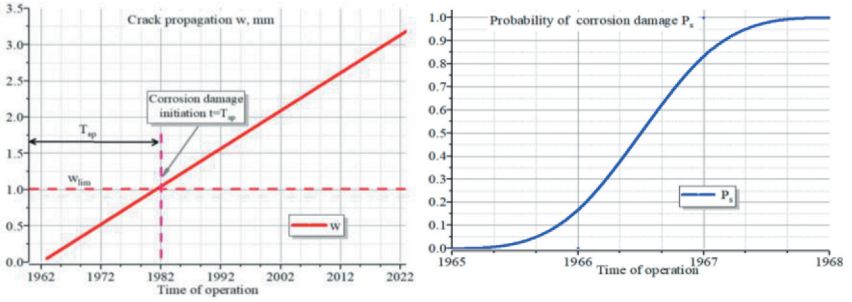
The cumulative probability of corrosion initiation (*Pi*) at time *t* is defined regarding the rapidity of carbonization depth propagation, defined by Equation (2):

$$P_i(t) = \Pr[Cov - X_c(t) < 0] \tag{17}$$

It is assumed, that the corrosion damage of reinforcement is initiated after the time when concrete cover severely cracks with limit width and its cumulative probability (P_s) at time *t* is:

$$P_s(t) = \Pr\left[t > T_{sp}\right] \tag{18}$$

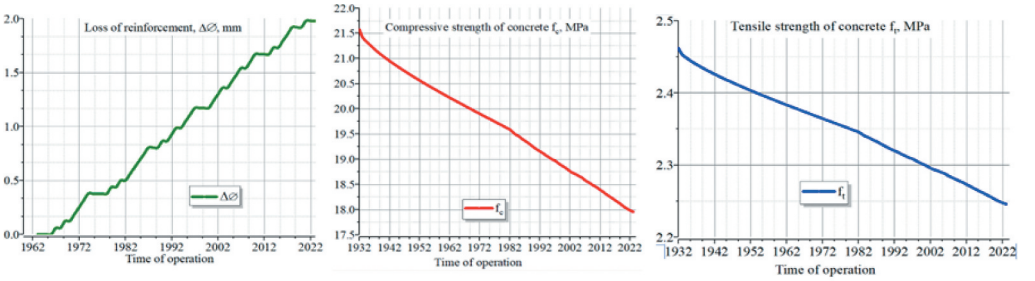
It is important to emphasize, that the construction of this asset was performed with accordance to design regulations of early 1930s`, which do not meet the requirements of nowadays in terms of both sustainability, transport capability and resilience. In addition, design practices of that time did not consider climate changes and cumulative effect of carbonization induced corrosion. This becomes obvious from the values of concrete cover (20 mm), which does not ensure requirements of sufficient protection of rebar from corrosion (see Figure 4).



a) b)

Figure 4. Results of assessment of corrosion initiation stage for the case study: a) carbonization depth; b) probability of carbonization induced corrosion initiation.

Considering the results, illustrated in Figure 4, it can be assumed, that the corrosion initiation point was reached after 20 years of operation of structure (1932-1950), which was further followed by crack initiation stage, the indicator of which is formation of 0.05 mm hairline crack. Graph $X_c(30s`)$ on Figure 4 demonstrates the results of similar calculations (Equation 2), if climate effects are neglected, which reveals underestimation of deterioration impact on structural safety.



Application of crack propagation model to the Dam-Bridge structure has shown, that after the crack initiation (about 30 years of operation, -1932-1963), cracking width was increasing at enhanced rates and reached the limit value of 1 mm, evoking the beginning of corrosion damage to reinforcement (see Figure 5). Time-dependent corrosion loss or diameter of rebar according to Equation (12) follows the linear trend and for studied concrete structure could reach the value of about ΔØ=2 mm (see Figure 6,a). Finally, the approach for assessment of corrosion-induced strength decrease of concrete in long-term operated structures was applied to Dnipro HPP complex and results are demonstrated by Figure 6, b-c.

a) b)

Figure 5. Results of assessment of crack propagation and corresponding probability of corrosion damage for the case study: a) crack development; b) probability of initiation of corrosion damage.

Results, obtained with the use of proposed empirical model in general correspond to on-site observations, described in several technical reports (Onyshchenko, et al, (2021)). In particular,

a) b) c)

Figure 6. Time dependent degradation factors in corroded RC structure (case study): a)the rate of corrosion loss of the rebar diameter in the case study; b) decrease of concrete compressive strength; b) decrease of concrete tensile strength.

worsened condition of structural components was observed during visual and instrumental inspection by Galat, et al (2022), which manifested itself in increased number of cracks, areas of corrosion of concrete and reinforcement in comparison with previous inspections (2008, 2017 2021). Carbonation depth, assessed with the use of chemical reaction between phenolphthalein and the alkaline environment of concrete, reached the values up to 45 mm (Galat, et al (2022)), which is slightly lower than assumptions from empirical model (see verification point on Figure 4). Similarly, crack widths, measured during inspections were 1- 20 mm, thus the calculated values are within the range. However, although the assumptions of empirical model us this study overestimate the rate of corrosion propagation, it could still provide reliable qualitive supposition. Similar observations were reported in reports of governmental authorities, published in social media (Politeks; Forpost). Further adaptation and refinement of empirical model could be performed with the use of laboratory tests on concrete samples with particular concrete properties and particular conditions (Blikharskyy et al, 2021).

4 CONCLUSIONS

This paper employed a time-dependent analysis for interpreting the deterioration processes in RC structures due to carbonization-induced corrosion, which is becoming critical due to exacerbated environmental conditions as a result of climate change and increasing CO_2 in the atmosphere. Empirical models for the assessment of carbonisation-induced corrosion are introduced and applied to a real case study of an important asset of transport infrastructure in Ukraine. Results revealed the paramount role of climate changes and increased CO_2 emissions, witnessed recent decades, on rate of ageing and decrease of service life of RC structures, which is an important factor worldwide. To attain the desired service life for concrete structures it is essential to account for the environmental stressors in design practice, incorporating appropriate concrete cover with a margin of safety to mitigate the risk of carbonation-induced corrosion. Simultaneously, a more methodical approach, involving the analysis of concrete structures in real-world conditions across different environments, is necessary to address this matter effectively.

Model-driven strategy for bridge measurement-system design

R. Galli & D. Briccola
University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Mendrisio, Switzerland

ABSTRACT: Increasing traffic volumes on aging structures force bridge operators to periodically evaluate infrastructure performance and assess safety using code and model-driven analyses. Of course, the integration of prediction and monitoring techniques improves the management of critical infrastructures providing meaningful information, but it is not easy to interpret hundreds of data. Nowadays, disruptive IoT technical advances suggest that data-driven approaches must be preferred to model-based. This is potentially harmful as it is not true that the more data collected, the more information gained on elements' condition and structural safety. Moreover, since technical decisions are supported by finite-element analyses it appears useful to profit from a priori knowledge of the structural behavior to support sensor placement and enhancing data interpretation. That way, the natural bottleneck to the amount of data imposed by code verifications is automatically considered enabling time and resource savings for superior bridge management.

1 INTRODUCTION

A way to enhance societal and economic benefits while effectively reducing the construction industry's carbon footprint is by extending the service duration of existing bridges.

As a result, extensive structural analysis is essential to assess the actual load-carrying capacity of aging infrastructures. For instance, when dealing with main bridges in a road network, an uncertainty quantification framework is needed to estimate the evolution in time of structural performance. That poses significant challenges to the scientific and technical civil engineering community as it requires the collection of multiple information on actual material parameters and loads and an extensive knowledge of reliability assessment methods.

However, collecting more data does not necessarily correspond to gaining more information on structural performance. Despite the relevance of understanding cause-and-effect scenarios for decision-makers is evident, the technological development of sensors and disruptive Internet of Things (IoT) techniques, advocating for data-driven approaches, sometimes encourages a too simplistic overreliance on sensor-based data collection for early warning.

By contrast, structural health monitoring (SHM) can help collect data on actual traffic loads, detect unexpected structural performance, and identify structural deficiencies through sound engineering judgment. Especially when dealing with complex bridges, as reported by Malomo D. (2020), the pure detection of changes in the performance of specific elements in time, without being aided by robust structural analysis, is not enough to choose how to intervene. Hence, the integration of dynamic and static analysis is crucial to assess aging bridges (Bertola N. J. (2019)).

Following this approach, for a specific bridge typology, the study demonstrates that to get the best out of computational and monitoring techniques, a-priori structural assessment is unavoidable, and it lays the foundation for both effective monitoring system design and robust data interpretation. Symmetrically, data collected through monitoring are of value for updating structural model parameters using Bayesian techniques if and only if the number and location of sensors are accurately selected.

DOI: 10.1201/9781003483755-311

2 SIGNIFICANCE OF A MODEL-DRIVEN STRATEGY FOR SENSORS PLACEMENT

The thrust towards digital-twinned asset management, a relevant topic at the interface between science and policy, will increase, posing several challenges and opportunities to the civil engineering community. Nowadays, this trend is encouraged by the availability of ever-increasing amounts of data collected in real-time using different types of sensors and high-computing infrastructures. Nevertheless, this emerging approach will represent a game-changer paradigm for bridge management if, and only if, meaningful information emerges from processing data. In other words, monitoring data does not have a value of information by themselves but only after robust data interpretation through numerical models. As emphasized by Smith, I.F.C (2016), this approach goes beyond anomaly detection, typical of the early-warning approach, but stems from cause-and -effect research to inform decision-making processes according to structural identification purposes. In structural identification, other than data interpretation, numerical models can aid civil engineers in measurement-system design by defining sensor type, number, and location, overcoming currently qualitative rules-of-thumb approaches. Of course, the larger the number of sensors, the larger the possible sensor-placement configurations, but not necessarily the information gain. Therefore, the goal of each measurement-system design is to reach a balance between the less-invasive measurement system and the information gain. That enables civil engineers not to be overwhelmed by large amounts of not-valuable data and to design cost-effective data acquisition systems. Conversely, it is true that dealing with sparse data sets, as data collection points are few, poses relevant challenges. In short, two tasks are impactful: the sensor configurations selection based on sensor-placement methodology, and the identification of mechanical parameters according to the actual condition state of the bridge, based on structural identification methodology. Several sensor-placement methodologies exist (Papadimitriou, C. (2004), Argyris, C. (2017) and Papadopoulou, M. (2014)). As per the data-interpretation methodology, the Error Domain Model Falsification (EDMF) methodology helps identify plausible mechanical parameters for structural modeling by evaluating model-instance predictions against field measurements through an iterative approach at each sensor location. The mechanical parameters corresponding to those structural models grounded in engineering judgment, whose outcomes (model instances) are compatible with recorded data, within a threshold bound, feed a candidate-model subset (CMS), while the other structural models are dismissed. These bounds are calculated based on the modeling and measurement uncertainties and a target reliability of identification, according to a predefined confidence level that represents a tradeoff between accepting incorrect models and falsifying the correct one. The CMS is later used to assess structural performance evolution in time. The EDMF methodology has proved to be effective for structural identification purposes even in the case of biased structural models if enough data measurements are used. Unfortunately, this is not the case for bridges characterized by only a few sensors each due to costs and integration challenges. In case of biased (wrong) modeling and few data, the real set of mechanical parameters is at risk of falsification, as inferred from Goulet, J-A (2013). As a result, a greater effort in modeling is needed, especially when dealing with complex structures. For instance, for very old bridges characterized by an evident state of obsolescence, well-recognized standard degradation models, such as the one developed by Coronelli D. (2004) can be introduced in the structural model used for EMDF. This approach can potentially reduce model bias and therefore the model predictions -measurements discrepancies, accelerating the identification of the candidate-models set. In short, for structural identification purposes, a model-driven approach is a rewarding choice both for measurement-system design and data interpretation.

3 MODELING APPROACH

In the following two finite-element models were employed to uncover the distinctive structural behavior of a Maillart-type deck-stiffened bridge to provide a sound basis for the EMDF approach. Moreover, it is shown that the finite element models serve to obtain meaningful information for measurement system design, limiting the type and number of sensors.

As physics-based models represent an idealization of reality, modeling simplifications as omissions of secondary elements, changes in the load distribution, and avoidance of soil-structure interactions can affect static and dynamic predictions at several locations and to varying degrees, vinifying the EDMF approach for structural identification. For this reason, to reduce the model bias in EDMF, a sound analysis of the possible loading scenarios to provide meaningful model instances was carried out. Despite being comprehensive, the analysis was necessarily simplified for the sake of brevity as explained in the next section.

A detailed description of the reinforced concrete deck-stiffened bridge, finite element models, and loading scenarios follows. For the sake of brevity, the aleatory uncertainty on model parameters was not considered, and deterministic finite element analyses were carried out. Moreover, we hypothesize dealing with a new bridge, therefore a linear elastic analysis adopting for reinforced concrete E = 30GPa was carried out and geometrical nonlinearities were not accounted for.

3.1 *Bridge geometry and materials*

Inspired by an existing Maillart bridge crossing a river and built in reinforced concrete in the 50s in Tessin by Walter Krüsi, a detailed structural model was reconstructed to carry out both static and dynamic analysis. Figure 1 shows a view of the bridge taken as an example to derive the actual bridge geometry, there briefly described.

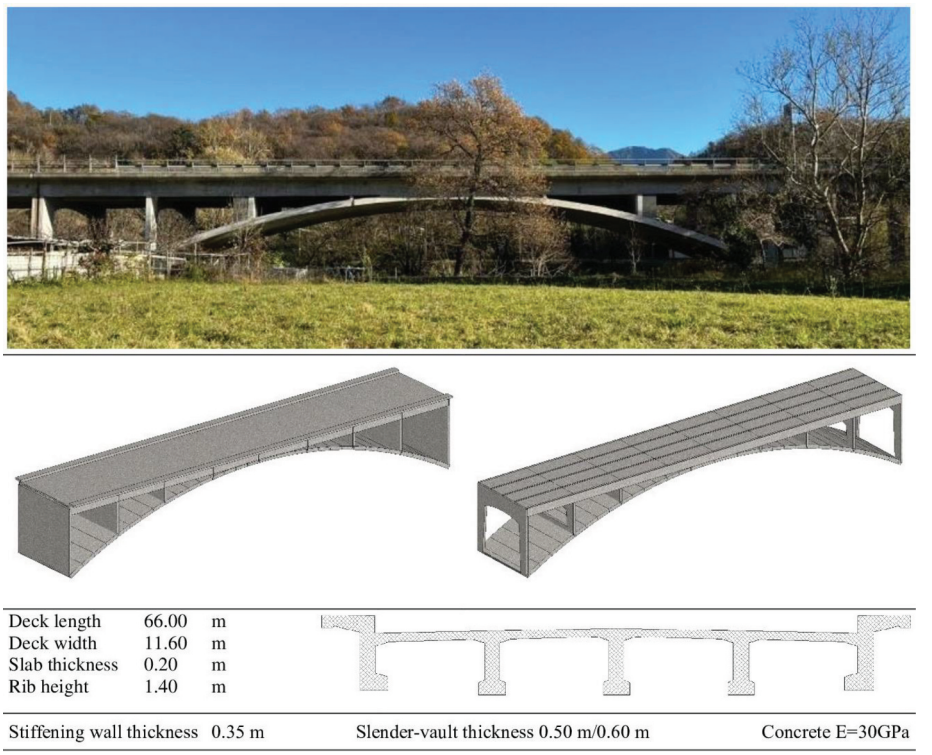

Figure 1. Viadotto Taverne-Torricelle, Lugano, 1951, finite element models and bridge characteristics.

3.2 *Finite element models*

1D- and 2D- finite elements were used to model the bridge and perform both static and dynamic analysis. Information gain, workload, and computational time are of course different. The number of elements and computational time, based on the computing PC performance in Table 1, are listed in Table 2. Despite a significant workload increase in modeling time, especially in applying traffic load according to influence line theory, and the intrinsic opportunity

with the 2D- model of getting information on torsional natural frequency and mode shapes, the two finite element models provide similar results as it will be shown in next section.

Table 1. Computing performance.

PC characteristics:	6 cores processor 2.30GHz with graphic board	16GB RAM

Table 2. Characteristics of finite element models.

1D - Finite element model	2D – Finite element model
147 beam elements	20,216 shell elements – 750 beam elements
5s for static and dynamic analysis	150s for static analysis – 350s for dynamic analysis

3.3 *Load case scenarios: Static analysis*

The self-weight, permanent loads (including pavement, safety barriers, additional equipment installations), and traffic loads were evaluated based on influence lines (1D- finite element model) and surfaces (2D- finite element model) according to design code specifications. In a highly collaborative structural system like this, the influence of kinematic fields such as localized settlements at springers and distortions like temperature and prestressing cannot be ignored. These factors can lead to significant internal force redistribution, potentially resulting in partial/global collapses. In case of localized settlements, both displacement direction and magnitude are meaningful to assess stresses in the deck. For this study, only horizontal component is of interest.

4 PROPOSED MEASUREMENT-SYSTEM BASED ON STRUCTURAL ANALYSIS

Accelerometers and strain gauges are valid monitoring sensors for structural identification purposes. Driven by cost-effectiveness and pursuing valuable structural health monitoring, the minimum number of such sensors can be established based on previous outcomes. To do that, the a priori knowledge of the dynamic response and the distribution of internal actions due to permanent, traffic, and imposed kinematic fields (temperature and localized settlements at springer) is meaningful.

Figure 2 shows the bending moment distribution along the deck as a function of increasing small (on the left) and large (on the right) horizontal displacement at the left/right springer.

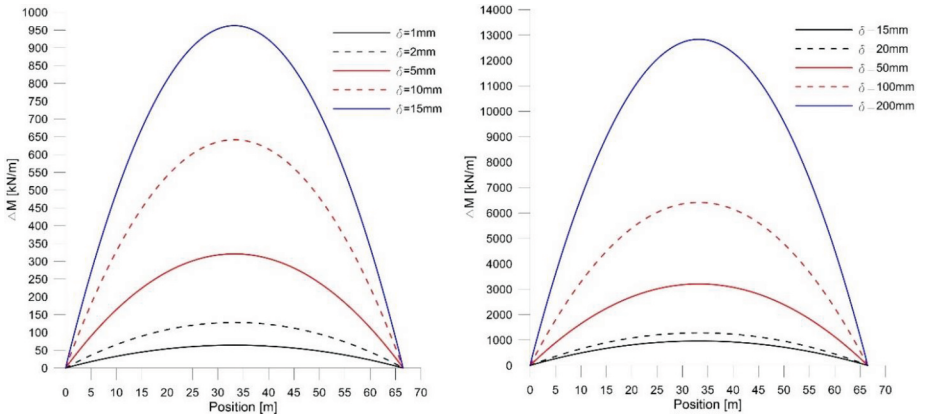

Figure 2. Additional bending moment along the deck due to a horizontal settlement occurring at one of the springers. Different magnitudes are considered.

A careful examination of the values obtained under a linear elastic analysis proves that there is not perfect direct proportionality between the settlement increase and the maximum bending moment at the midspan along the deck. That results from the high deck-arch collaboration typical of the Maillart-type deck-stiffened solution.

As the horizontal displacement's magnitude grows, the axial force in the vault diminishes, and there are noticeable variations in the bending moment along the deck. This illustrates the arch's stiffening effect on the deck: the lower the compression, the greater the bending moment along the deck.

Regarding the dynamic response, nine out of fifteen (the most important in terms of frequency for civil structures and participant mass, evaluated with modal analysis) are global modes, some of which are depicted with their nodes and antinodes in Figure 3. The two finite element models outlined in Section 3 differ in the natural frequencies and mode shapes they capture. Mode 11 signifies a global displacement along the longitudinal axis at a frequency of 15.42 Hz (1D-model) or 13.86 Hz (2D-model). Mode 4 represents a global displacement along the vertical axis, perpendicular to the deck, at a frequency of 3.42 Hz (1D-model) or 3.38 Hz (2D-model). Mode 1 is a rotation about the transversal axis at a frequency of 0.92 Hz (1D-model) or 0.83 Hz (2D-model). The 2D-finite element model's superiority lies in its ability to reveal torsional local and global mode shapes, which is crucial when dealing with highly collaborative structural systems.

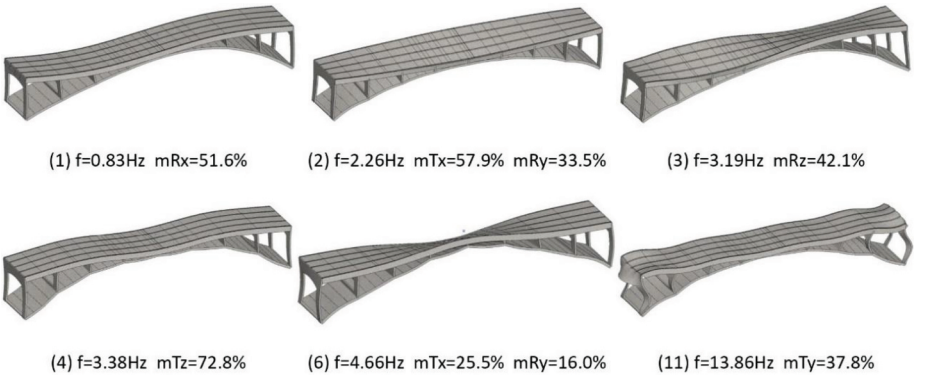

Figure 3. Eigenfrequencies and eigenmodes. Modes (1) Rotation about the transversal axis; (2) Translation along the transversal axis coupled with a rotation about the longitudinal axis; (3) Rotation about the vertical axis; (4) Translation along the vertical axis; (6) Translation along the transversal axis and rotation about the longitudinal axis; (11) Translation along the longitudinal axis.

The proposed model-driven strategy for bridge measurement system design follows:

(i) according to modal analysis, antinodes represent the most reasonable sections to place accelerometers as motion is maximum. The sensor number can be limited based on the accelerometer's capability of recording data in all directions after consideration of all mode shapes and corresponding antinodes.

(ii) after the installation of accelerometers, the comparison between model- and data-estimated natural frequencies can uncover possible cracking induced by corrosion, leading to stiffness changes. Severe material degradation has occurred if significant differences between model and data-driven natural frequencies exceed a threshold. Otherwise, linear elastic analysis is enough to determine the bridge's static structural response.

(iii) If that holds, adding to the measurement system strain gauges, suitable for strain measurements and internal action estimation, is crucial. That enables gaining more information on the structural response evolution over time. For the bridge under consideration, sections B, G, and I in Figure 4 are good points for strain gauge installation. Collected strain data can be analyzed using descriptive statistics to obtain meaningful information on data sets by evaluating measures of central tendency - like mean, median, and mode – and measures of variability like standard deviation variance, minimum and maximum,

kurtosis, and skewness, as well as quartiles. If the analysis of collected acceleration data reveals that no stiffness changes have occurred -see (ii) - then the mode of the strain data set can be considered because of permanent load, while variability relates to traffic loads (main variable action) or other loading actions.

(iv) Moreover, if no cracking occurred, it is worth adding tilt sensors at springers to detect settlements and interpret collected strain data evolution in time, considering the bending moment distribution shown in Figure 2.

(v) finally, temperature affects both internal force distribution in statically indeterminate structures and the performance of sensors like strain gauges. The use of thermocouples related to strain gauges and a priori knowledge of the temperature contribution to internal actions can be set as a benchmark against field measurements, eventually avoiding unnecessary model parameters updating. A bridge in operation experiences a significative non-linear temperature distribution that affects field measurements and depends on numerous parameters like bridge orientation, seasonal trends, solar radiation, pavement detailing, and cross-section shape (not only on its height).

Table 3. Location of nodes (e_0) and antinodes (e_{max}) for nine most important global modes.

Mode	1	2	3	4	5	6	7	8	11
Sec_e_{max}	E	I_{ext}*	E_{ext}	E	C	I_{ext}	I	G_{ext}	I
Sec_e_0	I	Axis	Axis	I	I	Axis	G	I	A

* The measurement is not in the axis for torsional modes.

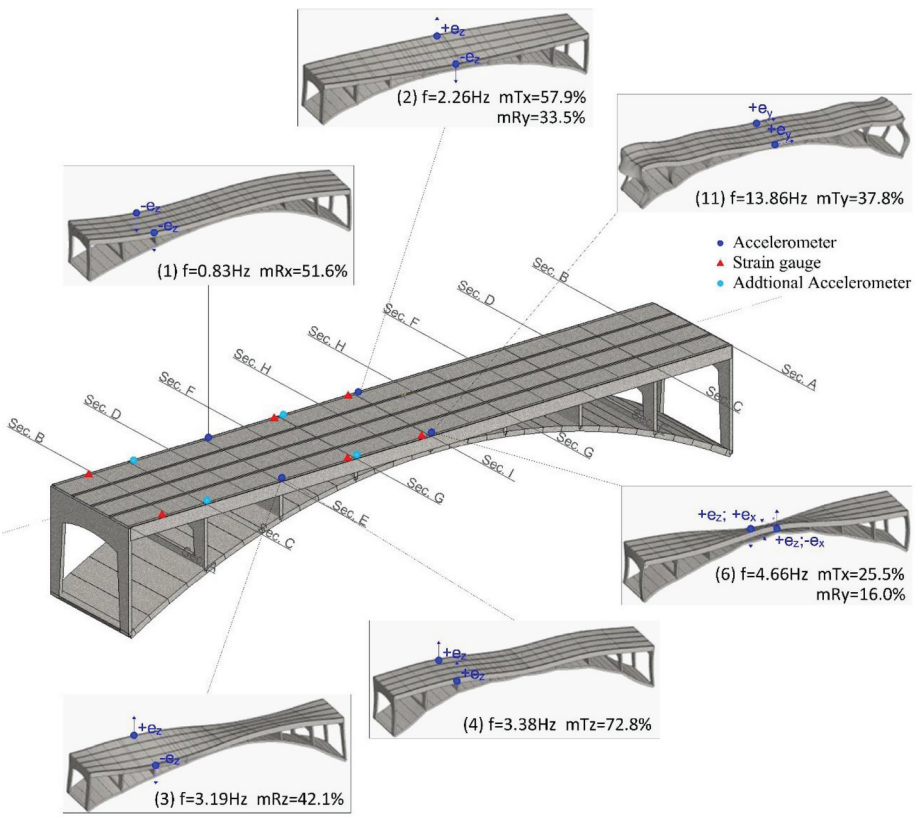

Figure 4. Sensor-placement plan based on static and dynamic analyses considerations.

In conclusion, the design of a measurement system is contingent on the type of monitoring activity, be it for damage detection or structural identification. Numerous sensors can be incorporated into a monitoring system. For example, strain gauges, which measure strain or deformation, and accelerometers, which evaluate the dynamic response of a bridge. Additionally, displacement sensors - such as laser, vibrating wire, or potentiometric technologies - and temperature sensors - like resistance or thermocouples - can be utilized. Lastly, load cells, which measure forces on a bridge (weight on the deck), and tilt sensors, which gauge the magnitude and direction of settlements, are other viable options.

Laying on that, the model-driven strategy proposed, and the model updating phase based on data is shown in Figure 5.

Figure 5. Steps of the proposed model-driven strategy for measurement-system design.

5 CONCLUSIONS

The benefits of bridge monitoring sensors include early detection of structural issues, cost savings on repairs, increased bridge lifespan, and improved safety for users. While challenges exist in terms of sensor installation, data management, and integration, future developments in wireless and MEMS (Micro-Electro-Mechanical Systems) sensor networks, IoT integration, and AI-based solutions hold promise for enhancing bridge monitoring systems. Advancements in the IoT enable the seamless connection between modeling and the digital realm through the

continuous exchange of recorded data and analysis outcomes. As highlighted by Bertola, N.J. (2020), robust data interpretation methodologies are imperative for asset managers to make informed decisions on intervention, while considering constraints on monitoring system invasiveness during bridge operation. Furthermore, considering the size of bridge stocks, and the available resources, the number and placement of sensors is usually limited. The goal is to minimize the number of installed sensors while retaining valuable information for structural identification. In the study, a model-centered approach to measurement-system design was proposed. A comprehensive examination of static and dynamic responses enables the determination of optimal sensor locations, the extent to which each accelerometer provides information on specific behaviors, and the assessment of mutual information gain among sensors. Moreover, a key objective was showing the need to integrate measurement-system design during the initial design phase. The methodology is flexible as it can be easily extended to other structures.

The key to success lies in tailoring the monitoring plan to the specific characteristics of each structure, thereby making a substantial contribution to ensuring the long-term safety of the infrastructure.

Quality assurance of intervention in reinforced concrete bridges

A.C.P. Martins, G.F.B. Milagres, J.M. Franco de Carvalho, C.A.F. Souza, F.G. Bellon, M.S. Andrade, D.S. Oliveira, K.M.L. César Jr & J.C.L. Ribeiro

ABSTRACT: Due to the nature of the loads and the environmental conditions to which bridges are exposed, these structures can be subject to rapid aging and deterioration. As a result, various pathological manifestations caused by chemical, physical, biological or mechanical agents may appear and develop. Thus, bridges require an effective monitoring and preventive maintenance program. Some types of materials, repairs and methodologies were discussed to evaluate the efficiency and control the quality of commonly used repair techniques, proposing an approach based on a database of inspected Brazilian bridges and their maintenance plans provided by the *Departamento Nacional de Infraestrutura e Transportes (DNIT)*. The most recurrent damage in reinforced concrete bridges were mapped and the most common repair interventions were identified. Finally, inspections were suggested to assist with quality control, acceptance and reliability of the repair, to ensure that the selected materials and techniques are suitable for each specific type of damage.

1 INTRODUCTION

Ensuring the integrity and safety of bridges requires continuous monitoring and timely execution of maintenance, repair, rehabilitation, or strengthening measures (Kasireddy & Akinci, 2015). Reinforced concrete structures suffer the loss of integrity over time due to degradation caused by chemical agents (alkali-aggregate reaction, corrosion, leaching, chloride and sulfate attacks, carbonation, efflorescence), physical (gradient of temperature, fatigue, overload, retraction, freeze-thaw cycles), biological (accumulation of organic matter, living organisms) or mechanical, and from this deterioration process arise pathological manifestations that affect the condition of the structures (DNIT, 2010; Helene, 2005; von Fay, 2015). Each of these agents can, individually or jointly, contribute in different ways to the emergence of damage in the structure. However, concrete deterioration is related to a single origin (Bolar et al., 2013).

The Bridge Management System (BMS) has the decision-making process as one of its most essential functions in bridge management, especially in prioritizing maintenance, repair, rehabilitation, and replacement (Contreras-Nieto et al., 2019; Lee & Kim, 2007). This process is vital to directing restricted budgets toward bridges that need maintenance and repair, requiring detailed information to select the most appropriate and cost-effective intervention strategies (Lee & Kim, 2007; Yehia et al., 2008). There is substantial pressure to extend the useful life of existing infrastructures, considering sustainability and their environmental impact. This circumstance forces the industry to offer more durable and efficient measures to preserve and repair concrete structures (Matthews, 2007).

Various repair and reinforcement materials and techniques have been implemented to rehabilitate these structures and fulfil the loads for which they were designed or even higher ones. However, it should be noted that several factors affect the selection and durability requirements of these interventions, such as the inappropriate selection of materials, lack of compatibility between the repair and the substrate, and the use of incorrect techniques for the intervention, creating the need to control the performance of the reinforcement, so that it is effective for the purpose for which it was carried out (Murthy et al., 2018; Su et al., 2021).

DOI: 10.1201/9781003483755-312

Techniques used to repair and reinforce concrete structures include sealing cracks by injection, stapling cracks, applying material to the surface to reconstruct or increase the cross-section, external prestressing, application of externally bonded reinforcement (EBR) or near-surface mounted (NSM), surface cleaning, application of corrosion inhibiting products, among others. Among the various techniques, several materials are used for different applications, depending on the need for the intervention. Existing materials include waterproofing, cement mortars, conventional concrete, polymer resins, polymer fibers, adhesives, and anti-corrosion protectors.

These materials and techniques aim to ensure that the structure has its mechanical strength restored or increased, as well as helping to protect the structure against aggressive agents, improving the chemical and physical resistance of the covering material of the structure, and can be applied as a preventive and corrective measure for the structural element (Sánchez et al., 2018).

As interventions on structures are carried out, greater inspection and maintenance requirements and criteria become essential since the interface between reinforcement or repair materials and the concrete substrate generally constitutes a zone of fragility for the reinforced structural element. Regarding the fatigue loading to which bridges are generally subjected, it is also necessary to monitor and assess the progressive damage that occurs in reinforced concrete structures that have been strengthened and repaired, and it is the duty of the person responsible predict the post-strengthening behaviour assessing the reliability of the techniques adopted (Brown et al., 2008; Manisekar, 2018; Song et al., 2022; Wang; Gupta, 2022).

This work surveys the main pathologies in a group of bridges inspected in Brazil by the *Departamento Nacional de Infraestrutura e Transportes (DNIT)*, which has work plans for maintenance interventions to map the occurrence of damage and make the association with maintenance and repair interventions in the structure. Based on these services, repair inspection methods before and after the intervention were listed to determine acceptability and guarantee the quality of the process.

2 RESEARCH METHODOLOGY

2.1 *Data collection and analysis*

For this study, 435 reinforced concrete bridges, inspected by the DNIT and with work plans for maintenance interventions, were selected and analyzed to map recurrent damage and associated maintenance services. These bridges constitute the *SGO - Sistema de Gerenciamento de Obras de Arte Especiais* and are managed by the DNIT. The bridges were classified according to structural typologies (Figure 1). The predominant structural system of the sample is a reinforced concrete beam (84.37%), followed by a reinforced concrete slab (11.03%).

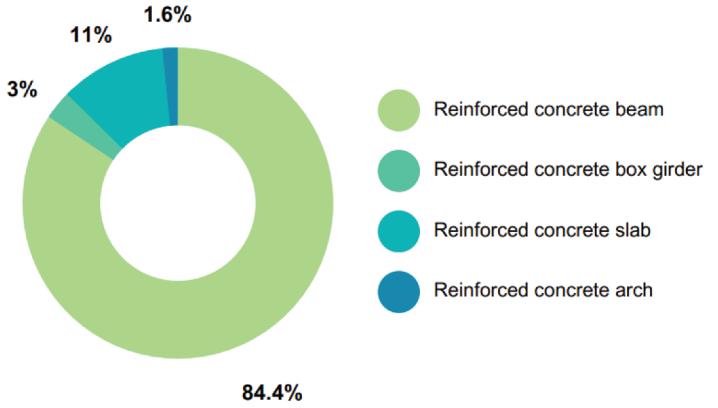

Figure. 1. Structural typologies of the bridges.

The sample universe of bridges was categorized for analysis based on two main criteria: the region of the country where the structure is located (Northeast, Southeast, North, South, Middle-West) (Table 1), and the longitudinal extent of the bridge, which was further classified into small spans, medium spans, or large spans (Table 2), the length of these structures varies from 4.30 to 693.65 meters and the width from 4.0 to 20.0 meters.

Table 1. Categorization of bridges by region.

Region	Sample universe	Percentage (%)
Northeast	168	38.62
Southeast	89	20.46
North	60	13.79
South	74	17.01
Middle-West	44	10.12

Table 2. Categorization of bridges by longitudinal extent.

Longitudinal extent	Sample universe	Percentage (%)
Small bridge: ≤ 30,0 m	219	50.,35
Medium bridge: 30,0 - 80,0 m	166	38.16
Large bridge: > 80,0 m	50	11.49

2.2 *Maintenance and repair interventions*

In this step, the methodology aimed to establish a correlation between the identified damages in the analyzed bridges and the corresponding repair services outlined in their respective work plans. For this purpose, each repair service underwent a detailed breakdown, with a clear description of its components, and an associated unit of measure was assigned to quantify the extent of repair required.

2.3 *Quality control of the intervention*

There are many non-destructive techniques used to evaluate and monitor structures, and they can also be applied to establish criteria for the acceptability and reliability of interventions, verifying the adherence of repair materials, delaminations, depth of cracks, among other properties. These methodologies include ultrasonic testing techniques such as impact echo, impact resonance, impulse response, along with acoustic emission and imaging techniques to determine the strength and assess the damage of concrete, among other methods (Gheorghiu; Rhazi; Labossiere, 2005; Hola; Schabowicz, 2010; Jaishankar et al., 2022).

The definition of quality control for interventions must involve the substrate of the structure repaired, acceptance of the quality of the products used, and the properties of the intervention (EN 1504). EN 1504 and ACI 228.2R provide guidelines for the checks to be carried out before, during and after a repair. In view of the stages that make up the repair activity, the type of test or observations that are appropriate for quality control of the intervention are established.

Concerning the condition of the substrate for applying the repair, both before and after the preparation stage, its properties must be checked, as shown in Table 3.

During the execution of the repair service, some checks are also necessary to ensure quality control of the repair and must be carried out, as shown in Table 4.

At the end of the services, to guarantee the correct execution, acceptability, and reliability of the services, inspections must be carried out by Table 5.

Based on the most recurrent damage to reinforced concrete bridges, the interventions carried out using non-destructive methods were associated with inspection, quality control, acceptability, and guaranteeing the reliability of the repairs carried out.

Table 3. Inspection methods for substrate condition.

Property	Inspection methods
Delamination	Hammer blow
Cleaning	Visual inspection
Surface roughness	Visual inspection, sand patch test or perfilometer
Surface resistance	Pulloff test; sclerometry
Cracks width and depth	Ultrasonic pulse velocity; Fissurometer
Crack activity	Glass plates; Extensometer
Vibration	Accelerometry
Moisture content	Visual inspection; resistivity test
Carbonation	Phenolphthalein; pH meter
Alkali-silica reativity	Cornell/SHRP rapid test
Freezing and thawing damage	Petrography
Steel area reduction	Ultrasonic pulse velocity
Presence of contaminants	Chemical analysis
Corrosion and cleaning of reinforcement	Visual inspection

Table 4. Inspection methods during intervention.

Property	Inspection methods
Temperature	Thermometer
Moisture	Higrometer
Precipitation	Visual inspection
Wind speed	Anemometer
Materials consistency	Consistency tests
Repair thickness	Visual inspection; cover meters

Table 5. Inspection methods to acceptability and reliability of interventions.

Property	Inspection methods
Location of delamination and voids	Impact-echo; Infrared thermography; Impulse response; Radiography; Ground penetrating radar
Coating finish	Visual inspection
Permeability	Karsten Tube Penetration Test
Injection of crack voids	Ultrasonic pulse velocity; Impact-echo
Bond strenght and quality	Pulloff test
Voids	Ultrasonic pulse velocity
Surface texture and color	Visual inspection
Rebar grip	Pullout test on steel bars

3 RESULTS AND DISCUSSION

3.1 *Damage mapping*

Table 3 presents the most recurrent types of damage identified in the group of bridges analyzed, together with the percentage occurrence of each. Through this table, it is possible to identify the main problems faced by the bridges analyzed, allowing maintenance and repair efforts to be directed towards the most recurrent types of damage and thus preserve the structural integrity and extend the useful life of these vital infrastructures.

1. Leaching and carbonation spotting: This type of damage refers to staining caused by the water infiltration into the concrete, followed by a chemical reaction with carbon dioxide from the air. These stains may indicate a deterioration process of the concrete, resulting in its loss of strength over time.

Table 6. List of the most recurrent damage types in analyzed bridges.

Damage	Unit	Occurrence (%)
Leaching and carbonation spotting	m²	90.57
Crack	m	85.52
Expansion joints damage	m	84.37
Disaggregated concrete	m²	69.66
Infiltration into the concrete	m²	66.21
Concrete displacement	m²	65.29
Uncoated reinforcement	m²	50.34

2. Crack: These are linear openings in the concrete, mainly caused by internal or external stresses that exceed the material's ability to resist. Cracks can compromise the bridge's structural integrity and facilitate the penetration of aggressive agents such as water and chlorides, leading to more significant damage.

3. Expansion joints damage: are designed to allow concrete to expand and contract in response to temperature changes. Damage to these joints can result in restriction of concrete movement, leading to cracking and failure of the structure.

4. Disaggregated concrete: This damage indicates significant degradation of the concrete around the reinforcement, leading to exposure and oxidation of the steel bars. The oxidation of the reinforcement can cause it to expand and break away from the surrounding concrete.

5. Infiltration into the concrete: the penetration of water, moisture, or other aggressive elements. Infiltration can accelerate the corrosion of reinforcement and contribute to the overall degradation of the concrete, making it less resistant.

6. Concrete displacement: This damage refers to situations where the concrete shifts or detaches, exposing the reinforcement. This can weaken the structure and increase susceptibility to other types of damage.

7. Uncoated reinforcement: This occurs when the steel bars of the reinforcement are not adequately coated with protective materials, making them more susceptible to corrosion. Corrosion of the reinforcement can lead to expansion and spalling of the concrete around it.

All these damages are common in reinforced concrete structures. It is not uncommon for bridges and other concrete structures to experience a combination of these types of damage over time. Factors such as environmental conditions, traffic loads, material properties, and design failures can contribute to the occurrence of these damages. These damages emphasize the importance of regular inspections, maintenance, and repair activities to ensure the safety, functionality, and longevity of reinforced concrete structures. By addressing these damages promptly, engineers and maintenance teams can extend bridges' lifespan and structural integrity.

3.2 *Damage and intervention association*

Each damage is associated with a set of maintenance and repair services. Certain simple damages correlate directly with maintenance and repair services (Table 4). However, in more intricate cases, the relationship between services depends on the specific element affected by the damage and the extent of reinforcement section loss, requiring a decision tree to represent this association (Figure 2).

Table 7. Common damages and services association.

Damage	Intervention type	Services
Leaching and carbonation spotting	Maintenance	Concrete surface cleaning with pressure water blasting
Expansion joints damage	Maintenance	Expansion joint cleaning
	Repair	Replacement of the expansion joint
Crack	Repair	Injection of structural adhesive based on low-viscosity epoxy resin

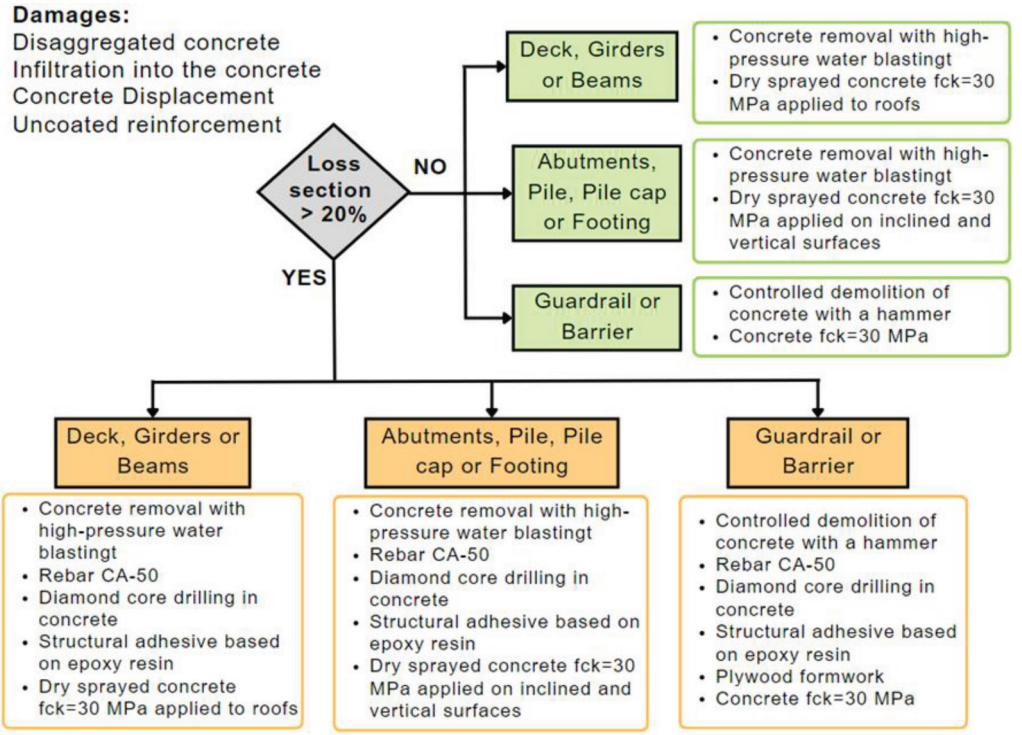

Figure 2. Decision tree for more complex repairs.

3.3 *Inspection methods*

For the services shown in Table 7 and Figure 2, Table 8 presents a proposal for some of the necessary inspections that involve the previous stages of the intervention, especially the substrate preparation, based on the recommendations of EN 1504 and ACI 228.2R. It should be noted that the inspection method depends on the service carried out and the type of surface damage.

Table 8. Necessary inspections in previous stages of the intervention.

Service	Damage	Inspection method
Concrete surface cleaning with pressure water blasting	Leaching spotting	Visual inspection and pulloff or sclerometry test for check the surface resistance
	Carbonation spotting	Visual inspection and Phenol-phthalein application
Expansion joint cleaning	Expansion joints damage	Visual inspection
Concrete removal with high-pressure water blasting or controlled demolition of concrete with a hammer	Disaggregated concrete	Visual inspection and pulloff test or sclerometry for check the surface resistance
	Infiltration into the concrete	Visual inspection and resistivity test
	Concrete displacement	Visual inspection and pulloff test or sclerometry for check the surface resistance
	Uncoated reinforcement	Visual inspection and pulloff test or sclerometry for check the surface resistance

Table 9 proposes some inspections during and after the intervention, based on the recommendations of EN 1504 and ACI 228.2R.

Table 9. Necessary inspections during and after the intervention.

Service	Inspection method
Replacement of the expansion joint	Visual inspection
Injection of structural adhesive based on low-viscosity epoxy resin	Glass plates or extensometer to identify crack activity and ultrasonic pulse velocity or impact-echo for check the crack injection
Concrete application	Consistency tests; visual inspections; Pulloff test and Ultrasonic pulse velocity
Steel bar anchoring with structural adhesive based on epoxy resin	Pullout test on steel bars

The proposed inspection methods and the results obtained during this stage are used to determine whether or not the intervention is acceptable, giving reliability to the repair or the need for a new execution.

4 CONCLUSIONS

Based on this study, it was possible to map the most recurrent damage in real reinforced concrete bridges and associate repair services with this damage more directly, making it possible to automate the decision-making process for intervention. The inspection methods proposed were related to the types of damage and services covered in the study, providing a range of possibilities. It is the responsibility of the engineer in charge of assessing the intervention services carried out to define which methods are best suited, ensuring that due attention is paid to the behavior of the structure and the repair after it has been carried out.

Fatigue analysis and maintenance strategies for details in long-span bridge girders

C. Deng, Y. Ren, X. Xu, Z. Fan & Q. Huang
School of Transportation, Southeast University, Nanjing, China

Y. Li
Guangdong Provincial Highway Construction Co.,Ltd., Guangzhou, China

ABSTRACT: Suspension bridges and cable-stayed bridges are dominant structures for super long-span bridges, where steel box girders, known as stiffened girders, are commonly used. Despite their advantages of light weight and easy construction, steel box girders are prone to suffer from severe fatigue damage. Excessive traffic volume and truck overloads are one of the external factors for the girders to have premature fatigue cracks. Critical details including U-ribs and truss diaphragms are reported to have the most fatigue cracks for their geometric features, seen at their welded joints. In this paper, fatigue performance of U-rib to deck joints, belonging to a suspension bridge, and truss-type longitudinal diaphragms, belonging to a cable-stayed bridge, is analyzed. Multi-scale finite element models (FEM) of the suspension and cable-stayed bridges are developed to calculate the fatigue life of the details under different load cases, based on cumulative fatigue damage law and S-N curves. The results are validated by field inspection records of the background bridges. Then, to prolong the life-cycle of the fatigue details, two maintenance actions are proposed and applied respectively. The thickness of the deck and U-rib of the suspension bridge is discussed and optimized through comparative study. On the other hand, the steel pipes of the diaphragms are replaced by bolted steel channels and the effects are proved to be satisfactory. These replacement strategies provide practical instructions for steel box girder maintenance and similar structures.

1 INTRODUCTION

Orthotropic steel girders (OSDs) are widely used in long-span cabled-stayed bridges and suspension bridges due to their light weight, high strength and construction convenience (Lu et al., 2019; Oh & Bae, 2013). Compared to bolted connections, welded connections are generally more commonly used for the complex internal structure in steel box girders. However, under alternating vehicle loads, fatigue cracks are prone to occur, which are difficult to discover at early stage but pose a huge threat to the safety of bridge structure as they grow. Inspection data revealed the presence of serious cracks in critical details, highlighting the urgent need of addressing fatigue issues. Multiple fatigue cracks were identified in different welded details of steel box girders. Notably, welded joints of U-rib to deck (Fu et al., 2018; Villoria et al., 2021; Yun et al., 2019) and rib-diaphragms (Guo et al., 2015) were reported to have serious cracks based on inspection data. Hence, U-rib to deck welded joints and longitudinal diaphragm welded joints are two critical fatigue details discussed in this study.

The fatigue behavior of these critical details has been fully investigated in many studies (Cui et al., 2020; Fu et al., 2018; Kainuma et al., 2017; Pengjun et al., 2019; Yang et al., 2016), in which S-N curve based linear cumulative fatigue damage theory and fracture mechanics are commonly used methods. Linear cumulative fatigue damage theory (Miner, 1945) is widely used in fatigue analysis due to its simple expression and convenience (Zhang et al., 2017). To obtain the fatigue effects under traffic loads, finite element (FE) numerical analysis and multi-

DOI: 10.1201/9781003483755-313

scale FE models are promising method as full-scale tests for large OSD is expensive and technically hazardous (Aygül et al., 2012; Cui et al., 2018; Yu et al., 2022; Zhang et al., 2015).

Fatigue cracking has become one of imperative issues of OSD (Zheng et al., 2019). However, few maintenance actions for OSD have been reported. Studies show that increasing the thickness of deck plate can significantly improve the fatigue life welded joints (Kainuma et al., 2017; Xiao et al., 2008). Ahmadivala et al. (2022) investigated the effect of applying a cement-based horizontal overlay by thickening the deck plate in the FE model. Some researchers proposed that a thickened U-rib edge can increase the fatigue strength of U-rib to deck joints (Heng et al., 2019, 2020; Luo et al., 2019; Zheng et al., 2019). Zhu et al. (2020a,b) suggested a thicker diaphragm and new cutout geometry under heavy traffic.

Previous studies focus on the thickness of deck plate or U-rib edge while some drawbacks remain unsolved. The traffic loads resembling real bridge traffic conditions are needed for acquiring accurate fatigue response. In terms of the maintenance measures, the effect of thickness of both the deck plate and U-rib is not further discussed. For another fatigue detail, i.e., the truss-type longitudinal diaphragm welded joint is seldom investigated, as well as its improvement measures. In this study, to evaluate the effectiveness of proposed measures and provide instructions for real bridge maintenance strategies, the FE models of two background bridges are developed. Then, the characteristics of real bridge traffic are analyzed and typical fatigue vehicle models are developed to apply on the FE models. The fatigue life of two welded details is calculated based on the linear cumulative fatigue damage analysis method. Finally, two replacement strategies are applied to two models respectively and subsequent fatigue life is estimated to make comparison with the former ones.

2 BRIDGE DESCRIPTION AND FE MODELS

Two critical details are analyzed in this study, i.e., the U-rib to deck welded joints of a suspension bridge and the truss-type longitudinal diaphragms of a cable-stayed bridge. Finite element models of the two bridges are developed. The modelling of the reinforced details is presented in 4.1 and 4.2.

2.1 *The suspension bridge*

One of the bridges chosen as a case study is a suspension bridge with a span of 1385m crossing the Yangtze River. The layout of the bridge is shown in Figure 1 and the detail of its U-rib of the deck is shown in Figure 2. The thickness of the girder deck plate and the U-rib adjacent to the deck is 12mm and 6mm respectively. According to the inspection records, the U-rib to deck welded joints of the OSD suffered from easily cracking. The number 12 U-rib, detected to have severe cracks,

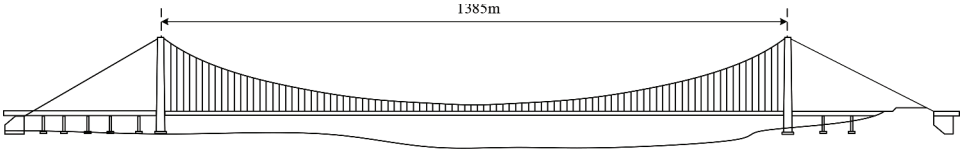

Figure 1. Layout of the suspension bridge.

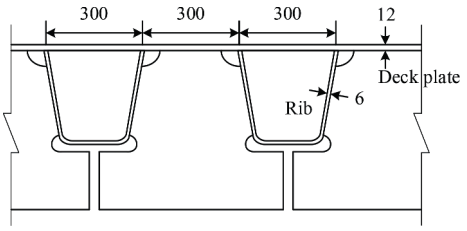

Figure 2. U-rib to deck welded joint (unit: mm).

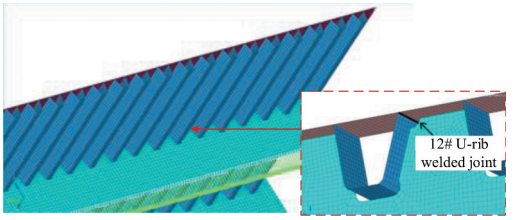

Figure 3. FE model A.

was chosen for the fatigue analysis. The main girder between two hangers was modeled by ANSYS software (model A), shown as in Figure 3, which has 48 U-ribs beneath the deck. For the concern of the computational efficiency, the bottom plate and its web members were simplified.

2.2 *The cable-stayed bridge*

Another background bridge is a cable-stayed bridge with a main span of 648m also crossing the Yangtze River. The main girder has two rows of longitudinal diaphragms. Two types of diaphragms were applied before reinforcement—solid types and truss types. In the truss-type diaphragms, top and bottom deck plates were welded by upper and lower chords, which are T-shape ribs, and they are connected by web members. It is noted that steel pipes were originally used as web members on this bridge, on which serious fatigue problems were detected. The inspection records indicated that some truss-type web members of the longitudinal truss diaphragms cracked at the welded joints and the cracks inclined to grow rapidly.

To obtain more accurate stress spectrum of the welded joint, a multiscale FE model (model B) of the cable-stayed bridge was established via ANSYS software, as shown is Figure 4. In the mid-span area, Shell elements were used to simulate the local model of the interested girder as well as one of its web members. Welded details of the web member were highly meshed to ensure the calculation accuracy.

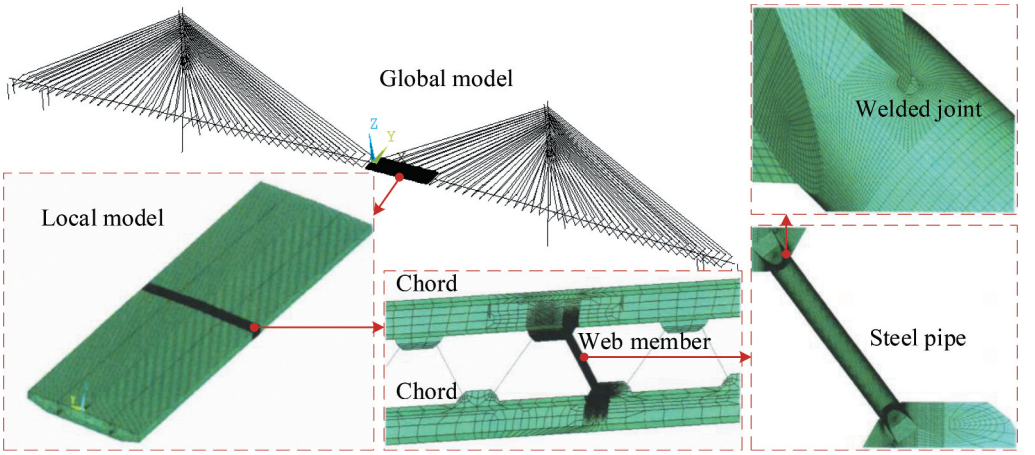

Figure 4. FE model B.

3 ACCUMULATIVE FATIGUE DAMAGE ANALYSIS OF CRITICAL DETAILS

3.1 *Fatigue damage analysis based on S-N curve*

Linier cumulative fatigue damage analysis, namely Stress-life method, is a widely used method to calculate the damage degree of steel components, which is based on S-N curve and the Miner's rule. The analysis of critical details includes three steps:

(1) Locate the most damaged details through field inspection or stress analysis.
(2) Obtain stress spectrum of the critical details under fatigue vehicle loads.
(3) Generate corresponding S-N curve and estimate fatigue life based on the Miner's rule.

S-N curve indicates the relation between stress and fatigue life, in which S represents stress range and N for number of cycles (Sun & Ye, 2022). The S-N curve used in the study is derived from the BS5400 (B.S.I. British standards BS 5400, 1980), which can be written as follows:

$$N \cdot \sigma^m = K_2 \tag{1}$$

where σ is the stress amplitude; m is the slope of the stress curve; N is the corresponding number of stress cycles; K_2 is the coefficient of fatigue strength.

The parameters of fatigue details discussed in Section 4 are shown in Table 1, based on BS 5400. Due to the variance of stress amplitude of steel girders, the S-N curves developed from constant amplitude fatigue tests are analyzed through the Miner's rule.

Table 1. The parameters of fatigue details.

Fatigue detail	Category	m	K_2
Rib to deck joints	C	3.5	4.23×10^{13}
Longitudinal diaphragms	D	3	1.52×10^{12}

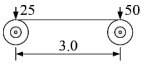
According to the rule, fatigue damage brought by each variant stress cycle can be calculated as n_i/N_i and the cumulative damage is defined as the sum of damage derived from every cycle, which can be written as:

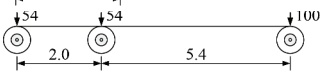
$$D = \sum_i \frac{n_i}{N_i} \tag{2}$$

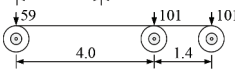
where n_i is the cycle number of the stress amplitude calculated by rain flow method (Downing & Socie, 1982); N_i is the cycle number of the stress amplitude on the S-N curves; D is the cumulative damage.

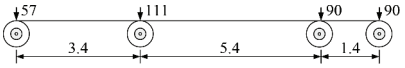
It is assumed that fatigue failure happens when accumulative damage D reaches 1.0. However, low stress cycles in the stress spectrum also cause fatigue damage, which are modified by introducing proportional coefficient to consider their effect. Despite the deviation of the Miner's rule, it is applicable due to its simplicity.

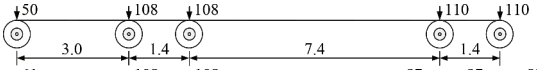
3.2 *Fatigue vehicle loads*

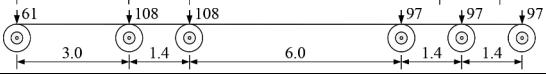












To reflect load responses of critical components under real traffic conditions, typical fatigue vehicle models are implemented from filed investigation to derive fatigue stresses. According to information from the Weigh-in-Motion (WIM) system from the background suspension bridge in 96 hours, 6 types of typical fatigue vehicle models are developed, as shown in Table 2, and their distribution on different lanes are shown in Table 3.

In order to estimate the traffic volume based fatigue life more accurately, a three-stage traffic growth model is introduced (Luo et al., 2021). The first stage is the short period after the bridge is put into service when the AADT grows linearly. In the second stage, traffic volume has an exponential growth curve until it reaches an upper limit. The traffic volume becomes stable at the upper limit in the third stage. The three-stage growth model can be written as follows:

$$y = \begin{cases} at + b_0 \\ e^{(b_1 + b_2 t)} \\ y_{\max} \end{cases} \tag{3}$$

where t is the time in years; a and b are the linear parameters of the first stage; b_1 and b_2 are the parameters of the second stage; $y_{\max}$ is the upper limit of traffic volume.

Table 2. The parameters of typical fatigue vehicles.

Vehicle type	Illustration*	Gross weight/kN	Proportion/%
1		75	39.63
2		208	13.12
3		261	15.28
4		348	4.46
5		486	3.87
6		568	23.63

* Length in meter and weight in kilogram.

Table 3. The lane distributions for different vehicles (%).

Vehicle type	1	2	3	4	5	6
Outside (slow) lane	12.60	65.44	14.55	67.95	68.77	63.18
Middle (driving) lane	37.41	31.10	52.91	30.67	29.86	34.83
Inside (fast) lane	37.41	31.10	52.91	30.67	29.86	34.83

4 FATIGUE ANALYSIS OF MAINTENANCE MEASURES

In this study, various maintenance strategies are simulated and analyzed through finite element simulation. In this section, the U-rib coupled with the deck of the suspension bridge (model A) and the longitudinal diaphragm of the cable stayed bridge (model B) are being replaced.

4.1 *Fatigue analysis of reinforced U-rib and deck*

Five reinforced models are developed considering different thickness combinations of U-rib and deck. Thickness of the details in FE models are shown in Table 4. Using the method in 3.1, the stress amplitudes and corresponding cycle numbers are calculated of the welded joints in each model. The cumulative fatigue damage of each detail under 6 million vehicles can be obtained by Equation 2, shown as in Table 4.

Table 4. The parameters and fatigue damage of fatigue details in different models.

Model	Deck/mm	U-rib/mm	Fatigue damage
Model A	12	6	2.06×10^{-1}
Model 1	12	8	1.99×10^{-1}
Model 2	12	10	2.11×10^{-1}
Model 3	14	8	3.31×10^{-2}
Model 4	16	8	7.83×10^{-3}
Model 5	18	8	1.22×10^{-3}

Compared to original model (model A), increasing the thickness of the U-rib has little influence on the damaged degree, which remains around 0.2, with the U-rib thicken from 6mm to 10mm. Based on that, when the thickness of the girder deck increases from 12mm to 18mm, D declines dramatically. It indicates that the thickness of deck dominates the fatigue life of critical details of U-rib to deck joints.

The traffic volume of the suspension bridge was 5400 thousand when it opened. Thus, the fatigue life of the joints of model A and model 5 without considering traffic growth can be deduced, which are 5.39 years and 925.93 years. According to field records, the welded joints of the bridge girder experienced fatigue cracks within the first 3 to 5 years, which aligns well with the estimated results. Based on the record of toll station on this bridge, the traffic volume stabilizes at $y_{\max}$ of around 2.6 million a year, as show in Figure 5. Therefore, the fatigue life of thickened deck in model 5 is 196.03 years and it can be expected that the critical detail generates no cracks during service time.

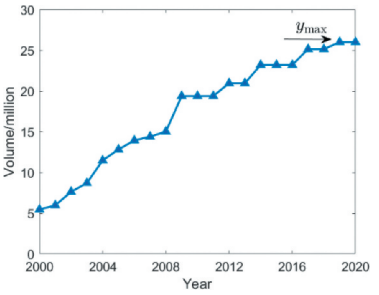


Figure 5. Traffic volume of the suspension bridge.

4.2 *Fatigue analysis of reinforced diaphragms*

The original steel pipes in the longitudinal diaphragms in the background cable-stayed bridge were replaced by two opposite steel channels with a height of 200mm, a few years after the inspection. The steel channels are connected back to back to the chords at gusset plates and stiffened by high-strength bolts, shown as in Figure 6. Using the high-strength bolts instead of welded joints can avoid stress concentration at the welded joints caused by geometric discontinuities. To quantify the effectiveness of the replacement method, one of the web members is simulated by steel channels, shown as in Figure 7. The detail category of the reinforced component belongs to C, according to BS 5400. Considering the similar geographic conditions between two bridges, the same fatigue vehicle loads in model A are applied to the reinforced model B. Using the method in 2.3, the D values of the fatigue detail before and after replacement are 0.422 and 0.0024, demonstrating the effectiveness of the replacement measure.

Since the opening of the bridge in 2005, the traffic volume in 2006, 2007, and 2008 was relatively low, with averages of 1.53, 2.01 and 2.30 million, respectively. After 2009, the annual traffic volume reached around 3.65 million. Based on the data, it could lead to the occurrence

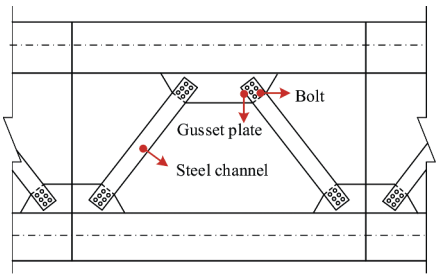

Figure 6. The layout of steel channels.

of fatigue cracks in the diaphragms within approximately 5.3 years. In fact, the bridge first observed the cracks at the welded joint of the diaphragms in 2008, approximately 3 years after its opening, which is in accordance with the simulation result. By Applying the same traffic growth as in model A, the fatigue life of reinforced diaphragm is expected to be 102.03 years, which is also promising for the safety of the OSD.

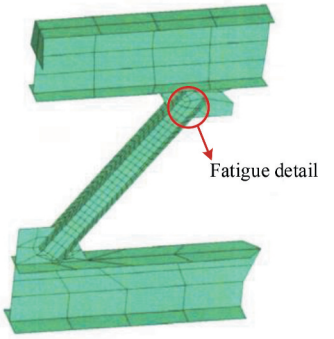

Figure 7. The local model of the steel channel.

5 CONCLUSION

This study presented a practical approach for fatigue analysis of OSD under vehicle loads. The proposed approach was applied to two types of fatigue details on the steel box girder, the web member to longitudinal diaphragm and the welded joints of U-rib to deck. In addition, improvement measures for two fatigue details were also investigated. Comparison of the fatigue life were made between the reinforced steel components and the original one to verify the effectiveness of the improvement measures. Based on the results, the following conclusion can be drawn:

(1) To simulate real traffic condition more accurately, vehicle characteristics such as vehicle type, lane distribution and traffic volume are analyzed.
(2) The fatigue analysis approach is applied to the welded joint of U-rib to deck and the joint of the truss-type longitudinal diaphragm. The fatigue damage of the critical details of U-rib to deck and the longitudinal diaphragm is 0.206 and 0.422 respectively. Both case studies obtain the fatigue life that are close to the real bridge components.
(3) Two maintenance strategies are presented for two details respectively. The thickness of U-rib and deck are modeled to increase to 8mm and 18mm, respectively. Results show that a thicker deck contributes more fatigue strength and the corresponding fatigue life is 195 years, considering traffic volume growth. On the other hand, the steel pipe of the diaphragm is replaced by the steel channels and the fatigue life after replacement is 102 years, using the proposed approach. Two strategies provide considerable improvement in fatigue life of two critical details, by 190 and 97 years, respectively.

A comparison of Italian and UK guidelines on the vulnerability assessment of bridges

Alessandro Lipari & Paolo Clemente
ENEA Italian National Agency for New Technologies, Energy and Sustainable Economic Development

ABSTRACT: The vulnerability assessment of bridges has proven to be a challenging task: as of yet, there is no universal approach for carrying out the assessment; besides, in spite of recent technological advances, it still greatly relies on visual inspections, hence with a certain degree of subjectivity, and the assessment outcome may be affected by some factors that are not obvious, such as full accessibility of the bridge and presence of latent defects.

This paper compares the structural vulnerability assessment of existing highway bridges included in two national guidance documents, namely the well-established UK Design Manual for Roads and Bridges and the recent Italian Ministry of Infrastructure and Transport's Guidelines. Both documents present risk-based methods for assessing the structural vulnerability of bridges, while exhibiting fundamentally different approaches. For instance, the Italian assessment defines a vulnerability class, to be combined with hazard and exposure classes in order to determine a structural risk rating; then, the overall rating affects the actions that need to be taken, e.g. subsequent inspections, structural assessment or monitoring. On the other hand, the UK guidance uses a risk scoring system, which also includes some parameters not strictly related to vulnerability, in order to determine whether the interval between principal inspections may be increased from the minimum requirement of 6 years; some input data for such risk scoring are also used to determine whether a structural assessment is required. Finally, both vulnerability assessments are applied to two sample bridges, highlighting similarities and differences between the two guidelines.

The presented comparison may allow for a better understanding of the factors governing the assessment outcome, for potential improvement of guidelines, and ultimately for more effective intervention prioritisation.

1 INTRODUCTION

Bridges are critical parts of a transport network and ensuring their safety is paramount while they are ageing. However, this has proven to be challenging: the bridge stock may be close to or have exceeded its expected lifespan, traffic loads have increased over the years, climate change imposes unpredicted actions, maintenance operations may be costly and typically causing undesired traffic disruptions, available resources are often tight (Clemente, 2020, Buffarini et al., 2022).

Assessing their vulnerability is a crucial step before proceeding to any structural assessment or maintenance planning. Vulnerability is greatly related to bridge condition rating, although other factors should be considered, e.g. the structural scheme. Although monitoring systems have been used (Clemente et al., 2019, Bongiovanni et al., 2021), collection of data about bridge conditions is still greatly relying on visual inspections and, as such, the outcome has a certain degree of subjectivity. Moreover, condition rating is seldom standardised, even within the same country, potentially leading to inconsistent outcomes.

To tackle this, some countries have adopted national guidelines in an effort to reduce subjectivity and enhance uniformity in inspection and assessment tasks. Among these, the Italian

Ministry of Infrastructure and Transport has recently issued the "Guidelines on risk classification and management, safety assessment, and monitoring of existing bridges" (Ministero delle infrastrutture e dei trasporti, 2022), whereas in the United Kingdom the Design Manual for Roads and Bridges includes more established procedures for the inspection and assessment of existing highway bridges (Highways England, 2021, Highways England, 2020, National Highways, 2022). Both guidelines are risk-based and follow a comparable multi-level approach.

The Italian guidelines comprise of six levels (0–5): census (L0), inspection (L1), definition of a Class of Attention (L2); then, according to the outcome of L2, an existing bridge may be required to proceed to a preliminary assessment (L3), accurate assessment (L4), or a network resilience study (L5, applicable only to high importance bridges). The Italian guidelines endorse a multi-risk methodology, as they take into account four main risks: structural-foundational, seismic, landslide and hydraulic. For each risk, a vulnerability class is computed and then combined with hazard and exposure classes, resulting in a Class of Attention (CA). The combination of each risk CAs leads to an overall CA, upon which depend further actions, such as frequency of periodic inspections, additional inspections, structural assessment or monitoring.

The UK guidelines are based on a broader set of documents. The parts applicable to bridges can be broadly divided into inspection, structural review, and assessment. As such, these stages can be related to the Italian levels L1, L2, and L3-L4. Two separate risk-based procedures are established: one at the inspection stage for a potential extension of the interval between principal inspections of certain bridges, the other at the structural review stage for assessing the need for a structural assessment.

This paper focusses on the structural vulnerability assessment of existing highway bridges and compares the methodologies required to establish the inspection process, along with other parameters affecting the structural vulnerability. In this work, structural vulnerability is intended as the vulnerability of the structure against any actions, except for earthquake, landslide and hydraulic actions. An overview of the structural risk evaluation to establish the need for structural assessment is also given – this aspect has been discussed in greater detail in another work (Lipari et al., 2024). The procedures are then applied to two case studies, and similarities and differences are highlighted.

2 THE ITALIAN AND UK METHODOLOGIES

The Italian and UK methodologies to rate highway bridge conditions and to estimate the structural risk are outlined in the following. Obviously, the structural condition level is a crucial input in assessing the vulnerability of an existing bridge, although not the only one. Consideration of multiple factors is indeed a remarkable feature of both methodologies.

Methodologies developed for bridge condition indices can be broadly groped into four different approaches, or a combination of those (Chase et al. 2016):

- ratio-based methods: a Bridge Condition Index is assigned based on the ratio of the current condition to the condition of the structure after its construction;
- weighted averaging approaches: similar to the previous, but the condition ratings of all individual elements are weighted by their contribution to the structural integrity of the bridge;
- worst-conditioned approaches: the overall condition rating is that of the element in the worst condition;
- qualitative methods: conditions are not reported on a numerical scale.

2.1 *Methodology proposed in the Italian guidelines*

The methodology underlying the Italian guidelines is multi-level, multi-risk and qualitative. It has to be applied by all road managers for bridges and viaducts longer than 6 m.

Risk is consistently rated upon a combination of hazard, vulnerability and exposure, resulting in a CA, which can be Low (L), Medium-Low (ML), Medium (M), Medium-High (MH), or High (H). The vulnerability class bears the highest influence on the structural CA, as the hazard or exposure classes do not vary the overall CA as much (Santarsiero et al., 2021). The overall CA determines which further actions to take (Figure 1).

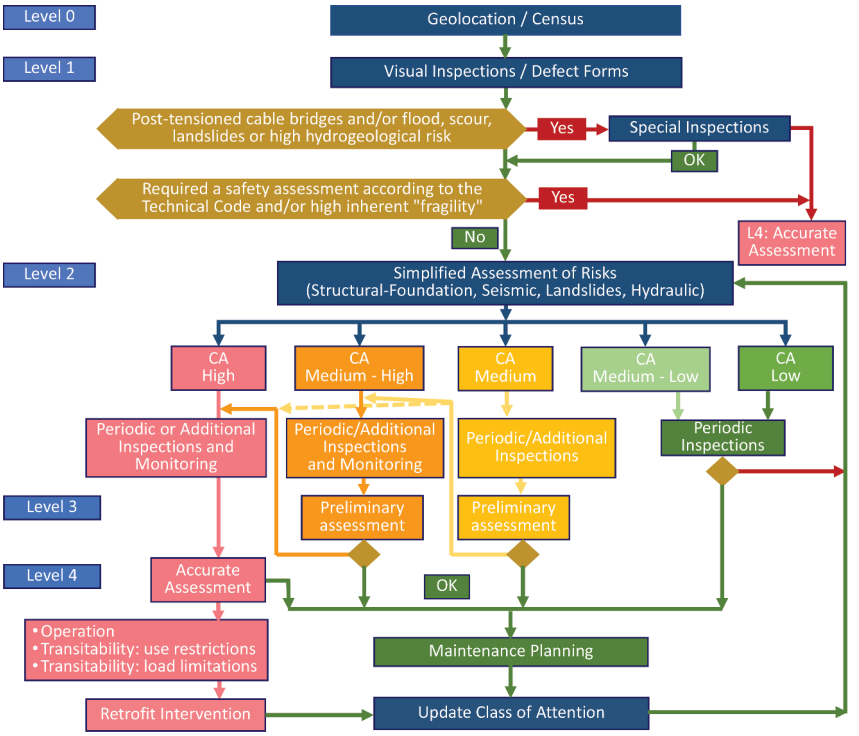

Figure 1. Multi-level approach according to Italian guidelines.

As can be seen, inspections can be classified into:

- *Periodic inspections*: to be carried out at minimum intervals, according to the CA resulting from an L2 evaluation and whether the structure had been previously subjected to periodic inspections or not; if so, intervals range from 6 months (CAs MH and H) to 2 years (CA L); otherwise, intervals are halved. Periodic inspections are visual, but it is recommended to carry out some basic non-destructive testing.
- *Additional inspections*: required to investigate the degradation process and the structural conditions whenever periodic inspections found significant damage, such for CAs M, MH or H. They must be carried out within 60 days from arising of their need, or at most every 2 years for CAs M, MH or H, and 5 years in other cases. Non-destructive tests must be performed, while load testing or dynamic testing may be performed.
- *Special inspections*: required for post-tensioned PSC bridges or landslide/scour/flooding-prone bridges; for post-tensioned PSC bridges, it is recommended to identify the tendon geometry from record information or non-destructive testing, and then to set out an investigation plan to ascertain the level of deterioration of the elements. In case of unsatisfactory results, an accurate assessment (L4) must follow.

The parameters required for determining the structural hazard, vulnerability and exposure classes are reported in Table 1.

Table 1. Input parameters for determining the structural risk.

Class	Parameter	Number of entry option
Hazard	Permitted load	5
	Average Daily Truck Traffic	3
Vulnerability	Level of deterioration	5
	Structural scheme	7
	Maximum span length	4
	Material	7
	Number of spans	2
	Speed of deterioration	3
	Design code	3
Exposure	Average Daily Traffic	3
	Average span length	3
	Alternative routes	2
	Obstacle crossed	3
	Transport of dangerous goods	2

The Level of Deterioration (LD) is based on an element-level damage survey, in which each defect type has its own listed severity (G = 1, 2, 3, 4, 5), and the inspector assigns its extent and intensity, each divided in 3 classes. From such detailed information, an LD can be computed for each element, then for each structural group (e.g., decks, piers, abutments, bearings, etc.), and ultimately for the whole structure. The LD of the whole structure is the worst LD among the structural groups, thus effectively endorsing a worst-conditioned approach, although some averaging is allowed when assigning the LD of a structural group, as long as there are no elements with levels MH or H.

An LD High (H) corresponds to severe defects (G = 4, 5) on critical elements, i.e., conditions for which the structural safety is at stake; a *critical element* is that highly subjected to degradation and whose damage could affect the global structural safety, such as half-joints or PSC tendons, or else an element in critical conditions. An LD Medium-High (MH) corresponds to severe defects (G = 4, 5) with high intensity on non-critical elements, but which could compromise the structural safety over time. An LD Medium (M) corresponds to defects G = 5 with low to moderate intensity on non-critical elements, or severe defects (G = 4, 5) with high intensity not potentially compromising the structural safety. An LD Medium-Low (ML) corresponds to defects G = 4 with low to moderate intensity on non-critical elements or numerous non-severe defects (G = 1, 2, 3), whereas an LD Low (L) has only a limited number of non-severe defects.

For full details, refer to Ministero delle infrastrutture e dei trasporti (2022) and ANSFISA (2022). Some relevant implications are reported here:

- when the LD is H, then the vulnerability class is H regardless of the other parameters; however, a vulnerability class H does not imply a level of deterioration H: in fact, a bridge with level of deterioration M or MH could have a vulnerability class H, depending on the other parameters reported in Table 1.
- when the vulnerability class is H, the structural CA is H regardless of the hazard and exposure classes; however, a structural CA H does not imply a vulnerability class H: in fact, a bridge with vulnerability class MH could have a structural CA H if either the hazard or the exposure class is H.

2.2 *Methodology proposed in the UK guidelines*

The UK methodology about inspections is set out in CS 450 (Highways England, 2021). Five types of maintenance inspections are applicable to structures with clear span greater than 0.9 m:

– *Safety inspections*: whose purpose is to identify significant deficiencies or signs of damage which represent or can lead to a danger to the public; they typically require frequent scheduling.
– *General inspections*: whose purpose is to provide information on the physical condition of all *visible* elements of the structure, consisting of a visual inspection of all parts that can be inspected without the need for additional access equipment; they shall be undertaken at intervals of 24 months.
– *Principal inspections*: whose purpose is to provide information on the physical condition of all *accessible* parts of a structure, consisting of a close examination within touching distance of the structure; they shall be undertaken at intervals of 72 months, or longer if appropriate, and are not required for spans below 1.8 m.
– *Special inspections*: whose purpose is to provide detailed information on a particular element, part, area or defect that is causing concern; they are considered in particular situations, e.g., cast iron structures, post-tensioned concrete bridges, structures with weight restrictions, damage following bridge strikes.
– *Inspections for assessment*: whose purpose is to provide the information required to undertake a structural assessment.

The interval between principal inspections may be increased to 8, 10 or 12 years, following a risk assessment comprising five categories, each with its own weighting W, as reported in Table 2. They include some parameters not related to structural vulnerability, such as those related to hydraulic risk and consequences of failure. The outcome is a total risk score T between 0 and 100, and the interval can be increased if $T \geq 65$.

Table 2. Input variables for determining the risk-based principal inspection intervals.

Category *(W)*	Parameter	Number of entry option	Risk score range
Structure type *(20%)*	Structural form	5	0-4
	Constituent material	10	0-4
	Age of the structure	4	0-2
	Headroom	3	0-1
	Span	3	0-2
Environment *(17%)*	Exposure to de-icing salts	3	0-3
	Scour	3	0-4
	Flooding	3	0-4
Inspection and assessment *(25%)*	Level of visual accessibility	6	0-5
	Likelihood of latent defects	4	0-3
	Assessment	4	0-4
Condition *(20%)*	Inspector's opinion (*)	3	2-3
	Condition performance indicator (average score) (*)	5	0-4
	Condition performance indicator (critical element score) (*)	5	0-6
	Signs of concrete deterioration (*)	3	0-3
Consequences *(18%)*	Applied loading	4	0-3
	Route supported	7	0-4
	Obstacle crossed	8	0-5
	Potential failure mode	3	0-2

(*) If conditions are not known or there are signs of concrete deterioration, interval remains at 6 years.

As can be seen, conditions are assessed using two criteria: the inspector's subjective condition rating (good, fair, or poor), and two *Condition Performance Indicators* (Condition PI). These are calculated using a severity/extent condition rating system on a scale 0-100: an *average* Condition PI score based on all elements, and a *critical* Condition PI score based on the

most critical element. PIs 40-65 are *poor*, 65-80 *fair*, 80-90 *good*, 90-100 *very good*. Note that, if the subjective condition rating is poor or a PI score is lower than 40 (which may be considered *very poor*), then this risk assessment is not permitted. Also, not all structures are in scope, e.g., complex structures are excluded.

Despite efforts in reducing subjectivity in the inspection process, including targeting the inspector's competency (Sandberg et al., 2022), several methods are used in practice for condition rating in the UK: one such method is reported in Atkins (2007), partly based on a previous method (Highways Agency, 2007), and outlined in the following.

Firstly, bridge elements are listed according to their importance, from Low to Very High importance. Examples of Very High importance elements are deck elements, half joints, piers; examples of High importance elements are abutments, bearings, joints, drainage, foundations.

Severity and extent of defects are assigned through 5 classes each, leading to an Element Condition Score, ECS, ranging from 1.0 (best) to 5.0 (worst). This is reduced by an Element Condition Factor ECF for Low to High importance elements, so as to determine the Element Condition Index ECI = ECS - ECF.

Moving from element-level to structure-level, two Structure Condition Scores are computed: the *average* SCS_{av} weighs the ECIs through an Element Importance Factor, ranging from 1.0 (Low importance) to 2.0 (Very High importance), whereas the critical SCS_{crit} is the maximum ECI among elements with Very High importance. Finally, as both SCSs range from 1 (best) to 5 (worst), they are rescaled into Condition PIs ranging from 0 (worst) to 100 (best).

Finally, every alternate Principal Inspection, a Structural Review is undertaken to determine the need for structural assessment, as set out in CS 451 (Highways England, 2020). The reviewer applies a Risk Appraisal, which is a numerical procedure based on the calculation of a risk score and a reliability score. Most input parameters are the same as in Table 2, albeit with different numerical values, while others differ, for instance change in condition or in loading since design or last assessment. A decision matrix then resolves the two scores to determine the need for assessment, recommending low to very high priorities.

3 APPLICATION TO CASE STUDIES

The procedures presented above are applied to two bridges belonging to Italian national roads and located in Southern Italy. The supported routes feature a single carriageway with two lanes and no restrictions in place.

3.1 *Case studies*

Bridge I is a three-span structure (maximum span 21.55 m), constructed presumably in the '80s and located in a rural area over natural ground. The structural scheme is made of a continuous RC beam-and-slab arrangement with diaphragms, supported over the piers (Figure 2a) and presumably over the abutments, which are neither visible nor accessible.

Defects are generally minor, with some areas of cracking in the external main beams (ECS = 3.3), likely due to corrosion of the embedded reinforcing bars (Figure 2b).

Figure 2. Bridge I: (a) main span view; (b) external beam with longitudinal cracking.

Bridge II is a large five-span structure (maximum span 89.8 m), constructed in the '70s and located in a rural area over a river at a great height. The first and the fifth spans are made of two deep RC beams with two end transverse beams. The structural scheme of the three main spans is made of steel-concrete composite girders supported over the piers, with half-joints (Figure 3a).

Defects are generally minor, except for some RC beams and piers which feature transverse and diagonal cracking (Figure 3b), likely due to shear (ECS = 4.3).

Figure 3. Bridge II: (a) bridge aerial view; (b) RC pier with diagonal cracking.

3.2 *Results and discussion*

According to the Italian guidelines, Bridge I has a ML level of deterioration; consideration of the other parameters in Table 1 increases the structural vulnerability class to M, mainly due to the effect of the speed of deterioration, whereas the hazard and exposure classes are respectively H and L. The resulting structural CA is M; therefore, besides periodic inspections every year, the structure has to undertake a preliminary assessment (L3), as well as an additional inspection if appropriate.

On the other hand, Bridge II has a MH level of deterioration; consideration of the other parameters in Table 1 results in a structural vulnerability class MH, whereas the hazard and exposure classes are respectively H and M. The resulting structural CA is MH; therefore, besides periodic inspections every 6 months, the structure has to undertake a preliminary assessment (L3), as well as an additional inspection, if appropriate.

When considering the UK guidelines, Bridge I has a good PI_{av} (82.0), while its PI_{crit} is poor (50.3). It would be possible to apply the procedure to extend the principal inspection interval, but since there are signs of concrete deterioration the interval remains at 6 years (Table 2). On the other hand, Bridge II has a fair PI_{av} (76.3), while its PI_{crit} is very poor (22.1), due to the shear cracks on a pier. As such, it is not allowed to increase the 6-year principal inspection interval.

When undertaking the UK structural review, both bridges are recommended to have a structural assessment with high priority. Bridge I is in better conditions, but the presence of critical elements, which cannot be adequately inspected during a principal inspection, leads to a more onerous score, and this is a parameter not included in the Italian rating.

Table 3 resumes the outcome of the inspection rating and assessment required. The PI_{crit} scores seem to be more onerous than the Italian LD, e.g., Bridge II is in the worst class in the UK, while in Italy is in the second worst. This is due to the fact that the most defective elements have not been considered critical elements, as defined in the Italian guidelines, whereas in the UK most structural elements are listed as of Very High importance, regardless of the significance of the observed defects on the structural integrity. On the other hand, the PI_{av} scores seem to align better with the Italian LD, in spite of the LD being based on the worst-conditioned element. This suggests that the UK condition rating is slightly more conservative than the Italian one. However, inspection intervals are considerably greater in the UK and, for the case studies presented, the recommendations for structural assessment are comparable.

Table 3. Outcome of inspection rating and assessment required according to Italian and UK guidelines.

	Italy			United Kingdom			
Bridge	LD	CA	Assessment	Opinion	PI_{av}	PI_{crit}	Assessment
I	ML	M	L3	Good	Good	Poor	High priority
II	MH	MH	L3	Fair	Fair	Very poor	High priority

Finally, it is worth noting that, for the Italian guidelines, priorisation within the class is not possible, as is the case for all qualitative methods, whereas for the UK guidelines it is possible to use the associated numerical values to establish a priority order.

4 CONCLUSIONS

In this paper, the Italian and UK risk-based methodologies for assessing the structural vulnerability of existing highway bridges are presented and applied to two case studies.

The vulnerability assessment is strictly related to the inspection process, although there are also other factors affecting the assessment. The Italian methodology is qualitative in nature and explicitly computes a vulnerability class, which is then combined to hazard and exposure classes to return Classes of Attention for specific risks, among which the structural risk. Conversely, the UK methodology is quantitative, but there is no explicit calculation of a vulnerability class.

Firstly, a stark difference is found in the time intervals between inspections: in Italy periodic inspections are at most every 2 years, with additional inspections as appropriate, whereas in the UK principal inspections are at least every 6 years, with general inspections every 2 years.

Secondly, the UK condition rating, in which average and critical condition performance indicators are scored on scales from 0 to 100, generally returns more conservative results than the Italian rating, which is assigned through five *levels of deterioration*, largely based on the worst-conditioned element. However, when examining the effects of the rating on the inspection process, the Italian guidelines seem more conservative: the UK scoring may be used to increase the interval between principal inspections through risk assessment, whereas the Italian level of deterioration is used to determine an overall Class of Attention, which may even reduce the interval of periodic inspections from the maximum of 2 years.

Thirdly, the two case studies show that results are comparable when evaluating the need of a structural assessment.

Finally, it must be noted that, in spite of both methodologies trying to reduce variation in the inspection process, subjectivity is still present, particularly when rating specific defects and estimating their importance on the structural behaviour.

The knowledge process for the structural assessment of existing concrete bridges with post-tensioned cables: Application to a case study

ABSTRACT: A structured project of knowledge is fundamental to comprehend the structural behavior of existing structures. The deeper and accurate is the level of analysis performed within, the lower is the approximation of evaluations and the higher the reliability of the outcomes. In the case of bridges with post-tensioned cables, this process gets trickier due to the hidden defects of the cables, indeed the level of approximation is also affected by the difficulty of not knowing *a-priori* their position and the impossibility of investigating all the cables. In this framework, this paper presents a methodology around the process of knowledge of these bridges, and its application to a case study. The aim of the method is reaching a deep level of knowledge for the proper characterization of the relevant variables, hence allowing to calibrate the values of the safety coefficients on the actual level reached, for a more accurate structural assessment.

1 INTRODUCTION

Nowadays, the road managers are dealing with the management of many infrastructures which for the most have reached the end of their design life with poor maintenance measures adopted in the time (Zhang, Liu, Liu, Lan, & Yang, 2022). Although some risk-based methodologies have been developed to provide instruments for expedite pointing out of critical evaluations (ANSFISA, 2022; Ministero delle Infrastrutture e dei Trasporti, 2020), a good amount of existing bridges (the damaged ones and/or with more vulnerable structural types, and/or the more exposed to traffic and those crossing urbanized areas or other infrastructures (Natali, Cosentino, Morelli, & Salvatore, 2023)) requires, or will soon require, an accurate assessment of the level of safety. For such purposes and to obtain reliable results, it is fundamental to properly define with limited uncertainties all the local and global parameters that characterize the capacity and the demand of the structure. Moreover, in the field of existing structures, it is also necessary to check the conservation status of the structure, pointing out defects and local/global vulnerabilities. Among the local level parameters, there are many to be statistically determined, so to be probabilistically treated (i.e. material strength and mechanical characteristics and hidden defects), and for which uncertainties (aleatory or epistemic) depend both on the accuracy of the measuring device and on the number of measures performed. Hence, besides choosing the more appropriate measuring devices and testing circumstances to maximise the related accuracy, to reach an appropriate and desired confidence level of the estimation it is necessary to properly evaluate the number of tests to be performed (the higher the number of the tests, the higher accuracy of the measures (Figure 1a) and the higher the confidence level, meaning reduction of uncertainties (Figure 1b)).

DOI: 10.1201/9781003483755-315

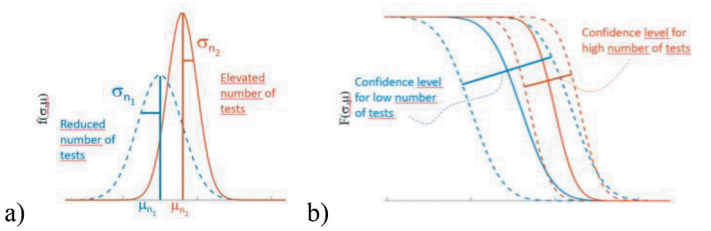

Figure 1. Examples of updating of a) Probability density function and b) Cumulative distribution function by increasing the number of tests (from n1 – reduced number of tests – to n2 – increased number of tests; with σ_i and μ_i, respectively, the standard deviation and medium value of the distributions).

The characterization of the local parameters gets harder when their population is not known in advance, as in the case of hidden defects of the pre-stressing system of Reinforced Concrete bridges with Post-Tensioned cables (RC-PT bridges). Indeed, in this case, the distribution and localization of defects is not known, so determining the amplitude of a significative sample is an iterative process. The method for the quantification and characterization of such defects is included in the procedure called "Special Inspection", which has been proposed and applied as showed within (Mazzatura, 2023; Mazzatura, Caprili, Salvatore, Casas, et al., 2023; Mazzatura, Caprili, Salvatore, Lupoi, & Ficociello, 2023). In this framework, this paper presents a methodology for designing the knowledge process aimed at the structural assessment of RC-PT existing bridges, with an application to a relevant Italian RC-PT viaduct. The aim of the method is reaching a deep level of knowledge for the proper characterization of all the relevant variables, including the hidden defects, hence allowing to calibrate the values of the safety coefficients on the actual level reached, for a more accurate structural assessment.

2 DESCRIPTION OF THE CASE STUDY AND DEFINITION OF THE PROCESS OF KNOWLEDGE

The 8-spans viaduct (Figure 2) is around 595 m long, and constituted of, starting from the left, three simply supported RC multi-beam decks and four *T-shaped* systems (the lateral ones are 70 m long, while the central ones are 116 m long). The peculiarity of the viaducts is the *T-shaped* systems, each one composed of one central pillar and two cantilever decks (Figure 3). The decks are composed of precast RC segments which are kept together and pre-stressed through post-tensioned Dywidag re-bars. The four *T-shaped* systems are, in the first construction stage, built one independent from the other one, then made continuous through shear connections. The constructive technique used for the realization of the decks of the *T-shaped* systems can be defined "intrinsically fragile", since the segments are kept together only by the pre-stressing system and the friction among the consecutive ones.

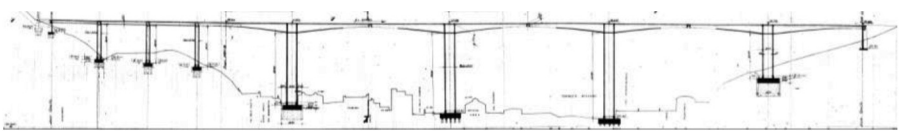

Figure 2. Longitudinal view of the viaduct.

The process of knowledge has been defined with the final aim of properly characterizing all the parameters that allow the definition of the demand and capacity of the structure, including the hidden defects that can be in the pre-stressing system, and organized as in the following: (i) Historical/critical analysis and of the original documentation; (ii) Investigation around the

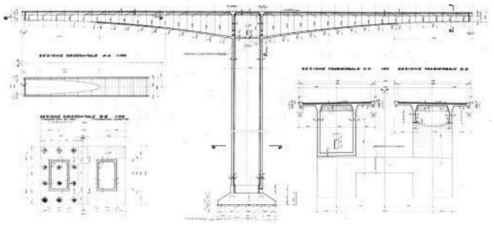

Figure 3. The *T-shaped* system.

global parameters that allow the definition of demand and capacity of the structure; (iii) Investigation around the local parameters for the definition of demand and capacity of the structure: characterization of materials, check of structural details, studies and *in-situ* surveys for the conservation status and damage of the Dywidag re-bars (the tests and *in-situ* actions have been planned accordingly to (Mazzatura, 2023; Mazzatura, Caprili, Salvatore, Lupoi, et al., 2023)). Furthermore, in parallel with the in-situ surveys, two numerical Finite Element (FE) models have been developed to understand, in the former, the stage constructions of the structure and its evolving stress state, and, in the latter, to simulate and calibrate the structural response of the structure to the external loads on the global investigations preformed, and then used for the evaluation of the demand. About point (i) of the methodology, there is plenty of original documentation available for this structure, together with a BIM model and all the results from a recent experimental campaign. This material has been used to characterize the current global and local geometry, the composition of the construction details and of the pre-stressing system, and, finally, the results from the experimental campaign have been adopted the for the *prior* materials mechanical characterization.

3 INVESTIGATIONS ON GLOBAL PARAMETERS

The investigations on global parameters comprehend global geometry, visual inspection for the conservation status, design of the in-situ surveys for the characterization of the natural frequencies of the system. Dealing with the global and constructive elements geometry, considering the plenty of material already at disposal from the original documentation, some spot measurements have been performed to check the correspondences, that have been positively verified. Regarding the conservation status of the structure, visual inspections have been performed and no local or global vulnerabilities have been identified - with reference to what it has been possible to inspect. The visual inspections have been completed with the so-called Special Inspections to investigate the conservation status of the pre-stressing system (§4.3). Finally, the dynamic behavior and natural frequencies of the system have been investigated through the Operational Modal Analysis (OMA). The OMA has been organized in different configurations that involve only the *T-shaped* systems. To better enhance the available instrumentation and time to perform such tests, the base configurations (Figure 4) involve two consecutive *T-shaped* systems, acquiring transversal (Y), vertical (Z) and longitudinal (X) directions in correspondence of the end zones of the decks, and Y and X directions in correspondence of the pillar. These acquisitions allow to catch the main modal shapes of the structure, including transversal vibration of the *T-shaped* systems, longitudinal movements of the viaducts, flexural and torsional movement of the decks. These base configurations are repeated for each couple of consecutive *T-shaped* system so that all configurations have at least one *T-shaped* system in common (in this way, the results can be merged and combined despite the non-simultaneity of the acquisitions). The tests were conducted during the night under conditions of complete disruption of vehicular passage, for a time acquisition of at least 45 minutes per each configuration (minimum time considering the expected first natural frequency).

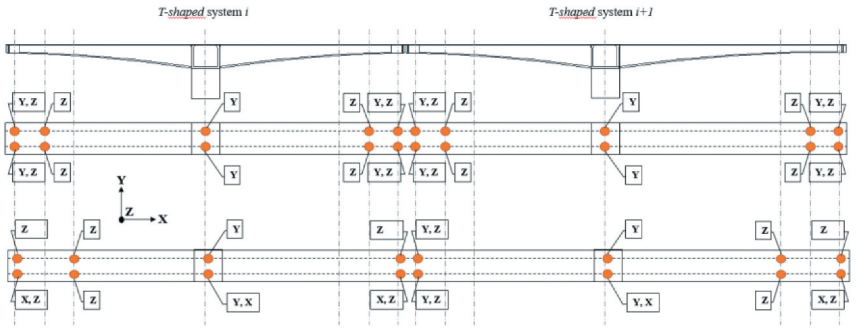

Figure 4. OMA tests: examples of the basic configurations for the acquisitions.

4 INVESTIGATIONS ON LOCAL PARAMETERS

The investigations on the local parameter include those for: checking the structural details, characterizing the materials properties, assessing the conservation status and damage of the pre-stressing system through *in-situ* surveys. Dealing with checking the structural details, *Georadar* has been used to have a view of the actual distribution of the reinforcement inside the segments of the decks, and then the correspondence with the original documentation has been positively verified. This matching allowed to consider the structural details fully characterized for the directly investigated zones and known with quite accuracy in the other zones.

4.1 *Concrete: Conservation status, prior material characterization and testing campaign*

The *prior* mechanical characterization of the concrete has been performed starting from the characteristic strength values according to the original documentation, and other assumptions and deductions according to literature and reference codes. Focusing into the *T-shaped* systems, concretes of pillars and decks' segments have to be analyzed separately. Table 1 gather the mechanical properties of the concretes: the characteristic cubic compressive strength R_{ck} has been deducted from the original documentation, which reported the parameter $\sigma_{r,28gg}$ as its corresponding value according to the standard of the time (R.D.L. 2229/1939 (*Norme per l'esecuzione delle opere in conglomerato cementizio semplice od armato. Regio Decreto Legge 16 novembre 1939.*, 1939)). $\sigma_{r,28gg}$ is equal to 400 kg/cm^2 for the pillars and 500 kg/cm^2 for the decks. The other parameters collected in the table are calculated consequently by adopting the related formulas from NTC2018 ("Norme tecniche per le costruzioni 2018- NTC 2018" 2018).

Table 1. Concrete: mechanical parameters according to the original documentation and derivations.

	Mechanical parameters						
Concrete	R_{ck}† [N/mm^2]	f_{ck}† [N/mm^2]	f_{cm}† [N/mm^2]	E† [N/mm^2]	ν†	G† [N/mm^2]	ϒ† [kN/m^3]
Pillars	40	33	41	33643	0.2	14018	25
Decks	50	42	550	35547	0.2	14811	25

† $R_{ck}/f_{ck}/f_{cm}$ = characteristic cubic/cylindrical/medium compressive strength; E = elastic modulus; ν = poisson modulus – not-cracked concrete; G = shear modulus – not-cracked concrete; ϒ = weight per unit volume.

The *prior* probabilistic modeling of the compressive strength of both the concretes has been done with the following assumptions: (i) a lognormal distribution is assumed; (ii) sample size *n'* is equal to 3 and degree of freedom *ν'* is equal to 10 (from JCSS Model Code JCSS probabilistic model code part 3: resistance models ("JCSS Probabilistic Model Code. Part 3:

Resistance Models," 2000)); (iii) the coefficient of variation CV' is assumed equal to 0.15, which is the typical value for concrete compressive strength ("JCSS Probabilistic Model Code. Part 3: Resistance Models," 2000); (iv) the characteristic strength value is the one deducted from the original documentation (40 and 50 N/mm^2 respectively for pillars and decks concrete). By this assumption, the *prior* probabilistic characterizations of pillars and decks concretes are defined by the following parameters: the characteristic values $\widehat{fc'}$ are respectively equal to 42.90 and 53.63 N/mm2, the medium values $\widehat{Rc'}$ are 51.69 and 64.62 N/mm2, and the standard deviations σ' are 5,343 and 6,681. The symbol 'is here adopted to distinguish *prior* knowledge from further updates.

In the framework of this study, the update of the *prior* distributions has been performed considering the experimental campaign recently executed, hence no other destructive or non-destructive tests have been performed. In the following, Table 2 collects the main information and deductions from the experimental campaign then used in this study to update the *prior* distributions.

Table 2. Relevant data from the experimental campaign for the characterization of decks and pillars' concretes.

Concrete	n†	μ† [N/mm^2]	σ†	f_{ck} † [N/mm^2]	E† [N/mm^2]	G† [N/mm^2]
Pillars	18	61,76	6,83	50,27	37987	15828
Decks	8	62,18	8,63	46,93	38064	15860

† n = sample size; μ = medium value of compressive resistance; σ = standard deviation; f_{ck} = characteristic value (5%); E = elastic modulus; G = shear modulus.

4.2 *PT cables: Special inspections for conservation status and tests for material characterization*

The Special Inspections for RC bridges with post-tensioned cables are required by the Italian Guidelines for existing bridges (Ministero delle Infrastrutture e dei Trasporti, 2020) to detect possible voids and defects in the pre-stressing system and quantify their severity. The general procedure for the design and execution of the Special Inspections (Mazzatura, Caprili, Salvatore, Lupoi, et al., 2023) is the following: (i) Phase 0a: Individuation of homogeneous populations within the pre-stressing elements, and relative zones to be investigated; (ii) Phase 0b: Special non-destructive surveys to assess the actual number and position of pre-stressed elements along the beam (through *Georadar* scans) and of possible voids (through *Tomography* scans); (iii) Phase 1a: Evaluation of the sample size and localization of the semi-destructive or locally destructive tests for each homogeneous population; (iv) Phase 1b: Execution of the semi-destructive or locally destructive tests. In this phase, concrete is removed till cable sheet, which is visually and through the *Endoscope* inspected to see its conservations status and detect possible damage. Then, a piece of sheet is cut away, together with grout, to assess the actual presence of voids and/or possible damage in the pre-stressing element (oxidation, corrosion, reduction of area). If defects are found in Phase 1b, it is necessary to progressively deepen the investigations.

Phases 0a to 1b have been applied in the framework of this study, with the additional evaluation of the mechanical properties of the Dywidag re-bars through hardness tests during Phase 1b. For each *T-shaped* system, and considering their symmetry, at least one zone has been individuated, corresponding to the changing of curvature of the Dywidag re-bars (Figure 5 – "Phase 0a"). After pointing out the exact location and geometry of the cables through *Georadar* acquisitions (no relevant differences with respect to the original drawings has been found), *Tomography* scans have been performed (Figure 5 – "Phase 0b") to localize possible defects. Figure 5 – "Phase 1a" shows in green the zones where Phase 1b actions have been executed: the green ones are those where defects could be present according to *Tomography* scans, while those in red are the other zones to be checked to conduct sample surveys. The Phase 1b activities highlighted that all the inspected spots are characterized by a good

conservation of the cables sheet, with no voids (grout fully present) and no oxidation of the Dywidag reinforcement. This suggests that there is a good probability that the pre-stressing system of the *T-shaped* structures is characterized by good conservation status, hence no further iterations of Special Inspections have been executed.

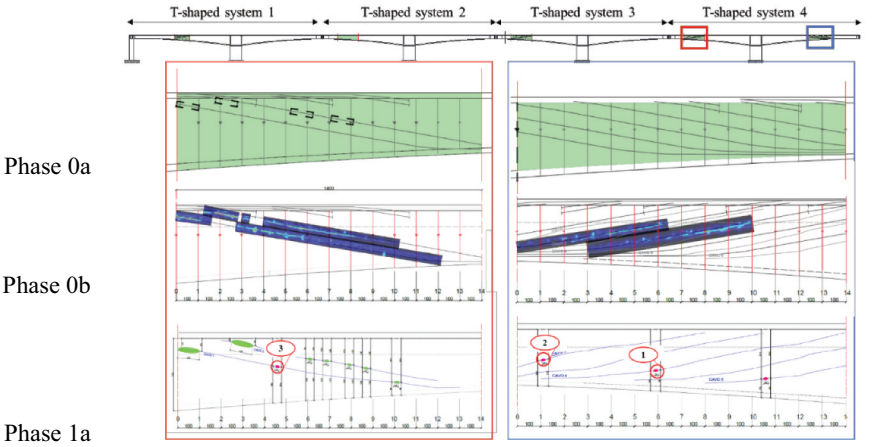

Figure 5. Special Inspections for the T-shaped systems: example of application to two inspected zones.

The hardness tests have been executed with a portable durometer in three zones (highlighted with red circles, Figure 5). A detailed procedure has been followed to obtain reliable results (Mazzatura, Caprili, Salvatore, Casas, et al., 2023). Table 3 gathers the results of the measurements and the correlations with the material strength according to ASTM E-140 (2019). The strength values derived from the tests are compatible with the one from the original documentation (where the ultimate tensile strength is at least equal to 10500 kg/cm^2). Despite only 3 tests could have been executed, the variability among them is quite low, and the low values of the coefficient of variation suggest the good executions of the measures, guaranteeing the reliability of the results.

Table 3. Measurements from the hardness tests.

Test spot	Medium Hardness [HV]	Ultimate tensile strength [N/mm^2]	CoV†	Sample size
1	294	919	1,6%	12
2	296	923	1,3%	12
3	299	936	4,7%	12

† CoV = Coefficient of variation.

The values deducted from the hardness tests have been used to update the *prior* characterization of Dywidag steel. The *prior* probabilistic modeling of tensile strength of Dywidag steel has been done with the following assumptions: (i) a lognormal distribution is assumed; (ii) sample size *n'* is equal to 50 and degree of freedom *v'* is equal to 10 (from JCSS Model Code JCSS probabilistic model code part 3: resistance models ("JCSS Probabilistic Model Code. Part 3: Resistance Models," 2000)); (iii) the coefficient of variation CV' is assumed equal to 0.025, which is the typical value for steel tensile strength ("JCSS Probabilistic Model Code. Part 3: Resistance Models," 2000); (iv) the characteristic strength value is the one deducted from the original documentation.

By this assumption, the *prior* probabilistic characterization of Dywidag pre-stressing system steel is defined by the following parameters: the characteristic value $\widehat{fy, p'}$ is equal to 884 N/mm^2 and the medium value $\widehat{fp, p'}$ is 1040 N/mm2.

5 POST-PROCESS OF THE RESULTS – GLOBAL PARAMETERS AND CALIBRATION OF THE FE GLOBAL MODEL

Two numerical FE models have been developed with the purposes of studying the evolution of the stress state and static scheme of the structure during construction, and of evaluating the demand in static condition. In the first model, all structural components were modelled using *beam* elements, with the aim of reproducing the construction phases from the assembly of the RC segments, the placement of pre-stressing system and post-tensioning application, to the variation of the static scheme following the insertion of shear connections. In this model, the cables have been modelled as elements working only in tension. In the second model, *shell* elements have been used to model of both deck and pillars to more accurately recreate the deformative behaviour of the structure, together with the structural response to external loads. In this model, the effects of pre-stressing system have been modelled by adopting the *equivalent loads* method and precautionary considering the relative short and long-term losses equal to 30%. In both models, global geometry has been deducted from the point cloud extracted from the BIM model at disposal, to represent the current geometrical configuration of the structure. The position of the pre-stressing system has been extracted from the original drawings, and updated, if necessary, thanks to the *Georadar* scans executed *in-situ* for the Special Inspection (§4.2). The constrains have been properly modelled through springs with difference stiffnesses for each degree of freedom in order to represent the actual behaviour. The second model has been appropriately calibrated based on the frequencies and modal forms obtained from the post-process of the accelerations acquired from the OMA executed *in-situ*. The data analysis and processing procedure allowed to point-out four main modes then adopted for the calibration of the FE mode (Figure 6): the modes 1 and 2 are flexional transversal modes in phase and in antiphase; the modes 4 and 6 are flexional vertical modes. The calibration procedure was conducted in a semi-automatic manner based on frequency matching, by verifying that the model's vibration modes were comparable with the experimental ones.

The parameters that have been updated in the calibration process are the elastic modulus of the decks and of the pillars, and the stiffness of the springs representing the shear connections between the consecutive *T-shaped* systems.

Mode 1. F= 0.47 Hz Mode 2. F= 0.71 Hz Mode 3. F= 1.36 Hz Mode 4. F= 1.56 Hz

Figure 6. Modal shapes of the FE model used for calibration process.

6 POST-PROCESS OF THE RESULTS – LOCAL PARAMETERS

The method to update the materials strength is defined according to ("JCSS Probabilistic Model Code. Part 3: Resistance Models," 2000) and considers, for the concrete, the knowledge acquired from the previously experimental campaign (Table 2) and, for the Dywidag re-bars, the values acquired from the hardness tests (Table 3). The so obtained *updated* probabilistic characterizations of pillars and decks concretes are defined by the following parameters: the characteristic values $\widehat{fc'}$ are respectively equal to 43.66 and 45,66 N/mm^2, the medium values $\widehat{Rc'}$ are 57,97 and 59,14 N/mm^2, and the standard deviations σ'' are 1,088 and 1,078. Regarding the Dywidag pre-stressing system, the characteristic values $\widehat{fy,pk''}$ is equal to 790,42 N/mm^2 and the medium value $\widehat{fp,p''}$ is 878,52 N/mm^2. With respect to the *prior* characterization, it can be noticed that most of the characteristic values have slightly reduced, but also the standard deviations, which highlights the increase of the accuracy of the evaluations.

7 EVALUATION OF SAFETY COEFFICIENTS ON THE ACTUAL LEVEL OF KNOWLEDGE

The partial safety coefficients have been calibrated following the entire process of knowledge and once the probability distributions of the material strength characteristics have been defined. According to JCSS formulations ("JCSS Probabilistic Model Code. Part 3: Resistance Models," 2000), the partial coefficients γ_M include both the model uncertainties γ_{mod} related to the type of mechanism to be checked and those related to the probability distribution of the material considered γ_{mat}, Equation (1).

$$\gamma_M = \gamma_{\mathrm{mod}} \cdot \gamma_{mat} \tag{1}$$

The model uncertainties follow a lognormal distribution with medium values μ and coefficient of variation CoV equal to, respectively, 1 and 0,1 for shear and torsion safety checks and 1,2 and 0,15 bending checks. The definition of the model uncertainties includes taking into consideration the aimed reliability index, that for the case study structure – consequence class 3 – is equal to 3,3, according to the fib Bulletin No.80 ("Partial factor methods for existing concrete structures. Fib Bulletin No. 80.," 2016). Following these considerations and by applying JCSS formulas, the resulting partial coefficient for modelling uncertainties are 1,11 for shear/torsion related safety checks ($\gamma_{mod,T}$) and 1,00 for bending related safety checks ($\gamma_{mod,F}$) Regarding the partial coefficients that considers material uncertainties γ_{mat}, JCSS formulations still have been adopted, which consider the *updated* mean values, standard deviations and final sample sizes following the whole and comprehensive process of knowledge performed on the study (§6). As an instance, γ_{mat} for pillars and decks concrete is 1,21, while for the Dyvidag steel is 1,10. Table 4 gathers the final partial safety coefficients to be adopted on concrete and steel materials composing decks and pillars of the *T-shaped* systems, when executing bending and shear/torsion safety checks, and compares these values to the ones according to NTC2018 ("Norme tecniche per le costruzioni 2018- NTC 2018," 2018). It can be noticed that there is a general reduction of the values thanks to the increase of knowledge reached.

Table 4. *Updated* partial safety coefficients for concrete and steel materials for bending and shear/torsion safety checks.

Material	Updated partial safety coefficients	Partial safety coefficients according to NTC2018 ("Norme tecniche per le costruzioni 2018- NTC 2018" 2018)	Variation
Pillars	$\gamma_{M,T}$† = 1,35	1,5	-10,0%
concrete	$\gamma_{M,F}$† = 1,21		-19,3%
Decks	$\gamma_{M,T}$† = 1,35	1,5	-10,0%
concrete	$\gamma_{M,F}$† = 1,21		-19,3%
Dywidag	$\gamma_{M,T}$† = 1,21	1,5	+5,22%
pre-stressing system steel	$\gamma_{M,F}$† = 1,10		-4,35%

† $\gamma_{M,T}$ = partial safety coefficient for shear/torsion safety checks; $\gamma_{M,F}$ = partial safety coefficient for bending safety checks.

8 CONCLUSIONS AND FUTURE WORKS

This paper proposes a methodology for the definition of the process of knowledge of existing pre-stressed reinforced concrete bridges with post-tensioned cables (RC-PT bridges). The aims of the proposed methodology is to properly characterize all the parameters that allow the definition of the demand and capacity of the existing RC-PT bridges, including a novel procedure for the detection and characterization of hidden defects ("Special Inspections" (Mazzatura, Caprili, Salvatore, Lupoi, et al., 2023)). Then, the safety coefficients for the semi-probabilistic static structural assessment are calibrated on the actual level of knowledge achieved. The

proposed method has been applied to a 8-spans RC-PT viaduct characterized by very peculiar decks are composed of precast RC segments which are kept together through post-tensioned Dywidag re-bars. The investigation campaign related to the local parameters, referring particularly to the mechanical characterisation of the materials, allowed to enlarge the sample size and thus its representativeness for the evaluation of the characteristic and average values of the resistances, bringing the decrease of the safety coefficients of the materials (Table 4). At the same time, the experimental investigations at global level allowed a proper calibration of the numerical mode, then more catching and representative of the actual structural behaviour and response of the whole system. The application of the proposed method highlights how a suitably designed and calibrated knowledge process may allow for a better characterisation of the relevant variables, thus reducing the relative uncertainties and possibly reducing the caution when assessing the level of safety.

Sustainable repair of concrete structures in Denmark

Jens Mejer Frederiksen & Christian Møller Nielsen
COWI A/S, Lyngby, Denmark

ABSTRACT: Repair of concrete structures must be considered very carefully and preferably only be used if the cause of the damage has been clarified and will be remedied. Furthermore, the repair must be able to achieve a durability that is comparable to the remaining life of the surrounding structure. Correct repair and possibly supplementary protection of concrete structures is in many cases a more sustainable and cheaper solution than replacing the same structure.

By March 2024, the authorities responsible for the management and maintenance of infrastructures in Denmark publish new General Work Specifications for the repair and protection of concrete structures.

The paper summarizes how the common European standards for repair and protection of concrete structures (the EN 1504 series) have been and will be further implemented in Denmark. Examples from the specifications are shown. The approach is applicable for other countries as well. To apply the standards the presumed methodology must be used.

It is presupposed that personnel have the necessary skills and adequate equipment and resources to design, specify and execute the work in accordance with the relevant part of EN 1504 and the requirements of the project specification. The skill levels for each function in the value chain of a repair project has been defined in the standard DS 2425. A training programme has been defined as well and training lectures are being planned.

The paper gives short illustrative examples of typical obstacles that can be met by the inspector of concrete structure to be repaired, the person in charge of the elucidation of defining the cause of damage and hence the extend, the person in charge of the design, the person in charge of pricing the works, the person in charge of the supervision and the person in charge of the execution.

1 INTRODUCTION

Since the mid-1980s, the production of concrete in Denmark has been subject to specific regulations that ensure the expected service life of all significant concrete structures in the construction and civil engineering sector. The starting point for the technical service life is 50 years of durability without significant maintenance for building structures. For infrastructure, the requirements for the technical service life have since the mid-1980s been raised to 120 years. This has essentially been achieved by increasing the requirement for cover thickness by +10 mm combined with the obtained understanding of how to avoid premature concrete deterioration.

Since the regulations came into effect in around 1985, there has not been a single case of premature deterioration or lack of durability of conditional concrete structures in Denmark to date, which is naturally very satisfactory.

Unfortunately, the same cannot be said for concrete structures predating this period. Back then, the available knowledge on concrete degradation and risks associated with different constituents and compositions of concrete was not effectively applied. Therefore, there are still some older structures in both buildings and infrastructure that need to be repaired or have their service life extended.

The pathological signs of degradation and damage typically result from either 1) frost damage, 2) alkali-silica reactions, 3) carbonation, or 4) chloride ingress. The first two initially

DOI: 10.1201/9781003483755-316

only lead to damages to the concrete but can later affect the load-bearing capacity of the structure critically if they progress.

The latter two cause damages to the reinforcement, and these damages typically fall into two different problem types. 'Carbonation' results in a uniform and extensive corrosion of the steel in the concrete, leading to delamination of the cover layer with a risk of passers-by near the structure being hit by concrete fragments. 'Chloride ingress', on the other hand, leads to more hidden, localized pitting corrosion that can cause a critical reduction in the cross-section of the reinforcement and thus collapse of the structural component. This has happened a few times in Denmark – fortunately without any loss of life. Hence, there is a strong focus on preventing a recurrence.

Other reasons for repair like exposure to fire, physical damage and overloading are naturally also relevant, but these types of repairs do not correlate with the initial quality of concrete in the same manner.

Table 1. Overview of the special Danish requirements (cf. [3]) as they have been practiced with success since the mid-1980s – only small modifications have been introduced in the period. Numbers with * are valid for infrastructures with an expected service life of 120 years.

Exposure category	Passive, P	Moderate, M	Aggressive, A	Extra aggressive, E	
Exposure class according to EN 206	X0	XC2	XD1	XD2	
	XC1	XC3	XS1	XD3	
		XC4	XS2	XS3	
		XF1	XF2	XF4	
		XA1	XF3	XA3	
			XA2		
Examples	Indoor (dry) and subsoil	Facades and other outdoor without salt	Mild saline environments and submerged	Direct salt exposure and freezing plus swimming pools	
	Exposure category (group of classes)				
Property	P	M	A	E	Unit
$f_{ck,cyl} \geq$	12	30	35	40	MPa
eqv$(w/c) \leq$	-	0.55	0.45	0.40	(by mass)
Binder type (Cement, fly ash, silica fume)	Restrictions according to DS/EN 206 DK NA				-
Strength class for cement, minimum	32.5	42.5	MPa		
Cover $c_{\min} \geq$	10	20	30 (40*)	40 (50*)	mm
Crack width $w_k \leq$	-	0.4	0.3	0.2	mm
Pre-stressed $w_k \leq$	-	0.3	0.2	0.1	mm
Air content $\geq$	-	4.5 %	4.5 %	4.5 %	(fresh, by volume)

The special Danish durability requirements for concrete are based on the principles now known from EN 206 ([2]), Annex F, Table F.1. Table 1 above illustrates the slightly stricter requirements imposed on concrete in Denmark, [3] compared to the requirements in EN 206 ([2]). Furthermore, Danish regulations, [3] have stricter documentation requirements compared to EN 206([2]), with regards to providing evidence of the concrete mix design of each produced and delivered batch.

Despite concrete requirements that provide the expected technical service life, there is still a need for repairs on brand-new structures, perhaps even to a greater extent than previously. This is mainly due to errors during construction, where deficiencies in the concrete cover on the reinforcement and in the concrete itself are often observed.

Table 2. How to come from 'repair method' according to [5] to the suitable product type with the 'General Work Specification ID' (A to G), cf. [7].

Repair method according to EN 1504-9	Execution method	Product type	Remarks	GWS type ID
3.1	Hand placement	Mortar or concrete	Used for repairs that are small enough to be executed by hand placement of mortar or concrete. It is of highest priority that the product is easy workable.	A
3.2 4.4	Fluid casting	Concrete	Used for larger repairs that can be cast in form at thicknesses over 35 mm.	B
7.1 7.2		Mortar	Used for small repairs that can be cast in form at thicknesses below 40 mm.	C
3.2 4.4 7.1 7.2	Underwater form casting	Mortar or concrete	Casting in form underwater Concrete or mortar Special concrete or mortar that, in its fresh state, does not wash out and can displace water from the form, eliminating the need for drying. Otherwise, like ID B or C	D
3.3 4.4 7.1 7.2	Casting on large surfaces	Wet sprayed concrete	In the wet spray method, a pre-mixed mortar-concrete blend is conveyed through hoses by a screw pump and sprayed onto the desired surface by compressed air at the outlet.	E
		Dry sprayed concrete	In the dry spray method, a dry mortar or dry concrete mix is conveyed through hoses by compressed air, and water is added only at the outlet, just before the material hits the substrate	F
3.2 4.4 5.3 7.1	Casting with slope, profiling	Mortar or concrete	Used for overlaying a concrete structure, possibly for simultaneous creation/restoration of slope conditions on upward-facing surfaces. Otherwise, like ID B or C	G

These deficiencies often include 'insufficient cover thickness' and 'inadequate compaction'. Consequently, whereas repairs previously mainly were made due to ageing of structures, repairs are now made on brand-new structures before they are even handed over and put into use. This places significantly higher demands on the quality of the repairs and the lifespan of repairs.

2 IMPLEMENTATION OF EN 1504

Since before its implementation in 2009, the incorporation of the EN 1504 series (cf. [5] for an introduction) into Danish repair regulations has been prepared, and adjustments have been made continuously as experiences have been gathered afterwards. Despite this, there has been a relatively slow adaptation to the methodology that is intended to be used.

With the latest revision, cf. [7] and [8], an assessment of suitability and a declaration of suitability have been introduced, as CE marking alone does not guarantee that a product is suitable for the specific application.

For repair products for concrete, the contractor must now ensure that an assessment of suitability has been conducted for the chosen products. This assessment should include, among other things, the following:

- A written statement regarding the suitability of the offered product(s) for each of the proposed repair types.
- Each product should be suitable for the respective casting method(s).
- The type testing shall cover the declared casting method(s).
- Identification information regarding workability.
- Identification of the intended repair type or method according to [5].
- Compliance with any additional requirements specified in the repair regulations or project specifications, e.g. electrical conductivity in case of application of cathodic protection.

The suitability assessment and declaration serve to ensure that the selected repair products are appropriate for the intended repair type and that they meet the necessary performance criteria. This helps to ensure the quality and effectiveness of the repairs carried out.

In Table 2 and Table 3 a way to come from 'the repair method found according to EN 1504-9′ to a 'suitable repair product type' is suggested.

Table 3. Guidelines for selecting product type and execution method based on orientation of the casting joint according to [9].

GWS type ID	A	B	C	D	E	F	G
Product type and method of execution	Mortar or concrete for hand placement	Concrete for fluid casting	Mortar for fluid casting	Mortar or concrete for underwater casting	Wet sprayed concrete	Dry sprayed concrete	Mortar or concrete for overlaying and profiling
Method according to EN 1504-9, [5]	3.1	3.2 4.4 7.1 7.2	3.2 4.4 7.1 7.2	3.2 4.4 7.1 7.2	3.3 4.4 7.1 7.2	3.3 4.4 7.1 7.2	3.2 4.4 7.1

3 COMPETENCES AND TRAINING PROGRAMME

EN 1504-9 (cf. [5]), Cl. 10, A.4.3.5 and Cl. A.10 are the places where the qualifications of people working with repair and protection of concrete structures are explicitly outspoken.

Cl. A.4.3.5 says:

"*... All assessments should be made by suitably qualified personnel with knowledge of investigation methods, structural design, maintenance, material technology and of the mechanisms which can contribute to the deterioration process of concrete structures...*"

Moreover Cl. A.10 states:

"*Personnel should be appointed who are familiar with protection and repair of concrete works and recognized as competent. This requirement requires to all persons involved in the repair process, including repair scheme designers, repair contractors and repair work inspectors. . .*"

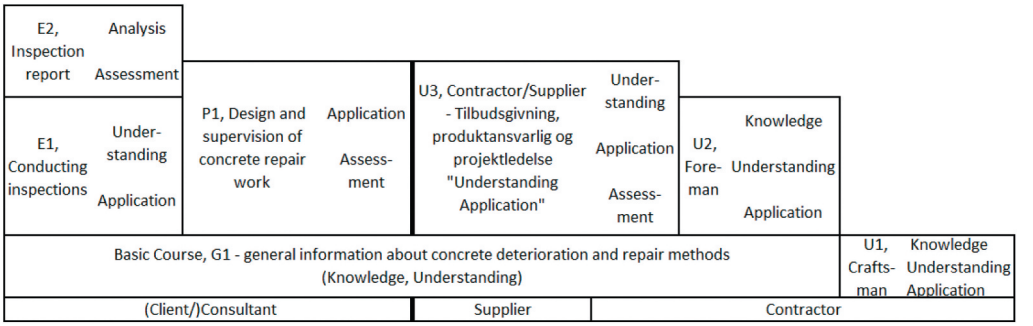

Figure 1. Schematic overview of the different courses being developed for training personnel to taking care of a repair project throughout the value chain and at all competence levels.

These general requirements and presumptions were adopted by the Danish concrete repair network named *Danrep* by unanimity. A task force was established and two years later the work crystalised in DS 2425, cf. [4].

In [4] Bloom's taxonomy [1] is used to define what skills levels are needed to carry out the individual functions in a repair project, cf. Figure 1 above. Further it defines how to verify obtained skill level at an exam. Several courses are being planned to provide the training. An overview of the courses and the corresponding skills levels is shown in Figure 1.

4 EXAMPLES

Below some examples are given – not to show the answers, but to illustrate the kind of cases that can be the reality in practice and what dilemmas they may encompass when it comes to the repair process. The examples shown are simple, but the dilemmas are generic.

A. **Insufficient compaction** of concrete structures that are to become watertight for many years is a severe execution fault. In Figure 2 an example of such a local defect is shown. Since there are requirements for watertightness a safe solution must be found. Additionally, the contractor has the duty as well as the right to reestablish the required quality. . .the following questions will typically arise:
   - What investigations are needed?
   - How can the Owner feel secure that the repair will be safe and durable?
   - How to make repairs with +50 years durability.
   - What measure will cause the minimal disruption to the progress on the construction site?

B. **Insufficient cleaning** of concrete surfaces prior to casting a new profiling layer may lead to lack a durability. The specification said: "*Before pouring new concrete against existing concrete, the surface must be cleaned by high-pressure washing or sandblasting so that it is free of organic material and layers that prevent good contact with the concrete.*"
   - The contractor regarded the surface shown in Figure 3 as being complying to the expectations. But does it?
   - The work was done as specified – a person did clean the surface with high pressure water. But is the outcome as specified?
   - The person responsible for the specification was sure it was a clear and concise text.

Figure 2. Poorly compacted concrete in a newly cast wall in a swimming pool.

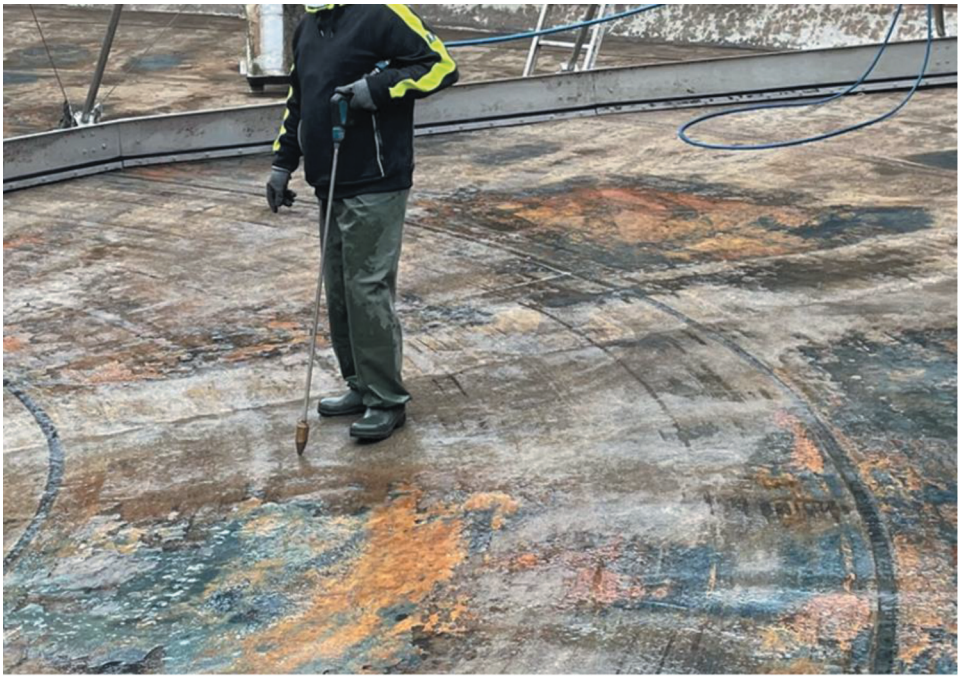

Figure 3. A surface after cleaning with high pressure water – but is the cleaning work finished and is the surface ready for application of a surface coating?.

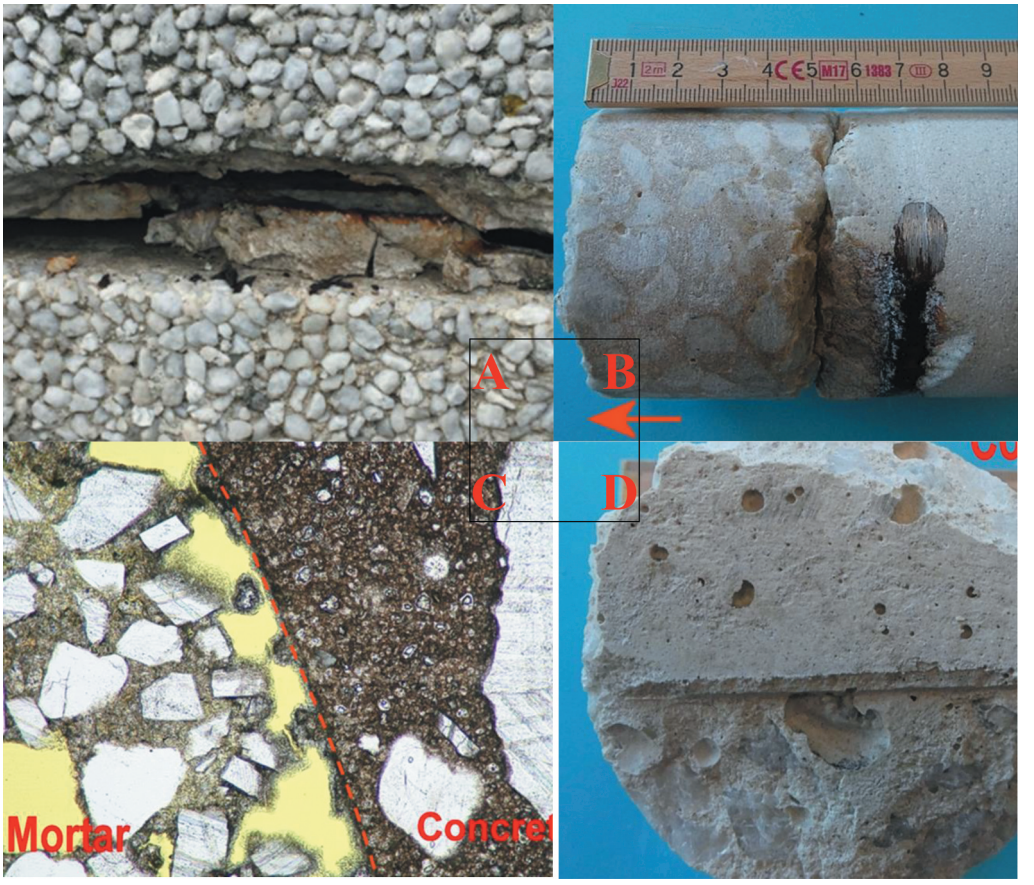

Figure 4. A) A local spot from a façade where a 0.2 kg piece of concrete spalled off. B) A sample taken in the damage (A) showing that the façade element is made up of concrete on the exposed side and mortar on the rear side. C) A close-up photo from microscopy of the sample (B)) showing a smooth casting joint between concrete to the right and a mortar to the left. D) shows that the rear side of the element has imprint of formwork i.e., formwork on the topside during casting.

- The person who did the pricing of the work may have thought that we can easily provide what is needed.

C. **The obvious cause of damage** can sometimes be misjudged and hence lead to misinterpretation and even misspecification of repairs. In Figure 4 is shown an example representing a façade of several thousands of square metres. The façade elements were casted with topside formwork on the rear side of the toe of the elements. This may have caused some irregularities during the casting manifested by trapped air pockets towards the formwork.

Hence, parts of the reinforcement may have been discovered to be exposed when demoulding. The issue of the trapped air pockets has called for a repair of the backside of the element's toe by applying a cement mortar.

This repair was made of low-quality mortar (compared to the concrete) and moreover proper preparation of the casting joint was not performed. Hence, this inadequate repair has enabled cracking (the poor casting joint), the consecutive corrosion and expansion of the reinforcement, and finally the concrete spalling.

The described casting irregularity may have easily been prevented by drilling air outlets or the like in the formwork. This measure was presumably applied, but not until it was discovered and thus after the production of some elements.

After a thorough inspection of the façade only a small number of initials faults like this was found. The key point of this example is that a thorough analysis to 'find the real cause of damage' must be made to specify the right repair – and that also the key to a successful repair according to [5].

The examples above touch on some of the issues that must be taken due care of in a repair project. I.e.:

- How to find and apply the correct measures to restore the properties of the structure without jeopardising the time schedule and the economy?
- How to define and communicate on what is sufficient to fulfil specifications of a qualitatively defined work?

5 SPECIFICATIONS

Besides following the route given in [5] via the exact cause of damage, the principles, the repair method and then choosing a suitable group of products (cf. e.g., Table 2 above) for the repair project, the new Danish General Work Specifications for repair and surface protection of concrete structures also direct a way to control the execution.

Stepwise requirements for the outcome of each work process of the repair work must be found acceptable to end up with a repair complying with the requirements for the repair work. For this the test methods given in EN 1504-10, [6] (meant for on-site use) can be applied. In Denmark these methods are supplemented by similar but more specific, simple test methods for use on site, cf. [11].

Finally, it shall be noted that with the new specifications [7] and [8] the authorities will aim at conducting repair works whenever needed and possible to obtain the most sustainable maintenance of the existing and new infrastructure as possible.

Vulnerability assessment of timber piles by bending wave and dispersive wave testing methods

W. Zatar & H. Nghiem
Marshall University, 1 John Marshall Dr, Huntington, USA

ABSTRACT: Timber piles have been used to construct many aging bridges, locks, dams, levees, and other structures in the United States. Degradation of these piles may adversely affect their structural integrity and eventually cause catastrophic failure. This study utilizes state-of-the-art non-destructive testing (NDT) techniques to assist with vulnerability assessment of timber piles employed in aging bridges. Two timber piles were nondestructively tested in the laboratory, where one was undamaged and the other suffered damage at different locations. Test parameters include size and location of defects. Four NDT testing and evaluation methods were utilized for the timber piles. The NDT testing and evaluation methods are bending wave, dispersive wave, a combination of dispersive-bending wave, and parallel seismic. The Wavelet transform advanced signal processing method was used to post-process the NDT data. Peak identification method was used to detect the pile tip for both the bending wave and the dispersive wave/bending wave tests. The experimental results reveal that the dispersive wave/bending wave accurately detected the defects in the timber piles. The wavelet transform approach successfully detected the piles' shallow defect and the pile tip. The parallel seismic testing captured the pre-planned defects accurately in the timber piles.

1 INTRODUCTION

In the United States, numerous bridges span waterways to facilitate river navigation. Commonly employed as foundational elements for these bridges, wooden and steel piles support various civil and military infrastructures, safeguarding lives, the environment, and property against floods. Most pilings within the country's water resource infrastructure surpass 50 years old. Unfortunately, there is a lack of documented evidence regarding their structural health. This scarcity arises from the inherent challenges of inspecting pile foundations embedded in the soil and the considerable cost associated with assessing the condition of pilings in the United States water resource infrastructure. The undisclosed conditions of these pilings could give rise to significant risks throughout infrastructure inventories nationwide.

While foundation pilings are typically designed for long-term durability, their failure carries the potential for significant structural and catastrophic consequences. Defects along the piles can be a primary cause of such failures. Employing an efficient inspection or NDT technique becomes crucial for enhancing maintenance management, enabling engineers to predict the current conditions of the pilings accurately.

Non-destructive testing (NDT) methods can be categorized based on stress waves (also called acoustic or mechanical waves), electromagnetic waves, electrical/magnetic fields, and others (Xiao et al., 2019; Zatar et al., 2020). For deep foundations, the following NDT techniques are commonly used (Wightman et al., 2004; Olson, 1996):

- *Surface-based NDT methods*: Sonic echo/impulse response (SE/IR); Flexural (bending) wave (BW); Ultra-seismic (US); Spectral analysis of surface waves (SASW); Ground penetrating radar (GPR); Dynamic foundation response; Electrical resistivity imaging/induced polarization.
- *Subsurface-based (a.k.a. borehole-based) NDT methods*: Parallel seismic (PS); Borehole sonic; Borehole radar; Cross-hole sonic logging; Induction field; Borehole magnetic.

DOI: 10.1201/9781003483755-317

The impulse response/sonic echo (IR/SE) methods, as detailed by Olson (1996), Finno & Gassman (1998), and Finno (2010), have found widespread application in assessing the lengths, continuity, and integrity of both recently installed and operational deep foundations. These foundations include concrete or timber drilled shafts and driven piles. The methodology detects defects such as cracks, breaks, pile necking, lengths, bulbs (indicating diameter increases), and soil inclusions (Figure 1a). The IR/SE method uses surface reflection techniques to identify compressive wave reflections.

The bending wave (BW) method, as outlined by Olson (1996) and Finno (2010), diverges from the compressional waves employed in the IR/SE methods. Instead, the BW method utilizes flexural waves to ascertain deep foundations' unknown depth and integrity. Unlike the IR/SE methods, the BW method is specifically tailored for applications involving "rodlike" deep foundations, such as timber or concrete piles and drilled shafts that extend visibly above the ground or water surface (Figure 1b). An example of BW test results for a timber pile is shown in Figure 3.

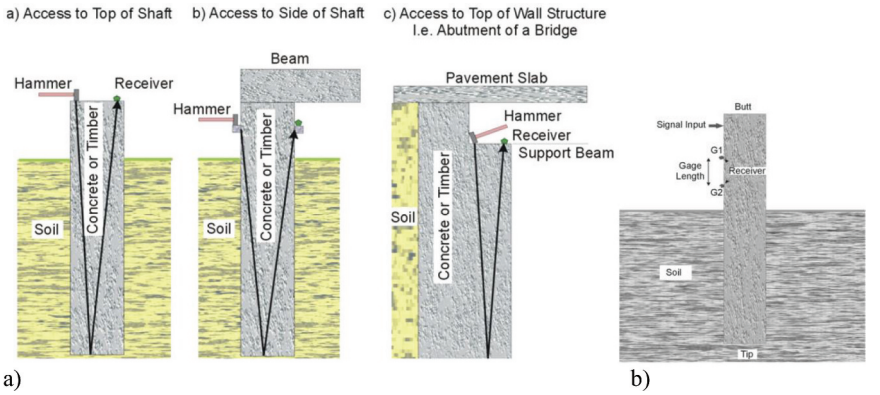

Figure 1. (a) IR/SE and (b) BW test methods.

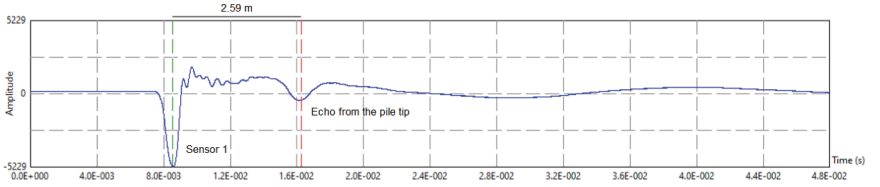

Figure 2. Examples of depth calculations using impulse response and sonic echo methods and BW test results for a timber pile.

The dispersive waves (DW) method can also be used to determine the cross-sectional integrity of a timber pile, as shown in Figure 3. The technique involves three significant steps:

1. Placing magnetic washers and accelerometers around a pile at "x" (x = circumference of the pile/4) apart around the circumference of the pile.
2. Striking on one washer and capturing the wave at the rest of the washers.
3. Calculating the velocity of the DW to travel from the impact washer to the other washers to gain information on the cross-sectional integrity of the pile.

Table 1 presents the comparison of test methods for timber piles.

The Parallel Seismic (PS) method, extensively studied by Niederleithinger (2012) and Liao et al. (2006), stands out as a prominent non-destructive testing (NDT) technique designed for borehole testing (Figure 4). This method has been widely researched and developed to determine the lengths of foundations with unknown dimensions. Notably, the PS method detects significant discontinuities within a foundation and provides valuable insights into the

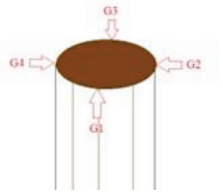

Figure 3. Cross-section integrity testing layout for a timber pile.

Table 1. Comparisons of NDT methods for timber piling.

Test Method	Investigation Type	Pile Exposure Required?
Mechanical Wave Velocity	Overall pile integrity	Yes, at least 4 ft
Cross-sectional using Dispersive Wave	Cross-sectional integrity on exposed pile only	Yes
Cross-sectional using Ultrasonic Wave	Cross-sectional integrity on exposed pile only	Yes

surrounding soil velocity profile. The procedure involves installing cased boreholes (water-filled if hydrophones are utilized) near the foundation under examination. The PS method proves particularly effective when testing long and slender piles (e.g., driven piles) is impractical using IR/SE techniques and when the top of foundations is inaccessible.

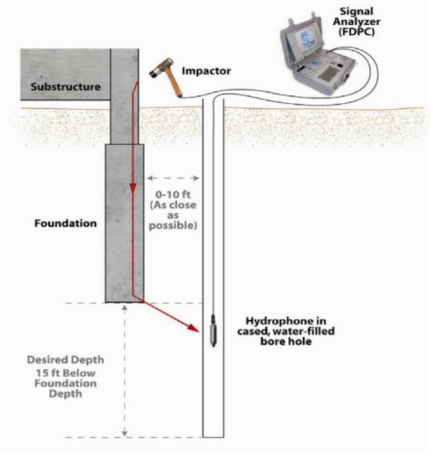

Figure 4. The Parallel Seismic (PS) method.

2 LARGE-SCALE TESTBED

A large-scale testbed has been designed to develop, test, and validate NDT methods for evaluating the conditions of wooden and steel piles. The testbed includes a three-dimensional steel-frame structure filled with sandy soils and pre-installed wood/steel pilings (Zatar et al., 2022a, 2022b). The steel frame was constructed with H-shaped columns, top/bottom beams, bracing systems, and perimeter steel walls (Figure 5). The overall dimensions of the frame are 2.74 × 2.74 × 3.05 m (width × length × height).

The experimental testing involves two pairs of timber piles and H-piles positioned strategically on the testbed. Each pair consists of one control pile devoid of artificial flaws and another intentionally featuring pre-planned defects. These four piles are situated at the corners of the testbed, as depicted in Figure 6. A 0.1-meter polyvinyl chloride (PVC) pipe, centrally positioned on the testbed, accommodates hydrophones for the parallel seismic (PS) non-

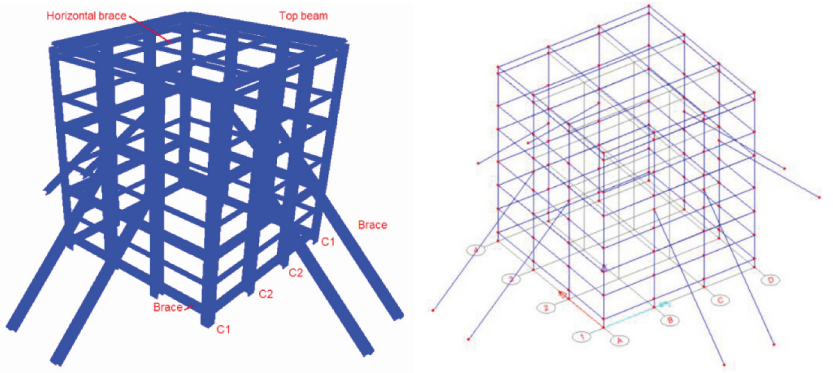

Figure 5. Overview and 3D model of the steel frame.

destructive testing (NDT) method (Figure 7). The elevation view of the testbed, incorporating the embedded piles, is presented in Figure 6. Key test parameters encompass:

1. Timber piles.
2. Various NDT methods were employed, including bending wave (BW), impulse response (IR), and parallel seismic (PS).
3. Sizes and locations of artificial defects on timber piles (Table 2).

Specifically, section losses in a rectangular shape representing the deterioration of the timber pile were deliberately introduced at 0.3 meters from the top (upper defects) and 0.3 meters from the bottom of the piles (lower defects). The piles were attached to the base plates connected to a strong floor (Figure 7). The bottom of the PVC pipe was sealed entirely to ensure it could hold the water needed to conduct the parallel seismic tests. The steel cage was filled with 30 tons of fine-grained construction sand (contained in more than 30 heavy-duty sandbags) to mimic the field environment of actual pile foundations. The testbed is ready to conduct laboratory testing of scaled wood piling to validate the condition assessment approach and water-filled plastic pipe and hydrophone, as shown in Figure 8.

Table 2. Test parameters.

Employed NDT methods	Type of defects	Size of defects	Location of defects
Bending Wave (BW) Parallel Seismic (PS) and Impulse Response (IR)	Section loss (rectangular shape)	0.25s × 0.5s	1' (12") from top of the pile

Figure 7. Piles and PVC pipe installed in the cage.

Figure 8. The testbed is ready to conduct laboratory testing of scaled wood piling for validation of the condition assessment approach (left) and water-filled plastic pipe and hydrophone (right).

3 TEST RESULTS

The sonic echo (SE) test method exhibits sensitivity to variations in pile impedance, which induces the formation of a reflected wave. A reduction in impedance, arising from factors like corrosion or decay, produces a reflected wave that, when combined with the incident wave, results in a downward peak (trough) in the signal. The process of interpreting a peak in the signal as a reflection indicative of a defect is called peak identification (PI). In a defect-free pile, only two peak reflections are typically observed in the measured signals, one from the impact impulse and the other from the reflection at the pile tip. The presence of intermediate peak reflections between the pile top and tip signals the existence of defects. However, the reflected wave from minor or deep defects may be weak and overshadowed by the incidence or reflected wave from the pile tip, posing challenges for the PI method in detecting such defects effectively. To address this limitation, wavelet transform (WT) comes into play. WT is widely employed for analyzing periodic, noisy, intermittent, and transient signals (Ni et al., 2017). Leveraging its sensitivity to phase information, the WT technique proves helpful in localizing pile damage, making it advantageous in scenarios where phase information is crucial for detection (Ni et al., 2017).

Three testing methods, including bending wave (BW), dispersive wave (DW), and mixed dispersive-bending wave (DW/BW), were conducted as schematically shown in Figure 9. Accelerometers and inhouse data acquisition were respectively used for sensing and recording the response of the tested piles subject to lateral and vertical impacts from different strikes produced by hard hammer (HH), baseball bat (BP), 1.8-kg sledgehammer (4-lb), bowling pin, and sphere. Different hammer types can generate distinctive frequencies of vibration. Some test results are presented in Figure 10 across Figure 13. The PI method can effectively be used to detect the pile tip in BW (Figure 9) and DW/BW (Figure 12) tests. The BW tests could only capture the upper defects (Figure 10). The combination of dispersive-bending waves (DW/BW) accurately determined upper and lower defects (Figure 12 and Figure 13). The WT method can detect the upper defect and the pile tip

(Figures 14, 15, and 16). The parallel seismic test was able to find both upper/more minor defects at the 12th strike (~0.91 m) and lower/more significant defects at the 36th strike (~ 2.74 m), as shown in Figure 17.

4 CONCLUSIONS

Based on the obtained test results, the following conclusions were drawn:

- The peak-signal reflection method known as "peak identification (PI)" proved effective in detecting the pile tip in both bending wave (BW) and dispersive-bending wave (DW/BW)

tests. However, the BW test exhibited limitations in capturing lower defects. The combination of dispersive-bending wave (DW/BW) was identified as a successful approach in accurately determining pre-planned defects, encompassing the pile's upper and lower sections. Additionally, the wavelet transform (WT) method successfully detected shallow defects in the piles and accurately identified the pile tip.
- The parallel seismic (PS) test demonstrated accuracy and effectiveness in capturing upper and lower pre-planned defects in the timber pile.

Maintenance plan optimization system based on remaining life prediction

A. Miyamoto
Prof. Emeritus, Dr. Eng., Yamaguchi University, Ube, Japan

ABSTRACT: In this paper, a maintenance plan optimization system (MPOS) which is a subsystem of the Japanese Bridge Management System(J-BMS) is described based on the results of remaining life prediction of the existing bridges. The proposed system that considered not only remaining life cycle cost (RLCC) but also rebuild cost stabilization is applied to existing bridge data on about 3,500 bridges that collected in J-BMS database (J-BMS DB) for practical use. Then, it is found that the system helps the efficiency of bridge engineers related to bridge management understand easily what are the major processes in the deteriorating bridges in the future, how to improve their performance, and what kind of repair/strengthening works is most convenient for the deteriorating bridges.

1 INTRODUCTION

The author has been developing a practical bridge management system (J-BMS) for bridge network in Yamaguchi Prefecture, Japan, which integrated with the concrete bridge rating expert system (BREX) that can be used to evaluate the serviceability (durability, load carrying capability) of existing concrete bridges (Miyamoto & Motoshita 2015). The J-BMS will be able to predict the deterioration process of existing bridge members, recommend a maintenance plan for repair and/or strengthening based on minimizing maintenance costs and maximizing quality, and estimate the maintenance costs in single bridge. In this system, the genetic algorithm (GA) technique was used to search for an approximation of the optimal maintenance plan. In this study, a comprehensive decision support system is developed for maintenance strategies with/without annual budget limitations based on life cycle cost analysis of an entire bridge inventory, which form part of a highway network. Especially, a maintenance plan optimization system (MPOS), a subsystem of the J-BMS, is described based on the results of remaining life prediction of the existing bridges. The proposed system that considered not only remaining life cycle cost (RLCC) but also rebuild cost stabilization is applied to existing bridge data on about 3,500 bridges that collected in J-BMS database (J-BMS DB) for practical use (Miyamoto, et al. 2009). Then, it is found that the system helps efficiency bridge engineers related to bridge management understand easily what are the major processes in the deteriorating bridges in the future, how to improve their performance, and what kind of repair/strengthening works is most convenient for the deteriorating bridges. In order to make the J-BMS developed by the authors a more practical tool, the MPOS that can be used for more than one bridge on the highway network has been developed. The system performs three tasks: (1) making it possible to draw up a maintenance plan that takes into consideration not only repair and strengthening based on structural soundness evaluation results but also reconstruction so that the peaks of future reconstruction costs can be saved; (2) provides a reconstruction cost stabilizing function to calculate a realistic service life of each bridge, and (3) drawing up a maintenance plan that satisfies the budgetary requirements for repair and strengthening for each year, taking into consideration budgetary constraints and construction requirements that can be specified by bridge administrators, and enabling the user to specify the year in which to perform repair or

DOI: 10.1201/9781003483755-318

strengthening for each bridge. Finally, the practicality of the proposed system has been verified by drawing up various maintenance plans by applying the system to the bridge data managed by Yamaguchi Prefectural Government.

2 OUTLINE OF J-BMS AND OPERATION FLOW

The J-BMS consists of the following three subsystems: (1) a bridge maintenance database system (J-BMS DB) for efficiently managing relevant data such as bridge specification data and inspection data, (2) a bridge deterioration diagnosis system (bridge rating expert system (BREX) and (3) a maintenance plan optimization system for drawing up an optimum maintenance plan (MPOS). Figure 1 shows the flow of operation of these subsystems (Miyamoto & Asano 2018). As shown in Figure 1, J-BMS is used as follows: (1) extract necessary data from the bridge specification database and the regular inspection database and download those data from J-BMS DB to BREX. Of the data thus downloaded, the inspection record data (xls. file) are used to enter, for example "main girder inspection" and "floor slab inspection" data, and the brx. file is used to enter, for example "bridge specifications" and "investigation/inspection" data. (2) Output BREX diagnosis data calculated from the input data as a CSV. file. The output data includes bridge name and BREX performance evaluation results such as "main girder-load carrying capability" and "floor slab-durability". Upload the CSV. file containing calculation data to J-BMS DB. Then the MPOS uses the uploaded data for making remaining life prediction and maintenance plan optimization.

3 DEVELOPMENT OF MAINTENANCE PLAN OPTIMIZATION SYSTEM (MPOS)

3.1 *System objectives*

The J-BMS that the authors have developed enables the user to specify an expected service life of each bridge so that a maintenance plan that satisfies the service life requirement for each bridge can be drawn up. In Yamaguchi Prefecture, however, about 57 percent of all bridges in the prefecture were built intensively in the 1950s to the 1970s (Morioka, et al. 2008). If, for example, maintenance plans for these bridges are to be drawn up by using an expected service life of 100 years, the resultant maintenance plans would call for the reconstruction of all those bridges in the 2050s to the 2070s. The proposed system, therefore, draws up a maintenance plan for each bridge in accordance with the maintenance planning flow shown in Figure 2, taking the reconstruction cost into consideration. The proposed flow consists largely of two steps: (1) drawing up a reconstruction plan for an existing bridge and (2) formulating a rational and effective maintenance plan, on the basis of that reconstruction plan, so that the repair/strengthening budget constraints and construction requirements for the year concerned can be met.

Each of the (numbered) items shown in Figure 2 is explained below:

(1) Service life maximization: A maintenance plan that maximizes the service life of an existing bridge is formulated in consideration of the conditions related to the bridge.
(2) Reconstruction cost stabilizing: The user specifies a reconstruction cycle according to the maintenance plan for maximizing the remaining service life of the existing bridge formulated as mentioned above so that annual reconstruction costs during that cycle are evenly distributed. This makes it possible to prevent reconstruction budget concentration and determine an expected remaining service life of the existing bridge. The next thing to do is to formulate a maintenance plan that satisfies this service life requirement.
(3) RLCC minimization: A maintenance plan that minimizes the repair/strengthening cost required during the expected remaining service life (remaining life cycle cost; RLCC). Under the maintenance plan thus formulated, however, repair and strengthening costs usually vary from year to year. The proposed system, therefore, performs either of the two tasks ((4) & (5)) described below.

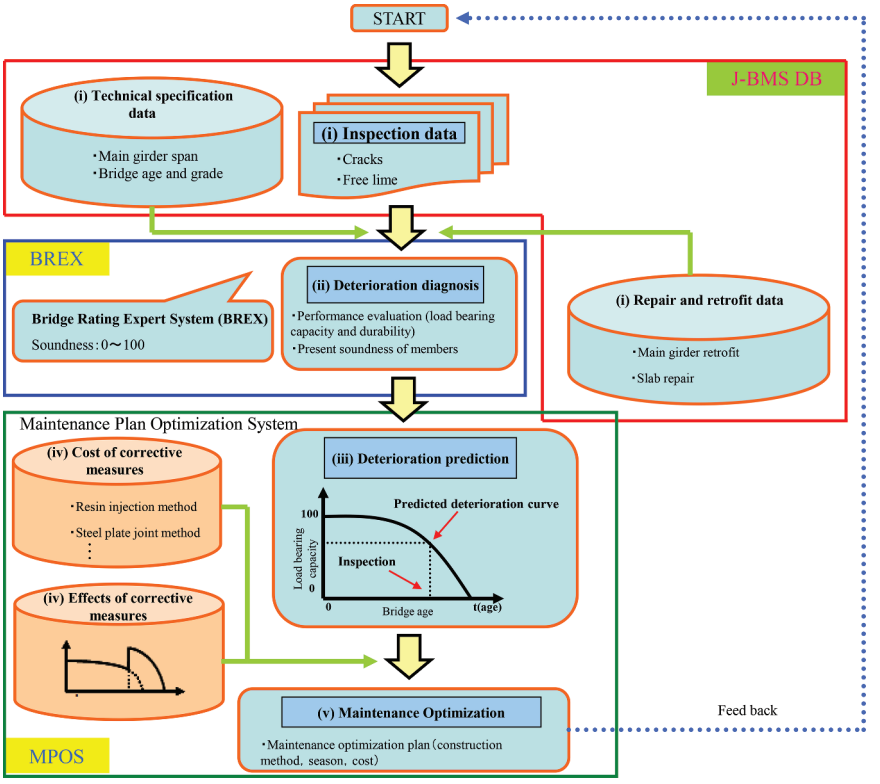

Figure 1. Whole configuration of J-BMS and operation flow in the system.

(4) Repair and strengthening cost stabilizing: The repair and strengthening costs are also distributed evenly.
(5) Planning within budget constraints: The upper limit of an annual budget is determined, and a plan is drawn up within budget. Thus, by shaving the peaks of repair and strengthening costs, the budget required for bridge management can be roughly estimated. Under increasingly tight budgetary constraints, however, the required amount of budget may not be available. The proposed system, therefore, performs the task described below.
(6) Allowing the user to specify a year in which to take action: By allowing the user to enter the upper limit of an annual budget, the system draws up a viable maintenance plan that meets the budgetary constraints.

3.2 *Bridge maintenance planning conditions*

This section describes the conditions that need to be specified for bridge maintenance planning.

3.2.1 *Bridge condition categories*

For the purposes of this study, the degree of deterioration of an existing bridge is expressed with an indicator called "soundness," which is rated on a five-point scale as shown in (Miyamoto & Motoshita 2015); Category V represents "the degree of material deterioration: low"; Category IV, "the degree of material deterioration: moderate"; Category III, "the degree of material deterioration: high"; Category II, "Influence on load-carrying capacity: minor"; and Category I, "influence on load-carrying capacity: major."

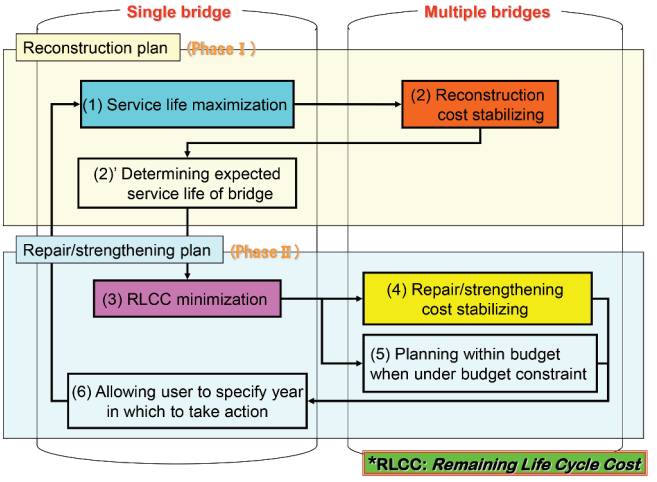

Figure 2. Maintenance plan optimization flow in MPOS.

3.2.2 *Deterioration curve*

Soundness, which is an indicator of the degree of deterioration of an existing bridge, was adopted as an indicator for maintenance planning. Soundness (vertical axis) h(t)n is measured on a 0 to 100, and its changes with time (deterioration curve) is expressed as,

$$h(t)_n = b_n - a_n(t - t_n)^c \tag{1}$$

where, t is the year; n, the number of times a remedial action was taken by year t; an is the slope of the deterioration curve at the time the nth remedial action has been taken; and b_n is the soundness of the existing bridge at the time the nth remedial action has been taken, which changes according to the effectiveness of the remedial action taken. The year of completion of the bridge is $t_{n=0}(=t_0)$, and c is the power exponent of the deterioration equation.

The deterioration curve expressed by Eq. (1) can be arbitrarily changed by adjusting the parameters a, b and c. The soundness in the year of completion of a bridge, b_0, and the power exponent c of the deterioration curve can be arbitrarily specified by the user. For the purposes of this study, b_0=100 and c=3 are used as the initial values.

The slope a_n of the deterioration curve can be calculated from the following equation by using the soundness $h(t)_n$ at the time of inspection:

$$a_n = \frac{(b_0 - h(t)_n)}{(t - t_n)^c} \tag{2}$$

where, the parameters a_n and b_n are updated every time repair or strengthening is carried out by using the following equations:

$$b_n = h(t_n)_n = h(t_n)_{n-1} + R \cdot \rho \tag{3}$$

$$R = \left(h(t_{n-1})_{n-1}\right) - \left(h(t_n)_{n-1}\right) \tag{4}$$

$$a_n = a_0 \cdot \eta^n \tag{5}$$

Figure 3 illustrates the effects of remedial actions on the deterioration curve. The symbols used in Eqs. (3), (4) and (5) the same as those used in Figure 3. In the equations, ρ is a parameter for reducing soundness recovery; a_0, the slope of the initial deterioration curve; and η, a parameter for increasing the rate of deterioration. In the determination of a deterioration curve, deciding on the method for determining the effects of remedial actions is a major challenge. In the proposed system, the slope of the deterioration curve, a_n, is

obtained by multiplying the slope of the initial deterioration curve, a_0, by η^n. If various data are accumulated in the coming years, the user can arbitrarily set the parameters η and ρ. The initial values of $\eta = 2$ and $\rho = 0.9$ have been adopted so that if maintenance actions have been taken in accordance with the upper limit of the number of maintenance actions shown in Table 1 (rightmost column), the maximum service life of an existing bridge becomes about 150 years.

3.2.3 *Repair/strengthening cost and the number of maintenance actions*
In the management of an actual existing bridge, repair/strengthening methods to be used may vary depending on the state of deterioration of the bridge. In this study, therefore, the repair/strengthening method, cost, area, and the upper limit of the number of maintenance actions are specified. The proposed system allows the user to specify the repair/strengthening cost, area, and the number of maintenance actions. As the initial values, the repair/strengthening costs and the upper limit of maintenance actions shown in Table 1 have been adopted. The costs (unit costs) in Categories I to III were determined based on the actual repair data. For the costs (unit costs) in Categories IV and V, data on actual repairs were not available because the damage to existing bridges is minor. If, however, existing bridges are to be maintained economically and efficiently, instead of repairing or strengthening them after their deterioration or damage has become apparent, it may be necessary to perform preventive repairs while deterioration or damage is still minor. This is why repair and strengthening methods have been specified for Categories IV and V, too. Table 1 needs to be modified to indicate more realistic maintenance actions or values according to various data such as data on examples of repair and strengthening.

3.3 *Details of maintenance plan optimization*

3.3.1 *Service life maximization*
The purpose of "(1) service life maximization" shown in Figure 2 is to draw up a plan that extends the service life of an existing bridge to the maximum extent possible. The objective function for this can be expressed as follows:

Objective function:

$$F_1 = Life \rightarrow \max \tag{6}$$

where, Life represents the remaining service life of an existing bridge (years), which can be calculated from the following equation:

$$Life = t_L - t_0 \tag{7}$$

where, t is time(years); t_0 is the year in which the bridge was built; and t_L is the end of the service life (years).

Constraints:

$$\sum_{t=t_0}^{t_L} x_{t,r} \leq n_{\max,r} \quad \begin{matrix} \text{incaseof no maintenance action at } t,\ r : x_{t,r} = 0 \\ \text{in case of maintenance action at } t,\ r : x_{t,r} = 1 \end{matrix} \tag{8}$$

where, x_t expresses whether or not a maintenance action is taken in year t; x_t,r expresses whether or not a maintenance action is taken in year t when in the category of state r; and $n_{max,r}$ is the upper limit of the number of maintenance actions taken in year t when in the category of state r. It is assumed, however, that in the year (t_L) in which an existing bridge reaches the end of its service life, the soundness $h(t_L)$=0. The soundness $h(t)$ is calculated from Eq. (1).

3.3.2 *Reconstruction cost stabilizing*
In this study, soundness and the categories of state have been related, and an upper limit is imposed on the number of maintenance actions allowed for each category of state. In order to

uniquely determine a maintenance planning result, therefore, existing bridges have been prioritized so that higher-priority bridges identified by the criterion shown below can be repaired or strengthened for a longer service life on a priority basis.

$$C_t \leq B_t \tag{9}$$

where, C_t is the reconstruction cost in year t; Bt is the reconstruction budget for year t; and t is years, where, $t \in [t_S, t_E]$, and t_S is the first year of the cost stabilizing period specified by the user, and t_E is the last year of that period. The reconstruction budget B_t is determined based on the total reconstruction cost during the cost stabilizing period.

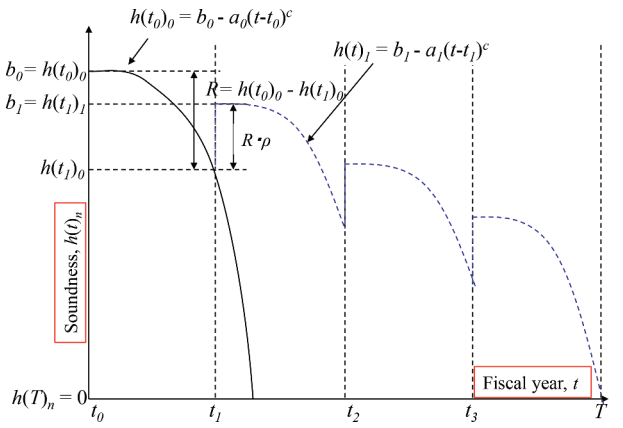

Figure 3. Effect of maintenance action on deterioration curve.

Table 1. Repair/strengthening costs & upper limits of the number of maintenance actions (assigned).

Category	State		Repair/strengthening method	Target area*	Unit cost (thousand yen/m²)	Upper limit of the number of maintenance actions
Ⅴ	Degree of material deterioration	Low	None	–	–	–
			Waterproofing	5%	16.0	1 time
Ⅳ		Moderate	None	–	–	–
			Repair(grouting)	10%	16.0	1 time
Ⅲ		High	None	–	–	–
			Repair (cross-sectional restoration)	20%	45.7	1 time
Ⅱ	Influence on load-carrying capacity	Minor	None (awaiting reconstruction)	–	–	–
			Strengthening (cross section + carbon fiber)	50%	130.5	1 time
Ⅰ		Major	Reconstruction	100%	1280.0	1 time

*: The ratio of repair or strengthening area by gross floor area(gross floor area =bridge length × wdth)(%)

3.3.3 *RLCC minimization*

The purpose of RLCC minimization is to formulate a plan that makes it possible to maintain the performance of an existing bridge until the end of its expected service period and minimizes the cost of doing so. The objective function, therefore, aims to minimize the repair and strengthening cost (RLCC) from the first year of the plan to the last year of the bridge's expected service life. The constraint is that the performance of the bridge needs to be maintained until the last year of its expected service life. These can be expressed as follows:

Objective function:

$$F_3 = \sum_{t=t_s}^{t_e} c_t \rightarrow \min \tag{10}$$

Constraint:

$$h(t) < level \tag{11}$$

where, t is the years ($t = t_S \sim t_e$; t_S is the first year of the plan, and t_e is the last year of the expected service life); $h(t)$, the soundness of an existing bridge in year t; and c_t, the repair and strengthening cost for an existing bridge in year t. The word "level" shown above represents "maintenance level." In order to prevent significant degradation of the performance of an existing bridge, the maintenance level is defined for the existing bridge, and the bridge is managed so that the soundness of the bridge does not become lower than the predetermined maintenance level. For this purpose, it is assumed that the maintenance level in Eq. (11) corresponds to the soundness $h(t)$=0, and the existing bridge is managed so that the soundness h(t) does not become smaller than zero. For the repair and strengthening cost c_t, the values shown in Table 1 are used.

3.3.4 *Planning within budget constraints*

If an annual budget for repair and strengthening needed to maintain the performance of existing bridges is set at a low level, adequate repair or strengthening cannot be performed. As a result, the bridges cannot be maintained until the last year of their expected service life, and it becomes necessary to reconstruct some of those bridges. If, however, an objective function is defined simply so as to enable as many existing bridges as possible to fulfill their service life, the following problems arise:

(1) Priority may be given to less-costly small-scale bridge repair or strengthening rather than more expensive large-scale bridge repair or strengthening.
(2) A system that indicates different reconstruction cycles every time it draws up a plan under the same constraints is not reliable enough for practical use.

To solve these problems, it was decided to provisionally prioritize existing bridges and draw up a plan that satisfies the following criterion and selects bridges to be repaired or strengthened according to that priority.

$$C_t \leq B_t \tag{12}$$

where, C_t is the repair and strengthening cost in year t; B_t is the repair and strengthening cost for year t.

The upper limit B_t of the repair and strengthening budget for year t in the constraint expression can be calculated from the following equation:

$$B_t = B_{t_S} \cdot (1+\gamma)^{t-t_S} + \alpha \tag{13}$$

$$B_{t_s} = \frac{\sum_{t=t_S}^{t_E} C_t}{\sum_{t=t_S}^{t_E} (1+\gamma)^{t-t_S}} \tag{14}$$

where,
γ is the rate of increase in annual budget; α is an additional cost to be added to annual budget.

3.3.5 *Allowing the user to specify a year in which to take action*

In cases where an existing bridge is repaired or strengthened, this function enables the user to specify a year in which to carry out repair or strengthening work, taking into consideration various factors related to construction work such as traffic restriction. In this study, the specification by the user of a year in which to take a maintenance action is used as a constraint, and a plan that takes "allowing the user to specify a year in which to take action" into

consideration is drawn up in accordance with the flow of the planning process shown in Figure 2. This is expressed by the equation shown below. In the equation, x_t, which indicates whether or not a maintenance action is taken in year t takes the value of "1" when a maintenance action is taken in year t and takes the value of "0" when no maintenance action is taken in year t. Thus, the user is free to select "0" or "1."

$$x_t = \begin{cases} 0 & : \text{in case of no maintenance action at year } t \\ 1 & : \text{in case of maintenance action at year } t \end{cases} \tag{15}$$

4 IMPLEMENTATION INTO J-BMS AND PRACTICAL APPLICATION

The proposed system, MPOS as mentioned above is installed into J-BMS as a subsystem. In this chapter, the system is applied to an actual bridge network in Ube City area, Yamaguchi Pref., Japan (total 169 concrete bridges) to evaluate its effectiveness (Yamaguchi Pref. Gov. 2003). And the example of specific maintenance plan from the MPOS is shown with corresponding computer displays for easy to understand.

Figure 4 shows a screen display of deterioration curve/specification input data for maintenance actions which is displayed when starting of this system. As shown in Figure 4, the screen which the deterioration estimation and specification of maintenance actions for main girder, as an example is composed form 3 different forms of purpose like shown below, namely a main window and 2 windows in order to display bridge data: ①**Flow**: The form that allows the user to access optionally into each function, and the process which is executed on the system is clarifies (function display). It is composed from the button of "Initial setting", "Data assignment", "Service life maximization", "Reconstruction cost stabilizing", RLCC minimization", P/S cost stabilizing", "Planning within budget" and "User set of specify year for action". By clicking on flow button, it is able to perform the correspondence step, ②**Data reference window**: The form to call up the screen which displayed bridge data. It is composed from the button of "Single" and "Group", and ③**Setting screen**: The different specification screen for each step of flow is displayed, and the input of data and condition is done by the user.

When the read in of the data file is complete, by clicking on the "Next" button near the right top of the screen, "single bridge data confirmation screen" and "bridge group data confirmation screen" as shown in Figure 5 are displayed, and the main window calls up "service life maximization specification screen" which is shown in Figure 6.

In the bridge group data confirmation screen (Figure 5), the information for all bridges which have been read in data is able to be confirmed. The details of bridge group data confirmation screen are described below: **(i) Reconstruction bridge number:** In this part, the graph is drawn with horizontal axis as fiscal year and vertical axis as maintenance action cost or number of bridges that need the maintenance action. In the example of Figure 5, the number of reconstruction bridges for each year is displayed, and 7 bridges is the biggest amount for the number of reconstruction bridge in a year, **(ii) Progress of soundness:** In this part, the graph is drawn with horizontal axis as fiscal year and vertical axis as bridge proportion. It shows the progress and distribution of soundness which has been classified in 5 condition categories (CategoryI~V) as shown in section 3.2.1. The soundness progress of main girder is shown in the example of Figure 5. It is able to selecting the target member (main girder or floor slab) from the check box in the lower part, **(iii) Maintenance action details:** The maintenance action for all bridges which read in data has been done is displayed in table format. The items of table are composed by the "(Maintenance) action year", "Bridge name", "Member", "Measure method" and "Costs". In the example of Figure 5, there is a part of before service life maximization which only "Reconstruction" is done. Then, in order to do "Reconstruction" for the whole bridge, it is different with the maintenance which is done on the member, so that in item of "Member" there is nothing being input. And by clicking on "Detail display" button on the right below the screen, the detail screen is displayed in different window, and **(iv) Total costs:** The total cost of reconstruction and maintenance which are done in the period of plan is displayed here. And by clicking on "Display of general information" button, it is able to confirm the detail information by opening the different window.

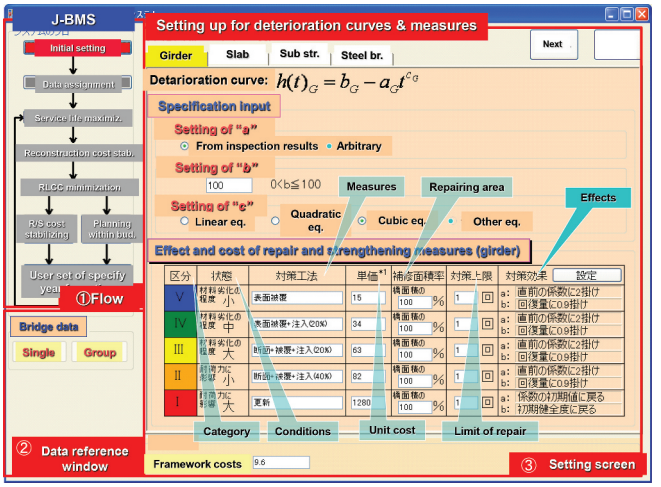

Figure 4. Deterioration curve/specification input screen of maintenance actions (for main girder).

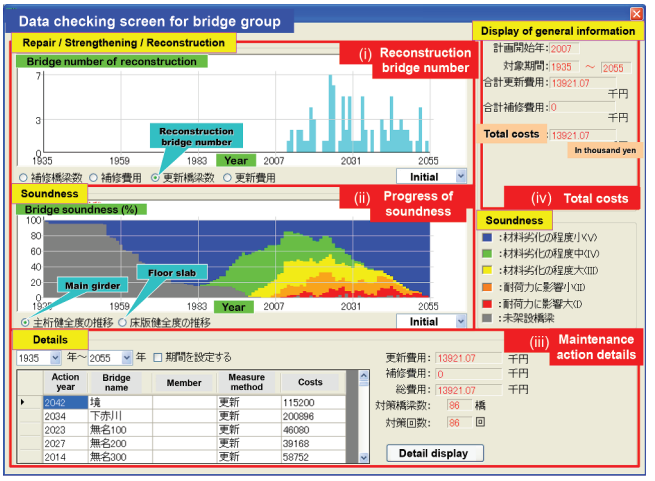

Figure 5. Screen display for bridge group data confirmation.

As the next step, service life maximization is then done due to the maximization setting of bridge service life. Based on the number of "Service life maximization setting" screen which is shown in Figure 6, the explanation is mentioned below: **(i) Calculation method for optimization:** The calculation technique which is used when performs the service life maximization is selecting here. Presently, for the calculation technique, only "Calculation time priority (Ramification model)" which is shown in service life maximization in step 1 is able to execute. In future, the development of "Precision priority (all search)" and "Standard (PSO)" is performing and the mounting is under planning, **(ii) Setting of effects:** The setting of maintenance action effects which is used in the calculation of service life maximization is done here. The setting of maintenance action effect is composed by "Measures", "Unit cost", "Repairing area", "Limit of repair" and "Effects". The annual value of this system is input by maintenance action setting which is shown in the setting of maintenance action effect. User is allowing to specify optionally in "Measures". It is able to specify "Effects" from pull down menu. Presently similar with the existing system, the value of slope "slope coefficient η =2", only the recovery "soundness recovery ρ = 0.9" is able to be selected (see section 3.2.2), **(iii) Action button:** By clicking on "Service life maximiz." button, the service life maximization calculation

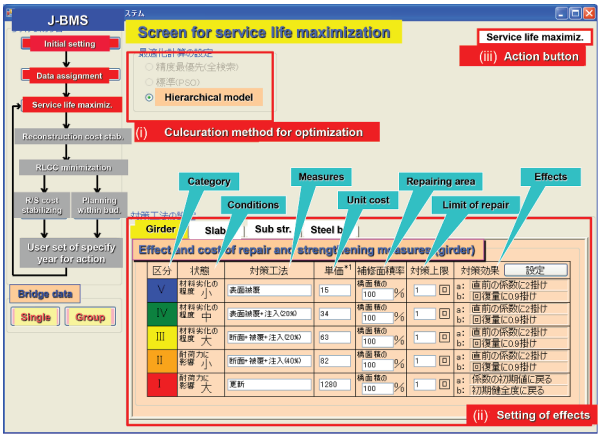

Figure 6. Screen display for service life maximization specification.

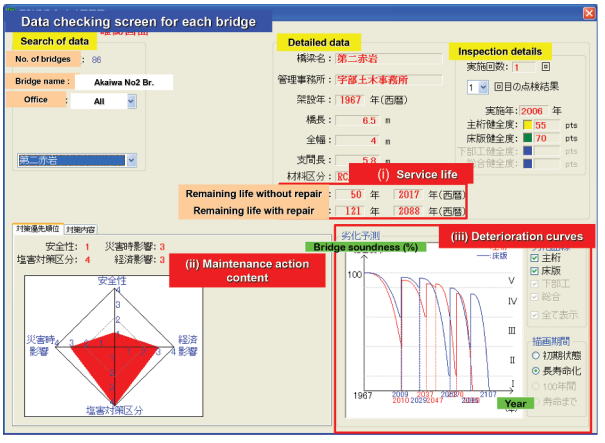

Figure 7. Single bridge data confirmation screen after performed the service life maximization.

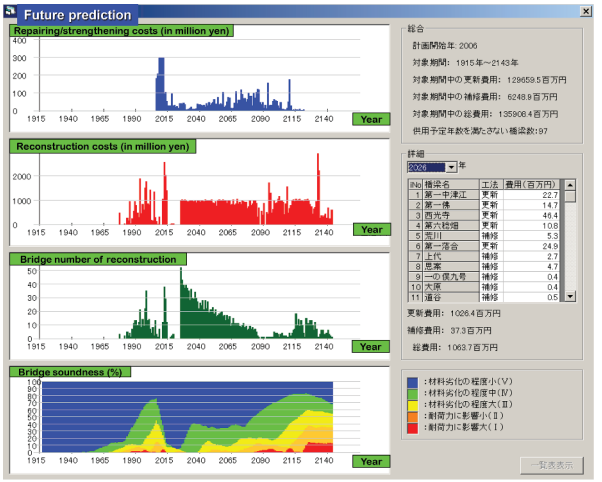

Figure 8. Future prediction screen after performed the RLCC minimization (bridge group).

is performs based on the contents which is input in "(i) Calculation method for optimization" and "(ii) Setting of effects". After the action is taken, the single bridge data confirmation screen is automatically showed.

The single bridge data confirmation screen after performed the service life maximization is shown in Figure 7, each of the number is described below: **(i) Service life:** The service life maximization is not performed, only initial service life is displays, and by performing the service life maximization, the bridge service life (the limit of bridge service life) after the service life maximization is displayed in Figure 7. In the example of Figure 7, the initial service life which is calculated from the normal inspection result is 50 years, reconstruction is need in 2017. However, by performing the service life maximization, the bridge service life could be extended until 121 years, which meant that reconstruction is need in 2088, **(ii) Maintenance action content:** The maintenance action that is taken for the selected bridge is displayed here. The maintenance action perform year is the year when the soundness is recovered in **"(iii) Deterioration curves"**. The maintenance action for main girder and slab are taken separately.

Figure 8 shows the result of a proposed optimal maintenance plan from the MPOS as the final step. From this figure, we found that it becomes easy understand what are the major processes in the deteriorating bridges in the future, how to improve their performance, and what kind of repair/strengthening works is most convenient for the deteriorating bridges.

5 CONCLUSIONS

The main conclusions of this study are as follows:

1) An integrated bridge management system for Yamaguchi Prefectural Government has been developed based on a basic policy for systematic bridge management, practical database system, etc with IT-based advanced monitoring system.
2) The system was applied to an actual bridge network in Ube City area, Japan to evaluate its effectiveness. As the results, it will be able to make the priority of repair/strengthening works of existing bridges based on the various information from the database system, then the system helps bridge administrators to establish the rational maintenance strategies.

Risk-informed approach to determining optimal bridge inspection frequency for periodic replacement policies

Arnold X.-X. Yuan & Wang Chen
Department of Civil Engineering, Toronto Metropolitan University, Toronto, Ontario, Canada

ABSTRACT: Bridges are a critical part of a highway transportation system. As bridges deteriorate, inspection becomes an essential task of a transportation agency's Bridge Management System to ensure that the structures are safe and that infrastructure renewal funds are effectively and efficiently allocated and invested. However, the current Ontario Structural Inspection Manual provides a rigid specification regarding the bridge inspection frequency: typically, two years. While this is deemed a conservative approach, it is imperative to review and enhance the current inspection strategy considering bridge type, age, and other factors that would affect the likelihood and consequences of accelerated bridge deterioration and, in the worst case, bridge failures. For this purpose, a research project was recently initiated, aiming to develop a risk-informed value of information framework to determine an optimal lifecycle inspection profile of a bridge. The paper presents a simplified version of the analysis framework. It contains a gamma process-based bridge performance deterioration model, Bayesian model updating, and value of information analysis considering both aleatory and epistemic uncertainties for age-based preventive replacement programs. Some interesting preliminary results of individual bridges are presented.

1 INTRODUCTION

Bridges are subject to various environmental and loading stresses. As a result, their structural reliability declines, slowly but steadily, with time. However, due to the large variations and uncertainties underlying the various degradation mechanisms, the deterioration rates fluctuate among bridges and along their ages. Therefore, bridge inspection plays a vital role in capturing these uncertainties and assisting maintenance and rehabilitation decisions involved in bridge asset management.

Currently, most transportation agencies employ a periodic bridge inspection strategy. Enacted through Ontario Regulation (O. Reg. 104/97) under the Public Transportation and Highway Improvement Act (PTHIA), Ontario adopted a bridge inspection frequency of 2 years in 1997, although the inspection frequency for major culverts (≥3m span) was later relaxed to 4 years if they were in good condition as outlined in the OSIM (MTO, 2018). Similarly, the Federal Highway Administration (FHWA) recommends a routine bridge inspection program at regular intervals not to exceed 24 months (FHWA, 2012). Frequent inspections will affect MRR decisions in cases where the results of two consecutive tests may be unlikely to change within the safety critical threshold, due to deterioration affected by measurement errors (Yang and Xie, 2021), as well as the safety and delay risk that inspection activities pose to inspectors and the public. Given this, a risk-informed inspection interval that takes into account the risk of missing inspection and the value of inspection can improve resource utilization efficiency and operational

DOI: 10.1201/9781003483755-319

effectiveness. Therefore, it is important to review the current inspection program and if possible, propose a new set of inspection policies for bridges based on their disparate risk profiles.

Early bridge inspection planning research aimed to maximize the overall reliability of the bridge network for a given inspection budget (Kim and Frangopol, 2011). The reliability-based approach holds that MMR is required when a structure reaches a critical threshold. The generic inspection planning process is to model the optimal inspection planning problem based on the defined reliability function, hoping to get the optimal inspection plans with the objective of minimizing the LCC and appropriate reliability constraints, or an optimal hazard threshold under maximizing life expectancy. Early research on reliability-based bridge inspection planning dates back to the 1970s in the airplane industry. In civil structural engineering, Sorensen (1993) described how inspection information could be used for bridge I&M decision-making. Much work followed subsequently, including, e.g., Barone and Frangopol (2013), Orcesi and Frangopol (2011), Kwon and Frangopol (2011), Barone and Frangopol (2013) and Xu and Azhari (2022). However, most of the reliability-based inspection studies focused on conceptual development trying to answer the question of how inspection planning should have interacted with maintenance optimization. The methodology taken there is largely probabilistic without much empirical support.

Recent data-driven deterioration modelling provides new opportunities for inspection planning using a value of information (VOI) framework (Howard, 1967, Straub and Faber, 2004, Pozzi and Kiureghian, 2013, Papakonstantinou and Shinozuka, 2014). VOI is defined as the difference between the lifecycle costs of a maintenance program with and without inspection. Current VOI research in the field of bridge asset management focuses on exploring the influencing factors affecting VOI for implementing rational inspection. Quirk et al. (2018) may be the first to analyze the VOI of inspection in a bridge management system by using Bayesian updating and analyzing the VOI of different parameters (prior probability, the likelihood of inspector-assigned condition ratings, and the economic) and scenarios (no information, perfect information, imperfect information). However, the time dependence associated with detection techniques will also have a significant impact on the decision outcome. To further analyze the utility of inspection information for decision-makers, Liu and Frangopol (2019) proposed a new framework for decision-making using inspection data, comparing two techniques with different probability of detection (POD) on VOI. Results show that the NDT with a low POD can achieve a higher VOI in the early years of service. Yang and Frangopol (2022) pointed out that POMDP is a promising method due to its excellent performance in complex I&M decision scenarios.

Despite all these, there are several major drawbacks of the existent VOI studies related to inspection planning. First, many studies did not consider the temporal variation of bridge deterioration. When the temporal variation is explicitly modelled, the VOI analysis does not consider the epistemic or sampling uncertainty related to the stochastic deterioration models. The purpose of the paper is to develop a holistic VOI analysis framework for determining the optimal inspection interval for bridges. In this framework, the bridge performance is measured by the Bridge Condition Index (BCI), which is widely used in Ontario and several other provinces across Canada. The BCI deterioration is modelled as a nonstationary gamma process, of which the shape parameter is further parameterized as a set of functions of multiple bridge attributes. Based on this nonstationary gamma process deterioration model, the VOI analysis can readily take into account reductions in both temporal uncertainty and epistemic uncertainty. This feature represents the unique and novel feature of the proposed VOI analysis framework.

The rest of the paper is organized as follows. Section 2 presents the deterioration model that was calibrated with Ontario's Open Bridge Performance Database. Section 3 presents the preliminary results of the VOI analysis. Section 4 concludes the paper with a few outstanding issues to be addressed in the future.

2 THE BRIDGE DETERIORATION MODEL

2.1 *Fundamentals of non-stationary gamma process*

The gamma process is well considered one of the most realistic and yet most flexible stochastic process models for modelling the monotonic and gradual deterioration occurring in long-life civil infrastructure systems. The gamma process has independent nonnegative increments that follow a gamma distribution with the following probability density function:

$$f(x) = \frac{\beta^{\alpha} x^{\alpha-1}}{\Gamma(\alpha)} e^{-\beta x}, \tag{1}$$

for $x > 0$. The shaper parameter α and the scale parameter β both must be positive. Such a gamma process is stationary when its mean path is a linear function of time. Sample paths of a gamma process are monotonically increasing, making it a good candidate for modelling physical deterioration phenomena in various infrastructure systems. To characterize the non-linearity exhibited in many real deterioration phenomena, the shape function can be extended into a time-dependent function. A common form is the so-called Weibull function as

$$\alpha(t) = \theta_2 \left(1 - e^{-\left(\frac{t}{\theta_3}\right)^{\theta_4}} \right) \tag{2}$$

As a result, a nonstationary gamma process is constructed, and its increment, defined as $\Delta X(t) = X(t + \Delta t) - X(t)$, is known as a gamma distribution, with the shape parameter given as $\Delta\alpha(t) = \alpha(t + \Delta t) - \Delta\alpha(t)$. More discussions of gamma process can be found in Noortwijk (2009).

The Bridge Condition Index (BCI) which is widely employed in Canada measures bridge condition with a range from 100 to 0. A newly built bridge has a BCI of 100, and its condition is expected to decline gradually with time. Therefore, the decline in BCI of a specific bridge relative to the perfect condition (BCI = 100) can be modelled by a nonstationary gamma process.

Since different bridges may have different designs, loading conditions, and climate, geotechnical and hydraulic conditions, the modelling can be further extended in three ways. One is through the fixed-effects modelling approach by expressing the model parameters as the following:

$$\theta_i(z_j) = \exp\left[a_{i0} + a_{i1} z_{j1} + \cdots a_{iA} z_{jA}\right] \tag{3}$$

where $i = 1, \ldots, 4$ denotes the labelling of the scale and parameters with $\theta_1 = \beta$ for the scale parameter; $j = 1, \ldots, B$ denotes the bridge (B is the total number of bridges in an inventory); $\mathbf{z_j} = (z_{j1}, \ldots, z_{jA})$ represents the bridge attributes (A is the total number of attributes); and a_{ik} represents the model parameter for θ_i and attribute z_k ($k = 0,\ 1, \ldots,\ A$). The parameterized model can be estimated using the maximum likelihood method. The other modelling approach is through the use of the random effects by considering $(\theta_1, \ldots,\ \theta_4)$ as a dependent random vector. In this approach, each bridge is thought to have its own set of model parameters, whose values are a random realization of the random vector. More details of the modelling approach can be found in Yuan and Pandey (2009).

2.2 *Sources of data*

The data source used in this study is the bridge conditions in Ontario dataset obtained from the Open Government Portal, and the maintenance history as well as traffic volume data provided by the Ministry of Transportation Ontario (MTO). This dataset contains an inventory

of 5054 bridges, with BCI records spanning from 2000 to 2020. The database also contains important attributes. However, other essential information such as the construction year and the last MRR activity was obtained from MTO directly. The attributes considered in the study included material, structure, highway function, number of spans and length of spans, geographical region, and the last maintenance records. Figure 1 presents the geographic distribution of structures in this dataset. Note that the bridge and culvert are both included in open data, but only the bridge will be focused on.

2.3 *Deterioration modelling results*

After data cleansing, data from 380 bridges were considered for the natural deterioration modelling from the first life cycle. The bridge attributes were available but not considered in this paper. As the first step, each bridge was fitted individually with the nonstationary gamma process model. A few mean paths of the individually fitted gamma process models and their BCI observations are plotted in the left panel of Figure 1. From the plots, it is clear that the deterioration pattern varies significantly from one bridge to another. The scatterplots of the model parameters of the 380 bridges are shown in the right panel. It further confirmed the great variability of the deterioration patterns. It is interesting to see that θ_1 and θ_2 are highly negatively correlated, and so are θ_3 and θ_4. The variances of $\log \theta_i$ are 1.83, 2.22, 12.8 and 1.08, respectively.

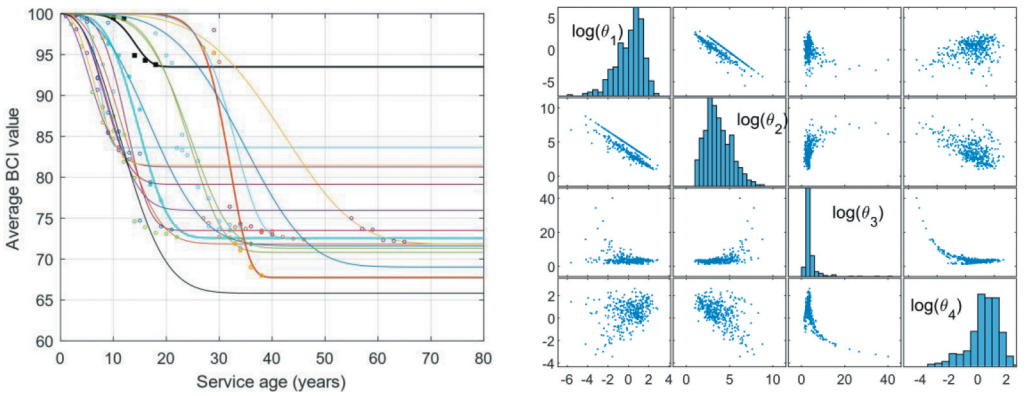

Figure 1. Sample individually fitted mean curves and the scatterplots of the model parameters.

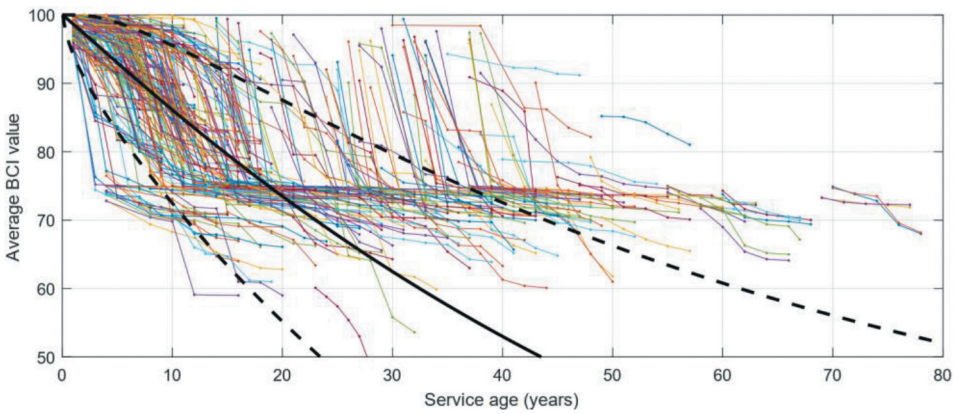

Figure 2. The pooled gamma process model and the observed individual sample paths.

The BCI data of the 380 bridges are then pooled and fitted to one common gamma process with the same model structure. The mean path and the 95% lower and upper bounds as well

as the observed individual sample paths are shown in Figure 2. The lower and upper bounds do not cover 95% of the sample paths, as they are supposed to do. This suggests that the bridge deteriorations exhibit significant heterogeneity that must be more carefully modelled.

Since the focus of the study is not on the deterioration modelling, further deterioration modelling results are not reported. From the value-of-inspection perspective, it is now clear that inspection can collect and accumulate BCI deterioration data that would help not only develop a more accurate deterioration model for the whole bridge inventory, but also develop a bridge-specific model, which then would help refine bridge-specific maintenance and rehabilitation plans. It is this point that the paper would like to illustrate in the following VOI analysis.

3 VALUE OF INSPECTION ANALYSIS

3.1 *The framework*

The basic notion of the value of information was established by Howard (1967). When it is applied for inspection planning, the VOI is calculated using the following simple formula:

$$\mathrm{VOI} = \mathrm{LCC}_0 - \mathrm{LCC}_1 \tag{4}$$

where LCC_0 and LCC_1 represent the lifecycle cost of the referencing bridge management program and that of an enhanced program, respectively. Several key questions need to be answered:

1) What is the referencing management program? This can be an age-based preventive replacement program. Alternatively, it may be a predictive condition-based maintenance program. Different referencing programs take different assumptions, which will definitely affect the VOI calculation.
2) What is the overall structure of the inspection program? For example, is it a periodic program with a fixed interval, or a non-periodic one?
3) What is the enhanced bridge management program? Is it a predictive condition-based program or an adaptive maintenance program?

In this study, the referencing program is an age-based, periodic preventive replacement program. The bridge lifetime is considered as a random variable of which the distribution is derived from the nonstationary gamma process model with randomized parameters as shown in Figure 1. The randomized parameters are assumed because, for a new bridge, it is unclear which set of parameters will fit the bridge. A bootstrap simulation is used to generate the random lifetime. The bridge life is defined as the time when the BCI drops for the first time below 50. The renewal theory is applied to obtain the optimal preventive replacement age for such a bridge. For that purpose, it is assumed that the preventive replacement cost is one unit, and the failure or corrective replacement cost is five units as the baseline, although a cost of ten units will also be used as a sensitivity analysis.

The inspection program is considered periodic. Different inspection intervals are considered: one year, two years, and four years. As new data are collected, the bridge-specific deterioration model is updated via Bayesian updating. With the new deterioration model, a forward-looking inspection plan is updated until the end of the planning horizon. The planning horizon is taken as 100 years. For brevity, this paper does not consider a preventive maintenance strategy; but rather, only preventive replacement is considered. In addition, the paper does not consider an aperiodic inspection program either, even though it may be more cost-effective. This is left for the future to investigate.

A unique feature of the proposed VOI analysis framework is the consideration of both temporal uncertainty and epistemic uncertainty. The temporal uncertainty was accounted for by the independent increments underlying the gamma process model, whereas the epistemic parameter uncertainty was characterized by Bayesian analysis. Yuan et al. (2021) presented an example of such analysis for a one-step inspection and maintenance program. However, the

problem we presented here was an extension for sequential decision-making involved in bridge management. Another extension is the use of a nonstationary gamma process. This requires additional computation that calls for advanced simulation techniques such as Markov chain Monte Carlo simulation.

3.2 *Models and parameters*

In the following VOI analysis, the optimal inspection interval is evaluated for an imaginary new bridge, which may be a random replica of the inventory of the 380 bridges. Without inspection, the lifetime of the imaginary bridge is a random variable of which the probability distribution can be derived from the gamma process model with a random set of parameters. For consistency, the four-parameter gamma process model is confined with $\theta_1\theta_2 = 100$. The bridge is said to reach its service life (and hence need replacement) whenever its BCI reaches 50 or below. Only the age-based replacement policy is considered. The inspection cost is taken as one unit, or \$1, whereas the preventive and corrective replacement costs are \$100 and \$500, respectively.

Since the gamma process model involves multiple parameters that are dependent on one another, a full-course Bayesian updating will be very computationally intense. To address the computational issue, a simplified, discretized scheme is employed. Specifically, since the new bridge is considered as a random replica of the inventory, the prior belief probability is taken as 1/380. As new data are accumulated, the belief probability is updated out of the 380 disparate cases. It is expected that the posterior probability will converge to the correct bridge identity. In other words, the Bayesian updating becomes a bridge identification problem.

3.3 *Results*

The baseline information before inspection is undertaken is a lifetime distribution that is derived from the gamma process model with parameters randomly drawn from the samples shown in Figure 1. The survival function of the lifetime distribution is shown in the left panel of Figure 3. The probability distribution exhibits a long tail, a common feature of mixed models. Based on this lifetime distribution, the cost rate curve of an age-based replacement program is shown in the right panel, which demonstrates that the optimal replacement age is 24.3 years with a minimized cost rate of \$5.88 per year.

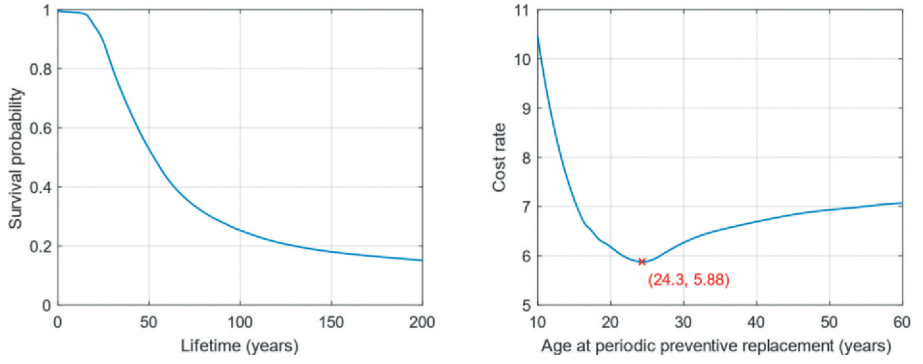

Figure 3. The survival function (left) and the cost rate function of an age-based replacement program (right).

As deterioration data accumulate from inspection, the optimal replacement age and the probability of the identified model keep updating. As a demonstration, Figure 4 shows the evolution of the two quantities over time at four different inspection intervals. With a given inspection interval, the posterior probability of the identified model increases along with time. As the inspection interval increases, less data accumulates and as a result, the rate of increase

in the posterior probability decreases. Both results are expected. Such a clear pattern is not shown in the posterior optimal replacement age, however. This is because the posterior optimal replacement age is a result of both an updated deterioration model and an accurate observation of the current BCI state. The former is an effect due to a reduction in epistemic uncertainty, whereas the latter is an effect due to a reduction in temporal uncertainty.

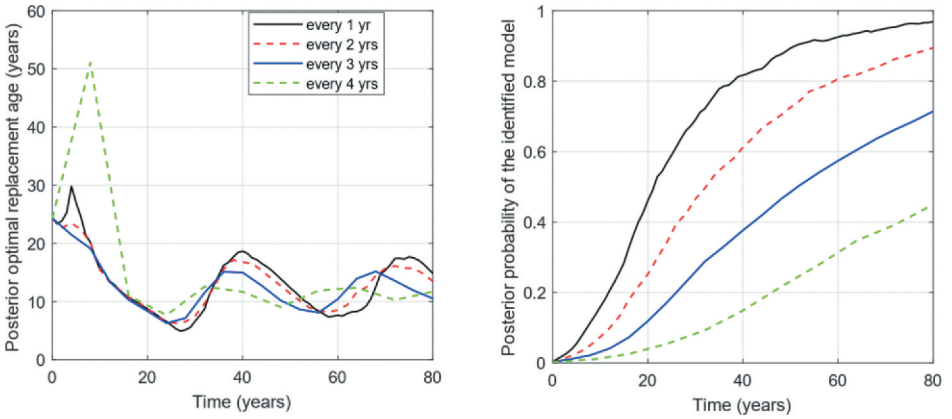

Figure 4. Evolution of the predicted remaining life (left) and the posterior probability of identified deterioration model (right) for bridge B100.

The average cost rates within the 80 years of planning horizon at different inspection intervals ranging from 1 to 8 years are computed using simulation. A few random samples are shown in Figure 5 for demonstration. The broken line represents the average cost rate for an age-based periodic replacement program without inspection. The optimal inspection interval with the minimal average cost rate is highlighted with a red arrow. The same bridge (B100) used in Figure 4 is also shown in Figure 5(d). For this bridge, an inspection interval of 4 years is optimal. Since different bridges have different deterioration patterns, the optimal inspection interval also varies. For the nine sample bridges, the minimal average cost rate with inspection is always lower than the cost rate without inspection, although the difference is almost negligible for bridges B150 and B200.

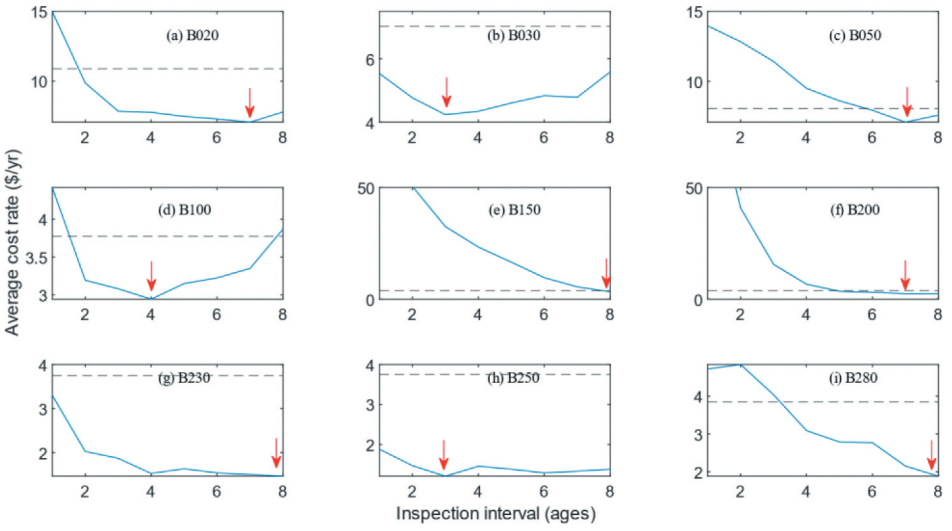

Figure 5. Sample results of the average cost rates at different inspection intervals.

The whole inventory of the 380 bridges is analyzed and the results are shown in Figure 6. Surprisingly, about 40% of the bridges have an optimal inspection interval of 8 years or even more. Only 8 out of the 380 bridges use the current inspection period – 2 years – as the optimal interval. This result is quite surprising and deserves further investigation. Another interesting observation of the analysis is made in the right panel of Figure 6: There are 31 points lying under the line of equality, suggesting a negative value of inspection. Further examination found that 14 of the 31 bridges have an optimal inspection interval of less than 8 years. This suggests that these bridges are better off doing no inspection. Note that the inspection cost is assumed to be 1% of the preventive replacement cost ($1 vs. $100). If the inspection cost increases, the number of bridges that are better off doing no inspection will also increase.

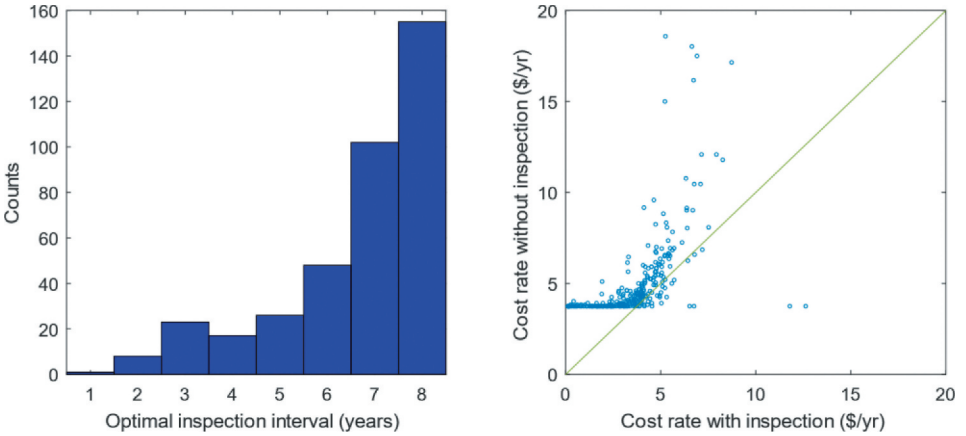

Figure 6. Histogram of the optimal inspection interval (left) and comparison between the cost rates with and without inspection (right).

It is worth highlighting that the optimal inspection intervals presented above are based on only a preventive replacement policy. Although the inspection results are utilized to update the replacement policy (in terms of the optimal replacement age), condition-based maintenance and rehabilitation policies may increase the value of inspection. This is left for future investigations.

4 CONCLUSIONS

Employing the notion of the value of information, this paper presents a novel approach to determining the optimal bridge inspection interval. The approach is unique in that it considers both the value of inspection in reducing temporal uncertainty and the value of inspection in reducing parameter uncertainty. The results showed that when only periodic replacement policies were practiced, the inspection intervals could be extended for a majority of the bridges in the inventory with some even better off doing no inspection. The inspection intervals are expected to be shortened when condition-based maintenance and rehabilitation policies are adopted together with an inspection program. This is left for further investigations in the future.

Fragility assessment of water-crossing bridge structures exposed to flood hazards

J.M. Patel & J.E. Padgett
Department of Civil and Environmental Engineering, Rice University, Houston, TX, USA

ABSTRACT: Given the scarcity of available studies related to flood-fragility assessment of bridges and the expected increase in frequency of future flooding events, this study is focused on deriving parameterized fragility models relevant to a class of bridges that capture both primary and secondary effects of flood events. Different parameter combinations of a multi-span simply supported concrete girder bridge class are considered, leveraging finite-element analyses to assess the performance of different bridge components subjected to flooding scenarios. Following statistical sampling and analyses across a comprehensive range of bridge parameters and loading and site conditions, probabilistic flood-fragility functions are derived using statistical regression models for the different failure modes considered. The results highlight the important role of combined primary and secondary effects in exacerbating bridge damage potential during floods. The developed fragility models can be combined with scenario-based or probabilistic flood models to support regional risk and resilience modeling for transportation infrastructure.

1 INTRODUCTION

Transportation infrastructure is repeatedly exposed to natural hazards which cause significant damage to components such as bridges and roadways and lead to cascading consequences for response and recovery efforts in affected communities (Argyroudis et al., 2019; Boakye et al., 2022). Severe storm and rainfall events can produce heavy flood-flow discharge which cause significant hydraulic forces to act on various components of water-crossing bridges and give rise to secondary effects from flooding such as scouring of bridge foundations. More than 50% of historical bridge collapses in the United States are attributed to flooding or secondary flood-related effects (Wardhana & Hadipriono, 2003; Xiong et al., 2023). Although the risks associated with water-crossing bridge structures subjected to flooding are widely recognized, the literature is scarce regarding probabilistic models of bridge damage potential considering the range of sources of uncertainties and parameters affecting bridge performance when subjected to flooding.

Previous studies have developed flood fragility curves for water-crossing bridge structures considering the effects of water pressure loading, scour formation, and debris accumulation (Anisha et al., 2022; Argyroudis & Mitoulis, 2021; Kim et al., 2017). However, these fragility analyses were either performed for a specific case study bridge structure, or the fragility curves were conditioned on a single intensity parameter which may not capture the full complexity of the loading scenario or the variations on structural parameters that may be of interest in a regional analysis. Ahamed et al. (2021) examined the effects of considering flow hydraulics and geotechnical uncertainties in the flood fragility assessment and found the significance of both, implying the fragilities developed without considering comprehensive intensity parameters may not be able to represent the appropriate flooding scenario. To assist comprehensive flood-risk and resilience assessment, flood fragility models should consider: (a) both primary (hydraulic loads) and secondary effects (scour formation and debris damming) stemming from a flooding event, (b) uncertainties associated with hydraulic, geotechnical, and bridge parameters, and (c) potential for generating fragilities for a given bridge parameters and variable flooding scenario. Recently, the notion of

DOI: 10.1201/9781003483755-320

parameterized fragility modeling has been advanced (i.e., models that estimate the conditional failure probability of a structure given not only a scalar hazard intensity measure, as common in traditional conditional reliability models, but instead a vector of predictors related to the hazard or structural parameters). While such models have been developed for different types of bridges considering different hazard scenarios beyond flooding (e.g., Jeon et al., 2019; Saeidpour et al., 2018), the existing literature on developing flood fragility functions for water-crossing bridge structures is scarce. Recently, there have been a few studies performed to develop flood fragility models (Anisha et al., 2023; Khandel & Soliman, 2021; Mendoza Cabanzo et al., 2022). However, these studies did not consider comprehensively the primary and the secondary effects of floods, or the analysis was restricted to specific bridge component only.

To address these gaps in the literature, the primary objective of this study is to develop parameterized flood fragility models associated with different failure modes of water-crossing bridge structures which can be used for bridge damage state probability prediction. The multi-span simply supported concrete girder bridge is selected as a representative case study bridge, as this bridge class is found to be particularly vulnerable during flood events (Padgett et al., 2008; Xiong et al., 2023). Flood hazards including hydrodynamic flood loads, buoyancy effects, scour formation, and wooden debris accumulation are considered in this study. Uncertainties related to the bridge, flood, and geotechnical parameters are considered in the analysis. The probabilistic fragility models are developed using logistic regression, given its closed form functional representation. The study proposes different fragility models for different failure modes that can be used to assess the safety of water-crossing bridges subjected to flood events.

2 FLOOD HAZARD QUANTIFICATION

2.1 *Water pressure effects*

Columns of water-crossing bridges generally have continuous exposure to water pressure forces due to riverine flow. Depending on the severity of a flood event, the bridge superstructure may also become exposed to flood flow. The horizontal force (F_h) due to the water pressure of the fluid flow can be calculated by:

$$F_h = 0.5 C_D \rho v^2 A \tag{1}$$

where C_D is the drag coefficient, ρ is the mass density of the fluid, v is the velocity of the flow, and A is the submerged cross-sectional area of the bridge pier (and portion of a bridge deck, if submerged) normal to the direction of the streamflow.

In addition to horizontal loads, uplift buoyancy forces act on the bridge superstructure when flow depth exceeds the height of the bridge substructure. This may lead to bridge deck unseating, resulting in bridge failure (Padgett et al., 2008; Xiong et al., 2023). The uplifting buoyancy force (F_b) can be calculated using Archimedes principle:

$$F_b = \rho g V \tag{2}$$

where V is the volume of the submerged superstructure; and g is the gravitational acceleration constant. This failure mode is commonly observed in the United States when the flow depth exceeds the deck level of simply supported bridges, particularly in older bridges which tend to lack any vertical connection between the bridge deck and bearings (Balomenos et al., 2020; Xiong et al., 2023). Assuming that resistance to vertical uplift forces on a bridge deck comes only from self-weight, the limit state functions g_1 and g_2 for this failure mode can be defined as:

$$g_1 = W - F_b \tag{3a}$$

$$g_2 = \mu W_{sub} - F_h \tag{3b}$$

where W is the self-weight of the bridge superstructure; W_{sub} is the submerged weight of the bridge superstructure; and μ is the friction coefficient at the connection between the bridge superstructure and the substructure. If adequate or alternative bearings and connections are provided between the superstructure and substructure, these limit state functions can be altered to accommodate the appropriate resistances. Failure is assumed if either Equation 3(a) or (b) yields a negative value.

2.2 *Scour formation*

When the shear stress caused by flood flow exceeds the critical shear stress of soil particles in the channel bed, these soil particles are transported along with the flow of water which results in the formation of a cavity in the channel bed. This phenomenon, when occurring along a water-crossing bridge foundation, is referred to as bridge scour formation. When scour is formed at a bridge location, the bridge foundation is additionally exposed to lateral hydrodynamic loads (as represented in Equation 1). Also, the unsupported length of the impacted column increases which may cause structural instability of the bridge. For bridges with deep foundations, the lateral and frictional resistance of the foundation system can also decrease due to the loss of the soil layer above. Hence, considering the effects of scour formation while assessing bridge safety is crucial.

2.3 *Wooden debris accumulation*
