Figure 2. Layout of Light-Weight T-Beam test.

3.2 *Test results*

The experiment employed a three-point loading method, as illustrated in Figure 2. An elastic rubber bearing with dimensions of 0.5 * 0.5m was positioned at the bottom, and another rubber bearing of dimensions 0.5 * 0.6m was placed 1.6m away from the center of the bottom bearing. Loading was conducted incrementally (F1 to F4), reaching cracking loads of 1930kN, 2120kN, 2120kN, 2490kN, respectively. As loading progressed, inclined cracks emanated from the loading point towards the support, gradually intensifying. Simultaneously, localized spalling of concrete occurred at the top or bottom. The shear damage patterns of the four sets of lightweight T-beam specimens are depicted in Figure 3. The beams achieved their maximum load-bearing capacity at loads of 4890kN, 4800kN, 4960kN, and 5140kN, respectively. This resulted in a reduction in the applied load, signifying the occurrence of web shear damage.

Table 1. Key parameters of the tests.

Beam	Top prestressing (angle)	f_{cu}(MPa)	Failure shear(kN)
F1	6ϕ15.2 (10◦)	55.3	4890
F2	12ϕ15.2 (10◦)	66.7	4800
F3	6ϕ15.2 (21◦)	55.3	4960
F4	12ϕ15.2 (21◦)	66.7	5140

4 INFLUENCE PARAMETERS

This paper compiles prestressed concrete deep beam tests, encompassing diverse cross-section forms (rectangular, T-shaped), varied prestressing methods (bonded post-tensioning, unbonded post-tensioning, and pre-tensioning), and a range of parameter variations including shear-to-span ratios, prestressing amounts, prestressing inclinations, and stirrup reinforcement ratios. The impact of these diverse parameters on structural shear capacity is systematically analyzed by normalizing shear stress with $\sqrt{f'_c}$, enabling a comparative assessment of structural capacity.

Figure 3. Shear failure mode of Light-Weight T-Beam specimens.

4.1 *Web reinforcement*

The upper limit on shear capacity is attributed to excessive stirrup reinforcement, where additional stirrup reinforcement fails to enhance shear capacity. This requirement is typically applicable to slender beams, as stirrup reinforcement exerts a more pronounced influence on them. In Figure 4, it is observed that for a small shear span ratio, the load-carrying capacity of the beam increases with the reinforcement ratio. The figure directly compares test beams with identical web reinforcement ratios. The Shahawy test indicates that when stirrup reinforcement $\rho_v f_y$ > 400MPa, the increase in load-carrying capacity with an increase in reinforcement ratio is insignificant, occurring at a corresponding stirrup reinforcement rate of approximately 1%. While the stirrup reinforcement rate in other tests is not extensively varied, it is evident that the beam's capacity increases until the reinforcement rate reaches $\rho_v f_y$ = 400MPa. Hence, it is evident that considering the quantity of web reinforcement is essential for assessing the shear capacity of prestressed concrete deep beams.

In both ACI 318-19 and AASHTO codes, the shear capacity of deep beams is predominantly modeled using STM, with minimum reinforcement ratio requirements, such as 0.25% or 0.3%. These values are notably smaller than the findings in the tests. Simultaneously, in

Table 2. Collected test specimens.

Parameter	Specimens
$\rho_v f_y$	Shahawy (1996) (B1-00-0R-S, B1-00-R-S, B1-00-2R-S, B1-00-3R-S, B1-00-2R2-S); Shahawy (1996) (B1-00-0R-N, B1-00-R-N, B1-00-2R-N, B1-00-3R-N, B1-00-2R2-N); Teng(1998) (P1-1-0-WO, P1-1-0-WV); Teng 1998 (P1-1-5-WO, P1-1-5-WV); Kang (1989) (YA6-4E, YA6-4W, YB6-5E,YB6-5W,YC6-7E, YC6-7W); Laskar (2010) (B1-N, B1-S, B2-N, B2-S)

σ_P	Teng(1998) (P-1a, P-1b, P-1b(2),P1-1-5-WO); Mahgoub (1975) (A5, C1, E2, E3); Kang (1989) (YB6-6E, YB6-6W, YB8-1E, YB8-1W,YB10-1E)
$V_P/\sqrt{f_c'}$	Wang(2009) (P1,P3, P4); Yang(2020) (BP2, BP3, BP4); Teng(1998) (P-1c(2), P-1d(2), P-1e(2)); Laskar (2010) (B2-S, B3-N); Author (F1, F2, F3, F4)

instances where the stirrup reinforcement strength is comparatively weak, there are limitations on restricting the reinforcement rate of the hoop reinforcement. Therefore, when imposing limits on reinforcement rates, it is crucial to consider both the value of the reinforcement rate and the yield strength of the stirrup reinforcement.

4.2 *Shear span ratio*

The shear span ratio consistently exerts a significant influence on shear resistance, evident in the Figure 4 as the shear capacity of the structure diminishes with an increasing shear span ratio. The above effects can be considered in the different models. For instance, in STM, the alteration in the inclination of the inclined compression column reflects this effect. Some models may explicitly incorporate a law inversely proportional to the shear span ratio, such as (a/d) or $(a/d)^{0.7}$. The provisions of the code, utilizing the traditional formulas (1) and (2) as upper limits, do not consider the influence of the shear span ratio. Consequently, in such cases, the model is constrained by design limitations for small shear span ratios, proving unfavorable and evidently uneconomical.

4.3 *Initial prestress*

In slender beams, various codes account for the influence of horizontal prestressing, but they do so in different ways. These considerations include the increase in cracking loads due to prestressing, reduction of horizontal strains, and reduction of the compressive strength of the concrete. In deep beams, such effects are typically not taken into consideration. However, the test results indicate that horizontal prestressing does have some influence on shear resistance.

4.4 *Vertical prestressing force*

In the AASHTO code, the vertical component of prestressing force is considered to enhance shear capacity, a consideration absent in the ACI 318-19. STM also necessitates the consideration of the external load effect of prestressing, although this is not explicitly specified. The authors of this paper conducted tests revealing that the vertical component of prestressing can indeed increase the shear capacity of deep beams. However, results from other tests, such as those by Wang, show the opposite effect. Wang's tests on unbonded rectangular beams differ from this paper's investigation on bonded T-beams. Moreover, when compared to Wang's results, this paper's tests incorporated a significantly higher arrangement of stirrup reinforcement (1% compared to Wang's 0.2%). Wang attributes the lower stirrup reinforcement performance to excessively large prestressing inclinations, hindering prestressing development. In contrast, this paper observes that, the majority of stirrup reinforcement remains below the yield strength. Overall, the tests in this paper suggest that the contribution of prestressing to the load-carrying capacity of prestressed deep beams is comparatively small.

5 DISCUSSIONS

The experimental design in this paper employed specimens with a shear span ratio (a/h) of 1, achieving a stirrup reinforcement ratio of 1.03%. This meets the minimum reinforcement ratio requirements outlined in the Strut-and-Tie Models (STMs) of ACI 318-19 and AASHTO, making it eligible for calculation as the upper limit value of shear resistance. Analyzing the results from Equations 1 and 2 alongside the two STMs, it is evident that the calculated value from Equation 1 closely aligns with the experimental values. Selecting Equation 1 as the upper limit value is considered reasonable and leans toward safety. In contrast, the value stipulated in the ACI 318-19 code is conservative, suggesting that the upper limit value for STM is somewhat biased towards safety. The primary factors influencing the small upper limit value for STM include (1) the issue of the width of the support versus the width of the tie, where

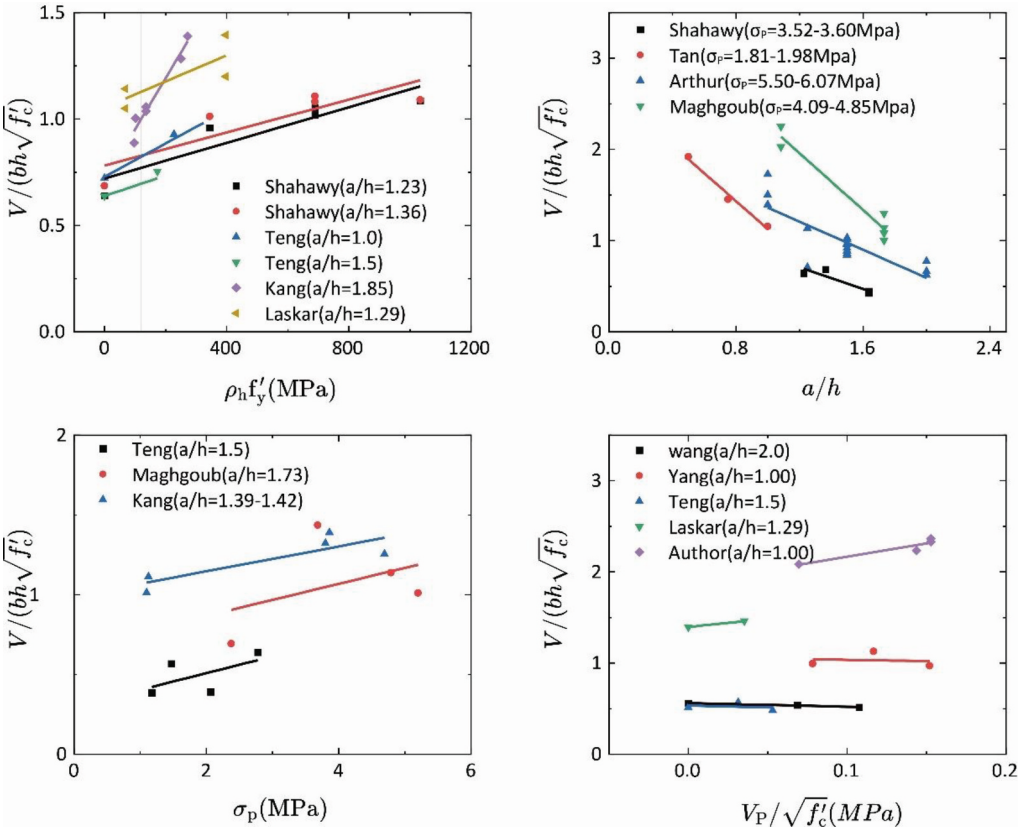

Figure 4. Influence of parameters on shear strength.

T-beams with flanges distribute the width of the support without causing localized damage, and (2) distinguishing only the effect brought by the minimum reinforcement rate, without considering the impact of concrete strength under high reinforcement rates.

Currently, this paper has concluded full-scale post-tensioning tests on bonded prestressed concrete, limiting the range of shear span ratios. Subsequent research should conduct additional tests with varying shear span ratios. Furthermore, addressing the limitations of the current STM model, specifically related to the influence of lower reinforcement ratios and improving calculations for the widening effect at the support, is essential. Investigating the impact of web width in post-tensioned prestressing requires further study, as does exploring the effects of grouting and the material of the pipe on the compressive strength of concrete. The influence of the vertical component of prestressing also necessitates more tests to discuss the effects of unbonded and bonded prestressing methods.

Table 3. Comparasion of different models.

		AASHTO				ACI 318-19			
Beam	Failure shear V_{exp}(kN)	Eq. (1)	Eq.(1)/ V_{exp}	STM	STM/ V_{exp}	Eq.(2)	Eq.(2)/ V_{exp}	STM	STM/ V_{exp}

Average			0.81		0.26		0.37		0.38

6 CONCLUSIONS

In conclusion, this study has provided a thorough examination of methodologies for determining the upper shear limit value of prestressed concrete deep girders. Through the four T-beam shear tests and collection of experimental data, the following conclusions have been achieved:

(1) The upper limit value of prestressed concrete deep beams is influenced by both the reinforcement ratio and shear span ratio. Longitudinal prestress has been observed to improve cracking and ultimate load capacities.
(2) AASHTO code is more suitable for determining the upper limit value for T-beams, in contrast to the ACI 318-19 code. Strut-and-Tie Model (STM) were found to underestimate the upper limit of shear strength.
(3) The influence of the vertical component of prestress necessitating further investigation.

Low carbon solution for short-span bridges: Soil-steel composite bridges versus concrete bridges

Guangli Du
Department of the Built Environment, Aalborg University Copenhagen, Denmark

Adam Czerepak
ViaCon Group, Product & Solutions Director - Bridges & Culverts, Wroclaw, Poland

ABSTRACT: soil-steel composite bridges (SSCB) are extensively utilized for constructing culverts and small-span bridges in numerous countries worldwide, particularly in Europe and North America. The widespread adoption of SSCBs is attributed to their various advantages, such as swift construction, easy installation, low maintenance, straightforward renovations or extensions, and high geometric flexibility, enabling seamless adaptation to terrain conditions and functional requirements. An alternative solution for such structures is the use of reinforced concrete bridges (RCB), including concrete boxes, slabs, frames, or beams bridges. Under the global shift towards a low-carbon strategy and reduction of greenhouse emissions from the transport sector, assessing potential solutions for culverts or small bridges, it is essential to consider their environmental impact. And this is a practice increasingly common across various economic sectors, including engineering.

This paper aims to compare the environmental impact of SSCBs and RCBs by analyzing selected 29 equivalent case studies from several European countries using the cradle-to-gate Life Cycle Assessment (LCA) methodology. Two key environmental impact indicators are selected for evaluation: global warming potential and energy consumption. Data for the analysis of these indicators are derived from Environmental Product Declarations (EPD) and the environmental database Ecoinvent v.3.8.

The case studies demonstrate the advantages of soil-steel bridges over reinforced concrete bridges in the chosen environmental indicators. The main reason for the superior performance of SSCBs lies in their highly efficient use of material mass to ensure the same functionality and load capacity comparing to the concrete solutions. The main load-bearing component of SSCBs is a thin and lightweight corrugated steel plate, which acts as a flexible shell interacting effectively with the surrounding compacted soil. This solution significantly reduces overall resource consumption and carbon emissions.

1 INTRODUCTION

Bridge construction contributes to a substantial share of carbon emissions and resource consumptions. Under the global shift towards a low-carbon strategy, the European Union requests a further reduction of CO2 emissions from the construction sector. Seeking sustainable practices in bridge construction is a key step towards resilient bridge structures with lower carbon emissions. For short span bridges, steel-soil composite bridge (SSCB) is widely adopted and functionally equivalent to the traditional reinforced concrete bridges (RCB). Comparing to RCB, SSCB is easy in construction, low maintenance and competitive cost. By replacing the on-site activities with off-site machines in prefabrication, SSCB can substantially reduce the construction waste by up to 40%. This is because RCBs require the on-site

DOI: 10.1201/9781003483755-154

formwork and reinforcement installations, while the main structure element of SSCB is prefabricated in the factory and bolted on-site, with very minimum equipment needed, and the use of the steel materials is 100% recyclable without loss in quality.

Several studies have conducted mechanical analyses on SSCB bridges; see Mellat et al. (2014), Flener and Karoumi (2009), Pettersson et al. (2015), and Wadi et al. (2020). However, there is a lack of study performed on environmental performance of these two types of bridge designs (Du et al., 2018). This study investigates the environmental performance of SSCB comparing with RCB using cradle-to-gate life cycle assessment (LCA) method associated with 29 equivalent case studies from several European countries. The analysis evaluates the indicator of global warming potential (GWP) in ton CO_2 equivalent and total primary energy demand in GJ, following the technical standards EN15804 for construction products. The indicator of GWP takes account of all substances that contribute to the climate change (IPCC 2013), while the indicator of total primary energy considers energy consumption including both non-renewable energy (e.g. fossil and nuclear) and the renewable energy (e.g. solar, wind, biomass, geothermal, hydro) sources. The functional unit in this study is defined as the entire bridge including all of the structural components during the design life span of 100 years. The analysis is carried out using the LCA calculator developed by ITB Poland Building Research Institute. The dominant structural components, key activities and materials that contribute to the most environmental impacts are tracked. Due to a significant reduction in self-weight, SSCB shows the comparatively low environmental impact over RCB solutions among all considered impact categories.

2 LCA METHODOLOGY

As defined in the ISO 14040 and ISO 14044 standards, Life Cycle Assessment (LCA) is a standardized and internationally recognized approach for quantifying the resource consumption, environmental impacts, emissions as well as the health impacts linked to a product or service through its whole life cycle. The LCA analysis of covers 7 modules, including material manufacture and transportation (A1-3), replacement of building components (B4), operational energy (B6), and waste processing (C3-4), as shown in Figure 1. Among those modules, the material manufacturing phase is the most dominant contributor to the total environmental impact throughout the entire life cycle. Although including B, C and D stages are in favor of SSCB, this study focuses on "cradle-to-gate" analysis covering modules A1-A3 quantifying the impacts associated with upstream material manufacturing. The declared modules are shown in Figure 1.

The material manufacture phase encompasses all the upstream processes of materials used to construct the bridge, from the extraction of raw materials until products are ready for use at the factory gate. To model the impact from this phase, the Ecoinvent database and EPDs containing the unit environmental profiles for each relevant material is applied. Each of the

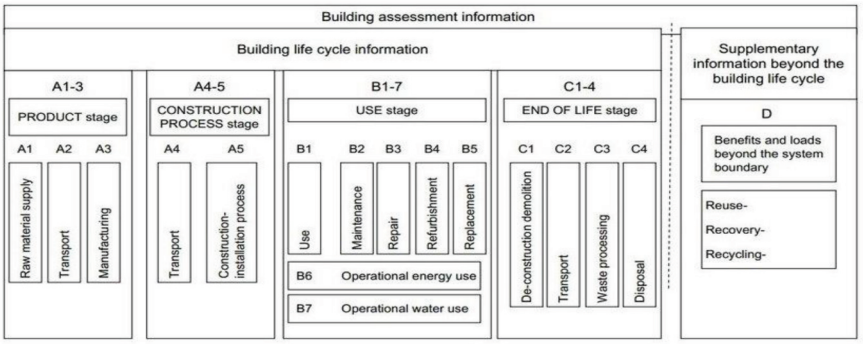

Figure 1. Life cycle modules.

unit environmental impact for the material or process is associated with air, solid and liquid releases linked to the material production, and then aggregated into the mid-point environmental impact categories. The summarized bills of material quantities of the selected bridge are obtained from the drawings and bills of material quantities.

Life Cycle Inventory data (LCI) is a key phase in the LCA that involves the detailed collection and quantification of data associated with the product. The data covers the inputs (energy, resources) and outputs (emissions, waste, etc). LCI databases as Ecoinvent, GaBi and Ökobau are widely used in LCA analysis and contain data for generic and average construction products. Besides, there are also a large number of environmental product declarations (EPD) data owned by the individual producers for a specific product or product groups. For this paper LCA analysis have been done for SSCB with environmental indicators taken from EPD and compared to RCB where the environmental indicators have been taken from Ecoinvent v.3.8. The EPDs are prepared based on data collected from the actual production site in accordance with European standards EN15804. The environmental impact of each process and material type is adopted to quantify the carbon emissions and energy consumption related to the bridge material manufacture scenarios.

3 SOIL-STEEL COMPOSITE BRIDGE (SSCB) AND REINFORCED CONCRETE BRIDGE (RCB)

The environmental performance throughout the life cycle of a bridge can be significantly influenced by the type of bridge chosen. Two commonly employed solutions for short-span bridges are the SSCB and the RCB, both serving the same purpose and often designed with a lifespan of 100 years.

The RCB typically comprises a reinforced concrete frame, concrete slab, or beams placed on bridge abutments, forming the load-carrying structure, see Figure 2. The construction of RCB takes about 3 - 4 months for a small RCB, including concrete foundations. In contrast to the SSCB, the construction of RCB involves scaffolding, formwork, reinforcing, and concrete pouring, considerably extending the construction time and, consequently, increasing environmental burdens.

On the other hand, SSCB is a simpler and functionally equivalent structure to RCB. It consists of a corrugated steel shell, usually protected against corrosion by hot deep galvanization and paint layers, surrounded by compacted frictional soil, see Figure 3. Depending on the bridge span, SSCB can be designed with different corrugation sizes and steel plate thicknesses. The steel plates are often divided into several corrugated and curved sections for easier transportation, bolting together on-site. After bolting, the conduit is backfilled with carefully compacted frictional soil. The shorter construction time of SSCB, compared to RCB (typically 3 - 4 weeks for a small bridge), significantly reduces traffic disturbances and mitigates associated environmental impacts, especially in cases of replacing old bridges. SSCB is primarily designed for short-span bridges, ranging from 3 to 20 meters. Recent advancements in deep

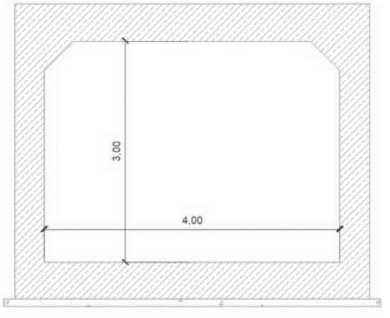

Figure 2. The example of RCB cross section.

corrugations and improved steel qualities have enabled relatively large spans, with a record documented in the Guinness Book of Records showcasing a maximum span of approximately 33 meters, built in United Arab Emirates in 2019.

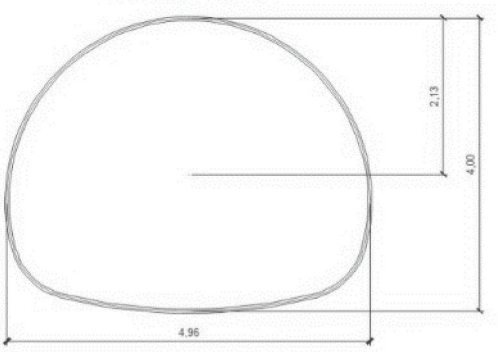

Figure 3. The example soil-steel composite bridge/culvert solution as an equivalent replacement for the RCB structure of Figure 2.

The rise in the popularity of SSCBs can be attributed largely to advancements in designing, manufacturing, and anti-corrosion protection techniques that allow to prolong life time up to 100 years which is usually required for bridges. This has effectively eliminated potential operational issues. SSCBs offer numerous advantages, including efficient use of material mass for desired bearing capacity, swift construction, easy installation, uncomplicated renovations or expansions, and exceptional geometric adaptability, allowing seamless adjustment to terrain conditions and functional requirements.

Due to the current emphasis on sustainable development in every sector of the economy, SSCBs are also being examined for their environmental impact. This is confirmed by LCA analyzes that will be presented in the following sections of this paper.

4 LCA OF SSCB AND RCB

The LCA was carried out on the basis of 29 projects from various European countries, where two solutions, SSCB and RCB, were proposed in each of these projects, equivalent in terms of load capacity and functionality.

These were culverts and bridges ranging from several to a dozen or so meters span (in cross-section). The comparative analysis was carried out for modules A1, A2 and A3 and for following environmental indicators:

- Global warming potential
- Total primary energy

The environmental indicators for each item were calculated using the LCA calculator developed by the "Instytut Techniki Budowlanej" in Warsaw, Poland (Figure 3). The calculation results are presented in Table 1.

The results presented in Table 1 were obtained by calculating the material mass multiplied by the environmental indicator given per ton. Designers derived the mass from drawings or Bill of Quantities (BOQ) tables. For RCB, the mass includes concrete, reinforcement bars, and backfilling, while for SSCB, it comprises steel plates, concrete foundations (for arches), and backfilling.

The backfilling material for both solutions was considered within the range necessary to complete each solution. For SSCB, the range is larger because the backfilling material is a part of the soil-steel solution contributing to the bearing capacity calculation.

Designers individually define this range, typically as span/2 for the left side and span/2 for the right side from the steel shell. Below, a few drawings of bridge cross sections (Figure 5-7) are presented as examples from the 29 analyzed projects.

Table 1. The values of environmental indicators for the SSCB and RCA solution from selected projects.

5 RESULTS

In all 29 cases studied, the use of SSCB resulted in more favorable environmental indicators. The reduction in environmental indicators when using SSCB compared to RCB is presented in Table 2. On average, there is a 47% reduction in GWP and a 34% reduction in energy consumption when using SSCB as opposed to RCB.

6 CONCLUSIONS

In the past, soil-steel composite bridges (SSCB) might have been considered a specialized or innovative approach. However, in the current era, SSCBs employing corrugated bolted plates or helically corrugated pipes have become widely popular for constructing culverts and small-span bridges across almost every European country, as well as in other continents, gaining global recognition for their significant potential.

This paper compared two types of commonly used short-span bridges SSCB and RCB. The SSCBs show advantages over the RCBs in A1, A2 and A3 phases, which is up to 74% less in the indicator of GWP and 66% in total primary energy. The main reason for the superior performance of SSCB lies in their highly efficient use of material mass to ensure the same functionality and load capacity comparing to the RCB solutions. The main load-bearing component of SSCBs is a thin and lightweight corrugated steel plate, which acts as a flexible shell interacting effectively with the surrounding compacted soil. This corrugated steel plate can be engineered to have a high strength-to-weight ratio, allowing for lighter bridge designs, compared to concrete bridges or other steel beam or grid bridges. A high strength-to-weight ratio and other advantages like fast construction and potential for recyclability makes this kind of solution more beneficial for the environment. This solution significantly reduces overall resource consumption

and carbon emissions. There are also other studies where more LCA phases (A, B, C, D) have been analyzed, comparing the SSCB and RCB solution. The results are in line with the thesis presented in this paper.

Soil-steel composite bridges, advantages – based on case studies

Baturalp Şentürk
ViaCon Turkey, Design Engineer, Istanbul, Turkey

Michael Nygaard Nonbo
ViaCon Denmark, Technical Sales Representative Business Unit Bridges & Culverts, Naestved, Denmark

ABSTRACT: Until a decade or two ago, soil-steel composite bridges (SSCB) could have been described as a niche or innovative approach. However, in present times, SSCBs utilizing corrugated bolted plates or helically corrugated pipes have gained widespread popularity for constructing culverts and small-span bridges across nearly every European country and have earned global recognition for their remarkable potential.

The surge in popularity of SSCBs can be attributed to the mastery and refinement of designing, manufacturing, and anti-corrosion protection techniques to a significant degree. As a result, potential operational issues have been effectively eliminated.

Several benefits of SSCB can be highlighted, including highly efficient use of material mass to achieve desired bearing-capacity, rapid construction, effortless installation, simple renovations or expansions, and excellent geometric adaptability, allowing seamless adjustment to both terrain conditions and functional needs.

SSCBs find their most frequent application as culverts, ranging from 1 meter to over 20 meters in span, serving as both culverts and small bridges. An impressive feat was documented in the Guinness Book of Records, showcasing the maximum span achieved, reaching approximately 33 meters.

The objective of this paper is to showcase a selected case studies, from different European countries, and from road and railway projects, to underscore the remarkable capacity of SCCB in overcoming challenging construction obstacles, leading to substantial cost savings and significantly shortened installation timelines.

1 ESKISEHIR ECOLOGICAL BRIDGE CASE STUDY

1.1 *General information*

The bridges made to protect wild animals' living areas purposes have been named ecological bridges in the market. The Eskisehir Ecological Bridge is the first ecological bridge constructed over the high-speed railway line in Türkiye. The main reason for constructing an ecological bridge for this site on Mihaliccik in Eskisehir was local wild animals. Before the construction, there were too many wild animals wasted by train crashes. These crashes brought the effect of decreasing the number of special wild species. The decrease in these numbers was disrupting the balance of nature's wildlife. In addition, it was difficult for the animals to access their nests on the opposite side of the road due to the train line, which blocked the roads that the animals used in their daily lives. On the other hand, these crashes also brought economic disfavors.

To eliminate these problems, biologists and engineers conducted many investigations before starting the project stage like following the animal traces and excrement at the construction site, to setting up the structure to the correct transition point for local animals like wild boar, wolves, red deer, etc. (see Figure 1).

DOI: 10.1201/9781003483755-155

Figure 1. a) The final situation of the bridge; b) The captures from the camera trap.

The structure is made from two segments of corrugated steel plates. The thicknesses of the plates were 7mm for the main part and 5.5mm for the ribbed part. Even though there was a rib plate, the plate did not cover all of the structure; the implementation was made one in two plates. The thicknesses were determined by finite element analyses (Plaxis was used as software for this project's design) (see Figure 2). For the live load analyses, the AASHTO HL93 truckload was taken into account in terms of emergency passings. The structure has 18.55m span, 9.65m rise, and 1.50m cover height parameter. The total top length is 46.55m and the total bottom length is 74.15m which were specified according to the wild animals' needs and the project site requirements such as electrical works. The steel plates were produced as S420 steel class and the total weight of the structure is 230 tones. The plates were connected by M20 class 8.8 bolts. While the use of FEM analysis, the AASHTO approaches have been used in terms of load factors. According to the results, the design was governed by combined utilization with M_{max} and N_{max} which caused the structure 99% of utilization.

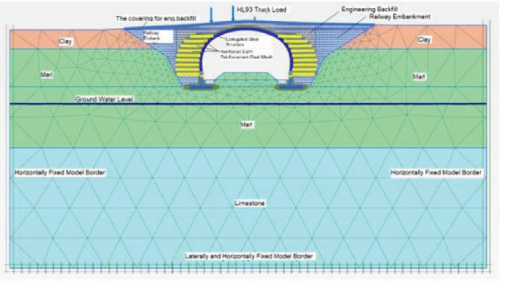

Figure 2. FEM model.

1.2 *Application and construction site challenges*

The designing and construction stage of the project was extremely challenging in terms of being included in the railway institution's budget and also the application site. This project would be applied on the high-speed railway line and the railway authority did not want to cut off railway traffic during the construction. All construction processes were performed during the nighttime zone when the railway is not actively working, generally between 10 pm and 5 am. Also, the weather conditions were tough during construction and concrete casting for foundations. To use the time efficiently, during the project application on the site, plates were assembled to create a ring at the assembly platform near the foundations, and lifting operations of assembled rings were managed overnight (see Figure 3). The structure installation

was finished in 23 days. All the construction stage including foundations, soil works, corrugated steel structure, etc. was completed in 2.5 months.

Figure 3. The construction site during the implementation.

Throughout the construction process, all the electrical current was cut off by the institution during the ring installation on the foundations. The electric current in the wire is 27000 Volt, and to select the cross-section of the project, this current is also taken into account. This means that the minimum distance between the structure plates and the electric line had to be 1.30m to prevent electrical jumping according to the engineer's suggestion. So, the structure dimensions were chosen due to not only railway heights, but also the electrical current line.

One of the main challenges for the analysis process by Plaxis is the huge peaking deflection during the engineering backfill construction stages. To decrease this deflection, the steel meshes around the structure have been applied every 1m in the engineering backfilling (see Figure 4). Also, the engineering backfilling has been applied on 0.3m layers and each layer compacted up to 95%.

Figure 4. Steel mesh application during construction.

After the construction stage of the project was finished, polyurea coating application was made on the inside structural plate face to obtain full waterproofing to prevent any electrical problems during the project's lifetime, also, umbrella water protection was applied over the structure. All the design details of the project were prepared by the ViaCon Türkiye design team including structural control, foundation dimensions, foundation control and layout of reinforced concrete rebar, and others. The design site model of the project was defined in Plaxis depending on the site soil investigation report which was prepared under the control of ViaCon Türkiye. Then, all stages of the project were modeled and analyzed to see the exact behavior of the system.

2 GEOMETRICAL ADAPTABILITY - THE SYRINGE IN GLADSAXE

The background for this project was that the capital city in Denmark, Copenhagen wanted to promote the interest in cycling. They decided to make it safe for the cyclists so they created a program as part of which municipalities within the capital could apply for funding of projects that would promote the use of bicycles as means transportation.

The design should include the connection from the MultiPlate structure to the sheet pile wall. The result was a traditional concrete headwall around the tunnel in one end (see Figure 5 a), at the other end of the underpass the idea was to make a beveled end with a slope of 1:3 (see Figure 5 b).

Figure 5. a) Concrete "portal" in one end; b) Long wing and slope at the other end.

Table 1. Profile data.

Profile	Year	Location	Span	Rise	Bottom length	Skew angle
VR9	2013	Gladsaxe, Denmark	4,77 m	3,83 m	49,85m	28°

As shown in the figure and in Table 1 with the skew angle of 28° the beveled end reached a length of approx. 15 meters. This almost syringe-like shape introduces a challenge when it comes to the soil pressure on the beveled end.

To stabilize this long beveled end the engineers of ViaCon made a combination of a concrete collar and a soil reinforcement using 7 layers of geogrids. The geogrid had a strength of 20 kN/m and was fastened to the side of the MultiPlate with L-shaped steel profiles. The grid was supplied in 1 meter width and the design consisted of 7 layers with a distance of 190 mm to 460 mm.

In order to ensure sufficient anchorage capacity, the length of the geogrid is min. 4 meters from the MP side plates. The contractor installed compacted gravel on top of each geogrid layer and the geogrids were stretched before backfilling.

The concrete collar was designed to be minimum 400 mm wide and cover the steel plates of 600 mm.

The design of this MultiPlate-structure shows the versatility in shaping the material fit the visual expression you want.

3 SIMPLE RENOVATION – PARTIAL RELINING

In 1983 this pedestrian/bicycle underpass was installed in the Municipality of Odense. The profile is a WB6/VR6 made from MultiPlate in the MP200 corrugation.

Sometime during this tunnels life and cycles of the asphalt repair work, the asphalt has been poured out in the full available width leaving cavities along the corrugated steel in which road salt was collected. This eventually created corrosion with local corrosion holes.

The road crossing the tunnel is a subjected to heavy traffic since it connects to one of the main roads to Odense. Hence, it would be of great inconvenience to demolish the old tunnel and reestablish a new one.

It was assessed that due to the low utilization in the bottom part of the tunnel the load carrying capacity of the existing structure was still sufficient. However, the corroded area needed to be sealed off.

In this case a partial relining with the bottom half of the slightly smaller WB4/VR4-profile was chosen (see Figure 6 a) and Table 2).

Figure 6. a) New bottom of WB4/VR4-profile placed inside an existing WB6-profile; b) Final result with wooden handrail in transition between old and new construction.

Table 2. Profile data.

Profile	Year	Location	Span	Rise	Bottom length
VR4-bottom	2021	Odense, Denmark	3,64 m	1,19 m	28,1m

When the new bottom is pulled/assembled in the existing tunnel, the gap between the profiles is filled with concrete. To prevent the new bottom floating upwards, Z-profiles bolted to its sides caught brackets welded to the existing structure.

To finish off the filled gap between the existing tunnel and the new bottom, and wooden handrail was made (see Figure 6 b)). Moreover, the asphalt was reestablished with an inwards slope along the steel bottom.

The process of partially relining the existing tunnel was both less inconvenienced and cheaper than replacing the tunnel.

4 RAPID CONSTRUCTION – THE FLYING TUNNEL

One of the advantages of the SSCB is their relatively low weight. This feature was utilized during the installation of this pedestrian underpass.

The pedestrian underpass is a part of a new bike path project stretching from Stenholt to Nørre Knudstrup along route 13 in Silkeborg Municipality.

Along this path a new underpass crossing Route 13 had to be made, and since this road is a main road with very heavy traffic the time it needed to be closed, should be reduced to an absolute minimum.

The closure time was decided to be in an extended weekend in relation to a public holyday in May 2023 given the contractor a 3-days window to cut open the road, excavate for and installing a 30 m pedestrian tunnel, backfill and reestablish the road with asphalt.

Figure 7. Assembled tunnel swiftly craned in place.

Table 3. Profile data.

Profile	Year	Location	Span	Rise	Bottom length	Total weight
VR8	2023	Silkeborg, Denmark	4,63 m	3,64 m	31,3 m	20,2t

The solution was to assemble a VR8-profile (see Table 3) in the MP200 corrugation on a temporary, prepared jobsite parallel to the main road. This was done well ahead of the actual closure time of the road, and the tunnel was assembled within reach of a mobile crane.

To even the load, 8 lifting brackets were temporarily bolted to the VR8-tunnel a connected to lifting frame. The weight of ca. 20t for +30m of complete tunnel was an easy task for the mobile crane making it a fast job (see Figure 7).

Thereby the contractor planning of the most critical logistics was limited to:

- their own excavators, machines and crew
- an external mobile crane
- an external asphalt crew

In comparison 20 t would have been the approximate weight of only a couple of meters of a similar sized precast concrete tunnel. A precast concrete solution would have required a big

number of carefully planned element deliveries to keep the mobile crane running effectively. Hence, increasing the risk of the entire installation.

The SSCB-solution kept the logistic chain very simply making it less likely that anything could go wrong.

5 CONCLUSION

As the above examples show, SSCB-solution are not only a technically effective choice, but also flexible and adaptive, making them an ideal solution for a variety of site and design conditions.

Currently, the use of SSCB employing either corrugated bolted plates or helically corrugated pipes has become extensively favored for the construction of culverts and short-span bridges. This approach has garnered worldwide acclaim due to its impressive capabilities.

The initial hurdles related to achieving an optimal design, seamless construction, and implementing suitable anti-corrosion protection measures have been successfully overcome. This progress highlights the adaptability and advancements in the field, showcasing how SSCB have evolved to address and surmount these challenges. The widespread acceptance of these structures on a global scale is a testament to their effectiveness and the refined techniques applied to ensure durability and longevity.

ABSTRACT: The physical and mechanical properties of structural materials depend on changes in natural factors, as well as changes in the structure of the surrounding environment caused by pollution of the environment, soil, and water as a result of human activity. The speed of movement of air and water, the penetration of moisture due to soil adhesion, as well as the spread and penetration of harmful substances create the risk of carbination of the concrete structures. These defects may seem innocuous initially, but in the long run can have deleterious effects on its lifecycle performance. Since the problem of determining the service life of a bridge is related to the durability of its elements, the article will consider the rate of carbonation of concrete and its effect on corrosion of reinforcementь as well as a study of the durability of the structure.

1 INTRODUCTION

Moisture penetration, air humidity, and the spread of harmful substances, salt, solar radiation, and temperature changes can lead to corrosion and carbonation of concrete, negatively impacting the performance of bridge structures. In many countries' regulatory documents, the service life of bridge structures is standardized to be between 70 and 100 years due to climatic conditions, regulatory requirements, and construction quality. The thickness of the protective layer of concrete and the duration of the concrete carbonation process are factors that influence the residual life of a bridge structure.

In Mongolia, due to inadequate waterproofing and delayed maintenance and repair work, bridge structures such as expansion joints, reinforced concrete spans, supports, and other components are constantly exposed to moisture, air humidity, and alternating freezing and thawing of water-saturated zones. This leads to surface carbonation of the reinforced concrete structure, the formation of cracks, and the onset of reinforcement corrosion, ultimately affecting the load-bearing capacity, strength, and durability of the bridge structure under constant load.

2 CONDITION AND OPERATION OF BRIDGES IN MONGOLIA

Mongolia's total road network is 112,893.8 km, and only 973 bridges are in use, according to a survey conducted in 2022. The survey results show that out of the total number of bridge structures in operation in Mongolia, there are 593 reinforced concrete bridges, 345 wooden bridges, 7 composite bridges, and 28 other types respectively (Table 1).

DOI: 10.1201/9781003483755-156

Table 1. Types of bridges.

Types	Number	Length	Percentage
		m	%
Concrete	593	32,527.71	60.88
Wooden	345	8,630.80	35.42
Composite	7	1,755.30	0.72
Other	28	1,419.00	2.88
Total	973	44,332.81	100

Approximately 60.88 percent of the existing bridges in Mongolia are reinforced concrete bridges. Issues such as investigating the technical conditions and load capacity of the bridges, determining the technical operational levels of bridge lifespan and damage of bridges, estimating the lifespan of bridge spans and other bridge-related facilities, repairing and reinforcing the bridge spans, and not reducing the load capacity of the bridges, increasing the load capacity, and increasing the road capacity/traffic capacity of the bridges have been severely raised. A pressing issue is the problem of predicting the service life of reinforced concrete structures and determining the durability of the bridge. (Khasnavch, et al., 2022)

According to the results of size studies: 231 bridges are less than 10 m long, 266 bridges are 10-20 m long, 270 bridges are 20-50 m long, 96 bridges are 50-100 m long, 63 bridges are 100-200 m long, and 47 bridges are more than 200 m long. By the time of construction of bridges in Mongolia: 5.65% were built before 1960, 36.38% in the period 1961-1990, 6.68% in the period 1991-2000, 16.44% in the period 2001-2010, 21.58% in the period 2010-2015, and 13.26% after 2015 (Figure 1).

As part of this study, 30 reinforced concrete bridges were selected from the bridges operating in the country, taking into account parameters such as year of construction, age, total length, type and length of foundations, supports and spans. The year of construction, survey of dimensions, service life and planning of the standard load capacity of the surveyed bridges, level of operation and risk assessment are shown graphically in Figures 2, 3 and 4. (JICA, 2015)

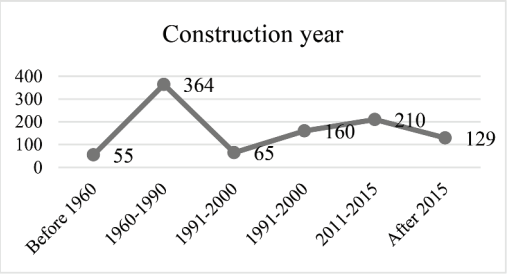

Figure 1. Construction year.

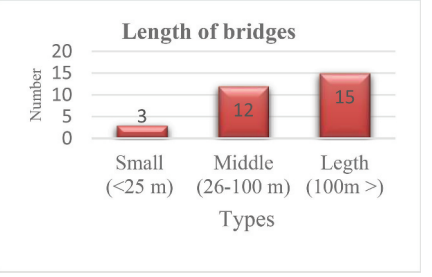

Figure 2. Length of bridges.

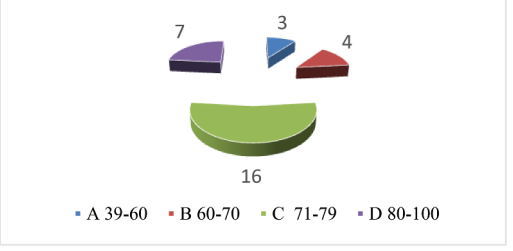

Figure 3. Bridge utilization rate.

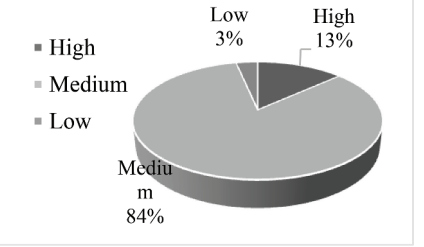

Figure 4. Bridge risk assessment.

3 CONCRETE CORROSION AND ITS INFLUENCE

The durability of concrete is usually understood as the ability to reliably maintain its original shape, dimensions, and physical and mechanical parameters when used under the influence of the environment. Concrete corrosion is a loss of quality caused by exposure to the environment without mechanical influence. Corrosion is a very dangerous phenomenon, since it occurs hidden for a long time and deteriorates the quality of concrete. This process has many reasons. (Dashjamts & Battsagaan, 2013)

Concrete corrosion is a complex physical and chemical process of interaction between the components of cement stone and the external environment and the resulting formation of undesirable compounds, sometimes their internal movement, which most often causes a decrease in the strength of concrete or its complete destruction. The main hazards for bridge structures are considered to be mineralized surface and groundwater containing various substances that differ in the degree of danger of substances dissolved in water, their content, temperature, and characteristics of concrete. Depending on the properties of the aggressive environment, corrosion can occur in the main directions, according to which the following types of concrete corrosion are distinguished. (Dvorkin & Dvorkin, 2006)

A. The first type of corrosion combines processes associated with the leaching of soluble parts of cement stone under the influence of water - the environment (water with low bicarbonate alkalinity, fresh water are especially dangerous). Leaching is understood as the process of dissolution and removal of calcium hydroxide Ca $(OH)_2$ (slaked lime) by water from the concrete body, and the graph of this process is shown in Figure 7. (Jiao, et al., 2016)

B. The second type of corrosion combines processes associated with exchange reactions between the components of the cement stone of concrete and an aggressive environment with the formation on the surface of concrete of amorphous, poorly soluble corrosion products that do not have astringent properties, as well as easily soluble compounds that are washed out with water. Corrosion occurs when water reacts with substances that accelerate the release of soluble compounds, such as lime (calcium oxide hydrate), that attack the concrete.

Components that contribute to the destruction of cement stone include carbonic acid and other water-soluble acids, such as sodium chloride and other chloride salts, as well as substances that increase the solubility of calcium oxide in water. (Larsen, 2020)

C. The third type of corrosion combines processes associated with an increase in the volume of the solid phase of cement stone minerals, deposition of corrosion products, freezing of water, or crystallization of salts in the pores. Crystallization corrosion is understood as the mechanical destruction of concrete and reinforced concrete structures from internal stresses that arise when the volume of constituent materials increases. This type of corrosion occurs when concrete is exposed to sulfuric acid salts (sulfates).

Under certain conditions, types of concrete corrosion can overlap with one another. In this case, it is necessary to identify the leading type of corrosion, the maximum speed of which determines the durability of the structure. For example, the second and third types of corrosion occur when concrete is exposed to water containing magnesium sulfate. Figure 5 shows a diagram of the types of corrosion of concrete under the influence of water and aqueous solutions. In addition to

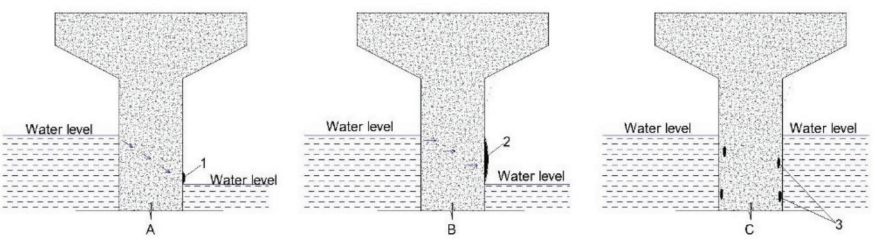

Figure 5. Types of corrosion and diagram of the formation mechanism.

the formation of concrete corrosion due to the action of aqueous solutions, reinforced concrete structures are also subject to other types of corrosion; in addition to concrete, corrosion of reinforcement is observed.

A. The first type of corrosion or leaching process; B. The second type of corrosion is a chemical effect on leaching; C. The third type of corrosion or the process of salt crystallization. 1-accumulation of lime and calcium carbonate, 2-occurrence of corrosion, 3-occurrence of corrosion inside the concrete body.

D. Corrosion due to freeze-thaw cycles In Mongolia, which has an extreme climate, bridge structures undergo repeated freeze-thaw cycles, leading to a deterioration in their quality. If there were no cracks in the concrete, water could not seep in and cause freezing. Cracks in concrete and reinforced concrete structures are common, and they are a leading indicator of damage. These cracks appear as a result of design errors and incorrect actions during concrete work. (Salmeron, et al., 2022)

According to the results of research by the Scientific Research Institute of Hydrometeorology for 2001-2010, when constructing a graph and taking into account the fluctuation of temperatures in April and October, it was found that the influence of zero temperature becomes borderline between freezing and thawing temperatures of concrete.

Immediately after concreting, due to the inability to create conditions for the normal process of cement consolidation, mass transfer occurs due to the evaporation of water, resulting in the formation of cracks on the exposed surface of the concrete. If the cement mortar begins to set, the cracks and pores formed on its surface will not close, and then water will seep in. The water inside will freeze and expand, forming a thin layer on the surface, resulting in cracks.

Concrete will crack to varying degrees due to repeated wetting and drying. It swells slightly when wet and contracts when cooled. As a result of shrinkage, cracks will appear, starting from the surface of the concrete. It will crumble, losing weight and structure, and strength is lost, leading to corrosion (Examples in Figures 6, 7 and 8). Essentially, this corrosion of concrete is not only the fault of moisture and water in the environment, but is also the result of improper actions by the contractor, who created the opportunity for water, moisture, and gas to enter the concrete structure during preparation and production.

If water could not penetrate the concrete, no matter how cold the environment, the concrete would not suffer structural failure due to volume expansion from freezing. Water in the pores of concrete does not freeze at a temperature of 0°C, and the freezing point of the very small amount of water that freezes in capillaries is well below 0°C. Therefore, the structure should be sealed to protect it from cold weather conditions. For example, reducing the water-cement ratio is a simple way to completely stop mass transfer in concrete at the first stage of compaction.

Figure 6. Concrete corrosion and defects on the reinforced concrete surface of a girder.

Figure 7. Concrete corrosion and defects on the reinforced concrete surface of an anchorage.

Figure 8. Concrete corrosion and defects on the reinforced concrete surface of a support.

When concrete is fully cured, less than 50% of the water in the composition reacts with the cement to form cement paste. Ordinary Portland cement absorbs 17-20% of its weight in water in 28 days and hardens. The residual water becomes excess water and eventually evaporates, forming capillaries. Scientists have confirmed that when concrete fully hardens, 23-25% of the cement by weight combines with water to form a solid.

According to the researchers, water seeping into 0.1-0.5 micron cracks and pores in concrete freezes and causes structural damage. However, it is believed that large pores will not be completely filled with water and will not be damaged by freezing. If air bubbles (closed pores) with a diameter of less than 0.2 mm are evenly distributed within the structure of the cement stone, researchers prove that the structure will not be destroyed during freezing. However, it can be seen that even if aeration additives are used only in the concrete of the bridge structure and methods are used to protect it from atmospheric exposure to cold, if the structure is washed with water due to insufficient drainage and the presence of capillary pores filled with water, cracks and damage will occur intensively.

The main condition for the destruction of concrete is the process of freezing and thawing. Repeated cycles of freezing and thawing lead to the gradual deterioration of concrete. This is due to the fact that during freezing, stresses arise that are close to the limit, which are destroyed during thawing. This failure mechanism is similar to the failure of a solid body as a result of repeated loading. Compacting the structure is considered the only reliable way to protect against physical corrosion, which reduces the quality of concrete due to wetting, drying, and freezing. Gibson in 1938 and Lerch in 1959 noted that the influence of the chemical activity of coarse and fine aggregates on the destruction of concrete is inevitable. Later, in 1964, Hadley studied the alkali-silicon reaction and believed that this reaction was a strange phenomenon.

4 DURABILITY STUDY

The strength of reinforced concrete structures is assessed by the corrosion of concrete and reinforcement. Corrosion of reinforced concrete structures occurs under the influence of O_2, Cl, and CO_2. Corrosion of reinforcement caused by Cl is more common in elements in contact with salt in bridge structures. To control the corrosion of reinforcement caused by Cl in concrete, it was carried out using a Proceq device from Resipod, Switzerland. The Resipod is a device that measures the electrical resistance of concrete surfaces. The electrical resistivity of concrete provides information about the state of reinforced concrete structures. The resistivity of concrete is directly related to the corrosion process and the corrosion rate of concrete. Figures 11 and 12 present the results of measuring the resistivity of the concrete surface of the structures of the studied reinforced concrete bridges using the Resipod device. (Hudson, et al., 2015)

For concrete and reinforced concrete structures with conventional Portland cement binders, with a specific resistance of less than 100 kΩcm, no corrosion of concrete reinforcement occurs, and with a specific resistance of 200-300 kΩcm, the process of corrosion of concrete reinforcement has begun. If the resistivity exceeds 300 kΩcm, it means that there is severe corrosion of the concrete reinforcement and additional measures must be taken to strengthen and protect the concrete. Although we conduct our research under the assumption that corrosion in reinforced concrete structures is primarily caused by carbonation of the concrete, we have observed evidence of galvanic corrosion due to the use of reinforcement in the grounding of the support.

Figure 9. Cracks arising due concrete supports.

Figure 10. Concrete strength of reinforced concrete structures.

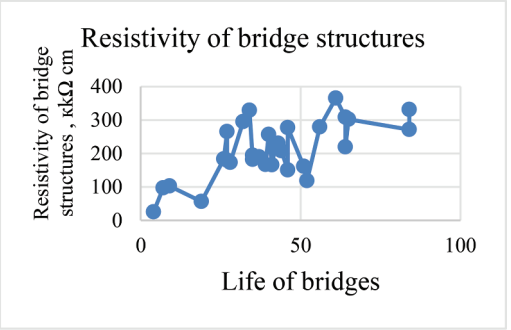

Figure 11. Comparison of resistivity of bridge structures.

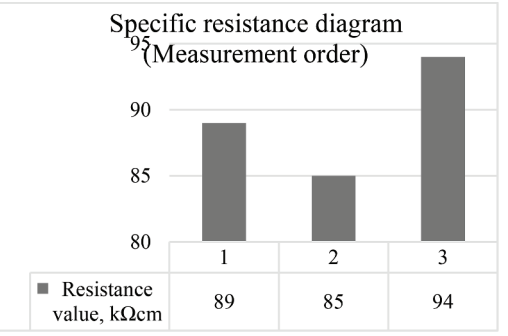

Figure 12. Results measured by Resipod.

4.1. *Experimental studies of bridge supports*

As part of the research, an examination and diagnostics of the operational condition of a - 162 m long reinforced concrete bridge across the Ongi River in Arvaikheer was carried out in August 2023. The bridge over the Ongi River is located on the Erdenesant-Arvaikheer road and has 9 spans with 5 beams 18 m long.

4.2. *Determination of the strength of concrete bridge structures (UPV test – Direct test method)*

The test results for the concrete strength of the Ongi River Bridge support structures were obtained using the UPV Direct test method and the Schmidt tool. The strength of the concrete of the main support was determined by direct ultrasound at 3-4 points, and the strength of the concrete of the edge support was determined by the echo method (UPV Indirect test method echo). In addition, the effect of carbonation of concrete was calculated when determining the strength of concrete using the Schmidt tool (Figure 10). The strength of concrete is checked by ultrasonic testing.

4.3. *Determination of the strength of concrete samples (Concrete Core Test)*

Using a HILTI 200 electric drill, a concrete sample with a diameter of 95 mm was taken from each support. After carbonation analysis, the sides were leveled and then pressed using a PSU-125 press machine (Figures 13 and 14). As part of the research, in August 2023, an examination and diagnostics of the operational condition of a 162 m long reinforced concrete bridge across the Ongi River in Arvaikheer was carried out. The bridge over the Ongi River is located on the Erdenesant-Arvaikheer road, has 9 spans with 5 beams 18 m long. (Kabashi, et al., 2015)

Figure 13. Removed from the supports cylindrical samples before the compression tests.

Figure 14. Removed from the supports cylindrical samples after the compression tests.

To check the progress of carbonation in concrete (CO_2), the depth of carbonation was measured by spraying a phenolphthalein solution onto samples taken from the bridge piers.

The carbonation depth of concrete ranges from 6-32 mm, with an average value of 15.9 mm. Table 2 shows the carbonation depth of drilled concrete samples (Figures 15 and 16).

4.4. *Corrosion of pole reinforcement (Half-cell potential test)*

In this experiment, we did not have Copper-Copper sulphate, so we used a Resipod device from Proceq, Switzerland. Table 2 presents the results of measuring the resistivity of the concrete surface of a reinforced concrete support with the Resipod device. The electrical resistivity of concrete is directly related to the corrosion process and the corrosion rate of the reinforcement. The electrical resistivity value of the bridge support concrete is 53.3-160 kΩcm.

Table 2. Degree of carbination, resistivity, strength of support's concrete.

No	Support	Carbination mm	Resistivity kΩcm	Strength of concrete mPa
1	A1	4	160	27.65
2	A2	8	125	29.78
3	P1	32	53.3	29.78
4	P2	13	70.5	27.65
5	P3	5	138	28.30
6	P4	20	57.8	28.30
7	P5	25	62	26.95
8	P4	20	98	26.95
9	P7		94	23.40
10	P8		94	28.30

4.5. *Corrosion of pole reinforcement (Half-cell potential test)*

In this experiment we did not have (Copper-Copper sulphate), so we used a Resipod device from Proceq, Switzerland. (Figures 17, 18). Table 2 presents the results of measuring the resistivity of the concrete surface of a reinforced concrete support with the Resipod tool. The electrical resistivity of concrete is directly related to the corrosion process and the corrosion rate of the reinforcement. The electrical resistivity value of the bridge support concrete is 53.3-160 kΩcm. (Hudson, et al., 2015)

Figure 17. The carbonation study of reinforced concrete supports using the Resipod device.

Figure 18. Measuring the resistivity of the concrete surface.

4.6. *Wear and damage to bridge supports*

Were observed, with no deep or wide cracks (structural or non-structural) in the 10 bridge supports. However, in the water contact area of some supports, the strength of the concrete was reduced due to the effects of freezing and thawing. This led to the exposure of some of the horizontal reinforced concrete reinforcement on P5, P6, and P7 supports (see Figures 19 and 20). No other damage or defects were observed in the reinforced concrete bridge supports.

Figure 19. Damage of freezing and thawing the concrete on P5 support.

Figure 20. Damage of freezing and thawing of of the concrete on P6 support.

5 CONCLUSIONS

1. With the development of the country, an urgent problem has arisen: the reduction in the performance of the structure and the acceleration of the degradation process, leading to the gradual "aging" of bridges and the loss of their operational qualities. This is manifested in the form of structural destruction, a decrease in the strength properties of concrete, and the formation of various kinds of cracks. Therefore, it is important to carry out inspection and diagnostic work on bridges, identify and analyze damage, and determine their preliminary service life.
2. According to the results of monitoring the bridge over the Ongi River, the strength of the concrete support is 20-32 MPa, the depth of carbonation of concrete is 6-32 mm with an average value of 15.9 mm, and the electrical resistivity of the concrete support is 53.3-160 kΩcm. The thickness of the concrete protective layer of reinforcement supports P5, P6, and P7 is less than designed, and therefore it is necessary to strengthen the bridge supports.

ABSTRACT: Bridge monitoring using displacement, strain, acceleration or rotation measurements during normal operation can be a good supplement to conventional manual bridge inspections. In order to detect damage from the measured signal, features must be extracted from the signal that are primarily damage-sensitive. In recent years, features based on the influence lines have been increasingly investigated. The influence line represents the simplified signal that can be measured with a sensor at a fixed position when a single vehicle crosses the bridge. In this paper, we present the new feature normalised integrated influence lines (niil). We show that niil is sensitive to damage, independent of vehicle geometry, velocity, sampling rate, deviation from ideal lane and robust against noise using the analytical bending beam and strain data from a real bridge that has been successively damaged. niil can be calculated based on the curvature, rotation or displacement influence lines.

1 INTRODUCTION

Bridges in Germany are usually designed for 100 years (Mehlhorn & Curbach 2014). Most bridges were built until 1980 and are prestressed concrete bridges (BASt 2023). Recently, prestressed concrete bridges from the 1960s to 1980s have suddenly started to fail or need to be replaced in the near future (Schlenga 2022). In Germany, the condition of a bridge is assessed by visual manual inspections every three years. Bridge monitoring can be an opportunity to observe old bridges between inspection intervals, especially bridges that have received a poor rating. In bridge monitoring, the condition of a bridge is assessed on the basis of the bridge movement which is measured via sensors. The most common sensors measure strain or acceleration. Strain can be measured with strain gauges or with fibre Bragg grating (FBG) sensors and acceleration with accelerometers (Zarate Garnica et al. 2021). The rotation can be determined using inclinometers or calculated from accelerometers (Hester et al. 2019). There are also non-contact solutions for measuring bridge movement, such as the displacement measured with the ground based radar (GBR) (Zarate Garnica et al. 2021).

The condition of the bridge cannot simply be deduced from the measured signal. Therefore, features are required for damage detection in bridge monitoring. The features must be damage-sensitive, robust against measurement noise and temperature changes and independent of the vehicle parameters, the vehicle velocity and the driving lane selection.

DOI: 10.1201/9781003483755-157

Further below in this section, we give a rough overview of some features for bridge monitoring. In section 2 we introduce the new feature normalised integrated influence lines (**niil**). In section 3 we analyse the new feature on the stepped Euler-Bernoulli bending beam and in section 4 on measurements of a real bridge. The paper is finalised with the conclusion.

1.1 *Related work and open questions*

Damage assessment using bridge monitoring is carried out in four stages (Rytter 1993). In the first stage, the presence of damage is recognised. The following stages can only be determined with a very accurate model of the real bridge which require a great effort to create. For this work, we assume that no sufficiently accurate model of the bridge is available and limit ourselves to damage detection (first stage). A monitoring system that does not use a model for damage detection belongs to the data-driven approaches. Furthermore, it is assumed that no data of damaged states are available, therefore only anomaly detection can be performed (Fugate et al. 2001). The vehicle parameters remain unknown during damage detection with the features.

The most frequently used features are based on the modal parameters. These include the natural frequencies, modes and curvatures of the modes. However, the modal parameters have some disadvantages, such as dependencies on the temperature, the lack of damage sensitivity or the use of derivatives (Brownjohn 2011, Cawley 2018). The calculation of derivatives is not trivial for real measurement data due to measurement noise. The determination of the modal parameters with the operational modal analysis is afflicted with further uncertainties.

An alternative to the modal parameters are features based on the influence line (IL). The IL can be the curvature, rotation or displacement IL. The curvature can be considered proportional to the strain if the deformations are small (Spura 2019). Some features based on the IL are not independent of the vehicle geometry. The transferability of some features that use the derivatives to real measurements with measurement noise can be doubted. There are only a few features available that are based on the displacement IL.

The most promising are the so-called *R* features. With the *R* feature, the ratio of two integrated ILs is used as a feature (Döring et al. 2022, Döring et al. 2023 and Jansen 2020). The ILs are determined at two different sensor positions. In Döring et al. (2023) we identified sensor positions for the curvature ILs that may have a high damage-sensitivity. For these sensor positions the integral of the ILs is zero and cannot be used for the *R* feature if the integral is in the denominator. Furthermore, the number of dimensions of the *R* features increases non-linearly with $(n_\mathrm{D} - 1)\, n_\mathrm{D}/2$ if n_D is the number of sensors. The visualisation of several *R* features is difficult and not easy interpretable. The features of Hong et al. 2016 and Wu et al. 2017 are similar to the feature niil presented here. These features are normalised to the integrated signal of one sensor. However, the sensor is not predefined and the integral of the selected sensor can become zero depending on the boundary condition and damage. Furthermore, these features are based on FBG sensors, which are expensive and cannot be easily attached to existing bridges.

2 NEW FEATURE

In this section we introduce the new feature normalised integrated influence lines (**niil**).

The integral

$$A(x_\mathrm{ref}) = A((s(x_\mathrm{ref}, d_F)) = \int_0^{L+a_\mathrm{T}} s\big(x_{ref}, x\big)\,\mathrm{d}d_F \approx \sum_{k=0}^{n_\mathrm{samples}} s(x_\mathrm{ref}, \Delta d_F \cdot k) \cdot \Delta d_F \tag{1}$$

of the superpositioned ILs $s(x_\mathrm{ref})$ in sensor position x_ref is formed from 0 to $L + a_\mathrm{T}$ as a function of the load position d_F, where a_T is the distance between the first and last axis. Assuming a constant velocity v, the load position d_F can be determined via the relationship

$$d_F = vt, \tag{2}$$

where t corresponds to the time. n_{samples} corresponds to the number of samples of a crossing, k is the sample number and d_F is the resulting step $\Delta d_F = (L + a_T) / n_{\text{samples}}$. The curvature, rotation or displacement IL can be used as the IL. The integrated signals (superpositioned ILs) are summarised in the vector

$$\boldsymbol{a} = [A(x_1)A(x_2)\cdots A(x_{n_{\text{sensors}}})]^{\mathrm{T}}. \tag{3}$$

Finally, the new feature

$$\mathbf{niil} = \frac{\boldsymbol{a}}{\sqrt{\boldsymbol{a}^{\mathrm{T}}\boldsymbol{a}}} \tag{4}$$

can be calculated by using normalisation. Normalisation is used to cancel out the influence of the load. The dimension of **niil** corresponds to the number of sensors n_{sensors} used and therefore does not grow exponentially, as with the R feature. We assume that feature **niil** has the same behaviour in terms of dependence on lane deviation and temperature as the R feature. We therefore recommend calculating the **niil** feature only for sensors within the same girder. This means that two **niil** features should be calculated for a bridge with two girders.

3 APPLICATION OF THE NEW FEATURE TO THE STEPPED EULER-BERNOULLI BENDING BEAM

In this section, we use the example of the analytical bending beam to show that the new feature **niil** is independent of the number of samples and thus independent of the sampling rate and velocity, as well as independent of the vehicle geometry. However, there must be a sufficient number of sampling points per vehicle crossing for damage detection. First, we present the setup in section 3.1. This is followed by the results in section 3.2, which are discussed in section 3.3.

3.1 *Setup*

We use the implementation of the stepped Euler-Bernoulli bending beam from Döring 2022a in Matlab, which we explained in detail in Döring et al. (2022). Figure 1 shows the bending beam with the main parameters. The beam in Figure 1 is a statically indeterminate system, since the beam consists of a continuous beam with three supports. The beam has the length L and the centre support is always located at $b_{\text{m}} = 1/2L$. The damage is modelled by a reduction in bending stiffness

$$\Delta EI = \frac{(EI)_1 - (EI)_2}{(EI)_1} \tag{5}$$

The bending stiffness $(EI)_2$ applies between b_1 and b_2 and $(EI)_1$ outside. To obtain the IL, the load F moves from 0 to L. We consider $n_{\text{sensors}} = 7$ sensors equidistantly distributed in the beam, which are represented by the magnifying glass symbol in Figure 1. The sensor positions were selected so that the potentially damage-sensitive sensor positions at $x_{\text{ref}} = 3/8L$ and $x_{\text{ref}} = 5/8L$ of the curvature ILs can be taken into account. These sensor positions are the positions where the integral of the IL for the undamaged beam becomes zero (Döring et al. 2023). Such sensor positions also exist for the integral of the rotation and the displacement ILs of the undamaged beam. The integrated displacement ILs for the undamaged beam become zero in $x_{\text{ref}} = \{0, 1/2L, L\}$ and the rotation ILs become zero in $x_{\text{ref}} = \{(1 + \sqrt{33})/32 \quad L, 1/2 \quad L, (31 - \sqrt{33})/32 \quad L\}$. The displacement is zero in the aforementioned sensor positions and is therefore useless. In contrast, the rotation is not equal to zero at the mentioned points. However, we only consider the potential damage-sensitive sensor positions for the curvature ILs.

For the following analysis, we consider the ten damage scenarios in Table 1. Damage scenario 0 is the undamaged beam. The damage scenarios with a 1 before the hyphen are scenarios in which the damage is in the centre of the field (between $b_1 = 0.2L$ and $b_2 = 0.3L$), in

scenarios with 2 before the hyphen the damage is above the centre support (between $b_1 = 0.45L$ and $b_2 = 0.55L$) and in the scenarios with 3 before the hyphen, the damage is such that no sensor is located in the damage location (between $b_1 = 0.2625L$ and $b_2 = 0.3625L$). The numbers after the hyphen show the reduction in bending stiffness ΔEI in percent.

To test the invariance of the new feature **niil** to the vehicle geometry, we consider six loadcases, whereby the load cases consisted of one to four loads. These represent the axes in simplified form. The distance between the loads and the amplitudes of the loads were selected at different values.

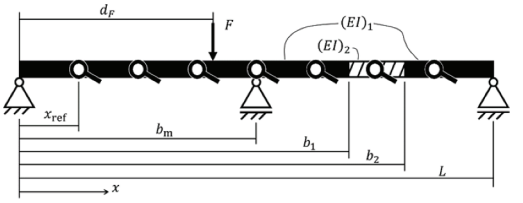

Figure 1. Drawing of the stepped Euler-Bernoulli bending beam with seven sensor positions (magnifying glass symbol) and the moving load F.

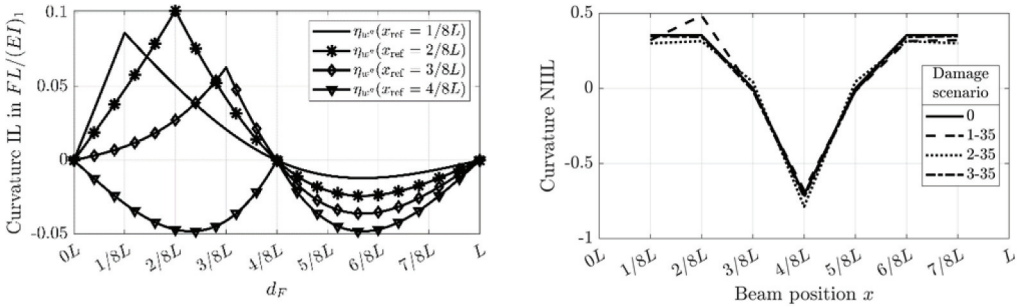
Table 1. Parameters for the damage scenarios. b_1 is the left limit of damage, b_2 the right limit of damage and ΔEI the reduction in bending stiffness.

Damage scenario	b_1	b_2	ΔEI
0	-	-	-
1-5	0.2 L	0.3L	5%
1-20	0.2 L	0.3 L	20%
1-35	0.2 L	0.3 L	35%
2-5	0.45 L	0.55 L	5%
2-20	0.45 L	0.55 L	20%
2-35	0.45 L	0.55 L	35%
3-5	0.2625 L	0.3625 L	5%
3-20	0.2625 L	0.3625 L	20%
3-35	0.2625 L	0.3625 L	35%



The different load cases lead to the same feature **niil**, therefore the configuration of the load cases is not presented. In addition, the resulting signals of the superpositioned ILs is analysed with 500, 1000 and 2000 samples. This determines whether **niil** is independent of the number of samples and the vehicle velocity.

3.2 *Results*

Figure 2a shows the curvature ILs with a unit load for the sensors in the left half of the beam. The course of the ILs for the undamaged beam for the mirrored sensors of the right field is mirrored in the centre support position b_{m}. After determining the superpositioned signals, the feature **niil** can be calculated for the seven sensors. These are visualised in Figure 2b based on the superpositioned curvature ILs for damage scenarios 0, 1-35, 2-35 and 3-35. The greatest deviation from damage scenario 0 can be observed for 1-35 in sensor position $x_{\mathrm{ref}} = 2/8L$, where also the centre of the damage is located. For damage scenario 2-35, there is also a greater deviation from scenario 0 for the sensor position which lies within the damage ($x_{\mathrm{ref}} = 4/8L$). No major deviation is noticeable for damage scenario 3-35. Here, as for the two other damage scenarios with damage, the value in the damage-sensitive sensor positions $x_{\mathrm{ref}} = 3/8L$ and $x_{\mathrm{ref}} = 5/8L$ is not equal to zero, which indicates the presence of damage. All curves for the different load cases and samples are superimposed. The feature **niil** based on the rotation and displacement IL shows a comparable behaviour. However, the **niil** courses based on

the rotation and displacement ILs visually show a higher deviation for damage scenario 3-35 compared to **niil** based on the curvature ILs.

Figure 3 shows the Euclidean distance of **niil** for the individual damage scenarios to damage scenario 0. The circle symbol represents the results for the feature **niil** based on the curvature ILs, the triangle symbol based on the rotation ILs and the square symbol based on the displacement ILs. First, it can be determined for all three variables that the Euclidean distance increases with increasing reduction in bending stiffness ΔEI for the respective damage position. If the sensor positions are within the damage – these are the cases with a 1 or 2 in front of the hyphen – then **niil** has the highest Euclidean distance based on the curvature IL compared to the rotation and displacement ILs. The highest Euclidean distance is observed for the damage scenario1-35. The Euclidean distance of **niil** based on the curvature ILs is second highest for damage scenario 2-35. Damage position 2 leads to the lowest Euclidean distance for **niil** based on the rotation and displacement influence lines. If the sensor is not located in the sensor position, **niil** performs comparatively worst based on the curvature ILs. For damage position 3, **niil** performs best based on the rotation ILs. Otherwise, **niil** based on the rotation ILs is the second best for damage positions 1 and 2.

a) Curvature ILs for different sensor positions the left beam half for an undamaged beam.

b) Feature **niil** based on the curvature influence lines for three damage scenarios.

Figure 2. Curvature influence lines and the corresponding feature niil.

3.3 *Discussion*

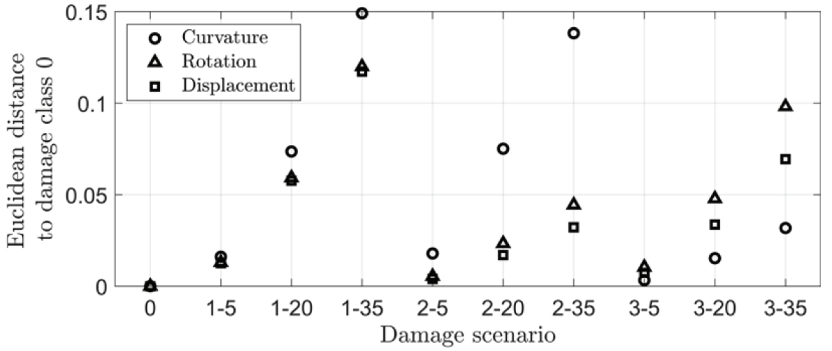


Figure 3. Euclidean distance of niil for the individual damage scenarios to the damage scenario 0. The results for niil based on the curvature ILs are represented by the circle symbols, those based on the rotation ILs by the triangle symbols and those based on the displacement ILs by the square symbols.

From the results, we can first conclude that the Euclidean distance with the feature **niil** can be used to detect damage in a bending beam based on the curvature, rotation and displacement

ILs. The Euclidean distance increases proportionally to the amount of the reduction in bending stiffness for a damage location. The feature **niil** is independent of the considered number of samples and thus independent of the velocity and sampling rate. Furthermore, **niil** is independent of the vehicle geometry, as the different load configurations lead to the same course of **niil**. Compared to the *R* feature, the new feature **niil** can be visualised and interpreted more easily. It can also be seen that **niil** based on curvature ILs shows a higher deviation from the undamaged beam for sensors located within the damage. A further investigation shows that the maximum, minimum or absolute maximum values of the signals are not independent of the vehicle geometry. This means that invariance to the vehicle geometry can only be achieved with the integral of the signals. The damage-sensitive sensor positions appear to have a smaller effect on the curvature IL, as the damage position 3 leads to a low Euclidean distance in comparison.

In the next section, the feature is analysed on measurement data of a real damaged bridge.

4 APPLICATION OF THE NEW FEATURE ON REAL DAMAGED BRIDGE

In this section, we present the feature **niil** using real measurement data from a damaged bridge. Firstly, we present the test setup in section 4.1. This is followed by the results in section 4.2 and the discussion in section 4.3.

4.1 *Setup*

The bridge BW 70 on the B279 federal road in Bavaria/Germany connects the towns Baunach and Breitengüßbach. We have already described this bridge in Döring et al. 2021. The bridge is a prestressed two-span bridge built as a continuous girder in 1962. Figure 4 shows the ground plan with the cross-section. The bridge has one lane in each direction and consists of two girders. One girder contains nine tension cables. During the construction of the replacement bridge, tests were carried out on the existing bridge. The bridge was successively damaged. 18 linear strain gauges were installed under the bridge. Figure 4 shows the approximate position of the sensors. An excavator with a total weight of 19.4 t was selected for the tests. For each damage scenario, the excavator made around 25 crossings per driving direction over the bridge. Due to the multiple crossings, the lane subsequently deviates between the crossings. For this reason, the feature is analysed for the independence of the lane deviation. One crossing consists of 3,800 to 4,000 samples. Firstly, six of the nine tension cables were successively cut in position C, represented by the square in Figure 4. This was followed by further cuts step by step through six tension cables in position D. While the letter of a damage scenario name hereinafter refers to the damage position, the number after the letter indicates the number of cut tension cables. The pre-processing consisted of removing the trend and extracting the time window in which the vehicle was on the bridge.

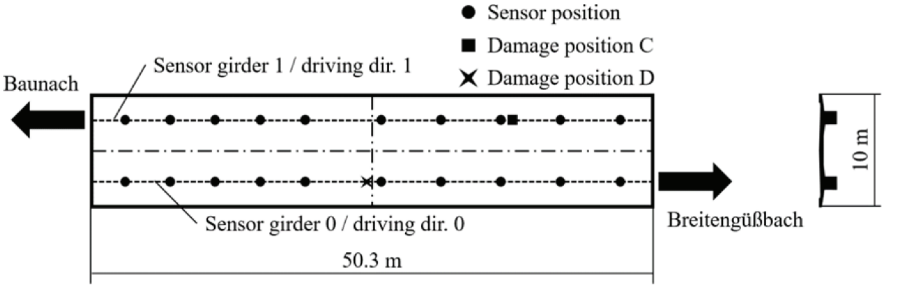

Figure 4. The left-hand side shows the floor plan of bridge BW 70 with the sensor positions and the damage positions. The cross-sectional area is shown on the right-hand side.

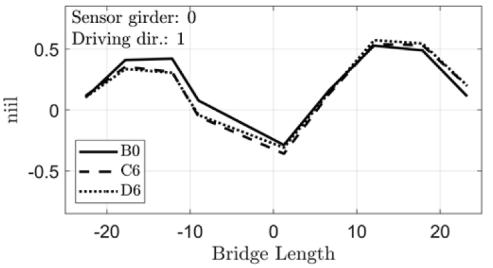
4.2 *Results*

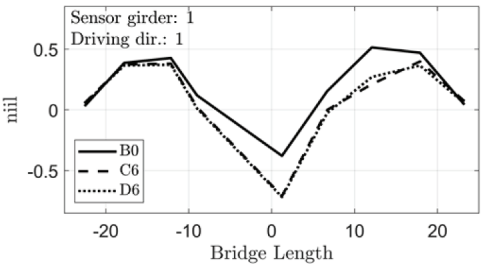
In this section, we present the results of the feature **niil** based on the strain signals obtained from the strain gauges attached to the bridge. The mean value of the feature **niil** can be seen in

Figures 5a and 5b for three selected damage scenarios for the crossings in direction 1. The damage scenarios are the undamaged bridge B0 (solid curve) and the scenarios C6 (dashed curve) and D6 (dashed-dotted curve). Figure 5a shows **niil** for the damage scenarios for the sensors in girder 0 and Figure 5b for the sensors in girder 1. Surprisingly, the largest deviation in Figure 5a is for the sensors in the left field, although the damage is in the right field. A greater visual difference is visible in Figure 5b for girder 1. Here, the largest deviation in the sensors is above the centre support and the field where the field in which the damage C is located. While there is a large difference between the damage scenario B0 and C6, the visual deviation from D6 to C6 is small.



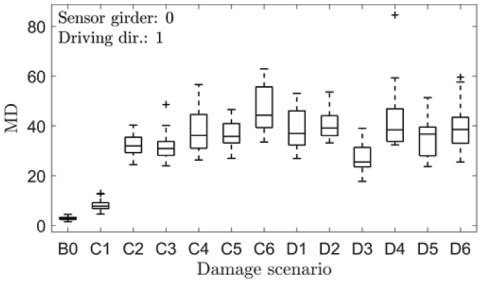
The Mahalanobis distance (MD) represents the distance from the case to be tested to the mean value normalised to the standard deviation of the reference state. Figures 5c and 5d show the MD to damage scenario B0 in the box plot for the individual damage scenarios. The lower edge of the box indicates the 25 % quantile, the centre line the median and the upper line the 75 % quantile. The whiskers show the outliers. If the outliers are too far from the box, they are represented by a plus sign. The outlier with the highest MD in girder 0 in Figure 5c for damage scenario B0 has a value of MD = 4.42, while the lowest outlier in damage scenario C1 has MD = 4.57. This means that there is no overlap between the two damage scenarios for any of the 25 crossings per damage scenario. We assume that **niil** is normally distributed within a damage scenario. Since **niil** has $n_D = 8$ dimensions in this example, 95.76 % of the crossings of the reference state are within MD ≤ 4 (Wang et al. 2015). The median for girder 0 for B0 in Figure 5c is MD = 2.83 and the median for C1 is MD = 7.75. In Figure 5d for **niil** based on the sensors of girder 1, the median for the damage scenario is MD = 2.83 and for the damage scenario C1 the median is MD = 8.41. In Figure 5d there is also no overlap between the scenarios B0 and C1. Here, the difference between the highest outlier of B0 and the lowest outlier of C1 is ΔMD = 2.33. The MD is higher for the other damage scenarios than for C1. In general, the MD in girder 1 is greater than in girder 0 for the individual damage scenarios. Girder 1 is the girder over which the vehicle drives and in which the damage is first introduced.

4.3 *Discussion*

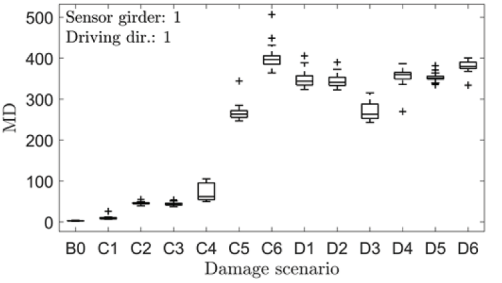


The behaviour of an artificially created crack may differ from that of a crack caused by several load cycles. By cutting the tension cables with a saw or drill, there is no contact in the cut area under pressure. The behaviour between the artificial crack and a crack caused by several load cycles should be the same if the vehicle is in the same field as the crack, as the crack opens under tension in both cases. However, if the vehicle is in the opposite field to the crack, the behaviour may be different, as the slowly formed crack is closed under pressure, whereas the artificially created crack remains open. However, the difference should be small, as on the one hand the load in the crack is significantly smaller because the vehicle is in the opposite field and on the other hand the concrete can take over the load transfer under pressure. A significant change in the MD to the undamaged bridge can already be observed after the first tensioning cable is cut. However, we cannot simply deduce the damage location from the comparison of the **niil** course. The MD increases proportionally to the damage up to damage scenario C6. After that, the MD decreases again slightly. However, from damage scenario C2 onwards, MD>20 already applies to all crossings of the other damage scenarios for both sensor girders. The MD is higher in the girder where the first damage position is located and over which the vehicle is driving. The outlier with the highest MD for damage scenario B0 is so low that there is no overlap with the other damage scenarios. From this, we conclude that the feature **niil** is sensitive to damage and that the influence of measurement noise is reduced and independence from lane selection in considered setup is achieved.

5 CONCLUSION



In this paper we introduce the new feature **niil**, which is based on the ILs. **niil** can be calculated for the curvature, rotation or displacement ILs. To calculate **niil**, the signal of a single crossing



a) **niil** for sensors in girder 0 and crossings in driving direction 1. The course represent the average value of the 25 crossings.

b) **niil** for sensors in girder 1 and crossings in driving direction 1. The course represent the average value of the 25 crossings.

c) Mahalanobis distance (MD) for feature **niil** to damage scenario 0 for sensors in girder 0 and the crossings direction 1.

d) Mahalanobis distance (MD) for feature **niil** to damage scenario 0 for sensors in girder 1 and the crossings direction 1.

Figure 5. Results of the niil for the bridge BW70. The top two figures show the feature niil for crossings in driving direction 1 and the bottom two figures show the MD to damage scenario 0. The figures on the left show the results for girder 0 and those on the right for girder 1.

over the bridge is first integrated for all available sensors. Then the integrated signals are summarised in a vector and normalised to the Euclidean norm. The feature **niil** thus corresponds to the *R* feature, whereby **niil** is easier to visualise and thus easier to interpret. **niil** is invariant to vehicle geometry, velocity and the considered sampling rate and is robust against measurement noise as well as lane deviation to a certain extend. **niil** was investigated on the bending beam and on a real bridge that was successively damaged. On the real bridge, it can be shown that the new feature leads to a significant increase in the MD from just one cut through the tension cables. The feature **niil** still needs to be investigated with further damage scenarios. In addition, the question arises as to how far the number of sensors can be reduced and whether **niil** is independent of the temperature. The results in section 4.2 indicate that the feature **niil** is well suited for anomaly detection. Furthermore, the damage-sensitive sensor positions in the analytical bending beam can now be used, as it is no longer necessary to divide by zero for the undamaged beam. It still needs to be clarified to what extent the damage-sensitive sensor positions from the bending beam can be transferred to real structures and to what extent they are robust against measurement noise.

ACKNOWLEDGEMENT

Vehicle speed estimation in BWIM systems via convoluted reciprocity

D. Cantero
NTNU Norwegian University of Science and Technology, Trondheim, Norway

C.W. Kim
Kyoto University, Kyoto, Japan

ABSTRACT: The first step in a BWIM system is to obtain the speed of the vehicle to be weighted. There exist several possibilities to estimate the vehicle's velocity, being the most popular the method that calculates the correlation between signals from two separate sensors. In practice, this method is sufficiently accurate for most BWIM installations. However, it does not perform well in certain situations, most notably in the case of an ideal simply supported configuration or for systems with highly asymmetric influence lines. This paper introduces a new theoretically consistent method, termed convoluted reciprocity, that allows for accurate vehicle speed estimates for any structural configuration and shape of influence line. This document presents in detail the theoretical background of the novel approach complemented by numerical simulations. The performance in speed estimation of the new method is compared directly to the estimates obtained via the correlation method. In addition, these methods are compared empirically with the measured responses of a scaled bridge under controlled laboratory conditions. The results show that the convoluted reciprocity idea does provide very accurate results, while it relies on the same sensor configuration of standard BWIM systems.

1 INTRODUCTION

A Bridge Weigh-in-Motion (BWIM) is an installation to estimate the weight of vehicles as they traverse a bridge at regular traffic speeds. This process relies on analysing the structural responses recorded, which are then processed to deduce details such as vehicle speed, axle configuration, individual axle weights, and the overall gross vehicle weight. Typically, BWIM installations utilize strain signals, often detected using transducers or directly through strain gauges affixed to the bridge soffit (Žnidarič et al. 2017). The placement of the weighing sensors is usually at the point of maximum strain response, specifically at the mid-span in the longitudinal direction. In the transverse direction, these sensors are positioned at various points across the section, and their signals are combined for use in the standard BWIM algorithm.

In the early days of BWIM technology, speed and axle detectors were positioned on the pavement near the bridge ends, resulting in traffic disruptions and durability issues. However, this approach was later replaced by alternative solutions that rely solely on sensors installed on the bridge soffit. These alternatives, known as FAD (free of axle detectors) or NOR (nothing on the road) solutions, were introduced by the WAVE project (OBrien and Žnidarič 2001). The supplementary sensors needed for FAD and NOR are typically situated at one-quarter and three-quarters of the span or on secondary elements with relatively shorter influence lines and distinctive sharp peaks (Kalin et al. 2006).

DOI: 10.1201/9781003483755-158

In the BWIM system, determining the speed of a passing vehicle is the initial step before moving on to axle identification and the final weight calculation. Thus, accurate vehicle weighing relies heavily on the precision of speed estimation. However, deducing the vehicle's speed from global strain signals is challenging (Yu et al., 2016) because these measured responses typically lack distinct sharp features. Moreover, structural dynamic components and noise contribute to the complexity. Speed estimation must be accomplished without prior knowledge of the vehicle's properties and axle configuration. Ideally, the signals used for speed estimation should exhibit clear peaks corresponding to each axle. However, achieving this ideal scenario is not always feasible due to the structural configuration of the bridge.

Arguably, the most commonly used approach for speed estimation involves calculating the cross-correlation (or simply, correlation) between signals measured at two different sections in the longitudinal direction (Yu et al., 2016). The speed is estimated by dividing the distance between sensors by the time lag that maximizes the correlation. For optimal performance, both signals should ideally be time-shifted copies. In Bridge Weigh-in-Motion (BWIM) installations, achieving this ideal scenario requires identical influence lines at the two measured locations, a condition rarely met in practice. However, if the influence lines exhibit very sharp peaks, enabling individual axle detection, the correlation-based speed estimation has been found to provide sufficiently accurate results (Hajializadeh et al., 2020). The experimental campaign conducted by Zolghadri et al. in 2016, aimed at estimating speeds for various bridges and vehicle types, concluded that the correlation method is generally effective, reporting average errors of approximately 9%. Consequently, this method is widely implemented for speed estimation, as exemplified by a recent study by MacLeod and Arjomandi in 2022. Nevertheless, when the asymmetry of the influence lines is too pronounced, the correlation method may yield inaccurate speed estimates. This limitation is recognized, and correction strategies have been proposed. Kalin et al. in 2006 introduced a correction based on qualified maxima, reporting satisfactory results even for simply supported bridges.

Nevertheless, there is no universally applicable method for speed estimation in standard BWIM installations. Consequently, the objective is to introduce a generic approach that can be employed across various bridge typologies. This paper puts forth a novel concept termed convoluted reciprocity (CR), aiming to establish a theoretically consistent method for speed determination, which was originally introduced in (Cantero and Kim, 2024). The proposed method is theoretically formulated, numerically examined, and validated through results obtained from laboratory experiments. The study involves a comparative analysis of the performance in speed estimation using the standard correlation approach and the new method based on CR.

2 CONVOLUTED RECIPROCITY

The determination of a bridge's quasi-static response resulting from the passage of a vehicle can be computed by utilizing the influence line. Specifically, the response at position A is obtained through the convolution of the influence line at A with the loading function (Frøseth et al., 2017), as depicted in Equation (1). The loading function, denoted as $P(t)$, is composed of a series of impulse functions with magnitudes P_j, each corresponding to an axle j, and these functions are time-shifted based on the axle distances and the speed of the vehicle, denoted as v, while I_A represents the influence line for the measured load effect at location A on the bridge.

$$S_A(t) = P(t) * I_A(t) \tag{1}$$

The influence line at another location B is I_B. The convolution of Equation (1) by I_B is:

$$S_A(t) * I_B(t) = P(t) * I_A(t) * I_B(t) \tag{2}$$

Taking advantage of the commutative property of the convolution operator, Equation (2) can be rewritten, using the definition in Equation (1), as:

$$S_A(t) * I_B(t) = S_B(t) * I_A(t) \tag{3}$$

The relationship described in Equation (3) is referred to as Convoluted Reciprocity (CR). This expression demonstrates that the convolution of the response at location A by the influence line at location B equals the convolution of the response at B by the influence line at A. This straightforward yet powerful theoretical outcome can be exploited for speed estimation.

Furthermore, the expression in Equation (3) can be generalized to a broader scenario. When multiplied by the loading function $P_C(t)$ for a vehicle of known speed (referred to as the calibration vehicle), it yields Equation (4). This signifies that the convoluted reciprocity relationship also holds between two arbitrary bridge locations, A and B, for responses to two separate vehicle crossing events. Importantly, this relationship remains valid for the responses of any two vehicles, irrespective of their axle configuration.

$$S_A(t) * S_{B,C}(t) = S_B(t) * S_{A,C}(t) \tag{4}$$

2.1 *Speed estimation procedure*

This section illustrates the procedure to estimate speed utilizing the CR relationship. The following explanation explores the case of a simply supported beam traversed by a 2-axle vehicle. At first, only the quasi-static response is simulated numerically using the open-source software VBI-2D (Cantero, 2024).

The procedure requires information from two sensors, say at ¼ and ¾ of bridge span. The influence lines and the responses due to the passing vehicle of unknown speed at these to bridge locations are shown in Figure 1.

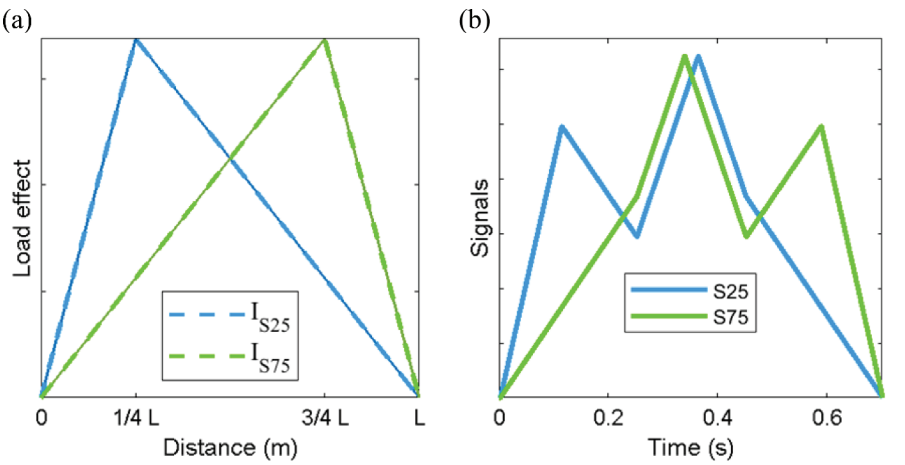

Figure 1. Available information for speed estimation; (a) Influence lines at two locations; (b) Measured signals during vehicle passage.

To estimate the speed the proposed method rescales the influence lines assuming different speeds and evaluates the validity of the convoluted reciprocity equality. While, by definition, an influence line is described in the space domain, the influence lines, $I_A(x)$ and $I_B(x)$, can be transformed into the time domain by knowing (or assuming) the vehicle's traversing speed,

denoted as v. The value of v that satisfies Equation (3) corresponds to the speed of the vehicle. For example, Figure 2 illustrates the outcomes of the left-hand side and right-hand side of Equation (3) for three different assumed speeds. In cases where the assumed speed does not align with the actual speed of the event, both sides of the convoluted reciprocity (CR) relationship (Figure 2(a) and (c)) manifest clear discrepancies. However, when the assumed speed matches the actual speed, then both results match (see Figure 2(b)).

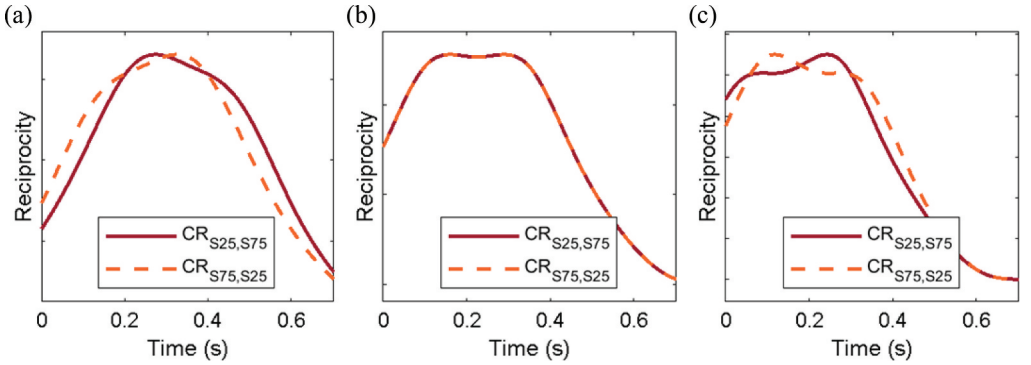

Figure 2. Convoluted reciprocity for a selection of assumed speeds: (a) v = 15 m/s; (b) v = 20 m/s; (c) v = 25 m/s.

For any given speed, the disparity between the right-hand side and the left-hand side of the equation is assessed using the norm of their difference. The value that minimizes this difference serves as the estimated speed of the crossing vehicle. To quantify the dissimilarity between both sides of the equation, this study recommends the use of the 2-norm. Figure 3(a) displays the norms for a range of guessed speeds, with the minimum value distinctly corresponding to the correct speed of the vehicle.

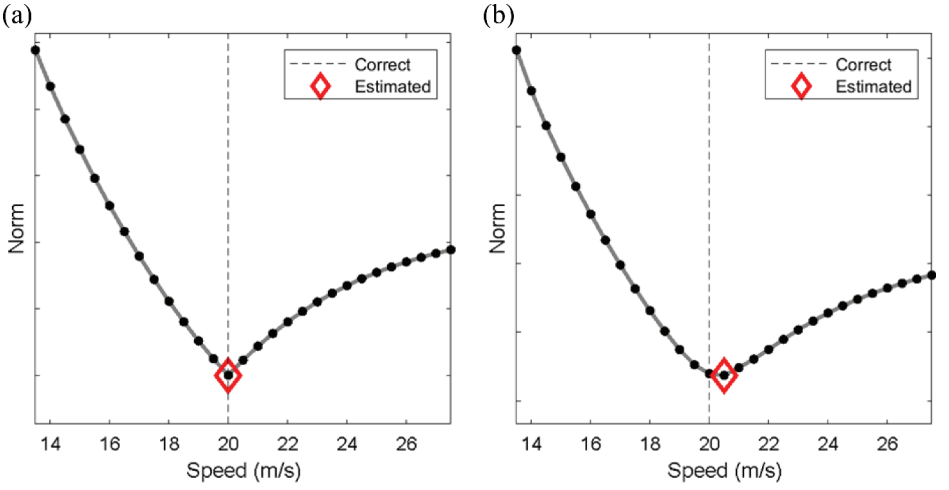

Figure 3. Norm of CR relationship for a range of speed guesses. (a) Ideal quasi-static response; (b) With dynamics.

The example depicted in Figure 3(a) utilized ideal quasi-static bridge responses, leading to a flawless speed estimation (20 m/s). However, when dynamic components of the bridge response are incorporated into the signals, the convoluted reciprocity procedure yields a speed

estimate of 20.41 m/s (2.06% error). For reference, Figure 3(b) displays the norms of the convoluted reciprocity for the range of speeds considered, highlighting the minor discrepancy attributed to the disturbances introduced by the dynamic components in the signals.

Therefore, the convoluted reciprocity (CR) relationship proves effective in deriving speed estimates. This has been demonstrated using the influence lines from each sensor. A comparable procedure can also be developed using the signals from a vehicle of known speed (referred to as the calibration vehicle), relying on the relationship provided in Equation 4. The speed estimation method based on influence lines is denoted as CRI, whereas the method utilizing signals from the calibration vehicle is called CRV.

3 SPEED ESTIMATION METHODS COMPARISON

This section examines the performance of speed estimation methods in the case of a simply supported beam. Initially, a numerical study is conducted, followed by the validation of results through an experimental study. Both CR methods, CRI and CRV, are employed and compared against the outcomes obtained using the standard correlation method.

3.1 *Numerical study*

A Monte Carlo simulation is executed, simulating 20,000 single vehicle events on five bridge spans crossed by 5-axle articulated trucks. The characteristics of the vehicles were randomly sampled, resulting in crossing events with varying geometries, axle loads, mass distributions, and suspension properties. For additional details regarding the adopted properties for the bridge models, vehicle models, and road profile, interested readers are directed to Cantero and Kim (2024). Additionally, the speeds of the vehicles were randomly sampled from a uniform distribution, with values ranging from 50 to 120 km/h (13.89 to 33.33 m/s).

Figure 4 quantifies the error in speed estimation statistically for the three methods under investigation. The findings distinctly reveal that the CR-based methods surpass speed estimation via correlation.

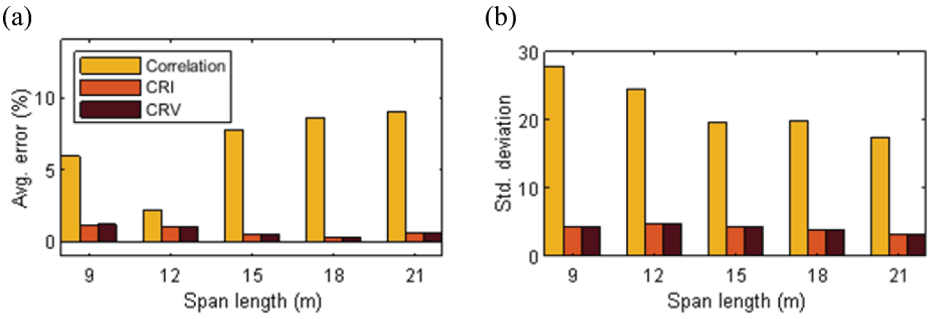

Figure 4. Speed estimation errors of simulated events. (a) Mean error (%); (b) Standard deviation.

3.2 *Experimental study*

A laboratory experiment was conducted to replicate the crossing of a vehicle on a bridge using a scaled setup of a beam traversed by a model vehicle. Figure 5 illustrates the 4-axle model vehicle employed in the experiment, which was moved across the access tracks and beam through a pulley system. The vehicle underwent back-and-forth movement across the beam 12 times, resulting in 24 crossing events. This loading sequence was carried out for two different constant speeds, specifically at V1 = 0.551 m/s and V2 = 1.048 m/s. The 5.6 m long steel beam was configured in a simply supported arrangement spanning 5.4 m. The beam was equipped

with strain gauges positioned at 25% (= ¼ L), 50% (= ½ L), and 75% (= ¾ L) of L, generating signals S_{25}, S_{50}, and S_{75}. The sampling frequency was 2048 Hz using the NI9237 data acquisition system. (For more details, refer to Cantero and Kim (2024)).

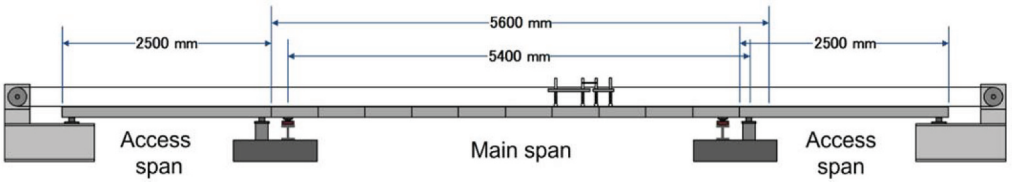

Figure 5. Experimental set-up.

Figure 6(a) presents a sample of the measured strain signals during the passage of a single vehicle traveling at speed V2. These signals underwent processing to eliminate noise using a zero-phase first-order Butterworth lowpass filter with a 1 Hz cut-off frequency. Utilizing known information about the vehicle and its traversing speed, the influence lines at each sensor location were determined through the matrix method (Obrien et al., 2006). The final influence lines considered in this study (depicted in Figure 6(b)) represent the average results extracted from multiple vehicle passages.

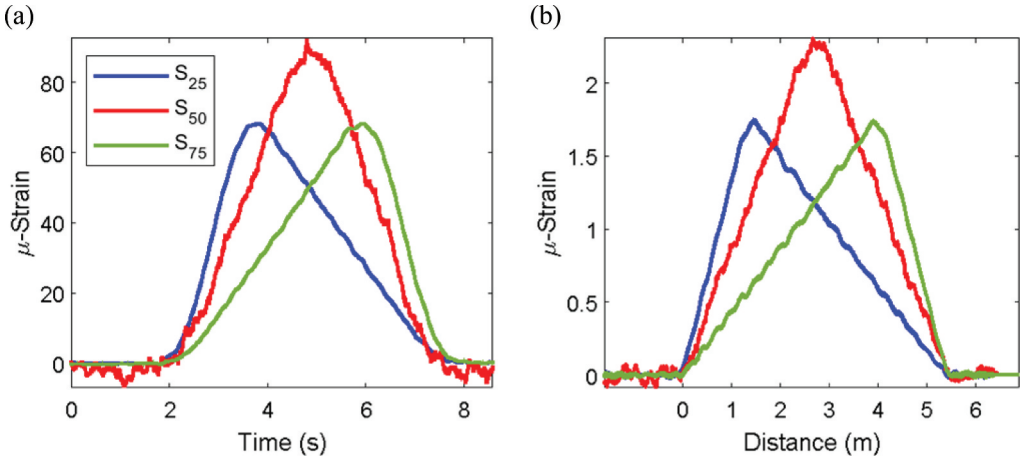

Figure 6. (a) Sample strain responses at 3 sensor locations; (b) Extracted influence lines.

Speed is estimated for all crossing events using the measured signals. The correlation method is computed, considering the correction strategy described by Kalin et al. (2006) based on qualified maxima. Additionally, both potential applications of the convoluted reciprocity approach were independently explored. The CRI method utilized the average influence lines depicted in Figure 6(b), while CRV employed the bridge responses from the initial event at speed V1. Figure 7 illustrates the estimated speeds for each method and event, facilitating a comparison with the actual speed value of the model vehicle. The results clearly demonstrate that for the novel speed estimation methods (CRI and CRV), the errors are significantly smaller than those based on correlation.

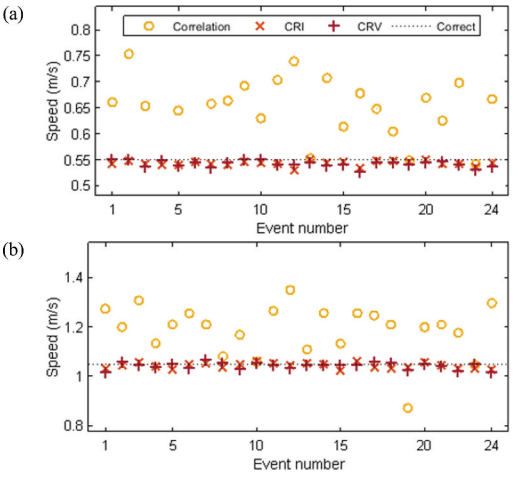

Figure 7. Speed estimation for various methods from experimental data, for speeds: (a) V1= 0.551 m/s; (b) V2 = 1.048 m/s.

4 CONCLUSION

This paper introduced a novel concept, convoluted reciprocity (CR), establishing a relationship between responses recorded at two distinct locations for two independent crossing events. This simple yet powerful idea was employed to propose a theoretically consistent method for determining the speed of passing vehicles. Two variations of the method were presented: CRI based on the sensors' influence lines and CRV based on the bridge response for a calibration vehicle. Their performance was numerically evaluated across a range of vehicle and bridge configurations, demonstrating that the newly proposed methods offer more accurate and robust speed estimates. To validate these findings, laboratory tests were conducted on a scaled bridge traversed by a model vehicle, and the analysis of the empirical data confirmed the results.

Therefore, this document has introduced and validated the concept of convoluted reciprocity. This theoretical discovery offers a novel approach to addressing the speed estimation problem. Its derivation relies solely on the properties of the convolution operation, making the result independent of the properties, configuration, or boundary conditions of the structure. In this regard, the outcome is universal, enabling the method's application with any two sensor locations in the longitudinal direction.

Strain-based FEM-aided bridge health monitoring: A case study

P. Rizzo & A. Enshaeian
Department of Civil and Environmental Engineering, University of Pittsburgh, Pittsburgh, PA

A. Ghahremani
Department of Mechanical Engineering and Materials Science, University of Pittsburgh, Pittsburgh, PA

ABSTRACT: This article presents a physics-based structural health monitoring (SHM) approach applied to a lenticular truss bridge to predict the deformations associated with the presence of transient loads. A detailed finite element model was generated using a commercial software to create an accurate model of the bridge. The presence of concentrated loads on the deck at different locations was simulated, and a static analysis was performed to quantify the deformations induced by the loads. Such deformations were then compared to the strains recorded by an array of wireless strain gages during a controlled truckload test performed by an independent third-party. The test consisted of several low-speed crossings at controlled distances from the bridge parapets using a truck with a certified load. The array was part of a SHM system that consisted of wireless strain gages, displacement sensors, and rotational gages. The results of the comparative analysis show that the proposed physics-based monitoring is capable of identifying sensor-related faults and of determining the load distributions across the bridge. In addition, the data relative to near four-years monitoring are presented and show the reliability of the SHM system as well as the challenges associated with environmental effects on the strain reading.

1 INTRODUCTION

There are over 600,000 highway bridges in the United States (Federal Highway Administration, 2019), each of which is assigned with a single-digit number (0 to 9) to describe the physical condition of its main parts (Pennsylvania Department of Transportation, 2023). If the lowest rating is greater than or equal to 7, the bridge is classified as good; if it is less than or equal to 4, the classification is poor. Bridges rated 5 or 6 are classified as fair (Federal Highway Administration, 2023). Currently, about 7.5% of bridges are labeled in "poor" condition (ASCE, 2021). In the U.S. each bridge must be inspected at least once every two years (U.S. Department of Transportation, 2023). However, periodic inspections may miss the onset of critical issues between two consecutive inspections. This is raising the attention towards cost-effective structural health monitoring (SHM) strategies that evolves the maintenance paradigm from time-based NDE in which a structure is inspected periodically, to permanent-based where sensors monitor 24/7 to flag, locate, and quantify damage as it happens. Strain is the most frequently monitored parameter in bridge health monitoring (Glisic, 2022).

In 2017, the Pennsylvania Department of Transportation (PennDOT) started a pilot bridge instrumentation program. Ten bridges across south and southwest Pennsylvania were instrumented during the period 2017-2019 with an array of commercial wireless sensors able to provide real-time information about static and (for some bridges) dynamic responses. The installations were completed by a company, hereinafter referred to as the Vendor, not

DOI: 10.1201/9781003483755-159

involved in the study presented here. One of the ten bridges is the iconic Smithfield Street Bridge, built nearly 140 years ago in the city of Pittsburgh (Figure 1).

In this paper, we present some results of a holistic study of the bridge. The study combined finite element (FE) modeling with the analysis of strain data. A high-fidelity FE model was developed using the commercial software ANSYS® to prove the reliability of the strain measurements, to determine the required sensitivity to detect subtle changes in the structure, and to simulate a few loading scenarios under pristine and simulated damage conditions. Specifically, the model was used first to predict the static deformation along two control members of the truss caused by the individual crossing of three AASHTO standard trucks. Three data-driven analyses were conducted. In the first analysis, the strains and the temperatures were examined to quantify the static response of the structure to thermal loading. Then, the effect of the temperature on the recorded strains was mitigated using a simple procedure to extract and isolate the effects of live loads, which indicates, in the context of this paper, the traffic load or any transient rapid event, such as impact, occurring on the bridge during normal operation. Finally, the live loads data were coupled to an unsupervised learning class based on outlier analysis (OA) to identify notable transient events. OA was chosen to leverage the experience of one of the authors (Lanza di Scalea, et. al., 2005; Rizzo, et. al., 2007; Bagheri, et. al., 2015; Zheng, et. al., 2020; Ghahremani, et. al., 2022). The study presented in this paper is part of a more comprehensive study that involve the analyses of several other bridges, which have been reported elsewhere (Rizzo and Enshaeian 2021, Ghahremani et al. 2022, Rizzo et al. 2023).

The scientific contribution of this paper lays on the holistic approach taken to monitor an old and iconic bridge. An extensive numerical analysis of the pristine bridge and of the bridge with a few simulated damage scenarios was completed using a high-fidelity model. The model was validated with the experimental measurements taken with an array of wireless sensors during a controlled truckload test. In addition, the measurements relative to three years of monitoring were examined using an ad hoc signal processing to successfully identify non-critical structural anomalies.

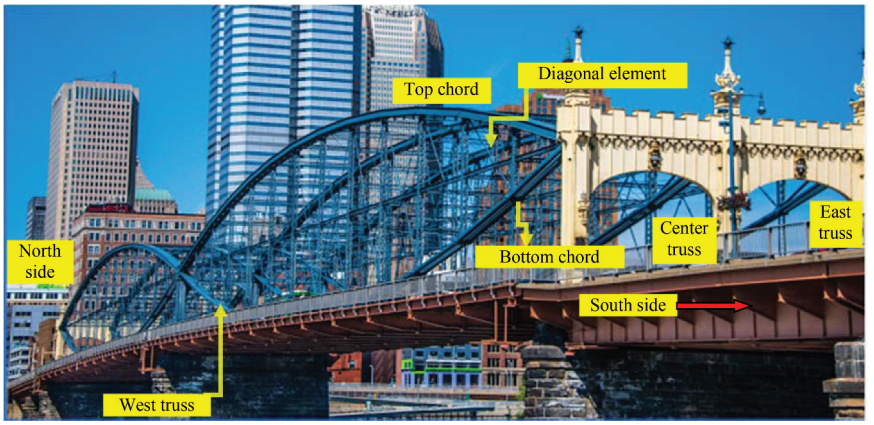

Figure 1. The Smithfield Street Bridge with directions and nomenclature.

2 THE BRIDGE AND THE NUMERICAL SETUP

The Smithfield Street Bridge is 542 m long and consists of seven spans. The iconic parts of the Bridge are Span 3, close to downtown, and Span 4, close to the South Side neighborhood. Span 4 is the subject of this study. The superstructure of spans 3 and 4 are made of riveted built-up lenticular through-trusses. For convenience, each lenticular truss is labeled as the west, center, and east trusses (Figure 1). Each truss is composed by three main parts: the top chord, the bottom chord, and the diagonal element. The top chord is formed by four I-shape

steel members riveted together. The bottom chord is formed by a variable number (six to eight) of bars pinned together. The diagonal element is instead a single bar. Table 1 lists the areas of the cross-section of those elements instrumented with the wireless strain gages.

In July 2019, the Vendor, which was not involved in the study presented here, instrumented the trusses of Span 4 with 18 wireless strain gages. Shortly after installation, a truckload test was performed using a 26,272 kg truck. The steer axle was 7,992 kg and the drive 'tandem' axles were 18,280 kg. First, the truck travelled northbound twice (Tests 1 and 2) crawling at about 8 km/h on the left lane. Then, the truck stopped at both ends of span 4. Tests 1 and 2 were repeated with the truck crawling northbound on the right lane (Tests 3 and 4). After that, the truck was directed southbound, and Tests 1 to 4 were replicated and are labeled as Tests 5 and 6 (right lane) and Tests 7 and 8 (left lane).

The high-fidelity FE model of the superstructure and the deck of Span 4 was created in ANSYS 2020 R2. To make the static analysis computationally manageable, the following simplifications were made: (1) the small longitudinal components found under the deck and the stiffeners of the floorbeams were not modeled; (2) the splice plates and a few other connection members were neglected; (3) the rebar of the concrete deck were replaced by a steel plate under the deck; (4) the portals were approximated; (5) the bottom chord was modeled as a single 203.2 x 254 mm2 (8" × 10") steel bar instead of the actual ten 203.2 x 25.4 mm2 (8"×1") bars; (6) the top chord became a rectangular element with the cross-section area equal to the total cross-sectional area of the true chord. A total of 880 structural components, more than 244,700 finite elements, and over 698,700 nodes constituted the final model. A screenshot of the FE model is shown in Figure 2. The Young modulus of structural steel (200 GPa, 29,000 ksi), and the typical type A concrete (24.1 GPa, 3,500 ksi) were considered.

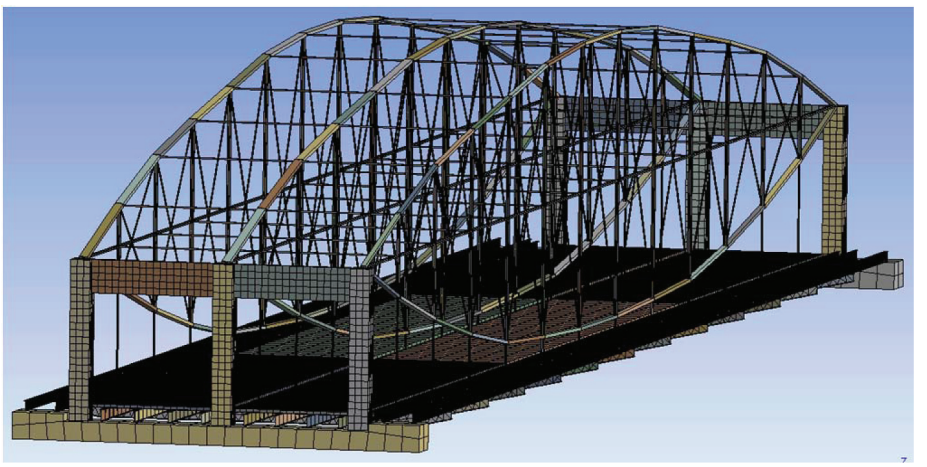

Figure 2. Screenshot of the FEM of the Smithfield Street Bridge.

3 NUMERICAL SIMULATIONS

Three AASHTO (American Association of State Highway and Transportation) trucks, namely the ML-80, the H20, and the HS20 were selected. A fourth truck, identical to the truck used to perform the load test, was considered. The static analyses calculated the deformation generated by each individual truck on the two diagonal members hereinafter labelled as L1U2 (Figure 3) and L1′U2′, monitored with two strain gages. These members are considered control members because they sustain the largest stress among the components being monitored. Each truck was placed on the northbound left lane. A few truck positions were considered to identify the location that maximizes the deformation of control members. Figure 3

provides a close-up view of the setup relative to the AASHTO ML-80 truck, near to member L1U2, i.e., close to the north end of span 4. The distance of the rear wheels from the north portal ranged between 7.620 m to 15.24 m at 1.27 m interval in order to find the largest numerical load and strain.

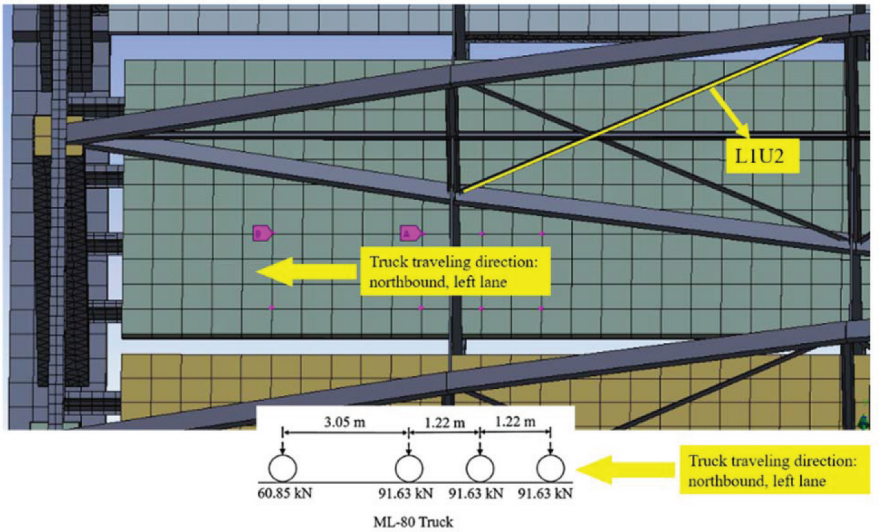

Figure 3. Numerical analysis of the ML-80 truck. The pink dots locate the position of the truck wheels.

The same approach was applied to calculate the largest values on the diagonal member close to the south side of the bridge. The same numerical analysis was applied using the other three trucks. The maximum calculated strains in the two diagonal members of the center truss are presented in Table 1. Owing to the linearity of the model, the numerical deformations are proportional to the weight of the truck. It must be noted though that the points of application of the forces, i.e. the position of the wheels, differ from truck to truck along the longitudinal direction but the distance of the right wheels from the parapet are the same.

Table 1. Numerical maximum strain at the two control diagonal members of the Span 4 center truss as a result of the presence of a single truck. Values expressed in με.

Truss member	Truck Type Company Truck	ML-80	H20	HS20
Member L_1U_2	80.89	114.1	62.28	98.95
Member $L'_1U'_2$	80.92	114.3	62.33	99.05

The FE results relative to the truck used in the field were compared to the experimental results reported by the Vendor. The case of crossing the northbound left lane twice is presented here. The strains measured by sensor S09, bonded to the diagonal member L1U2 (see Figure 3) were equal to 67.0 and 66.9 με. These values are about 17% lower than the calculated numerical deformation of 80.9 με listed in Table 1. The experimental values recorded by the sensor bonded to the diagonal member L'1U'2, were equal to 71.5 and 71.2 με, i.e. only 12.3% lower than the numerical prediction of 80.9 με. The difference between the numerical and the experimental value is likely due to a discrepancy between the numerical and the real (but unknown) lateral distance of the truck from the east parapet. To prove this hypothesis,

we considered the case of the same truck 1.91 m away from the centerline instead of the 0.89 m simulated location. The numerical strain of member L1U2 is now 69.2 με, just 3.3% higher than the experimental values recorded by the sensor. Similarly, when the numerical truck is 1.27 m (50 in.) from the center truss, the calculated strain of member L'1U'2 is equal to 77.09 με, just 7.8% higher than the recorded values from the corresponding sensor. The outcome of this analysis is that a direct comparison between the FE estimation and the experimental measurements suffers from the lack of knowledge about the exact lateral position of the truck. Nonetheless, the agreement between the numerical and the experimental results is quite good and prove the reliability of the model.

4 THE STRUCTURAL HEALTH MONITORING PARADIGM

The data from the 18 strain gages were processed using a general framework designed by the Authors and implemented in MATLAB®. For the sake of space, only a few results can be presented here. To minimize any bias attributable to the temperature, a simple procedure was implemented. The procedure was as follows. First, the raw strain data and the raw temperature data were synchronized by up-sampling and interpolating the temperature data. Then, the 15-minutes moving average for both parameters was calculated and the difference between the raw and the moving averaged strain was calculated to obtain what hereinafter is referred to as the "true strain".

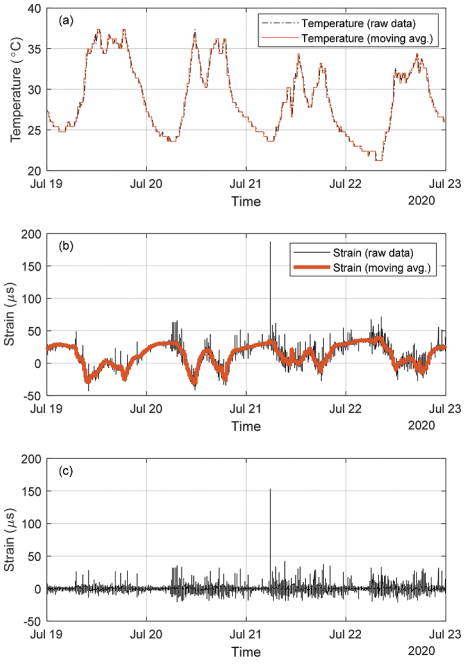

Figure 4. Mitigation strategy to isolate transient events. (a) Top. Raw and 15-minutes moving average of the temperature data. (b) Center. Raw and 15-minutes moving average of the strain data. (c) Bottom. Live load strain.

The effectiveness of the procedure is shown in described above was demonstrated further with Figure 4, which shows the data recorded by one sensor on July 19 – 23 of year 2020. The steel temperature and the corresponding moving average are presented in Figure 4a and they overlap because metal heating or cooling takes longer than 15 minutes. The raw strains and the corresponding moving average are presented instead in Figure 4b. The moving average is

clearly tied to the temperature trend. The decrease of the temperature increases the strain and vice versa. The raw strains are instead a combination of traffic and thermal load. The difference between the two, i.e. the true strain, is presented in Figure 4c. Besides the fact that the absence of traffic is seen in the early hours of each day, Figure 4c shows a peak (152 με) triggered by the crossing of a very heavy truck traveling southbound.

The data analysis was extended to include three years, 01 – August – 2019 to 31 – July – 2022. This included the analysis of the thermal effects. An example of raw strains and the corresponding raw temperatures from one of the 18 sensors is shown in Figure 4. The graph is bound the ±4σ interval and a linear regression whose equation and the corresponding R^2 are displayed.

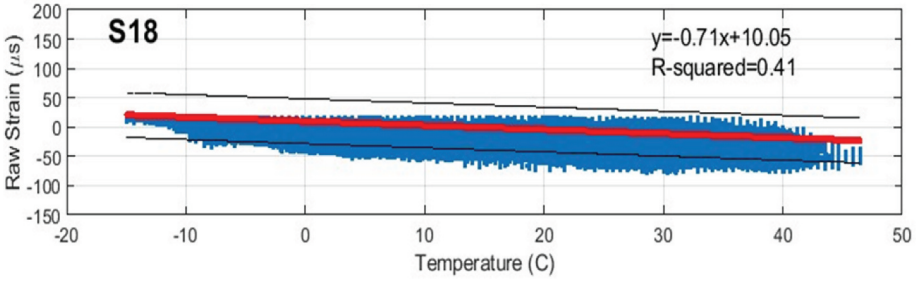

Figure 5. Raw strain vs raw temperature recorded by one of the 18 gages for three years.

The slope for each sensor is visualized on the bridge schematics of Figure 6. Consistent with the presence of an expansion joint at the south end of Span 4, eight of the nine slopes calculated from the sensors bonded on the south end of the bridge are higher than the corresponding slopes from the north end. The only exception is S12, for which the value of -0.34 με/°C is smaller than the slope calculated for gage S07 (-0.53 με/°C). The strain gradients across the nine monitored members located on the north end are nearly the same. The only relevant exception is the diagonal member of the center truss, i.e. gage S09. It is interesting to note that the slope at

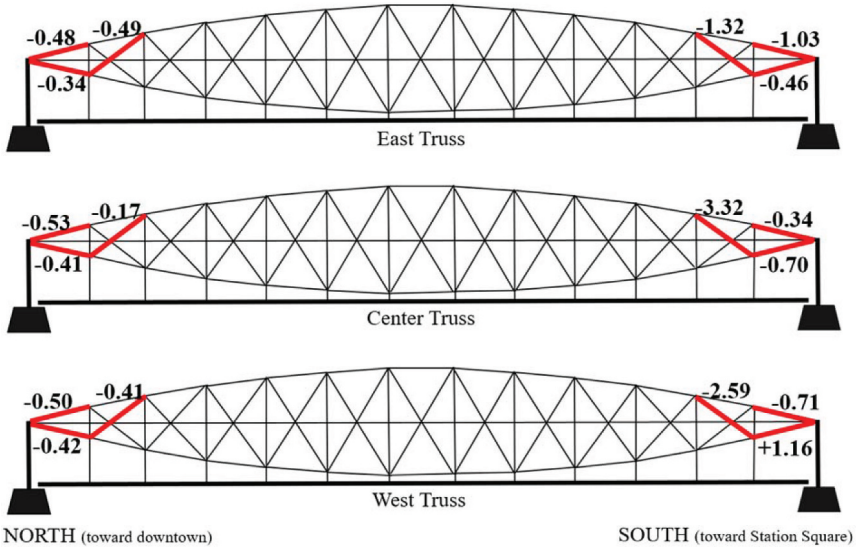

Figure 6. Drawings of the east, center and west truss with the members instrumented and the corrsponding strain rate expressed in με/°C.

S04 is 51% the value of S16 (-1.32 με/°C vs -2.59 με/°C), and 40% the value of S10 (-1.32 με/°C vs -3.32 με/°C). Notably, the slope associated with S10 (-3.32 με/°C) is nearly twenty-fold the value calculated for S09 (-0.17 με/°C). Such difference is not seen in any other pair. Finally, the cross comparison of the bottom south east and west chord suggests that the west chord expands more than its east counterpart, despite the cross-section of the latter is smaller.

Finally, the "true strains", which represent an accurate quantification of the deformation triggered by the live loads, were analyzed. For the sake of space, the results of the outlier analysis OA are presented. OA is a novelty detection method that establishes whether a new configuration of a given system is discordant or inconsistent from the baseline configuration, which consists of an existing set of data (or patterns) that describes the normal operative conditions. In this study multivariate OA was performed by computing the Mahalanobis squared distance (MSD) [Bagheri et al. 2015, Zheng et al. 2020, Rizzo et al. 2007] was used, and each truss was considered individually. As such, the input vector contains the true strains from six sensors. The baseline consisted of all the data collected during the month of August 2019. This relatively short interval was deemed to be representative of the baseline because the OA was applied to the true strains, and the true strains are unbiased by thermal effect. The threshold was instead set as the upper value of 4σ. The results of the OA relative to the west truss are presented in Figure 7. The figure shows the reliability of the analysis at identifying outliers of a certain significance.

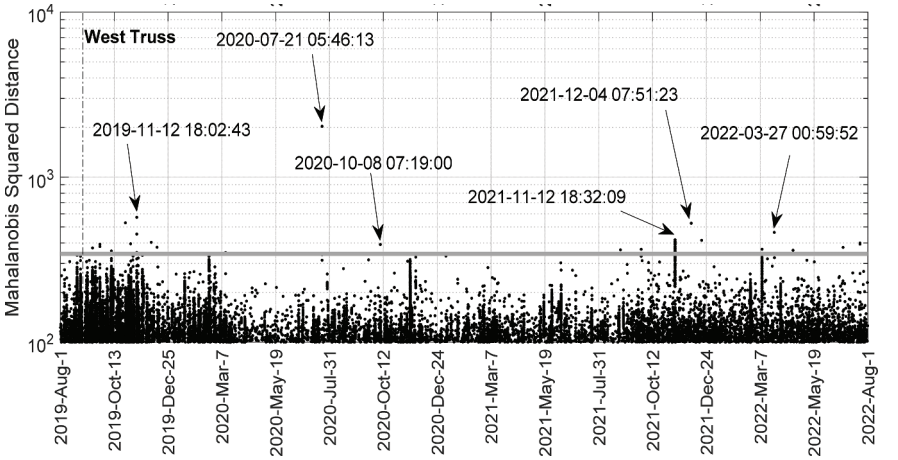

Figure 7. Mahalanobis squared distance applied to the strain gage data on the individual trusses. From top to botto, east, center, and west truss.

5 CONCLUSIONS

This paper presented some results of a fully comprehensive study about the Smithfield Street Bridge one of the oldest and most iconic bridge in the city of Pittsburgh. The study consisted of modeling the bridge with a commercial finite element software to predict the deformation of those members that are currently monitored with wireless strain sensors bonded to some of the members of the three lenticular trusses that represent the superstructure of Span 4. The deformation calculated from the numerical model were calculated under the assumption that the bridge is subjected to the load of a truck of with well-defined geometry and weight. One of these trucks was identical to the vehicle used by the private company to perform a truck load test. The results from this truck test were compared with the numerical results predicted with the FE model and they show very good agreement, despite uncertainties about the lateral distance of the truck from the centerline of the bridge. Then, the paper presents the experimental analyses of the strain data that were conducted to evaluate the effects of the temperature to identify any anomalous behavior of the

members being monitored, and to identify structural anomalies using a multivariate statistic based on outlier analysis. Overall, it was observed that the south side of the west truss exhibits slightly larger thermal deformations than its east counterpart. The outlier analysis revealed some isolated peaks that can be attributed to heavy traffic or a sudden transient event of different kind.

Actual bridge verification of monitoring technique using optical fiber sensors

S. Aoki
Shutoko Technology Center, Structural Technology Research Laboratory

T. Maeshima & I. Iwaki
Nihon University, College of Engineering

ABSTRACT: Japan's Metropolitan Expressway is an expressway network linking major cities around the capital, Tokyo. In legally-mandated inspections once each 5 years, the need to construct scaffolds and individual differences between inspectors were issues in close visual inspections of RC decks. The authors investigated a method for evaluating the deterioration of deck slabs by monitoring with optical fiber sensors (length: 1000 mm). To understand the relationship between actions and responses, the strain in RC deck slabs was monitored using 245 kN and 118 kN constant load vehicles. The strain on the underside of RC deck slabs with a crack density of 9.8 m/m^2 was 37 μ under the action of 245 kN and 19 μ under 118 kN. In a laboratory test under live loads similar to those in actual bridges, the strain immediately before punching shear failure was 500 μ or more, indicating that failure is not urgent at present.

1 INTRODUCTION

Japan's Metropolitan Expressway (Shuto-kosoku-doro) is a network of automotive expressways linking Yokohama, Saitama and other major cities in the Tokyo Metropolitan area, centering on the nation's capital, Tokyo. Although the Metropolitan Expressway was originally constructed in preparation for the opening of the 1964 Tokyo Olympics, fast-paced road construction was necessary at the time, and for this reason, much of the system was constructed above rivers and general roads, where land for construction could be secured easily. About 75 % (approximately 240 km) of the total service length of 330 km consists of elevated structures. Of the total length, about 40 % (approx. 145 km) of all routes have been in service for 40 years or longer, and deterioration with age has become a problem (Figure 1). The conditions of use have now become severe, as the average daily traffic volume of the entire Metropolitan Expressway system is 1 million vehicles/day, and in particular, the volume of large vehicles is about 5 times greater than on general roads.

The Route No. 3 Shibuya Line of the Metropolitan Expressway is an automotive expressway with a total length of 13.5 km, which is connected to a national expressway with a distance of approximately 350 km between the capital, Tokyo, with Nagoya, the largest city in the Chubu region. This route was opened to service in 1971 and has now been in use for 52 years, and the current daily spot traffic volume exceeds 130,000 vehicles.

As a monitoring method which makes it possible to grasp the overall state of a bridge, "Bridge-Weight-In-Motion (BWIM)" was proposed in a previous study [1], [2]. This method is used as a system for specifying vehicles and evaluating the soundness of the target bridge as a whole based on deflection (strain) measurements. However, because it is necessary to measure the weight of vehicles accurately, and it is essential to accurately acquire data on vehicle

DOI: 10.1201/9781003483755-160

traffic characteristics such as speed, course, wheel position, etc., and use multiple vehicle detection sensors, the challenges accompanying the enormous volume of data acquisition and data analysis have been mentioned. Moreover, the high cost of the various types of sensors and the time required in sensor installation are also issues.

In addition, the general method for quantitative evaluation of the condition of RC deck slabs is judgment based on the deflection or crack density of the bottom surface of the deck slab. However, the need to construct scaffolds for close work and variations in judgments of hammering tests and recording of the crack length by individual inspectors were issues.

Therefore, in this research, the authors investigated a monitoring technique for RC deck slabs utilizing optical fiber sensor (hereinafter, OFS) [3], [4], [5], which are used in long-term monitoring of social infrastructure, and studied an evaluation method that is different from the conventional techniques based on deflection and crack density.

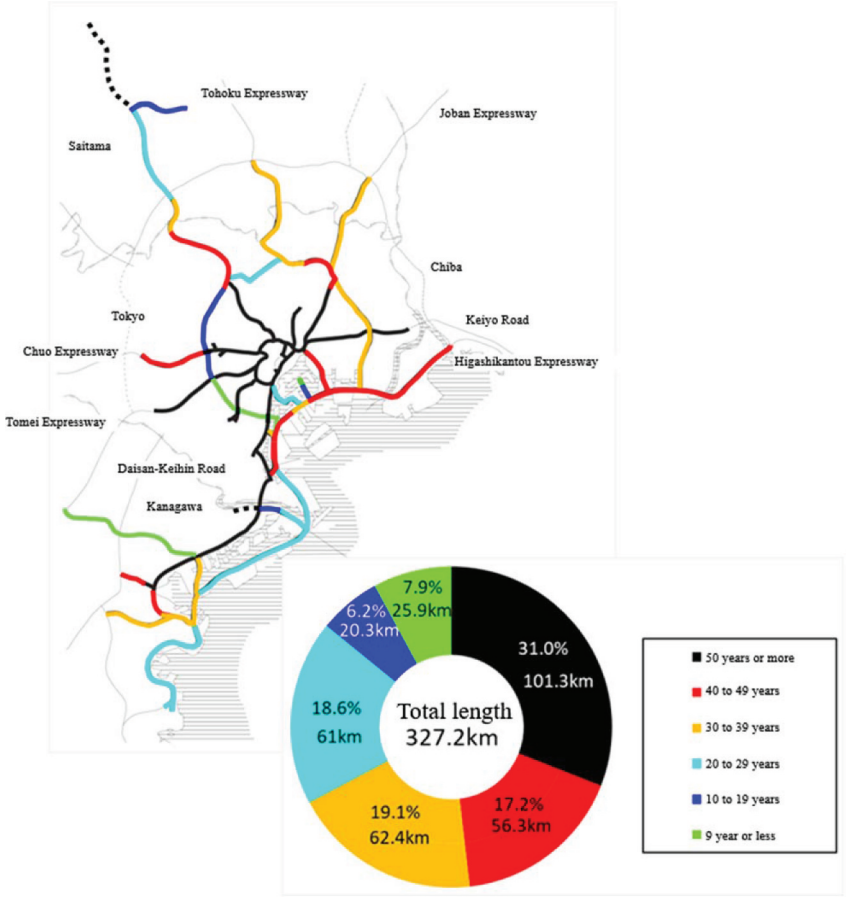

Figure 1. Routes of the Metropolitan Expressway by years in service and service length.

2 STRUCTURAL SPECIFICATIONS AND INSPECTION HISTORY OF RC DECK SLAB

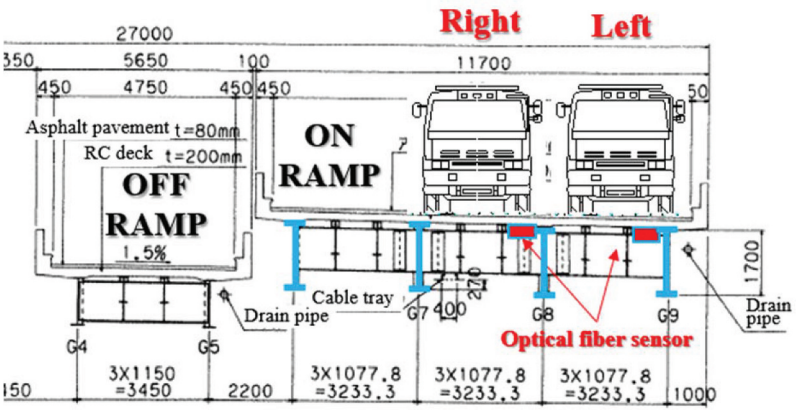
2.1 *Structural specifications*

The RC deck slab used as the target of monitoring in this research is a steel I-girder bridge that was completed in 1971 and is a 4-girder structure with a span length of 30 m, deck slab span length of 3.2 m, and a deck slab thickness of 200 mm (Figure 2).

Because the deck slab was designed prior to 1972, decreased durability due the smaller number of reinforcing bars required at the time was a concern. Therefore, two stringers (longitudinal reinforcing members) were added between each pair of main girders in 1999. In addition, as an environmental measure for areas alongside the expressway, sound-absorbing panels were installed under the deck slab in 2000 to reduce the reverberation on general roads. These sound-absorbing panels are also used as scaffolding during close visual inspections.

2.2 *Inspection history*

The oldest inspection history of this section is a photographic record of the deck slab taken in 1990 (Figure 3a). In the inspection method used at that time, the condition of the underside of the deck slab was photographed in each trave (deck slab section enclosed between girders and cross beams), and the progress of deterioration was judged by comparing these photographs and the condition of the next time the bridge was photographed. However, because installation of the sound-absorbing panels made it impossible to photograph the underside of the deck slab, close visual inspection was adopted. After the sound-absorbing panels were installed, close visual inspections were conducted in 2008 and 2014, but in 2017, deterioration in the form of tortoise shell-like cracking, spalling of the cover concrete over the reinforcing bars, and an abnormal hollow sound in hammering tests were reported (Figure 3b).



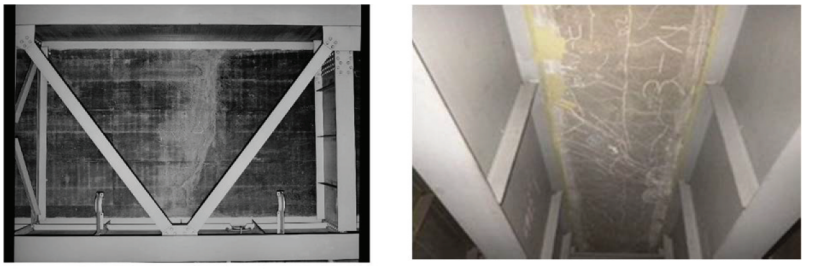


Figure 2. Sectional view showing monitoring positions.

(a) (b)

Figure 3. Photographic record of underside of RC deck slab.

3 CLOSE VISUAL INSPECTION OF RC DECK SLAB

3.1 *Inspection method*

To understand the current condition of the RC deck slab, a new visual inspection in close proximity to the underside of the deck slab was conducted, cracks that could be observed visually were traced with chalk, and a crack diagram was prepared. The total length of the cracks was calculated from this crack diagram, and the crack density[6], expressed as length per unit area (m/m^2), was arranged. Figure 4 shows the crack diagram and crack density.

3.2 *Inspection method*

As a result of the visual inspection, the crack density in the trave with the largest value was 9.8 m/m^2. Since the pavement had been replaced, and waterproofing work was also performed on upper side of the deck slab in November 2007, water leakage was not observed from the bottom surface. Significant deterioration was apparent in four traves, as shown in Figure 4. While cracks could also be seen in other traves, the progress of cracking was slight and the crack density was limited to about 3 m/m^2. No progress of the crack density was observed in close visual inspections carried out in the winter (February 2023) and summer (August 2023).

4 STRAIN MONITORING OF BOTTOM SIDE OF RC DECK SLAB

4.1 *Outline of OFS*

To evaluate the degree of deterioration of the RC deck slabs in which cracks had occurred, the strain under the action of live loading was monitored. As the sensors to be used in monitoring, OFS capable of measuring cracked concrete surfaces were selected. Conventionally, 60 mm foil-type gauges are used when measuring the strain of concrete structures, but because these gauges only measure a local range, it is not possible to measure the maximum strain due to opening/closing of cracks. However, OFS make it possible to monitor strain as the average strain including cracks in the optical fiber sensor by fixing the string-shaped sensor, with a length of 1 meter, to the bottom surface of the RC deck slab with screws. The sampling period was set at 100 Hz.

4.2 *Installation positions of OFS*

The installation positions of the OFS are shown in Figure 5. Two RC deck slabs with conspicuous cracking ("cracked RC decks") were selected and installed in the bridge axial direction, and adjacent deck slabs with only slight cracking ("sound RC decks") were also installed.

4.3 *Outline of load vehicle measurements*

In the actual bridge measurements, strain under the action of load vehicles was measured by driving the load vehicles on the left and right lanes, respectively. The gross weights of the load vehicles used here were 239 kN and 114 kN. The dynamic measurements were conducted at night-time, when the traffic volume was comparatively slight. The vehicle speed was 60 kph. The travel cases are shown in Figure 6.

4.4 *Monitoring results*

In the results of monitoring of the actual bridge (Figure 7) in Case 1, the strain on the left lane deck (load: 239 kN) was 37 μ, while that on the right lane deck (114 kN) was 24 μ. In Case 2, the strain on the right lane deck (239 kN) was 26 μ and that on the left lane deck (114 kN) was 19 μ. In all cases, the strain was small.

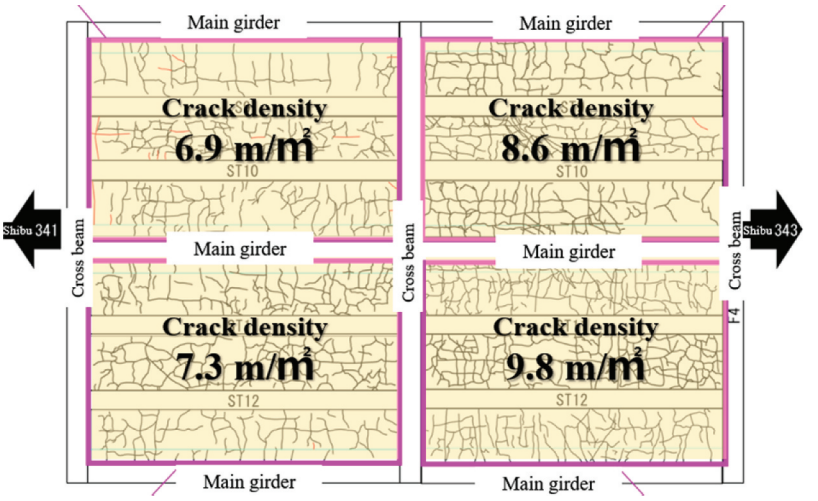

Figure 4. Result of close visual inspection (crack density).

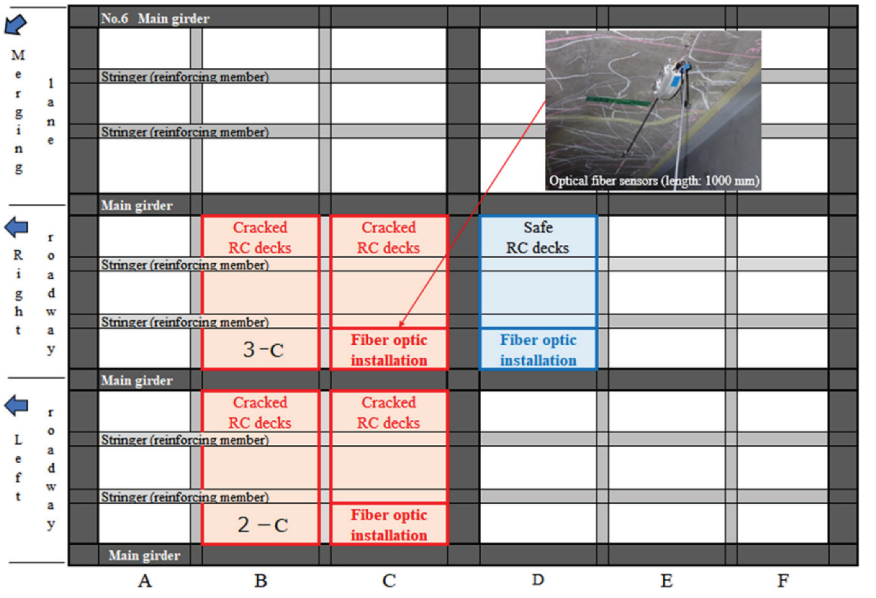

Figure 5. Installation positions of OFS installed on underside of RC deck slab.

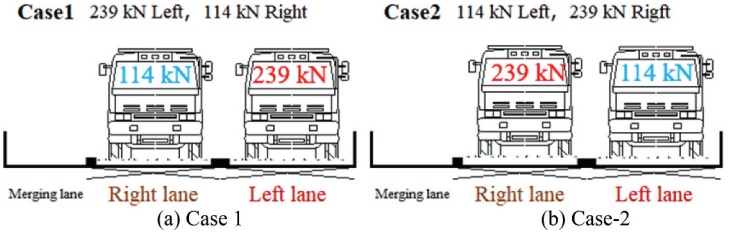

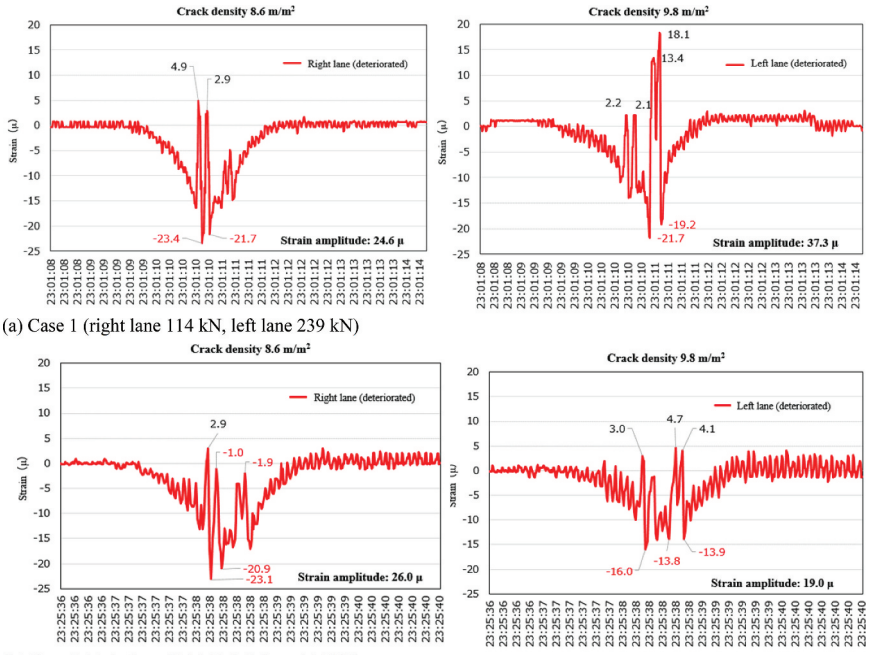

Figure 6. Travel cases in load vehicle measurements.

5 LABORATORY TEST

5.1 *Outline of laboratory test*

In addition to monitoring the RC deck slabs at the actual bridge, a laboratory test was conducted by preparing sample RC deck slabs and applying wheel loads similar to those that act on actual bridges by using a wheel load running test device[7], [8], which is used to evaluate the durability of RC deck slabs. This device cyclically loads a steel wheel set to the wheel load as the force of a hydraulic rotating crank, and can evaluate fatigue durability up to shear failure.

The loads applied in this test were increased in increments of 10 kN by running the load wheel 100 times at each 10 kN increment, assuming the wheel loads that act on actual bridges. Loading was carried out at 5 levels up to a maximum load of 98 kN, as shown in Figure 9. After reaching the maximum load of 98 kN, the maximum load was increased further, and the test was continued until shear failure occurred, assuming a targeted crack density of 10 m/m^2.

(a) Case 1 (right lane 114 kN, left lane 239 kN)

(b) Case 2 (right lane 239 kN, left lane 114 kN)

Figure 7. Strain during load vehicle travel; (top) (a) Case 1, bottom (b) Case 2).

5.2 *Test results*

Figure 10 shows the relationship between the crack density and the strain amplitude until punching shear failure occurs, which was obtained as a result of the wheel load running test. Strain of approximately 200 μ was generated at the crack density of 10 m/m^2, and the strain amplitude immediately before ultimate shear failure was approximately 500 μ (crack density: approx. 16 m/m^2). When these results were compared with the results of monitoring at the actual bridge, the strain of the actual bridge was 37 μ under loading of approximately 75 kN (= 149 kN/2 axles) and the crack density of 9.8 m/m^2. Because this is about 1/10 of the strain in the laboratory test, the current condition of the bridge was not urgent, and follow-up observation was considered to be an appropriate response.

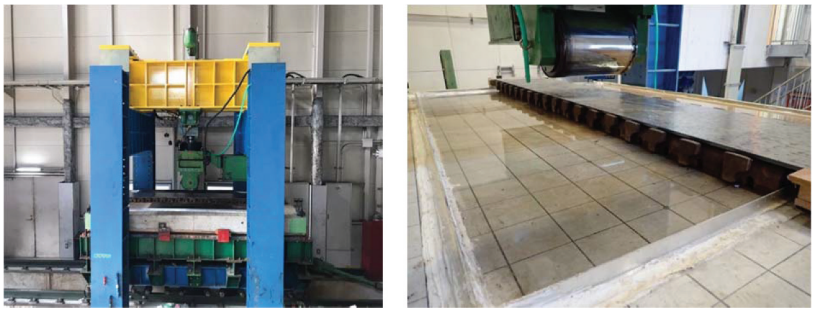

Figure 8. Wheel load running test device.

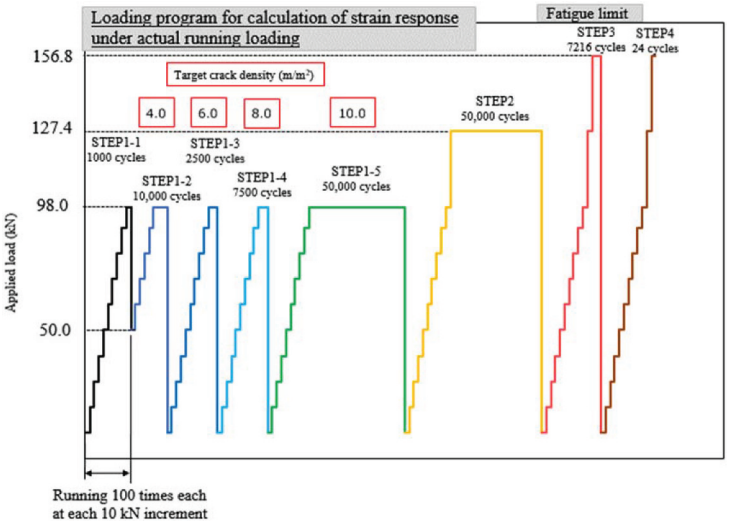

Figure 9. Loading steps in wheel load running test.

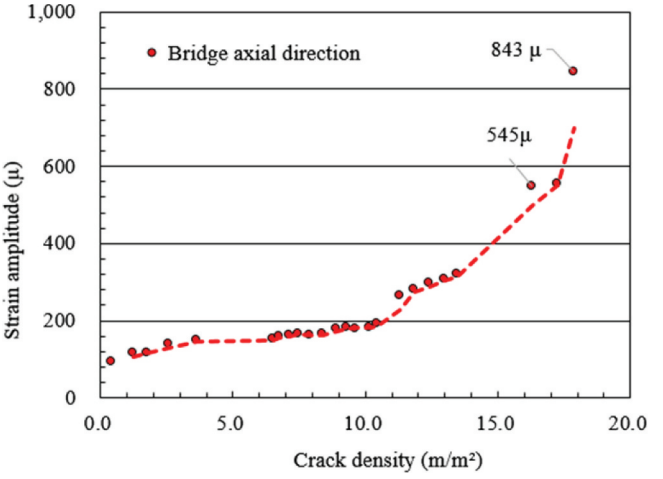

Figure 10. Relationship of strain amplitude and crack density.

6 CONCLUSIONS

Unlike the conventional method for evaluation of the degree of deterioration of RC deck slabs, in this study, the strain at the bottom side of the deck slab was measured using OFS, and the current state of the deck slab was evaluated from the relationship between the strain measured at the actual bridge and the strain obtained in a laboratory test. Because the changes in strain could be measured until ultimate shear failure occurred in the laboratory test, it is now considered possible to propose the timing of repairs of the RC deck slabs of actual bridges in a deteriorated condition based only on the strain obtained by monitoring.

However, because cracks progress rapidly if water penetrates from the pavement into the interior of an RC deck slab, the authors wish to conduct future research to clarify the conditions of the use for the proposed technique, including the timing of the start of monitoring, and the selection and assignment of the priority order of deck slabs that require monitoring.

ACKNOWLEDGMENTS

This research was conducted in collaboration with the Nihon University College of Engineering. We would like to thank the staff and students of the institutions to which the authors belong for their generous cooperation in investigating the health of RC deck slabs. We would like to take this opportunity to express our gratitude to all concerned for their invaluable assistance.

Bridge Weigh-in-Motion applied to heritage iron truss bridges in France

F.-B. Cartiaux, V. Le Corvec & J. Semiao
OSMOS Group, Paris, France

B. Jacob
Université Gustave Eiffel, Champs-sur-Marne, France

ABSTRACT: Bridge Weigh-in-Motion (B-WIM) systems use the deck of a bridge as a scale for the estimation of the gross vehicle weight (GVW) and axle loads. Thus, the bridge design has a strong incidence on the performance, and even on the applicability of B-WIM. Usual bridge types for B-WIM are common beam girder concrete or composite bridges or concrete slabs, for which numerous application cases are described in the literature. In the frame of the "Ponts Connectés" (smart bridges) research program funded by the French government, two heritage iron truss bridges have been instrumented with sensors to monitor structural health issues, including B-WIM sensors. Both bridges are long continuous iron truss boxes spanning the Loire River, with respectively five and eleven 45-meter-long spans. This configuration, and the historical background of these nineteenth century assets initially designed for light local traffic, makes them a challenging case study for B-WIM application. The B-WIM system implemented is the WIM+D solution by OSMOS. Load tests on the bridges were carried out in April 2022, to adjust the B-WIM system and to assess its performance according to COST 323. One system was accepted in class C(15) and the second one in class B(10), which are very fair results for such B-WIM applications. This paper describes in detail the B-WIM system implemented, its adaptation to this particular type of bridges, and the results of the load test. Technical considerations to explain the different performance on the two bridges despite of their similarity are also discussed.

1 INTRODUCTION

Road infrastructure owners and managers can get significant benefit from an accurate knowledge of the real traffic level, in terms of asset management (Dolcemascolo et al., 2015), road and truck safety including overweight detection (Jacob et al., 2010), and assessment of the impact of the traffic in terms of damages to optimize the maintenance operations (Schmidt et al., 2013). To get this knowledge, Weigh-in-Motion (WIM) solutions allow estimating the gross vehicle weight (GVW) of each individual vehicle, sometimes along with its silhouette and load by axle, without interrupting the traffic flow.

Usual WIM systems use road sensors installed inside the pavement, which implies works with road closures, sensitivity to the pavement conditions, and inconvenience when the road must undergo pavement maintenance works. Bridge-WIM (B-WIM) solutions avoid these issues, by using a bridge located anywhere along the road as a scale. Sensors are installed on the bridge, either on a bottom flange of main girders, or under the deck, avoiding works on the road itself and allowing a high robustness of the WIM system, insensitive to pavement conditions.

DOI: 10.1201/9781003483755-161

As a counterpart, the accuracy of a B-WIM system for GVW and axle load strongly depends on the bridge design and may highly vary from one bridge to another. Classical applications of B-WIM use common reinforced or prestressed concrete bridges and are well documented (Cartiaux et al., 2021, 2023a). This contribution paper reports a particular case study on two historical iron-truss bridges, initially designed for light local traffic in the nineteenth century, over the Loire River in France.

This study takes place in the frame of the "GeRICO" research project, supported by the French government and steered by the Cerema as part of the "Programme National Ponts". The project lasted over two years from 2021 to 2023, including the continuous monitoring of the two bridges over 18 months, and a load test performed in April 2022. The accuracy test results of the B-WIM system are discussed in this paper.

2 BRIDGE-WIM SOLUTION

2.1 *The WIM+D solution*

The B-WIM solution called "WIM+D" was first released by OSMOS in 2018 (Cartiaux et al., 2019) and has been operational on at least 15 bridges as of 2022 (Cartiaux et al., 2023b). It relies on strain measurements on main girders and slabs by optical strands. Compared to previous B-WIM techniques, the novelty of the OSMOS WIM+D solution is to separate the estimation of GVW and axle loads.

GVW is obtained from sensors measuring global effects on main girders, where vibration effects are smooth and influence lines are accurate. Meanwhile, only one sensor per main girder is required, usually not more than two or four, to obtain an accurate GVW estimation whatever the transverse location of the vehicle.

The vehicle speed is derived from the time gap between peak measurements from the sensors dedicated to the GVW estimation and additional sensors located on a next span.

The axle load is obtained from additional sensors measuring local strain, like the bending of a short-span element (concrete slab or longitudinal stiffener on an orthotropic deck) under wheel loads. Only one axle load sensor is required for each traffic lane over the bridge, i.e., two sensors on common road bridges. The axle load is computed by distributing the previously estimated GVW on the several axles identified by the axle load sensors, with ratios deduced from the relative amplitude of the local effect for each axle.

2.2 *COST 323 methodology for the performance assessment*

Assessing the accuracy of an on-site WIM system requires a dedicated verification procedure, which implies to use a sample of vehicles as reference loads and let them drive on the bridge at various speeds, in all available traffic lanes (and even out of lane). The GVW of each test vehicle is measured on a certified weighbridge, before and after each test period. If needed, axle spacing and loads are measured at the same occasion to get their reference values.

The accuracy assessment is carried out by comparing the results given by the B-WIM as the vehicles are driven on the bridge to these reference values. A statistical analysis of the relative errors of GVW or axle load is carried out. Thus, a significant number of test vehicle passages is required. A usual accuracy assessment of the WIM+D system implies two or three different vehicles, each one of them running at least 10 to 20 times back-and-forward on the bridge. As a result of this statistical analysis, the system is eventually accepted into an accuracy class.

Such accuracy classes are defined according to the COST 323 methodology, taking into account the statistical uncertainty related to the number of measures, the environmental test conditions and the reproducibility or repeatability (Jacob et al., 2002, Brouste, 2021). The COST 323 defines accuracy classes ranking from A(5) to E(30): The best class A(5) means that a given proportion of the relative errors (depending on the test conditions, typically 95%) is less than 5% for GVW, while the worst class E(30) requires the same proportion of relative errors below 30%.

On an isostatic prestressed concrete deck in good conditions, with four main beam girders and 32 m long spans, the WIM+D system was accepted class A(5) (Cartiaux et al., 2023a).

3 IMPLEMENTATION ON IRON TRUSS BRIDGES

3.1 *Description of the bridges*

The Haut-Village and the Mauves bridges are two historical iron truss bridges spanning the Loire River upstream the city of Nantes, in western France (Figure 1). Both were built in 1882 for light local traffic of horse-drawn carts, and now supporting modern road traffic. They have a very similar design: a single box girder made of iron truss, with main spans of 45 m in length. The piers are made of masonry founded on timber piles in the riverbed. The Haut-Village bridge is 225 m long with five spans, and the Mauves bridge is 482 m long with eleven spans.

One main difference shall be noticed between the two bridges: the Mauves bridge underwent a refurbishment of the road slab and transverse beams in 2020, when the historical brick arches were replaced by a thin slab made of ultra-high performance fiber reinforced concrete (UHPFRC). The Haut-Village bridge keeps its historical brick arches on one span, while they were replaced by a reinforced concrete slab on the four other ones, which were rebuilt after World War II.

Figure 1. Haut-Village Bridge (left) and Mauves Bridge (right).

3.2 *Sensor installation*

Numerous sensors have been installed on both bridges in the frame of the GeRICO project, for different purposes beyond WIM, like operational modal analysis and model updating (Cartiaux et al., 2023c). They include many optical strands for strain measurement, accelerometers for vibration assessment and some extensometers. We only focus here on the few optical strands used for WIM: six of them for each bridge, among 26 in total on the Haut-Village bridge and 18 on the Mauves bridge.

The set of WIM-dedicated optical strand strain sensors is divided into three categories, according to the purpose of each measurement:

- Two "Gross Weight Sensors" are set on the lower flange of the main lateral truss beams at mid-span, to record strain due to the main bending of the deck structure,
- Two "Speed Sensors" are similarly set on the next span. The speed of the vehicle is estimated and then used to compute the GVW.
- Two "Axle Load Sensors" are measuring local strain while axles are crossing the bridge. On the Haut-Village bridge, they are set under the concrete slab, but unfortunately it appeared that the local bending was not significant enough in this case to give an acceptable result for the axle loads. Whereas, on the Mauves bridge, these sensors are set longitudinally under the UHPFRC slab and give very good results.

Figure 2 displays the sensor setup for the example of the Mauves bridge, on two consecutive spans ("T6" and "T7"). The setup for the Haut-Village bridge is similar.

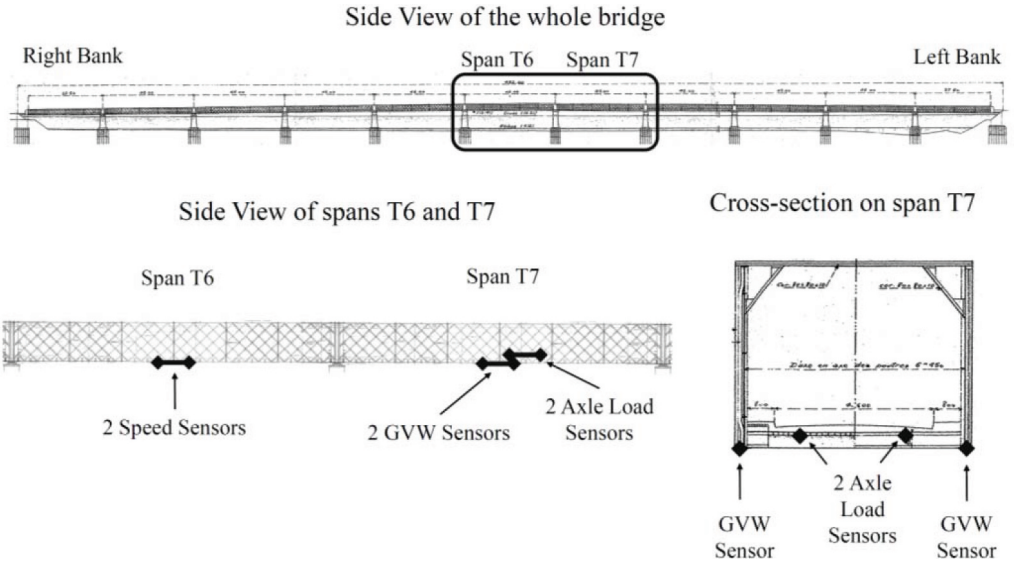

Figure 2. Sensor setup on the Mauves Bridge: only sensors used for the WIM.

3.3 *Load test for the adjustment and performance assessment*

In a B-WIM system, the bridge deck itself is a part of the measurement device. Its mechanical response to the traffic loads is used to deduce the GVW and axle loads. Thus, this response is learned by performing a load test for the adjustment of the B-WIM.

This load test consists in several passages of different vehicles at various speeds on the bridge. It can also be used to assess the performance of the system, provided that the passages used for the adjustment are separated from the ones used for this assessment. It is recommended to perform one test for the adjustment and a second test for the assessment (Cartiaux et al., 2023a). However, in the case of the two iron-truss bridges, the load tests took place on one single day for each bridge: April 20, 2022, for the Haut-Village and April 21, 2022, for Mauves. So, the same test was used for both adjustment and assessment, with two separated sets of passages in each test.

Table 1 reports the test conditions for adjustment and assessment of the WIM+D performance on both bridges.

Table 1. Summary of the load tests.

Bridge and vehicles	GVW (tons)	Passages (tons)	Passages for adjustment	Passages for adjustment
Haut-Village				
2-Axles lorry	9.3	24	4	19
Tractor	3.4	24	Not used: for information only (light weight)	
Mauves				
Heavy 2-Axles lorry	12.1	20	2	7
Light 2-Axles lorry	9.2	22	4	18
Tractor	6.9	9	Not used: for information only (light weight)	

Due to load limitations on the bridges, only vehicles up to 12 tons were used for the load test. However, the B-WIM relies on the flexibility of the bridge deck, thus it needs some

significant strain under the effect of the traffic. This is not the case with light vehicles. Indeed, the 2-axles lorries used for the load test induce strain levels with an order of magnitude of 0.015‰ in the iron truss elements, which is very low, but sufficient for being used as input data for the B-WIM. The tractor with a GVW less than 7 tons did not induce sufficient strain on the monitored elements to give a satisfactory performance. Thus, it was decided to assess the performance for vehicles over 9 tons only and to set this value as the lower limit of operation of the B-WIM for the case of these bridges.

Figure 3 displays the raw strain measurements obtained on the six sensors of the Mauves bridge for one passage of the 12-tons lorry: This strain is due to the bending of the two spans, one after the other, along with a light hyperstatic effect due to the continuity of the bridge deck (negative strain on span T6 when the vehicle is driven on span T7). Also, the strain measured by the axle load sensors (in blue) under the UHPFRC slab show very clear peaks which are correlated to the axle loads.

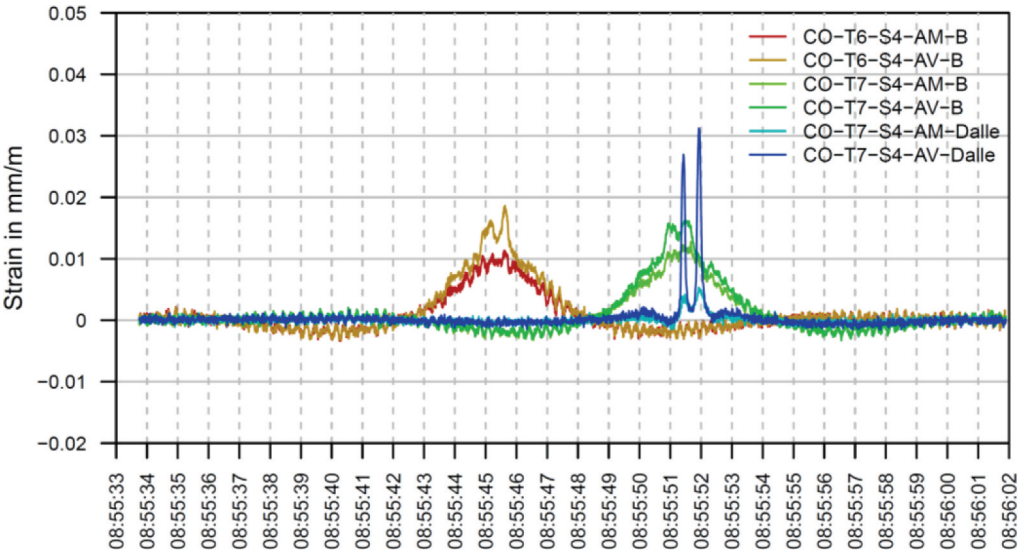

Figure 3. Strain data measured by the six sensors of the Mauves bridge under the 12-tons lorry.

4 PERFORMANCE ASSESSMENT

4.1 *Accuracy for the gross vehicle weight*

The Haut-Village and Mauves bridges are challenging for the application of B-WIM, compared to usual cases with shorter, less numerous, or even isostatic spans. Indeed, the B-WIM methodology relies on the strain of the bridge deck, which means that the whole influence line of the measured strain should theoretically be considered. In the case of such long continuous decks, highly hyperstatic, the length of this influence line is virtually of a few hundreds of meters, which induces issues for the distinction of consecutive vehicles. Moreover, the iron truss structure, aged of more than 140 years, increases uncertainties compared to more classical deck designs.

The issue of hyperstaticity is addressed by selecting a truncated part of the signal: only the short period when the vehicle is driven on the span where each sensor is set is used for the B-WIM, while hyperstatic effects measured before and after are neglected. This choice induces some risk for the accuracy of the GVW estimation, however, it has the advantages of a light pre-processing of the data and a good efficiency for the distinction of consecutive vehicles.

The accuracy of the B-WIM system is assessed according to the COST 323 action. Depending on the test conditions, i.e., reproducibility and repeatability, and of the sample sizes,

a minimum level of confidence π_0 is required to meet an accuracy class defined by a tolerance δ (in %). The probability (or frequency) of the error laying in the interval $[-\delta,\delta]$, must be above π_0. Accuracy classes are defined by the tolerance on GVW, from A(5) to D(25), the number in brackets being this tolerance. The tolerances for the other quantities (axle loads, group of axles loads...) are larger than for GVW (Jacob et al., 2002).

Table 2 releases the results of the performance assessment on both bridges, for the GVW, with the details of the analysis. π_0 is the minimum required level of confidence, which corresponds to the lowest acceptable tolerance δ_{min}, i.e. the interval $[-\delta_{min},\delta_{min}]$, for the test conditions and sample size. δ is the tolerance of the accepted class listed in the COST 323, with a higher confidence level π.

Table 2. Performance assessment of the B-WIM for the Gross Vehicle Weight (GVW).

Bridge and test set	π_0 (%)	δ (%)	δ_{min} (%)	π (%)	COST 323 Class	Max Error (%)	Min Error (%)
Haut-Village							
All passages (24), for info.	94.7	15	14.2	96.2	C(15)	6.8	-17.6
Assessment only (35)	94.0	15	12.2	98.5	C(15)	6.8	-9.0
Mauves							
All passages (42), for info.	93.5	10	8.0	98.1	B(10)	7.1	-12.6
Assessment only (35)	93.0	10	7.4	98.8	B(10)	7.1	-5.2

For each of the two bridges, one passage is neither used for adjustment nor for assessment, because it has been considered as an outlier regarding the statistical distribution of all other passages. For both bridges, it corresponds to the minimum (algebraic) error. However, we decided to include these two outliers in the "all passages" sets for both bridges, the result of which is given for information only.

The Haut-Village B-WIM is accepted in Class C(15) and the Mauves one in Class B(10) for the GVW. We notice that there is no difference on the result if we consider all passages (including outliers), or only the ones dedicated to the assessment. In the case of the Mauves Bridge, the value 7.4% for δ_{min} means that the system is very near to Class B+(7), which is a very good result for a B-WIM on this type of bridge deck.

4.2 *Accuracy for the axle load on the Mauves bridge*

The accuracy for the axle loads is relevant on the Mauves bridge only, where the UHPFRC slab enables a good detection of the axles. The results are classified according to the COST 323 methodology, with details as released in Table 3.

Table 3. Performance assessment of the B-WIM for the axle load, on the Mauves Bridge.

Test set	π_0 (%)	δ (%)	δ_{min} (%)	π (%)	COST 323 Class	Max Error	Min Error
All axles (84)	94.7	10.9	10.8	95.0	B+(7)	10.4	-13.4
9 tons 2-axles lorry (44)	96.0	15	11.0	99.5	B(10)	10.4	-11.1
12 tons 2-axles lorry (40)	95.9	15	13.1	98.2	B(10)	10.1	-13.4
Front axles (42)	93.5	8	5.4	99.5	A(5)	0.5	-2.9
Rear axles (42)	93.5	15	11.6	98.6	B(10)	10.4	-13.4

The results for the axle loads are very good, with a B-WIM system accepted in class B+(7). The better class assessed for the axle loads compared to the GVW is explained by the statistical methodology of the COST 323: the sample of axles is wider than the one of vehicles, and the accuracy classes for axle loads have a wider tolerance δ. We notice excellent results for the front axles with class A(5) and less than 3% relative error in absolute value.

By contrast, the strain measurements on the aged thick reinforced concrete slab of the Haut-Village bridge are not relevant for the axle load estimation. This illustrates the strong incidence of the secondary structures of the bridge deck used for axle load estimation by the WIM+D system: the local bending must be significant, which is not fulfilled on every type of bridge. The UHPFRC thin slab of the Mauves bridge appears as a perfect type of structure for this purpose.

5 DISCUSSION AND CONCLUSION

5.1 *Difference between the two bridges*

This case study is a unique opportunity to study the performance of B-WIM systems on two similar bridges unusual for this application, due to high hyperstaticity and historical age, yet with an interesting comparative study due to slight differences between the two bridges.

Indeed, the span length and the general design of the iron truss decks are the same, but the Mauves bridge did benefit from recent refurbishment works in 2020. These works include a complete rebuilding of the secondary transverse elements of the deck, with a new UHPFRC slab to carry the road, and the addition of a lateral way for cycles and pedestrians. The Haut-Village bridge still stands with secondary transverse elements dating back to its rebuilding after World War II, or even earlier for one of the five spans.

Despite of its larger number of spans which increases the uncertainty related to hyperstaticity (eleven spans versus five), the Mauves bridge gives better results for the application of B-WIM: It is accepted in class B(10) for the GVW and B+(7) for the axle loads, whereas the Haut-Village bridge is accepted in class C(15) for the GVW and is not conclusive (and not classified) for axle loads.

This result shows that the main structures of the bridge deck are not the only factor of efficiency for the B-WIM, and secondary structures have also some incidence, even indirectly, for the estimation of the GVW. Indeed, it is assumed that the new transverse beams and UHPFRC slab of the Mauves bridge have a mechanical behavior more repeatable and linear than the aged concrete slab and brick arches of the Haut-Village bridge. This reduces the uncertainty on the B-WIM result for the GVW, even if the latter is deduced from global bending of the main spans only: the participation of secondary structures to this bending cannot be neglected. We assume also that a significant part of the global bending rigidity of the Haut-Village bridge is due to these uncertain secondary elements, which is less the case for the Mauves bridge.

5.2 *Conclusion and perspectives*

The case study of both Haut-Village and Mauves bridges gives very encouraging results for the application of B-WIM to historical highly hyperstatic iron truss bridge decks. With a performance assessment in class B(10) for the Mauves bridge and C(15) for the Haut-Village bridge according to COST 323, the accuracy of the WIM+D system for the gross vehicle weight is convenient for the purposes of statistical analysis of the traffic loads and for the detection of large overweight.

The performance regarding the axle loads is strongly dependent of the secondary structures of the bridge decks, which are very different from one bridge to the other. The aged concrete slab and brick arches of the Haut-Village bridge appear unsuitable for the purpose of axle detection, whereas the new UHPFRC slab of the Mauves bridge is an ideal structure for axle load estimation. Thus, the WIM+D system has been accepted in class B+(7) for axle loads on the Mauves bridge. This is one of the best performances yet achieved for a B-WIM regarding the axle loads, and it is worth to note that this is achieved on a type of bridge deck which is unusual for B-WIM applications, compared to more common concrete or composite beam girders. This performance is also achieved despite of a high hyperstaticity of both bridges, with several continuous long spans of 45 m.

Such historical bridges, initially designed for light local traffic of horse-drawn carts and relying on aged iron truss deck structures, deserve a specific attention regarding the real traffic

loads and are often subject to load limitations. This case study shows that B-WIM with the WIM+D system is a suitable solution to assess the real level of traffic on the bridge and to detect overweight vehicles, with an accuracy comparable to the one obtained on more common bridge decks. The low quantity of strain sensors involved (six only for one bridge) and the light and portable setup makes it an economical solution compared to classical WIM systems inside the pavement. B-WIM could thus become a standard way to assess traffic conditions on historical iron-truss bridges.

ACKNOWLEDGMENTS

The authors wish to thank the Loire Atlantique Department for supporting this research by making the Haut-Village and Mauves bridges available for this study. They are grateful also to the partners of the GeRICO project: SCE, Strains, and the City of Angers. This research received a financial support from the French government in the frame of the "Programme National Ponts", steered by the Cerema.

Assessment of the accuracy of Bridge Weigh-In-Motion (B-WIM) system in Indonesia

W. Nugraha, S. Ramadhani & G. Sukmara
Directorate General of Highway, Ministry of Public Works and Housing, Republic of Indonesia

ABSTRACT: Bridge Weigh-in-Motion (B-WIM) systems have become increasingly popular in Indonesia due to their ability to measure the weight and axle load of vehicles without the need for them to stop at a weighbridge. As a permanent and reliable system, B-WIM has been installed in several locations throughout Indonesia for over three years. The purpose of this research is to assess the accuracy of the B-WIM system in various locations and identify the factors that influence its precision. The study utilizes the calibration procedure outlined in the COST 323 standard for accuracy assessment. Ten bridges were calibrated, with five of them undergoing recalibration after years of operation. The results show that B-WIM systems generally provide high accuracy in measuring gross vehicle weight (GVW). However, the accuracy of axle-specific weight measurements was found to be relatively lower. The relationship between bridge types and accuracy classes was explored, revealing that short-span girders, both steel and precast concrete girders, exhibited high accuracy levels when the pavement condition was well-maintained. Recalibration was found to improve accuracy, except for one site with a longer timespan between calibrations, possibly due to pavement deterioration. The findings highlight the importance of maintaining pavement conditions to minimize dynamic effects on B-WIM measurements. Managerially, this research provides valuable insights for transportation authorities in Indonesia to identify areas for improvement in the B-WIM system and ensure reliable and precise measurements for various purposes, including overloading law enforcement and bridge condition evaluation.

1 INTRODUCTION

Overloading vehicles pose significant challenges to the infrastructure of developing countries like Indonesia, causing extensive damage to bridges and roads. Such damages can result in catastrophic failures, road closures, and expensive repairs, necessitating urgent measures to address this issue (Jacob & Cottineau, 2016). One solution lies in enforcing laws against overloading vehicles, which requires the weighing of heavy vehicles. However, weighing vehicles on a weighbridge, which is the traditional method for determining vehicle weight and axle load, presents challenges. It requires vehicles to come to a complete stop, leading to traffic congestion and sometimes allowing heavily loaded vehicles to pass without being weighed at all (Karim et al., 2014). This approach is inefficient, particularly on roads with high traffic volume. In recent years, the emergence of Bridge Weigh-in-Motion (B-WIM) systems has provided an alternative solution. These systems enable vehicle weighing to be conducted as vehicles pass over a bridge, eliminating the need for them to stop (Nugraha et al., 2022). This method is more efficient and less disruptive to traffic flow, addressing the shortcomings of the traditional weighbridge approach (Gajda et al., 2018).

B-WIM is a Weigh-in-Motion (WIM) system that utilizes a bridge as the weighing medium, measuring the response of the bridge due to vehicle loading as vehicles pass over it (Nugraha & Sukmara, 2016). Various types of bridges, such as girder bridges and culvert bridges, can be

DOI: 10.1201/9781003483755-162

used for B-WIM (van Loo & Žnidarič, 2019). The bridge response is captured using a set of strain transducers connected to a data acquisition and processing system (Lydon et al., 2016). This system collects and processes the response data to provide essential information, including gross vehicle weight (GVW), axle load, axle distance, vehicle speed, and vehicle classification (Brouste, 2021). The Moses algorithm is employed to transform the transducer response into accurate weighing results (Moses, 1979). With the sensors installed beneath the bridge, the B-WIM system ensures long-term reliability without direct contact between the sensors and vehicle tires (Kalhori et al., 2018). B-WIM has been successfully implemented in multiple locations across Indonesia for over three years, providing valuable vehicle data for road authorities and supporting overloading law enforcement efforts.

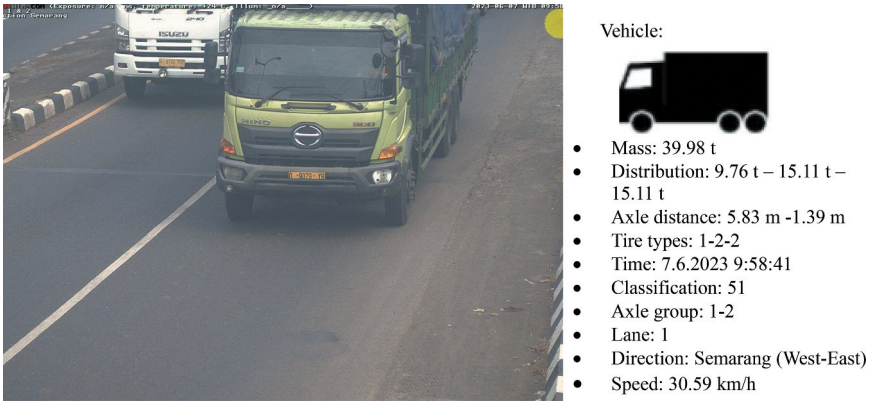

Figure 1. Example of B-WIM vehicle weighing measurement result.

Provides an example of B-WIM vehicle weighing measurement results, illustrating a 3-axle truck with a gross vehicle weight (GVW) of 39.98 tons. It is evident that this vehicle is significantly overloaded, with each axle load exceeding the legal maximum of 10 tons. Specifically, the first axle load measures 9.76 tons, while the second and third axles carry loads of 15.11 tons each. This means that the vehicle is overweight by more than 50%. Such overloading poses a significant risk as it accelerates the deterioration of roads and bridges beyond their designed lifespan. By employing B-WIM to instantaneously measure vehicle weights, road authorities can effectively enforce regulations by identifying license plates and measurement results. This proactive approach helps to address the problem of overloading, consequently mitigating the issues associated with road and bridge deterioration.

This research aims to evaluate the reliability and accuracy of B-WIM systems in Indonesia. It focuses on assessing their performance in measuring vehicle weights and axle loads, understanding factors affecting accuracy, and comparing B-WIM measurements with the COST323 standard (Laboratoire Central des Ponts et Chaussées, 2002). These evaluations are crucial for real traffic measurement, overloading control, and infrastructure assessment. The research employs the COST 323 calibration procedure to determine accuracy classes and provide valuable insights to transportation authorities. The goal is to identify areas for improvement, ensuring precise measurements for overloading control and infrastructure management, enhancing overall transportation efficiency in Indonesia.

2 METHODOLOGY

In this research, the evaluation of B-WIM measurement accuracy will be conducted using the calibration procedure outlined in the COST 323 standard (Laboratoire Central des Ponts et Chaussées, 2002). As part of the installation process, it is essential to perform an initial calibration of the WIM system. This procedure involves using a pre-weighed vehicle or truck,

which has been weighed using static weighbridge station, as shown in Figure 2. The static weighing measurements include data such as gross vehicle weight (GVW), single axle load, axle group load, and axle distance. The pre-weighed truck is then driven over each line of the WIM system, repeating the process a minimum of 10 times. To determine the accuracy class of the WIM system, Jacob (2000) proposed a method that calculates the confidence interval width (δ). This calculation incorporates the mean, standard deviation, and the number of vehicle passes per lane for the calibration vehicle weighing data. Finally, the obtained confidence interval width (δ) is compared to the accuracy class tolerances specified in the COST 323 standard, as illustrated in Table 1.

Figure 2. Pre-weighed truck for calibration.

Table 1. Tolerances of the accuracy classes (δ in %)(Laboratoire Central des Ponts et Chaussées, 2002).

Criteria (type of measurement)	Domain of use	Accuracy Classes:Confidence interval width δ (%)						
		A (5)	B+ (7)	B(10)	C (15)	D+ (20)	D (25)	E
1. Gross weight Axle load:	Gross weight > 3,5 t Axle load > 1 t	5	7	10	15	20	25	>25
2. group of axles		7	10	13	18	23	28	>28
3. single axle		8	11	15	20	25	30	>30
4. axle of a group		10	14	20	25	30	35	>35
Speed	V>30 km/h	2	3	4	6	8	10	>10
Inter-axle distance		2	3	4	6	8	10	>10

This research aims to classify and evaluate the accuracy class of each B-WIM site by employing the proposed method. In order to ensure precise measurements, several sites have undergone annual recalibration. This study also explores the relationship between accuracy class and time, shedding light on the long-term performance of B-WIM systems. Furthermore, the influence of paving conditions on the accuracy of B-WIM measurements is closely monitored and discussed. It is evident that the accuracy of B-WIM is highly dependent on the condition of the pavement on the bridge and its approach. Additionally, various types of bridges, including Steel Composite Girder, PCI Girder, Culvert, and Voided Slab bridges, have been

utilized for B-WIM systems in Indonesia as listed in Table 2. This research also investigates the relationship between bridge types and accuracy class, providing valuable insights into the performance and suitability of different bridge structures for B-WIM applications.

3 RESULTS AND DISCUSSION

In this research, a total of 10 bridges were calibrated, with 5 of them undergoing a second calibration after years of operation. As an example, the calibration run of ID010 for lane 1 in 2022 is presented in Table 3. Site ID010 is situated on Jalan Tol Lingkar Luar Jakarta KM 54 +20 B and features a precast concrete I-girder bridge with two lanes. For both Lane 1 and Lane 2, the calibration run was conducted with the vehicle passing 11 times. The calibration truck utilized was a 3-axle statically weighed truck, with a gross vehicle weight (GVW) of 21.62 tons as displayed on Figure 3. The axle weights for the first, second, and third axles were 6.54 tons, 7.64 tons, and 7.44 tons, respectively. Mean and standard deviation values were calculated for the differences between B-WIM measurements and static weighbridge measurements of the calibration truck, considering parameters such as GVW, single axle, and group axle. These mean and standard deviation results were utilized in calculating the width of the confidence interval (δ).

Figure 3. Static GVW measurement result of calibration truck.

Table 3. Calibration runs of site ID010 for lane 1 (2022).

	GVW Static Scale	GVW BWIM	Difference		W1	W2	W3	Diff W1	Diff W2	Diff W3	Diff Group
No	ton	ton	ton	%	ton	ton	ton	%	%	%	%

11	21.62	21.7	-0.08	-0.37%	6.56	7.57	7.57	0.31%	-0.92%	1.75%	0.40%

The determination of the delta class was performed using the method proposed by Jacob (2000), as specified in the COST323 standard, as displayed in Table 4. For Lane 1, the mean average difference in gross vehicle weight (GVW) was found to be 0.45% with a standard deviation of 1.12%. The mean average difference in axle 1 weight was -0.61% with a standard deviation of 1.70%. Similarly, the mean average difference in the group of axles, which refers to the combined weight of axle 2 and axle 3 of the truck, was 0.97% with a standard deviation of 1.68%. These calculations were then repeated for Lane 2 using the same method. It is noteworthy that all parameters, including GVW, group of axles, and single axle, obtained the highest accuracy class of A(5) for both Lane 1 and Lane 2. These results indicate that the B-WIM system on Site ID010 performed exceptionally well with the highest level of accuracy.

Table 4. Accuracy class determination for ID010 2022 calibration.

	Lane 1			Lane 2		
Parameters	GVW	Group	Single	GVW	Group	Single
Number of run	11	11	11	11	11	11

St Dev	1.12	1.66	1.70	1.03	1.39	2.03
Delta Critical, δ_{crit}	3.50	3.50	3.20	3.10	2.90	4.00
Delta Class, δ	5	5	5	5	5	5
Class	A(5)	A(5)	A(5)	A(5)	A(5)	A(5)

The accuracy class results obtained from the calibration of ten bridges are presented in Table 5. Among these bridges, five sites underwent calibration twice after years of operation. The repeated calibration allowed for an assessment of the accuracy class over time, providing insights into the system's performance and potential changes in accuracy. By conducting multiple calibrations, this research was able to explore the consistency and reliability of the B-WIM system's accuracy class across different sites and evaluate any variations that may arise. The findings from these repeated calibrations contribute to a comprehensive understanding of the long-term accuracy and performance of the B-WIM system in various bridge locations.

The analysis of Table 5 reveals that the B-WIM system generally achieves a high accuracy class for gross vehicle weight (GVW) measurements. Across the ten bridges, GVW measurements consistently obtained accuracy classes ranging from the lowest C(15) on two bridges to predominantly A(5) on seven bridges. This demonstrates the B-WIM system's capability to accurately measure the total weight of vehicles passing over the bridges. However, a closer examination of the accuracy classes for individual axle loads reveals a lower level of precision compared to the GVW measurements. Only three bridges achieved an accuracy class of A(5) for single axle measurements, while the majority exhibited accuracy classes ranging from B+(7), B(10), C(15), D(25),

Table 5. Accuracy class of All ID site calibration.

		2023	A(5)	A(5)	A(5)	A(5)	A(5)	A(5)

and even E(30) and E(35). These findings suggest that the B-WIM system may encounter challenges in accurately capturing axle-specific weight information. One possible explanation for this disparity could be the placement of the axle detection sensors below the bridge slab. Depending on the thickness of the slab and pavement, the sensors may not directly sense the axle response due to minimal generated signal. Consequently, this introduces greater uncertainty in the measurement of single axle loads compared to the GVW, leading to lower accuracy class ratings.

The impact of recalibration on B-WIM measurement accuracy was analyzed by plotting the critical confidence interval width, (δcrit), on the y-axis against the year of calibration on the

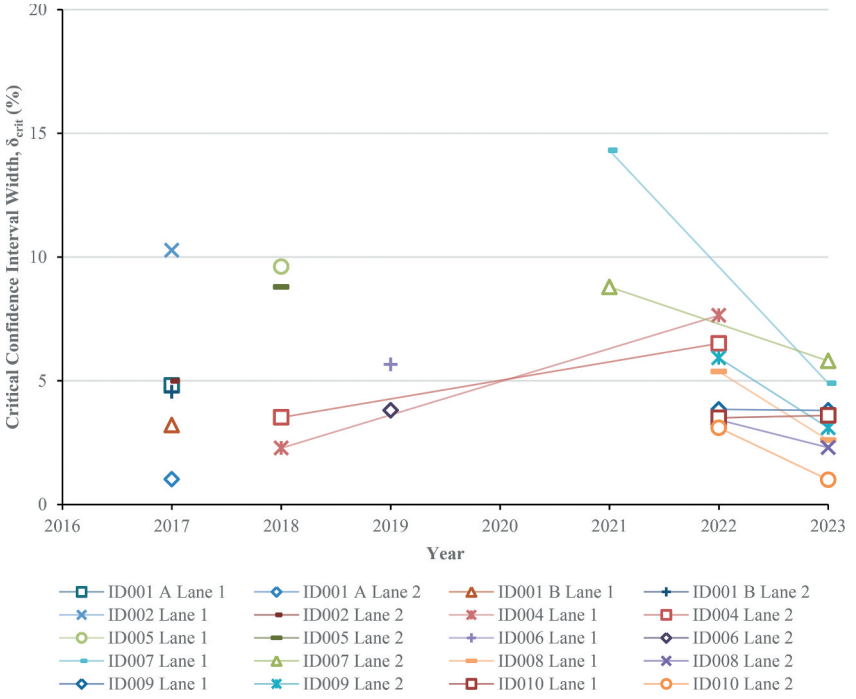

Figure 4. Critical confidence interval width (δcrit) of GVW measurements.

x-axis. In Figure 4, the critical confidence interval width for GVW measurements was specifically chosen to provide a clear analysis. The results indicated that the majority of recalibrations (four out of five sites) resulted in improved accuracy, as reflected by lower δcrit values compared to the initial calibration. This demonstrates that recalibration can enhance the accuracy of B-WIM measurements by determining new calibration factors and improving the measurement results. However, it is worth noting that Site ID004 exhibited lower accuracy after recalibration. This discrepancy may be attributed to the four-year interval between calibrations, which suggests possible pavement surface and approach deterioration on the bridge. To maintain measurement accuracy, recalibration at intervals of 1-2 years is recommended, as evidenced by the four sites that underwent recalibration within this timeframe after the initial calibration. Given that several sites installed between 2017 and 2019 have only been calibrated once, it is essential to prioritize their recalibration in the near future to ensure the sustained accuracy level.

Based on the findings presented in Table 5 and Figure 4, an investigation into the relationship between bridge types and accuracy class can be conducted. The majority of measurements classified as A(5) were obtained from PCI girder bridges. However, it should be noted that some of these bridges exhibited lower accuracy class due to poor pavement conditions on the bridge surface and approach. For instance, Site ID002, the Air Ibul Besar bridge located on Jalan Lintas Timur National Road in Palembang City, South Sumatera, demonstrated relatively low accuracy class on Lane 1. The GVW measurement had a class of C(15), the group of axles had a class of B(10), and the single axles had a class of E(30). Although the pavement on top of the bridge was in good condition, as it had recently been resurfaced during calibration, the steep incline of the approach, as shown in Figure 5, caused vehicles to de-accelerate before passing the bridge. This resulted in significant impacts and dynamic effects during the measurement process, ultimately lowering the accuracy class for this particular bridge.

Figure 5. Site ID002 pavement condition.

Among the evaluated bridge sites, only Site ID005 stood out as a non-girder bridge, specifically a voided slab bridge, which is not an ideal bridge type for B-WIM due to limited measurement route alternatives. As expected, this bridge demonstrated relatively low accuracy class. The weak lateral connection between the voided slab components had a significant impact on accuracy, even for GVW measurements, which generally exhibited high accuracy in

bridge WIM systems. Furthermore, single axle measurements showed the lowest accuracy compared to other bridge types. This was attributed to the installation of axle detection sensors on the bottom of the voided slab, as the bottom part of the top flange was inaccessible. Consequently, the measurement of axle responses from passing vehicles was weakened due to interference caused by the void between the two flanges of the voided slab. The results emphasize the importance of a well-maintained pavement surface and approach on bridge WIM systems to minimize the dynamic effects of vehicles passing over the bridge and ensure minimal differences between B-WIM measurements and static measurements. In line with the recommendations of COST323, short-span girders, both steel and PCI, offer high accuracy levels. However, it is crucial to maintain the pavement in good condition to ensure optimal measurement accuracy.

4 CONCLUSIONS

In conclusion, this research focused on the evaluation of B-WIM measurement accuracy in the context of bridge installations. By employing the calibration procedure outlined in the COST 323 standard, the accuracy classes of the B-WIM systems at various bridge sites were assessed. The findings revealed that while the gross vehicle weight (GVW) measurements generally exhibited high accuracy classes, the accuracy of axle-specific measurements was comparatively lower. The results highlighted the influence of bridge types, such as PCI girder bridges and voided slab bridges, on measurement accuracy, with the latter presenting challenges due to weak lateral connections and sensor placement. It was also observed that recalibration, when performed on a regular basis, led to improved accuracy. However, sites that underwent infrequent recalibration or experienced deteriorating pavement conditions exhibited lower accuracy levels. The implications of this research are significant for transportation authorities and bridge managers. The accurate measurement of vehicle weights plays a crucial role in enforcing overloading regulations and assessing the impact of heavy vehicles on bridge and road deterioration. By utilizing B-WIM systems, authorities can identify overloaded vehicles and implement targeted law enforcement measures to protect infrastructure and ensure road safety. Furthermore, the findings emphasize the importance of maintaining optimal pavement conditions and considering bridge types in B-WIM installations to enhance accuracy.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to the Ministry of Public Works and Housing, Republic of Indonesia for their invaluable support and provision of necessary facilities, which have been instrumental in the successful completion of this research. Additionally, we would like to extend our sincere thanks to PT Jasa Marga Tollroad for generously sharing the data required for this study, enabling us to conduct a comprehensive analysis. Special thanks are also due to Cestel d.o.o and its Indonesian counterpart, PT Bia Tekno Solusi, for providing the B-WIM system in Indonesia, as well as for their unwavering support and assistance throughout the research process. The contributions of these organizations have played a vital role in the realization of this study, and we are deeply grateful for their invaluable collaboration.

Bridge weigh-in-motion event detection using wavelet scattering features and unsupervised learning

Vahid Bokaeian, Jeremy Bowmaster & Kaveh Arjomandi
Department of Civil Engineering, University of New Brunswick, Fredericton, Canada

ABSTRACT: This study introduces an unsupervised approach to categorize the acceleration time history of a highway bridge into three distinct classes: vehicle events, the bridge's free vibration, and noise. We employ a combination of wavelet scattering networks and principal component analysis for extracting features, while the Gaussian mixture model is utilized for clustering the data segments into these classes. The results are compared to a manually adjusted database of events identified through computer vision, aligned with the acceleration data to define event intervals. The effectiveness of this method in identifying events from the bridge's acceleration data is evident. It successfully detected all events without omission and accurately separated the free vibrations.

1 INTRODUCTION

Bridge Weigh-in-Motion (BWIM) refers to methods for estimating vehicle weights as they cross a bridge at highway speeds. Unlike traditional weighing stations, BWIM systems do not require vehicles to stop, thus providing a non-intrusive means of collecting weight data. This technology is particularly useful for infrastructure management, allowing for the monitoring of overweight vehicles that may damage roadways and bridges, and for enforcing weight limits.

The roots of Bridge Weigh-In-Motion (BWIM) technology can be traced to the 1960s, gaining significant momentum in the mid-1970s due to the groundbreaking efforts of Fred Moses (Moses 1979). This technology is based on the concept of an 'influence line' (IL), a representation that illustrates the effect of a unit load at varying positions on a bridge on a specific response, such as strain or bending moment, at a designated point on the structure. Before deploying the algorithm, it's essential to calibrate the bridge, which involves establishing its IL. This calibration process generally requires driving vehicles with known weights over the bridge and recording the resultant responses. Moses' algorithm assumes that the total influence at any given moment is the cumulative effect of the individual axle weights at their respective locations on the bridge. Through the resolution of these equations, it becomes possible to approximate the weights of the separate axles.

Many researchers have used the concept of influence line to estimate axle weights and vehicle weights on bridges, and axle detection is a critical process in most of them, where the accuracy of the algorithm for weighing axles is highly dependent on two key parameters: vehicle speed and axle spacing (Algohi, Mufti, and Thomson 2018; He et al. 2021; Macleod and Arjomandi 2022; MacLeod and Arjomandi 2023). There have been different non-IL-based methods proposed by researchers, but most of them are limited to specific traffic scenarios (Yu, Cai, and Liu 2021), not verified by real traffic data (Chatterjee et al. 2006; Zhou et al. 2021), or are computationally expensive (Zhou et al. 2020; Zhu, Li, and Zhang 2022).

While these methods have served their purpose, they sometimes lack adaptability, computational efficiency, and precision. These shortcomings can lead to inaccurate

DOI: 10.1201/9781003483755-163

measurements, increased maintenance costs, and potential structural vulnerabilities. The integration of Artificial Intelligence (AI) into BWIM systems offers the potential to enhance adaptability and accuracy, paving the way for more resilient and efficient infrastructure monitoring. This study is part of a research project defined in the Smart Structures Research Group (SSRG), University of New Brunswick, that aims to develop an AI-integrated BWIM system that utilizes sensor data for precise event detection, classification and weight estimation on highway bridges. The system also implements computer vision techniques to adeptly categorize vehicles, focusing on their presence, axle count, and spacing.

2 METHODOLOGY

2.1 *Structure instrumentation*

The chosen structure for instrumentation is a single-span prestressed concrete girder bridge which functions as an overpass for Route 2 and is situated proximate to the town of Sackville, NB, Canada. The bridge was erected in the year 1994, and the specified speed limit on this bridge section of the highway is 110 kph. The bridge is identified as L930 by the New Brunswick Department of Transportation and Infrastructure (NBDTI).

The bridge's underside has been equipped with thirty sensors, as shown in Figure 1:

- Nine accelerometers, which record uniaxial vibrations, facilitate modal analysis, thereby yielding essential model data.
- Fifteen foil strain gauges are purposed to record the overall response, aiding in weight determination algorithms, while an additional four strain gauges are designed to measure localized strain in the deck, particularly to identify the axles of traversing vehicles.
- Furthermore, a Basler ace acA1440-73gc GigE camera has been installed to consistently capture visuals of the vehicular movement across the bridge, operating at a frequency of 10 Hz.

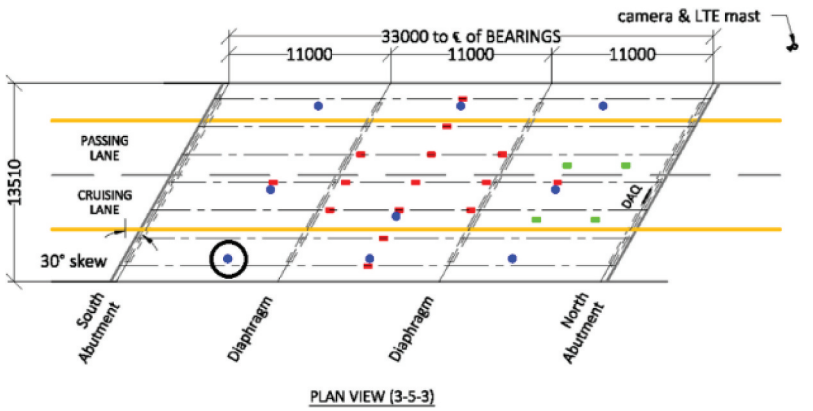

Figure 1. L930 sensor layout. This instrumentation plan is intended for general BWIM research and we only utilize acceleration data from a singlesensor (indicated by a black circle in Figure 1) for the current study.

2.2 *Dataset preparation*

In this study, the YOLOv8n model is specifically trained to detect vehicles in the region of interest (ROI) of the bridge images. By applying the YOLOv8n model to the preprocessed images, vehicles present in the ROI are detected and localized. These images are utilized to prepare an approximate start and end time for events that occurred on the bridge. After

observing acceleration data for the same period of time, a dataset of manually identified events (including time intervals in which there is vehicle(s) between the two expansion joints on the bridge) is prepared.

2.3 *Time series feature extraction*

2.3.1 *Data preprocessing*

The first step in the feature extraction process is to read and preprocess the acceleration data. The raw data is typically stored in TDMS (Technical Data Management Streaming) files, with a sampling frequency of 1280 Hz. The time and acceleration values are extracted from the raw data and organized into arrays for further processing.

After preprocessing the data, the acceleration data is windowed, which involves dividing the data into smaller windows of equal time duration (window size) 0.5 seconds, or 640 samples. Windowing allows for the analysis of the acceleration data in smaller segments, enabling the detection of events that occur within specific time intervals. By analyzing the acceleration data in these windows, it becomes possible to identify patterns associated with bridge events.

2.3.2 *Wavelet scattering features*

The foundational principle of the wavelet scattering transform is rooted in a technique known as the wavelet transform. This method involves utilizing wave-like oscillations, known as wavelets, which are adaptable in scale and position to closely match a given signal. By combining these wavelets linearly, a new representation of the signal is created. The application of the wavelet to the signal results in a series of coefficients. These coefficients illustrate the correlation between the wavelet and the signal, offering a new depiction of the original signal that encompasses both time and localized frequency information (Jean Effil and Rajeswari 2022). This characteristic makes the wavelet transform an effective tool for analyzing nonstationary signals, primarily due to its capacity for time-frequency localization. However, one limitation of this method is its lack of translation invariance (Liu et al. 2020).

Building upon the wavelet transform, the wavelet scattering transform aims to create representations that are invariant to translation and resilient to deformations. It achieves this through a combination of convolution, nonlinear processing, and scaling operations. The scattering transform extends the signal data across various decomposition paths, effectively delocalizing it (Jean Effil and Rajeswari 2022). This approach has been recognized for its efficacy in classification tasks, as pointed out by multiple studies (Andén and Mallat 2011; Bruna and Mallat 2011; Liu et al. 2020; Seydoux et al. 2020).

In this paper, the notations used in (Andén and Mallat 2011; Liu et al. 2020) are followed. Consider a signal denoted as $f(t)$ being analyzed. The construction of filters for capturing the full range of frequencies in this signal involves the use of a low-pass filter ϕ and a wavelet function Ψ. The low-pass filter, represented as $\phi_J(t)$, yields descriptions of f that are invariant to local translations at a predefined scale T. We use the notation Λ_k to describe a set of wavelet indices that offer an octave frequency resolution Q_k. By dilating the wavelet Ψ, we can create a multiscale high-pass filter bank $\{\Psi_{j_k}\}_{j_k \in \Lambda_k}$.

The implementation of a wavelet scattering transform is realized through a deep convolution network. This network iterates over a combination of traditional wavelet transform, nonlinear modulus, and averaging operations. The convolution process $S_0 f(t) = f * \phi_J(t)$ generates a feature of f that is locally translation invariant. However, this process also results in the loss of high-frequency information. The lost high-frequency details are recaptured using a wavelet modulus transform defined as Equation 1:

$$|W_1|f = \{S_0 f(t), |f * \Psi_{j1}(t)|\}_{j_1 \in \Lambda_1} \tag{1}$$

To obtain the first-order scattering coefficients, the wavelet modulus coefficients are averaged with ϕ_J, as shown in Equation 2:

$$S_1 f(t) = \left\{ \left| f * \Psi_{j1} \right| * \phi_J(t) \right\}_{j_1 \in \Lambda_1} \tag{2}$$

To retrieve the information lost in this averaging, we consider $S_1 f(t)$ as the low-frequency component of $\left| f * \Psi_{j_1} \right|$. The complementary high-frequency coefficients are then extracted through Equation 3:

$$|W_2| \left| f * \Psi_{j1} \right| = \left\{ S_1 f(t), \left| \left| f * \Psi_{j1} \right| * \Psi_{j2}(t) \right| \right\}_{j_2 \in \Lambda_2} \tag{3}$$

This leads to the definition of the second-order scattering coefficients, as shown in Equation 4:

$$S_2 f(t) = \left\{ \left| \left| f * \Psi_{j1} \right| * \Psi_{j2} \right| * \phi_J(t) \right\}_{j_i \in \Lambda_i}, \; i = 1, 2. \tag{4}$$

By iterating this process, we define wavelet modulus convolutions as Equation 5:

$$U_m f(t) = \left\{ \left| \left| \left| f * \Psi_{j1} \right| * \ldots * \left| \Psi_{j_m} \right| \right| \right\}_{j_i \in \Lambda_i}, \; i = 1, 2, \ldots, m. \tag{5}$$

Averaging $U_m f(t)$ with ϕ_J results in the m-th-order scattering coefficients, as shown in Equation 6:

$$S_m f(t) = \left\{ \left| \left| \left| f * \Psi_{j1} \right| * \ldots * \left| \Psi_{j_m} \right| * \phi_J(t) \right| \right\}_{j_i \in \Lambda_i}, \; i = 1, 2, \ldots, m. \tag{6}$$

The final scattering matrix, which is shown in Equation 7:

$$S_m f(t) = \left\{ \left| \left| \left| f * \Psi_{j1} \right| * \ldots * \left| \Psi_{j_m} \right| * \phi_J(t) \right| \right\}_{j_i \in \Lambda_i}, \; i = 1, 2, \ldots, m. \tag{7}$$

amalgamates all orders of scattering coefficients to describe the signal features, where l represents the maximum decomposition order.

The network's translation invariance is up to the scale determined by the averaging operation through the low-pass filter ϕ_J. As an inherent property of the wavelet transform, the features $Sf(t)$ exhibit stability against local deformations.

Despite its structural resemblance to conventional CNNs, the wavelet scattering network differs in two main aspects. Firstly, the filters are preset rather than learned. Secondly, the features extracted are not solely from the output of the last convolution layer but also from the combination of all layers (Liu et al. 2020).

In this research, a wavelet time scattering decomposition network using the Gabor (analytic Morlet) wavelet was created in Matlab. In the standard setup, the wavelet scattering network has two layers. This is based on the standard architecture of scattering networks, which are designed to capture both first-order and second-order scattering coefficients. The first layer captures the first-order coefficients, which are wavelet transforms of the signal. The second layer further processes the output of the first layer, capturing second-order coefficients.

2.3.3 *Dimensionality reduction*

With a sampling frequency set at 1280 Hz and a signal length of 640 samples, the output from the wavelet scattering network, following the specified configuration, results in an array of dimensions 5x105 for each window. These arrays are subsequently reshaped into single rows comprising 525 elements each. They are then vertically stacked, creating a dataset with dimensions 7198x525, which includes 525 variables and 7198 instances. In the process of conducting principal component analysis (PCA), the first 20 principal components were selected. These components account for over 95% of the variance in the data, and serve as features for the subsequent clustering algorithm.

2.4 *GMM*

In this study, we utilize features that have been dimensionally reduced via the PCA algorithm to group acceleration data. The clustering is achieved through the implementation of a Gaussian mixture model (Reynolds 2009). This model is centered around identifying a collection of K Gaussian distributions, each characterized by its mean μk and covariance Σk (for k = 1…K), which collectively provide the most accurate representation of the data set. Distinguished from the K-means clustering algorithm, the Gaussian mixture model offers a probabilistic framework, adding flexibility. This flexibility is evident in its ability to handle anisotropic covariances, accommodate clusters with differing internal variances, and apply a soft decision boundary for classification (Reynolds 2009; Seydoux et al. 2020).

Similar to the K-means algorithm, clustering based on the Gaussian mixture model is influenced by initial conditions and may result in convergence to a local rather than a global optimum. To address this issue, we performed the clustering with 100 random starting points. We then selected the clustering with the lowest Negative Log Likelihood (NLL). The NLL serves as a metric for evaluating the cost function within the optimization process. Utilizing this method aids in reducing the likelihood of converging to a local optimum, a notable risk given the iterative nature of the algorithm and its sensitivity to the initial conditions (You, Li, and Du 2023).

3 RESULTS AND DISCUSSION

As previously mentioned, 'events' in our context refer to the periods when one or more vehicles are present between the two expansion joints on the bridge. The rationale for choosing to cluster the acceleration data into three categories was to test the effectiveness of the current method in distinctly categorizing the three types of acceleration data, namely:

- Noise,
- Free vibration of the bridge,
- Vehicle-induced vibrations (referred to as 'events').

An example of how the final clustering compares with the actual recorded events is illustrated in Figure 2.

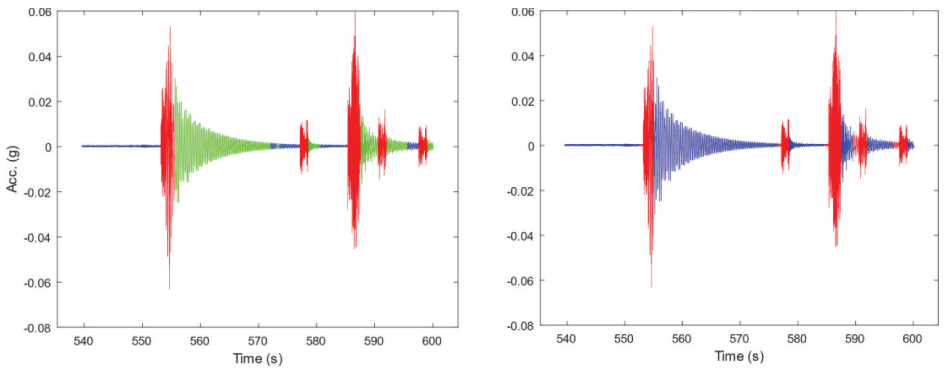

Figure 2. Sample result of event detection.

Upon reviewing the results from the entire dataset, it is obvious that the algorithm demonstrates proficiency in distinguishing event intervals within the acceleration history data. Nonetheless, a more detailed analysis is necessary to accurately assess the precision and reliability of this technique. In the next section, we will delve into an in-depth exploration of the confusion matrix, along with a thorough examination of both false negatives and false positives, to gain a more comprehensive understanding of the algorithm's robustness.

3.1 *Confusion matrix*

The confusion matrix serves as a tool for assessing the efficacy of classification algorithms. It can be structured as follows, according to (Fawcett 2006):

Table 1. Definition of confusion matrix.

Actual \ Predicted	Predicted Positive	Predicted Negative
Actual positive	True Positive (TP)	False Negative (FN)
Actual Negative	False Positive (FP)	True Negative (TN)

Typically, confusion matrices are utilized in supervised classification tasks. In these tasks, a model is trained on labeled data to learn specific patterns, which it then applies to predict labels for new, unlabeled inputs. However, our research employs an unsupervised method, as the classification model was developed without the use of manually identified events. Instead, we apply the concept of a confusion matrix to draw comparisons between manually identified events and the segments of data that have been clustered.

First, the noise and free vibration classes need to be merged into a "Non-event" class .Assuming that the current method is capable of accurately separate out the 3 classes of acceleration data, we made another assumption, and that is if we look at the mean absolute peak acceleration in all windows in a given class C (MAP_c), the "Event" class will have the highest MAP:

It is then necessary to combine the noise and free vibration classes into a single category, which we termed 'Non-event'. Operating under the assumption that this method could effectively segregate these three types of acceleration data, we introduced an additional hypothesis. This involves examining the mean absolute peak acceleration (MAP) across all data windows within a specific class C, denoted as (MAP_c). The formula for MAP_c, is given as Equation 8:

$$MAP_c = \frac{\sum_{i=1}^{n_c} max\left(abs\left(Seg_{i,c}\right)\right)}{n_c} \tag{8}$$

n_c: number of windows assigned to cluster C,

$Seg_{i,c}$: window i in cluster C.

Based on the MAP values, we ranked the classes and merged the two with the lowest MAP values into the 'Non-event' category. The confusion matrix can now be formed, as tabulated in Table 2.

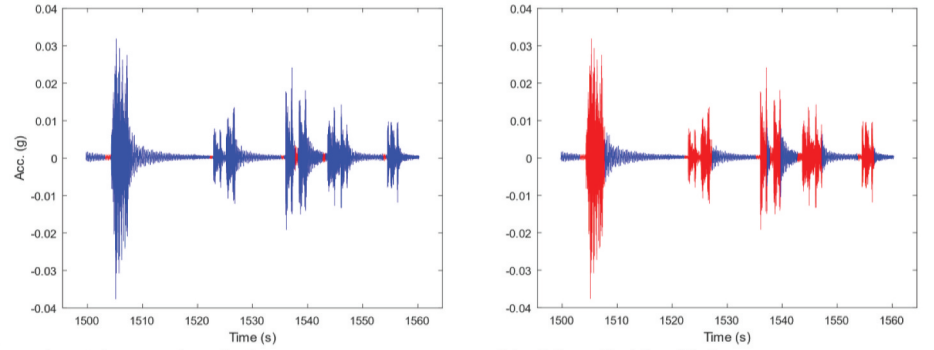

Table 2. Confusion matrix.

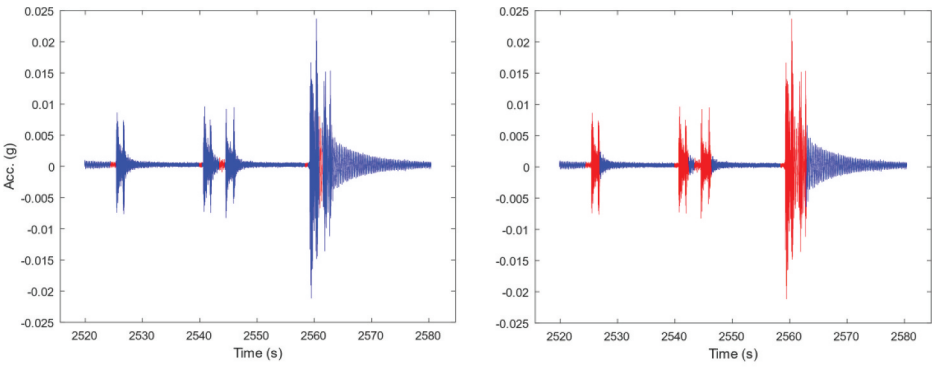
		Predicted Class	
		Event	Non-Event
Actual Class	Event	1899	491
	Non-Event	73	4735

Initial observations from the confusion matrix indicate a notable presence of false detections, particularly false negatives, which might initially suggest a risk of overlooking some events. However, this preliminary assessment requires a deeper analysis. In the next section we will look at these false classification in detail.



3.2 *False classifications*

Samples of false negatives and false positives event detection are illustrated in Figure 3 and Figure 4.

a) False negatives (red) b) Manually identified events

Figure 3. A sample of false negative detection.

a) False positives (red) b) Manually identified events

Figure 4. A sample of false positive detection.

An analysis of all misclassifications reveals two primary causes. Firstly, the manual identification of the dataset involves analyzing images at a rate of 10 frames per second and correlating these with acceleration time history indexes. This method may lead to some inaccuracies in event labeling. Secondly, for the purpose of comparing classification outcomes, it was necessary to assess the data windows individually. Events identified manually might start or end within these window intervals, necessitating the inclusion of entire windows as events, which can contribute to misclassifications.

Nevertheless, it's noteworthy that no actual events were missed by the algorithm. The majority of false detections occur immediately before or after actual events, typically lasting just 1-2 windows (0.5-1 seconds), a relatively brief duration. The proposed method is a reliable approach for differentiating between events, the bridge's free vibration, and noise. Our future research will focus on classifying these detected events (and correlated events from other sensors installed on the bridge) based on the number and types of vehicles involved and determining vehicle parameters for a new hybrid BWIM system.

4 CONCLUSION

In this study, an unsupervised approach was introduced to distinguish vehicle-induced vibrations (referred to as 'events') from bridge free vibrations and noise, using data from a single-channel accelerometer on a concrete highway bridge. This approach involved employing

a wavelet scattering network to derive stable features from acceleration data segments. Once the dimensionality of these initial scattering features was reduced, the refined features were input into a Gaussian mixture model (GMM) classifier. This classifier's objective was to optimally fit N normal distributions to the data, with N being a pre-set value of 3 in our study, corresponding to event, free vibration, and noise categories. The window classifications obtained were then cross-referenced against an event dataset, which was developed using an adapted YOLOv8n model and manually fine-tuned.

Based on our findings, the effectiveness of this method in identifying events from the bridge's acceleration data is evident. It successfully detected all events without omission and accurately separated the free vibrations. Consequently, this method proves to be sufficiently reliable for extracting an event dataset, paving the way for further enhancements and research in our Bridge Weigh-In-Motion (BWIM) system.

Machine-learning for analyzing bridge displacement using radar data

M. Arnold
ci-tec GmbH, Karlsruhe, Germany

S. Keller
Institute of Photogrammetry and Remote Sensing (IPF), Karlsruhe, Germany

ABSTRACT: This paper introduces a novel machine-learning approach based on non-invasive ground-based radar (GBR) time series data for classifying short-span bridge vehicle crossing events. GBR is used to remotely measure the bridge displacement, which is otherwise difficult to acquire but is an essential quantity for Structural Health Monitoring (SHM). For a comprehensive Bridge SHM, monitoring traffic is beneficial to gain knowledge about the actual loading situation. This can be challenging with global responses like displacement. This study indicates that it is possible to classify crossings as single- or multi-presence from displacement signals using tree-based learners and MiniRocket. Thus, our approach serves as a proof of concept to establish remote and data-driven displacement approaches in the context of BWIM. We rely on recordings of the bridge deck taken by an unmanned aerial vehicle as reference data. Despite a small, imbalanced, and biased dataset, we achieve a balanced accuracy of 90%.

1 INTRODUCTION

Bridges are an essential part of any transportation system. Failure can lead to fatalities, but even a gradual decline in loading capacity may already significantly impact freight traffic. Therefore, it is necessary to assess their condition regularly. In Germany, bridges are inspected periodically, frequently visually. These superficial inspections may detect external damage, including cracks, but they do not provide any information about the behavior of the bridge itself, like the load-bearing capacity. On the other hand, to apply adequate measures such as load restrictions, it is vital to have insights into the weight of vehicles to which the bridge is exposed.

So-called weigh-in-motion (WIM) systems are usually deployed to monitor traffic, but they typically require directly attached sensors, inflicting damage on the bridge (Paul & Roy 2023).

Pavement-based WIMs have direct contact with vehicles, simplifying traffic characterization, but the sensors are exposed to significant stress. Nothing-on-road (NOR) bridge WIMs (BWIM) try to avoid traffic exposure by only attaching sensors to the lower side of the bridge and using the bridge itself as a scale (Yu et al. 2016). To minimize interference, remote and non-invasive systems have been investigated (Ojio et al. 2016). While BWIM reduces both the system complexity, sensor exposure, and cost, signal analysis becomes more challenging. Accordingly, traffic characterization from vehicle crossings, henceforth called events, is still an active field of research. Many standard BWIM Structural Health Monitoring (SHM) methods cannot handle multiple-presence crossings and instead require single-vehicle events (OBrien et al. 2006; Ieng 2015). Such single-events must be detected automatically for a BWIM under normal traffic conditions. Moghadam et al. (2023) introduce a method for calculating a bridge influence line from multi-presence crossings. However, they recommend using a different approach for single crossings since it is more exact, making a differentiation between single and multi events desirable.

DOI: 10.1201/9781003483755-164

Kawakatsu et al. (2023) use Deep Learning (DL) for BWIM. They train Convolution Neural Networks (CNN) to classify traffic using equally long strain time series. According to their study, the CNNs can handle multi-presence events. However, they do not study the effects of several vehicles. Ground-based radars (GBR) have recently been investigated for monitoring bridges (Gentile & Bernardini 2010; Michel & Keller 2021a, b, 2022). Since they are easy to set up and require little maintenance, inspections can be performed on the fly. More importantly, GBR measures the bridge displacement. Displacement is highly relevant in SHM, reflecting bridge stiffness and bearing capability (Zhao et al. 2015). However, it is difficult to measure. With GBR, this data is accessible directly and accurately (Michel & Keller 2021a), making it a significant contender for NOR BWIM. Since deflection is challenging to measure, displacement-based BWIM has barely been studied. For instance, Ojio et al. (2016) have determined the bridge displacement with a camera. They use a second camera, not the displacement, to monitor the traffic and extract relevant features like the axle count. However, additional hardware increases the costs. Extracting traffic information from the displacement time series directly would be cheaper. Arnold & Keller (2020) and Arnold et al. (2021) show that Machine Learning (ML) based data-driven processing of bridge displacement signals is possible. They exploit a Random Forest (RF) and a CNN to detect and extract vehicle crossings successfully. As a next step, these events need to be analyzed regarding their potential for traffic characterization. Firstly, detected events should be differentiated between single- or multiple-presence events. One big challenge is that displacement, unlike strain, does not contain a localized bridge response. Furthermore, events and their corresponding time series are of varying length due to different vehicle numbers, speeds, and lengths. Varying-length time series classification is an active but insufficiently studied topic. One option is to extract features from a given time series (Bier et al. 2022). Other approaches like Random Convolutional Kernel Transform (ROCKET) (Dempster 2020) or MiniRocket (Dempster et al. 2021) achieve state-of-the-art results in public databases (Dau et al. 2019). In this paper, we will use a feature-based approach and MiniRocket to introduce an ML-based single-/multi-classification. More specifically, the main contributions of this paper are:

- a detailed description of the GBR data and the UAV dataset used in this study,
- a profound investigation of a varying-length bridge crossing classification in terms of single- versus multi-presence events using different ML approaches,
- an in-depth analysis of the potential of data augmentation for time series event classification,
- a comprehensive application of our approach to an entirely unknown dataset.

In Section 2, we will explain the setup for GBR measurements and describe the used dataset. Our methodology, including preprocessing, feature extraction and ML-models is detailed in Section 3. The results of our approach are laid out and discussed in Section 4. Finally, Section 5 summarizes the main findings of this study.

2 GBR MEASUREMENTS AND DATASET

In this section, we will briefly describe the GBR measurement setup. A more detailed explanation can be found in Michel & Keller (2021a), for example. Afterwards, we will introduce the UAV dataset for single-event classification.

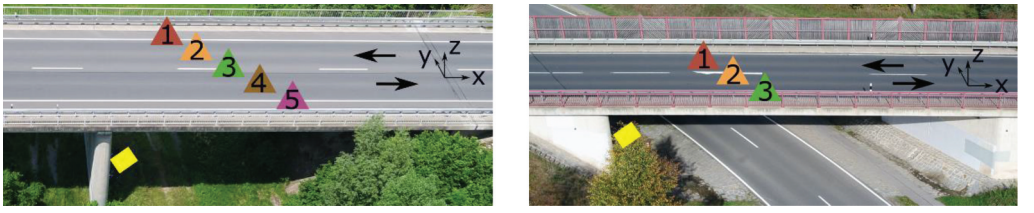

Figure 1. Overview of Bridge A (left) and Bridge B (right), including their reflectors.

2.1 *GBR measurement setup*

Measurements have been conducted at two bridges in Germany, henceforth referred to as Bridges A and B. To achieve a high signal-to-noise ratio five respectively three corner reflectors have been attached at the bottom of Bridge A and B. Both bridges and the approximate positions of the corner reflectors are shown in Figure 1. Bridge A has two fields, yet only one is monitored.

While Bridge A has undisturbed measurements, the vehicles using the street below Bridge B can cause significant disturbances in the time series data (Michel & Keller 2021a). On both infrastructures, one lane is present for each driving direction, as indicated by the black arrows. The yellow rectangle in Figure 1 represents the GBR. Its measuring principle is based on frequency modulation and interferometry (Gentile & Bernardini 2010). Modulation allows the GBR to measure multiple points along its line of sight (LOS). The maximum range resolution Δr amounts to 0.75m, according to

$$\Delta r = \frac{c}{2 \cdot B} = 0.75\ m, \tag{1}$$

with the speed of light $c = 3\times10^8$ ms^{-2} and a bandwidth B = 200 MHz. That is, every 0.75 m, the bridge displacement can be measured by summing up all reflected signals. For this purpose, all reflectors are spread along the x- and y-plane to make them distinguishable measurement points. The displacement is deducted using interferometry. With a sampling rate of 200 Hz, the phase shift $\Delta\varphi$ of each point is measured and then transformed to vertical displacement Δz using

$$\Delta z = \frac{\lambda}{4\pi}\frac{R}{\mathrm{h}} \cdot \Delta\varphi, \tag{2}$$

where h is the height difference between bridge and GRB, R is the distance of the GBR to a measurement point and λ is the GBR wavelength.

2.2 *Dataset*

To acquire ground truth data for the event classification, an unmanned aerial vehicle (UAV) has been deployed to film the bridge topside. During postprocessing, those videos have been synchronized with the radar data and used to build a database of vehicle crossings. Table 1 gives a general overview of the dataset for both bridges. As mentioned before, disturbances occur at Bridge B. We will only regard undisturbed events in this work. Overall, 1111 vehicles have been recorded for Bridge A and 730 for Bridge B. Since an event can contain several vehicles, the number of events is smaller, with 964 events for Bridge A and 500 for Bridge B, respectively. Besides the small dataset size, the imbalance of the dataset poses another challenge. This is true in two ways: Firstly, multi events are scarce compared to single events. Secondly, trucks appear less often than cars. Since trucks are inherently slower than cars and cars tend to cue behind a slow truck, trucks are underrepresented in single-events. In the case of Bridge A, for example, 241 trucks are single events, whereas 608 single events contain cars.

Table 1. Overview of the UAV-recorded events used for the event classification.

Bridge	Vehicles	Trucks	Cars	Events	Single Events	Multi Events
A	1110	341	769	962	849	112
B	491	114	377	343	271	72

While single events can differ significantly, multi-presence events come in an even greater variety: For instance, two heavy trucks might cross the bridge simultaneously in opposite directions. This scenario would be very relevant for SHM due to the significant stress induced on the bridge. Still, it is also challenging to visually differentiate from a single-event using only time series displacement data. To better understand, Figure 2 shows one single and one multi event for each bridge, although these examples do not cover the broad spectrum of traffic situations in the dataset. The corresponding time series data for all reflectors is drawn below each UAV

image. For each vehicle, its time on the monitored field is highlighted. Since there are overlapping areas in the lower plots, these are classified as multi events. Bridge A multi event shows a truck finishing its overtaking maneuver of another truck on the bridge field. The time series already resembles a single event of a very slow vehicle, e.g., when compared to the Bridge B single event. Thus, parallel crossings are barely distinguishable from single events. Attributing the maximum displacement or the maximum load of such an event falsely to one vehicle would lead to overestimating the bridge load and possibly to unnecessary reinforcements. A small car follows after the two trucks, but the vibration heavily masks the bridge bending the car causes. Finally, the Bridge B multi event shows a more straightforward example of two consecutive cars. The curious signal shape of RB3 in the Bridge B single event can be attributed to the fact that more than one displacement component is measured by the GBR (Michel & Keller 2021a).

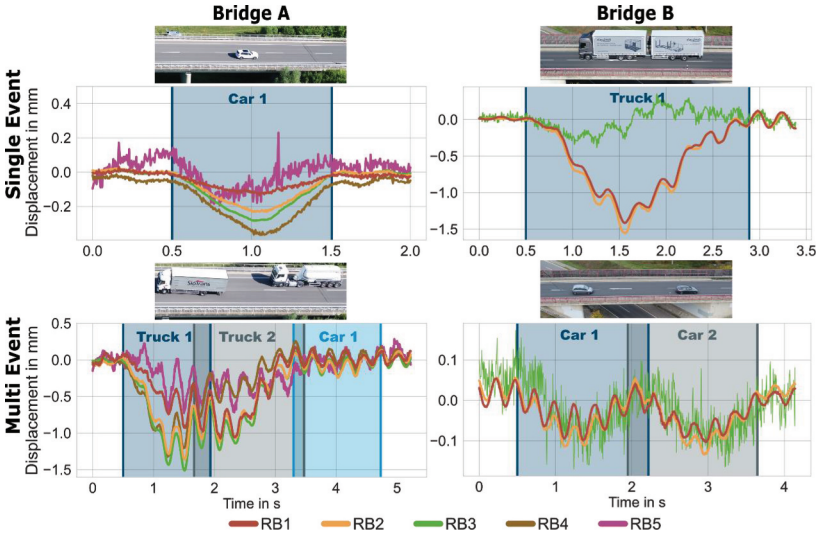

Figure 2. Example for a single (upper) and a multi event (lower) for Bridge A and Bridge B.

Figure 2 gives the impression that it could be sufficient to monitor the length of an event or its maximum displacement for one or two reflectors to classify it successfully. To illustrate that the distributions for both classes overlap significantly regarding such features, Figure 3 shows the duration of an event and the maximum displacement for reflector 3 of Bridge A and their corresponding Kernel Density Estimations (KDE). Although multi events tend to take longer, two consecutive cars are often faster than a single truck. And events of two trucks crossing the bridge in parallel on opposite lanes might last as long as a single truck event. On the other hand, most multi events have a higher deflection since slow and heavy trucks are involved, yet a clear decision boundary is not apparent. Although these two features alone are not enough to make a correct classification, additional features in combination with ML might be more successful.

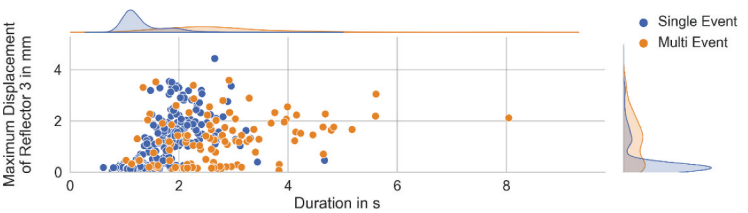

Figure 3. Maximum displacement and duration with normalized KDE.

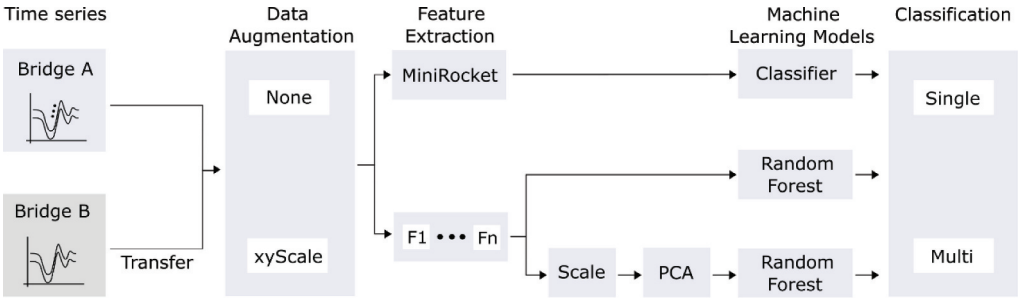

Figure 4. Schema of the methodological classification approach.

3 METHODOLOGY

In this chapter, we will shortly explain the methodology of the single- and multi-presence classification. Our proposed methodology consists of three steps: the data augmentation, the feature extraction and the ML models to classify the events. Figure 4 provides the schema of all steps.

3.1 *Preprocessing*

As evident from Section 2.1, bridges can have a varying amount of measurement points. For this study, we assume that at least two points are available at each bridge. Therefore, we use the two reflectors 2 and 4 for Bridge A and 1 and 3 for Bridge B, respectively. For comparison, we also train our models with all five reflectors of Bridge A. We split Bridge A data into training, validation, and test sets using a 70:15:15 ratio, with each subset mirroring the overall distribution of single and multi events. Finally, to investigate transferability, we did not train our models on the dataset of Bridge B.

In accordance with Ruiz et al. (2021), we try to minimize the amount of preprocessing, i.e., we did not normalize the time series. We ensure, that all time series start at a displacement of 0 mm by removing the offset. As described in Section 2.2, single events tend to have a smaller maximum deflection. To mitigate this bias, we apply data augmentation in the form of y-scaling. We choose five values in the range of -0.1 mm to -4.0 mm (see Figure 3) superimposed with random values, in which the maximum displacement of each event would be scaled. To tackle the bias in duration, we oversampled all single-events by factors 2 and 3 and downsampled all multi events accordingly. We combine both scalings (xyScale) and compare it to no augmentation (None).

3.2 *Feature extraction*

Both approaches are based on features extracted from the time series. The features of the RF classifiers are listed in Table 2, together with the functions to extract them. We have extracted every feature for each used reflector time series. With 14 features, this yields 28 features for two reflectors and 70 for five reflectors, respectively. We also train an RF after scaling the features and applying principal component analysis (PCA) to reduce the dimensionality. We use eight components since they explain over 95% of the variance for the None dataset.

Unlike manual feature selection, MiniRocket uses random convolutional kernels to extract 9,996 features itself. The properties and specifications of those kernels can be followed by Dempster et al. (2021). We use the sktime implementation (Löning et al. 2019), which can handle variable-length input. The final extracted feature of each convolution is the proportion of positive values (PPV). Theoretically, the number of kernels can be regarded as a hyperparameter. However, Dempster et al. (2021) recommend using 10000 kernels. Due to using the PPV and the bias from the convolution results, normalization is unnecessary.

Table 2. These 14 features have been extracted from the GBR time series data $\underline{x}$. For calculation, the Python-packages numpy and scipy have been used. All non-default values are stated.

Feature No.	Name of Feature	Basis of Calculation
1	Maximum	max($\underline{x}$)
2	Minimum	min($\underline{x}$)
3	Mean	mean($\underline{x}$)
4	Standard Dev.	min($\underline{x}$)
5	Skewness	skew($\underline{x}$)
6	Kurtosis	kurt($\underline{x}$)
7	Median	median($\underline{x}$)
8	Length	ken($\underline{x}$)
9	Quantile25	quantil($\underline{x}$, 0.25)
10	Quantile75	quantil($\underline{x}$, 0.75)
11	NbrPeaks	len(find_peaks($\underline{x}$, distance=4, width=5, rel_height=0.5))
12	xMinPosRatio	argmin($\underline{x}$)/len($\underline{x}$)
13	Power	sum($\underline{x}^2$)/len($\underline{x}$)
14	MAD	median_abs_deviation($\underline{x}$)

3.3 *Machine learning models*

Using the validation set, we apply grid search to the models in the second to last column in Figure 4 to find the optimal set of hyperparameters. Since the dataset is imbalanced, we use "balanced_accuracy" as the score for the grid search. Furthermore, we apply class weights during training. The features extracted from MiniRocket are passed to a classifier.

For small datasets with less than 10000 observations, like in the None case, a ridge classifier is recommended by Dempster et al. (2021). Otherwise, logistic regression, which we use for xyScale, is suggested. Since MiniRocket is independent of y-scaling, we might introduce overfitting to the classifier with our data augmentation approach.

4 RESULTS AND DISCUSSION

The study's objective is to investigate the potential of ML approaches to classify GBR variable-length time series vehicle crossings. Table 3 shows the results of the single vs. multi event classification concerning Overall Accuracy (OA), Precision (P), Recall (RC) and Balanced Accuracy (BA).

Concerning Bridge A with two reflectors, all models have an OA, P, and RC above 90%. However, these values are heavily skewed since single-events are much more present. Therefore, we included BA, the average of recall from each class. All BAs are close to each other, between 82% to 87%, with MiniRocket having the highest score. These results are deceptive, as there are correlations between duration and maximum displacement and event type, as described in Section 2.2. Figure 5 highlights this aspect. The decision boundary for MiniRocket in the left plot almost exclusively depends on the duration, with every event longer than 2.5 s classified as a multi event.

The boundary becomes more complex after applying xyScale data augmentation. Fewer long single-events are now misclassified as multi events, as seen in Figure 5 on the right. Conversely, MiniRocket has more difficulties with medium-length single-events. The effect of xyScale also shows in the BA of all three models. RF and PCA RF achieve a worse BA since they have to find more complex relationships. MiniRocket improves with data augmentation, achieving the best results for two reflectors on one bridge, with a BA of 90%. Considering the small size of the dataset and without providing any prior domain knowledge, these are very auspicious results. Figure 5 also shows that short multi events are still misclassified as single-events. Heavier augmentation in time might solve this issue. When using five reflectors, we did not expect any additional information in those time series, but on the contrary, to achieve worse results due to the higher complexity. Accordingly, RF and MiniRocket achieve equal or worse results. Interestingly enough, PCA RF has better results than with only two reflectors. One explanation could be that the driving side is more distinct with more data, which can help detect multiple events.

Finally, the tests on Bridge B show that a transfer to an unknown dataset can be successful to a certain degree. With None augmentation, all models suffer again under the correlation depicted in Figure 5. The BA is even 90% and above. This score is partially due to the more extensive dataset, where usual events, e.g., cars following a truck, are more prominent, whereas complex events, such as two trucks simultaneously, are rare. The transfer seems challenging for RF and MiniRocket trained with xyScale, since even OA and RC are around 50%. Only PCA RF has values of over 80% and even a BA of 74%. As with five reflectors for Bridge A, the PCA appears to extract robust features. Considering that both bridges have unequal numbers of fields and are of different size, this is a promising result regarding transferability.

Table 3. Test results for all classificators.

Bridge	Number of Reflectors	Data Augmentation	Model	OA	P	RC	BA
A	2	None	RF	0.91	0.97	0.93	0.85
			PCA RF	0.94	0.95	0.98	0.82
			MiniRocket	0.95	0.97	0.98	0.87
		xyScale	RF	0.90	0.94	0.93	0.76
			PCA RF	0.90	0.95	0.94	0.79
			MiniRocket	0.98	0.98	0.97	0.90
	5	xyScale	RF	0.94	0.94	0.99	0.76
			PCA RF	0.95	0.97	0.98	0.87
			MiniRocket	0.94	0.96	0.97	0.84
B		None	RF	0.96	0.97	0.98	0.94
			PCA RF	0.92	0.97	0.93	0.90
			MiniRocket	0.95	0.97	0.96	0.93

			PCA RF	0.84	0.89	0.92	0.74
			MiniRocket	0.59	0.97	0.50	0.72

5 CONCLUSION

This paper introduced a data-driven ML approach to classifying multi-variate GBR time series from bridge vehicle crossings. The GBR data originates from two bridges in Germany, which a UAV also monitors as ground truth. One bridge has been used for training, validation, and testing, whereas the second bridge only served as a test set to evaluate transferability. We also investigated the effect of varying measurement points as input. The classification goal is to differentiate between single- and multi-presence events. Particularly challenging is the variable length of the time series and the correlation of the length with a class. For this purpose, we have examined the potential of data augmentation. Methodically, we implement and apply three different ML approaches. We use an RF with 14 hand-crafted features per reflector as input, an RF that uses the output of a PCA as input. Finally, we compare their performance to MiniRocket, a state-of-the-art ML model in time series classification. It shows that MiniRocket outperforms the other models when applying data augmentation to tackle biases. With a BA of 90%, it achieves satisfying results.

Concerning transferability to an utterly unknown bridge, MiniRocket needs to catch up in BA compared to PCA RF and has only a BA of 74%. Keeping the second bridge out of the training cycle allowed us to test the transferability and reduced the training size, making it more challenging for the models. In the future, we will monitor further bridges from which the models can more easily extrapolate to new structures. Also, pre-training in combination with DL could be exploited to widen our dataset.

In sum, we showed that a data-driven classification of GBR data is possible. These promising results can link an event detection, as described by Arnold et al. (2021), and a GBR-based BWIM, which focuses, in the first step, on single-events. With this, a non-invasive and remote BWIM and SHM would be possible.

Accuracy of BWIM considering autocorrelation in bridge dynamic response

K. Maruyama, I. Yoshida & H. Sekiya
Tokyo City University, Setagaya-ku, Tokyo, Japan

ABSTRACT: Many researchers have developed the bridge weigh-in-motion (BWIM) techniques to estimate axle weight and gross vehicle weight (GVW) of the traveling vehicles. BWIM assumes that the bridge response due to traveling vehicles results from the influence line and the vehicle specification, such as the axle spacing and weight. However, traveling vehicles also cause dynamic responses. In this study, the dynamic response is considered in the observation error with autocorrelation in the time domain. Specifically, it is considered in the covariance matrix of the observation error. The accuracy of three methods, Mehtod-1A; ordinary least square method (OLS), Method-1B; OLS with low-pass filtering of displacement response, Method-2; proposed method considering autocorrelation in bridge dynamic response, are compared. Methods 1B and 2 contribute to enhanced estimation accuracy; however, it is worth noting that Method 1B introduces biases in the estimates due to filtering.

1 INTRODUCTION

In order to maintain the integrity of bridges, it is important to have a system that can efficiently and simply evaluate the current state of the loads acting on the bridge and utilize them for maintenance management. The causes of damage in steel bridges include corrosion and fatigue. In this study, we focus on fatigue, which is caused by repetitive stresses due to moving vehicles. In particular, high stresses caused by heavy vehicles have a significant impact on fatigue.

Gross vehicle weight (GVW) and axle weights are sometimes estimated by gauges installed at toll gates. However, these gauges have some problems such as the need for traffic control during installation and high cost. As a system for measuring traffic loads using bridges, Bridge weigh-in-motion (BWIM) was proposed by Moses in the 1970s (Moses, 1979). BWIM is a method of estimating the axle weights by considering the bridge as a weighting scale, measuring the strains or displacements of the bridge caused by the moving vehicle. Over the past several decades, BWIM technology has attracted attention as a promising tool for overweight enforcement, fatigue prediction and maintenance planning over the past few decades.

Throughout the past few decades, numerous BWIM algorithms have been developed, aiming either to estimate static axle weights or to identify the dynamic time history of axle forces in moving vehicles (Yu et al. 2016). The former methods are more straightforward, as they assume that the bridge response attributed to a moving load can be expressed as the product of the influence line and the axle weight (He et al. 2019, Lydon et al. 2016). Yoshida et al. (2021) proposed Bayesian BWIM (BBWIM). Within the BBWIM framework, conventional BWIM can be interpreted as assuming white noise for observation and modeling errors (Yoshida et al. 2023). In this paper, we investigate the accuracy of estimated weights using the conventional method with/without filtering, and BBWIM considering autocorrelation in bridge dynamic response. The study utilizes synthesized observation data of bridge displacement with colored noise.

2 ALGORITHM FOR BWIM

2.1 *Method-1, Conventional method*

Moses' proposed algorithm for static BWIM has gained widespread utilization. This algorithm employs the least-squares method to estimate axle weights by minimizing the sum of squared residuals between the measured and the predicted bridge response. The predicted bridge response is calculated based on influence line and information regarding the target vehicle. The predictive equation for the bridge response derived from the influence line is denoted by equation (1).

$$\boldsymbol{z}_D = \boldsymbol{H}_I \boldsymbol{x}_W + \boldsymbol{v} \tag{1}$$

where $\boldsymbol{z}_D$ denotes the measured bridge response (In this study, displacement response), $\boldsymbol{H}_I$ represents an influence line matrix, $\boldsymbol{x}_W$ represents a vector comprising axle weights, and $\boldsymbol{v}$ represents a vector of residual between the measured and predicted responses essentially, the observation and modeling error. The formation of $\boldsymbol{H}_I$ is contingent upon the axle information from vehicles in each data, with the number of columns aligning with the total axle count across all vehicles. For more details, refer to previous publication (Yoshida et al., 2023).

The conditional probability $P(\boldsymbol{x}_W|\boldsymbol{z}_D)$ for a given observation value $\boldsymbol{z}_D$ can be calculated from Bayes' formula.

$$\boldsymbol{P}(\boldsymbol{x}_W|\boldsymbol{z}_D) = \frac{P(\boldsymbol{z}_D|\boldsymbol{x}_W)P(\boldsymbol{x}_W)}{P(\boldsymbol{z}_D)} \tag{2}$$

The concept of maximum a posteriori (MAP) estimation is widely known in a Bayesian inverse problem. The MAP estimate for the optimal x value is obtained by maximizing the logarithm of the numerator, which is the product of the conditional probability $P(\boldsymbol{z}_D \mid \boldsymbol{x}_W)$ and the prior probability $P(\boldsymbol{x}_W)$. The solutions derived are dependent on the selection of prior information. To achieve solutions independent of this selection, non-informative priors can be employed, where axle weights are estimated solely from the measured bridge response induced by a passing vehicle. For a non-informative prior, a prior with a uniform distribution or a Gaussian distribution with a very large standard deviation can be assigned. In this case, the objective function is represented by the following residual sum of squares:

$$J = (\boldsymbol{z}_D - \boldsymbol{H}_I \ \boldsymbol{x}_W)^T \boldsymbol{R}^{-1} (\boldsymbol{z}_D - \boldsymbol{H}_I \ \boldsymbol{x}_W) \tag{3}$$

where $\boldsymbol{R}$ is the covariance matrix of $\boldsymbol{v}$. When the residual $\boldsymbol{v}$ is independent and identically distributed (i.i.d.), $\boldsymbol{R}$ is given by the following:

$$\boldsymbol{R} = \sigma_{\boldsymbol{R}^2} I \tag{4}$$

where $\sigma_{\boldsymbol{R}^2}$ is the variance of the residual, $\boldsymbol{I}$ is identity matrix. The MAP estimate that minimizes equation (3) is obtained by

$$\hat{\boldsymbol{x}}w = \left(\boldsymbol{H}_I^T \boldsymbol{H}_I\right)^{-1} \boldsymbol{H}_I^T z_D \tag{5}$$

2.2 *Method-2, BBWIM method considering autocorrelation in bridge dynamic response*

The underlying assumption posits that the bridge displacement response can be effectively decomposed into two distinctive components: a static component associated with the vehicle weight and a dynamic component arising from the first vibrational mode of the bridge. Equation (4) corresponds to assuming that the residual is uncorrelated noise in the time domain, i.e., white noise. However, as shown in Figure 1 which indicates an example of dynamic component of actually measured bridge response caused by a moving vehicle, the noise or residual $\boldsymbol{v}$ is clearly correlated and is not white noise. The proper modeling of the covariance matrix $\boldsymbol{R}$ necessitates the inclusion of non-diagonal components (Yoshida et al. 2023). The correlation

of the residual in the time domain is considered in the autocorrelation matrix $\boldsymbol{C}$. The autocorrelation function $cor(j\Delta t)$ for the dynamic component is calculated numerically using

$$cor(j\Delta t) = \frac{1}{m\sigma_{R^2}} \sum_{i=1}^{m-j} v(i\Delta t)v(i\Delta t + j\Delta t) \tag{6}$$

where Δt is the time increment, $t = i\Delta t$, $\tau = j\Delta t$, and m is the number of measured data points. The autocorrelation matrix $\boldsymbol{C}$ is calculated by the autocorrelation function. The autocovariance matrix $\boldsymbol{R}$ is derived by taking the product of the autocorrelation matrix $\boldsymbol{C}$ and the variance of the residuals σ_R^2.

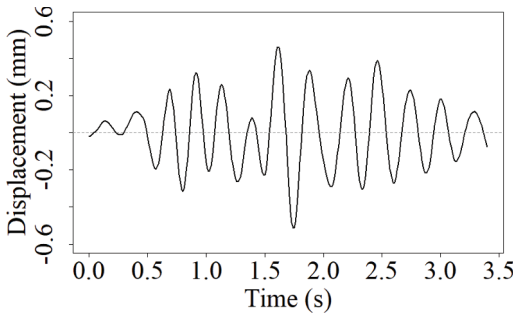

Figure 1. Dynamic component in measured data.

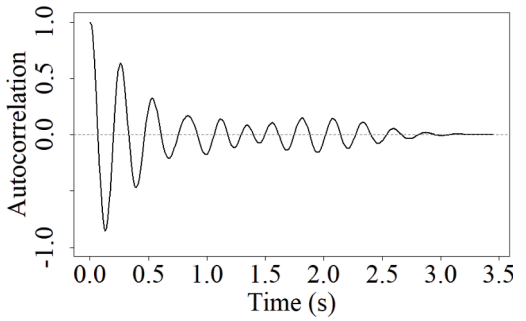

Figure 2. Autocorrelation function of dynamic component in measured data.

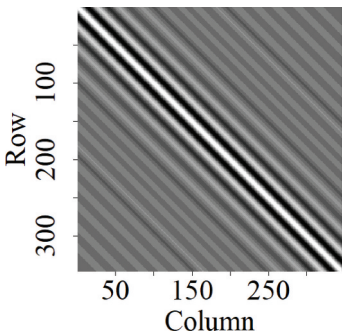

Figure 3. Contour map of autocorrelation matrix C of the dynamic component.

$$\boldsymbol{R} = \sigma_{\boldsymbol{R}^2 C} \tag{7}$$

The least-squares solution that minimizes equation (3) is obtained by

$$\hat{\boldsymbol{x}}_W = \boldsymbol{P}\boldsymbol{H}_I^T \boldsymbol{R}^{-1} z_D \tag{8}$$

$$\boldsymbol{P} = (\boldsymbol{H}_I^T \boldsymbol{R}^{-1} \boldsymbol{H}_I)^{-1} \tag{9}$$

where $\boldsymbol{P}$ is the posterior covariance matrix of the estimate $\hat{\boldsymbol{x}}_W$.

3 SIMULATED COLORED NOISE FOR SYNTHESIZED OBSERVATION DATA

The simulated colored noise is synthesized based on the dynamic components in an actual measured data, which is shown in Figure 1. The autocorrelation function of the dynamic component is calculated by applying equation (6). Figure 2 illustrates the autocorrelation function of the dynamic components (Figure 1) observed in the measured data. The contour map of the autocorrelation matrix $\boldsymbol{C}$ of the dynamic component is shown in Figure 3. When white noise is assumed, in other words, when using the conventional method (Method-1), the diagonal component of $\boldsymbol{C}$ takes a value of 1, and the others take a value of 0. For colored noise, it takes values between 0 and 1 dependent on the distance from the diagonal component (time lag). The simulated colored noise is generated based on the autocorrelation matrix $\boldsymbol{C}$ (Figure 3) of dynamic component in the measured displacement response. Ten generated colored noises are shown in Figure 4. The standard deviation of the simulated colored noise is assumed to be 5% of the maximum amplitude for static component. The dynamic component in the measured data displays non-stationarity, while the simulated noise conforms to a stationary pattern. Delving into the consideration of non-stationarity is recognized as a promising avenue for future research.

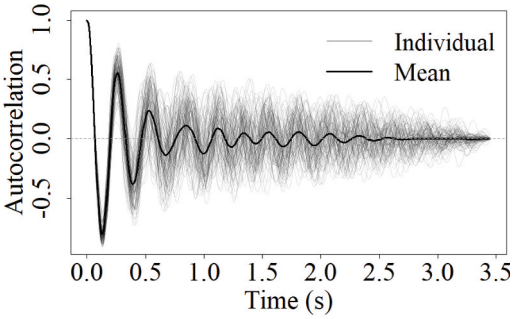
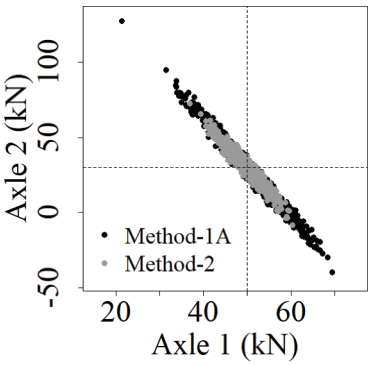
4 ESTIMATION OF AXLE WEIGHTS BY METHOD-1 AND -2

4.1 *Procedure for estimation of accuracy of the methods*

Monte Carlo simulation (MCS) of estimation of axle weights is performed by using the simulated displacement response with colored noise to investigate the validity of modeling the covariance matrix $\boldsymbol{R}$. In the MCS, 1000 response displacement time histories with autocorrelation are gane-rated, and then axle weight and GVW are estimated for each synthesized response data.





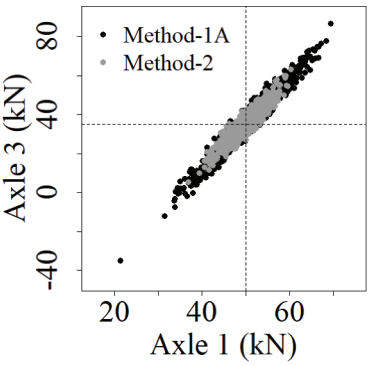


Figure 7. 100 autocorrelation functions calculated from the dynamic components of a three-axle vehicle single driving and their mean.

(a) Comparison of Axle 1 and 2

(b) Comparison of Axle 1 and 3

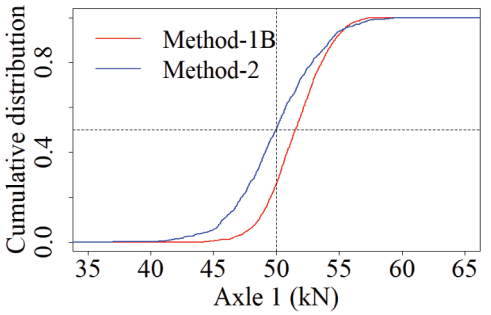
Figure 8. The scatter plot of estimated axle weights.

The moving vehicles are assumed to be two-axle and three-axle. The vehicle specifications are shown in Figure 5. The measurement section of the bridge is 30 m in length with two lanes, one for driving lane and the other for passing lane. It is assumed that the influence line is estimated by the displacement response measured at the center of middle girder. The influence line is used for both lanes because the cross section of the bridge is symmetrical.

In this study, two cases of driving conditions are assumed. Case-1 is single driving of three-axle vehicle, and Case-2 is in-line driving of two-axle and three-axle vehicle. In both cases, the vehicle speed is constant at 10 m/s (36km/h). Figure 6 shows examples of synthesized displacement responses including simulated colored noise for each case. The estimation accuracy of three methods is compared. Method-1A is ordinary least square method (OLS), which is conventional method, uses identity matrix for correlation matrix $\boldsymbol{C}$. Method-1B is also a conventional method, however it uses a 1 Hz low-pass filter to remove dynamic component from the observation data for BWIM. These two methods estimate the axle weight using equation (5). Method-2 considers the dynamic component in the covariance matrix $\boldsymbol{R}$ and uses equations (8) and (9).

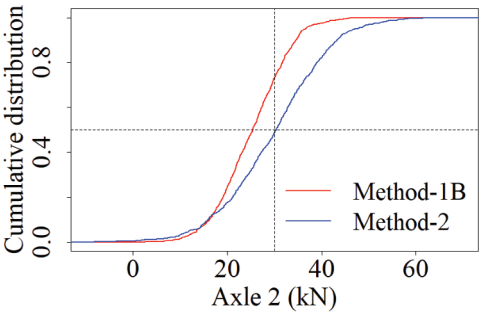
Method-2 employs a correlation matrix $\boldsymbol{C}$, estimated as the mean of the autocorrelation functions derived from 1000 simulated colored noises. An example of the autocorrelation function $cor(j\Delta t)$ assuming single driving of a three-axle vehicle is shown in Fig. 7.

4.2 *Case-1, single driving case*



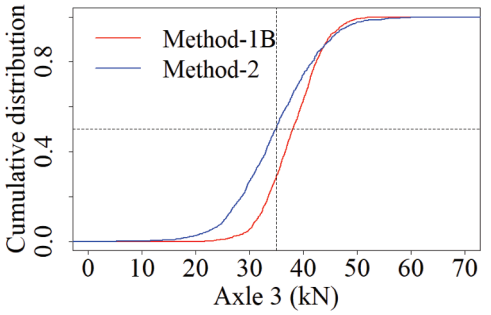
Single driving case of the three-axle vehicle namely, Case-1 is discussed in this section. The 1000 estimated weights of a three-axle vehicle for the 1000 synthesized observation data are shown in Figure 8. This figure compares estimated weights by Method-1A and Method-2. The dash lines in the figure show the actual weight of each axle. As can be seen in the figure, strong negative correlation is observed between adjacent axles, which means when the first axle weight estimate is larg.er (smaller) than the true value, the second axle estimate tends to be smaller (larger). The standard deviations of the estimated weights are summarized in Table 1. The standard deviations of the estimated axle weights using Method-1A are approximately twice those for Method-1B (with low pass filter) and Method-2.

Table 1. The standard deviations of the estimated axle weight by each method.



Method	Axle 1	Axle 2	Axle 3
1A	6.39	21.23	15.31
1B	2.35	7.26	5.20
2	3.35	10.87	7.80

Figure. 9 compares the cumulative distribution functions (CDFs) of each estimated axle associated with the Method-1B and Method-2. In the case of Method-2, the median values (i.e., the values for a cumulative probability of 0.5) of all three CDFs closely match the actual weights shown by the vertical dashed line. Method-1B has the smallest standard deviation among the three cases, however, it shows a bias (relative errors of the mean values). The bias of the first, second and third axle weight estimated by Method-1B are 3.1, -15.6, and 8.7 % respectively. The low pass filter (Method-1B) reduces the variability of the estimation results, however causes bias due to the distortion of the displacement response caused by the filtering.



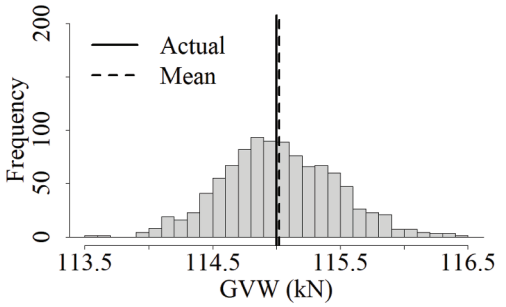
A histogram of the GVW estimated by each method is shown in Figure 10. The standard deviations of the estimated GVW by Method-1A, -1B, and -2 are 0.44, 0.22, and 0.22, respectively. Similar to the axle weight, Method-2 demonstrates an enhancement in estimation accuracy for GVW. The bias of the estimated GVW by Method-1A, -1B and -2 are 1.8×10^{-2}, 10.0×10^{-2}, 0.4×10^{-2} % respectively, which are extremely small by all methods. No significant bias is observed even with Method-1B. Conventional BWIM systems, employing Moses' method (Method-1) that overlooks dynamic components in the measured response, can

(a) Axle 1

(b) Axle 2

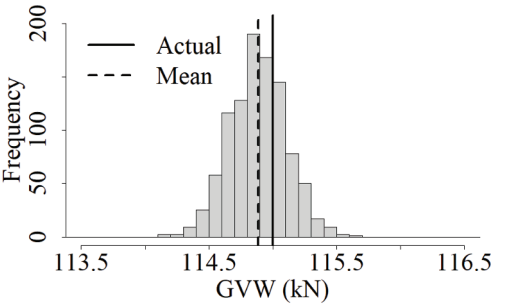
(c) Axle 3

Figure 9. The cumulative distribution function of axle weights estimated by Method-1B and -2.



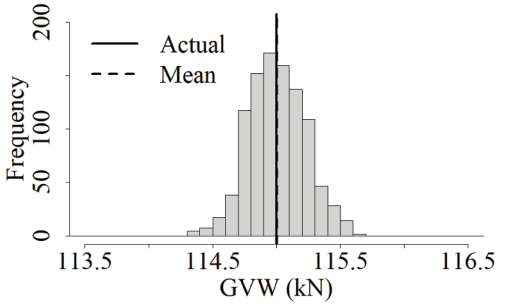
provide reasonably accurate estimates of GVW. However, in situations where precise axle weight information is crucial, such as in pavement maintenance applications (Pais et al., 2013), it is advisable to utilize Method-2 (BBWIM). This method, which considers the auto-correlation of observation noise, proves instrumental for the precise estimation of axle weights.

Table 2. The bias of measured gross vehicle weight in Case-2 [$\times 10^{-2}$ %].



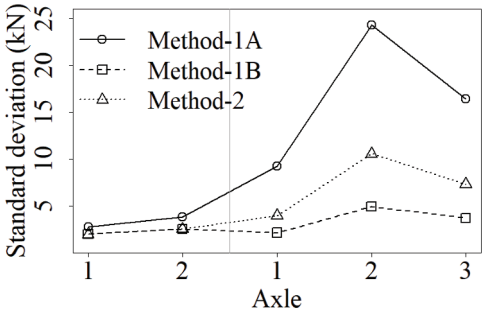
Test vehicle type	Method-1A	Method-1B	Method-2
Two-axle	0.2	12.9	3.2
Three-axle	3.6	-18.2	0.1

4.3 *Case-2, in-line driving case*

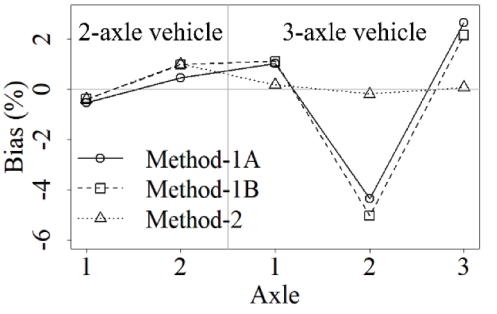


A case involving two vehicles, referred to as Case-2, is also studied. The distance between vehicles is assumed to be 10 m. Parameters such as the axle weight are the same as in Case-1. As in Case-1, 1000 synthesized responses were generated for the observation data to estimate axle weights and GVW. Figure 11(a) summarizes the standard deviations of the estimated axle weights by the three methods. As in Case-1, the standard deviations by Method-1B, -2 are much smaller than those by Method-1A. The improvement in estimation accuracy is more pronounced for three-axle vehicles than for two-axle vehicles. This suggests that Method-2 is more effective for vehicles with a larger number of axles and shorter axle spacing. The bias in the estimated axle weights, as shown in Figure 11(b), is significantly reduced, particularly for

(a) Method-1A



(b) Method-1B



(c) Method-2

Figure 10. Comparison of estimated gross vehicle weight.

(a) Standard deviation of estimated each axle weight

(b) The bias of estimated each axle weight

Figure 11. Comparison of estimated axle weight in Case-2.

the second axle of a three-axle vehicle, when using Method-2. As shown in Table-2, the bias in GVW estimation is small as in Case-1.

5 CONCLUSION

In conventional BWIM, the residual, configured observation and modelling errors, is typically handled by presuming identical and independent noise within a probabilistic framework. In this study, a comparative accuracy analysis was carried out for three methods: conventional BWIM (Method-1A), conventional BWIM with low-pass filtering (Method-1B), and Bayesian

BWIM (Method-2). The evaluation was performed via a series of numerical simulations employing synthetic data. Method-2 specifically considers the autocorrelation of dynamic components within bridge responses using the covariance matrix $\boldsymbol{R}$. While both Method-1B and Method-2 result in a reduction of the standard deviation of the estimated weights, Method-1B shows biases in estimated weights due to the influence of filtering. Notably, the BBWIM method (Method-2) proves advantageous as it does not incur a significant computational cost, making it suitable for real-time vehicle monitoring.

In this study, the covariance matrix $\boldsymbol{R}$ is derived from the dynamic component, assuming stationary correlated observation noise. However, it is acknowledged that some measured data exhibit strong non-stationarity. The consideration of such non-stationarity is deferred for future exploration.

ABSTRACT: Bridge Weigh-In-Motion systems can be installed and serviced on highway bridges to provide measurements of truck traffic without interrupting traffic. This paper presents the application of Gaussian Process Modeling to BWIM. The Kriging metamodeling approach, allows for the strategic selection of training vehicles to generate a BWIM metamodel. The proposed approach extends the BWIM concept of influence area from response time histories to geometric input spaces from the strain response wave. The simulated dynamic response of simply supported bridges in the US Interstate Highway System were performed using Finite Element Modeling of moving loads, generating response waves. Geometric properties of the response waves are the input to train the Kriging metamodel of a predefined training truck group. The performance of the prediction of the GVW is evaluated with the ASTM WIM Standard.

1 INTRODUCTION

Cost effective solutions through Transportation Infrastructure Management approach can support decision making regarding the investment of limited resources. Managers collect high quality data to offer the best information to the stakeholders. Data regarding individual bridge structural conditions and the functional characteristics of the traffic continuously populate large databases to provide quality information for managers to aid in decision making. Examples of this data include the number of axles and the gross vehicle weight (GVW) of heavy truck traffic. This information can be used for the structural design of future bridges and assessment of the remaining service life of current infrastructure.

Weigh stations are the traditional way of obtaining such information with a very accurate result. However, weigh stations are costly and time-consuming to implement. In this context, the concept of smart infrastructure, specifically Weigh-In-Motion (WIM) technology, is an alternative tool that can provide valuable data. The original concept of WIM systems, called Pavement Weigh-In-Motion (PWIM), is to place sensors directly into the pavement, measuring vehicle properties while they cross over the sensors themselves. Although these systems are advantageous, their installation requires lane closures, putting workers in potentially dangerous situations adjacent to moving traffic; and damaging the pavement by cutting or excavating for sensor installation. Further, the dynamic interaction between the pavement and the truck can significantly affect the error in the results (Wall et al, 2009).

DOI: 10.1201/9781003483755-166

Another WIM approach, suggested initially by Moses in 1979 and known as Bridge Weigh-In-Motion (BWIM), is to instrument the structural members of a bridge and use the bridge itself as a calibrated sensor. This approach, installing relatively inexpensive sensors underneath the bridge, provides a cost-effective solution without the costs and risks to construction workers, and damage to the pavement associated with PWIM sensors. There are a variety of proposals for sensor types and locations, and methods for post-processing the raw data recorded by BWIM systems (Yu et al, 2016). For example, the Moses' proposal (1979) is based in minimization of the error between the predicted bending moment and the measured bending moment of a beam-slab bridge. Ojio and Yamada (Ojio & Yamada, 2002) introduced the influence area method, calculating the area under the strain response curve, adjusting for velocity, and using a calibration factor identified from a test calibration truck. Orthotropic algorithms use different optimization routines to minimize the error objective function. Some of these optimization methods are the conjugate direction method (Jacob et al, 2001), genetic algorithms (Jiang et al, 2004; Au et al, 2004; Deng & Cai, 2009), least-squares method and regularization technique (Law et al, 2006). The reaction force method (Ojio & Yamada, 2002; Muñoz et al, 2011) uses the influence line of the reaction force, which allows the axle detection. Other approaches like artificial neural networks (Kim et al, 2009; Hitchcock et al, 2012) offer similar accuracy with the traditional BWIM algorithm using the influence line concept without any knowledge of the bridge behavior. Lobo-Aguilar and Christenson (2019) proposed a simplified approach for shear strain data measured at one third of the span using the difference of magnitude at the discontinuity of record. These methods can be potentially improved using Artificial Intelligence. In this paper, the Kriging metamodeling technique is used as a data post-processing tool that provides a prediction of GVW. Various input parameters are considered to develop general rules for different scenarios, varying the length of the simulated bridges and simulated sensor location.

Kriging, also known as Gaussian process modeling or best linear unbiased prediction (BLUP), is a stochastic modeling algorithm used for generating a simpler model of a complex problem. Gaussian process prediction is used for interpolation, regression, and prediction (Rasmussen & Williams, 2006; Sacks et al, 1989). Applications in two- and three-dimensional input spaces can be found in geostatistics, environmental science, hydrogeology, environmental and climate models, among other specialties. Modern geographic information systems (GIS) include Kriging as an analysis tool. Broader research has demonstrated that Gaussian process prediction could be used in a general context. Sacks et al. (1989) described Gaussian Process Regression (GPR) in computer experiments, and Williams and Rasmussen (1996) described GPR in the machine-learning context. Additionally, Sakata et al. (2003) evaluated the applicability of Kriging metamodeling method to engineering structural optimization providing a stiffened cylinder example. Raponi et al. (2019) proposed the Kriging-Guided Level Set Method (KG-LSM) for the topology optimization of crash structures in both linear elastic and non-linear test cases, addressing the limitations of the state-of-the-art methods for crashworthiness due to strong nonlinearities and discontinuities characterizing the problem. Dang et al. (2020) approximated the dynamic responses of dynamic structures under seismic excitations with Kriging metamodels and then used them to construct fragility curves of the structures. Ligeikis and Christenson (2020) used Principal Component Analysis (PCA) and Ordinary Kriging to metamodel frequency response functions magnitude and phase vectors obtained in experimental structural dynamics tests.

This paper explores critical aspects needed to apply Kriging metamodeling to BWIM GVW prediction. Metamodels were trained with geometrical properties and PCA of the horizontal strain response waves as input space parameters and the GVW as metamodel output. The metamodels were used for GVW prediction and the results compared to the weight data generated in the simulation. Different bridge lengths, sensor locations, training groups, and pre-processing techniques were explored. General rules are identified to aid users in the application of Kriging metamodeling for BWIM of various bridges.

2 THERORETICAL AND EXPERIMENTAL BACKGROUND

2.1 *Kriging metamodeling*

Originally developed as a spatial interpolation tool in geo-statistics (Krige, 1951), Kriging was first proposed as a metamodeling method for computer experiments by Sacks et al. (1989). Metamodeling can reduce the associated computational costs by substituting an expensive computational model with a metamodel, a functional approximation of the original model that is much faster to evaluate.

Several variations of Kriging exist with varying levels of complexity (Christensen, 2001; Wackernagel, 2003; Santner et al, 2003). Ordinary Kriging (OK) is the most widely used Kriging method and was employed for this study. The correlation function (also called kernel or covariance function) relates the correlation between two input samples being crucial in the application of Kriging. There are many different correlation functions that can be used for metamodeling purposes (Lataniotis et al, 2020). Stein (1999) recommended the Matérn (1986) class kernel covariance for physical processes, which was utilized for this study.

2.2 *Geometric manipulation of response waves to generate input spaces*

All the theory behind the generation of Kriging input spaces from the RW can be found Agüero-Barrantes (2022). In these manipulations, the dimensionality of the strain waves is reduced by the calculation of the geometric properties under the curve (centroids and area) and its perimeter. Another proposed parameter is the first principal component of the application of PCA (Jolliffe, 2002). Subsequently, vectors of these new parameters are used as inputs to a Gaussian process model to approximate the weight of the passing vehicles.

2.3 *Experimental validation*

The experimental validation of this research was published in Agüero-Barrantes et al (2022) where the results of the application of this proposal were performed in a single-span simply supported steel bridge. The experimental results demonstrated that a comparable WIM performance for GVW prediction (ASTM, 2017) was obtained comparing the results are with other BWIM methodology (Agüero-Barrantes et al, 2021) with advances in terms of sensor reduction, installation ease, and data processing.

3 FINITE ELEMENT SIMULATION

In order to provide further insight into BWIM, simulations of the traffic stream and the RW are performed. The following general procedure is presented for every Kriging metamodel input space explored.

Finite element modeling (FEM) of a single-span simply supported bridge was developed. The structure was modeled with beam-type elements with vertical and rotational degrees-of-freedom to include displacements, velocities and accelerations. The vehicle axles were modeled as impulsive loads crossing over a beam at constant velocity, which does not interact dynamically with the bridge, which is reasonable assumption for the purpose of this paper purposes (Yang et al, 2004). The FEM simulation was verified using prior BWIM measurement in Connecticut and Costa Rica (Lobo-Aguilar, 2018; Agüero-Barrantes et al, 2021).

The chosen scenario for the BWIM simulation is the US Interstate Highway System. The simulated vehicle types where chosen based on the most representative vehicle classes moving across the United States according to USDOT (2000). The vehicles used for this study (FHWA classes 06, 08, 09, and 10) cover 84.1% of the truck fleet and 86.2% of the travels on US highways. After selecting the vehicle classes, the axle spacing criteria is based on AASHTO (2018) and Hallenbeck et al (2014). The traffic speed range is based on De Leonardis et al (2018).

Further detail of this simulation criteria can be found in Agüero-Barrantes (2022).

4 PREPROCESSING, METAMODELING AND PERFORMANCE CRITERIA

Ordinary Kriging was chosen to implement BWIM for this study. The MATLAB-based uncertainty quantification framework UQLab (Marelli & Sudret, 2014, Lataniotis et al, 2020) was used for the metamodeling generation. In this research, a gradient-based optimization was selected to maintain repeatability in the results. UQLab uses the MATLAB function fmicon() in the gradient-based optimization case. Homogeneous (homocedastic) noise variance was included in the metamodeling calculation, available through the UQLab's command SigmaNSQ.

The performance reported in this research is based on ASTM E1318 standard (2017), which defines the functional performance requirements for PWIM systems that predicts the GVW of vehicles. The ASTM E1318 standard specifies that 95% of the GVW values produced by the WIM system must be within the tolerance limit. The tolerance limit for GVW is ±10% for WIM Systems Type I and ±15% for WIM Systems Type II. For reference purposes, all GVW prediction results include these limits, however, in this research an ASTM E1318 calibration simulation was not performed since the calibration group specified in the standard does not work well the proposed Kriging methodology. The calibration truck criteria used here included three trucks, specifically one three-axle (class 06), one four-axle (class 08), and one five-axle truck (class 09) with variable loading conditions, as described in Agüero-Barrantes (2022). A comparable number of ASTM's calibration runs were proposed to train the Kriging metamodel with the geometric input approach.

In regards of preprocessing, the MATLAB's function cluster() using a Gaussian Mixture Model (GMM) as input was the clustering technique tested in this research. The GMM model was generated with the function fitgmdist(). When clustering is used, more than one metamodel is generated to predict the GVW of the traffic stream. The data clusters are assigned to the corresponding metamodel to improve the performance of the GVW prediction. Strain response wave data can be filtered to retain the static behavior of the bridge using a low-pass filter (LPF). In this study, the simulated response wave data was filtered with an eight-pole LPF with a cut-off frequency of 70% of the first natural frequency of the bridge, as an additional preprocessing tool to compare with non-filtered data results.

5 RESULTS FROM FEM SIMULATION

Three input spaces were explored after FEM simulation, data preprocessing, and geometric-based input space generation. The first input space to explore, tagged as IS1, is based on the area under the response wave A_{RW} and the centroid of this area in the time axis t_c (horizontal centroid); the second and third input spaces tagged as IS2 and IS3, are detailed in Agüero-Barrantes (2022).

Multiple bride lengths (S= 20.4 m, M= 41.1 m, L= 54.9 m), sensor positions (CE= close-to-end, MS=mid-span) and training groups were considered in the simulation. For example, Figure 1 shows the performance of the IS1 prediction based on 1000 vehicles using FEM simulation to generate RWs. The results are sorted by training group (tagged as group A and B) and after that by the highest percentage of compliance between the ±10% tolerance limit (Type I) represented by black bars, and finally by the highest percentage of compliance between the ±15% tolerance limit (Type II) represented by grey bars.

Type II performance is fulfilled (95% or higher compliance) in all length cases of CE sensor location with no preprocessing, with small influence of the training group. That means that preprocessing (clustering or filtering) does not improve the performance for CE sensor location. When the sensor is placed at MS and no preprocessing is performed, the Type II performance is fulfilled in three simulation cases, the clustered data results improved the performance, however the results from LPF data improve the performance from three to five compliant cases.

Regarding Type I performance fulfillment (95% or higher compliance), only two cases are compliant. The first case is the 27.3 m-long (90 ft) bridge with a close-to-end sensor location and GMM cluster preprocessing (tagged as S/CE/GMM in Figure 1a), trained with group A, where

the GMM clustering was able to improve the Type I performance from 89.5% between the ±10% tolerance limit (without clustering) to 95.8% with GMM clustering. The second case corresponds to the 54.9 m-long (180 ft) bridge with a close-to-end sensor location and LPF preprocessing (tagged as L/CE/LPF in Figure 2a), trained with group B, where the GMM clustering was able to improve the Type I performance from 68.7% between the ±10% tolerance limit (without clustering) to 95.3%.

Full performance results, including IS2 and IS3, can be found in Agüero-Barrantes (2022).

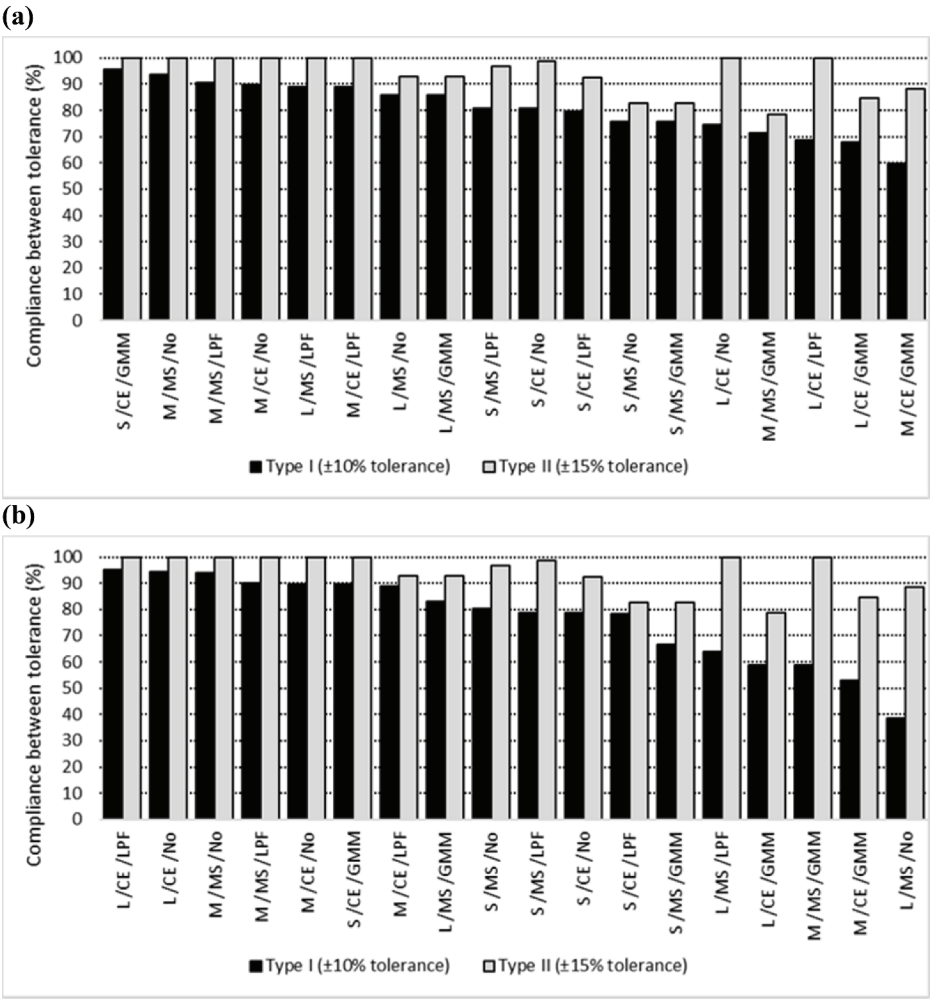

Figure 1. IS1 simulation performance analysis for (a) Group A, (b) Group B (CE= close-to-end, MS=mid-span, S= 20.4 m, M= 41.1 m, L= 54.9 m).

6 CONCLUSIONS

This paper presents a summary of the applied methodology to predict the GVW of moving trucks, based on simulated traffic data, and using Kriging metamodeling to ease the calculation process. This analysis provides insight of the artificial intelligence application to BWIM. Different geometric input spaces, bridge lengths, sensor locations, training groups, and preprocessing techniques were studied. This research demonstrates very promising results to use

Kriging metamodeling for the GVW prediction with a single sensor, without measurement or calculation of the vehicle velocity.

An example was presented, based on the ASTM E1318 performance requirements for WIM systems, Type II performance can be fulfilled for all analyzed bridge lengths with close-to-end sensor location and no preprocessing. Regarding satisfying the Type I WIM system performance, it is compliant in some cases involving Gaussian Mixture Model clustering and Low Pass Filtering. The upcoming challenge to investigate Kriging metamodeling for GVW prediction is to improve the performance to fulfill Type I WIM system requirements. It is recommended to analyze the spatial correlation of the input-output space data, developing BWIM specific covariance functions.

Challenges of implementing bridge weigh-in-motion on a century-old steel-riveted railway bridge

D. Hekič, M. Kosič, J. Kalin, A. Žnidarič & A. Anžlin
Slovenian National Building and Civil Engineering Institute, Ljubljana, Slovenia

ABSTRACT: This study explores the challenges and methodologies involved in implementing bridge weigh-in-motion (B-WIM) system on a century-old steel riveted railway bridge. A unique aspect of this study, funded by the EU H2020 Shift2Rail Joint Undertaking, was the adaptation of B-WIM systems to the specific constraints of railway bridges since, traditionally, this technology is used to collect heavy gross vehicle loading data on road bridges. The paper details the experimental setup on an old steel-riveted railway bridge, including sensor placement and calibration processes. It highlights the complexities encountered, such as differences in bridge response due to passenger and other type of trains. It introduces the system calibration strategy using known axle loads from passenger locomotives. The study provides insights into the structural response of old steel bridges under traffic loads, contributing valuable data to the field of railway bridge monitoring and maintenance.

1 INTRODUCTION

With a few exceptions (Liljencrantz et al. 2007), the bridge weigh-in-motion (B-WIM) systems have been primarily used for road bridges. The BridgeMon project (Ni Choine et al. 2014) showed that the algorithms used for road bridges can be adapted for use on railway bridges, with some constraints related to vehicle design. At the same time, B-WIM measurements within the Assets4Rail project (Anžlin et al. 2020) exposed some new challenges, likely associated with the complex behaviour of old steel bridges (Lachinger et al. 2021).

This recently concluded project, which received funding from the Shift2Rail Joint Undertaking under the EU H2020 funding, aimed to contribute to the modal shift by developing new railway asset monitoring and maintenance technologies. Part of the project was the fatigue lifetime assessment of existing steel railway bridges, considering realistic traffic loads and structural response under actual traffic loads. Performing B-WIM measurements on a century-old steel riveted bridge and under all the traffic on the bridge required some simplifications of the applied procedures. One was the B-WIM system calibration procedure, which applies axle loads and distances of statically weighed calibration vehicles as a reference. In this case, the system was calibrated using axle loads and distances of a passenger train locomotive taken from the publicly available technical specifications.

The implemented strategy worked well for random passenger trains. However, deviations have been observed when correlating the B-WIM weights of the trains with the measured displacements near the mid-span of the bridge. This paper presents the calibration procedure and monitoring results and discusses possible reasons for the load-dependent phenomena and/or challenges at B-WIM weights estimation.

2 TEST BRIDGE DESCRIPTION

The tests were performed on a 100-year-old steel-riveted bridge, shown in Figure 1. The bridge consists of two parallel steel superstructures placed on masonry abutments, spaced

DOI: 10.1201/9781003483755-167

16 m from each other and positioned obliquely to the track alignment. The distance between the structural bearings is 18.5 m. Each superstructure is 5 m wide, and the height between the rolling surface and the road below is 4.8 m. The superstructure is designed as a grillage made of steel sections connected with rivets and no welds.

Figure 1. View from the top (left) and bottom (right) of the old steel riveted bridge.

The main (plate) girders are 210 cm high and 1.2 cm thick. Its upper and bottom flange are both 25 cm wide. Close to the bridge mid-span, the thickness of the bottom flange is increased to withstand the bending moments. The 75 cm high cross girders with 32 cm width flanges distribute the load between the two main girders. The stringers (secondary longitudinal beams), placed under the railway sleepers, distribute the load to the cross girders. They are 50 cm high with 25 cm wide flanges. 1.2 cm thick steel plates are used for all stringers. The track consists of UNI 60 rails and indirect and rigid fastening systems. The wooden sleepers are anchored to the structure with metal anchor bolts.

Besides structural elements whose primary purpose is to carry vertical loads, bracing below the deck, made primarily of riveted L steel sections, carries horizontal loads. It consists of wind bracing (WB) and lateral torsional buckling bracing (LTB) of longitudinal beams.

3 EXPERIMENTAL SETUP

The bridge measurement system considered various types of sensors. The 3-axial MEMS accelerometers (DEWESoft 2023) were labelled from A01x, A01y, A01z to A12x, A12y, A12z. Four inductive strain transducers, labelled e1 to e4, measured strain in micrometres per meter (μm/m). The setup also comprised two linear variable differential transformers, LVDT1 and LVDT2, for measuring displacement. The 12 foil-type strain gauges, labelled SG01 to SG10, SMP1 and SMP2, acquire the strains in μm/m. Sensors SG01 to SG10 were used to measure the structural response, while SMP1 and SMP2 captured strains in railway rail for B-WIM axle and velocity detection purposes. The disposition of the sensors in plain view is shown in Figure 2.

After on-site inspection, the initial sensor disposition had to be adjusted as some locations were unsuitable for the sensor installation. The geometry of the entire bridge was measured on-site, and a 3D model with final sensor disposition was created (Figure 3). This model served as geometry input for creating the BIM model and integrating the sensor data in the BIM model, which was a separate test of the EU project.

Strains from the SG07 sensor installed at the midspan of the S2_L element were used to calculate the axle loads of the ongoing traffic. SG06 sensor was installed parallel to the SG07 sensor at the S2_R element. E1 sensor was installed at the midspan of the WB diagonal, which connects the CG1 and CG2 elements. SG05 was installed at the top flange of the CG4 element, and SG06 was installed at the bottom flange. SG09, SG10, and E3 sensors were mounted on the S2_L element, as shown in Figure 4.

The accelerometers A09-A12 were installed on the top flange of the PG elements, and the A01-A08 on the bottom flange. Displacements were measured with LVDT1 and LVDT2 at the left and right PG midspan, respectively. SG03 and SG04 captured strains in PG at LVDT1 and LVDT2 locations, respectively. SMP1 and SMP2 sensors were glued on the bottom side of the

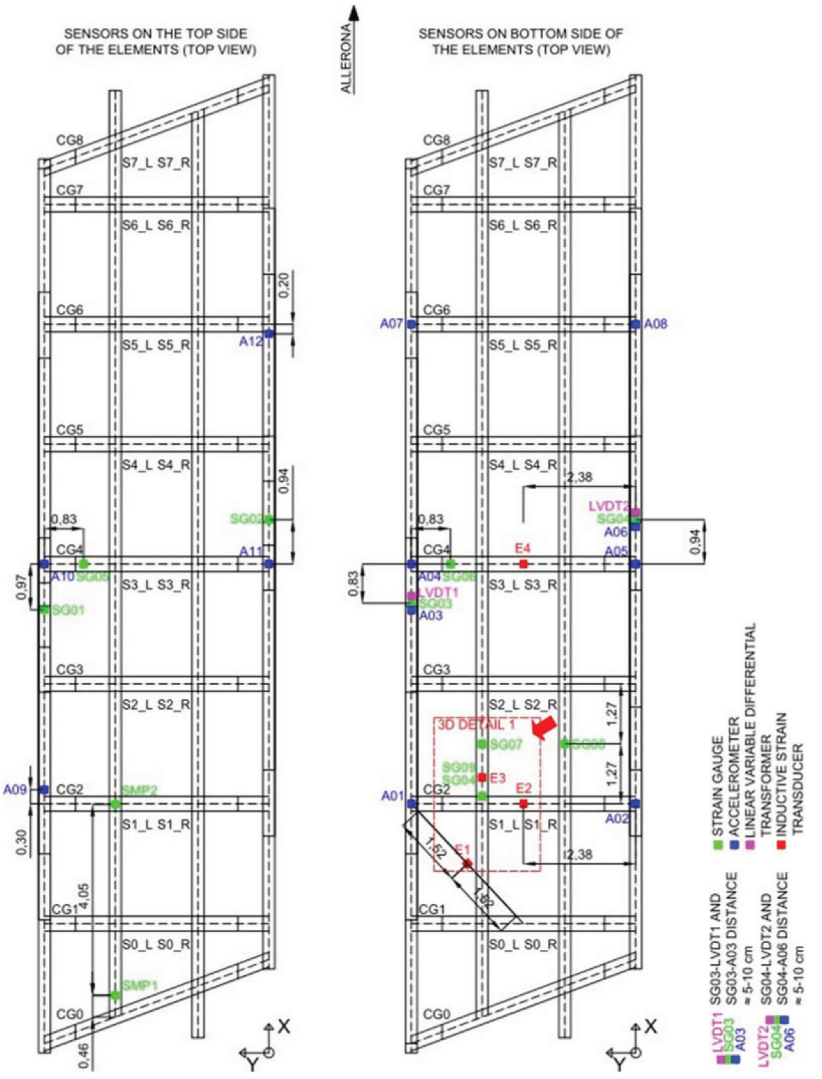

Figure 2. Disposition of the sensors in plain view on the upper (top) and lower side (bottom) of the elements.

rail to detect trains' axles and velocities for the B-WIM calculations. Finally, only SMP1 was used to detect axles. E2 and E4, installed at the midspan and the bottom flange of cross girders, provided inputs to calculate the speed of the crossing trains.

4 CALIBRATION OF THE B-WIM SYSTEM

B-WIM systems collect axle loads, axle distances and headways of all heavy freight vehicles crossing the instrumented bridge. This information is vital for optimised bridge safety analysis, which ensures structural integrity and safety of bridges and, at the same time, allows for optimal management of bridge stock. Calibration of any WIM system is essential to ensure the accuracy and reliability of measurements.

During the bridge testing, 23 train passages were recorded over 14 hours, most driving at approximately 90-100 km/h. This included seven passenger trains exhibiting similar responses and eight long freight trains. The remaining eight passages were unclassified.

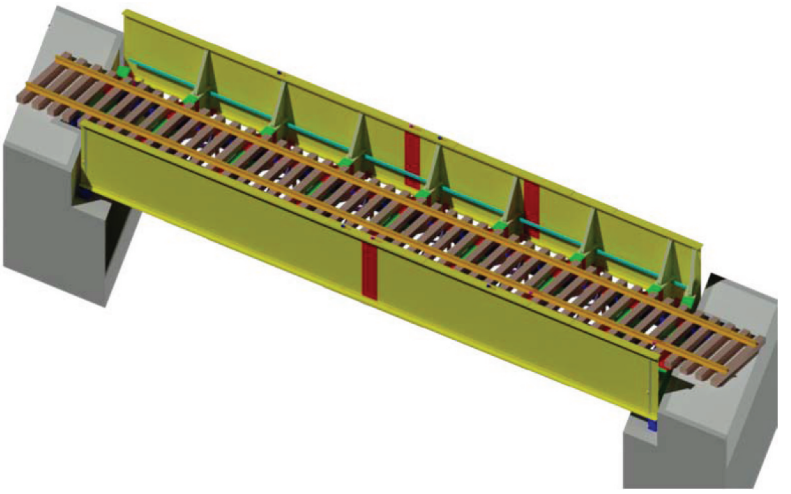

Figure 3. The 3D bridge model with sensor locations.

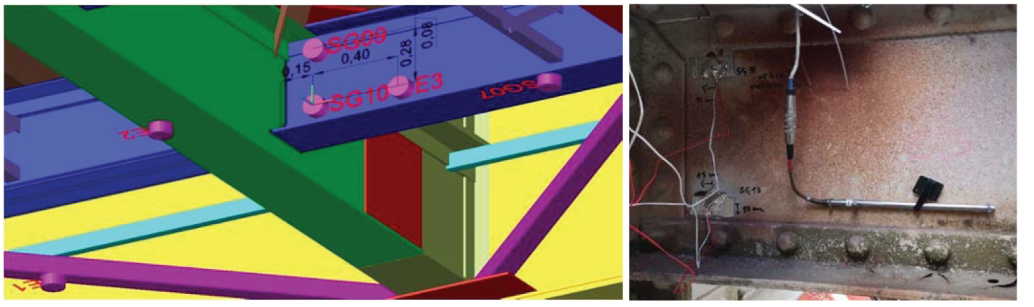

Figure 4. 3D view of the position of sensors SG07, SG09, SG10, E2, and E3 (left); installed sensors SG09, SG10 and E3 mounted on the bridge.

The B-WIM system calibration accounts for all bridge details, like concrete and steel thicknesses, which influence the relationship between the weights calculated by the B-WIM algorithm from the measured strains and the actual axle loads. For road-based B-WIM systems, calibration typically involves vehicles with statically weighed axle loads that cross the bridge multiple times. The mean value of the actual vs. measured weight ratios is taken as the calibration factor and is used to convert the strain-based results into kN.

Implementing this procedure on railway tracks is challenging as the weighing stations for trains are not always available. Furthermore, hiring a calibration train to perform multiple crossings is expensive and time-consuming. In our study, we had no information about the axle loads of the trains passing over the bridge. Nevertheless, it is beneficial for railway B-WIM applications that the weights of the locomotives are relatively consistent, especially of the electric passenger locomotives that do not carry fuel or passengers (Figure 5). The study revealed that the locomotives of these trains were of the type E.464, each with a gross weight of 72 tons (Locomotiva FS E.464. 2021).

Upon examining the signals from the B-WIM system, it was noted that the locomotives in all seven passenger train passages had almost identical axle distances and similar weights. Hence, it was assumed these were the same type of locomotives, suitable for use in calibration. The calibration factor was adjusted to align the mean Gross Vehicle Weight (GVW) of these locomotives (12 overall) to 72 tons. The standard deviation of the GVWs was 3.3% of the mean, placing the accuracy of the locomotives' GVWs in the accuracy class B(10) according to the European specifications for weigh-in-motion (Jacob et al. 2002).

Figure 5. Locomotive type E.464, captured during the test (left) and from Wikipedia (Incola 2021) (right).

5 INITIAL FE MODEL

The test bridge model was designed using the software package MIDAS Civil (2020). Its extruded 3D view is given in Figure 6.

All structural elements were formulated according to the Timoshenko beam theory, with the effect of shear deformations considered. The connections of all elements were assumed to be fixed at both ends, except for bracing elements, which were assumed to be pinned at both ends. The geometry, cross-sections and material properties were defined according to the original design documentation and on-site measurements. To model its exact geometry, rigid links were used to connect centroids of interconnected elements. While the cross-section of stringers and cross girders did not vary with length, the cross-section of the plate girder near the mid-span had more stiffening plates on the flanges. Therefore, five different cross-sections were defined only for modelling plate girders. Figure 7 compares the model with the actual structure, focusing on the cross–girder–plate detail. Rigid links were defined in the FE model to take into account the stiffening effects provided by the connection.

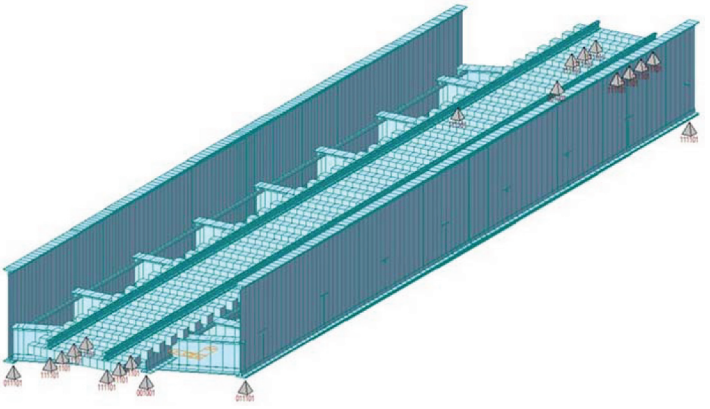

Figure 6. Extruded 3D view of the initial finite element (FE) model.

6 MANUALLY CALIBRATED FE MODEL

To more realistically estimate the remaining lifetime of the considered bridge, the initial FE model was manually calibrated to match the measured response. The calibrated FE model afterwards served to estimate the number of cycles for fatigue estimation in critical details. A series of measurements were performed for this purpose: accelerations (ambient vibrations), strains and displacements (under passing trains).

Figure 7. Cross girder – plate girder detail: structure (left) and FE model (right).

Table 1. Comparison of natural frequencies: Measurements, initial and calibrated FE model.

Frequency [Hz]	Measurements	Initial FE model	Calibrated FE model
1st bending	11.0 – 11.5	14.6	11.8
1st torsion	16.0	19.2	16.0

An enhanced frequency domain decomposition (EFDD) technique (Structural Vibration Solution 2023) was used to identify natural frequencies and mode shapes. Table 1 summarises the comparison of the measured natural frequencies with those obtained from the initial and calibrated FE model. 1st bending and 1st torsional natural frequencies were used to calibrate the FE model.

The close agreement between the measured and modelled frequencies for both bending and torsional modes was achieved mainly with additional mass, which was taken into account as a uniform increase of steel density for all steel structural elements by 11 %. This mass increase was identified by comparing the detailed 3D model (Figure 3), which included all the non-structural elements and connecting plates. While the overall mass of the initial FE model was 33 tons, the overall mass of the calibrated FE model was 37 tons (both masses exclude the mass of the sleepers and rails). Another essential modification of the initial FE model was the reduction of Young's elastic modulus of all structural elements by 5 % to globally take into account the weakened structural elements due to corrosion and loosened connections. While structural bearings, according to the design documentation, enabled the rotation of the supports both in longitudinal, transverse and vertical directions, it was observed on the site that due to corrosion of those bearings, the rotations in transverse and vertical directions might have been prevented. This was taken into account in the calibrated FE model.

Measured and modelled displacements and strains were primarily compared for passenger trains. Trains were simulated statically in the FE model, moving point forces (axles) step by step. Axle loads and distances needed to form the train in the FE model were obtained from the B-WIM.

Figure 8 compares displacements for measured response and responses of the initial and calibrated FE models during the train passage nr. 3 (passenger train). The first and last vehicles in this train were electric locomotives (Incola 2021), which were among 12 locomotives used for B-WIM calibration. GVWs of locomotives and wagons were estimated as 69.8 t, 37.1 t, 38.3 t, 36.9 t, 34.9 t, 36.7 t, 36.0 t, 37.0 t and 69.2 t. Note that although displacements capture the global response of the bridge, the number of valleys in the signals is not the same as the number of vehicles in the train. This is mainly due to the wheelbase of the wagons, which is greater than the span length.

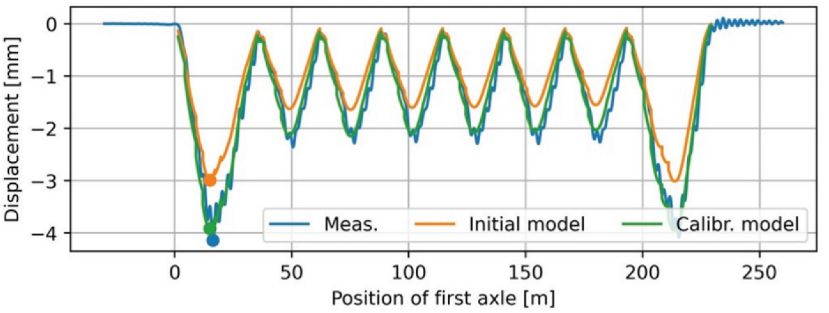

Figure 8. Comparison of measured and modelled displacements during train passage nr. 3 (passenger train) at LVDT1 sensor for the initial and manually calibrated FE model.

Comparing the FE model responses with the measurements in Figure 8, it is clear that the calibrated FE model agrees well with the actual structure. Minimum values of the measured, initial FE and calibrated FE model response are marked with blue, orange and green markers and amount to -4.1 mm, -3.0 mm and -3.9 mm, respectively.

Figure 9 compares the measured and modelled responses under the train passage nr. 9, which is a light train of unidentified type and does not contain the locomotive for B-WIM calibration. GVWs of locomotives and wagons were estimated as 49.2 t, 48.0 t and 50.3 t.

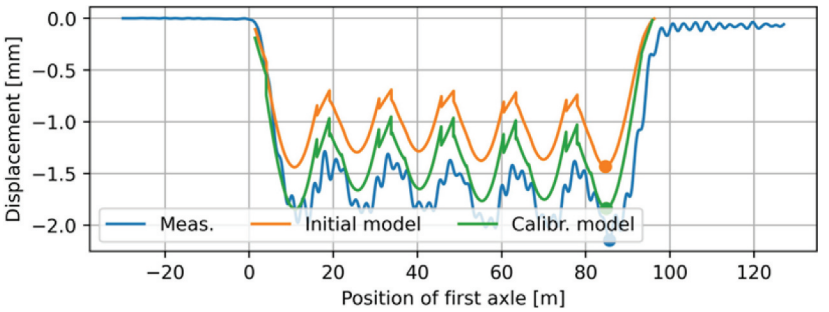

Figure 9. Comparison of measured and modelled displacements during train passage nr. 9 (light train, unidentified type) at LVDT1 sensor for the initial and manually calibrated FE model.

A comparison of the minimum measured and modelled responses of -2.1 mm, -1.4 mm and -1.8 mm (markers in Figure 9) indicates that a match of the calibrated FE model with the measurements is poorer than for the train passage nr. 3. Similar trend was observed for other train passages which are not shown in this paper, mainly for the ones which did not contain the calibration locomotives. This deviation might identify the load-dependant phenomena, such as flexibility of the connections or non-linear friction in the structural bearings. The deviation can also be viewed in the way that the weights of lighter trains were underestimated, resulting in the underestimated response of the FE model. Finally, the ratio of the mass of the calibration locomotive versus the mass of the bridge is high - approximately 2, suggesting that both the B-WIM algorithm and the FE model should be upgraded to account for the inertia effects of the passing trains, which are negligible for the roadway (concrete) bridges.

7 CONCLUSIONS

The B-WIM system application on a century-old steel-riveted railway bridge introduced challenges associated with its complex behaviour under train loading. The study demonstrated that the B-WIM system setup effectively monitored the bridge performance under the traffic

loading. The calibration procedure was adapted for railway B-WIM applications using passenger train locomotives with known and stable gross weights to calculate the calibration factors for B-WIM measurements. Those results were used to simulate the train passages in the FE model and compare the modelled and measured responses. Such a calibration process proved effective for railway B-WIM measurements but highlighted the need to extend the calibration to diverse train types.

The calibrated FE model provided an excellent match with the measured 1st bending and 1st torsional frequency. It also matched well with the measured displacements at the mid-span of the bridge, especially for the train passages that included the calibration locomotive. Deviations from the measurements were observed for trains that differed from the passage trains in terms of weights and axle configurations, indicating the possible load-dependent phenomena and/or inaccurately estimated B-WIM weights.

The results contributed to understanding the dynamic performance of old railway bridges under ambient vibrations and under train passages. Moreover, they highlighted the important contribution of the railway B-WIM systems, which provide the necessary data to calibrate the FE models on the response under train. Future research will focus on the calibration methods and explore the structural specifics and detailed modelling of various bridge designs to improve the accuracy and reliability of B-WIM measurements for railway applications. Moreover, B-WIM algorithms and the FE models should be improved to account for the dynamic response of the bridge and bridge-vehicle interaction, mostly due to large vehicle-to-bridge mass ratio.

ABSTRACT: New technology for continuous and accurate monitoring of bridges is presented. The technology is based on radio interferometry and allows bridge deformation monitoring with down to sub-millimeter accuracy over spans of several hundreds of meters in all weather conditions. As the technology allows affordable 24/7 3D monitoring of both slow changes over years as well as accurate characterization of vibration modes, it is a suitable data source for digital twins and bridge condition evaluation through data analysis techniques including artificial intelligence. This paper presents a case study where the system has been installed on a 220-meter suspension bridge. The basic operation of the technology and the deployment configuration on the bridge are described. The performance of the system is analyzed and compared against an optical reference measurement system. Finally, the suitability of the new monitoring technology for different bridge types is discussed.

1 INTRODUCTION

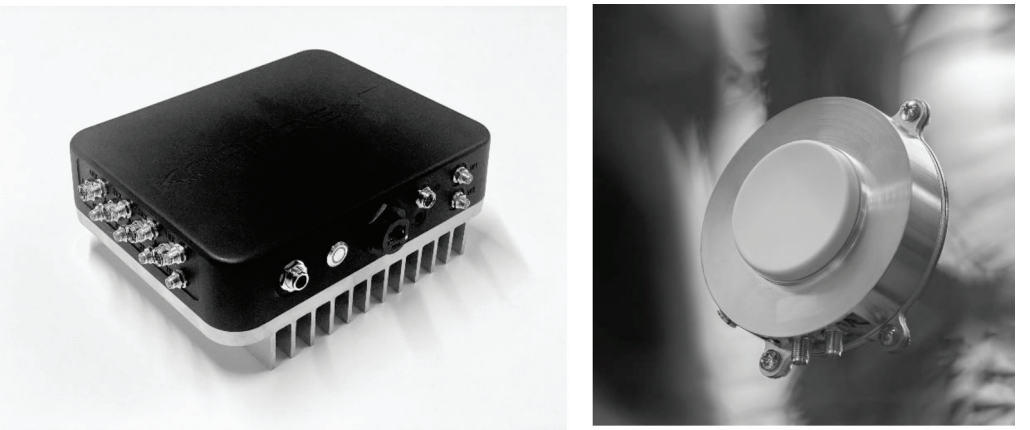
With the aging bridge infrastructure there is a continuous need to improve structural health monitoring (SHM) technologies. Especially the ability to reliably, continuously, accurately and directly measure both slow and fast movements in bridges has been practically absent. Continuous 3D displacement data also opens new opportunities for sophisticated data analysis techniques for the estimation of the remaining structural lifetime.

In this paper we present a new radio based SHM technology that is designed exactly for this purpose. We analyze its performance in a case study where the technology was tested in a real bridge. The case study was arranged in co-operation between the Finnish Transport Infrastructure Agency and Koherent, a Finnish start-up company established in 2019 that has developed the technology. The bridge, an old suspension bridge with 220-meter span, was selected as it already has rich SHM instrumentation that can be used for measurement data comparison.

In Section 2 we describe the technology itself. Section 3 introduces the bridge and the reference instrumentation. Section 4 describes the installation and the running of the case study. The results are analyzed in Section 5. Finally, in Section 6 we give conclusions.

2 THE NEW MEASUREMENT TECHNOLOGY

2.1 *Measurement principle*



The main principle is the very accurate measurement of distance between the sensors. Radio signals in the 5 GHz Wi-Fi band are sent from sensor to sensor and the accurate distance between the reference points of the sensors is measured constantly. This is based on

DOI: 10.1201/9781003483755-168

interferometric measurement, i.e., measurement of the radio signal phase. The intrinsic accuracy of the phase measurements is good enough to reach a precision of a few tens of micrometers in the distance measurement. The system constantly measures the instrumental phase response which is removed from the data. This allows a high absolute accuracy for the measurement as well as eliminates any drift caused by hardware aging. The oscillator used as the time standard is accurate enough not to cause a noticeable distance error within the measurement precision.

2.2 *Hardware*

The hardware components are 1) the radio unit (RU); see Figure 1a, that forms the signals to be transmitted and processes the received signals; 2) the active sensor unit (SU), see Figure 1b, that actually transmits and receives the measurement signals. Up to four SUs can be connected to a single RU with coaxial signal cables. The reference point to which all the positions or distances refer to is a couple mm below the middle of the round plastic cover.

a) b)

Figure 1. a) Radio Unit (RU); b) Sensor unit (SU).

Figure 2 Illustrates the Koherent system architecture for SHM. The RU is connected to the computing cluster, e.g., through a 4G or 5G network. The computing cluster both controls the measurement hardware and computes the distances between the sensor reference points. The maximum supported position update rate is 200 Hz, allowing 3D measurement of vibrations in the structure up to 100 Hz frequency. In large structures, much lower measurement rates can be used. Also, long-term changes in the structures can be monitored by the same system, i.e., it covers time scales from 10 milliseconds to several years.

Deployment of the system requires power and communication for the radio units. The power requirement is 10 watts for continuous measurement. The power can be reduced significantly by using a low-duty-cycle mode where the measurements are conducted e.g. once per hour. In such usage a solar panel would suffice. In icy conditions it is possible to switch on heaters in the sensor units. This will increase the power consumption to almost 30 watts. The radio units are equipped with Wi-Fi and Ethernet that allow many different communication options to the computation cluster. The communication cluster can be in the cloud, edge cloud or on-premises. During installation, there is no need to measure the sensor positions: the system will measure the mutual geometry automatically upon start-up.

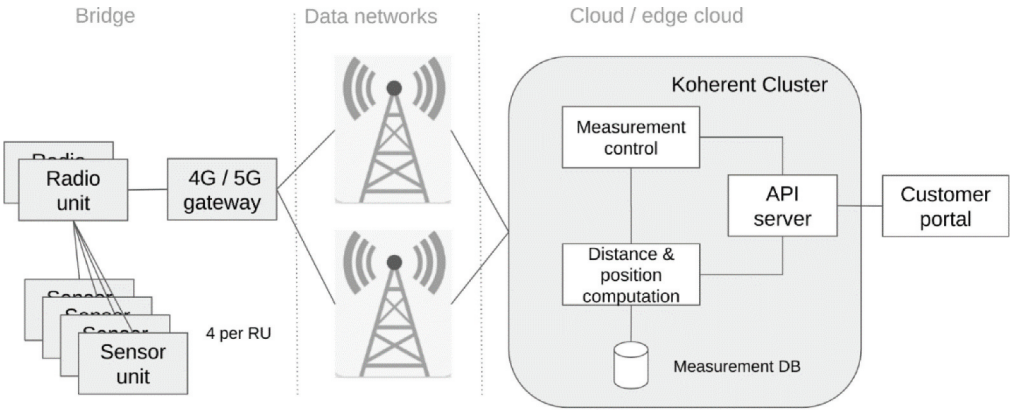


Figure 2. Koherent system architecture for structural health monitoring.

2.3 *Key features*

The main advantages of the new measurement technology are

1) the ability to measure distance changes accurately (within 0.1 millimeters) over distance of hundreds of meters when a clear line-of-sight is available between the sensors and the changes in air refractive index are compensated (point 5 in the limitations below);
2) low instrumental drift in the measurement over the years: the estimated distance remains within a few tenths of a millimeter regardless of the measurement distance;
3) insensitivity to weather: due to the low operation frequency, rain, snow, fog, dust etc. do not have significant impact;
4) significantly better tolerance to interference compared to RTK GNSS.

Only points 1 and 2 were validated with high confidence in this case study. Points 3 and 4 were validated to some extent. However, the conditions on the test bridge were not especially challenging in those respects.

Also, it should be possible to measure relative displacements through a wall, assuming the radio propagation characteristics of the wall (e.g., water content in the wall) do not change significantly. However, that has not been validated in practice.

The main limitations of the technology in its current form are

1) the need for clear line-of-sight for the highest accuracy;
2) the need for power (10W) and communication for each radio unit;
3) the need for cabling for each sensor unit;
4) sensitivity to nearby radio reflections when the highest accuracy is required (far-away reflections can be compensated);
5) need to compensate for the signal propagation speed in air when highest accuracy is required (this can be done e.g., with a fixed calibration link that is constantly monitored);
6) collection of snow and ice on the sensors will affect the measurement accuracy (if not removed by the heating in truly adverse conditions).

3 KIRJALANSALMI BRIDGE AND THE REFERENCE INSTRUMENTATION

Kirjalansalmi bridge, see Figure 3, is a suspension bridge situated in south-western part of Finland near the city of Turku. Road 180 where the bridge is situated, connects a vast archipelago to mainland. The bridge was built in 1963. The main span of the bridge is 220m and the effective width is 10 m. The deck structure consists of two steel truss girders, transversal truss girders, secondary beam girders and a concrete slab.

Kirjalansalmi bridge has an SHM system. The first monitoring system for the bridge was built in 2007. The system has been renewed step by step and some new sensors have been added. Today the monitoring system has strain gauges in main structures, temperature sensors, accelerometers, deflection sensors and a separate weather station. The system is used to provide continuous data about the behavior of the bridge structure due to traffic loads and temperature. The original monitoring system has a two-dimensional (X/Y) displacement sensor. The infra red transmitter is placed on the immovable concrete end support of the bridge and the reflector is placed on the maintenance walkway hanging from the bridge structure. This displacement sensor is also working as reference instrumentation to the Koherent measuring system.

Figure 3. Kirjalansalmi suspension bridge with 220-meter main span.

4 INSTALLING THE NEW SYSTEM AND RUNNING THE MEASUREMENTS

4.1 *Measurement configuration*

In order to compare the Koherent monitoring system against the existing laser-based system, the crossbeam with the laser reflector was chosen as the attachment point. This is about 46 meters from the northernmost pillar and roughly one fourth of the total span of the bridge. The sensor attachment points can be seen in Figure 4. This under-the-bridge deployment was seen as the easiest option as there was no need to install sensors on the pylons and on top of the deck (risk of vandalism). The downside was the sub-optimal measurement geometry as will be seen below.

Three sensors were attached to the cross-beam, one near the laser reflector and the others near the ends of the beam. The movements of these sensors were measured with reference to the three sensors attached to the north pillars. As the monitoring is based on the distance measurement between the sensors on the beam and the sensors on the pillars, the highest accuracy could be achieved in the direction of the bridge. The height difference of the upper and lower sensors in the pillars was about 6 meters. This meant that any up-down movement, or movement in the z-axis, of the bridge deck translated to distance differences in the measured links at a ratio of roughly 6/46 = 0.13. Therefore, to achieve an accuracy of 1 mm in the deck z-movements, an accuracy of 0.13 mm was required in the distance measurement. Similarly, the horizontal distance between the pillar reference sensors was about 12 meters, leading to somewhat better geometry for y-movements (transverse movements of the bridge deck).

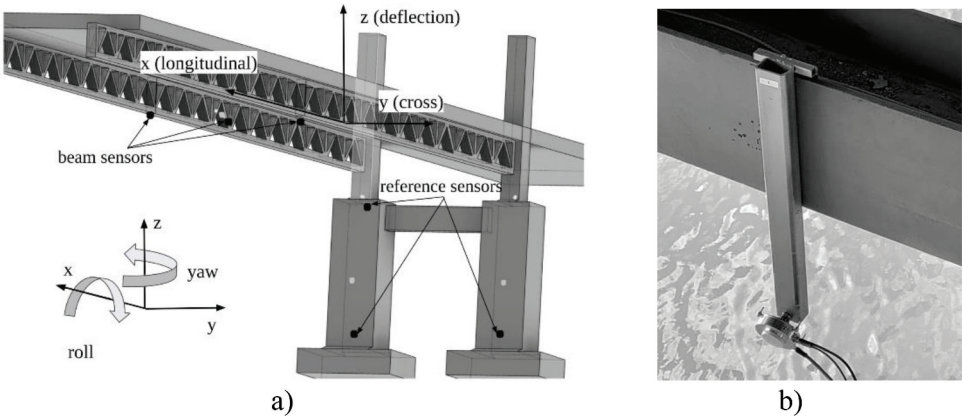

Figure 4. a) Installation plan, coordinate system and parameterization. b) Sensor installed on the cross-beam.

As we had three sensors attached to the beam, in addition to the translatory movement of the beam in x, y, and z, it was also possible to measure the changes in the beam's orientation. With this sensor geometry, two angles could be measured: the roll angle, i.e. the tilting of the deck, and the yaw angle (turning around the vertical z-axis).

4.2 *Installation*

Three radio units were used: one for the beam and one for each of the two northern pillars. These were connected to two 4G modems with Ethernet cables to send the data to cloud for processing in the computation cluster, see Figure 2. AC power from the bridge was available for both the radio units and the modems. The installation of the equipment took one full day. A harness had to be used for the pillar installations. The system was already operational during the same day.

After the system startup the geometry of the reference sensors was measured by using the distance measurement between the sensors. The actual measurement of the crossbeam movement ran continuously and autonomously for four weeks. All the crossbeam measurement parameters were stored in a cloud database 100 times per second.

5 MEASUREMENT RESULTS AND THEIR ANALYSIS

5.1 *Parametrization*

It would have been possible to measure and report the position of each individual sensor on the cross beam with respect to the reference sensors. However, it was decided to calculate five positional values for the beam that are more useful for interpretation of the bridge behavior: the linear movements of the beam center point in x, y, and z directions as well as the roll and yaw angles. These values were estimated by the cluster based on the continuous individual distance measurements between the sensors on the beam and the reference sensors on the pillars.

5.2 *Dynamic events*

Figure 5 Shows a typical bridge crossing by a heavy vehicle (a truck with a trailer) from the south. The dashed line is the Koherent measurement while dots represent the laser measurements. The third graph from top shows the vertical deflection of the cross beam. First, when the truck enters the bridge at the southern end, at approximately 05:28:45 UTC, the northern end starts moving upwards. When the truck crosses the measurement point, we can see a larger movement, about 240 mm, downwards. Lighter vehicles enter the bridge at the time when the truck leaves the bridge causing again an upwards movement. The fourth graph shows how the bridge deck tilts around 0.12 degrees towards east, reflecting the fact that the truck uses the

eastern lane. The first and the second graphs show x and y movement, respectively. One can see that the cross beam moves about 10 mm to north, which is natural as the truck bends the part of the bridge deck north of the cross beam downwards and therefore makes it shorter.

Comparing with the laser reference system measurement, we can see that the match is quite good for the vertical (z) deflection measurement. However, there is a clear deviation in the lateral (y) measurement. This could be related to the 1.5 meter vertical distance between the prism and the sensor combined with bridge deck tilt. However, the deviation does not match the tilt angle measurement and is most likely an unidentified problem in the laser measurement. This problem is even clearer in Figure 6 with the truck moving from north to south, as the laser system completely fails to record any lateral movement which is very clearly visible in the Koherent measurement data. Again, the observed bridge deck tilt is not sufficient to explain this behavior. Figure 7 shows a zoomed-in version of Figure 6 and illustrates good match in estimated movement in the deflection direction (z-coordinate).

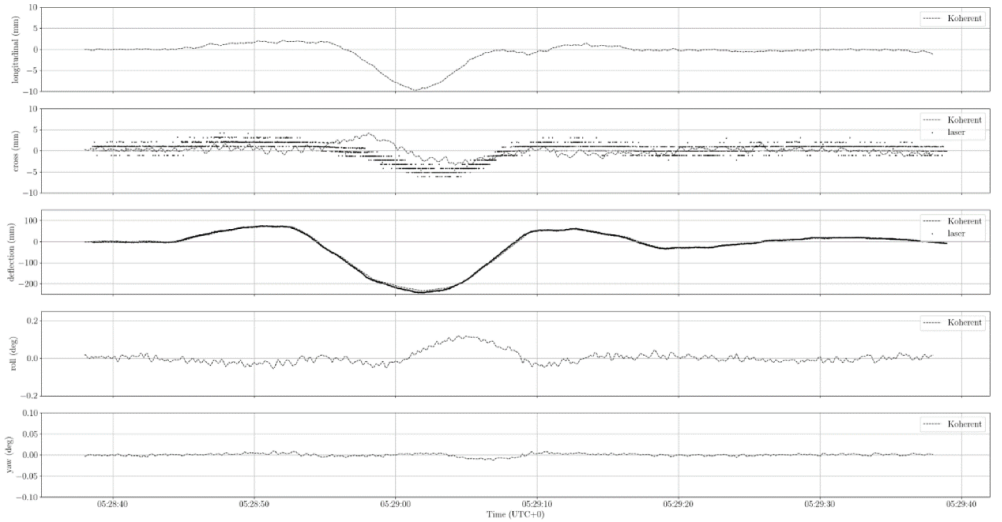

Figure 5. Large vehicle moving northbound.

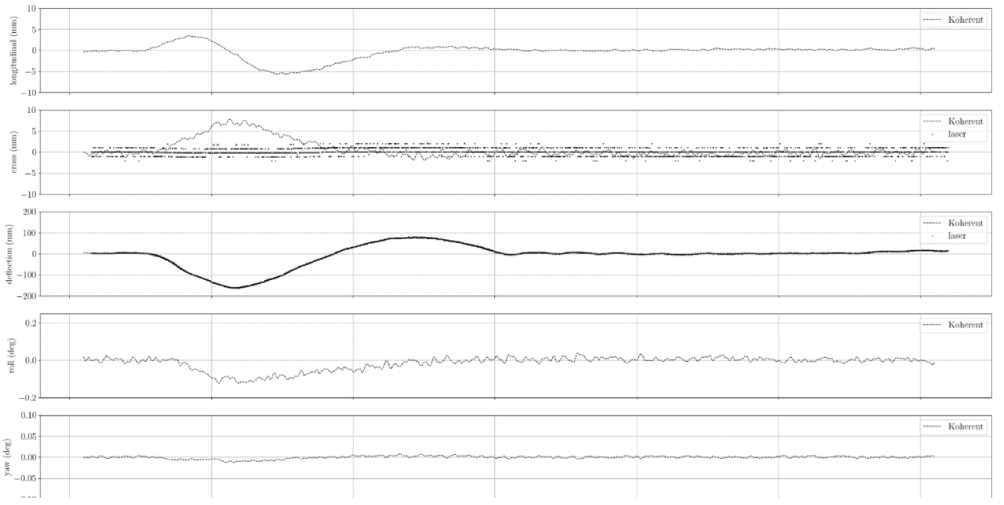

Figure 6. Large vehicle moving southbound.

5.3 *Long-term stability*

The drift in the Koherent measurement system during the four-week test project was studied by comparing it against the laser system. Fifteen-minute averages of the difference in z-coordinate were computed for the four-week period and shown in Figure 8. The two systems are in agreement within 1 mm. Because of the measurement geometry ratio 1:8, the drift in the distance measurement between the sensors over the 46 meters distance has drifted at most ~0.1mm over the four-week period. Figure 8a also nicely reveals the diurnal thermal cycles of the bridge.

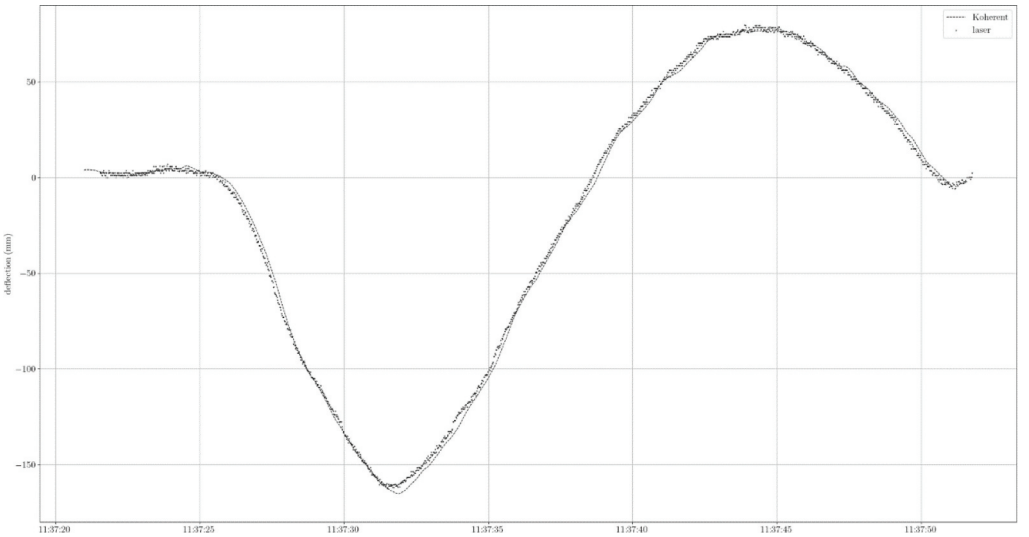

Figure 7. Zoomed in version of the deflection estimate (z) of the large vehicle moving southbound in Figure 6.

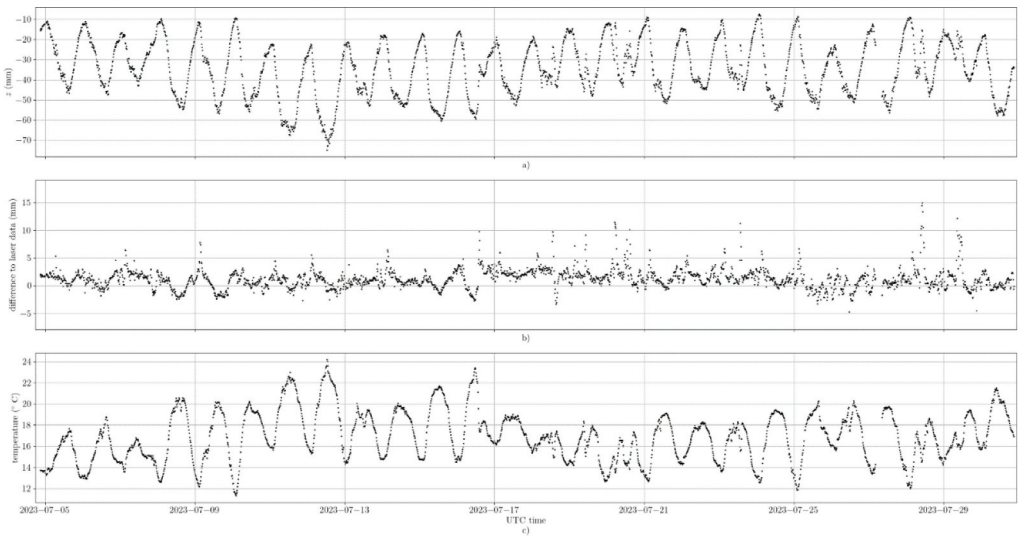

Figure 8. Each point represents a fifteen-minute average of a) z-coordinate (deflection), measured by Koherent; b) difference between Koherent and the laser measurement; c) temperature.

5.4 *Displacement measurement precision*

Figure 9 shows an event where a large vehicle crosses the bridge early in the morning while the bridge is otherwise silent. Figure 9a and 9b show the relative change in the estimated parameters. One can also observe how the bridge vibrates long after the vehicle has passed. Figure 9c shows a period of 10 s just before the vehicle enters the bridge. The measurement precision is on the order of 0.1 mm for the vertical movement and 20 micrometers for the longitudinal movement (relative distance precision). Because of the radio-interferometric measurement principle, this result does not depend on the distance until the distance increases to a point where the thermal noise in the received radio signal starts to dominate the result. With the current parameters this happens roughly at 300 meters distance and can be extended even further by increasing the signal integration time.

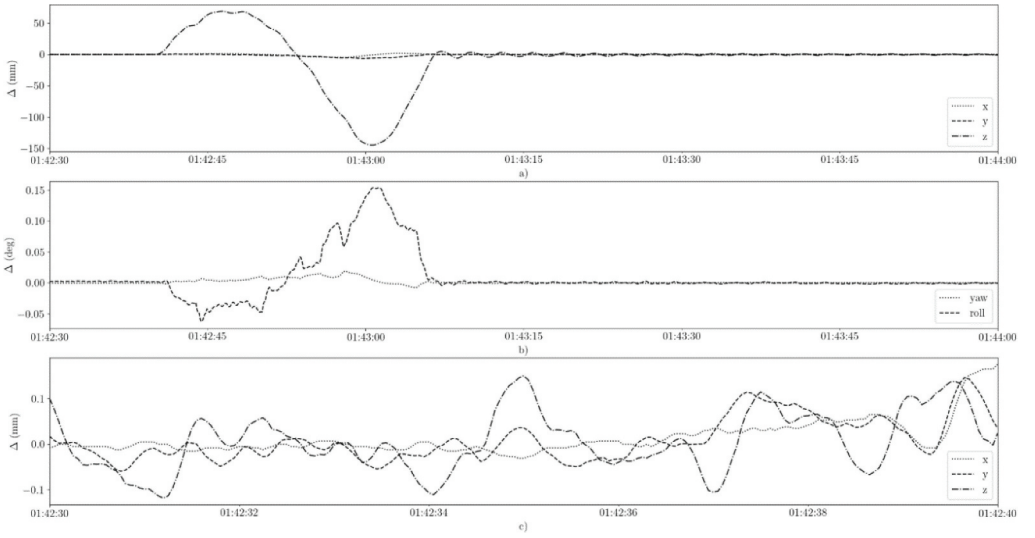

Figure 9. Estimates from a silent bridge at night with a single large vehicle crossing a) x-, y-, and z-coordinates; b) yaw and roll angles; c) zoomed in of x, y, z just before vehicle enters the bridge.

6 CONCLUSIONS

The presented case study shows the usability of the new technology for continuous bridge monitoring. Especially the dynamic and long-term accuracy were confirmed. Even with the non-optimal measurement geometry of 1:8, the vertical deck movements were still monitored with 1 mm accuracy. Also, the fast bridge movements were accurately monitored. The instrumental drift in distance measurement was found to be at most on the order of 0.1 mm. The intrinsic precision of the displacement measurement with the quiet bridge was found to be 20 micrometers. As the system is relatively easy and fast to install and offers a direct window to highly accurate and continuous bridge deformation data, we believe it can play a significant role in ascertaining the safety of old bridges.

A regression based B-WIM method for railway bridges

S. Lachinger, J. Struhar & M. Ralbovsky
AIT – Austrian Institute of Technology GmbH

ABSTRACT: The Scope of the presented study is a Bridge-Weigh-in-Motion (B-WIM) method for the identification and quantification of train axles (loads and distances) using a regression-based machine learning model trained with synthetic generated train responses from trains passing over the bridge structure and data from structural health monitoring (SHM).

The B-WIM method uses synthetic train responses, generated with a calibrated numerical model of the bridge structure. Using a database with a large set of different generic train configurations (axle loads and distances) synthetic structural responses at different sensor positions are generated. The synthetic responses are downsampled and Peak-based features are derived and split into a training and a validation dataset for a regression-based machine learning model.

The trained machine learning model is used to calculate predicted axle loads and distances. Validation for synthetic data is then done by comparison with the known axle configurations for the generic train database. In upcoming steps of the ongoing research project, the trained machine learning model will then be used for identification of the axle loads and distances of the real trains passing over the bridge structure using features derived from the recorded monitoring data.

1 INTRODUCTION

Weigh-In-Motion (WIM) systems are generally used to measure traffic loads in road and railway networks during vehicle passage. Usually, these measurement systems are mainly designed for the detection of overloaded vehicles (e.g. trucks in road networks or freight wagons in train networks). Some operators use this data to line out overloaded wagons or trucks after passage to reduce damage to the rail or road infrastructure. The recorded data can also be used as base for statistical evaluation or for the derivation of load models for the assessment of structures (Sjaarda et.al., 2020). In this study the focus is on railway applications.

WIM systems, where the sensor reaction measured on a bridge is used to inversely calculate the traffic loads, are called Bridge Weigh-In-Motion (B-WIM) systems. These systems can be especially useful when no WIM system is installed in the area of interest in the traffic network and also, when the installation of a commercial WIM system would be too expensive or an installation on the track, as needed for approaches using measurements on the rail itself (Pau, Vestoni, 2021), would be not feasible due to limited access to the track, which can be a common problem especially in railway networks. (Žnidarič et.al. 2016) showed an application of a B-WIM method for a steel truss railway bridge based on the evaluation of influence lines. Another advantage of B-WIM is, that data from existing SHM installations can be used to calculate the traffic that generated the measured responses.

For railway applications not only the maximal load on a track is out of interest, but also the total sequence of axle loads is important, e.g. for the assessment of cumulative fatigue damage on steel structures within the network. Here the measured axle load sequences per train can be used to derive route specific fatigue load models, that are less conservative than fatigue load models from design codes. For the project DEEB-Infra two different B-WIM methods have been derived with the aim to get additional load data for the extrapolation of

DOI: 10.1201/9781003483755-169

valid fatigue load models for different parts of a railway network without permanently installed WIM-system. One B-WIM method, developed by the project-partner TU-Darmstadt (Riedel et.al. 2023) calibrates the axle loads based on the dynamic response of the bridge structure during train passage and tries to minimize the differences to a calibrated numerical model of the bridge. The advantage of this approach is, that it can handle resonance effects during train passage if they are also present in the numerical model. On the downside this approach does only calculate axle loads, the axle distances must be measured separately, e.g. with light barriers installed on the track. The second B-WIM method, which is introduced here, is developed by project partner AIT and uses an approach incorporating a regression-based machine learning model (MLM). It can derive axle loads and axles distances together with the downside that it is based on a static evaluation, so is not able to consider resonance effects within the measured response. As resonance effects should be avoided in generals and are much more likely to happen on high-speed railway lines this approach seems suitable for most tracks and bridge structures that are not excited in their resonance frequencies. The presented results are still intermediate at the time of writing this paper and cover the basic concept and results for synthetic (perfect) training and test data. The project is still ongoing and final validation of the method will be done in subsequent publications.

2 CONCEPT OF THE B-WIM METHOD

The presented B-WIM method is based on regression using a machine learning model (MLM) with the aim to predict the axle loads and distances of a train that passed the bridge structure. Figure 1 gives an overview over the approach for the B-WIM method.

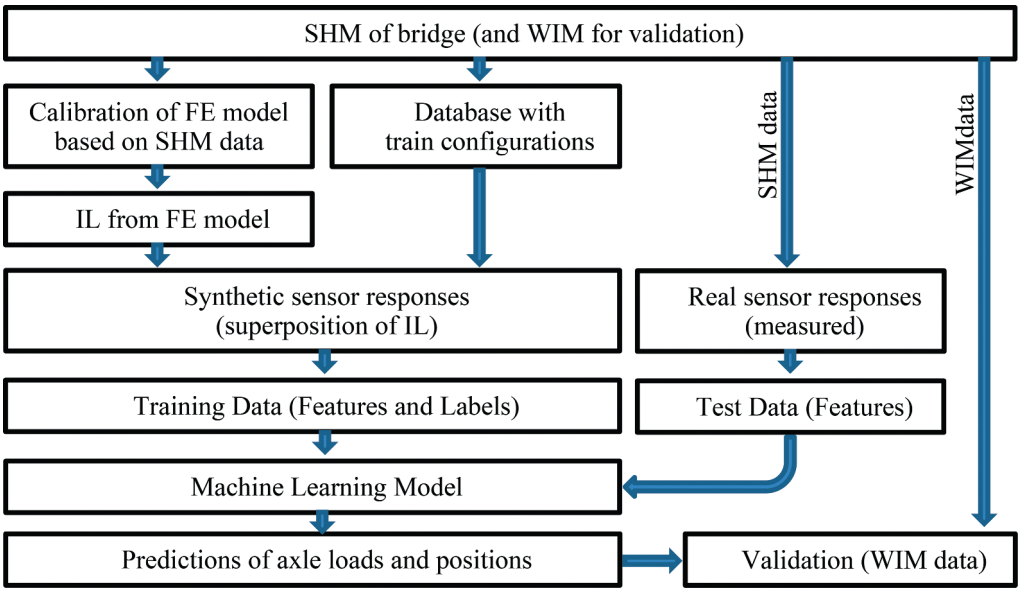

Figure 1. Basic approach used for B-WIM.

2.1 *Bridge structure*

For generation of the synthetic test data a real bridge structure is taken into consideration. The considered bridge, shown in Figure 2, for demonstration of the B-WIM method is a century old single span steel truss bridge located in Austria which is currently still under operation.

Figure 2. Steel railway bridge used for demonstration of B-WIM method.

The bridge has several signs of its age and defects, that initiated a large monitoring campaign and the development of a numerical model that was calibrated based on monitoring data. Also, a commercial WIM system is installed on the track providing the data for the validation of the B-WIM method. The bridge structure and the calibration of the numerical model is described in (Lachinger et.al., 2023). For the demonstration of the B-WIM method in this study influence lines (IL) of the calibrated model are used. As the quality of the predicted loads using B-WIM increases with sensors capturing the local response of the structure, i.e. directly show axles and/or bogie loads, the chosen IL represents sensor positions of a strain gauges at the longitudinal girder – which carries the sleepers – approximately in the middle of the bridge structure. Using sensor positions which represent more the global response of the structure, i.e. at the main truss, would lead to a decrease in the prediction quality.

2.2 *Training data*

In the first step a numerical model of the bridge structure is calibrated to give a good representation of the actual structure. Different approaches for the calibration of the model can be used, for the calibration of a FE-model an approach using least squares minimization of the difference of all sensor values was presented in (Lachinger et.al., 2023). From the calibrated numerical model, influence lines (IL) are derived for the considered sensor positions. Using an existing database with nearly 5000 train configurations (axle loads and axle distances) synthetic sensor responses for each of the train configurations are generated by superposition of the IL multiplicated with the respective axles loads, shifted by the absolute axle positions. This approach is valid for bridge structures where linear elastic behavior can be assumed (e.g. steel bridges). If no linear elastic behavior can be assumed, the total train responses can be calculated directly, which is numerically more expensive. Figure 3 shows an example of a generated synthetic sensor response and the corresponding axle loads of the train configuration. All sensor responses are evaluated in the distance domain. For sensor responses from actual monitoring the train speed can be used for the transformation.

The features are derived from the synthetic sensor responses. Therefore, the synthetic sensor reactions are down sampled into a Peak-Valley sequence using a peak finding algorithm. A set of features is calculated for each individual peak of the sensor reaction. Per peak the following features are calculated with reference to a set cut off limit, as shown in Figure 4:

- Peak amplitude (to cut off limit)
- Distances to adjacent valleys (left and right side)
- Peak-Valley amplitude (left and right side)

- Area under sensor reaction between left and right valley
- Absolute position of the peak and relative position (=0 if reference peak)

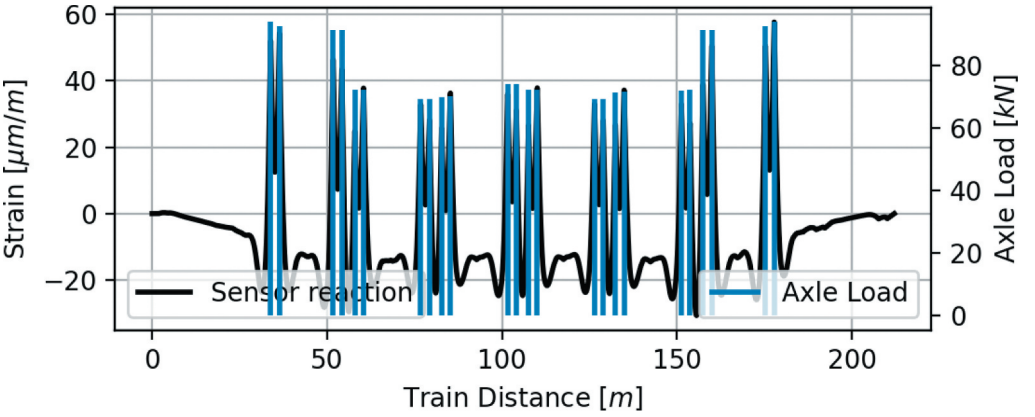

Figure 3. Example of synthetic sensor reaction and train axle loads.

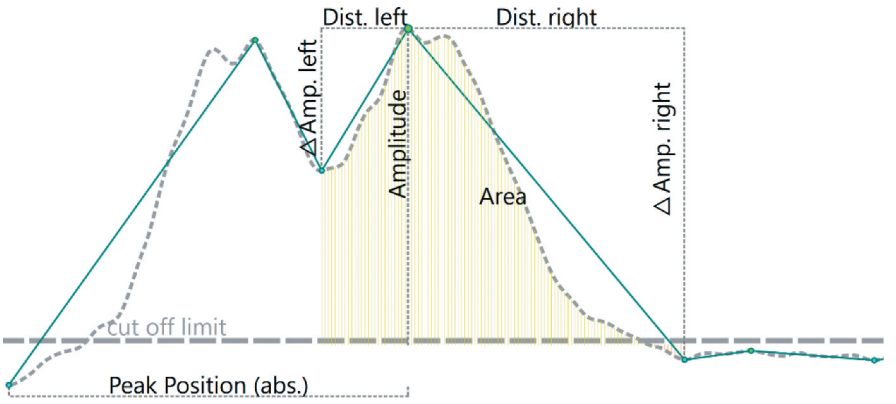

Figure 4. Features derived from individual peaks.

The complete feature set for each peak (when reference peak) must consider the influence of all axles that are at the bridge structure at once. Therefore, preceding and subsequent peaks to the reference peak are considered with their relative position, if they are within the scope of the IL before and after the considered sensor with the peak of the IL positioned at the sensor position. This also represents the sensor position on the bridge structure as the IL usually equals the bridge length. The labels for each peak are the axle loads and positions relative to the peak position of the axles in the scope (between the valleys) of the reference peak. The set of features and labels from the synthetic sensor reactions is used as training data for the MLM.

2.3 *Computational implementation of the MLM*

The Python toolkit scikit-learn was used for this study which provides an easy to implement set of different MLM that also can be exchanged easily to test different models. For the current study a Random Forest regressor was used, as it showed to give the best results after comparison of different MLM within the scikit-learn toolkit. It also has decent performance and some traceability of the results if necessary.

The primary challenge in the computational implementation was to prepare the data pre-processing pipeline in very flexible way, that enables to switch used sensor or used feature set very quickly in one spot and to evaluate the impact of a change. The pipeline stages de-construct the input train data into the feature set that can be predicted by the regressor. So, the pipeline needs to remember some information (e.g. absolute peak position) to enable the re-construction of predicted labels, i.e. axle loads and relative position to reference peak, into a complete train configuration.

- The first stage in the pipeline splits the signal from the selected sensor reaction into smaller pieces. The pipe stage hops over all signal peaks and cuts pieces with the length of the IL of the signal and within this cutout calculates the requested features, as described in Chapter 0.
- The second stage transforms the feature lists with variable length in a zero padded matrix of fixed shape (number-of-features, max-length-of-value-list).
- In the third stage each of the features will be normalized (scaled) to give equal weights to the individual feature types. This also makes the regression more robust against outliers.
- The fourth stage reshapes all the scaled values from one signal block to a 1-D value array that can be fed to the regressor.

Postprocessing involves the re-construction of the predicted label data into complete train configurations and extraction of additional information (e.g. peak-valley sequences) that can be used for calculation of metrics to validate the results against the measured train data from WIM measurements.

3 B-WIM METHOD FOR SYNTHETIC TRAIN DATA

The synthetic dataset was randomly split. 90% of the dataset formed the training dataset and 10% of the dataset the validation (or test) dataset for validation checks to see if the model can predict synthetic axle loads. Figure 5 shows an example for the data of one wagon within a train in the validation dataset. The solid black line shows the (synthetic) sensor response and the dashed blue line the down sampled data used for the calculation of the features. The magenta bar indicates position and amplitude of the (known) axle loads and the red circle markers show the predicted loads that should ideally match with the tip of the magenta bars. In the example in Figure 5 we see a pretty good match between label loads and predicted loads.

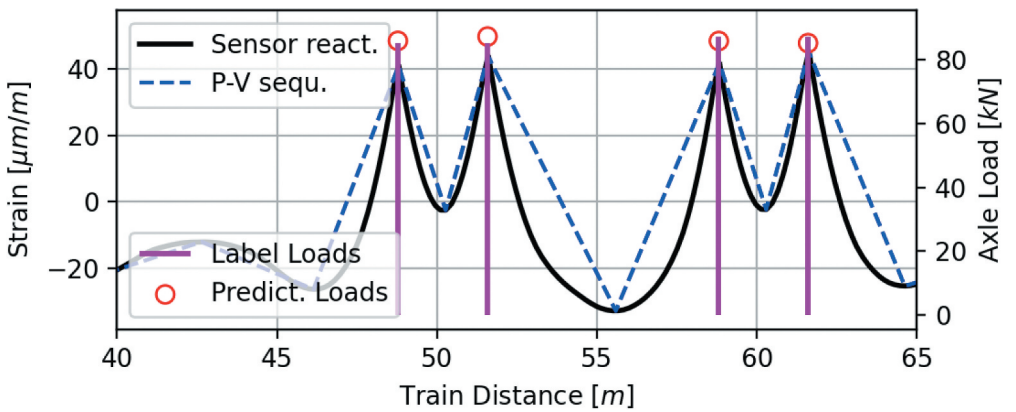

Figure 5. Example comparison of labels and prediction for a wagon of a sample train.

To get a good overview of the results the predicted loads are evaluated: (i) for the totals of the individual trains (total length and load sum) and (ii) peakwise by evaluation of the predicted loads between the preceding and successive valley for each peak. For the peakwise evaluation the following parameters are considered for the differences between label and predicted loads:

- Number of axles per peak
- Load sum per peak
- Center of gravity

Figure 6 shows histograms of these evaluation parameters for the synthetic test data of a chosen sensor considering data from 490 train responses. It can clearly be seen, that for the chosen sensor with the used parameters the synthetic data gives very good results, but individual outliers exist.

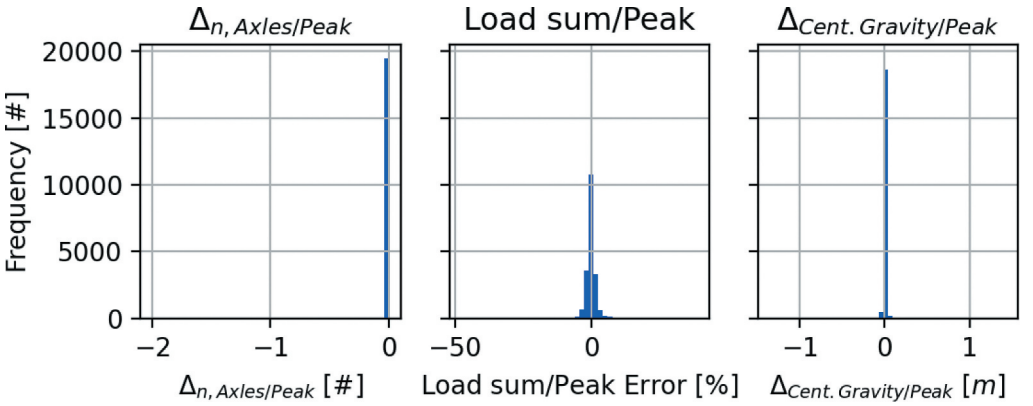

Figure 6. Peakwise evaluation of synthetic test data.

Table 1 sums up the metrics for total and peakwise evaluation of the predicted loads. Three different metrics are shown: (i) ME is the mean error of the prediction and shows the bias of the predicted results, (ii) MAE is the mean absolute error of the prediction and (iii) RMSE is the root mean squared error of the prediction which is the standard deviation of the prediction error. MAE is in general more robust against outliers than RMSE.

Table 1. Metrics for synthetic test data.

Evaluation	Paramter	Unit	ME (Bias)	MAE	RMSE
Total	Length	[m]	0,0034	0,0130	0,1098
	Load sum	[kN]	-0,3470	1,9798	7,0277
Peakwise	Nr. Axles	[#]	0,0028	0,0028	0,0540
	Load sum	[kN]	-0,0284	1,1027	2,2557
	Center of Gravity	[m]	0,0047	0,0095	0,0833

The metrics in Table 1 show very little bias and deviations. MAE and RMSE only indicate minor deviations around the true values. Only very few individual outliers exist. Concluding the proposed B-WIM method can predict the synthetic (and perfect) loads very good, which is prerequisite for the upcoming usage of the trained MLM for real data from SHM.

4 CONCLUSIONS AND OUTLOOK

A new Bridge-Weigh-in-Motion (B-WIM) method is introduced in this paper and a proof of concept is shown for synthetic structural responses. The B-WIM method uses a regression-based machine learning model which is trained on a dataset derived from synthetic structural responses of about 5000 train configurations calculated as passing over a (calibrated) numerical model. For this "perfect" data the method can predict the axle loads and distances of trains passing the bridge structure with a very small error.

In the ongoing work on the project, the machine learning model, trained with the synthetic dataset will be taken to predict real train passages by using a test dataset generated from data from structural health monitoring. Validation will be done against data from a commercial Weigh-In-Motion system installed at the same track the bridge structure is located. Results from these real testing will be presented in upcoming publications.

ABSTRACT: Multiple breakthroughs have emerged across various applications due to deep learning. These advancements can also be adapted for Bridge Weigh-In-Motion (BWIM) systems. A deep learning-based algorithm has been developed previously by the authors, which can be integrated into these systems. That algorithm shows promising results when compared to so-called static methods. One of the main contributions of our developments is handling the error of the preprocessing steps more efficiently. A developed axle load estimator is presented in this paper that builds on our previous solution, and which was tested in operation on a cable-stayed bridge. The algorithm handles multi-lane scenarios more efficiently when compared to our previous solution. The comparison of this novel algorithm and Moses' algorithm is also presented in this paper. Our solution achieves lower error rates both on a synthetic dataset, and a real measurement-based annotated dataset.

1 INTRODUCTION

Bridge Weigh-in-Motion (BWIM) systems monitor the traffic of a bridge. Not only detecting vehicle presences but also axle load estimation of vehicles is a vital task of these systems (Carraro et. al 2019). Civil engineers can perform advanced fatigue and damage analysis (Lee et al. 2022) of the bridge based on real traffic data. It helps predict the bridge life cycle and schedule maintenance.

A monitoring system has been already installed on the Monostor bridge on the Hungarian-Slovakian border, connecting Komárom and Komárno (Szinyéri et al. 2023a, Kollár et al. 2023). Uniaxial strain gauges are placed under the bridge deck. These strain gauges provide data for the BWIM system. Strain gauges are placed in two cross-sections of the bridge. Sensors can be grouped into two sensor arrays based on the cross-sections. The main sensor array consists of 16 strain gauges (named T1-T16), while the secondary sensor array consists of 10 strain gauges (named T201-T205, T212-T216). Their setup is also presented in Figures 1 and 2. Two lanes are present on the bridge: in the so-called HU→SVK lane, vehicles are traveling from the Hungarian side to the Slovakian side of the bridge, while vehicles are crossing the bridge in the opposite direction in the SVK→HU lane.

Our research group has previously investigated the aforementioned steel bridge with orthotropic deck and has created a deep learning-based axle load estimation approach (Szinyéri et al. 2023a). This axle load estimation solution assumes that speed and axle location information have already been calculated in the preprocessing steps. It has been already shown that this solution can handle errors of these preprocessing steps more efficiently when compared to traditional, Moses' algorithm-based static methods (Szinyéri & Kovari, 2023b). The most significant disadvantage of the system is that it performs worse when vehicles are present in multiple lanes. This paper aims to solve this issue and create an algorithm that is better than Moses' algorithm under these circumstances as well.

The paper is structured the following way: a literature review and a summary of the used dataset are presented in Section 2. The upgraded deep learning-based solution is discussed in

DOI: 10.1201/9781003483755-170

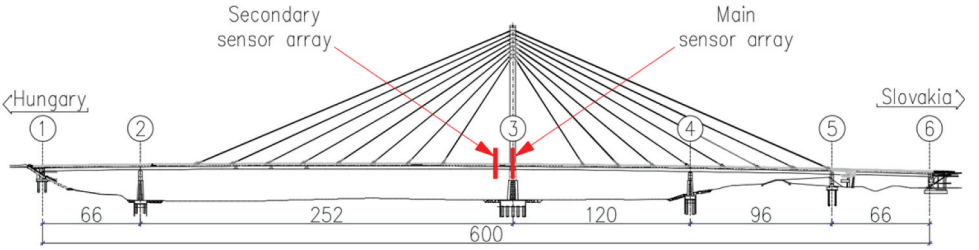

Figure 1. Side view of the bridge. The cross-section of the main and the secondary sensor array can be seen in this figure.

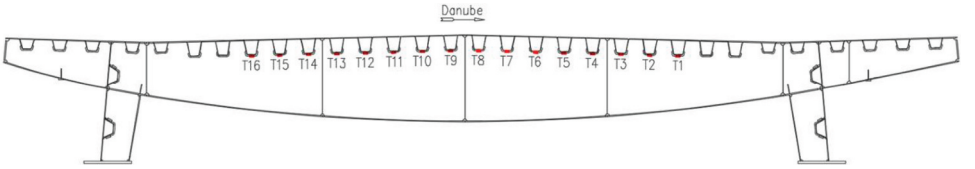

Figure 2. Cross-section with the main sensor array consisting of sixteen strain gauges.

Section 3. The solution is evaluated on a synthetic dataset in Section 4 and on a real measurement-based annotated dataset in Section 5. Finally, Section 6 gives a summary of this paper, states conclusions, and outlines the direction of further work.

2 LITERATURE REVIEW

First, the pipeline of the system and a brief introduction of preprocessing steps are presented. Then, the state-of-the-art axle load estimating methods are presented. Finally, the BME-Simulated I (BME-S1) synthetic dataset is presented which will be used for evaluation in Section 4.

A prerequisite of estimating axle loads is knowing the proper axle locations and speed of each vehicle; axle spacings can be also derived from this information. The pipeline of BWIM systems usually has four main steps: the first step is detecting vehicle time windows (Ma et al. 2020), thus a time interval, when each vehicle was crossing above the sensor arrays. The second step is estimating the speed of each detected vehicle (He et al. 2017). It can be done since sensors are installed in two cross-sections, and the measured strain responses of each vehicle in the two sensor arrays are very similar to each other. The next step is detecting axle locations (Chatterjee et al. 2006), while the last step is estimating axle loads (Carraro et al. 2019). Finally, the calculated axle loads and axle spacings can be used for extracting further information. This paper focuses on the last step, thus the problem of axle load estimation based on known speed and axle spacing information is to be solved.

Four axle load estimation algorithms are discussed in this section. Other axle load estimation algorithms are just modifications of these algorithms; therefore, they are not detailed in this paper, only mentioned.

The traditional algorithm of axle load estimation is the Moses' algorithm (Moses 1979). It was the first algorithm presented in the literature about 40 years ago. Several modified algorithms have been developed since the publication of this method which are based on this approach. Carraro et. al (2019) created a comparison of these static algorithms. These solutions are based on the simulation process. If we know the proper parameters of vehicles crossing the bridge, then we can simulate the strain response of the bridge. This simulation process uses the concept of influence line (Moses 1979) or influence surface (Szinyéri et al. 2023). It is assumed that the axle spacings and speed of each vehicle were calculated before using Moses' algorithm. The task is then to calculate axle loads that produce the most similar simulated strain signals when compared to measured signals.

The Virtual Axle Method (He et al. 2019) is a developed version of Moses' algorithm, leveraging the knowledge of each vehicle's speed. Axle locations and axle loads are calculated in the same module in this case.

There are several deep learning-based algorithms in this field as well, which can be used not only for axle load estimation but also for estimating speed or axle locations. Wu et. al (2020) presented BwimNet, which is a Physics Informed Neural Network (PINN) that calculates all important parameters of a vehicle in only one module. State-of-the-art of PINNs was presented by Cuomo et al. (2022).

Our research group has previously created the BME-Simulated I (BME-S1) dataset (Szinyéri et al. 2023a), which is a public dataset in this field. It is also suitable for deep learning-based supervised training of neural networks. It is a large synthetic dataset, which contains 96 012 training vehicle samples and 12 808 test vehicle samples. Several traffic scenarios are modeled in this dataset. Each scenario can be grouped by the aspect of whether vehicles are present in one lane or both lanes. A subset of scenarios contains close-range following vehicles, while others do not. These close-range following vehicles (Ma et al. 2020) are also called convoys. This dataset is also suitable for incremental development. A small, annotated dataset is also attached to this dataset to ensure that a solution working on the synthetic dataset also works on the measured signals.

If proper axle spacings and speed of each vehicle were known, then Moses' algorithm would be the best algorithm to fit the simulated signal to the measured signal and to calculate the most proper axle loads. Our deep learning-based solution achieves better results when compared to Moses' algorithm on one-lane scenarios when these errors are considered (Szinyéri & Kovari, 2023b). On multi-lane scenarios, they have achieved nearly the same error so far. In this paper, a developed version of this deep learning-based approach is presented, which solves the problem of multi-lane scenarios by achieving better results than Moses' algorithm.

3 CONTRIBUTION

The developed deep learning-based solution is presented in this section, which is trained for multi-lane scenarios as well. Only the modified algorithm is presented in this paper, the former version of the algorithm can be found in (Szinyéri et al. 2023a).

The algorithm still relies on knowing proper axle locations and speed. The solution continues to operate based on the application of a neural network. The neural network computes the axle loads of one vehicle, while it also takes other nearby vehicles into account. The neural network has four input parameters, four input tensors. The first tensor describes the axles of the examined vehicle by tensors derived from strain signals. The second tensor describes the other axles by the same computation. The third parameter describes the lane of each axle. The last parameter is a distance matrix. The algorithm has four substeps: the first substep creates the aforementioned tensors. The second substep creates a local descriptor vector for each axle. The third substep creates a global descriptor vector for each axle, considering the effect of other axles as well. Finally, axle loads are extracted from these global descriptor vectors. Each parameter and substep is detailed below.

First, the methodology of creating the input parameters is described. As mentioned before, time window of a vehicle, axle locations and speed of each vehicle are supposed to be known. First, new computed channels are derived from strain signals by summing some of the sensors. T1-T8, T1-T5, T9-T16 and T12-T16 sensors are summed in our solution. Then, these signals are dilated so that the mean of values inside the time window of the examined vehicle equals zero. Then, the tensors are extracted from these strain signals by the usage of axle time windows. An axle time window is derived from the axle location and speed for each axle. If the axle location is defined by the timestamp t, the vehicle speed is v, the required window size is T samples, and the required resampling distance is L, then $\Delta t = L/v$ defines the time difference between two samples, so the axle time window can be defined as extracting the strain value in the $[t-(T/2)*\Delta t;\ t-(T/2-1)*\Delta t,\ \ldots,\ t-\Delta t, t,\ t+\Delta t,\ \ldots, t+(T/2)*\Delta t\ ]$ moments. In our case, the resampling distance (L) was set to 200 mm and T was set to 73. The resampling is done by cubic interpolation. Figure 3 gives an illustration of this process.

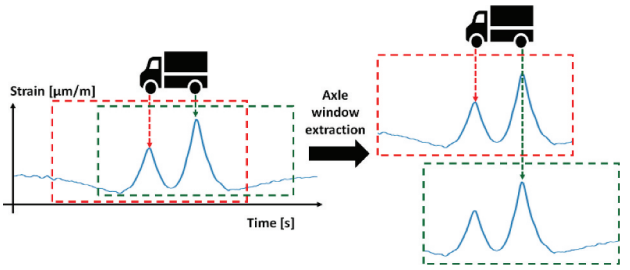

Figure 3. The step of extracting the time window of an axle. The strain signal represents a derived channel.

The lane information is only an index of the lane. The distance matrix is a $\mathbb{R}^{NxM}$ size matrix, where the $D[i,j]$ element describes the distance of the i-th and the j-th axle in the moment when the i-th axle is in the cross-section of the main sensor array. Figure 4 describes the calculation method. The examined vehicle has N axles and the nearby vehicles including the examined vehicle itself have M axles in total.

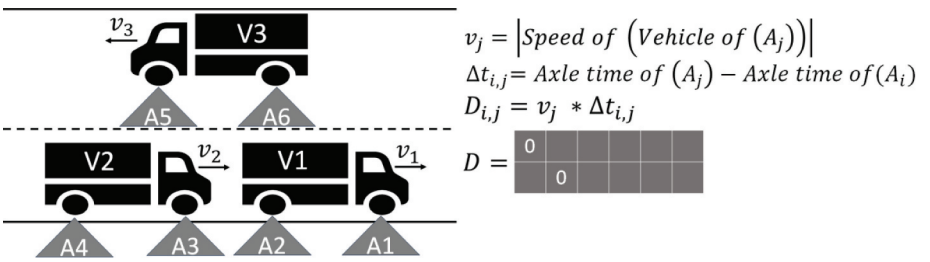

Figure 4. Illustration of extracting the distance matrix. Here $N = 2$ and $M = 6$ if vehicle *V1* is selected.

The neural network is a composition of three dense neural networks. Figures 5 and 6 describe the architecture of the neural network, while the algorithm is presented in Algorithm 1. The *SignalOfAxles* tensor in the algorithm represents a $\mathbb{R}^{NxChxT}$ sized tensor, it contains the preprocessed signal of each axle. The *SignalOfOther Axles* also contains these axles and the other axles nearby; it is a $\mathbb{R}^{MxChxT}$ sized tensor. The parameter *Ch* defines the number of channels which is four in our case. The first N elements of the *SignalOfOtherAxles* tensor equals the *SignalOfOtherAxles* tensor since they contain the axle information of the examined vehicle. The *Lane* tensor contains the index of each axle. The *D* matrix was described before. The *LocalNet* is a dense neural network that contains 256, 512, 128 and 24 neurons in each layer; thus, this network can be described as a $\mathbb{R}^{Ch*T} \rightarrow \mathbb{R}^{24}$ transformation. It encodes the window of each axle without knowing about other axles. *GlobalNet* is another dense neural network that contains a $\mathbb{R}^{24+24+1+1+1} \rightarrow \mathbb{R}^{48}$ transformation. The input of this net is the encoded vector of two axles, the lane index of each axle and the distance of them. *NxM* pairs of local descriptors are concatenated with lane and distance information, and then these results are summed for each axle of the examined vehicle. *RegNet* does the regression step; thus, it extracts the axle loads from each descriptor vector; it is a $\mathbb{R}^{48} \rightarrow \mathbb{R}^{1}$ transformation. It contains a residual connection (Szegedy et al 2017) that means concatenating the input and the output tensor, so it is like boosting in fact.

Data augmentation techniques are used during the training of the neural network. The goal is to prepare the neural network for several error types.

The first augmentation technique is used to prepare the network for the vehicle speed error given by the preprocessing steps. It is modeled by a Gaussian noise added to the ground-truth speed value.

The second augmentation technique is applied to prepare the network for the axle location error given by the axle detector. Gaussian noise is added to the timestamps of the axles. The

Algorithm 1 . Computing axle loads from tensors.

Input: *SignalOfAxles[N, Ch, T], SignalOfOtherAxles[M, Ch, T], Lane[M], D[N, M]*
Output: *AxleLoads[N]*

1. *LocDescrOfAxles* ← [*LocalNet*(*Flatten*(*SignalOfAxles[i]*)) **for** *i* **in** *1..N*]
2. *LocDescrOfOtherAxles* ← [*LocalNet*(*Flatten*(*SignalOfOtherAxles[j]*)) **for** *j* **in** *1..M*]
3. **for** *i* **in** *1..N*
4. **Begin**
5. *AxleLoads[i]* ← *RegNet*(**Σ** [*GlobalNet*(
6. *Concat*(*LocDescrOfAxles[i], LocDescrOfOtherAxles[j], Lane[i], Lane[j], D[i, j]*))
7. **for** *j* **in** *1..M*])
8. **end_**

timestamp of an axle shows the time when a vehicle is crossing above the main sensor array. Therefore, a noisy D matrix is created for each case.

The third augmentation technique models the noise that can be observed in the signals. It is also modeled by adding Gaussian noise. The noise level is set differently in all cases. Other research (Wu et al. 2020) used similar techniques as well.

The Symmetric Weighted Mean Absolute Percentage Error (SWMAPE) is used as a loss function during training. It is used instead of Mean Absolute Percentage Error (MAPE), since it gives numerical stability during backpropagation. If the $y \in \mathbb{R}^N$ vector represents the expected axle loads and the $\hat{y} \in \mathbb{R}^N$ vector represents the calculated axle loads, then the SWMAPE error can be calculated the following way:

$$SWMAPE(\hat{y},\ y) = \frac{100\%}{N} \sum_{i=1}^{N} \frac{|y_i - \hat{y}_i|}{(|y_i| + |\hat{y}_i|)/2} \tag{1}$$

If we have several vehicles, then the accumulated SWMAPE error is the mean of SWMAPE errors for each vehicle.

4 EVALUATION

Evaluation of the deep learning-based solution is described in this section. The comparison of this method and Moses' algorithm is also included. First, the results achieved on the BME-S1 synthetic dataset are discussed; then, experimental tests on real measured data are provided.

Two types of error levels are described. Each error level describes the vehicle speed error and the axle location error of the preprocessing steps, and the noise observed in the signal. Data augmentation is handled the same way as in Section 3. The standard deviation of the Gaussian noise in each case is presented in Table 1.

Table 1. List of defined error levels. Standard deviations of vehicle speed, axle location and signal error are given for augmenting test data.

	Speed	Axle location	Signal
Error level	error [km/h]	error [1/100 s]	error [μm/m]
Ground-truth	0.0	0.0	0.0
Noisy	1.5	0.3	2.0

Table 2 describes the errors achieved when ground-truth data is provided. The gross vehicle weight (GVW) equals the sum of axle loads. Mean Absolute Percentage Error (MAPE) of calculated GVWs and given GVWs are computed. Mean Signed Percentage Error (MSPE) describes how each axle load estimator tends to underestimate or overestimate the GVW or axle loads of the vehicles (AW). The standard deviation of the percentage errors is also presented for axle weights and gross vehicle weight as well. It can be seen in the table, that our development achieves better results than Moses' algorithm on one-lane scenarios and multi-lane scenarios as well. The difference between the two axle load estimators is even higher when considering multi-lane scenarios.

Table 2. Error of the estimated axle weight (AW) and gross vehicle weight (GVW) for each axle load estimator on both one-lane and multi-lane scenarios when no noise is added.

Dataset	One-lane		Mutli-lane	
Metric	Proposed Method	Moses algorithm	Proposed method	Moses algorithm
GVW MAPE [%]	**1.51**	2.17	**2.43**	3.44
GVW MSPE [%]	-1.36	-2.01	0.14	-2.06
GVW σ[%]	**1.34**	2.32	**3.88**	5.82
AW MAPE [%]	**2.02**	2.40	**3.68**	5.30
AW MSPE [%]	-1.51	-2.12	0.36	-2.16
AW σ[%]	**2.33**	2.78	**6.16**	11.0

Table 3 describes the errors achieved when noise is added. It is shown in the table, that the neural network is still better than Moses' algorithm on one-lane scenarios, but the gap is not as large as in multi-lane scenarios. The developed neural network achieves better results than the Moses' algorithm on multi-lane scenarios. The gap is larger in this case than in one-lane scenarios.

Table 4 describes the results achieved on the multi-lane dataset. It can be seen that if only the heaviest vehicle is evaluated in every scenario, the errors are kept near as low as in one-

lane scenarios. Since only the heavy vehicles are important in most bridge engineering applications e.g. damage and fatigue analysis, it is a promising result.

Summarizing the results, it can be stated that our proposed method outperforms the traditional method, especially in the multi-lane scenarios.

Table 3. Error of the estimated axle weight (AW) and gross vehicle weight (GVW) for each axle load estimator on both one-lane and multi-lane scenarios when noise is added.

Dataset	One-lane		Mutli-lane	
Metric	Proposed method	Moses' algorithm	Proposed method	Moses' algorithm
GVW MAPE [%]	**2.37**	3.11	**3.32**	4.27
GVW MSPE [%]	-1.39	-2.44	0.18	-2.50
GVW σ[%]	**3.02**	3.28	**4.97**	6.39
AW MAPE [%]	**3.99**	4.42	**5.32**	6.91
AW MSPE [%]	-1.48	-2.60	0.42	-2.67
AW σ[%]	5.75	**5.51**	**8.19**	12.02

Table 4. Error of the estimated axle weight (AW) and gross vehicle weight (GVW) for each axle load estimator on multi-lane scenarios when noise is added.

Dataset	All vehicles		Only the heaviest vehicle	
Metric	Proposed method	Moses' algorithm	Proposed method	Moses' algorithm
GVW MAPE [%]	**3.32**	4.27	**2.35**	3.13
GVW MSPE [%]	0.18	-2.50	-0.16	-2.46
GVW σ[%]	**4.97**	6.39	**3.12**	3.36
AW MAPE [%]	**5.32**	6.91	**3.66**	4.61
AW MSPE [%]	0.42	-2.67	0.07	-2.56
AW σ[%]	**8.19**	12.02	**5.14**	5.95

5 EXPERIMENTAL RESULTS

End-to-end tests are also carried out. The pipeline contains a deep learning-based axle detector (Kawakatsu et. al 2020, Lorenzen et al. 2022) and a vehicle speed estimator using the peak-to-peak approach (He et al. 2017) in the current phase of development. A smaller set of real scenarios is available for us. The real annotated dataset contains 10 two-axle, 3 five-axle and 2 four-axle vehicles crossing the bridge. Only the heaviest axle and the gross vehicle weight of each vehicle are available for all vehicles. Results are presented in Table 5. One of these cases is a multi-lane scenario, others are one-lane scenarios.

It can be seen that the neural network achieves lower MAPE errors when estimating gross vehicle weight or the heaviest axle load of each vehicle. The Moses' algorithm tends to underestimate both the axle loads and the gross vehicle weight based on the MSPE metrics but even if axle loads were forced by scaling to set this error to be zero, the Moses' algorithm would still have worse or near the same performance since standard deviation of percentage errors is lower for neural networks.

6 CONCLUSION

The development of a deep learning-based solution is presented in this paper. It is tested on the BME-S1 dataset which is a large synthetic dataset. The new solution performs better when compared to the previous version of this algorithm or Moses' algorithm.

Table 5. The error of the estimated gross vehicle weight (GVW) and the error of the estimated heaviest axle weight (HAW) of each axle load estimator.

Metric	Proposed Method	Moses' algorithm
GVW MAPE [%]	**2.22**	3.88
GVW MSPE [%]	-0.09	-2.85
GVW σ[%]	**2.74**	3.95
HAW MAPE [%]	**3.32**	4.26
HAW MSPE [%]	-1.98	-3.31
HAW σ[%]	**3.47**	3.53

Both our algorithm and Moses' algorithm cannot handle failing sensors. Further work should focus on cases when one or more sensors do not work properly. Deep learning-based solutions can be effective in this field as well. Further work should also focus on camera-based BWIM systems as well to prepare the system for more complex traffic scenarios as well.

ABSTRACT: This paper presents a quantitative analysis of load estimation through augmented Kalman filter (AKF) for dynamic systems subjected to moving forces with position uncertainties. AKF incorporates unknown inputs with estimated system states, enabling the filter to estimate unknown forces. Identification algorithms like AKF often necessitate knowledge of the position of a moving load; however, the uncertainty in force position is frequently overlooked in the analysis. These uncertainties may stem from a variety of factors, including sensor noise, measurement inaccuracies, or the inherent variability in the force's intended path. For example, vehicle position tracking can be achieved through straightforward methods like entry and exit sensors, assuming a constant velocity model. Alternatively, it can involve more sophisticated remote sensing techniques, such as computer vision or LiDAR-based systems, which provide a more accurate representation of the vehicle's position. In this context, this paper presents a pioneering effort to quantify the impact of load estimation precision in scenarios involving moving forces with position uncertainties under diverse conditions using AKF. The study focuses on a simply supported bridge case, with the tuning of AKF parameters accomplished through the L-curve method. Tests involving various position noise levels combined with different velocities of the applied forces were conducted.

1 INSTRUCTION

Moving loads are ubiquitous in mechanical and civil engineering within daily lives. In many instances, a comprehensive understanding of the moving loads applied to structures proves beneficial. Consider, for instance, the context of a bridge—a structure designed to bear moving loads, playing a critical role in supporting everyday urban activities. The precise knowledge of the moving forces on the bridges can be great helpful for structure maintenance and improving bridge design (Lydon 2016). Therefore, the identification of dynamic loads stands as a paramount undertaking.

Significant efforts have been dedicated to the field of moving force identification. Direct measurement methods, such as axle-level instrumentation (Cantieni 1992), have been proposed. More recently, attention has shifted towards indirect measurement methods, commonly referred to as Bridge Weigh-in-Motion (BWIM) (Yu 2016). Moses (Moses 1979) early proposed the BWIM method, employing influence lines and strain measurements. Law (Law 1999) proposed a frequency and time domain method to retrieve the dynamic load history. OBrien (OBrien

DOI: 10.1201/9781003483755-171

2006) applied Tikhonov regularization to reduce algorithm inaccuracies. Liu (Liu 2020) used compressed sensing theory to shorten the sample length of response data for identification.

In addition to analytical methods and the influence line method, the Kalman filter (KF) has become a potent and promising tool for moving load identification. The KF is a recursive optimal estimation algorithm that achieves precise estimation by integrating the model of the system and measurement data (Welch 1995). Lourens (Lourens 2012) introduced the augmented Kalman filter (AKF), which incorporates unknown inputs with estimated system states, enabling the filter to estimate unknown forces. Based on Lourens' work, Lai (Lai 2022) applied the AKF to moving load identification, assessing its accuracy through field tests. Lai's work presented the feasibility and effectiveness of utilizing the AKF in time-variant systems.

Following the literature review conducted above, existing research reveals certain limitations. Notably, identification algorithms frequently require knowledge of the position of a moving load, yet they often overlook positional noise (Feng 2015). Basic methods, like entry and exit sensors, assuming a constant velocity model, can accomplish this task (Lai 2022). Conversely, more advanced techniques, such as computer vision or LiDAR-based systems, offer a heightened precision in representing the vehicle's position. Regardless of the chosen method, it is crucial to recognize the inevitable presence of positional errors, which can impact the accuracy of identification.

Therefore, this paper investigates the effect of the load position noise on the moving force identification of the AKF. The study focuses on a simply supported Finite Element (FE) beam. The tuning of AKF parameters was accomplished using the L-curve method, and tests of various position noise levels along with different velocities of the forces were conducted. The subsequent sections of the paper are structured as follows: Section 2 provides the relevant equations, Section 3 presents the numerical tests, and finally, Section 4 comprises the conclusion and discussion.

2 MODELING

2.1 *Equation of motion*

The analysis incorporates a Finite Element Method (FEM) discretization to model the structural response under the influence of a dynamic load. This discretization employs one-dimensional beam elements within a two-dimensional space, each node having three Degrees of Freedom (DOFs). Figure 1 serves as an illustrative representation of the model, depicting a simply supported beam subjected to two moving forces, denoted as f_1 and f_2. These forces represent a singular vehicle with two axles in motion at a given velocity s and a fixed axle distance b_1.

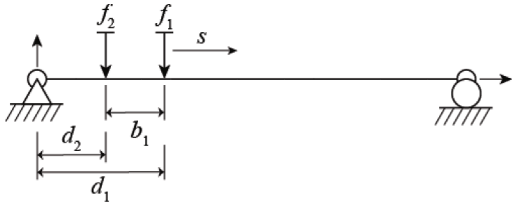

Figure 1. Diagram of a simply supported beam subjected to a two-axle vehicle.

The equation of motion of the FE model can be represented as:

$$M\ddot{u}(t) + C\dot{u}(t) + Ku(t) = S_f(t)f(t) \tag{1}$$

where $u(t) \in \mathbb{R}^{n_d}$ represents the displacement vector, n_d is the number of DOFs of the model. $M \in \mathbb{R}^{n_d \times n_d}$, $C \in \mathbb{R}^{n_d \times n_d}$, and $K \in \mathbb{R}^{n_d \times n_d}$ are the global mass matrix, damping matrix, and

stiffness matrix, respectively, $f(t) \in \mathbb{R}^{n_f}$ denotes the input load vector, n_f is the number of the input loads, $S_f(t) \in \mathbb{R}^{n_d \times n_f}$ represents the load distribution matrix indicating how moving loads apply to the system.

The damping is modeled through the famous Rayleigh damping i.e. C is a linear combination of the stiffness and mass matrices:

$$C = \alpha M + \beta K \tag{2}$$

where α and β are the Rayleigh damping coefficients of M and K, respectively.

2.2 *AKF modeling*

Suppose the discretization time step size is set to Δt. $\bullet_k$ denotes the current time is $k\Delta t$. The augmented stat vector $X_k \in \mathbb{R}^{2n_d+n_f}$ is defined as:

$$X_k = \begin{bmatrix} u_k \\ \dot{u}_k \\ f_k \end{bmatrix} \tag{3}$$

where $\boldsymbol{u}_k$ represents the displacement state vector, $\dot{u}_k$ represents the velocity state vector, and $\boldsymbol{f}_k$ is the force vector.

The augmented state-space representation of both the bridge and the vehicle is expressed as:

$$\begin{cases} X_k = A_{k-1} X_{k-1} + w_{k-1} \\ z_k = H_k X_k + v_k \end{cases} \tag{4}$$

where $A_{k-1} \in \mathbb{R}^{(2n_d+n_f)\times(2n_d+n_f)}$ is the augmented system matrix, defined as:

$$A_{k-1} = \begin{bmatrix} A_d & B_{d,k-1} \\ 0 & I \end{bmatrix} \tag{5}$$

where A_d and $B_{d,k-1}$ are obtained by discretizing the continuous system matrix A_c and B_c defined as:

$$A_c = \begin{bmatrix} 0 & I \\ -M^{-1}K & -M^{-1}C \end{bmatrix} \tag{6}$$

$$B_c(t) = \begin{bmatrix} 0 \\ M^{-1}S_f(t) \end{bmatrix} \tag{7}$$

The augmented output influence matrix $H_k \in \mathbb{R}^{n_z \times (2n_d+n_f)}$ is contingent upon the measured DOFs. $z_k \in \mathbb{R}^{n_z}$ represents the measured vector and n_z is the number of the measured points. The process noise w_{k-1} denotes the zero-mean noise in the state equation and is characterized by the associated covariance matrix $Q \in \mathbb{R}^{(2n_d+n_f)\times(2n_d+n_f)}$, and v_k is the zero-mean measurement noise with associated covariance matrix $R \in \mathbb{R}^{n_z \times n_z}$.

The covariance matrix $\boldsymbol{Q}$ is expressed as:

$$Q = \begin{bmatrix} Q_u & 0 \\ 0 & Q_f \end{bmatrix} \tag{8}$$

Where $Q_u = \mathrm{diag}\left(\sigma_u^2\right) \in \mathbb{R}^{2n_d \times 2n_d}$ is the covariance matrix of the displacement and velocity, and $Q_f = \mathrm{diag}\left(\sigma_f^2\right) \in \mathbb{R}^{n_f \times n_f}$ is the covariance matrix associated with the white force noise. Both σ_u^2 and σ_f^2 serve as tuning parameters in this study, influencing the system's response to uncertainties in the displacement, velocity, and external force components.

The equations of the Kalman filter are given as:

i. Measurement update

$$\begin{aligned} L_k &= P_k^- H_k^{\mathrm{T}} \left(H_k P_k^- H_k^{\mathrm{T}} + R\right)^{-1} \\ \hat{X}_k &= \hat{X}_k^- + L_k\left(z_k - H_k \hat{X}_k^-\right) \\ P_k &= (I - L_k H_k) P_k^- (I - L_k H_k)^{\mathrm{T}} + L_k R L_k^{\mathrm{T}} \end{aligned} \tag{9}$$

ii. Time update

$$\begin{aligned} \hat{X}_{k+1}^- &= A_k \hat{X}_k \\ P_{k+1}^- &= A_k P_k A_k^{\mathrm{T}} + Q \end{aligned} \tag{10}$$

where $\hat{X}_k^-$ and $\hat{X}_k$ are the prior and posterior estimation of the augmented state vector at k-th step respectively, P_k^- and P_k are the prior and posterior error covariance matrix at k-th step respectively, and L_k represents the well-known Kalman gain.

2.3 *AKF tuning*

For the covariance matrix Q, the tuning process from the L-curve method is selected. When employ the L-curve, σ_u^2 and σ_f^2 are assumed to share the same value. Initially, σ_u^2 is determined based on the minimum error norm $\left\|z_k - H_k \widehat{X}_k^-\right\|_2$. σ_u^2 is searched within the given range $\left[\min\left(\sigma_u^2\right), \max\left(\sigma_u^2\right)\right]$ with an exponential step size of $^{10}1$. For each value of σ_u^2 the range of σ_f^2 given by $\left[\min\left(\sigma_f^2\right), \max\left(\sigma_f^2\right)\right]$ is searched for the minimum error norm. σ_u^2 is then selected at the corner of the L-curve. Subsequently, σ_f^2 can be decided by the smooth error $\|f_k\|_2$ and the error norm $\left\|z_k - H_k \widehat{X}_k^-\right\|_2$ obtained given the fixed σ_u^2 and the same range $\left[\min\left(\sigma_f^2\right), \max\left(\sigma_f^2\right)\right]$. For further details, interested readers can refer to Lourens et al. (Lourens 2012); Lagerblad et al. (Lagerblad 2019).

3 NUMERICAL EXAMPLE

3.1 *FE model*

This section investigates a single span simply supported bridge model subjected to moving forces. The detailed parameters of the finite element (FE) model are outlined in Table 1. The model comprises 12 elastic-beam-column type elements, resulting in a total of 35 DOFs, as presented in Figure 2. Measurement channels were positioned at the vertical DOFs of five nodes within the model, as illustrated in Figure 2.

Table 1. FE model parameters.

Parameters	Value	Parameters	Value
Length (m)	30	Section inertial moment (m^4)	0.8
Element number	12	Elastic modulus (Pa)	3×10^{10}
Density (kg/m^3)	3000	Damping coefficient α	1.5×10^{-1}
Section area (m^2)	3	Damping coefficient β	5×10^{-5}

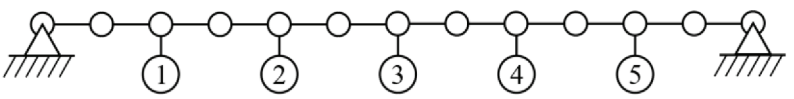

Figure 2. FE model and the measurement placement.

To introduce the model error, the elastic modulus and the damping coefficients were multiplied by a random number generated from a normal distribution with a mean of 1 and a standard deviation of 0.05. The mode properties after the introduction of the model error are shown in Figure 3.

Position noise is introduced to simulate the identification uncertainty of the tracking method, formulated as follows:

$$\mathrm{d}_{k+1}^{i} = \mathrm{d}_{k}^{i} + [s + \mathcal{N}(0, PNL \times s)] \times \Delta t \tag{11}$$

where d_{k}^{i} represents the location of the ith axle force of the vehicle at the kth time step, PNL denotes the position noise level, and s is the velocity of the vehicle.

To evaluate the accuracy of the identification, the error is computed as the norm of the difference between the true and estimated axle force vectors, expressed as:

$$E = \frac{\|f_{true} - f_i\|}{\|f_{true}\|} \times 100\% \tag{12}$$

where f_i represents the identified force vector over the crossing period and f_{true} is the true force vector of the same length.

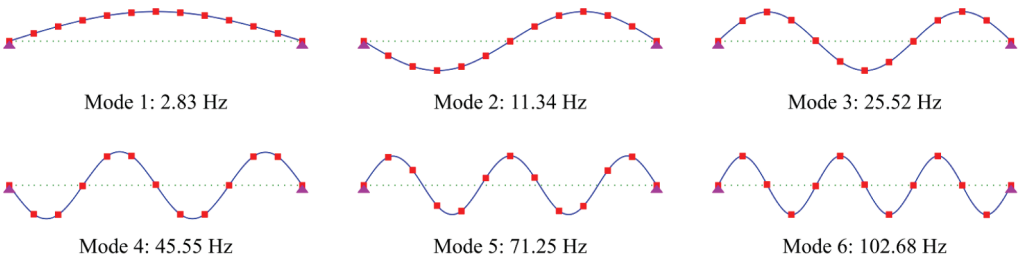

Figure 3. Mode shape and mode frequency of the adjusted FE model.

3.2 *Tuning results*

The following scenario is considered: a vehicle with two axles, specifically, the first axle (denoted as f_1) with a weight of 68.7 kN and the second axle (denoted as f_2) with a weight of 127.5 kN, is applied to a bridge at a constant velocity of 20 m/s. A white noise of 5% was introduced to the true response and the force position data. This scenario is analyzed in the presence of model errors. The sampling frequency is 200 Hz. The initial force variance $P_0^{f_i}$ is set as 4×10^{10} kN^2 and the rest initial state variance is set as 0 kN^2, indicating that the filter assumes the bridge to be static before the vehicle enters. For this study, σ_u^2 was searched

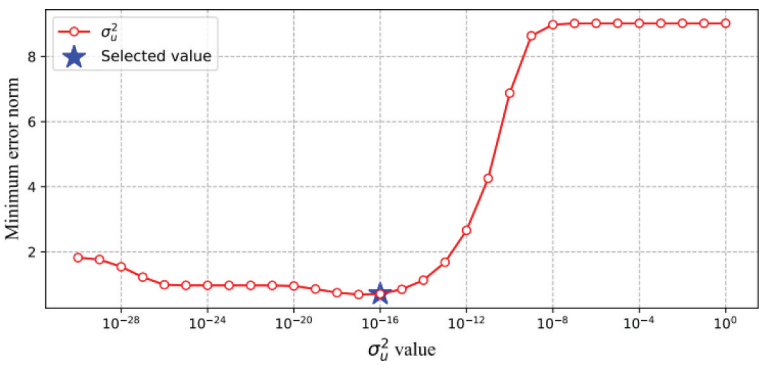

Figure 4. Tuning process of σ_u^2.

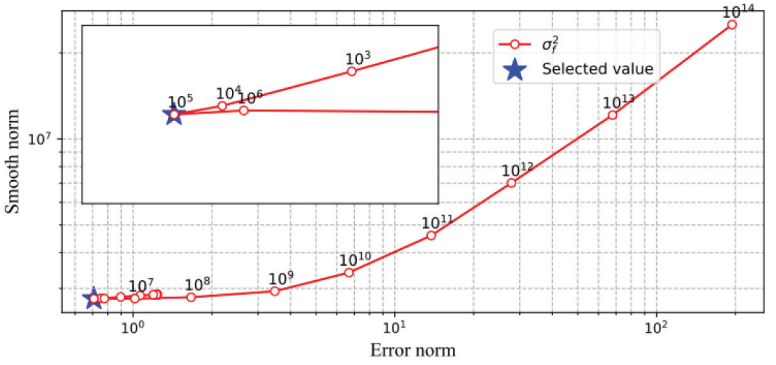

Figure 5. Tuning process of σ_f^2 given $\sigma_u^2 = 10^{-16}$.

within the range of $[10^{-30}, 10^{0}]$ with an exponential step size of 10^{1} while σ_f^2 was assigned the range of $[\sigma_u^2 \times 10^{0}, \sigma_u^2 \times 10^{30}]$ with an exponential step size of 10^{1}. The tuning process was plotted in Figure 4 and Figure 5 and the parameters were selected as $\sigma_u^2 = 10^{-16}$ and $\sigma_f^2 = 10^{5}$.

3.3 *AKF results*

This study examines the impact of varying noise levels on the precision of identification results for a two-axle vehicle at different velocities, using the same vehicle configuration as detailed in subsection 3.2. Four distinct levels of force position noise—1%, 2%, 5%, and 10%—have been chosen for analysis. Additionally, three different velocities—20 m/s, 30 m/s, and 40 m/s—are taken into consideration. Consequently, a total of 12 test combinations are investigated. For each combination, 50 tests are conducted to derive statistical measures of the identification accuracy. The sampling frequency is held constant at 200 Hz throughout this study. The parameters of the filter were chosen to be the same as those employed in the tuning process and aligned with the results obtained from the tuning phase.

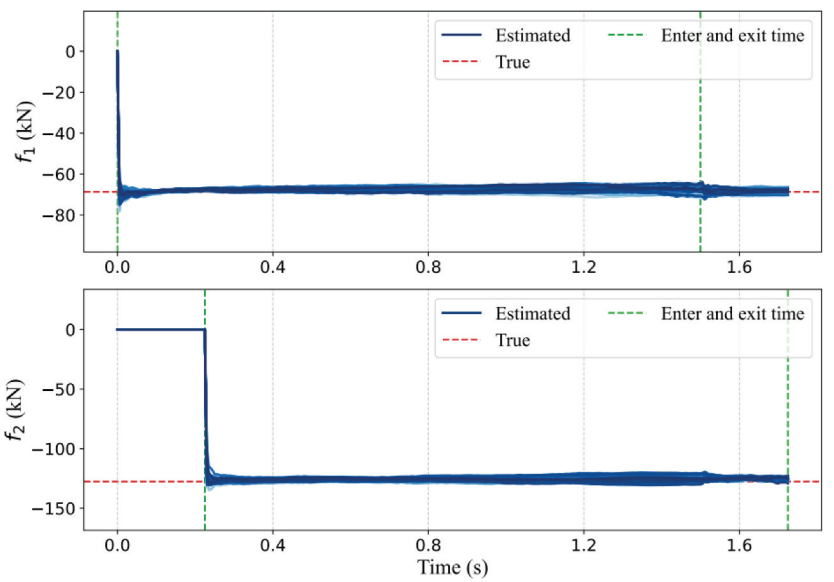

Figure 6. Estimation of axle force with the position noise of 1% for a velocity of 20 m/s.

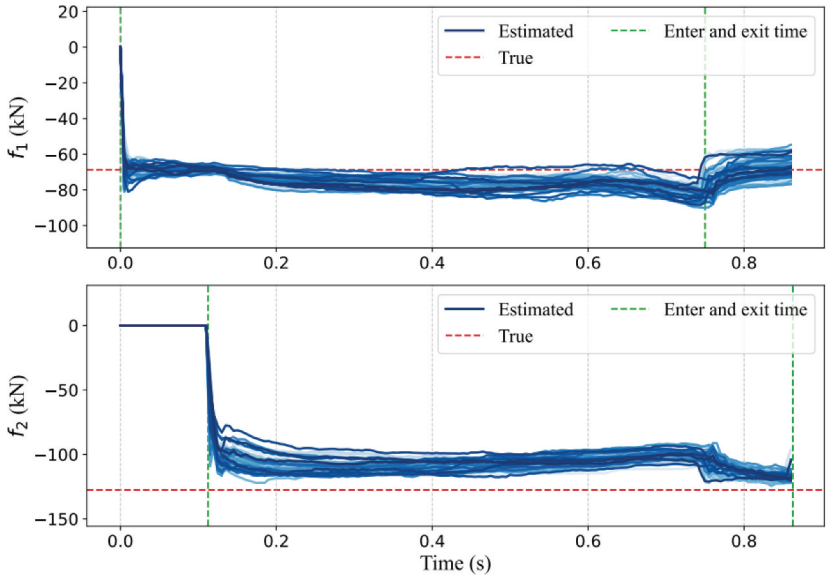

Figure 7. Estimation of axle force with the position noise of 10% for a velocity of 40 m/s.

Figure 6 and Figure 7 depict the time history of force estimation and uncertainty for two extreme cases: 1% position noise at 20 m/s and 10% position noise at 40 m/s, respectively. In scenarios with low noise levels, the estimated force values closely align with the true force values. Conversely, under conditions of high noise, the filter encounters challenges in accurately tracking the true value, yet it still produces results that are sufficiently accurate.

Table 2 presents detailed error values. The identification error for a single axle and the sum weight exhibit an increase with higher levels of position noise, as indicated in the table. The filter faces greater difficulty in accurately estimating the true force with heightened position noise. Additionally, at a velocity of 40 m/s, the identification errors are larger than those observed at lower velocities. Higher velocities result in a shortened crossing time, offering the estimation process less input information, and the presence of more axles introduces additional unknown states. Cases at 30 m/s exhibit better performance compared to those at

Table 2. Mean (standard deviation) of error of different combinations.

Velocity (m/s)	20				30			
PNL (%)	1	2	5	10	1	2	5	10

f_2 (%)	11.35 (±0.81)	11.55 (±1.02)	12.78 (±1.80)	17.01 (±2.59)				
Sum (%)	5.96 (±0.47)	5.90 (±0.52)	6.26 (±0.73)	8.05 (±1.19)				

* PNL: position noise level.

20 m/s, which may be attributed to the tuned parameters being more suitable for scenarios with a velocity of 30 m/s.

4 CONCLUSIONS

In this study, we conducted an analysis of force identification using an AKF for structure subjected to moving forces with position uncertainties. The analysis took into account both model and response errors. The impact of position noise was investigated through numerical analyses on a simply supported bridge subjected to a two-axle vehicle. The vehicle was modeled as two constant concentrated forces moving with a fixed distance and a specified velocity. The results indicate that position noise leads to a decrease in identification accuracy across all velocity cases. This effect is particularly strong at lower velocities, while at higher velocities, the impact is less significant.

Certain limitations exist in the current framework, such as the omission of dynamic effects related to moving loads and a primary focus on scenarios involving a single two-axle vehicle. Ongoing research efforts are dedicated to addressing these limitations and enhancing the comprehensiveness of the proposed methodology.

Improvements in providing overviews of future bridge interventions, their possession windows, and costs

H. Mehranfar, B.T. Adey & S. Chuo
Chair of Infrastructure Management, Institute of Construction & Infrastructure Management ETH Zurich, Switzerland

ABSTRACT: Bridge managers estimate intervention requirements years in advance. They do this to help ensure that work that needs to be carried out can be planned appropriately in terms of quality and timing. These initial estimates must be done at least 10 years before an intervention is required and perhaps even up to 20 years. These large time periods are required so that detailed investigations can be carried out, decisions can be made as to what should be done, work sites can be planned that exploit synergies between multiple interventions, that intervals can be built into train schedules so that there is enough time to do the work, and then the construction sites can be planned in detail. This paper proposes a methodology to be used by bridge managers to obtain a consistent and complete overview of these future bridge interventions and give indications of the required possession windows required in train schedules, and the approximate costs. The methodology is an improvement on the existing bridge management system methodologies in that it uses nonhomogeneous transition probabilities, instead of homogeneous ones, and explicitly estimates the risks associated with different types of bridge failure as a function of the condition states of the different structural components. Existing methodologies do not explicitly consider failure risk in this manner. The methodology is demonstrated using a 100m-long steel truss bridge in Switzerland. The results are visualized using BIM, which allows bridge managers to better understand the algorithmic results and facilitates discussions between multiple stakeholders of the planning process to prioritize interventions. The use of the methodology is expected to improve both effectiveness and efficiency of the intervention planning process.

1 INTRODUCTION

In the current intervention planning process, the estimation of intervention requirements for bridges is often conducted in a somewhat iterative and qualitative manner. This usually involves discussing the findings of inspection reports by bridge managers with inspectors and engineers in order to ensure a shared understanding of bridge conditions to enable informed decision-making regarding the intervention requirements for bridges over future planning periods. This process is challenging and time-consuming due to the lack of a systematic and efficient methodology to generate an overview regarding all possible upcoming interventions. This lack not only makes it difficult to have a complete overview of the required possession times and financial requirements for executing interventions but it may also lead to deviations in scheduling of interventions to be executed at the ideal time. This will likely result in frequent service disruptions as well as excessive intervention costs. Consequently, a systematic methodology to efficiently estimate intervention requirements in a digital environment would help bridge managers reduce service disruptions and intervention costs by facilitating

DOI: 10.1201/9781003483755-172

a common understanding of intervention requirements, their required possession times and costs using available data on the condition of bridges. Such a methodology addresses the gap in the current intervention planning process.

There exist numerous methodologies aiming at helping bridge managers in their decision-making on estimating the required interventions. For example, (Adey and Hajdin 2011, Adey *et al.* 2015) proposed methodologies to determine the optimal intervention strategies for a bridge portfolio using asset-level information. These methodologies, although efficient and systematic, could not provide complete and detailed estimates of intervention requirements. Such details include conducting analyses on the component (or element) level, estimates of failure risks, required possession windows, and costs. Each of these gaps was addressed in different ways in several works. For example, (Martani *et al.* 2021, Kim *et al.* 2022) focused on making their estimates on the component level. (Adey *et al.* 2010, 2012) proposed methodologies to estimate the failure risks associated with the bridges. (Adey and Hajdin 2011, Burkhalter and Adey 2021, 2022) made estimates of intervention costs and required possession windows in their work. Despite some works such as (Mehranfar, Adey, *et al.* 2023b) proposed a methodology to cover all of these aspects for providing a detailed and complete overview of intervention requirements for aiding bridge managers in their decision-making, they were not being integrated into BIM.

This paper proposes a methodology to systematically generate a complete overview of intervention requirements, their required possession windows, costs, and associated failure risks over multiple planning periods. The methodology, furthermore, pipelines this information efficiently to be presented in BIM in a user-friendly manner.

2 METHODOLOGY

An overview of the steps for generating a complete overview of intervention requirements along with their visualisation in BIM over multiple planning periods is provided in Figure 1.

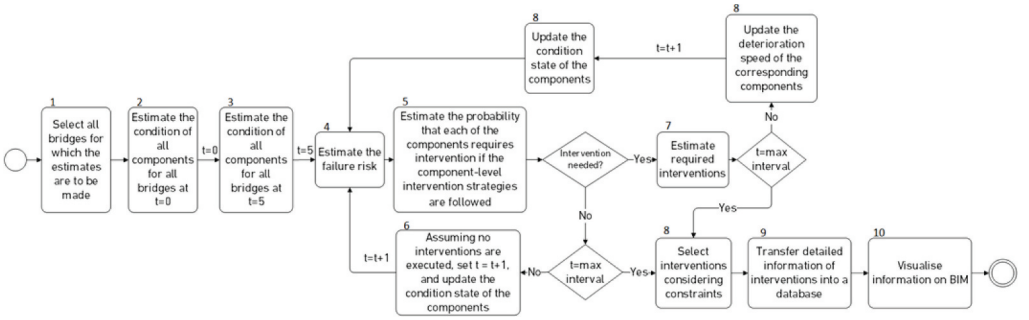

Figure 1. Steps to estimate and visualize component-level intervention requirements.

Step 1: Select all bridges for which the estimates are to be made. The bridges that are being investigated in detail do not need these estimates.

Step 2: Estimate the condition of all components for all bridges at t=0.

Step 3: Estimate the condition of all components for all bridges at the start of the planning period to be considered, for example, t=5.

Step 4: Estimate the failure risks at t=5.

Step 5: Estimate the probability that each of the components will require intervention if the component-level intervention strategies are followed.

Step 6: Assuming no interventions are executed, set t = t+1 and repeat Steps 3 to 6 until the probabilities of components requiring intervention and the failure risks have been estimated for each of the years in the planning period.

Step 7: Estimate the required interventions. If the probability of requiring an intervention on at least one of the components is higher than the threshold value set, or the sum of the failure risks in the planning period is higher than a specific threshold value, it is considered that an intervention is to be executed on the bridge in this period, and information is given on the possible intervention types and the one that has the most likelihood, the possible and most likely possessions window requirement, and the expected intervention costs as a function of the type of intervention and possession windows.

Step 8: Select intervention interventions considering the constraints, e.g., thresholds for triggering execution of interventions, and propose interventions to postpone if the execution of all interventions is not possible: If it is known that not all interventions are possible within the planning period, e.g., due to a restricted budget even at this early stage, the indicator of the risk of failure is used to prioritize the bridge interventions, i.e., the bridges exhibiting the highest risk are first on the list. The bridges lowest on the list are postponed until the costs of the interventions included in the list are below the allocated budget.

Step 9: Transfer the detailed information of interventions into a database. The details regarding the selected component-level intervention, along with the information regarding the required possession windows, expected costs, and associated failure risks are transferred into a database to be used for visualization.

Step 10: Visualize information on BIM. The information regarding the intervention requirements that exist on the database is pipelined into the BIM of bridges to generate a user-friendly and complete overview of component-intervention requirements on the bridges.

3 EXAMPLE BRIDGE

Figure 2 shows the BIM of the example steel truss bridges, which consists of multiple components. These components, as shown in Figure 2, are trusses, girders, bearings, abutments, foundations, and the pier. Five discrete condition states on a scale of one to five are used to describe the different damage severities of the components that include the specific details of each condition state. A Condition State of 1 (CS1) implies that the component is in perfect condition, while CS5 states that the component is at the end of its lifecycle. These are assumed for all components in the same way done in (Mehranfar, Adey, *et al.* 2023b).

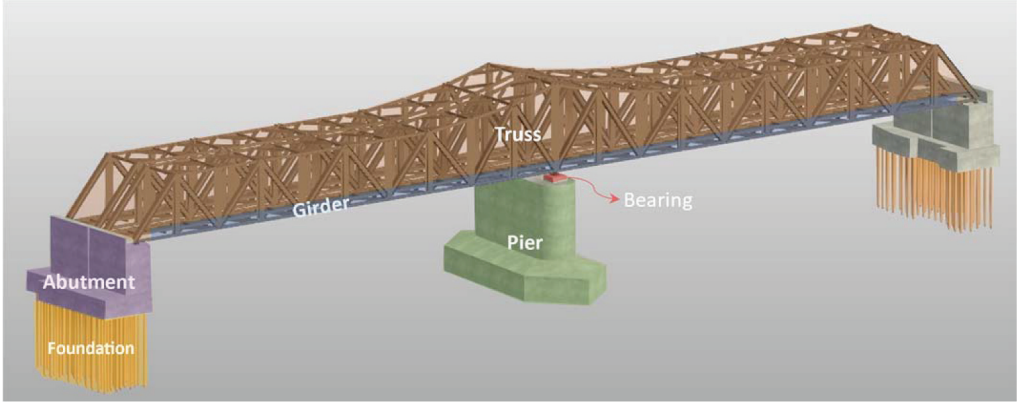

Figure 2. BIM of the example steel truss bridge.

3.1 *Condition of components at t=0 and t=5*

The current CS of the components is estimated by comparing the damage indicators mentioned in the inspection reports with the definition of CSs for the bridge components. For the

components that this information was not available, CSs were estimated using the method proposed by (Chuo *et al.* 2023). It is estimated that at t=0, foundations are in CS3, abutments are in CS2, the pier is in CS2, the bearings are in CS4, girders are in CS3, and the truss is in CS3.

The future CS of the components at t=5 was estimated using a probabilistic discrete state model with nonhomogeneous transition probabilities as done in (Mehranfar, Adey, *et al.* 2023b). In this model, the transition probabilities are for a one-year period as one year is usually the time between two consecutive routine inspections on the bridges. Additionally, the deterioration rates are assumed to accelerate by 2% as a function of the times maintenance interventions are executed on the components. The deterioration rates reset to default when the component is replaced.

A summary of the CS of the components at t=5 is provided in Table 1. It is seen that it is highly likely that the foundations are in CS3, abutments in CS2, the pier in CS2, bearings in CS5, girders in CS3, and trusses in CS3. These are estimated by multiplying the CS of the component in t=0 with the probability that their CS transits into the possible future CS within 5 years.

Table 1. A summary of the CS of components at t=5.

	CS				
Component	1	2	3	4	5
Foundations	0%	0%	63%	26%	12%
Abutments	0%	78%	18%	3%	1%
Pier	0%	75%	20%	4%	1%
Bearings	0%	0%	0%	33%	67%
Girders	0%	0%	47%	31%	22%
Trusses	0%	0%	47%	31%	21%

3.2 *Component-level intervention strategies*

There are multiple possibilities for the type of interventions that can be executed on each component. These are dependent on the severity of the observed damages. For example, in a planning period, one of three different intervention types including rehabilitation, renewal, and replacement can be executed on a damaged truss. These intervention types are defined to reflect the increasing effort and work required for interventions for all components in the same way discussed in (Mehranfar, Adey, *et al.* 2023b, 2023a).

Total costs of executing each intervention type on each component are estimated in terms of owner and user costs. The owner costs are roughly calculated using a reference pricing index (SFSO 2021). The user costs are approximately calculated with respect to the added travel time due to taking alternative connections during the possession windows required for the execution of interventions in the same way explained in (Mehranfar, Adey, *et al.* 2023a). An example of the intervention costs for the trusses is shown in Table 2. This table states that the more complex and intensive the work, the more expensive it becomes. These values are estimated for all components in the same manner.

Table 2. Example intervention costs for trusses.

Intervention type	Unit owner cost (mu/m^2)	Area (m^2)	Duration of the service disturbance (weeks)	Owner cost (mu)	Service disturbance costs (mu)
Rehabilitation	75	2'200	4	165'000	1'302'480
Renewal	150	2'200	10	330'000	3'256'200
Replacement	400	2'200	15	880'000	4'884'300

To account for the imperfection execution of interventions, the effectiveness of interventions for improving the condition of components to CS1 is assumed to be 85% for rehabilitation, 90% for renewal, and 100% for replacement. These values are illustrative, and they should be adjusted when implemented in a bridge management system.

The intervention strategies for the components are assumed to be:

- Execute no interventions when components are in CS1 or CS3.
- Rehabilitate when components are in CS3.
- Renew when components are in CS4.
- Replace when components are in CS5.

3.3 *Failure risks*

Failure risks need to be estimated in order to prioritise the initiation of a detailed investigation of the bridges recommended by the intervention strategies if not all of them can be initiated. Failure risks are estimated using fault tree analysis. Three fault trees are developed to estimate the probability and consequences associated with the failure of bridges to provide sufficient service, depending on the condition of the components. The top events of these fault trees are defined to cover the severity of the serviceability failure, which is a function of the severity of the component failures, i.e., "restricted service", "closure for up to two months" and "closure for more than two months". The occurrence of each top event results in the execution of different immediate interventions on the components.

The basic events include gradual and sudden deterioration events. These events occur due to a combination of different loads, e.g., excessive traffic loads, flooding, etc. More specific information regarding the use of failure risks for estimating the serviceability failure due to the execution of immediate interventions is found in (Mehranfar, Adey, *et al.* 2023b).

Connecting the estimates of failure risks to the condition of components allows setting a threshold on added total failure risks. Such thresholds can later be used to compare the level of failure risk with the predefined threshold to prioritise interventions. Figure 3 shows the evolution of the failure risks over time for the example steel truss bridge. Here, the threshold is considered as the value of failure risks if all components are in CS4. It is seen that the bridge manager can postpone the execution of interventions until t=11 as the failure risks meet their threshold at that time.

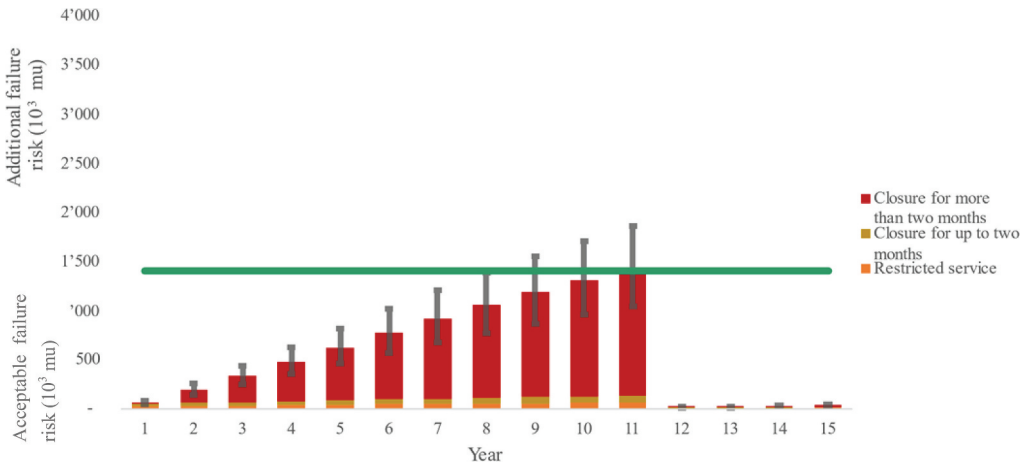

Figure 3. Evolution of failure risks considering a failure risks threshold.

4 ESTIMATES OF MOST LIKELY COMPONENT-LEVEL INTERVENTIONS

An overview of estimated most likely component-level interventions following consideration of component-level intervention strategies is provided in Table 3. This table serves as a starting point for discussing what activities will be precisely required for the bridge. It is assumed that the interventions are required to be executed on the components when the condition of bridge components meets the criteria mentioned in their intervention strategies. It is seen, for example, that the bridge abutments are highly likely to require rehabilitation in the period between t=6 and t=10 and if this intervention is executed on the abutments, it is likely that it will take 11 weeks to complete. Of this time, no service disturbance is needed for 6 weeks, and a service restriction is needed to be implemented for 4 weeks.

Table 3. The most likely intervention between t=6 and t=10 and between t=11 and t=15.

Planning period (expected year)	Component	Intervention type	Expected duration (weeks)	Expected required possessions (weeks) if done alone			Expected owner costs (10^3 mu)
				None	Restrictions on the traffic	Closure	
t=6 to t=10 (year 6)	Foundations	Rehabilitation	12	6	5	1	90
	Girders	Rehabilitation	6	2	4	-	330
	Trusses	Rehabilitation	8	5	3	-	165
	Bearings	Replacement	4	3	1	-	120
	Abutments	Rehabilitation	11	6	5	-	100
t=11 to t=15 (year 15)	Pier	Rehabilitation	10	6	4	-	480

5 VISUALISATIONS OF COMPONENT-LEVEL INTERVENTION ESTIMATES IN BIM

So that bridge managers have a better understanding of the component-level intervention estimates, BIM is used to visualise the evolution of CSs and the most likely intervention requirements over multiple planning periods. More detailed information regarding the use of BIM for infrastructure management is found in (Elshani 2023, Mehranfar, Chuo, *et al.* 2023, Chuo *et al.* in prep).

Figure 4 represents an example of the visualization of component-level CSs evolution and intervention estimates during multiple planning periods developed in the Autodesk Revit® environment. For example, it is seen in (a) that the CS of bridge foundations in t=5 is represented using a specific colour code. Further information regarding the CS of foundations, is also provided upon clicking on the foundation. As another example, an overview of intervention requirements in the planning period between t=6 and t=10 is shown in (b) for the example steel truss bridge.

6 CONCLUSION

This paper presents a systematic methodology for estimating a complete overview of component-level intervention requirements in the early phases of the intervention planning process. A demonstration was conducted on a steel truss bridge with a length of 100 m located in Switzerland, along with visualisations in BIM. The main novelty of the proposed methodology is in concentrating on the bridge components instead of bridges, the use of

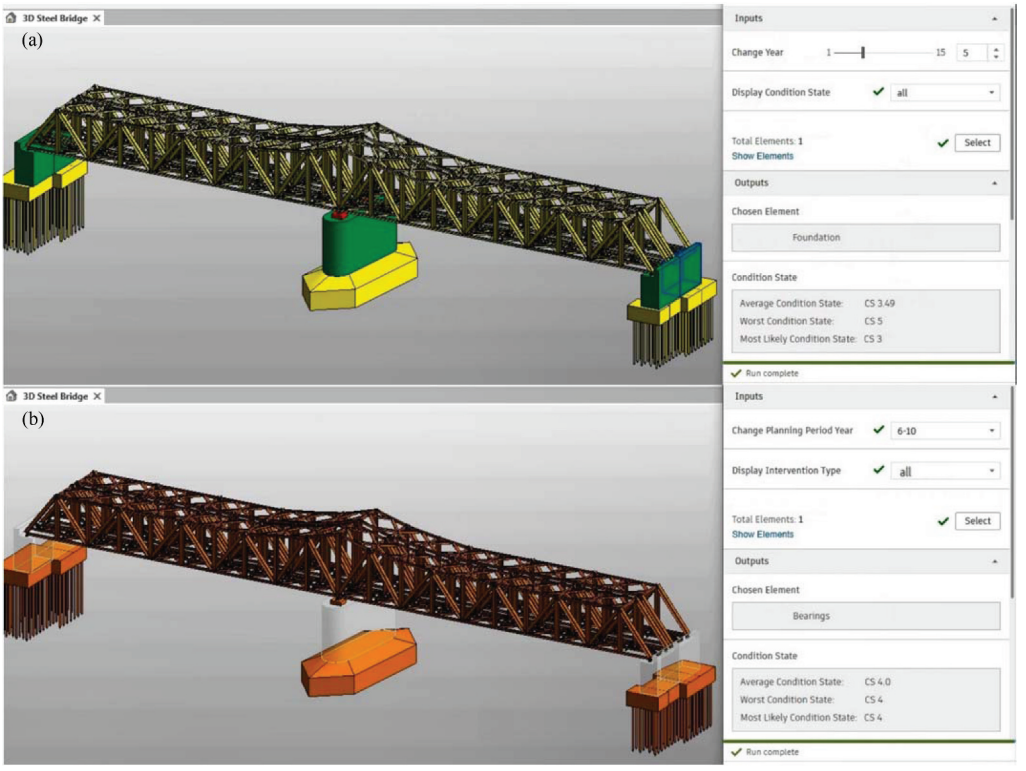

Figure 4. Example of illustrating the evolution of CSs (a), and the intervention requirements (b) over multiple planning periods using BIM.

nonhomogeneous transition probabilities connected to the number of times that a maintenance intervention is executed on the components and visualizing results in BIM.

The probabilistic modelling used in this paper considers a discrete scale of 1-5 in order to ensure compatibility with models used in the state-of-the-practice. The estimates of failure risks are made by developing tree fault trees with respect to the severity of the service disturbance. The consequences are estimated in terms of both user and owner costs associated with executing immediate interventions. The failure probabilities are estimated as a function of the CS of the components. The component-level intervention estimates are visualised in BIM to provide bridge managers with a new perspective that can help them make decisions and communicate with other stakeholders in the intervention planning process. Such visalisations are particularly beneficial when the component-level intervention estimates are generated for a portfolio of bridges within a transportation network.

Future research must focus on streamlining the connection between a complete overview of component-level intervention estimates and BIM in an efficient manner. This includes investigating how the BIM for bridges should be generated to ensure scalability and how the information should be exchanged.

ACKNOWLEDGEMENT

This work is part of the STABILITY research project that is supported by the ETH Mobility Initiative and the ETH Zurich Foundation. The authors would like to thank Dr. Saviz Moghtadernejad of the National Research Council Canada for her insights and feedback during the development of this work.

Connecting predictive algorithms to BIM to improve the planning process

S. Chuo, H. Mehranfar & B.T. Adey
Institute of Construction and Infrastructure Management, ETH Zürich, Zürich, Switzerland

G. Elshani
BPR Dr. Schäpertöns Consult GmbH, München, Germany

ABSTRACT: Bridge managers estimate the intervention requirements, and their associated costs, required possession times and failure risks in years advance. They communicate this information to multiple stakeholders involved in the intervention planning process using reports and tables. As it is difficult for stakeholders to process all the information in short periods of time this process can lead to misinterpretations, which in turn can lead to multiple iterations and discussions. With the rise of algorithms and BIMs to predict, plan, and manage future interventions, there is now an opportunity to use these tools to improve the efficiency of the planning process. This paper presents a methodology to do this, i.e., to demonstrate how predictive algorithms can be connected to BIM to facilitate discussions of the multiple stakeholders involved in the intervention planning process, and how the process can be improved. The methodology is demonstrated on a railway steel truss bridge in Switzerland.

1 INTRODUCTION

With the rapid advancement and ubiquitous use of information and communication technology, digital data and tools become increasingly pragmatic for the effective and efficient management of railway infrastructure. To that effect, European Commission's Sustainable and Smart Mobility Strategy calls for an action plan of 82 initiatives to bring European transport on track for the future, which includes issuing "recommendations for the transition to automation and digitalisation and their impact on the transport workforce" (European Commission, 2020). With digitalisation becoming a crucial driver to modernise infrastructure management, it has the potential to enable predictive maintenance to plan interventions in advance, with the goal of minimising disruption to traffic operation for the users. However, the digital transformation entails data availability, access, and exchange within an infrastructure management organisation, in order to support interlinked databases for asset data management solutions and big data for maintenance prediction (European Committee of the Regions et al., 2019). This requires reliable data collection, compatible tools and systems to facilitate data management and sharing across different entities, digital solutions to process data and support future intervention planning, as well as formulated coordination to mediate decision-making between entities.

The decisions on intervention planning are applied to a network of infrastructure assets and their components, and maintenance interventions that aim to sustain the existing level of service need to be estimated and communicated to other stakeholders who rely on that information for their own decision-making. With the requirement to plan and coordinate interventions years in advance, infrastructure managers need to have an express knowledge of the evolution of asset condition into the future, as well as the intervention requirements, including their associated costs, required possession times, and failure risks. As infrastructure management advances

DOI: 10.1201/9781003483755-173

towards digitalisation, such as the use of data-driven algorithms to determine the optimal intervention programs, their implementation will functionally evolve the decision-making process for infrastructure managers. This in turn enables objective, effective, and efficient decision-making for existing assets and future infrastructure expansion. The improvement to the intervention planning process through digitalisation is a complex challenge that requires an understanding of: (1) the current intervention planning process within different infrastructure management organisations, (2) digital tools available to facilitate the decision-making for intervention planning of infrastructure assets, and (3) coordination between these digital tools and interaction between these tools and the infrastructure managers. Therefore, this paper provides an overview of the railway intervention planning process, as well as demonstrates how digitals tools such as predictive algorithms and building information models (BIMs) can be connected to make intervention decisions.

2 INTERVENTION PLANNING PROCESS

Although academic research continues to develop state-of-the-art methodologies concerning intervention planning as well as life-cycle analysis and management, there lacks real-world application (Frangopol & Soliman, 2016). Consequently, for the railway transportation industry to accept and implement the proposed methodologies, it is necessary to prescribe guidelines for their adoption, and to evaluate the improvement in efficiency by comparing the current industry practice and any proposed changes to the intervention planning process. Schraven et al. (2011) outlined the decisions needed in infrastructure management, with regard to infrastructure objectives, technical and functional performance, and interventions. Jamali and Adey (2016) examined the effect of management decision processes to determine the optimal management strategy, where the processes were modeled using Business Process Model and Notation (BPMN) and they were compared to assess the impact. Adey (2019) defined a conceptually ideal road infrastructure management process at a high level, however, no differentiation was made between the management of a large network (e.g., national) and a small network (e.g., regional). There is currently no complete overview of the railway infrastructure management process in the literature, only some descriptions of specific subprocess exist, such as the estimation of the railway intervention program (Burkhalter & Adey, 2018).

To understand the typical railway intervention planning process, the planning activities are modeled based on firsthand experiences and interactions with railway companies. The model is inspired by their internal documents (e.g., guidelines or reports), and interviews were conducted

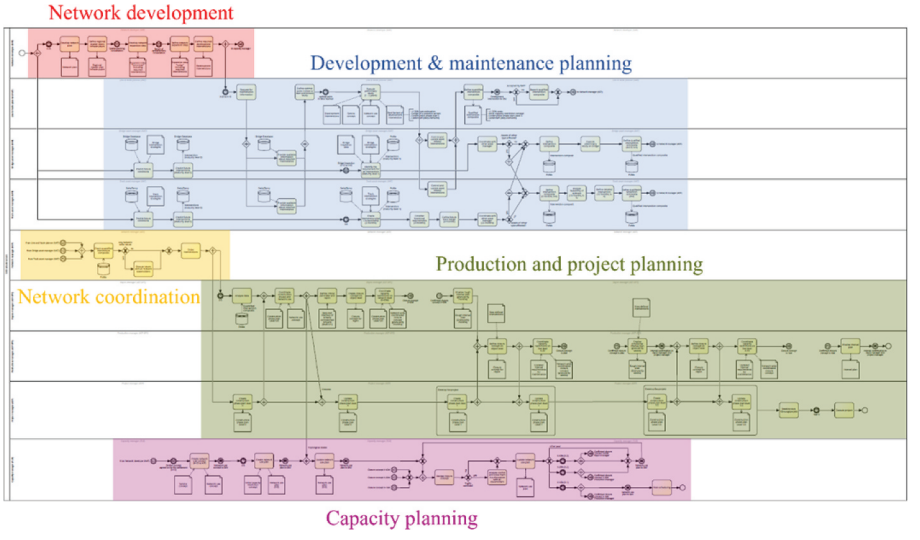

Figure 1. Main groups of railway intervention planning activities.

with the stakeholders who are involved within the process and make decision. The results are modeled using BPMN, so the planning activities are organised according to the actor. Figure 1 illustrates the main groups of intervention planning activities in the railway context.

To decide on the maintenance interventions on the assets, there needs first an overview of their condition states at present, and an understanding of how these conditions states will evolve (i.e., deteriorate) over time. With this information available, the intervention requirements are estimated, where the granularity can be based on the asset, component, or element level, in increasing level of detail. The interventions depend on the definition of intervention strategy, i.e., all interventions to be executed considering all possible condition states. The estimated intervention requirements are refined into intervention programs, i.e., the exact interventions to be executed considering the specific condition states. This typically means that the individual interventions are then clustered into projects, taking into consideration economical, topological, structural, and resource dependencies. The planning of project execution requires coordination between the intervention requirements and required service to be provided, e.g., a rehabilitation of a railway steel truss requires a weekend of possession time to set up and perform the work, therefore the railway service cannot be offered during that time due to closure of the corridor. This results in phased construction plans to detail the sequence, duration, and schedule of work activities, and in the railway context it also leads to an adjusted train schedule for the passengers and corridor availability for the freight trains, in terms of service cancellations or speed reduction.

The coordination between governments, agencies, and relevant stakeholders is an intricate and iterative process, where the collection, storage, distribution, and access of information and data form the foundation of decision-making on interventions. Therefore, digital solutions such as data-driven predictive algorithms offer an opportunity to streamline the required estimations and decisions throughout the intervention planning process, and BIM provide a collaborative platform to manage the digital information of infrastructure assets. These tools will become vital to the digitalisation of effective and efficient intervention planning in the future.

3 DIGITAL TOOLS IN INTERVENTION PLANNING

3.1 *Intervention planning predictive algorithms*

With an understanding of the current condition state, deterioration rate and future condition state, infrastructure managers are able to determine the optimal intervention programs using predictive algorithms, planning for what interventions need to be carried out on what infrastructure assets at what time in the next planning period taking into consideration the synergies between assets (Burkhalter & Adey, 2022; Mehranfar et al., 2023a, 2023b). These algorithms provide information on the component level, e.g., a railway bridge may consist of trusses, girders, bearings, abutments, foundations, piers, rails, sleepers, and ballast. This level of detail is important, especially in the railway context considering that most data are recorded only on the asset level, and the existing industry practices are usually qualitative and time-consuming. The quantitative and data-driven algorithms are therefore more effective and efficient, and the results allow infrastructure managers to be in the position to make systematic early estimates of future interventions on their portfolio of assets.

This is an improvement over the existing practice, where the provided information for intervention planning is often in the form of reports or tables, and although they contain all the necessary details with regards to a specific asset or a portfolio of assets, they often take more time to absorb and understand by other stakeholders. The difficulty to process all the information, coupled with the constraint to make decisions in a short amount of time, lead to multiple iterations and discussion to clarify intervention requirements, so everyone can agree on what should be done to maintain the assets. Therefore, the intervention planning predictive algorithms would help facilitate communication between the stakeholders in the planning process, particularly years in advance to help determine the timing of required detailed investigations by engineering offices.

3.2 *Building information modeling*

As the railway transportation industry prepares the shift towards digitalisation, BIM becomes increasingly relevant in infrastructure maintenance planning, as the digital representation of the physical asset and its functional characteristics facilitate a shared knowledge resource for information to support improved decision-making. While BIM applications for bridge maintenance have been developed extensively (Panah & Kioumarsi, 2021), there is limited BIM application for railway maintenance, where the focus has mostly been on design and construction, such as railway track alignment (Huang et al., 2011), code compliance checking (Häußler et al., 2021), and planning of construction process (Neves et al., 2019).

The difficulties are the result of interoperability issues between BIM tools, and the use of openBIM has been proposed, which enables collaboration, communication, and exchange of information without restricting solutions to a specific software. For example, Ciccone et al. (Ciccone et al., 2022) used openBIM to create a single digital model of an existing 47 km railway line in Italy. This is important because a railway line may consist of tracks, turnouts, stations, crossings, bridges, and tunnels, and the coordination of maintenance interventions relies on an understanding of the dependencies and impact between railway assets. However, the model created by Ciccone et al. does not include the visualisation of asset condition states and required interventions across time, which is critical to infrastructure managers in communicating with other stakeholders during the intervention planning process for decision-making.

4 DEVELOPMENT OF BIM FOR THE EXAMPLE RAILWAY BRIDGE

The methodology to demonstrate how predictive algorithms can be connected to BIM is described using a railway steel truss bridge in Switzerland spanning over a river, and it is 110 m in length and 11 m in width. There are two parallel steel trusses, where the upstream truss was built in the 1920s to replace the original bridge built in the 1870s, and the downstream truss was built in the 1960s. The bridge comprises one pier in the middle, two abutments on each end, 12 roller bearings on the pier and abutments, and two pairs of girders to support the two railway tracks.

The asset owner of this railway bridge does not have an existing digital model, therefore the original design drawings were requested and used as reference to model it in 3D using Autodesk Revit as the BIM authoring tool. The design drawings provide guidance in terms of the exact components that are part of the bridge, as well as the scale and location for each component relative to the rest of the bridge structure. Google Maps and Google Earth were also used as additional public sources of visual reference, so the satellite imagery, aerial photography, and street maps help model the railway bridge as realistic as possible.

To establish an efficient workflow, a family catalogue of railway bridge components was created to standardise asset modeling, as this methodology is expected to apply to a portfolio of bridges in the future. While creating these objects, the geometry that represent the 3D objects are considered so they can be modelled parametrically (e.g., length, width, height,

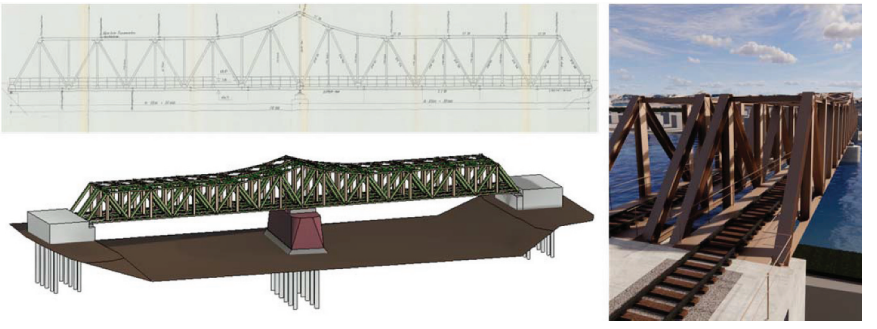

Figure 2. The example bridge represented by its cross section in 2D drawing and its 3D model.

etc.), as well as the information that underly them (e.g., construction year, materials, etc.). Additional considerations are also made, such as interoperability between different BIM authoring. This is important because it allows the models to potentially be used by other stakeholders using other software for decision-making. This results in the parametric modeling of bridge components in the Level of Development of 200, sufficient for the purpose of intervention planning which is early in the planning process. Figure 2 shows the cross section of the example railway bridge from 2D drawing, the 3D digital model of the bridge modeled using the family catalogue, and its 3D rendering.

Apart from the geometric models, other semantic data have also been included in the standard objects of the family catalogue in the form of parameters. This is especially relevant for the data exchange across different databases and digital systems, considering identity data that are unique to the internal referencing of the infrastructure management organisation, as well as open data schema specification such as the latest Industry Foundation Class (IFC) format IFC 4x3, which now includes rail and infrastructure components. This results in a Level of Information of 300.

5 CONNECTING PREDICTIVE ALGORITHMS TO BIM

5.1 *Setting up Revit project*

The connection of predictive algorithms on intervention planning to BIM leads to an intuitive understanding through the visualisation of asset component condition states and intervention requirements over time. Therefore, to efficiently use the family catalogue and to reach the proposed visualisation, a specific setup needs to be done on the Revit project containing the bridge assets. This setup includes the arrangement of the project parameters, global parameters, filter rules, filter overrides, and view settings.

The project parameters are needed to store information about the condition states, their deterioration, and different aspects of the planned interventions. These parameters have been assigned using the Revit category the components belong to. So, all components will automatically have the named parameters available in the instance information. This embedded information can then be used for the proposed visualisation, and any other use cases of the digital model to be expanded on in the rest of the intervention planning process (e.g., network coordination and construction planning).

To provide values as a basis to compare the user input with the calculated values for the condition states and interventions on the components, global parameters are also required in the BIM project setup. The assignment of these parameters works similarly to the project parameters mentioned earlier, using component categories as a basis for the assignment.

To visualise the information that the different components possess, view specific filter overrides are used. These filters follow defined rules, where two parameters are being compared. In the case of the values fulfilling the conditions, the filters will become active in the view, providing either one or multiple line, pattern, and transparency overrides of the bridge components. Using these filters provides a quick and straightforward visualisation of the given data on condition states and intervention requirements. It is important to note that these filter overrides apply only specific to a certain view in the Revit user interface, and this would leave the global visibility of the bridge components unaffected.

For the colour overrides provided by the view filters to become visible, the visual style of the active view should be set on either ‘Shaded’ or ‘Consistent Colours’. To set this up in Revit projects, view templates should be used, which can then be applied to the views as needed. Using a view template also generalises the view specific filter overrides, making the manual setup for every single view unnecessary.

All other parts of the project setup, including project parameters, global parameters, and filter rules can be transferred between projects using the ‘Transfer Project Standards’ tool. By utilising this transfer, the proposed methodology can also be applied to existing BIM models, empowering the infrastructure managers to exploit the potential of predictive algorithms for decision-making.

5.2 *Setting up dynamo*

After the railway bridge is modeled and the parameters of the project are established, the BIM is now ready to connect to the output from the intervention planning algorithms, and the data to be connected include the bridge component condition states and intervention requirements. The condition states are recorded from 1 to 5, with state 1 representing as good as new, and state 5 representing replacement should be immediate. Each condition state has a certain probability, and based on the expected gradual deterioration, these probabilities also change over time. The interventions include the attributes of planning period and intervention type. The planning period takes place on a 5-year interval, e.g., year 1 to 5 is planning period 1, and year 6 to 10 is planning period 2. This is consistent with the planning of intervention execution in a certain time window, especially when this is done years in advance. Intervention type depends on the definition of the intervention strategy, in terms of rehabilitation, renewal, or replacement. Each intervention type has its associated cost and possession requirement, and they are important for the clustering of interventions in the optimal intervention programs.

In the BIM authoring tool Revit, Dynamo is a preinstalled open-source plug-in, and it is a direction connection with the Revit interface, making it possible to easily access and export elements to and from it. A Dynamo script is developed to automate the dynamic assignment of condition states and interventions to the corresponding components in the model from the output of the predictive algorithms, as well as to provide visualisation using colour filters in the 3D model. Although there are many steps needed to make the connection work, the three main stages are: (1) data import, (2) value assignment, and (3) output visualisation. In addition to the built-in nodes provided in Dynamo that serve the standard functions and workflows, custom nodes were also created to fulfill the needs of specific tasks that are not included in the standard library. Figure 3 outlines an overview of the Dynamo script that was developed to connect the conditions states and interventions from the predictive algorithms to the BIM, i.e., importing the algorithm results and assigning them correctly to their associated components, and visualising the results based on defined filter rules for the colour overrides in the model.

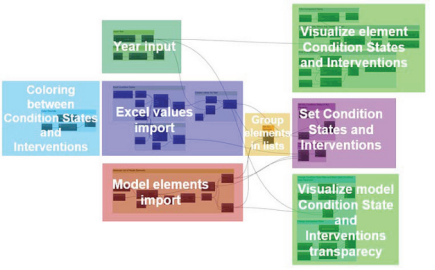

Figure 3. Overview of the Dynamo script.

5.3 *Using the digital tool for decision-making*

Finally, with the connection between the predictive algorithms and BIM established, Revit becomes the platform between the digital tools and the infrastructure managers who need to make decisions on the interventions. Instead of working with the 3D model itself and the complicated Dynamo script which could be intimidating for those not familiar with visual programming and coding, an interactive user interface is incorporated using the Dynamo Player in Revit. This graphic interface is used to provide more detailed information, apart from the colour overrides which can be seen in the 3D model itself, as well as a more intuitive way of handling the model and its parameters by introducing dropdown manus and action buttons. It supplies the users with input options, such as changing the evaluated year. Furthermore, it is separated into acquiring information on the component level, giving data about the condition states and interventions of one selected component of interest, as well as filtering out all components that are in one specific condition state or fulfil an intervention filter on the global scale. Figure 4 demonstrates the Dynamo Player user interface to the right, indicating the

inputs and outputs, as well as the resulting visualisation in the 3D model in the form of colour overrides on the railway bridge components.

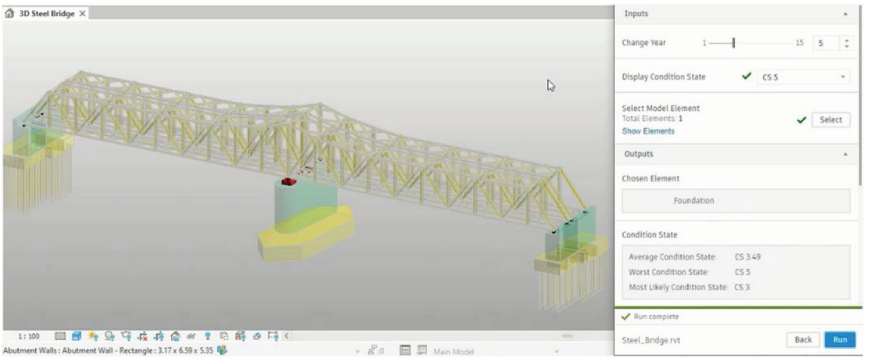

Figure 4. Demonstration of the user interface and connected results in Revit.

In the example, by selecting the global transparency for condition state 5 in year 5 in the input section of the Dynamo Player, it runs the Dynamo script as described earlier, and only components that satisfy the filter requirements would be visible. This allows the ability to see components even in a complex model where there are significantly more components, or the model is developed on the element level, so they might appear to be small in the 3D model. In addition to the visual representation of the condition states and interventions using colour overrides, the information about the selected component is also displayed in the output section of the Dynamo Player, such as the name of the selected component (referred to as element in Figure 4), the calculated condition states (i.e., average, worst, and most likely) based on the probabilities of the five states, as well as the five condition states and their probabilities (not shown in Figure 4).

6 CONCLUSIONS

In the intervention planning process, predictive algorithms and BIM have the potential to transform decision-making and how stakeholders interact with each other. The connection between these digital tools is demonstrated on an example railway bridge, where the results are visualised in BIM with colours, and an intuitive user interface is shown. However, it is important to note that this methodology is not meant to replace the existing process, but rather supplement infrastructure managers with a robust tool that takes advantage of the latest state-of-the-art technologies, which provides a general overview of the asset condition states and supports the decision-making process for the necessary interventions.

The methodology can also be applied to intervention planning of other infrastructure assets. For example, although there are some differences between the railway and road intervention planning process, especially in terms of how teams are defined and organised as well as the tools and methods used to make decisions throughout the process, the procedure to make intervention decisions is similar as described in Section 2. Also, even if the asset condition states are recorded on the element level, as is the case in most road asset management databases around the world, the method of the predictive algorithms can still be applied to that level of detail, and the results are expected to be very similar to that of the existing algorithms for railway interventions. Therefore, the connection between the predictive algorithms and BIMs would still be useful for road infrastructure managers to make and communicate their decisions with other stakeholders.

It is expected that the digital models will need to be continuously updated and enriched, to reflect the decisions and/or modifications made to the planned intervention on infrastructure assets. As part of the challenge to improve data quality over time, a single source of truth becomes an important anchor that connects the information that might exist in different models and different databases. This source would lay the foundation for a better

management of asset data. Nonetheless, the methodology allows stakeholders in the intervention planning process to collaborate more effectively. The 3D models would serve as a common visual platform for joint assessments, planning, and decision-making. With data integrated into these models, the interdependencies between components and between assets can be analysed, allowing for more informed and coordinated decisions on maintenance, repairs, and optimisations. This shared digital environment enhances communication between teams while enabling the railway networks to be managed with increased efficiency.

ACKNOWLEDGEMENTS

Bridge deterioration modeling considering the climate change effects

S. Moghtadernejad, Z. Lounis & J. Zhang
National Research Council Canada, Ottawa, Canada

ABSTRACT: The effective management of bridge maintenance activities requires planning for necessary interventions in the future. Such planning is crucial to establish maintenance schedules with minimal life cycle costs and environmental impacts. Achieving this depends on reliable deterioration prediction models that consider key factors influencing deterioration and the associated uncertainties. Presently, predominant deterioration models in practice use inspection data and Markov models with the assumption of constant deterioration rates. However, factors like age, maintenance activities, traffic variations, and climate change can alter deterioration rates and transition probabilities of bridge elements over time. Climate change, particularly, with rising temperatures and extreme weather events, accelerates bridge deterioration. This study provides an overview of deterioration prediction models capable of accounting for temporal dynamics of bridge deterioration, where time-variant transition probabilities are modelled as functions of the factors influencing the deterioration process. Subsequently, it discusses their merits and challenges for practical implementation.

1 INTRODUCTION

Bridges are crucial components of transportation infrastructure, providing safe and efficient transport of people, goods, and services. However, they are subject to various factors that can cause deterioration, such as environmental exposure, traffic loads, and aging. With the increasing age of infrastructure and the need to ensure safe and efficient transportation networks, bridge deterioration modelling remains a critical tool for effective infrastructure maintenance and management. Bridge deterioration modelling is a process of estimating the rate at which a bridge's condition will degrade over time based on various factors such as material properties, design specifications, traffic loads, environmental conditions, and maintenance history. The objective of bridge deterioration modelling is to provide critical insights into the expected life cycle performance of bridges over time, estimate potential damage and the remaining service life of bridges, and help bridge owners and managers plan effective maintenance and repair strategies. It helps with improving safety, maximizing the service life of bridges, managing assets effectively, and optimizing decision-making.

Climate change is causing significant variations in temperature, precipitation patterns, and extreme weather events and its impacts on bridge infrastructure are becoming increasingly concerning. One of the most significant effects of climate change is the acceleration of bridge deterioration across various regions globally. As temperatures rise, adverse chemical reactions within construction materials accelerate, consequently the deterioration process is expedited (Shirkhani et al., 2023). Changes in weather patterns, such as increased precipitation in certain regions, can impact the corrosion speed of construction materials. More frequent and severe climate-induced events, such as floods, hurricanes, heavy rainfall, and storms, can pose risks

DOI: 10.1201/9781003483755-174

to bridge structures (Moghtadernejad et al., 2020). For example, intense precipitation can erode soil around bridge foundations and compromise their integrity. Floods impose immense pressure on piers and abutments, which can lead to scouring or even the collapse of bridges. Heatwaves contribute to the thermal expansion in bridge materials and cause cracks and deformations that weaken the structure. Moreover, climate change can result in more frequent freeze-thaw cycles in some regions which can affect materials like concrete. Coastal bridges face additional threats due to rising sea levels and saltwater intrusion. Saltwater corrodes reinforced concrete and steel bridges and accelerates the deterioration process. Storm surges and coastal erosion further compromise the integrity of these bridges. In regions with permafrost, rising temperatures trigger ground thawing that undermines the stability of bridge foundations, making them more susceptible to settling and erosion.

The climate-induced changes in bridge deterioration rates make existing predictive models less reliable. This may lead to unforeseen failure of bridges, long traffic disruption, high rehabilitation and replacement costs, and significant negative socio-economic impacts. It is therefore necessary to evaluate, maintain and manage bridges under the effects of future climatic loads and incorporate the potential impacts of increased temperature, precipitation and wind on the deterioration of bridge structures.

This paper investigates how one can incorporate climate change effects into deterioration models to allow for more accurate predictions and enable the development of optimal bridge maintenance plans. In the following section, a comprehensive overview of existing bridge deterioration models is provided based on their underlying methodology, along with a discussion of their limitations and merits for implementation in practice. Subsequently, promising deterioration models are further investigated to assess their flexibility for incorporating climate variations into the deterioration modeling process.

2 BRIDGE DETERIORATION MODELS

2.1 *Classification*

Bridge deterioration models include two primary classifications: mechanistic (also referred to as physical models) and empirical (also referred to as data-driven) models, which may exhibit either stochastic or deterministic characteristics. Mechanistic models are rooted in physical principles and aim to model the underlying mechanisms driving deterioration processes within bridges. They often involve complex physical laws, chemical reactions, and mathematical equations governing the deterioration process. These models are developed to predict the deterioration of various elements based on the triggering deterioration mechanism. For example, in the literature, several analytical models are developed for predicting deterioration of reinforced concrete decks, including models for predicting freeze-thaw damage (Bazant et al., 1988), carbonation damage (Isgor & Razaqpur, 2004) or chloride-induced damage (Zhang & Lounis, 2009). Nickless (2017) investigated the application of available mechanistic deterioration models to bridge management and design practice in Colorado.

Mechanistic models are a valuable tool in bridge deterioration prediction and can be highly effective when properly developed and validated. However, despite their potential benefits, there are some limitations to their use in bridge deterioration prediction. One challenge is the need for reliable data on the properties of the bridge materials and the environmental conditions. Additionally, the development of mechanistic models can be time-consuming and computationally intensive, making them more difficult to implement on a large scale or on a portfolio of bridges. Finally, these models may not capture all complex interactions that can contribute to bridge deterioration, which brings forward the importance of investigating other types of models.

Contrary to mechanistic models, empirical models rely on observed condition data without explicit consideration of underlying physical principles. These models utilize statistical methods to infer patterns from historical data and make predictions based on the observed trends. They are relatively simple to use and require fewer input parameters than mechanistic

models. Thus, these models have inherent limitations because they may not be able to capture the underlying physics and mechanics of the deterioration process as accurately as mechanistic models, and are limited by their assumptions and simplifications of the complex deterioration mechanisms of bridges. In addition, the accuracy and effectiveness of these models rely heavily on the availability and quality of data, which can be difficult to obtain. However, they can be continuously improved by collecting new data and refining the modeling techniques.

Both mechanistic and empirical models can have stochastic or deterministic attributes. Stochastic models incorporate random variables to include inherent uncertainties in the deterioration process and account for the variability in deterioration rates due to various influencing factors. On the other hand, deterministic models provide predictions without considering randomness and assume constant or predictable deterioration behavior based on fixed parameters and conditions.

An example of the application of empirical models includes the work done by (Ilbeigi & Ebrahimi Meimand, 2020) who used the historical data of bridges in Ohio to create an ordinal regression model to statistically examine the effects of bridge characteristics on variations in its conditions and predict the future bridge conditions. The outcomes of this study indicate that bridge characteristics such as age, average daily traffic, deck area, and structural material, are statistically significant variables that explain variations in bridge deterioration.

Machine learning methods, such as Artificial Neural Networks (ANN), also fall under the category of empirical models. These methods have gained popularity among researchers (Huang, 2010) due to their immense potential in handling vast datasets containing various variables, including age, temperature, precipitation, etc. However, the adaptation of these models in practice is slow due to their mathematical complexity, the requirement for more sophisticated software and the fact that the users cannot see what happens in the prediction process but are supposed to assume the results as appropriate.

In recent years researchers have combined different types of models and data sources to provide more accurate predictions of bridge deterioration over time (Lethanh et al., 2017; Li et al., 2023; Mizutani et al., 2017; Mohammed Abdelkader et al., 2019). These hybrid models typically incorporate structural analysis and environmental data, information on past maintenance and repair records, as well as other relevant data such as traffic patterns and weather conditions. Examples include combining Markov models with mechanistic deterioration models, ANNs, or Bayesian Networks (BNs), to improve the deterioration predictions.

2.2 *Models currently used in practice*

In practice, few agencies prefer predicting the deterioration of bridges using mechanistic models. These agencies determine bridge service life using the capacity of its elements to withstand different stresses and loss of strength reaching a specific threshold. Another approach involves predicting the expected service life of an asset based on the time until corrosion, determined by the material's resistance to chloride ions (Zhang & Lounis, 2009). However, applying these approaches at a network level can be challenging due to the need for extensive data on asset dimensions and conditions.

As inspection methods advanced and agencies started to collect and store inspection data more frequently and systematically, bridge deterioration prediction in practice shifted towards using the inspection data. According to the IABMAS survey of bridge management systems (Mirzaei et al., 2014) most existing bridge management systems and deterioration models around the world are based on element-level condition state inspection. Most bridge management systems use Markovian deterioration prediction models, which are suitable for dealing with the uncertainties in the deterioration process. Some use a combination of Markovian and Weibull models. These models are well suited to the "severity and extent" condition state inspection, such as in the Ontario Structure Inspection Manual (Ministry of Transportation Ontario, 2018). Few have more sophisticated deterioration prediction models that provide the ability to have different deterioration rates for a given element under differing environments (e.g., benign, moderate, and severe environments).

To the best of the authors' knowledge, current deterioration prediction models utilized in bridge management systems do not directly account for climate change or extreme weather events. According to a survey conducted by Stantec (Ellis, 2023), the current emphasis is on integrating the impacts of climate change in risk assessments related to factors such as flood risks, scour, permafrost effects, and similar concerns.

To propose a model for bridge deterioration that is capable of incorporating the effects of climate change, it is helpful to adapt the existing models that are already in use within the industry. This will facilitate its acceptance and implementation, since familiarity with established models reduces reluctance from practitioners and decision-makers, and offers a smoother transition toward incorporating the updated models. Moreover, adapting an existing model has the advantage of building upon a framework that has already undergone validation and scrutiny, which potentially requires fewer resources for implementation in standard practices. Consequently, in the subsequent section, a close examination of the most commonly used deterioration prediction models in practice will be conducted.

3 DETERIORATION MODELS TO INCORPORATE CLIMATE CHANGE EFFECTS

3.1 *Markovian models*

In a Markov model, the bridge component condition is assessed at regular intervals, e.g., annually. During each interval, the bridge component either stays in the same state or moves to a lower state (Parzen, 1962). In homogenous Markov models, the probability of transitioning between states remains constant, irrespective of the asset's age or past events, a principle known as the "memoryless assumption". Future condition predictions are calculated by multiplying the current state by the transition probability matrix.

$$y_k = \sum_j x_j P_{jk} \quad for\ all\ k \tag{1}$$

where j is the condition state in this period, x is the fraction in state j, and p is the transition probability from j to k. Roelfstra et al. (2004) noted that the coefficients of the probability matrix can be represented in two ways: 1) as the percentage of an element that changed from state j to state k after one inspection interval, or 2) the probability of an element to pass from condition state j to condition state k after one inspection interval.

These models are commonly employed in bridge management systems to predict the future condition of structures and plan maintenance activities. Most Markov models do not take into account the impacts of climate change and extreme weather events on the deterioration of bridge components. The conventional Markov model is simple and efficient at both project and network levels and can deal with the uncertainties in the deterioration process (Lounis, 2000; Madanat et al., 1995; Moghtadernejad et al., 2021; Setunge & Hasan, 2011). However, it has several limitations that are highlighted by, Thompson & Ford (2012) and Morcous (2006).

Markov models use data from inspections of the condition state of the infrastructure over time to estimate the deterioration curves. Hence, the quality of data plays a significant role in the accuracy of deterioration prediction and the resulting lifecycle cost estimations. Despite the recent progress towards more frequent and accurate monitoring of bridges, real-world data often do not exist in sufficient quantity, contain errors and discrepancies, and are not always suitable for estimating the transition probabilities. Roelfstra et al. (2004) compared Markov models to numerical simulations of corrosion damage. They noted that a lack of inspection data for the worst and second-worst condition states can lead to unreliable predictions made by Markov models.

Since transition probabilities are calculated for a constant period, inspection records should reflect this time interval to be accurate. However, inspections from the data do not necessarily occur at constant intervals (Morcous, 2006). Thompson & Ford (2012) highlight the inability

of the model to efficiently consider the interactive effects between deterioration mechanisms of different bridge elements, such as the interaction between deteriorating joints and the surrounding deck area. They claim these models are too basic for specific applications, especially due to their "memoryless assumption," i.e., the deterioration rate does not change with time.

To overcome the limitations of homogenous Markov models with respect to the stationarity of the transition probabilities, researchers have proposed various modifications and enhancements to the model. Some have compartmented the data based on factors, such as weather and traffic conditions, into the model to account for their impact on bridge deterioration. Other researchers have proposed using non-homogenous Markov models that allow for time-varying transition probabilities. For example, in a significant research paper published by Mizutani & Yuan (2023), the authors introduced a continuous-time Markov chain characterized by regime switches. Within these regimes, state transitions depend on an underlying, latent Markov chain that captures the overall aging pattern of an asset.

As more data on projections of future climatic conditions under different emission scenarios and their impacts on bridge deterioration become available, non-homogenous Markov models (NHMMs) are likely to become even more reliable, allowing transportation agencies to make informed decisions about when to conduct maintenance or rehabilitation activities considering the impacts of climate change (Pandey & Lounis, 2023). However, there are some challenges associated with the use of NHMMs in bridge deterioration prediction. One challenge is obtaining high-quality data, which is critical for accurately training and validating the model. A second challenge is selecting a relevant emission scenario and projecting future climatic data for temperature, precipitation and wind considering the non-stationarity of climate and modeling their impacts on bridge deterioration. Another challenge is identifying the most relevant variables to include in the model, since having too many variables can lead to overfitting, while excluding important variables can lead to inaccurate predictions.

3.2 *Weibull models*

The homogeneous Markov model described earlier, while simple, might be too basic for the prediction of deterioration rates, especially for assets with a long service life. The most prominent limitation is the "memoryless assumption," implying that the deterioration rate does not change with time. As Markov models are very adaptable, one can overcome this limitation by adding age dependency to them, and make it into a so-called "Weibull survival probability" model. The Weibull curve has the following functional form:

$$y_{1g} = \exp\left(-1.0 \times \left(\frac{g}{\alpha}\right)^{\beta}\right) \tag{2}$$

Where y_{1g} is the probability of the element not failing at age g, given no maintenance action is taken between year 0 and g; β is the shaping parameter, which determines the initial slowing effect on deterioration; and α is the scaling parameter, calculated as:

$$\alpha = \frac{\mathrm{t}}{(ln2)^{1/\beta}} \tag{3}$$

where t is the median service life expectancy from the model. A shaping parameter of 1 is mathematically equivalent to a Markov model, where the transition probability does not vary with time. Higher shaping parameters slow the initial rate of deterioration, which then accelerates as the asset gets older. It's important to note that the Weibull model does not alter the Markov median service life expectancy; however, it can assess the uncertainty in service life expectancy. As the shaping parameter increases, the range of uncertainty narrows. The shaping parameter in the Weibull model can be determined through a statistical method called "maximum likelihood estimation". This process involves systematically testing various values of the shaping parameter (β) until the best fit to the data is achieved.

One valuable use of the Weibull model is in capturing the start of deterioration, i.e., transitioning from the best to the second-best state. While the Markov model shows a rapid decline in condition, which is often unrealistic for new assets, the Weibull model can slow this onset, making the initial stages of deterioration more realistic. Additionally, it is beneficial in analyzing the transition from the second-worst condition state to the worst state. Unlike the Markov model, it refines this estimate and offers a measure of uncertainty in the time to failure. For assets already in the second-worst state, the Weibull model estimates what fraction will fail within a specified time period, which can help with more accurate budgeting for different intervals like a 2-year budget or a 10-year horizon. Hence, the pertinent inquiry is how to integrate climate change factors into bridge deterioration modeling using the Weibull model. Addressing this necessitates exploring an alternative to this approach akin to the Weibull model, yet one that accommodates additional explanatory variables beyond just age, called "Cox Survival Probability Model". The equation for the Cox model is:

$$y_{1g} = \exp\left(-1.0 \times \left(\frac{g}{\alpha}\right)^{\beta}\right) \times \exp(b_1 X_1 + b_2 X_2 + \ldots + b_n X_n) \tag{4}$$

where the variables X_n are explanatory variables such as traffic volume, environmental factors, etc. They can be continuous variables or binary values. The coefficients b_n are determined by linear regression or can be estimated in the same manner as the Weibull shaping parameter. The multiplier can shift the survival probability either upward or downward. If all explanatory variables are zero, then the multiplier will have no effect.

Despite the potential of this model in developing a deterioration model that fully accounts for influencing variables, the model requires analyzing individual state transitions independently and may demand extensive data collection and management. Moreover, researchers have found out that, it is unusual for more than three or four explanatory variables to have a beneficial effect on the Cox model (Thompson & Ford, 2012).

3.3 *Ordered probit models*

An alternative approach for agencies to predict asset deterioration considering influencing factors such as age, traffic, climate conditions, etc., is the Ordered Probit model (Thompson & Ford, 2012). This model is useful for assets with discrete, ordered condition states such as the National Bridge Inventory (NBI) or the Ontario Structure Inspection Manual (OSIM) rating systems. In this model, the likelihood of an asset being in a specific condition state at a given time (t) is determined by life expectancy factors and threshold parameters (μ).

These thresholds act as boundaries between condition states. For example, for a 1-4 rating scale, 1 being the best and 4 the worst, depending on the model sum ($\sum \beta x$) and threshold parameters (μ), the probability of being in a certain condition state follows a normal distribution. In this model, one can isolate the impact of one specific variable (e.g., temperature) on the predicted condition state of an asset while keeping all other factors constant. Mathematically, the exact probability of an asset being in any condition state follows the cumulative standard normal distribution with the variable X taking the following forms:

$$P(CS = 4) = \left[\sum \beta x\right] \sim N(0,1) \tag{5}$$

$$P(CS = 3) = \left[\mu_1 - \sum \beta x\right] \sim N(0,1) - \left[-\sum \beta x\right] \sim N(0,1) \tag{6}$$

$$P(CS = 2) = \left[\mu_2 - \sum \beta x\right] \sim N(0,1) - \left[\mu_1 - \sum \beta x\right] \sim N(0,1) \tag{7}$$

$$P(CS = 1) = 1 - \left[\mu_2 - \sum \beta x\right] \sim N(0,1) \tag{8}$$

where:

$P(CS = i)$ = Predicted probability of an asset being in condition state CS i;

x = set of independent variables, e.g., age, material type, environment/climate, etc.;

β = set of parameter estimates corresponding to independent variables;

μ = threshold parameters, which in comparison to parameter estimates and variable values, indicate the likelihood of being in a given condition state;

$[\mu_2 - \sum \beta x] = X$ value that can be used to calculate normal distribution test statistic;

$N(0,\ 1)$ = indicates the cumulative, standard normal distribution with mean = 0 and standard deviation = 1

4 DISCUSSIONS

It is established that accurate estimation of bridge condition states is crucial for effective planning of interventions. However, most deterioration models used in practice assume a constant deterioration rate over time, which does not reflect reality. Therefore, there is a need for a practical approach to account for diverse variables (e.g., age, environmental conditions, maintenance activities) that influence the deterioration rate of bridge elements.

After conducting a comprehensive review of existing literature and interviews with practitioners, certain methods have emerged as promising for further exploration. Integrated Markov/Weibull models, or Ordered Probit models offer the advantage of accommodating a wider range of explanatory variables, including age, climate change and extreme weather events. Due to their probabilistic nature, these models can incorporate uncertainties in input variables including different climate projections. To implement this approach effectively, historical data must be compartmentalized to represent different variables, e.g., climatic change observed over past years. By estimating transition probabilities for each compartment, the "variations" in the rate of deterioration concerning different or combinations of different explanatory variables can be examined. This analysis enables the forecasting of future deterioration rates, allowing for practical maintenance strategies aligned with changing climate patterns.

While these methods hold significant promise, there are several obstacles to extracting their full potential. This is mostly due to the need for comprehensive data collection efforts to obtain high-quality historical data across various climatic conditions. As a general guideline, the Weibull and Cox models need around 200 or more inspection pairs for a realistic prediction. If the model is partitioned, then each separate model needs to have around this sample size. Faster data collection can be achieved through the integration of real-time data streams and sensors into predictive models to have a nuanced understanding of bridge deterioration under changing environmental conditions. However, in the absence of comprehensive historical data, improving the accuracy of deterioration models becomes challenging. Even small variations in transition probability values can lead to significant fluctuations in the deterioration predictions. This sensitivity underscores the importance of reliable historical data. The absence of a long inspection history introduces substantial uncertainties, making it difficult to establish a precise correlation between climatic changes and the deterioration rate of bridge elements. Incorporating the effects of climate change into the deterioration model under such circumstances could introduce unnecessary complexity and potentially lead to unreliable predictions.

Additionally, as indicated in Figure 1, climate projections for the next 20 years, under the worst-case scenario SSP5-8.5, indicate an increase of around 0.6 °C. This increase is not expected to significantly alter the speed of deterioration for bridge elements (gradual deterioration). Hence, immediate concerns should focus on collecting sufficient data and considering the increasing occurrence and severity of climate-related hazards, such as floods, scour, and storms, which can lead to sudden deterioration. Understanding the potential implications of these events on bridge elements and incorporating this knowledge into risk mitigation strategies and improving the resilience of bridges, should be prioritized over attempting to incorporate small temperature variations into the deterioration model in the absence of sufficient

data to produce accurate results. By addressing these immediate threats in the risk analysis process, bridge management practices can be more effectively tailored to mitigate the impacts of climate change on bridge elements.

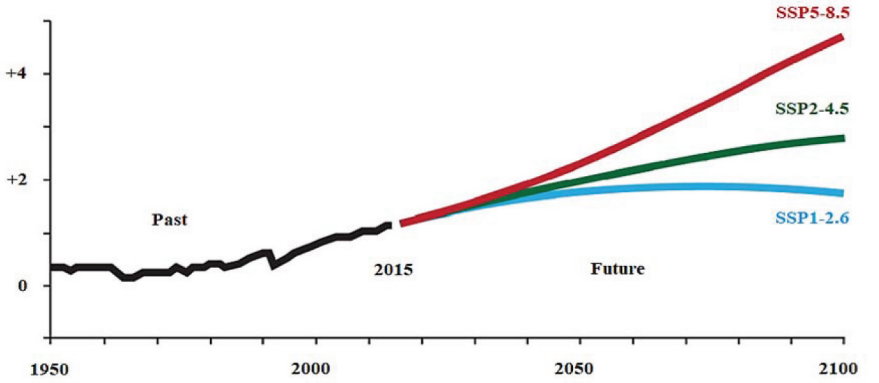

Figure 1. Global temperature change projections under the three SSP based emissions scenarios adapted from ClimateData.ca.

Application of open deep learning datasets for building vision-based bridge condition monitoring solutions

K. Tomaszkiewicz & T. Owerko
AGH University of Krakow, Krakow, Poland

ABSTRACT: The operational phase of bridges is the longest phase in the entire structure's life cycle. During this phase, defects occurring in earlier stages of the life cycle may become apparent. Structural condition monitoring and defect detection at an early stage of their formation make it possible to react faster, protect the damage and stop or delay the degradation process. To support the engineer's work, deep learning-based solutions are becoming popular. However, to make solutions based on such algorithms effective and helpful for the engineer, it is necessary to provide a good dataset to train them. This paper summarizes publicly available open datasets of bridge damage images that can be used to train DL algorithms for classification, object detection and segmentation. The presented approach refers to the usability of datasets from the point of view of training DL algorithms, as well as the usability of algorithms trained on their basis to support the bridge engineer's work.

1 INTRODUCTION

The operational phase is the longest phase in the bridge entire life cycle. This phase is strongly determined by factors occurring at earlier stages of the life cycle, which have a significant impact on the structure's future performance. Monitoring the structure's working and its response to environmental conditions and the loads, along with periodical inspections of the structure's technical condition, make it possible to detect defects at an early stage of their formation. This makes it possible to react more quickly, to protect the damage and to stop or delay the degradation process of the damaged element of the structure, and thus of the entire structure.

In most countries, a significant number of bridges are in the operational phase, and budgets for maintenance and repair of structures are increasing. More than 43,500 bridges in the U.S. are in poor condition and have been classified as "structurally deficient", 224,000 bridge spans need repair, and 78,800 bridges should be replaced - and it would take nearly 30 years to repair these structures at the current rate (A.R.& T.B. Association, 2022). Due to the important role of the operational phase, there is a need for methods that will improve the bridge monitoring process.

To support the engineer's work during monitoring the condition of structures and performing inspections, solutions using artificial intelligence algorithms, in particular deep learning (hereafter: DL), are becoming available. They are applied not only for image analysis, but also for analyzing video recordings, data from SHM systems, etc. (Dong & Catbas, 2021; Sabato et al., 2023; Zhang et al., 2022). In terms of detecting damage visible on images, these algorithms make it possible to quickly assess the technical condition of a bridge, and thus detect damage at an early stage. They are an important support for the engineer's work especially in those cases where the damage is not visible to the human eye and may be undetected during the engineer's inspection.

The basis for creating effective and robust DL algorithms which can be used to support the engineer's work is the datasets on which the algorithms are trained. Evaluation of the quality and effectiveness of a solution based on a trained DL algorithm for damage detection purposes

DOI: 10.1201/9781003483755-175

should be based not only on the analysis of metrics and evaluation tools characteristic for the machine learning domain. The solution's effectiveness should also be considered from the perspective of the domain knowledge of bridge engineering, and thus the quality and effectiveness of the solution should be evaluated in relation to domain requirements included in standards, manuals, or other documents. This form of evaluation is possible only if the basis for training the algorithm is a well-prepared and described dataset. Despite the quick development of DL algorithms, also in bridge damage detection on images, the availability of data on which algorithms can be trained is limited. There are papers summarizing the progress in the field of machine learning with a description of the used datasets, including for non-vision data (Bianchi & Hebdon, 2022b). However, these works provide only basic parameters of datasets, such as the dataset name, reference, type of presented damage, material of damaged element, size, availability, year of creation, or reference to the experiment in which the dataset was used. However, they do not address the fundamental issue, that is, the effectiveness of these datasets in relation to domain knowledge and the ability to meet the requirements of the bridge industry.

This paper summarizes open datasets in the form of bridge damage images that can be used to train DL algorithms for classification, object detection and damage segmentation. The presented approach addresses the usability of datasets from the point of view of training DL algorithms (type of dataset count, dataset balancing, etc.), as well as the usability of algorithms trained on their basis to support the bridge engineer's work (whether they describe the size of the damage, the cause of the damage, etc.). The paper is a discussion of the quality of creating, documenting, and sharing damage datasets.

Chapter 2 presents the key aspects addressed in the datasets analysis in terms of their usability for DL purposes and in relation to the bridge engineering domain knowledge aspects. A datasets description based on established criteria is presented in Chapter 3. Chapter 4 shows the practical application of DL-based solutions for vision-based bridge monitoring. Chapter 5 summarizes the work.

2 METHOD OF REVIEW

This paper is concentrated on the analysis of open bridge damage image datasets, which are dedicated to solving three basic groups of problems for which DL algorithms are used, i.e. classification, object detection and segmentation. Only datasets for which the dataset authors have declared that the dataset is used for bridge solutions (e.g. in the dataset name or description) are included. By "open datasets", the authors of this paper mean such data, the obtaining of which does not require contact with the author, and the data are available immediately for download. This paper excluded those datasets where, despite the authors' declared availability, references to the datasets did not work, showed an error, or returned information about planned future availability. Such datasets which are the result of merging other datasets are also not included. The review was conducted to consider the usefulness of the dataset with respect to aspects related to the training of DL algorithms and the ability to use algorithms trained on the considered datasets to solve bridge engineer problems.

Regarding the aspects related to the training of DL algorithms, attention has been given to:

- The size of each class in the dataset, and thus the balance of the dataset - which has a direct impact on what metrics should be applied to the dataset under consideration (Tomaszkiewicz & Owerko, 2022),
- The resolution of the images, including making the original images available for adaptation to the size of the input data for the selected neural network - which has an indirect effect on the class of algorithms that can be used in the solution,
- The data storage format, including the type of compression that affects the quality of the source data (Bouderbal et al., 2021; Dodge & Karam, 2016; Gandor & Nalepa, 2022),
- The way in which data is organized (folder structure, file name, clarity of class naming),
- Explanation of the meaning of labeling - when describing classes numerically as "0", "1", etc.

- The degree of complexity of the surface to be analyzed (resolution of the source information in the space of the problem domain) - e.g., different colors of concrete, different lighting conditions of the photo, the presence of noise in the photos, etc.

Regarding the aspects related to the evaluation of the ability to use algorithms trained on the considered datasets to solve bridge engineer's problem, attention has been given to:

- The type of damage represented in the dataset,
- How the images were acquired - including the type of equipment used, the conditions under which the images were acquired
- Explanation by the authors of the way in which the images were annotated - on what criteria the decision was made to assign a class to the damage, extract the damage area for object detection, or assign pixels as damaged for segmentation of the data. In particular, attention was paid to whether the authors created annotations based on guidelines, instructions, etc.
- Correctness of image annotations - whether the images received correct annotations,
- Description of the bridge elements to which damage images correspond (the name of the element, material, type of bridge object indicating the nature of the work of the structure),
- Size of the damage - e.g. width of the crack,
- Cause of damage - e.g. fatigue cracking.

3 REVIEW OF OPEN DEEP LEARNING DATASETS OF BRIDGE DAMAGE IMAGES

This chapter is organised in such a way that at the beginning, in tabular form (Table 1), it presents the classes that each of the datasets contains, their size and image, labels and masks parameters. A detailed overview of each dataset is presented below the table, providing a description of its characteristics and a discussion of its quality and usability.

Table 1. General Characteristics Of The Datasets.

Dataset name	Class	Number of images or damages	Images, labels, and masks parameters
"SDNET2018" (Dorafshan et al., 2018)	Bridge deck - C cracked	2025	Images:
	Bridge deck - U uncracked	11595	256x256px RGB (.jpg)
	Wall - C cracked	3851	
	Wall - U uncracked	14287	
	Pavement - C cracked	2608	
	Pavement - U uncracked	21726	
"crack-detection" (tjdxxhy)	0 - cracked	4055	Images:
	1 - noncracked	2014	224x224px RGB (.jpg)
			Labels: (.txt)
"Concrete-Bridge-Crack-Dataset" (MCBDD-ZRE)	Cracks	1050	Images:
	Background	2772	200x200px RGB (.jpg)
"CCNY Concrete Structure Spalling and Crack database (CSSC)" (CCNY Robotics Lab, n.d.)	Crack - accept	13448	Images:
	Crack - nonaccept	11652	100x100px RGB (.jpeg)
	Spalling - accept	7376	
	Spalling- nonaccept	11747	
	Crack - accept	12422	Images:
	Crack - nonaccept	11678	130x130px RGB (.jpeg)
	Spalling - accept	8574	
	Spalling- nonaccept	11350	

(*Continued*)

Table 1. (*Continued*)

Dataset name	Class	Number of images or damages	Images, labels, and masks parameters
"Multi-classifier for RC bridge defects" (Hüthwohl et al., 2019)	Corrosion - rust staining Corrosion - no rust staining ExposedReinforcement - exposed reinforcement ExposedReinforcement - no exposed reinforcement MultiClassifier - cracks MultiClassifier - spalling MultiClassifier - scaling MultiClassifier - no defect MultiClassifier - efflorescence	355 415 223 203 789 427 168 452 311	Images: various sizes RGB (.jpg)
"Cambridge Bridge Inspection Dataset" (Huethwohl, 2017)	Potentially unhealthy Healthy	691 337	Images: 299x299px RGB (.jpg)
"The COncrete DEfect BRidge IMage: CODEBRIM" (Mundt et al., 2019)	crack spallation exposed bars efflorescence corrosion stain	2507 1898 1507 833 1559	Images: various sizes, RGB (.png) Labels: (.xml)
"Bridge Crack Library" (Jin et al., 2022)	non-steel crack images steel crack images noise images	5769 2036 3195	Images: 256x256 px, RGB (.jpg) Masks: 256x256 px gray scale (png)
"Bridge Crack Library 2.0" (Jin & Li, 2022)	crack	23 400	Images: 256x256 px, RGB, (.jpg) Masks: 256x256 px gray scale (.png)
"Labeled Cracks in the Wild (LCW) Dataset" (Bianchi & Hebdon, 2021b)	Images with normal crack widths Images with dilated crack widths	3773 959	Images: original with diffrent sizes/ 512x512 px RGB (.jpeg) Masks: original with diffrent sizes/ 512x512 px gray scale (.png)
"Corrosion Condition State Semantic Segmentation Dataset" (Bianchi & Hebdon, 2021a)	corrosion	440	Images: 512x512px RGB (.jpeg) Masks: 512x512px RGB (.png)
"NCCD-PF - A pre-failure narrow concrete cracks dataset for engineering structures damage classification and semantic segmentation" (Tomaszkiewicz & Owerko, 2023)	classification dataset - cracked classification dataset - uncracked segmentation dataset	668 4720 5388	Images: 224x224px RGB (.jpg) Masks: 224x224px RGB (.png)

One of the largest datasets for the concrete crack classification in terms of size is the dataset ***"SDNET2018"*** (Dorafshan et al., 2018). It was built from 230 images of cracked and non-cracked concrete, including reinforced concrete (54 images of bridge decks and 72 images of walls) and unreinforced concrete (104 images of pavements), which were divided into sub-images. It should be noted that there is a large imbalance of images of cracked and uncracked concrete for each class. The images were taken using a 16-MP Nikon camera from a distance of 0.5m, without using the zoom. In addition, they contain obstructions including shadows,

surface debris, inclusions, scaling and also show different colors and textures of concrete surfaces. The damage is not always located in the central part of the image. What is interesting to note is that the set of non-cracked photos also includes photos of expansion joints, which makes the researcher's solution more robust. The images show cracks with widths ranging from 0.06mm to 25mm. The bridge piers for which the images were acquired were located at the Utah State University system, material, and structural health (SMASH) laboratory, the wall and pavement images came from USU campus. This shows that the images of walls and pavement are not representative of the operating conditions of bridges.

The ***"crack-detection"*** dataset (tjdxxhy) for concrete crack classification presented in the paper (Xu et al., 2019), was created by artificially expanding the dataset presented in (Wang et al., 2019). The original images (1024x1024px) were cropped to 512x512px images. From the resulting 8272 images, blurry images were removed, which gave a set of 6069 images. From this set of images, a training and validation set was randomly selected, and the images were cropped to 224x224px. The images are presented in .jpg format, and class assignments are presented in . txt files by assigning the digit "0" or "1" to the file name, but the dataset authors do not explicitly define these designations. The analysis conducted by the authors of this paper made it possible to specify the number of individual damages for each class. The dataset authors do not define the crack widths, but visual assessment allows to conclude that these are very large damages, probably out of limits. The dataset also includes images with shadow, strong exposure, with cracks only on the edges (which cover a small percentage of the image) or cracks where vegetation is present. Damage is found not only in the central part of the image, but also near the edges. There are also cracks with many branches and complex geometry.

The dataset for the concrete crack classification problem is also the ***"Concrete-Bridge-Crack-Dataset"*** (MCBDD-ZRE). The dataset contains very different concrete surfaces in terms of color, finishing quality, lighting of the photo. The authors do not define the crack widths values.

The ***"CCNY Concrete Structure Spalling and Crack database (CSSC)"*** dataset (CCNY Robotics Lab, n.d.) is a dataset dedicated to the problem of crack and spalling classification, which was developed with the help from Civil Engineers. It should be noted, however, that analyzing the "nonaccept" subset, it is possible to also find images that, in the opinion of the authors of this paper, should be classified as cracked into the "accept" set. It is not clear what damage classification criteria the dataset's authors adopted. The photos vary widely in terms of color, concrete surface finish. Some of the photos are zoom in on the damage, but some are shots of a larger section of the space. It should be noted the possible use of a part of the dataset, i.e. spalling photos for other applications. Most of the photos show very large damage, in which the reinforcement is clearly exposed. It is therefore possible to use the photos to build a dataset for detecting reinforcement in exposed concrete.

The ***"Cambridge Bridge Inspection Dataset"*** (Huethwohl, 2017) is a dataset of bridge inspections which, as defined by the authors, is used to classify concrete defects such as cracking, graffiti, vegetation, and blistering. However, all these defects are included as a common "Potentially unhealthy" class - the authors of the dataset did not divide this class into different types of damage in more detail, hence it is not possible to train an algorithm on such a prepared dataset to detect each type of damage. The other class is the "Healthy" class. The images contain different colors of concrete surfaces and cracks of large width, but there is no information about the width of the crack and its cause. Only for 18 photos, information about the element from which the damage occurred, i.e. concrete wall, is given in their name.

The ***"Multi-classifier for RC bridge defects"*** dataset (Hüthwohl et al., 2019) is dedicated for classification of concrete surface defects such as corrosion, exposed reinforcement, cracks, spalling, scaling, efflorescence. It was created based on self-collected image samples and Departments of Transportation inspection databases. The number of individual classes is shown in Table 1. It should be noted that it is not clear how to classify the images into the "general" category, since it also includes such damage that could be classified into the other listed classes. For the most part, the damage is very visible in the photos, taking up most of the image.

"The COncrete DEfect BRidge IMage: CODEBRIM" dataset (Mundt et al., 2019) is dedicated for classification and object detection of concrete surface defects such as crack, spallation, exposed bars, efflorescence, corrosion stain. The images were acquired under varying

weather conditions on 30 bridges. The bridges were characterized by varying technical condition, degree of damage and surface appearance. The dataset consists of 1590 images, in which 5354 bounding boxes (largely with overlapping defects) and 2506 nonoverlapping background bounding boxes were annotated. The dataset was prepared in several variants (original images in full resolution with bounding box annotations, images with the extracted crops/patches with class labels from the bounding boxes, images with the cropped patches with corresponding class labels, which were divided into training, validation and test sets for machine learning, the set balanced to reproduce the results of the authors' experiment (Mundt et al., 2019).

The ***„Bridge Crack Library"*** dataset (Jin et al., 2022) is a dataset for semantic segmentation of cracks which is based on 1180 raw images collected during inspections of in-service bridges. In addition, the ***„Bridge Crack Library 2.0"*** segmentation dataset (Jin & Li, 2022) is a dataset of crack images synthetically created based on the "Bridge Crack Library" dataset (Jin et al., 2022).

The ***„Labeled Cracks in the Wild (LCW) Dataset"*** (Bianchi & Hebdon, 2021b) is a dataset which is dedicsted for crack segmentation. It consists of real images extracted from structural inspection reports of the Virginia Department of Transportation (VDOT). A characteristic feature of the dataset is that it presents cracks in a global scene rather than a close-up of the damaged surface. The damage was annotated using GIMP software, and the authors also provide image annotation guidelines (Bianchi & Hebdon, 2022a). The authors also provide images scaled to 512x512px, used for training and testing the DeeplabV3+ model.

The ***"Corrosion Condition State Semantic Segmentation Dataset"*** (Bianchi & Hebdon, 2021a) is dedicated for segmentation of steel component corrosion, where the classes are four corrosion class categories: [good, fair, poor, severe]. Images were annotated according to the corrosion condition guidelines of the American Association of State Highway and Transportation Officials (AASHTO) and the Bridge Inspector's Reference Manual (BIRM). The data was collected from Virginia Department of Transportation (VDOT) bridge inspection reports. Guidelines for annotating photos in reference to the abovementioned documents and examples of annotation with explanation were also included with the dataset.

The **"NCCD-PF - A pre-failure narrow concrete cracks dataset for engineering structures damage classification and semantic segmentation"** dataset (Tomaszkiewicz & Owerko, 2023) is dedicated for classification and semantic segmentation of narrow cracks (with a width below the limiting value specified in EC 1992-1-1, i.e. 0.3mm). It contains images of cracks occurring on various elements of engineering structures (bridges, viaducts, tunnels) made of reinforced concrete (including abutments, tunnel walls, concrete barriers, pillars). The photos were taken during the construction and inspection of engineering structures, at various stages of the structure's operation. The damages are varied in terms of the causes of damage.

4 PRACTICAL USE

The use of open datasets for building vision-based bridge condition monitoring solutions is important for several reasons. DL-based solutions allow to analyse large data sets and that can detect very small damages that may not be visible to the human eye. Such structural damage can be an indication of an on-going material degradation process, and early detection of such damages can help optimise the bridge operating costs by avoiding costly repairs and extending the life of bridges. Images acquired using, for example, UAV imagery, particularly for areas that are difficult to access, can help to diagnose these areas more effectively. However, to make an informed decision about the risk to the structure caused by the occurrence of a particular type of damage, it is necessary to make a connection between this damage and aspects such as the time of the damage and the location of the damage.

One example of this is concrete surface damage in the form of shrinkage cracks. These appear after the concrete has been poured and are closely linked to the concrete hardening process. Their appearance on the concrete surface may occur within the first few hours or days after concrete pouring (depending on factors such as the size of the element, environmental conditions, type of concrete surface curing). By detecting and inventorying such damages, including consideration of the time when the photograph was taken, it is possible to make assumptions about

the probable cause of the damage by relating the time when the damage occurred to the structure's construction schedule. For example, the detection of cracks in the lower part of the abutment just after pouring may suggest that they were caused by concrete shrinkage, while their occurrence after placing the load on the structure, or at the stage of test loading, may indicate that the element is not working properly or that there is a structural defect. For this reason, it is important that in creating the dataset it is also important to fill it with information such as, among other things, the type of element damaged and the cause of the damage.

By linking the information about the damage detected on the image with the Digital Twin of the bridge, it can also be used to verify the cause of the damage, e.g. by analysing the stress state of the element. On the other hand, machine learning algorithms can be supported by information from the Digital Twin of the bridge about the assignment of image data to a specific structural element. Providing such information as input for DL algorithms can help to identify regions of interest for which further diagnostics will be carried out.

5 CONCLUSION

The conducted analysis indicated that despite the increasing interest in the use of deep learning-based algorithms for bridge damage detection, there is significantly limited access to open datasets of bridge damage images. There is also no standardized way to create datasets of structure damage. In particular, the authors of datasets do not address aspects that are important for a bridge engineer during the description of datasets, such as the size of the damage, the cause of the damage, the relation of the damage to the element's work, among others. In many cases, the method of class assignment, bounding boxes or pixel classification is not described by the authors. There are also such datasets where, despite defining the possibility of detecting with them several types of damage, all images are grouped into a single class, which makes it impossible to accurately detect a specific type of damage, and thus to use such a dataset. Therefore, it is important to focus on the careful preparation of data for training machine learning algorithms, and the selection of metrics and ways to verify the correctness of the obtained solutions in the perspective of the bridge engineers' domain knowledge. Such an approach can allow the creation of more robust algorithms that not only achieve good results from the perspective of deep learning metrics, but also provide important support for the bridge engineer's work.

ACKNOWLEDGMENTS

The authors would like to acknowledge the support from the project Europe's Rail Flagship Project 4 - Sustainable and green rail systems that has received cofounding from the Horizon Europe Framework Programme (HORIZON) under grant agreement number 101101917 and Ministry of Education and Science in Poland under grant agreement number MEiN 5337/HE/2023/2. The project is being implemented at the AGH University of Krakow in 2022-2026.

F. Basone & M. Longo
SACERTIS Ingegneria S.r.l., Torino, Italy

ABSTRACT: This work investigates the influence of pavement conditions on the bridge response. When monitoring is available for the bridge at study, a correlation between the response, usually in terms of acceleration, and the roughness level can point out the need for a maintenance intervention. This paper focuses on the preliminary numerical work devoted to the study of vehicle-bridge interaction, taking advantage of a combined usage of a commercial and of a research code. The case study is a 4-span 60m long highway viaduct in the Northern Italy. Static and dynamic tests were performed after the installation of the SHM system (MEMS clinometers and accelerometers) and its dynamic behavior was continuously monitored in conditions of pre- and post-paving. A FE model was established with SAP2000 and updated to account for the experimental results. As a positive novelty of this work, the analysis of bridge-vehicle interaction is tackled by exploiting the capabilities of the commercial code and of a previously developed research code, named INTER. The structural matrices and the relevant tables of nodes are extracted from SAP2000 and, after some manipulations, adopted as input data to INTER. The interaction analysis accounts for roughness and adopts an ad-hoc developed 13-DOFs vehicle model, representing the one adopted in tests. Preliminary results show the influence of the roughness on the acceleration of selected points, investigating the variability of results tied to the generation of roughness profiles from the PSD function in Eurocode1.

1 INTRODUCTION

In the last two centuries, the progress of technology, materials and industrial world have led to a massive construction of bridges for roads and railroads. Nowadays, the civil engineering community tackles the need for the assessment and maintenance of bridges designed with obsolete codes for less intensive traffic, while, in conjunction with the evolution of structural schemes and the adoption of advanced materials, it faces the challenge of a design accounting for several extreme environmental load conditions. Within this framework, the dynamic interaction between a bridge and a travelling vehicle (VBI, Vehicle-Bridge Interaction) plays a fundamental role in a wide range of issues, as an analysis of the recent literature shows. VBI accounting for the effects of pavement roughness conditions the fatigue life analysis (Bhetuwal et al, 2022) and introduces an additional damping to the bridge (Stoura & Dimitrakopoulos, 2020). VBI allows for indirect bridge monitoring, since modal identification and damage detection are possible through the analysis of the dynamic response of an instrumented vehicle crossing the bridge. The topic, investigated since the pioneering work of YB Yang et al (2004), has generated wide research efforts both on the theoretical aspects (Yang & Yang, 2018) and on the structural health monitoring techniques based on vibration measurements (Zhu & Law, 2015) that is still ongoing (Yang et al, 2022). The contemporary presence of VBI and seismic excitation is accounted for (Paraskeva et al, 2017). The dynamic response of a new type of structure that is still at the proposal level, the submerged floating tunnel, is

DOI: 10.1201/9781003483755-176

investigated under the coupled effect of hydrodynamic loads and crossing vehicles (Mulas et al, 2018; Lin et al, 2022).

Pavement roughness is one of the factors affecting the bridge response under vehicle traffic. Due to the repeated passage of vehicles, roughness generally increases, worsening the quality of the generic roughness profile that can be detected on the bridge at study. Inspection is necessary to establish the degradation level, and usually a threshold is introduced for the need of maintenance. Aim of this work is investigating the effect of the roughness on the bridge response, both from an experimental and a numerical point of view, to verify whether the bridge response can be assumed as an indicator of pavement degradation. The case study is a 4-span reinforced concrete (RC) highway viaduct, instrumented for structural health monitoring (SHM) purposes and subjected to both static and dynamic tests, under a passing truck. Numerical analyses adopt a complete 3D model of the structure, generated with SAP2000, an ad-hoc developed 13 DOF (degrees of freedom) vehicle model and roughness profiles generated from the PSD function of Eurocode 1. Coupled equations of motion of the VBI problem are integrated following the work of Feriani et al. (2008, 2010), as last implemented in the research code named INTER (Maneo, 2016). This paper presents selected experimental and numerical results of the research work just described.

2 THE CASE STUDY

The structure at study is a highway RC bridge built in the late 1960s and located in Northern Italy (see Figure 1). The 4-span bridge is approximately symmetric about mid-span. The overall length of approximately 60 m is subdivided into 9m-long end spans and two 20m-long central spans. All the spans are simply supported at the ends, with abutments at the two ends and intermediate piles in the central zone. The supports of each span are devices made of multipurpose reinforced neoprene rubber sheets and strips. Joints between adjacent spans are placed below the pavement. Each deck girder is composed of six beams with reinforced concrete slabs having a constant height equal to 20cm (see Figure 2). The beams at the end spans have constant height while the two central ones have variable height (1.20m ÷ 1.70m).

2.1 *SHM system*

The reference structure was instrumented by clinometers and accelerometers for SHM purposes. In 2019, a set of 58 MEMS bi-axial clinometers and 42 tri-axial accelerometers was

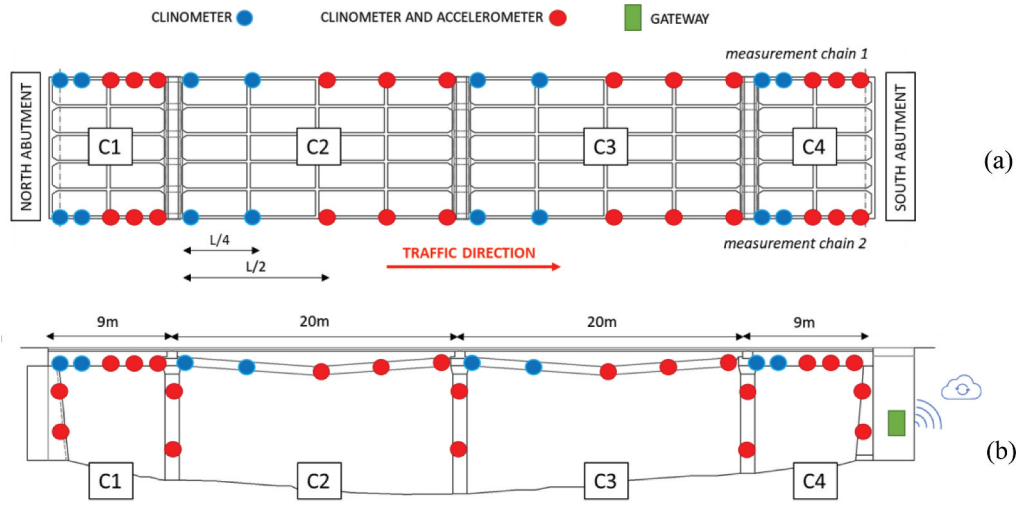

Figure 1. Plan view (a) and lateral view (b) of the bridge with the sensors positioning.

placed on the bridge, and one IoT Gateway was installed on one of the abutments. The biaxial MEMS clinometers measure along two axes, i.e. x and y, aligned to the transversal and longitudinal directions of the bridge respectively, whilst the triaxial MEMS accelerometers have the additional z-axis oriented along the vertical direction. Both accelerometers and clinometers are equipped with a 32-bit microcontroller, humidity and temperature sensors.

The precabled SHM system is made of two chains of clinometers and accelerometers placed along the two external beams of the deck. In all spans, each chain is made of 5 sensors (2 clinometers and 3 accelerometers), placed approximately at midspan, at ¼ of span and near the bearings**.** Figure 1 shows a plan and lateral view with the sensors positioning. Static (clinometers) and dynamic (accelerometers) MEMS sensors measure residual deformations and vibrations due to traffic. Each clinometer provides synthetic statistical parameters (mean value, standard deviation, maximum and minimum rotation), internal temperature and relative humidity, with a sampling frequency of 208 Hz. Tri-axial accelerometers provide continuous data along 3 axes, with a range of ±2 g and a bandwidth of 100 Hz. Acquisition parameters are tunable with remote control.

The continuous monitoring system promptly notifies anomalies due to two alerting systems. The first one detects rapidly growing anomalies; algorithms at the gateway level notifies in semi real-time short-term phenomena. The second performs long-term controls at the cloud level, to detect slow changes in the structure behaviour (long-term phenomena). In both cases, a degree of robustness is provided through multi-parameter cross-checks among sensors in space and in time.

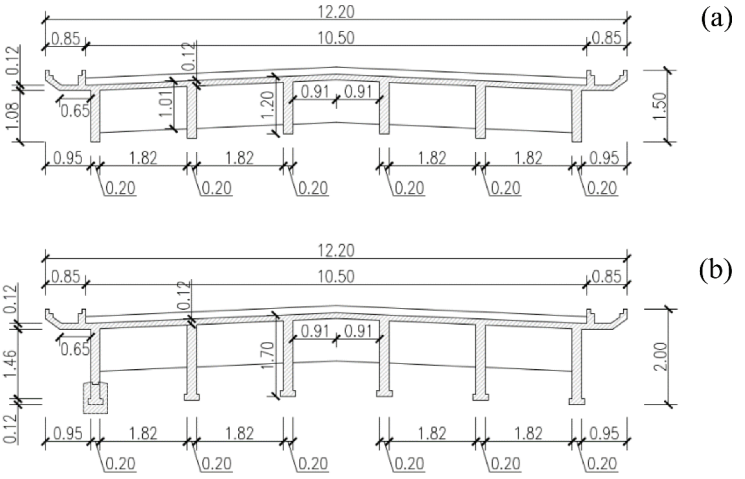

Figure 2. Cross-section of the bridge: (a) end spans; (b) central spans.

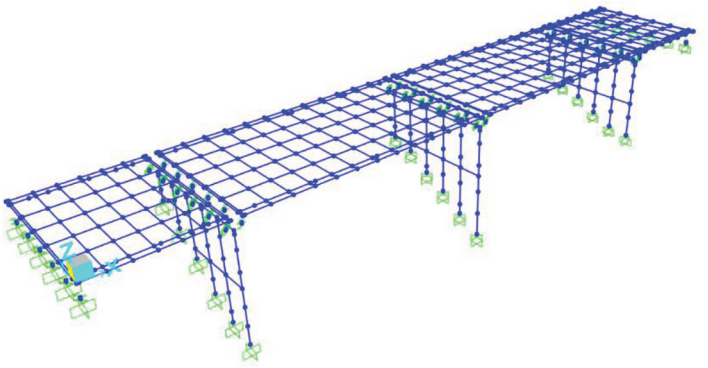

Figure 3. Three-dimensional view of FE model.

2.2 *FE modeling of structure*

The 3D finite element (FE) model of the structure, developed within the SAP2000 software platform, is based on the bridge cross-section, different for end spans (Figure 2a) and for central spans (Figure 2b), and is shown in Figure 3. Each span has been discretized through 6 DOFs beam elements in both the longitudinal and transversal direction, having proper mechanical and geometric characteristics. To take into account the stiffening behavior of the slab in transverse direction, fictitious transverse elements have been added ad deck level. Elastomeric supports are modelled by *links elements* that simulate the device stiffness in three mutually orthogonal directions.

2.3 *Description of experimental tests*

Experimental tests under a moving truck were carried out in absence of traffic, to avoid that the accelerometer signals are contaminated by the transit of other unknown vehicles. Figure 4 shows the adopted vehicle, the heaviest (44 tons) that can circulate on the viaduct without special authorizations. The vehicle moved with three different speeds (i.e. 20, 40 and 60 km/h), on a known trajectory, either on driving or on overtaking lanes. Seven months after the tests, the viaduct was re-paved, suggesting the existence of degraded pavement conditions during the tests.

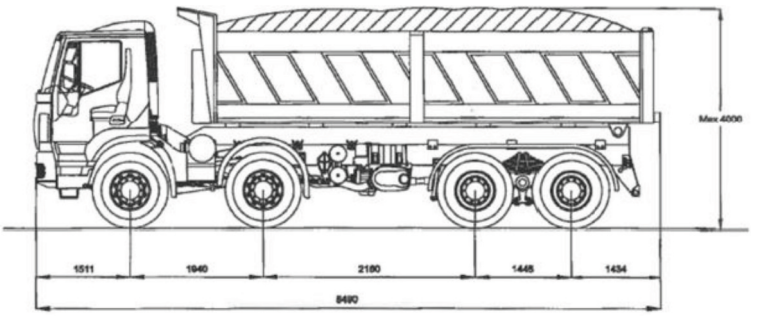

Figure 4. Geometric characteristics of the vehicle (units: cm).

Figure 5 shows the time history of the vertical acceleration of two sensors at the second span midspan, on the right beam (Figure 5a, b) and on the left beam (Figure 5c, d). The first two plots refer to the transit of the truck on the driving lane; for the last two, the truck is moving on the overtaking lane. In both cases, the signal refers to the sensor closer to the moving vehicle. The vehicle travels at 40km/h for cases (a) and (c) and at 60 km/h for cases (b) and (d). Even though the magnitude of the max acceleration appears independent on the vehicle speed, a different shape is found for the two speeds. The response of the left beam during the overtaking test (Figure 5c,d) is remarkably smaller than the one of the right beam during the driving test (Figure 5 a, b).

3 NUMERICAL MODELLING: ROUGHNESS AND VEHICLE

Experimental profiles provide a more realistic and smoother description of the road surface roughness, while numerical ones, generated by assigning random phases to amplitudes respecting a given Power Spectral Density (PSD) function of the roughness, describe different situations with a variation of the PSD parameters. This work adopts the PSD function G_d proposed by Eurocode1:

$$G_d(n) = G_d(n_0)\left(\frac{n}{n_0}\right)^{-w} \tag{1}$$

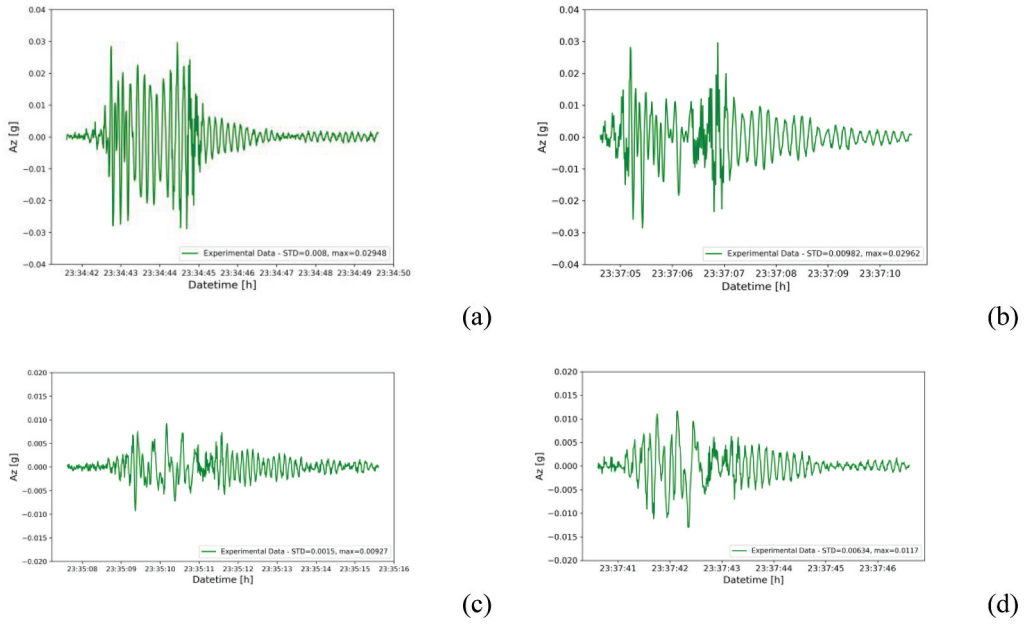

Figure 5. Vertical acceleration at 2nd span midspan for a vehicle moving on the driving lane at (a) v=40 km/h; (b) v=60km/h and for a vehicle moving on overtaking lane at (c), v=40 km/h; (d) v=60 km/h.

where n_0 = 0.1 cycles m^{-1} is the reference spatial frequency, $G_d(n_0)$ is the corresponding value of the spectrum, and w is an exponent equal to 2. EC1 provides parameters value for roughness classes. In this work, only the first five (from A to E) are considered, listing very good, good, medium, poor and very poor pavement roughness. Class A pavements correspond to a newly paved highway, while the B-C values can be considered as a lower limit for main roads. Figure 6a shows four profiles at the border between classes A and B, B and C, C and D and D and E. Figure 6b shows three class B profiles generated with different seeds. Class C is not allowed by standard codes for the paving of bridges and highways, but is still acceptable for main classes of roads; the lower limit for the case study is hence the class B.

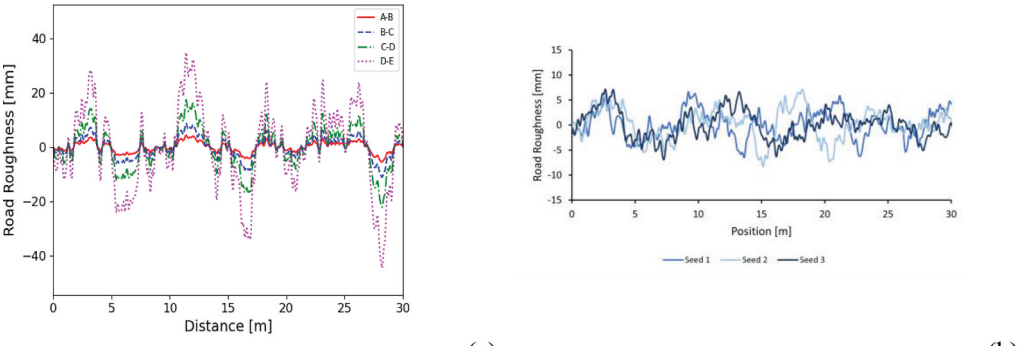

Figure 6. Roughness profiles: (a) different classes, same seed; (b) class B, three different seeds.

A 3-D mechanical system with 13 DOFs (Figure 7) was developed in this work, to simulate the truck adopted in the dynamic tests (Gou et al, 2001). The model has four independent axes and two rigid masses, the engine and the trailer, connected through a 3D hinge. Each body is connected, through the suspension system (a spring/dashpot device), to four unsprung

masses that in turn are connected to the ground through another spring/dashpot device representing the tires.

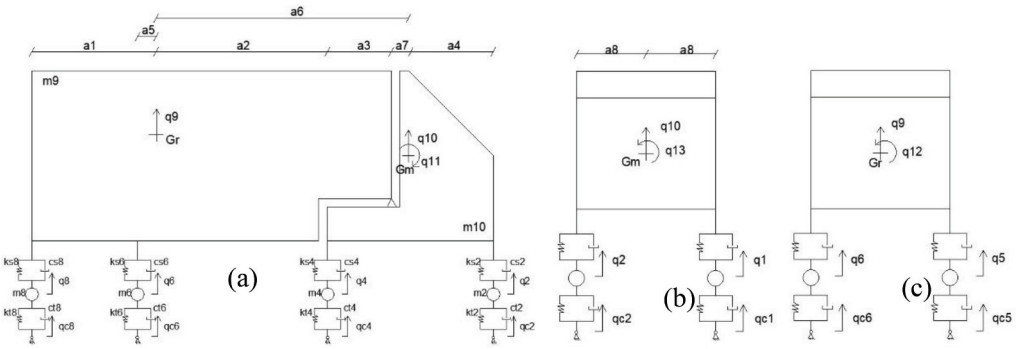

Figure 7. 13-DOF model of the truck: (a) lateral view; (b) front view; (c) rear view.

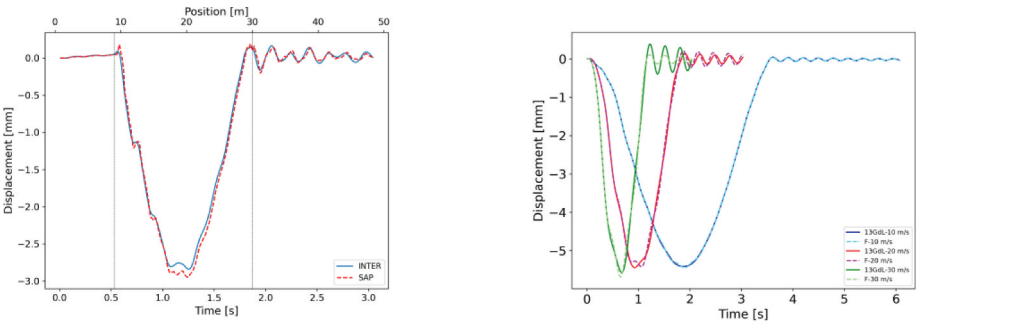
Each tire has a vertical DOF that is constrained to move as the corresponding contact point on the bridge. The equation of motion of the system is derived under the following assumptions: (a) the vehicle travels at a constant speed along a straight line parallel to the bridge axis; (b) horizontal and vertical motion are uncoupled; (c) a perfect contact takes place at massless points; (d) only vertical contact forces are transmitted at contact points.

4 NUMERICAL SIMULATION OF INTERACTION

In this work, the VBI coupled problem is solved by deriving the coupled equation of motion and subsequently devising an uncoupled iterative solution procedure. In this way, bridge and crossing vehicle are analyzed separately: the vehicle is subjected, on its wheels, to roughness and bridge motion and the bridge is subjected to vehicle's contact forces. Under the assumptions listed at the end of the previous paragraph, Lagrange's equations allows to define mathematically the problem of vehicle-structure interaction with a system of ordinary differential equations:



$$\frac{d}{dt}\left(\frac{\partial T}{\partial \dot{q}_k}\right)+\frac{\partial V}{\partial q_k}+\frac{\partial D}{\partial \dot{q}_k}=0 \;\; k=1,\ldots,n_{dof} \tag{2}$$

In Equation (2), T is the total kinetic energy of the system composed of bridge and crossing vehicles, V is the potential energy of the same system and D is the dissipation function that accounts for energy dissipation due to both the bridge and the vehicle masses motion. The equation of motion obtained in this way describes the coupled vehicle-structure behavior. The assumption of massless contact points uncouples the mass matrix of the coupled system. The system of equations is solved through a forced decoupling of the equations (obtained by moving to the right-hand side both coupling and time-dependent terms) associated to an iterative procedure, established at each step of the time history. Convergence is achieved when, at two subsequent iterations, the value of contact forces at the system interface is within a prefixed tolerance (Feriani et al. 2008, 2010). This work adopts a recent version of the code INTER (Maneo, 2016).

In this work, the potential of the iterative procedure is fully exploited through a numerical interface in MATLAB© between SAP2000 and INTER. The MATLAB© code reads the relevant data of the SAP2000 FE model and, after same manipulation, writes them in a format compatible with the code INTER. Data includes the structural matrices, the coordinates of nodes and the numbers of equation associated to each DOF of each node. An extensive

validation has been performed on the transfer procedure, by adopting several FE models. As an example, Figure 8a reports the time history of the vertical displacement at midspan of the 2nd span, due to a vertical force of 400kN travelling along the bridge axis at a speed of 60 km/h. The two vertical dashed lines mark the time instants when the travelling force enters and exits the span. The agreement between the numerical response of the two codes is excellent: the small discrepancies can be tied to the different algorithm adopted by the two codes to subdivide (and to transfer) the applied force to the mesh nodes, that are generally different from the contact point.

The 13-DOF vehicle validation is performed on the FE model of a 30m long bridge (Feriani et al 2008, 2010). The vehicle travels along the bridge axis, at three different speeds, namely 10, 20 and 30 m/s, and over a smooth profile (no roughness). Figure 8b shows the results for the time history of the midspan displacement: at each speed, results are practically coincident with those generated by a set of forces equal to the static values of contact forces transmitted by each wheel, thus validating the derivation and implementation of the new vehicle model.

(a) (b)

Figure 8. Validation of the research code, time history of midspan displacement: (a) INTER vs. SAP: force travelling along the bridge axis; (b) 13-DOF vehicle and static forces transmitted by the vehicle travelling along the bridge (Feriani et al. 2008, 2010) axis.

5 RESULTS

The dynamic analysis aiming to detect the roughness effect on the response has been tackled by means of a probabilistic approach, not having any knowledge beforehand of profile measurements in site. The focus of the analysis is to determine a plausible roughness class from the direct comparison of the experimental vertical acceleration time-history and its numerical counterpart, which combines the structural responses due to twenty separate analyses for each roughness class. The code INTER allows the user to account for the variations of roughness in the longitudinal direction, with the adoption of semi-random profiles, as well as in the transverse direction, by assigning a different profile to the vehicle's left and right wheels. Hence, each analysis is characterized by the adoption of different profiles, while remaining in the same roughness class.

In this work only the analyses referring to the tests at 60 km/h are considered, as this is the speed that resembles the most the actual service conditions of the structure. In fact, the other four tests have been exploited mostly as validation of the obtained results and are not shown here for the sake of brevity. In addition, separate analyses are carried out for the dynamic tests on the two lanes, which form the deck of the bridge, due to the different level of acceleration recorded.

Figures 9a, b shows (in dark green) the experimental vertical accelerations, recorded at the 2nd span midspan, due to the truck moving over the driving lane and the overtaking lane, respectively. Each signal is recorded by the sensor closer to the moving vehicle. The results indicate that the roughness conditions on the two lanes differ quite noticeably. The numerical counterpart of the test is obtained by extracting, at each time instant, the maximum and

minimum values of the results of the twenty analyses adopting profiles belonging to the same class. Hence, a numerical "fuse" (in light green) is obtained, and the fuse that better matches the experimental results is chosen. For the driving lane, numerical and experimental accelerations are in agreement if the selected profiles belong to the geometric mean of the regularity class B, while for the overtaking lane the target has been set to the geometric mean of class A. This outcome may be explained with the different traffic conditions on the two lanes, as the majority of heavy vehicles stays on the right side of the deck, causing a more concentrated and extended decay of the regularity conditions of the road surface.

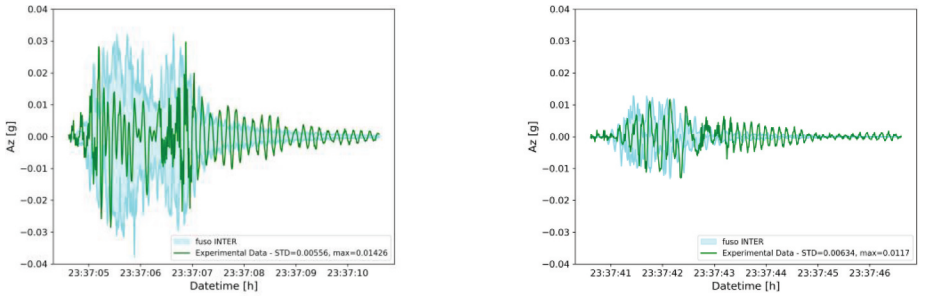


Figure 9. Vertical acceleration at the 2nd span midspan, truck traveling at v=60km/h: (a) on the driving lane, numerical fuse due to geometric mean of roughness class B; (b) on the overtaking lane, numerical fuse due to geometric mean of class A.

6 CONCLUSIONS

Aim of this work was to investigate the effect of the pavement roughness on the experimental response of a highway bridge, a relevant issue from the maintenance point of view. The preliminary work here shown was focused on the numerical simulation of experimental tests, where a truck crosses the bridge. The results have shown that, even though the experimental results cannot be reproduced exactly, due to the lack of knowledge of the real roughness profile and the imperfect knowledge of the truck mechanical properties and trajectory, it is possible to identify the roughness class of the pavement from the bridge response. This result validates the numerical procedure and suggests further developments, based on the continuous monitoring data available.

As shown here, recorded accelerations can differ considerably based on the pavement conditions. As a final aim of this research work, the SHM data analysis should first individuate a set of synthetic parameters able to classify the level of recorded acceleration. Second, the parameters values should be connected to a roughness class. While a poor quality of roughness reduces the safety of passing vehicles, denoting the need for maintenance, care must be taken in the data analysis, since road roughness represents a further confounding effect in the evaluation of structural response, in addition to thermal conditions (Darò et al, 2023). The reason for any variation of the dynamic behavior should be investigated, to avoid erroneous interpretations. In this respect, the analysis of data in the frequency domain should always be performed.

Further studies will focus on the analysis of data of the continuous SHM system. Even though not shown here for the sake of brevity, a preliminary comparison of accelerations recorded before and after a re-paving intervention was performed. Synthetic but significant parameters that can be easily extracted from the records, as peak values, standard deviation and RMS, were able to catch the different pavement quality, showing the feasibility of the procedure just suggested.

CREDITS

This paper stems from the work performed by M. Riso and A. Sgambati during their MS thesis in Civil Engineering at Politecnico di Milano, under the guidance of M.G. Mulas. Data

on the bridge (FE model and experimental data) are due to Francesco Basone and Monica Longo of Sacertis Srl, where M. Riso and A. Sgambati performed a stage period. The contribution of former students R. Pantalena, T. Carta and L. Candido in developing the code INTER is gratefully acknowledged.

ABSTRACT: In civil engineering and architectural applications, Micro Electro-Mechanical System (MEMS) accelerometer-based inclinometers are widely used due to their cost-effectiveness. However, a major challenge associated with these devices is their long-term durability and reliability. Typically, commercial inclinometers are employed to calibrate low-cost solutions over time, which ultimately increases monitoring costs and significantly reduces their economic advantages. To address this limitation, this paper presents a novel approach based on Artificial Intelligence (AI) to evaluate the long-term performance of the low-cost inclinometer called LARA (Low-Cost Adaptable Reliable Anglemeter). This AI-driven tool utilizes a Multilayer Perceptron to predict the inclination of a monitored steel structure under real environmental conditions. By comparing the predicted results with actual on-site measurements, potential inaccuracies in the low-cost inclinometer can be automatically detected, indicating the need for recalibration. The effectiveness and applicability of the proposed tool are demonstrated through a study conducted on a real steel frame located in Spain. This study demonstrates how the AI-based approach can enhance the assessment of the low-cost inclinometer's performance and its suitability for long-term monitoring of real structures.

1 INTRODUCTION

In the midst of the fourth industrial revolution, often referred to as Industry 4.0, civil engineering and architecture are experiencing profound changes (Alaloul et al. (20202)). These disciplines are being reshaped by the digital era, altering traditional methodologies for planning, designing, constructing, and maintaining infrastructures and buildings. Leading this paradigm shift are sophisticated technologies like Artificial Intelligence (AI), which have the capability to perform tasks traditionally dependent on human intelligence. AI tools include a wide range of applications.

Structural health monitoring (SHM) stands as a highly promising area of research within civil engineering and architecture, aimed at enhancing the safety and reliability of structures. Traditionally, SHM techniques rely on sensors and physical inspections to evaluate the health of the infrastructures. However, the development of AI technologies is transforming SHM into a more dynamic and anticipatory field. A review of the application of AI tools in bridge SHM applications was presented in Sun et al. (2020).

DOI: 10.1201/9781003483755-177

Sensors play a key role in SHM applications by enabling the collection of real-time data on-site. Among the most common sensor types are structural sensors like accelerometers and inclinometers, and environmental sensors for measuring the environmental temperature. Nevertheless, the high costs of traditional commercial monitoring solutions often restrict their use in conventional structures, where most structural pathologies are found. To tackle this challenge, a variety of low-cost monitoring solutions have been developed over the past decade. In addition to their reduced cost, these devices are also traditionally distinguished by their versatility and adaptability. Among the wide array of low-cost monitoring devices, inclinometers, also known as tilt sensors, deserve special attention for their widespread application across structural SHM applications.

A cost-effective method for measuring inclinations documented in the literature, involves the use of Micro-Electro-Mechanical Systems (MEMS) accelerometers. Nevertheless, this monitoring approach also comes with certain inherent technological challenges. Primarily, these devices necessitate periodic calibration to ensure precision and are prone to drift, which can compromise the reliability of their readings without consistent recalibration. Additionally, their sensitivity to environmental factors like temperature and humidity may adversely affect their accuracy. Moreover, low-cost sensors typically have a reduced operational lifespan, leading to greater maintenance and replacement expenditures over time. To mitigate these issues, various artificial intelligence applications have been explored in a number of works. For example, Podder et al. (2023), proposed an artificial intelligence application for MEMS-Based Sensors and manufacturing process optimization, Guo et al. (2023), studied the temperature drift compensation of a MEMS accelerometers, Pan et al. (2010), used neural network to compensate a quartz accelerometer, and Hoang et al. (2020) applied an AI tool to improve the inclination measurement of a MEMS accelerometer.

A principal challenge associated with low-cost inclinometers is to assure their long-term durability. For accurate and consistent operation over extended periods, it is often necessary to validate their precision against more expensive commercial alternatives. This requirement for on-site validation leads to an increase in the monitoring expenses, thus diminishing the cost-benefit of utilizing low-cost devices. To address this issue, the present study introduces an AI-based methodology designed to validate the long-term performance of low-cost inclinometers. This methodology correlates the historically predicted responses for different environmental conditions, to autonomously detect inaccuracies in the inclinometer readings. This approach eliminates the need for expensive monitoring instruments by leveraging exclusively on structural and environmental data, specifically humidity and temperature, collected through low-cost sensors. The application of the proposed methodology is applied to the low-cost inclinometer Low-Cost Adaptable Reliable Anglemeter (LARA) (Komarizadehasl et al. 2022) and it is validated through the long-term monitoring of a real steel frame located in Spain.

The structure of this paper is as follows: Section 2 reviews the main features of the low-cost inclinometer LARA, detailing its design and essential components. Section 3 introduces a new AI tool designed to assess the impact of environmental factors, namely temperature and humidity, on the inclination measurements provided by LARA. The implementation of this methodology is demonstrated in Section 4 through the analysis of a real steel frame. Finally, the main conclusions are drawn in Section 5.

2 LOW-COST ADAPTABLE RELIABLE ANGLEMETER (LARA)

LARA (Figure 1), acronym for Low-cost Adaptable Reliable Anglemeter, refers to a monitoring device designed to measure structural parameters (accelerations or inclinations). Unlike most low-cost accelerometers in the literature, LARA possesses a distinctive feature: it can be remotely configured to operate as either a triaxial accelerometer or inclinometer (Komarizadehasl et al. 2022). When functioning as an inclinometer, LARA utilizes the gyroscopes within its accelerometers along the X, Y, and Z axes to determine the orientation with respect to the gravitational force. LARA working as inclinometer can reach a precision of up to 0.002º working in the static mode for a measurement range between 0º and 4°.

LARA consists of five precisely aligned and synchronized MPU9250 chipsets, complemented by a multiplexer. Each MPU9250 chipset is equipped with an accelerometer, gyroscope, and magnetometer, enabling comprehensive data collection and analysis. LARA employs a strategy to enhance its performance by averaging measurements from the five MPU9250 sensors, all operating together with a multiplexer TCA9548A. This approach effectively improves the accuracy of the reference low-cost sensor, MPU9250, from 0.055° to 0.002°. These sensors are connected to an Arduino Due board microcontroller functioning as a data conditioner, and to a Raspberry Pi single-board computer.

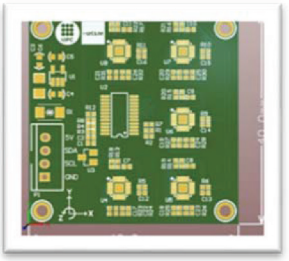

Figure 1. LARA monitoring system.

This monitoring solution is designed as a user-friendly Internet of Things (IoT)-based sensor, simplifying the setup process. Once the sensor is installed on a structure, it only requires connection to a 5V, 2.5A battery or a power source through the Raspberry Pi adapter to send wirelessly throught the internet the measured information according to programmed settings.

3 ARTIFICIAL INTELLIGENCE TOOL

In this section, a novel Artificial Intelligence (AI) tool, designed to analyze the impact of environmental factors such as temperature and humidity on inclination measurements is introduced. The subsequent sub-sections provide detailed descriptions of the tool's principal features, its architecture, and the methodology employed in its training.

3.1 *Multilayer perceptron architecture*

The developed AI tool is based on a Multilayer Perceptron (MLP), a class of artificial neural network characterized by its sequential multi-layered arrangement of neurons. MLPs are defined by their feedforward structure, wherein data moves unidirectionally from input to output layers, without any loops or cycles within the network. With an adequate number of hidden neurons and properly curated training data, MLPs have the capability to approximate any continuous function with the desired accuracy.

The MLP was based on the scikit-learn package Pedregosa et al. (2011), a comprehensive open-source machine learning library. This tool includes a powerful data preprocessing algorithm, which include but are not limited to, feature scaling, categorical variable encoding, missing values imputation, and feature selection. Furthermore, its compatibility with other Python libraries facilitates efficient data handling and visualization, which is crucial during the model development and deployment stages.

The designed MLP models aim to forecast X-axis inclinations of LARA by analyzing LARA's Y-axis rotations, along with temperature and humidity readings from low-cost environmental sensors. Once trained, the model can be applied to detect irregular measurements through a comparison between its predictions and the actual X-axis rotations recorded by LARA. A discrepancy between these predicted and observed rotations may signal an error (such as calibration errors, unaccounted external loads, or potential structural damages).

Future work will focus on enhancing the method's capability to distinguish between these errors.

The configuration of the input layer, hidden layers, activation functions, output layer, and solver in the MLP proposed for this study are outlined below:

- Input Layer: The input layer is composed of three neurons that process the normalized data for on-site Y-axis rotations, temperature, and relative humidity. The Y-axis rotations are recorded by LARA, while temperature and humidity are monitored using the low-cost sensor SHT22, which is widely used in a variety of research applications (see e.g. Mobaraki et al. (2022)).
- Activation Functions: The rectified linear activation function (ReLU), obtained from the scikit-learn library, is the chosen activation function for the neurons.
- Output Layer: The output layer is comprised of a single neuron that outputs the LARA-measured X-axis rotations.
- Solver: The 'adam' solver from the scikit-learn library is selected.

A typical architecture of the proposed MLP is summarized in Figure 2. This architecture includes two hidden layers, denoted as i and j, with m and n hidden neurons, respectively.

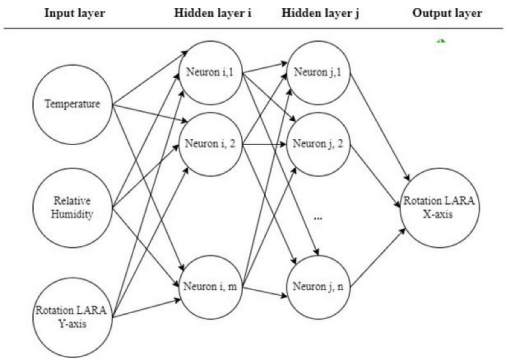

Figure 2. Typical architecture of the proposed MLP.

The following section describes how the network's architecture is customized and trained specifically for the analyzed case study.

4 CASE STUDY

In this section, the main characteristics of case study and the main aspects of its monitoring program, are first described. Then, the developed AI tool is customized for the analysis to check the long-term performance of LARA in this structure. Finally, obtained results are analyzed.

4.1 *Description of the structure and monitoring program*

The case study corresponds with a steel gable frame (Figure 3.a) located at the Institute of Technology at the University of Castilla-La Mancha in Cuenca, Spain. Its dimensions include a length of 11.5 meters and a height of 6 meters. This frame is constructed using HEB 300 columns and IPE 400 beams.

The selection of this building was influenced by its beneficial features for reducing wind impacts. This is due to its ideal placement and the wind-shielding barriers on its roof. Additionally, the roof is mostly subject to sporadic live loads during maintenance, minimizing their effect. Therefore, the main changes in the building's structure are driven by environmental elements like temperature and humidity.

The structures have been under continuous monitoring since it was built in 2008 to assess the effects of differential settlements. The monitoring strategy includes monitoring soil moisture at 27 locations, 4 inclinometers and 4 thermometers. A detailed explanation of the results of the monitoring program is presented in González-Arteaga et al. (2019). The gable frame under study was monitored with an inclinometer model EL Tiltmeter SC. This device provides measurements of both one-axle inclinations and temperatures with 1 arc second and 30×10-5°C resolutions. This inclinometer, as shown in Figure 3.b, was positioned at the connection between the beam and the column, and it records readings at 15-minute intervals.

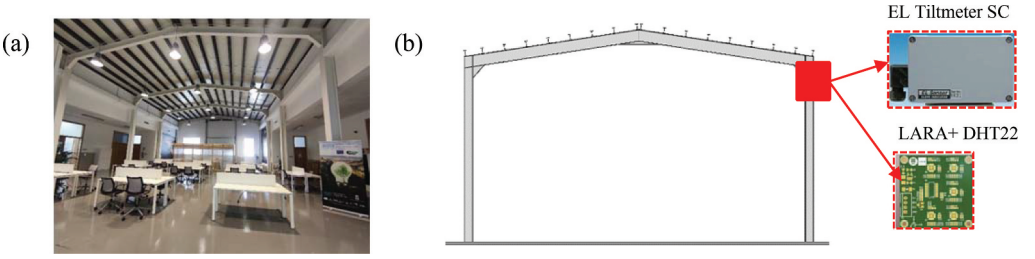

Figure 3. Monitored steel gable frame and inclinometer location.

The low-cost monitoring solution incorporated in this structure consisted of two sensors: (1) LARA, which measures inclinations in three axes, and (2) DHT22, which measures environmental temperature and humidity. Both sensors were installed at the same location as the commercial inclinometer as indicated in Figure 3.b. The reading interval for both sensors is set at 15 minutes to facilitate comparison with the commercial inclinometer. Additionally, both sensors were connected to the electrical power supply of the building.

To illustrate, Figure 4 presents the inclinations and temperatures measured by the commercial inclinometer on February 20th, 2023. The analysis of this figure highlights the significant influence of temperature on the rotations of the structure.

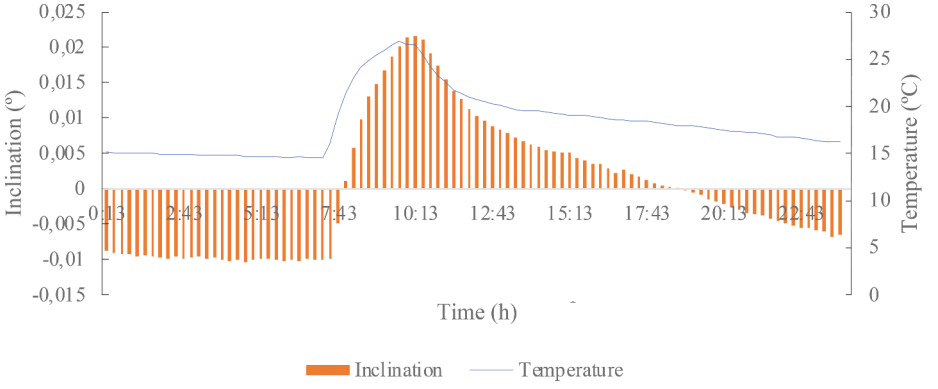

Figure 4. Evolution of temperature and inclination in one day (February 20th 2023).

Figure 5 Presents a comparison of the inclination data recorded by a commercial sensor versus the data from LARA during a monitoring period of three days, from the 20th to the 22nd of February 2023. The examination of this data reveals that while LARA has a relatively lower precision, both sensors display comparable patterns in detecting the influence of environmental factors over time. It is important to highlight that in this research, the commercial inclinometer's function is strictly to confirm the accuracy of LARA's measurements, facilitating the calibration process for the MPL developed in the next section. The Standard Deviation, SD and the Mean Square Error, MSE, obtained from the comparison of LARA and the commercial sensor are 0.02408 and 0.00058, respectively.

Figure 5. Comparison of the inclinations between EL Tiltmeter SC and LARA From February 20th to February 22nd, 2023.

4.2 *AI Tool*

After empirical analyses, the MLP was designed with a consistent structure of three hidden layers, each layer housing 5 neurons. Additionally, the learning rate was set at 0.0001 to enhance the efficiency of the model's training process. The training of this architecture was exclusively based on the information from the low-cost sensors from January 10th till May 17th, 2023, with an interval of 15 minutes. Over this period, a total of 5790 data points, including temperature, humidity, and rotations in X and Y axes, were recorded, and analyzed. This data was randomly divided into the three following sets: (1) a training dataset, which included 70% of the total data; (2) a cross-validation dataset, comprising 15% of the data; and (3) a testing dataset, also making up 15% of the data.

4.3 *Results*

Displays a comparison of the X-axis rotational predictions made by the MLP tool against the actual readings recorded by LARA from the test dataset.

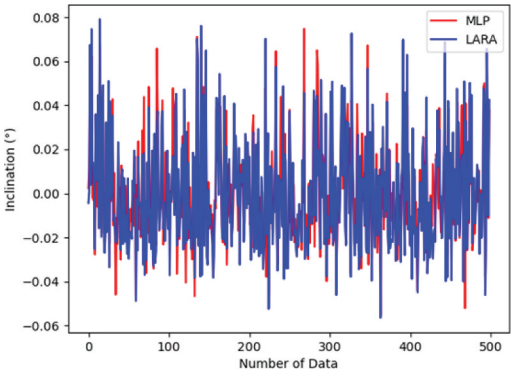

Figure 6. Comparison of the X-axis rotations predicted by the MLP (red) tool and those obtained by LARA (blue) from January 21st to April 1st 2023.

Based on the comparison of the predicted results and those obtained by LARA for the same analyzed period, the Mean Squared Error (MSE), and the Standard Deviation (SD) were calculated. The obtained values were MSE 0.0004, and SD 0.0187.

The probability density of errors with the fitted normal distribution is characterized by a mean of 0.00037 and a SD of 0.0187. This function is presented in Figure 7.

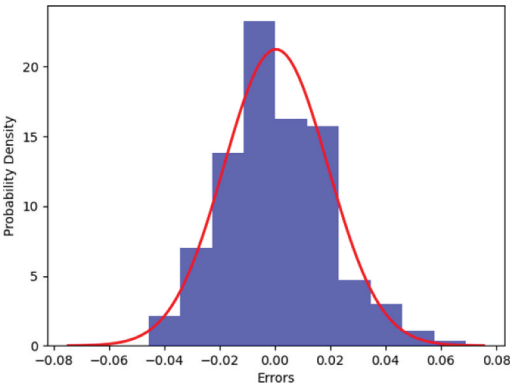

Figure 7. Probability density of errors with fitted normal distribution in the test set.

The calculated MSE values over a predetermined environmental cycle (such as a day) can serve as indicators for the potential necessity of LARA recalibration. This need arises when the acquired values surpass those obtained through a comparison of LARA with a commercial inclinometer.

In Figure 8, the MSE of 10 specific day of March 2023 are displayed. The analysis of this figure shows the reliability of the results obtained as the threshold from the comparison with the commercial inclinometer (MSE of 0.00058) is not exceeded. Exceeding this MSE threshold in the future might indicate the need of recalibration of the low-cost sensor.

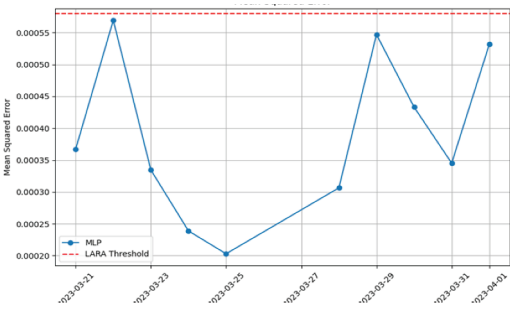

Figure 8. Example of the MSE Of MLP model result from April 21st To 1st Of May 2023.

5 CONCLUSIONS

While Micro Electro-Mechanical System (MEMS) accelerometer-based inclinometers offer cost-effective solutions for civil engineering and architectural applications, their long-term durability and reliability have been a challenge. To address this limitation and avoid the costly calibration with commercial inclinometers, we proposed an innovative Artificial Intelligence (AI)-based approach. The AI-driven tool utilizes a Multilayer Perceptron Neural Network to predict the inclination of a monitored steel structure under real environmental conditions. By comparing the predicted responses with actual on-site measurements, we can automatically

identify potential inaccuracies in the low-cost inclinometer, thus indicating the need for recalibration.

The application of our proposed AI tool is specifically designed for the low-cost inclinometer LARA (Low-Cost Adaptable Reliable Anglemeter) and was demonstrated through a study on a real steel frame. The results highlighted the effectiveness and applicability of the proposed approach, showing its ability to accurately evaluate the long-term performance of LARA under real-world conditions. This innovative approach provides a reliable and cost-efficient solution for monitoring structural inclinations, ensuring the structural health and safety of buildings without compromising on accuracy and reliability. In future works, the application of the developed AI-tool in bridges will be studied.

ABSTRACT: Machine learning stands out as one of the most widely researched fields in the industry, where it has demonstrated great abilities to model complex system dynamics. This paper takes advantage of one of those models, Bayesian networks (BNs), for analyzing such dynamics in the infrastructure field. Specifically, bridge health monitoring tasks, which are crucial to prevent from dangerous changes within the structure's behavior and ensure the durability of the bridge. However, such modeling requires to capture a substantial amount of data, which can be time-consuming. Considering this challenge, this work aims to accelerate the deployment of these models through related transferable expertise. This involves leveraging data from similar systems to facilitate the learning process of the network. Specifically, two methods, PC-MAX-TL and DBLogLP, are proposed for estimating the structure and parameters, respectively, of the BN under such settings. PC-MAX-TL is an adaptation of the PC-MAX method (a well-known constrained-based structural learning algorithm) tailored to incorporate auxiliary knowledge, while DBLogLP is based on log-linear pooling principles. To demonstrate the reliability of PC-MAX-TL and DBLogLP, an empirical evaluation will be conducted using data from a real scenario: the San Mamés bridge in Bilbao (Spain). This bridge is composed of six different spans that are evaluated independently, and therefore, can be used to address the data scarcity of a certain target span. Then, the results will be compared against the model estimated just with PC-MAX from two perspectives: graphically, looking at the conditional dependencies found in the BNs; and quantitatively, analyzing (1) the network's mean log-likelihood, and (2) the log-likelihood variance. Thus, we demonstrate the proposed methodology's effectiveness, and justify for this bridge that we can accelerate in some days the deployment of the machine learning-based monitoring system.

1 INTRODUCTION

The construction of infrastructures is one of the ancient fields of human development, for which nowadays there are different devices designed to monitor their health evolution along time. Either in industrial environments or for the daily use of people, these systems are thought to withstand extremely variable loads. Therefore, it is important to carefully sensorize them to avoid changes that could affect the endurance of the structure. Since it is impossible to prevent from all kinds of hazards, the usual way of proceeding is to model the behavior of the system and use machine learning techniques to detect deteriorations, thus performing anomaly detection. When these anomalies are spread over time, the infrastructure's model can experience concept drifts, causing it to no longer behave as it used to. One way of modeling that behavior is through BNs, which allow to represent the dependencies of variables

DOI: 10.1201/9781003483755-178

according to the dynamic response of the system and return a measure of how well the model fits the incoming data. However, a correct analysis depends on the collection of sufficient data, something that could require days or even weeks. This problem can be addressed fusing networks of similar characteristics to accelerate the deployment of the model during the earliest stages of data acquisition. Nevertheless, this solution does not consider the particularities of the new data that, indeed, affects the dynamic response. Two methods, PC-MAX-TL and DBLogLP, are proposed for estimating the structure and parameters of the model that represents the incoming data through transferable expertise based on the similarity of other infrastructures with respect to the model of interest. Then, the proposed methodology will be tested with data from a real scenario, the San Mamés bridge in Bilbao (Spain), and evaluated through different analyses against a model obtained with conventional methods.

The paper is organized as follows. Section 2 provides the necessary knowledge about the different types of BNs covered throughout this paper. Section 3 reviews relevant state-of-the-art approaches related to the fusion and construction of networks as well as other transfer learning techniques. Section 4 details the proposed methodology. Section 5 describes the data, and analyzes the results obtained. Finally, Section 6 concludes the paper.

2 THEORETICAL FRAMEWORK

A BN is a machine learning model denoted as $\mathcal{B} = (\mathcal{G}, \theta)$ that comprises a direct acyclic graph (DAG) $\mathcal{G}$ and a set of parameters θ for which $\mathcal{G} = (V, A)$ is defined as a set of nodes V, and a set of arcs $A \subseteq V \times V$ between these nodes. When these arcs are not oriented, they are called edges E. For learning $\mathcal{B}$ we have a dataset $\mathcal{D}$ with n different variables $\mathcal{X} = \{X_1, \ldots, X_n\}$ and N instances $\mathcal{D} = \{x^{(1)}, \ldots, x^{(N)}\}$. Each arc in A represents a probabilistic dependence between variables, therefore, for each DAG there is a set of conditional dependences and independences embedded in the parameters θ for the conditional probability distribution (CPD) associated to each variable. Then, the joint probability distribution (JPD) of $X_1, \ldots, X_n$ can be factorized using these CPDs. For continuous variables each CPD can be seen as a conditional probability density function (PDF), that can be defined such that:

$$f(X) = \Pi_{i=1}^{n} f(x_i | X_{Pa(i)}) \tag{1}$$

where $\boldsymbol{Pa}(i)$ denotes the parents of X_i in $\mathcal{G}$. We can classify continuous BNs into three main types depending on the assumptions made about the data distribution. These types are parametric, non-parametric and semiparametric BNs.

Parametric BNs assume that the BN can be modeled using a finite number of parameters, where the most popular is the linear Gaussian Bayesian network (LGBN) (Shachter & Kenley, 1989). This type of model assumes that each conditional PDF can be modeled using a Gaussian distribution, for which the mean is a linear combination of some regression coefficients β associated to each node and its parents, and a variance σ^2. On the other hand, non-parametric BNs do not assume any specific distribution for the data. Consequently, there is an unknown, potentially infinite number of parameters in the model. Considering this scenario, Hofmann & Tresp (1996) introduced a non-parametric type based on kernel density estimation (KDE) called KDE BNs. Here, the PDF is estimated taking into account the contribution of each individual instance, becoming a more flexible, but demanding solution, that depends on the training data size and the correct selection of the bandwidth matrix, which acts as a smoothing parameter. Finally, the semiparametric BNs (SPBNs) (Atienza, et al., 2022) encompass both types using Linear Gaussian (LG) CPDs to model parametric relationships, and conditional KDEs (CKDEs) to model the non-parametric ones.

Similarly, there are also different ways of estimating a BN, for which the structure of the data and its corresponding parameters are learnt. There are three main structural learning approaches: constrained-based, which perform conditional independence (CI) tests to assess whether two subsets of variables are conditionally independent given another subset, for instance the PC family methods (PC (Spirtes & Glymour, 1991, PC-Stable (Colombo & Maathuis, 2014) or PC-MAX

(Ramsey, 2016); scored-based, where the best structure is found through an optimization algorithm such as in hill-climbing (HC) (Bouckaert, 1994; and hybrid, where usually the skeleton of the graph is first found through constrained-based methods, and then a scored-based algorithm is used to orientate the edges. Then, depending on whether the CPDs of the nodes are Gausssian or not, the parameters can be obtained through different methods. For this work, we will use the standard maximum likelihood estimate (MLE) or the normal reference rule extended to the multivariate case (Wand, 1992) for bandwidth estimation, respectively.

3 RELATED WORK

Transferring expertise from related problems can be helpful for addressing challenges such as data scarcity or time constraints. This way, we can facilitate the learning process of a new BN taking advantage of the acquired knowledge. However, before exploring the different technologies related to the use of transferable expertise, it is crucial to have some knowledge about the fusion of networks within a specific domain. This process involves the fusion of structures and parameters during the construction of the new network.

Two popular techniques for the fusion of parameters are the *linear pooling* (Stone, 1961) and the *log-linear pooling* (Genest, 1984), for which a weighted arithmetic average and a geometric average are used, respectively, to aggregate the parameters of k models. In terms of structures, the first approach was made in Matzkevich & Abramson (1992) with FUSE_-DAGS. Here, given two DAGs $\mathcal{G}_1$ and $\mathcal{G}_2$, the fusion of structures is performed as the union of their nodes and intersection of their arcs, i.e., $\mathcal{G}_3 = (V_1 \cup V_2, A_1 \cap A_2)$. On the other hand, since the structural fusion usually requires a common topological order among the nodes, two methods for transforming a DAG $\mathcal{G}$ into another given a topological order of nodes were introduced in Matzkevich & Abramson (1993). However, Peña (2011) later critiqued these methods and proposed a set of corrections as well as a complexity analysis. Alternatively, Puerta, et al. (2021) proposed a transformation algorithm and a heuristic search to identify and establish the optimal order, whereas Feng, et al. (2014) introduced a set of desirable properties to any DAG, like avoiding cycles and preserving the conditional independencies. Considering these properties, they proposed a set of addition and deletion rules for the structure learning together with a fuzzy fusion (Liu & Song, 2001) for the parameter aggregation.

Moving to the transferable expertise, we will refer to the model of interest as the target $\mathcal{G}_0$, and the K models for which we have enough data as the auxiliary tasks $\mathcal{G} = \{\mathcal{G}_1, \ldots, \mathcal{G}_K\}$. One of the most important contributions to the state of the art is the work conducted in Luis et al. (2010), where they proposed a modification of the PC algorithm, PC-TL, that linearly combines the information provided by different tasks with the target. This combination is performed considering just the most similar task on each iteration of the learning process. Additionally, they proposed two methodologies for aggregating the parameters, the distance based linear pool (DBLP) and the local linear pool (LoLP). Jia et al. (2010) extended this approach to a soil fertility grading issue by considering, not only the similarity, but also the geographical position of land squares, where it adjusts the weight factors of the linear combination based on the geographical position. Recent contributions such as Hou, et al. (2022) introduce a varying coefficient for parameter learning that adjusts the dependence on the target as the available data increases, whereas Hao et al. (2021) proposed an updating BN model for virtual machines performance estimation, where the structure and parameters are updated according to a re-weighting of the data based on the model performance.

4 METHODOLOGY

The structure learning process of this method is mainly constrained-based although it additionally uses HC to eliminate possible cycles and orient the remaining edges. We refer to it as the PC-MAX-TL algorithm. PC-MAX-TL has been adapted to work without any constraint with both Gaussian and non-Gaussian variables, for which LGBNs and the Fisher's Z test are used in the Gaussian case, and SPBNs and the conditional correlation independence (CCI)

test (Ramsey, 2014) in the non-Gaussian. In addition, we present the distance-based log-linear pooling (DBLogLP), which is an aggregation method based on DBLP for the fusion of parameters. This novel aggregation method has the advantage of preserving the conditional independencies and addresses the fusion of PDFs for both Gaussian and non-Gaussian domains. The steps that describe the complete learning process are the following:

1. PC-MAX phase.
   a. Global similarity estimation.
   b. PC-Stable adjacency phase.
   c. Max p-value orientation.
2. HC phase.
   a. Generation of a new fused dataset $\mathcal{D}_f$ for the edge orientation.
   b. Cycle detection. If no cycle is detected use HC to orient the edges, otherwise handle the conflicting arcs and then orient.
   c. Return the best DAG.
3. MLE and DBLogLP for aggregating the target and the auxiliary tasks parameters.

4.1 *PC-MAX-TL*

PC-MAX-TL can be seen as a hybrid learning method with strong constraints into the search space of HC. First, it uses a constrained-based approach that takes advantage of the proposed methodology for PC-TL and one of the algorithms from the PC family, PC-MAX, to analyze the conditional dependencies of the graph. Then, a second phase uses the score and search method HC to address typical problems of this kind of algorithms.

Among the contributions proposed by PC-TL to find a better $\mathcal{G}_0$, there is a metric to measure the similarity S_k between a given auxiliary task and the target. This metric is calculated as the product of a global S_{g_k} and a local S_{l_k} similarities, and used to get the task with the highest value, i.e. the closest task, during the PC adjacency phase. These similarities are defined as:

$$S_{g_k} = dep_k + ind_k, S_{l_k}(X, Y|S) = \begin{cases} 1 \; if \; I_0(X, Y|S) = I_k(X, Y|S) \\ 0.5 \; if \; I_0(X, Y|S) \neq I_k(X, Y|S) \end{cases} \tag{2}$$

$$S_k(X, Y|S) = S_{g_k} \cdot S_{l_k}(X, Y|S) \tag{3}$$

where dep_k and ind_k are respectively, the number of common conditional dependencies and independencies between $\mathcal{G}_k$ and $\mathcal{G}_0$, and $I_0(X, Y|S)$ and $I_k(X, Y|S)$ are the statistics of their CI tests for each pair of X and Y variables conditional on a subset S. Bearing this in mind, $I_F(X, Y|S)$ is defined as the linear combination of the target with its closest auxiliary task:

$$I_F(X, Y|S) = \alpha_0(X, Y|S) \cdot abs(I_0(X, Y|S)) + \alpha_k(X, Y|S) \cdot abs(I_k(X, Y|S)) \tag{4}$$

where *abs(I)* denotes the absolute value of the statistic, and α refers to its confidence factor.

4.1.1 *PC-MAX phase*

The similarity evaluation from PC-TL remains the same for PC-MAX-TL (step 1a). However, to evaluate the edge removals and arc orientations during our PC-Stable adjacency phase (step 1b), it is needed a suitable metric to assess the confidence of each continuous CI test in the combined independence measure. To do so, we kept the reasoning used for the confidence factor α in the original PC-TL, and defined a new confidence factor α_0 such that:

$$\alpha_0 = \frac{N_0}{N_0 + N_k} \tag{5}$$

where N_0 is the size of the target dataset $\mathcal{D}_0$ and N_k the size of the most similar auxiliary dataset $\mathcal{D}_k$. This way, the trust on the target test increases proportionally to N_0, resulting in better independence assessments during the earliest stages of the data acquisition and ensuring

future convergences. On the other hand, we reformulated Equation (4) to use the p-value of the statistic during the arc evaluation such that:

$$p_F(X,\ Y|S) = \alpha_0 p_0(X,\ Y|S) + (1-\alpha_0)p_k(X,\ Y|S) \tag{6}$$

where $p_F(X,\ Y|S)$denotes the combined p-value for each pair of X and Y variables conditional on a subset S. Then, the remaining edges are oriented as possible according to PC-MAX with the combined independence measure (step 1c).

4.1.2 *HC phase*

The result of the PC-MAX phase can be a DAG, although most of the times we end up with a partially directed graph (PDG) that occasionally has cycles. To deal with those situations, we defined the algorithm presented in step 2, where the final orientation is conducted using HC with the k-fold cross-validation log-likelihood score function described in Atienza, et al. (2022). Here, it is important to note that the search space of HC is constrained to the undirected edges that were retained from step 1. Consequently, HC is forced to preserve the arcs of $\mathcal{G}_0$. The cycles are handled by removing one combination of conflicting arcs at a time and adding it into the search space of HC, thereby leaving the decision of either reversing or removing the conflicting arc to the algorithm. However, when $\mathcal{D}_0$ does not contain enough instances the results of the final orientation might be poor due to the lack of information. Therefore, we decided to include a 10% data from the two most similar auxiliary tasks selected throughout the previous phase to address this issue. The result is a new fused dataset $\mathcal{D}_f$ that improves the orientation process leading to better arcs. From this loop, we end with a list of possible DAGs of which the most suitable is selected using the mean of the log-likelihood as a measure of the structure goodness.

4.2 *DBLogLP*

After the structure estimation, the parameters are obtained integrating the knowledge from the target and all the auxiliary tasks. To do so, we obtain a set of initial parameters for each dataset using MLE with the estimated DAG from PC-MAX-TL. This way, it is ensured that the parameters of both target and auxiliary tasks come from the same set of parents, otherwise the aggregation with DBLogLP (step 3) would not be possible. The procedure of DBLogLP first calculates a geometric average of auxiliary parameters that are later combined with those of the target, thereby preserving the conditional independencies. The mean PDF for node i is defined as:

$$\bar{f}(X_i) = \prod_{k=1}^{K} f_k(X_i)^{w_{ki}} \tag{7}$$

where w_{ki} is the weight associated to the auxiliary task k for the PDF of node i. This weight is calculated as the normalized inverse of the maximum Kullback-Leibler divergence (KL) between the auxiliary conditional PDF $f_k(X_i)$ and the target conditional PDF $f_0(X_i)$ (Koliander et al., 2022). Then, the resulting parameters from Equation (7) are integrated with those of the target in the following way:

$$f_0^{'}(X_i) = f_0(X_i)^{c_N}\bar{f}(X_i)^{1-c_N} \tag{8}$$

where c_N is the confidence coefficient that indicates how much to trust the estimations of the target. Similarly to α_0 in Equation (5), this coefficient depends on the number of instances from the target. Therefore, it is obtained as:

$$c_N = \frac{N_0 - N_{min}}{N_{max} - N_{min}},\ 0.25 \leq c_N \leq 0.75 \tag{9}$$

where N_{min} and N_{max} are the normalization factors that must be defined at the beginning of the algorithm. Here, we decided to limit the values of the confidence coefficient c_N to keep the trust in the target parameters between the 25% and 75%. Thus, neither the target is completely ignored, nor the auxiliary tasks. It must be noted that depending on the type of BN, the parameters to be combined are different. For Gaussian nodes, we will have to aggregate LG

CPDs whose parameters are the variance σ^2 and the regression coefficients β, while for non-Gaussian nodes we have CKDEs and the bandwidth matrix.

5 EXPERIMENTS

We will use data from our Aingura Insights Edge device deployed at the San Mamés bridge in Bilbao, Spain. The bridge incorporates a mixed metallic structure with V-shaped supports and consists of six different spans whose characteristics are slightly different, allowing us to categorize them as different structures within a common system (the bridge). The total length of the bridge encompasses 323 m, but each span has a specific length. These lengths are 53 m for spans 1 and 5, 60 m for spans 2, 3 and 4, and 37 m for span 6. Each span has its corresponding dataset, which is composed by different pairs of natural frequencies and damping factors estimated from accelerometers readings by proprietary algorithms deployed at the edge device. These variables capture the dynamic response of the bridge, expressed through natural frequencies characterized by mixtures of Gaussians and damping factors following Gamma distributions. Anyhow, we will evaluate the methodology under both Gaussian and non-Gaussian circumstances. The data used for this purpose was collected between the 23rd of March and the 3rd of May 2023, which represents approximately 1000 vehicles per day. We run one experiment per target span, while the five remaining spans are use as auxiliary data. With respect to the configuration of the experiments, we have selected different significance level for each CI test associated to each BN. In the case of LGBNs and the Fisher's Z test, we use a 0.05 significance level, however, experimentally we found that this level was too restrictive for the CCI test. Hence, in that case, we incremented the value from 0.05 to 0.08. Additionally, N_{min} and N_{max} are set to 20 and 1500 in both LGBNs and SPBNs. Finally, we have selected the first 3000 instances for the training sets of the auxiliary data, whereas the target sample is gradually incremented in batches of 40, starting in 20 until 2000. The remaining data is saved for testing.

That said, the first thing we can notice when we draw the DAG of the standard PC-MAX (Figure 1), is the inability of the algorithm to find relationships between the nodes at the earliest stages of the data acquisition. Besides, the SPBN is unable to correctly assess the type of the nodes in the DAG, where the white nodes are LG CPDs and the grey nodes CKDEs. Here, the natural frequencies 3 and 5, and the damping factors 2 and 4, were set as Gaussian nodes, when as we mentioned earlier they look like mixtures of Gaussians and Gamma distributions, respectively. On the contrary, it can be seen from Figure 2 that PC-MAX-TL is able to address this issue quite effectively. In fact, it correctly captures the dependencies of the natural frequencies establishing arcs from the first two to the third, fourth and fifth, while each of them is paired with its damping factor both in LGBNs and SPBNs (NAT_FREQ and DAMP in the graph).

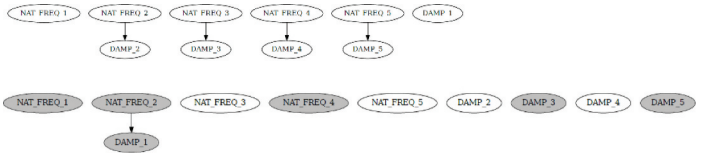

Figure 1. PC-MAX DAG from span 1 with 20 instances. Top: LGBN. Bottom: SPBN.

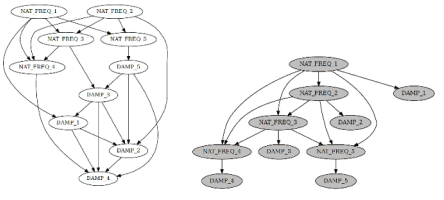

Figure 2. PC-MAX-TL DAG from span 1 with 20 instances. Left: LGBN. Right: SPBN.

As regards the quality assessment of the network in terms of mean log-likelihood (Figure 3), the PC-MAX-TL models (blue lines) exhibit better starting points in general. Then, they maintain the score within a small range of variation, whereas the network alone (PC-MAX) needs some time to reach such level. The convergence of both systems depends on the model, for instance, in span 1 it happens around 1000 and in span 6 it is almost immediately, but around 500 instances most of them have converged or reduced significantly the difference. However, we also see some drops in the means of spans 1 and 5 within the SPBN, as well as span 6 in both LGBN and SPBN. In this case, the issue may lie within the training set. The inclusion of certain portions of noisy data during experiments could be contributing to an increase in the system's variability, consequently resulting in a drop in the score. On the other hand, the SPBNs seem to be more sensitive to this noise than the LGBNs due to their parameter aggregation methodology, which requires the fusion of bandwidth matrices, thereby affecting to the smoothing of PDFs in the CKDE nodes.

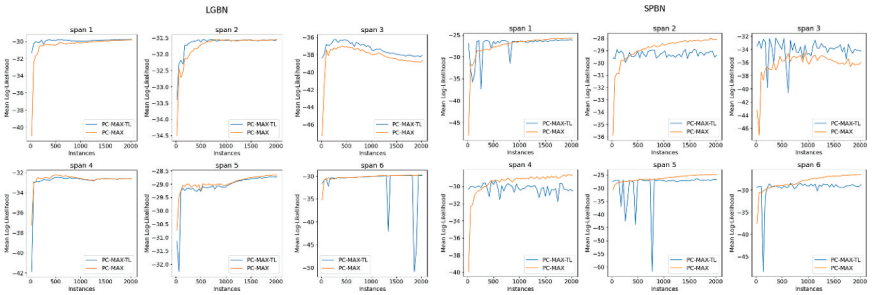

Figure 3. Networks mean log-likelihood. Left: LGBN. Right: SPBN.

Finally, the stability analysis (Figure 4) shows that the deviations of the PC-MAX-TL models (blue lines) exhibit very few variations from the very beginning, returning more stable measures with lower deviations in practically all cases from both LGBNs and SPBNs. In fact, even in the scenarios where the deviation of PC-MAX is lower, the stability tends to converge to the level of PC-MAX-TL, that is the case of spans 2 and 4. Additionally, it can be seen that the drops in the means detailed in the previous paragraph match the peaks in the deviations, which as mentioned, is caused by an increase in the variability of the data. However, even under the presence of noise their stability levels are higher than in PC-MAX. For instance, the deviations of spans 1 and 3 in the SPBN are 10 to 20 units lower.

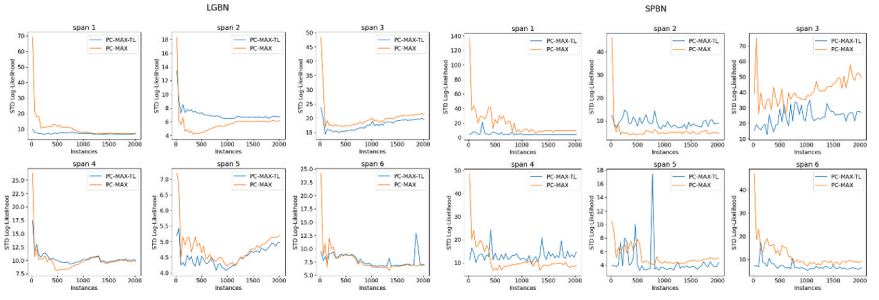

Figure 4. Networks stability. Left: LGBN. Right: SPBN.

6 CONCLUSION

The use of transferable expertise has been the basis of our methodology composed by two novel procedures, PC-MAX-TL and DBLogLP, for which we have reviewed all the aspects involved in the network construction and justify their reliability for building and aggregating models in presence of data scarcity. PC-MAX-TL returns DAGs with much better conditional

dependencies compared to PC-MAX at the earliest stages of data acquisition, and its combination with DBLogLP ensures a much more stable model despite the noise, which is crucial for its application in the industry. The convergences achieved in terms of mean log-likelihood are around 500 instances, while the stability returns better scores throughout the whole experiment. Therefore, considering that on average the San Mamés bridge gets 1000 impulses per day, the most important impact is that the required time for the bridge health monitoring systems could be reduced by one or two days.

Anomaly detection with switching Kalman filter and imitation learning

Zhanwen Xin & James-A. Goulet
Polytechnique Montreal, Montreal, Canada

ABSTRACT: The detection of anomalies in structural health monitoring (SHM) time-series is notoriously difficult, because one needs to separate reversible patterns caused by the environmental factors and loading, from the baseline irreversible degradation, whereas anomalies typically consist in long-term drifts that have an effect that is orders of magnitude smaller than the reversible patterns. The switching Kalman filter (SKF) has been shown to be an effective tool to address these challenges by quantifying the probability of a switch between different regimes corresponding to normal stationary conditions and abnormal non-stationary ones. Current applications of the SKF have relied on the probability of regime switch as a proxy for detecting anomalies. Despite its capacity to outperform threshold-based detection approaches, it remains prone to (1) missed alarms when the reversible and irreversible pattern separation fails, and (2) false alarms when the predictive capacity of the stationary model is too limited. Previous works have shown that these issues can be mitigated by replacing an alarm triggering policy based solely on the probability of regime switch, with imitation learning (IL) agents that build policies based on the probability of regime switch as well as the trend hidden state. This study further enhances the IL agents by including high-dimensional hidden states vectors as well as by leveraging multiple time steps from the data history. The IL agents that have learnt the underlying dependencies between the high-dimensional hidden state estimates and the labeled actions, which in our context, are whether to trigger an alarm or not, are tested on time series including synthetic and real ones collected on a bridge located in Canada. The results show that the new method provides anomaly detection agents that improve the detectability of anomalies, and are self-adaptive to new stationary conditions.

1 INTRODUCTION

Detecting anomalies in time series is an effective way to identify infrastructures' deterioration before they can be visually observed (Pimentel et al, 2014). Time series anomaly detection methods have the potential to be scaled to infrastructure networks because they do not require a physics-based model of the structure's behaviour (Hamida & Goulet, 2022). Schmidl et al. (2022) categorized the methodologies for time-series anomaly detection as distance, forecasting, and reconstruction-based methods. Among them, the distance and forecasting methods were shown to be effective (Sarmadi & Karamodin, 2020; Willm, 1967) in identifying outliers, yet prone to missed and false alarms in SHM anomaly detection, where the anomalies typically consist in long-term drifts of baselines overlapped by reversible patterns with much bigger magnitude.

The switching Kalman filter (SKF) is a good fit for the detection of baseline changes in structural health monitoring (SHM). Compared to the Hidden Markov Models (HMM) which often model hidden states as discrete variable (Coraça et al., 2023), the state space of the hidden variables in SKF is continuous. Previous studies have shown its effectiveness in baseline extraction (Goulet, 2017), estimation of periodic patterns (Nguyen & Goulet, 2018b), and detection of non-stationary regime quantified by probability values (Nguyen & Goulet, 2018a). However, the probability of the non-stationary

DOI: 10.1201/9781003483755-179

regime sometimes fails to identify regime switches, has delays, or triggers undesirable false alarms, especially when the triggering threshold is not well calibrated. This issue has been partially mitigated by an imitation learning (IL) decision-making framework, that triggers alarms by considering not only the probability of non-stationary regime, but also the baseline estimation of local trend (Khazaeli, 2022). The framework removes the necessity of setting a threshold on the probability of regime switch, and is capable to detect anomalies with lower magnitudes and longer durations compared to only using the probability of non-stationary regime. Yet, it is limited to low-dimensional features and time series with a single anomaly, which prevents it from being used in practice where multiple anomalies might happen during the life of an infrastructure.

The IL task in the decision-making framework typically employs neural networks, which are suitable for the problems having large dimensionalities. This allows us to further leverage the hidden states estimated by the SKF through the inclusion of higher dimensional features and history data in the input of neural networks instead of being limited to the two-dimensional features for the existing decision-making framework. On the other hand, the existing framework is not compatible with time series including multiple anomalies because the model is not able to adapt to new stationary regimes after a non-stationary one. In this paper, we proposed a reference regime, with which the models can be reset during a new stationary regime, and thus continuously detect anomalies.

The objectives of this paper are twofold: (1) it is to include high-dimensional features in the decision-making framework, and (2) to develop a detection method that can handle multiple subsequent anomalies. The structure of this paper is the following: Section 2 reviews the SKF and IL methods, Section 3 presents the methodology of this study, Section 4 presents experiments on a synthetic time series and a real one measured on a bridge, comparing the performance of the SKF and the new framework.

2 BACKGROUND

In this section, the principles behind the switching Kalman filter and imitation learning, as well as their limitations are introduced.

2.1 *Switching Kalman filter*

The Kalman filter is used for decomposing the signal of a stationary linear dynamic system by recursively estimating the moments of hidden states between pairs of consecutive time steps (Welch & Bishop, 2001). By denoting $\boldsymbol{X}$ as the vector including all the hidden states, $\boldsymbol{y}$ as the observed signal, $\mathbf{A}$, $\mathbf{F}$, $\mathbf{Q}$ and $\mathbf{R}$ as the model matrices, and $\mathscr{L}$ as the likelihood of observing $\boldsymbol{y}$ given the model prediction, the Kalman filter from time step $t-1$ to t is summarized by

$$\left(\mu^X_{t/t}, \Sigma^X_{t/t}, L_{t/t}\right) = \text{Filter}\left(\mu^X_{t-1/t-1}, \Sigma^X_{t-1/t-1}, y_t; A, F, Q, R\right) \tag{1}$$

where the subscript t/t denotes the updated estimate at time t using all the observations up to t. In Bayesian dynamic linear models (BDLM), the model matrices, $\mathbf{A}$, $\mathbf{F}$, $\mathbf{Q}$ and $\mathbf{R}$, can be built modularly using various generic components (Goulet, 2020) such as (a) baseline components that describe the local level (LL), trend(LT), and acceleration (LA) of time series; (b) periodic components that capture the harmonic periodic (PD) or non-harmonic kernel regression (KR) patterns, and (c) a residual component which represents the model errors that cannot fit in any other explainable components.

The switching Kalman filter (SKF) is an extension of the Kalman filter that allows modeling non-stationary signals, made of multiple stationary regimes (Murphy, 1998). The Kalman filter transiting from regime i at time $t-1$ to regime j at t is represented by

$$\left(\mu^{i,j}_{t/t}, \Sigma^{i,j}_{t/t}, L^{i,j}_{t/t}\right) = \text{Filter}\left(\mu^i_{t-1/t-1}, \Sigma^i_{t-1/t-1}, y_t; A^j, F^j, Q^j, R^j\right) \tag{2}$$

Given the hidden states estimation in regime i at time $t-1$, it estimates the moments of the hidden states at time t by using model j, as well as the likelihood of the regime transition from i to j by comparing the observed signal $\boldsymbol{y}$ and the model prediction. By denoting $\pi^{l}_{t-1|t-1}$ as the probability of regime i at time $t-1$, and $Z^{i,j}$ as the pre-defined transition probability from $s_{t-1} = i$ to $s_t = j$, the probability of the regime j at time t is computed by

$$\pi^{j}_{t/t} = \sum_{i=1}^{S} M^{i,j}_{t-1,t/t}, \tag{3}$$

$$M^{i,j}_{t-1,t/t} = \frac{L^{i,j}_{t/t} \cdot z^{i,j} \cdot \pi^{i}_{t-1|t-1}}{\sum_{i}\sum_{j} L^{i,j}_{t/t} \cdot z^{i,j} \cdot \pi^{i}_{t-1|t-1}} \tag{4}$$

The hidden states estimated in different transitions can then be merged with $L^{i,j}_{t/t}$ and $\pi^{j}_{t/t}$ by using Gaussian mixture reduction (Runnalls, 2007). With the closed-form solution to estimate the probability of different regimes, SKF was shown to be effective in detecting anomalies in real time series by relying on the probability of the non-stationary regime as a criterion for triggering alarms (Nguyen & Goulet, 2018a). However, this probability may fail to capture the regime switches when time series are affected by unobserved external factors, or when it is subject to high level of noise. Figure 1 showcases a time series affected by a high level of noise, where the stationary regime is defined by a constant local trend. The non-stationary regime's probability, simply denoted as π, remains around zero at all times, yet the local trend hidden state (x^{LT}) switches to a new range after the regime change, indicated by the vertical dot-dashed lines. In such a case, an anomaly detection policy relying solely on the non-stationary regime's probability without considering other hidden states would be prone to missing alarms.

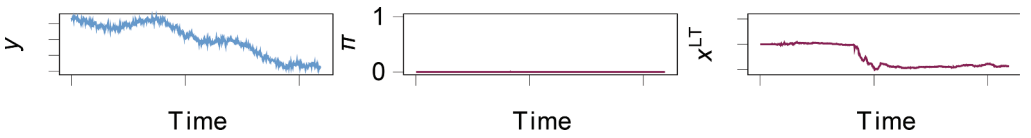

Figure 1. Limitation of the switching Kalman filter. The stationary regime in the time series y has a constant speed. The vertical dot-dashed lines indicate the time step when the speed changes. The non-stationary regime's probability π fails to capture the regime change. Yet, the local trend hidden state (x^{LT}) correctly estimates the speed change with a time delay.

2.2 *Imitation learning*

Imitation learning (IL), also known as behaviour cloning and learning from demonstration, maps a given state directly to an action without considering the long-term sequential effects (Zheng et al, 2022). The objective of an IL agent is to reproduce experts' demonstrations on how to act as a function of states. The expert's demonstration set consisting $\boldsymbol{D}$ instances is defined as $D = \{D_1, D_2, \ldots, D_D\}$, where each demonstration D_i is a state-action pair, i.e., $D_i = \left(s_i, a_i^{\mathrm{expert}}\right)$. For the anomaly detection in SHM, Khazaeli (2022) employed IL algorithms to determine whether a structure is in a normal or abnormal state given the monitoring data at time t. The state space at each time step t was defined by $s_t \in S = \left\{\mu^{LT}_{t|t}, \pi_{t|t}\right\}$, where $\mu^{LT}_{t|t}$ is the expected value of local trend hidden state, and $\pi_{t/t}$ is the probability of the non-stationary regime estimated by the switching Kalman filter. The actions are whether to trigger an alarm or not, $a_t^{expert} \in A = \left\{a^0 : \text{trigger an alarm}, a^1 : \text{not trigger an alarm}\right\}$, which are labeled from synthetic anomalies. His results showed that IL agents are capable to detect anomalies with lower magnitudes and longer durations compared to only using the probability of regime switch. However, the framework in this study is limited to low-dimensional features and deterministic setups. Time series with multiple anomalies, each defined by a regime switch, are not

compatible with the existing method because the local trend used in the state space cannot adapt to new stationary regimes. In the next section, we will introduce a new methodology, in order to overcome their limitations.

3 METHODOLOGY

This section presents a decision-making framework that leverages the high-dimensional hidden states from SKF, and a reset mechanism for the local trend in order to allow decision-making agents to adapt to different trend-stationary regimes.

3.1 *State-action pairs as the input and output of decision-making agents*

Decision-making agents for SHM must be able to handle high-dimensional states as the input for the reasons that (1) multiple hidden states other than the local trend and the probability of the non-stationary regime in SKF might contain useful patterns that contribute to the anomaly detection as shown in Figure 1; (2) patterns are typically time-dependant as anomaly develops with time, so the hidden state estimates not only at the current time step, but also at previous ones should be considered in the decision making. By using neural networks as the supervised imitation learning model, the state space can be expanded to higher dimensions simply by increasing the number of input nodes.

The action output of triggering an alarm or not is labeled according to the non-stationary (**ns**) and stationary (**s**) regimes in time series. Figure 2 depicts the labeling of the two regimes partitioned by different range of the synthetic anomaly's local trend, which gradually shifts from 0 to a negative value $-m$ following a Gaussian cumulative distributed function with random mean and variance scaled by $-m$. The anomaly duration is defined by the 95% confidence interval bounded by $-0.025m$ and $-0.975m$. The non-stationary regime begins with the anomaly, and ends when the SKF detects it and returns again to the new stationary regime. The pairs of the high dimensional input state and the output action defined above form the demonstration set D to train the IL decision-making agents.

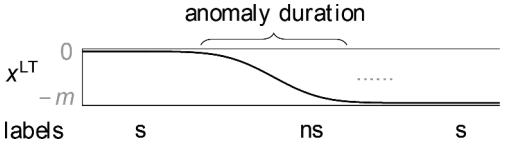

Figure 2. Labeling of non-stationary (ns) and stationary (s) regimes, which corresponds to the action of triggering an alarm or not respectively, according to the anomaly local trend(x^{LT}).

3.2 *Reset mechanism for the local trend*

As presented in Figure 1, the local trend hidden state X^{LT} is a key feature in our imitation learning decision making framework. The departure of X^{LT} from the trend baseline of the stationary regime contributes to the anomaly detection policy. However, when the time series is in a new stationary regime, where the X^{LT} baseline changes to a new level, the model trained on the previous baseline will no longer be valid and will fail to continuously detect anomalies unless it is retrained on the new regime. This causes issues in practice because SHM time series typically spans from years to decades, during which multiple anomalies may happen. To avoid retraining models in each stationary regime and to have a continuous anomaly detecting system, it is more effective to reset X^{LT} to a fixed baseline for different stationary regimes.

In order to develop such a reset mechanism and adapt X^{LT} to new trend-stationary regimes, we propose two new hidden states namely the local-trend reference $\boldsymbol{X}^{LTr}$ and the local trend in agent's vision X^{LTa}, where $X^{LTa} = X^{LT} - X^{LTr}$. The agent makes decisions based on the difference between the actual local trend estimated by the SKF, and the reference value, which is estimated by the Kalman smoother (Murphy, 1999). The stages to determine X^{LTr} are

illustrated in Figure 3, along with time-series observations (y) and the probability of regime switch (π). At the initialization stage of the analysis, $\boldsymbol{X}^{\mathrm{LTr}}$ is defined as the smoothed local trend at time step t_0 using all the future observations until the end of the initialization stage corresponding to the time t_1 when the standard deviation of the smoothed estimation $\sigma^{LT}_{t_0|t_1}$ is smaller than a pre-defined threshold $\tilde{\sigma}^{\mathrm{LT}}$. After the initialization, $\boldsymbol{X}^{\mathrm{LTr}}$ remains constant in the stationary stage. The non-stationary stage begins when π is bigger than a threshold $\tilde{\pi}$ corresponding to the time t_2, when the model realizes that a new $\boldsymbol{X}^{\mathrm{LTr}}$ is needed, but cannot be estimated yet, because the local trend estimate is not stable enough to be used as a reference for the new regime. Hidden states are considered as stable at the time step t_4, $\tilde{n}_w$ steps away from t_3, when $\pi < \tilde{\pi}$. $\tilde{n}_w$ is a pre-defined number of waiting steps. The Kalman smoother is employed to estimate the local trend at t_4 using all the future observations until time t_5, where $\sigma^{\mathrm{LT}}_{t_4|t_5} < \tilde{\sigma}^{\mathrm{LT}}$. Eventually, $\boldsymbol{X}^{\mathrm{LTr}}$ stays constant for the remaining of the new stationary stage.

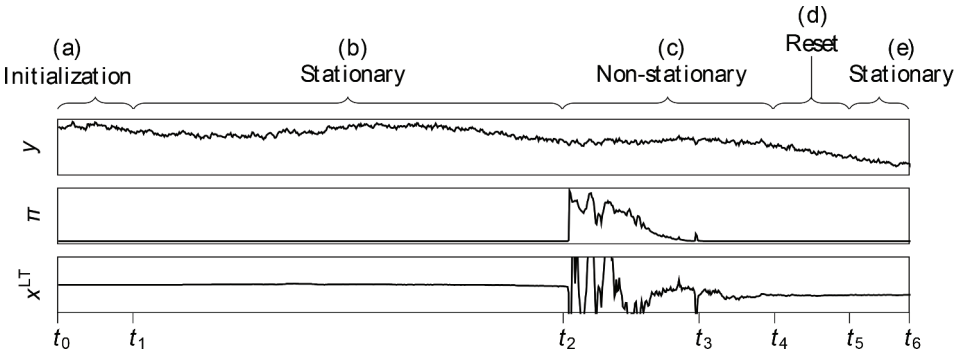

Figure 3. Reset mechanism for x^{LT} in one time series including five stages.

Figure 4 presents an example estimating the $\boldsymbol{X}^{\mathrm{LTr}}$ and $\boldsymbol{X}^{\mathrm{LTa}}$ in a time series including three regimes with reset hyperparameters $\tilde{\sigma}^{\mathrm{LT}} = 0.01$, $\tilde{\pi} = 0.1$ and $\tilde{n}_{\mathrm{w}} = 50$. The local-trend reference for the first regime converges quickly to the true value thanks to the accurate prior knowledge. As the time series enter the second regime, the x^{LT} estimate fluctuates, and the reset process for x^{LTr} and x^{LTa} is triggered. When x^{LT} becomes stable again, x^{LTr} is estimated using the Kalman smoother, and converges gradually to the true value. It is reset again when the time series is in the third regime, after which x^{LTr} is estimated and converges again. The reset local trend $\boldsymbol{X}^{\mathrm{LTa}}$ has a baseline around zero in different regimes, as required by the continuous IL agents.

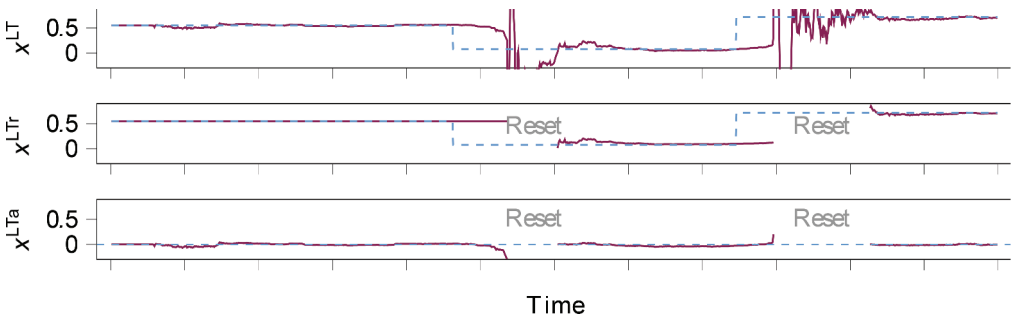

Figure 4. Estimation of local-trend reference x^{LTr} and local trend in agent's vision X^{LTa} in one time-series having three regimes with different local trends.

3.3 *SKF-IL framework for anomaly detection*

The proposed anomaly detection framework for coupling SKF and IL is designed for online operation on cases presenting small changes in the irreversible baseline, which are developing over long periods, such as corrosion, crack-opening, foundation settlements, etc. The IL agents

are trained using synthetic time series where the true labels are available as defined in Section 3.1. The pretrained agents then operate on real time series where labels are unavailable. The input hidden states of the IL agents in the training and testing process are estimated by the SKF presented in Section 2.1 and the reset mechanism in Section 3.2. Figure 5 shows a flow chart of the above-mentioned process.

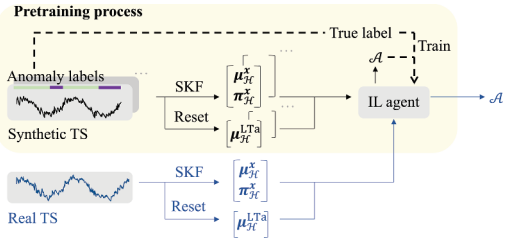

Figure 5. The training and testing process of the SKF-IL anomaly detection framework. μ_H^x represents the mean values of hidden states over time history H, π_H^x is the probability of the non-stationary regime.

4 EXPERIMENTS

An IL decision-making agent modeled by a neural network with two fully connected hidden layers of 64 hidden units, is trained with 900,000 demonstrations, $D_t = \left(s_t, a_t^{\text{expert}}\right)$, pulled out from 1,000 synthetic time series. The state space consists of the non-stationary regime's probability (π), the expected value of the local trend in the agent's vision (μ^{LTa}), as well as the expected value of the residual component (μ^{res}), at previous time steps with a logarithmic spacing from t to $t-128$, i.e., $S_t = \left\{\pi_{t-128,t-64,\ldots t-1,t}, \mu^{\text{LTa}}_{t-128,t-64,\ldots t-1,t}, \mu^{\text{res.}}_{t-128,t-64,\ldots t-1,t}\right\}$. The activation function is the rectified linear unit, and the objective function is defined by the cross-entropy loss. The pre-trained agent is tested on unseen synthetic time series in Section 4.1, and on real time series measured on a bridge in Section 4.2.

4.1 *Synthetic data*

This section verifies the anomaly detectability of the IL agent and the effectiveness of the reset mechanism for handling multiple anomalies. A synthetic time series (y) spanning 20 years is

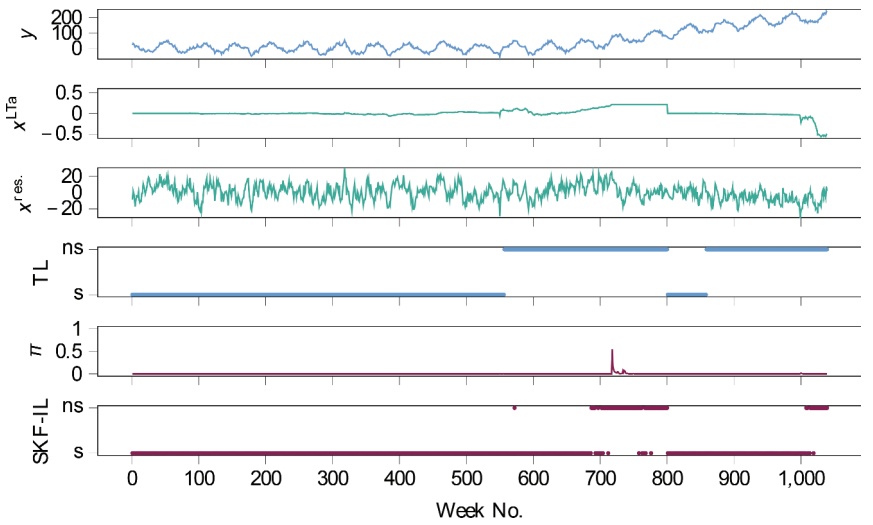

Figure 6. Testing the IL decision-making agent on a synthetic time series with two anomalies.

generated with BDLM as displayed in Figure 6. Two anomalies that shift the local trend are randomly introduced in the 557th and 859th week as indicated by the dot-dashed lines. The pre-processed hidden states x^{LTa}, x^{res}, the true labels (TL) of anomalies, the regime-switching probability π, and the decisions made by the SKF-IL agent are plotted along with y. The SKF relying only on π is capable to identify the first anomaly in the 718th week, and misses the second one with a threshold of 0.1 as in the reset mechanism. By contrast, the SKF-IL agent triggers one alarm much earlier in the 572nd week and again continues from the 687th week during the first anomaly. In addition, it detects the second anomaly missed by π in the 1008th week.

4.2 *Bridge data*

In this section, the performance of the pre-trained agent is tested on a time series measuring the elongation on a bridge. The elongation measurements are dependent on the temperature, which can be modeled by using the observation matrix $\mathbf{F}$ in the Kalman filter. The data is continuous, and the raw time series, covering the period between 2019/08/16 and 2021/11/16 is aggregated during a preprocessing step to a unified time step interval of two data points per week. It is assumed to have a zero local trend, given that no structural anomalies were observed during this period. A synthetic anomaly that shifts the zero local trend to 0.023 mm/year is introduced on 2020/11/12, as indicated by the dot-dashed lines in Figure 7, whereas the changes in the dashed local level baseline is difficult to be visually identified in the y-plot.

The hidden states of x^{LTa}, x^{res}, the true anomaly labels (TL), the probability of the non-stationary regime π estimated using the SKF, the anomalies detected by the forecasting method Prophet (Taylor & Letham, 2018), as well as the anomalies identified by our SKF-IL agent, are plotted following the elongation measurements y. The estimation of x^{LTa} remains around zero, but has fluctuations after the anomaly is introduced. The values of π gradually drifts from 0 to 1 in July 2021. Following the threshold that defines a non-stationary regime in the reset mechanism, $\tilde{\pi} = 0.1$, the SKF detects the anomaly on 2021/07/16 with a delay of more than eight months, which will be even longer if the threshold is set higher. The Prophet algorithm fails to detect the anomalies, and provides two false alarms that are triggered before the anomaly is introduced with an interval width threshold of 99%. Without the need of

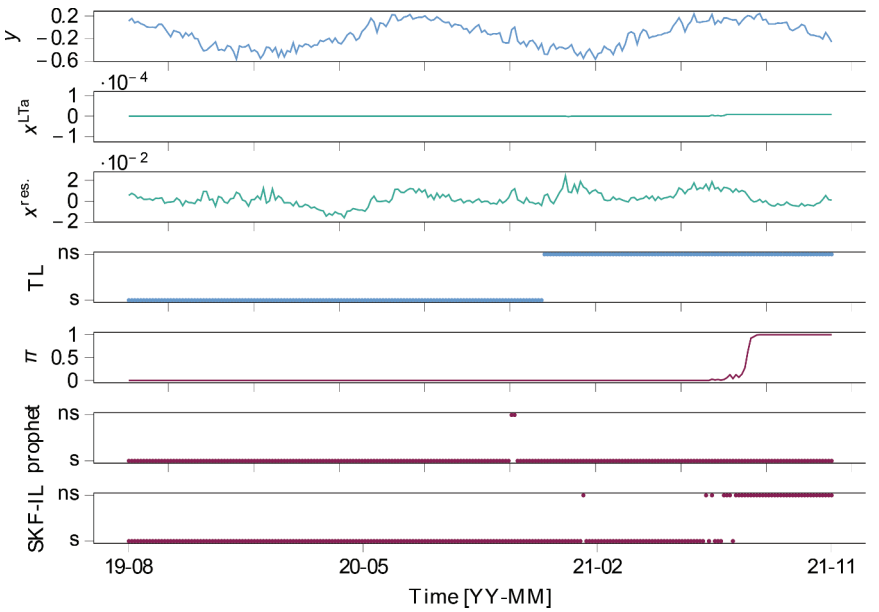

Figure 7. Testing the IL decision-making agent on a real time series measured on a bridge with one anomaly that shift the zero local trend to 0.023 mm/year.

defining a triggering threshold for the non-stationary regime's probability, the pre-trained agent detects the anomaly firstly on 2021/01/01 with a delay of less than two months, and continuously triggers more alarms after 2021/07/05. Results obtained from the real data validate our experiment on the synthetic one, where the hidden state estimates' history contributes to a decision-making policy that is capable to detect anomalies earlier than the one relying only on the non-stationary regime's probability.

5 CONCLUSION

This paper introduces a decision-making framework that detects the regime switches in time series, which is commonly encountered when anomalies develop in infrastructures. The existing switching Kalman filter identifies the regime switch by defining a threshold for the non-stationary regime's probability, which is prone to missed or delayed alarms. The imitation learning (IL) agent presented in this paper leverages hidden states in addition to the non-stationary regime's probability, as well as the history data in the decision-making process. Experiments on a synthetic time series and a real one measuring the elongation of a bridge have shown that the proposed agent can detect the regime switches earlier, reduce missed alarms, and self-adapt to new stationary regime, which allows it to continuously detect anomalies. Although much work remains to be done to probabilistically evaluate the agents' performance in big datasets, its reliability showcased in this paper makes it a promising anomaly detection framework for structural health monitoring.

ABSTRACT: In recent years, structural health monitoring (SHM) has advanced significantly, providing insights about structures with the integration of Big Data and Machine Learning tools. Modern SHM involves extracting features to capture structural behavior, providing valuable insights. The Random Decrement Technique (RDT) is crucial in estimating free responses and frequency-features through System Identification (SID) techniques. Despite the effectiveness of RDT and SID in SHM, a comprehensive sensitivity analysis of parameters and resulting frequency-features is still a topic of research. This article analyses the parameters for RDT and Hankel alternative view of Koopman (HAVOK) approach in extracting modal parameters from a real structural bridge in Andoain, Spain. The study reveals that extending the Hankel horizon minimizes damping factor variance, and increasing averaged segments or the time duration of these segments ensures stable numerical values of the estimated modal parameters. Ultimately, the algorithm parametrization depends on the resource constraints in desired monitoring deployments.

1 INTRODUCTION

In the last decades, standards, and regulations like those described in Gatti (2019) have been created to ensure the safety and correct operation of mechanical structures. These standards help to prevent catastrophic failures that could lead to loss of lives and resources. Furthermore, these regulations contain guidelines regarding materials, structural design, modal analysis, static and dynamic testing, among others. SHM has emerged as a vital component for structural maintenance by using technological innovations, such as sensors and embedded systems, to revolutionize monitoring in mechanical structures. These developments provide real-time actionable insights into the well-being of structures, enabling to predict, prevent, and respond to potential failures with precision.

The accuracy and reliability of SHM systems are fundamentally dependent on the calibration of the parameters that are used for their algorithms. Furthermore, ensuring that these parameters are correctly set is the basis of the proper operation of SHM algorithms as shown in Sirin-goringo et al. (2008), Górski (2015) and Reynolds et al. (2016). Without accurate calibration, the effectiveness of SHM systems diminishes, and the vital decisions based on the collected data become prone to error. Therefore, parameter calibration is an essential step in SHM systems to prevent structure failures and, by extension, to protect the lives of those who depend on them.

In this article, the relation between the input parameters for a proposed data driven SHM scheme and the resulting frequency-features of this scheme is studied. A systematic parameter sweeping

DOI: 10.1201/9781003483755-180

approach is employed to evaluate the influence of input variables on the resulting modal parameters. The studied SHM scheme involves generating the random decrement signature of the studied structure using mechanical vibration signals and generating a state-space model these signatures. This approach uses the Hankel alternative view of the Koopman operator method, known as HAVOK, to extract the natural frequencies and damping factors of the studied structure.

2 RELATED WORK

2.1 *Structural health monitoring schemes*

SHM was initially described by Houser et al. (1997) as using sensors and structural analysis to identify failures or changes in structures. It was also defined by Aktan (1996) as a conditional assessment tool where raw data from sensors are used to analyze existing changes in the behavior of an analyzed structure over time.

Data driven SHM approaches employ sensors data to create stochastic models as tools to detect structural abnormal behavior. The deployment of these methodologies is computationally less expensive than model-based methods, furthermore, these methods can be scalable to online operation for several structures without the dependence of any physical model. Nevertheless, data-driven SHM methods have some challenges and limitations regarding physical interpretation, calibration, and assumptions over the data as exposed by Sun et al. (2020). With the arrival of Big data, advanced embedded systems, and Machine Learning methods, some of these challenges have been tackle, providing more reliable SHM methods and successful deployments such as the presented by Tidriri et al. (2016) and Magalhaes (2009).

Recent machine-learning-based and big-data-based SHM methods typically consist of four stages. Firstly, the data are acquired and preprocessed to extract the information related to the structure. Then, mathematical models are built using model-based or data-based methods. Subsequently, features that contain meaningful information from the structure are extracted. Finally, these features are used to create a baseline of the bridge as a way of identifying anomalies or faults within the structure.

2.1 *Frequency-features for structural health monitoring*

Frequency-features stand out as the foundation of vibration-based damage detection in structures. Regarding SHM, natural frequencies and damping factors are frequency-features that are closely connected with structural stiffness, mass, and damping parameters as exposed by Sun et al. (2020). However, their estimation is highly sensible to external loads, noise, and sometimes is not suitable for detecting minor faults in real deployments.

In recent years, several authors presented methodologies for frequency-feature extraction that tackle some challenges regarding structural fault detection. Some of the most recent frequency-feature extraction approaches are depicted in Table 1. These approaches are mainly focused on creating signal-based models from an approximation of the structural free response using System Identification techniques and variations from existing model structures. Moreover, the estimation of the impulse responses of the structures is mainly performed using the RDT which stands as a proper signal processing technique to estimate the free response of structures subjected to random excitations.

3 CONCEPTUAL FRAMEWORK

This section presents an overview of the key concepts and principles that underlie the used SHM scheme for the presented approach.

3.1 *Random decrement technique*

The RDT is a signal processing tool that has been used in recent years for vibration-based-SHM. This method aims to extract an approximation of the structural free responses when the analyzed structure is subjected to random zero-mean excitations.

This method consists of three phases. Firstly, a threshold for the amplitude s_{th} and slope of the vibration signal $s(t)$ are selected. Then, the time segments that match the initial conditions are extracted, and finally these segments are averaged to cancel the effect of random excitations and preserve the deterministic response of the structure. Some variations of the RTD using several triggering conditions are presented by Brincker et al. (1992), Cioara et al. (2000), Alampalli et al. (2005) and Amador et al. (2022). The resulting signal of the RDT is commonly called random decrement signature (RDS) which can be written as

$$s_{rds}(t_\tau) = E[s(t_\tau)|s_{th}] \approx \frac{1}{l_{rds}} \sum_{k=0}^{l_{rds}-1} s(\tau_k), \tau_k \in (t_{thk}, t_{thk} + \tau), \tag{1}$$

where $E[\,\cdot\,]$ is the expected value, $t_{thk}, \quad k \in \mathbb{Z}_+$ is the time where $s(t)$ crosses s_{th} and $t_\tau \in (0, \tau)$, whereas $\tau \in \mathbb{R}$ is the duration of the free responses and l_{rds} is the number of segments used for the computation of the RDS.

3.2 *Hankel alternative view of Koopman operator*

System Identification techniques are data-driven tools used to fit data from dynamic systems to mathematical model structures as an approximation of said system. HAVOK is a recent SID technique that creates and approximation of the Koopman operator of non-forced dynamic systems by using time embedding and singular value decomposition tools. The HAVOK model structure can be written as

$$v(n) = Av(n-1) + Bv_{\eta+1}(n), \tag{2}$$

with $A \in \mathbb{R}^{\eta \times \eta}$ and $B \in \mathbb{R}^{\eta \times 1}$, where as η is the model's order. The HAVOK model is computed from the truncated matrix $V_{\eta+1} \in \mathbb{R}^{\eta+1 \times \eta+1}$, which contains the $\eta + 1$ principal components of observed sensors. The model in Equation (2) uses the last principal component of $V_{\eta+1}$ as an artificial force that excites the system. This representation allows to identify and compensate non-linear behavior that can introduce noise in the estimation of natural frequencies of the studied dynamical system. Simulated validation of several non-linear systems illustrates the effectiveness of HAVOK method as shown in Brunton et al. (2017).

4 PROPOSED ANALYSIS

The following assumptions are stated for the proposed analysis:

a. The data is acquired at a constant sample frequency f_s, ensuring that the signals remain free from aliasing.
b. The sensors data $s(t)$ contain the information about the spectrum of the studied structure within its frequency range.
c. The model order η of the HAVOK SID model can be estimated by using eigen realization information criterion or stability diagrams as shown in Bakir (2011) and Bauer (2001).
d. The set of eigenvalues Λ used for extracting the natural frequencies and damping factors have a stable-underdamped characteristic.

4.1 *Frequency feature extraction*

The proposed feature extraction scheme for vibration based SHM is presented in Figure 1. This SHM scheme has been implemented in several applications using different SID techniques such as the described by He et al. (2011). On the other hand, some variations of the RDT such as the presented by Vesterholm et al. (2020) have been used to extract frequency-features. The proposed enhancement of this SHM scheme and its description is next explained.

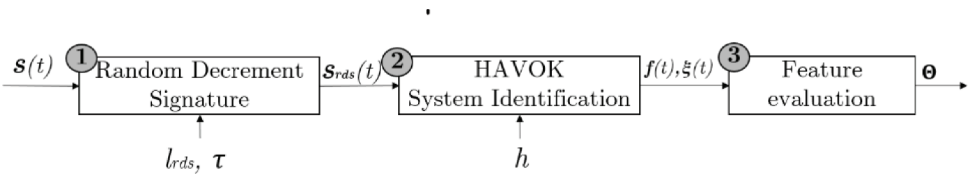

Figure 1. Proposed data-driven SHM scheme using RDS and SID for feature-feature extraction.

1. The input vibration signals $s(t)$ that monitor the structure are used to compute the RDS of each channel using a time duration per segment τ and averaging every l_{rds} segments. The triggering condition for this scheme is defined as

$$C_s := \left\{ (m\sigma_s(1-b) < s(t)\sigma_s(1+b)) \& \left(\frac{ds(t)}{dt} < 0 \right) \right\} \tag{3}$$

   where $m\sigma_s$, $m \in R$ is a multiple of the standard deviation σ_s of the raw signals, while b is a regulator variable between 0 and 1 that allows to identify the initial condition of the RDS into a band of search for numerical purposes. Furthermore, since the time derivative must be less than zero for the triggering condition, only decreasing impulses are considered for the RDS generation. The use of a multiple of the standard deviation $m\sigma_s$ in Equation (3) is intended to set a statistical threshold for anomaly detection. Events or responses that deviate from the normal behavior by a specified number of standard deviations are correlated with the random excitation across the structure. Furthermore, this criterion has found application in various deployments, presented by Xu et al. (2015) and Zhang et al. (2016). Moreover, the used of a range band of search for the initial conditions was presented in Vesterholm et al. (2020), such a band gives flexibility to the search of the initial condition amplitude of the RDS for numerical data. Finally, the RDS can be computed averaging $s(t)$ at the times $t_{C_s k}$ that meet the C_s condition as

$$s_{rds}(t_\tau) = E[s(t_\tau)|C_s] \approx \frac{1}{l_{rds}} \sum_{k=0}^{l_{rds}-1} s(\tau_k), \tau_k \in (t_{C_s k}, t_{C_s k} + \tau) \tag{4}$$

   For multivariate analysis, Equation (3) must be applied to the principal component of the vibration signals and the RDS of each channel can be extracted independently based on this criterion with Equation (4). The principal component of the signals can be obtained using SVD techniques as reported by Shlens (2014).
2. Once the RDS signal $s_{rds}(t)$ of each channel is extracted, the HAVOK model is computated using the RDS of all channels as input data for the algorithm. A model in the form of Equation (2) is obtained for each group of RDSs. Following *Assumption (a)* and *Assumption (d)*, if the sampling frequency of the raw data f_s is constant, then the natural frequencies f_n and damping factors ξ_n can be computed with the discrete model matrix A and f_s as

$$f_n := \left\{ \frac{f_s}{2\pi} \left(\log(\rho)^2 + \beta^2 \right)^{\frac{1}{2}}, \lambda = \rho e^{\mp i\beta} \in \Lambda \right\} \tag{5.1}$$

$$\xi_n := \left\{ -\frac{\log(\rho)}{\left((\log(\rho))^2 + \beta^2 \right)^{\frac{1}{2}}}, \lambda = \rho\ e^{\mp i\beta} \in \Lambda \right\} \tag{5.2}$$

$$\Lambda := \{\lambda \in C | \|I - A\lambda\| = 0\} \tag{5.3}$$

with $\rho \leq 1$ and $\beta \neq [-\pi, 0, \pi]$. Furthermore, based on *Assumption (b)*, if the sensors are properly preprocessed, then, the modal parameters of Equations (5.1), (5.2) and (5.3) represent the physical behavior of the studied bridge.

3. The set of natural frequencies and damping factors are stored and evaluated through the sample mean and standard deviation statistical measurements.

Based on the SHM scheme previously discussed, the frequency-features were generated for several numerical values of l_{rds}, τ and h. Finally, the set of sample means, and standard deviations of the modal parameters were computed for each group of input parameters.

5 VALIDATION ASSESSMENT

5.1 *Experimental set-up*

The 12-th Andoain St is a prestressed concrete slab bridge with an urban major arterial functionality class. The monitoring of the infrastructure was led by the company Aingura IIoT, who instrumented the bridge beams with piezoelectric accelerometers. A general view of the bridge and its sensors scheme are shown in Figure 2.

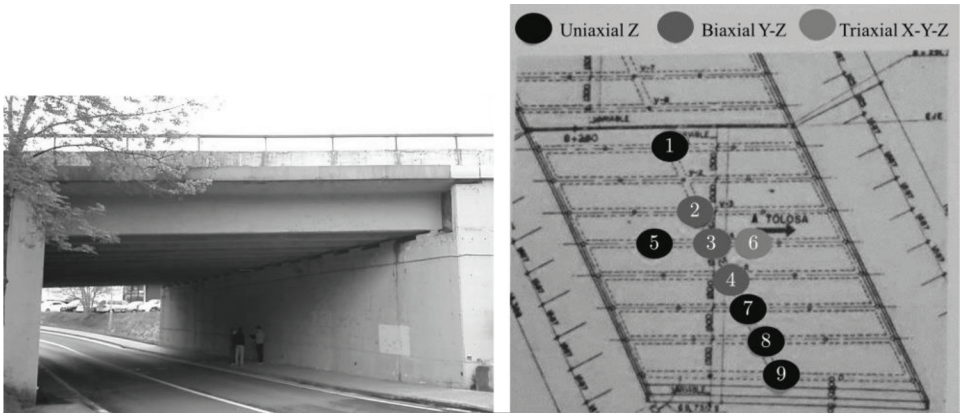

Figure 2. 12 Andoain St bridge location and sensor placement specifications.

The sensors data were collected by an embedded system at a sample frequency of 350 Hz. A subset of data collected between 05/06/2023 and 12/06/2023 was used to validate the proposed methodology. The parameters used in the evaluation of this methodology are shown in Table 2.

Table 2. Parameters used for the implementation of the proposed methodology.

Description	Parameter	Value
Amplitude for RDS	s_{th} [-]	$1.6\sigma_s$
Sample frequency	f_s [Hz]	350.0
Sensors used for the analysis	s(t) [-]	$[s_1(t), s_3(t), s_5(t), s_9(t)]$
Bandwidth for triggering condition	b [-]	0.2
Model order for HAVOK model	η [-]	8
Time interval of transient segments	τ [s]	[0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0, 4.5, 5.0, 5.5, 6.0, 8.0, 10.0]
Number of segments for RDS computation	l_{rds} [-]	[5, 10, 20, 30, 40, 50, 100, 150, 200, 350, 500, 750, 1000, 1500, 2000]
Horizon for Hankel time embedding	h [-]	[9, 10, 11, 12, 13, 18, 20, 22, 23, 28, 33, 38]

The selection of the input parameter sets was made based on the parameters used in SHM deployments within the literature as reported by Xu et al. (2015) and He et al. (2011). For the selected study period, 64583 segments were extracted using the criteria of Equation (3). In total, 2520 experiments were carried out in which 1000 samples of frequency-features were extracted for each experiment. In addition, the computational time necessary to extract the frequency-features was calculated for each set of input parameters.

5.2 *Frequency-features results*

The impact of increasing the numerical value of the input parameters on the sample mean of the frequency-features is depicted in Figure 3. In general, the value of the computed natural frequencies decreases as the input parameters increase. Furthermore, the numerical value of the natural frequency only converges to a numerical value with the increase of l_{rds}. Specifically, the modal parameters exhibit convergence in their sample means when more than 700 segments (input param tested=10 for l_{rds}). On the other hand, the damping factors increase their numerical value with l_{rds} and decrease with τ and h. Moreover, the rate of change of the damping factors is high for all the Hankel horizon tested while the damping factors rate of change seems to have a smaller variation as τ and l_{rds} increase.

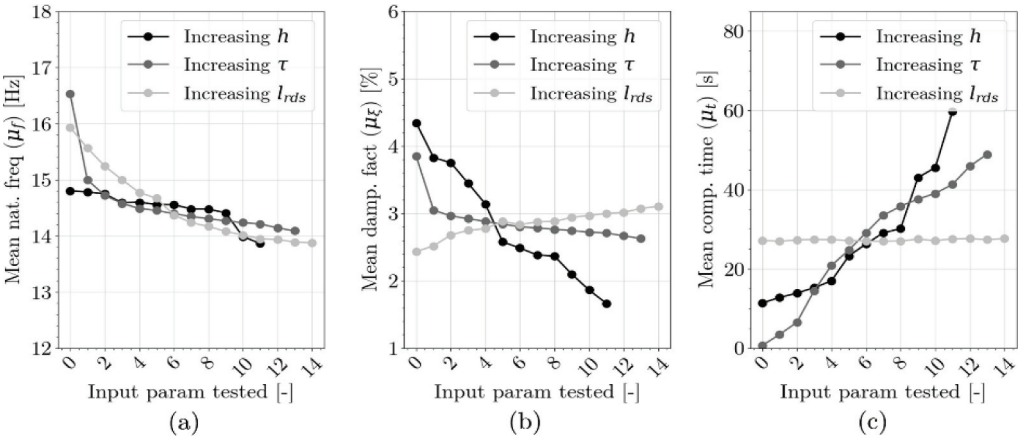

Figure 3. Sample mean of the frequency features and computing time for the tested experiments as a function of the input parameters. (a) Natural frequencies. (b) Damping factors. (c) Computational time.

The Hankel horizon has the highest impact in the computational time of the frequency-features for the tested experiments, while the number of averaged segments does not seem to have a significant impact on computational costs compared to the other two evaluated parameters, as it is shown in Figure 3.

Figure 4 depicts the variation of the frequency-features as a function of l_{rds}, h and τ. The standard deviation of the natural frequencies follows a similar pattern to the mean sample values. Increasing l_{rds} minimizes the standard deviation of the natural frequencies. Likewise, as all input values increase, the standard deviation of damping factors decreases. The experiments with highest h have the lowest standard deviation in the computed damping factors.

Since h and τ have the most significant impact on the computing time, a comprehensive sensitivity analysis was conducted to observe the behavior of the frequency-features when these parameters are fixed. Figure 5 provides a comprehensive joint sensitivity analysis by fixing h and τ to common values used in the literature such as the presented by Górski (2015) and Farhey (2005).

Figure 5 demonstrates that, by fixing h, the frequency-features converge to a stable mean and standard deviation as l_{rds} increases. Additionally, increasing τ accelerates the convergence rate. On the other hand, increasing h has no effect on the convergence rate of the numerical value of the frequency-features sample mean and standard deviation. Nevertheless, the value of h generates

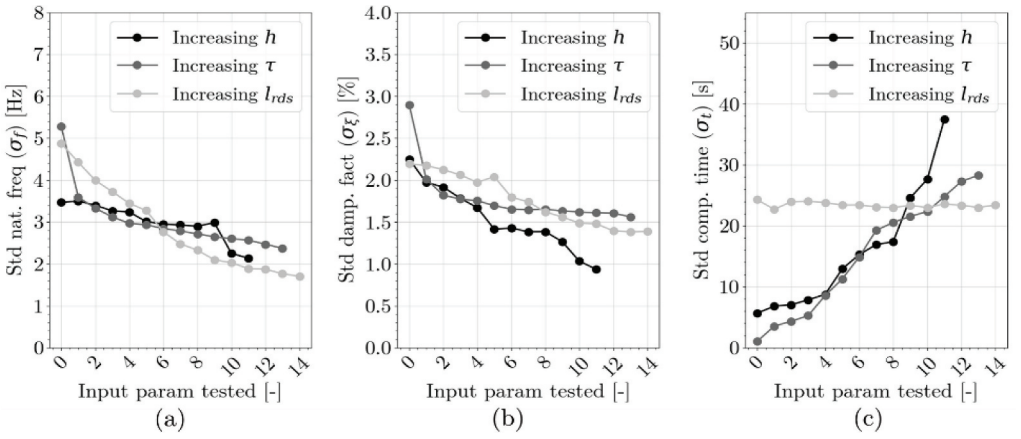

Figure 4. Sample standard deviation of the frequency features and computing time for the tested experiments as a function of the input parameters. (a) Natural frequencies. (b) Damping factors. (c) Computational time.

a change in the convergence value of the natural frequencies in such a way that a higher h generates a higher natural frequencies sample mean and a lower damping factors sample mean.

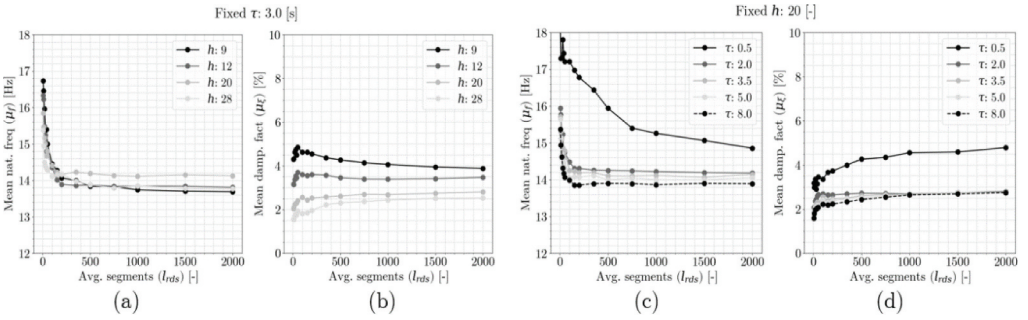

Figure 5. Sample mean and standard deviation of the frequency features as a function of the number of averaged segments. (a) Natural frequencies for several Hankel horizons fixing τ = 3[s]. (b) Damping factors for several Hankel horizons fixing τ = 3[s]. (c) Natural frequencies for several segments durations fixing h=20[-]. (d) Damping factors for several segments durations fixing h=20[-].

6 CONCLUSION

This study introduces a sensitivity analysis of frequency variables in SHM methods. The evaluation assessment showed that employing different input parameters for a structural health monitoring scheme can lead to variations in the obtained frequency-features when using the same mechanical vibration dataset. To compute a low variance set of frequency-features at a low computational cost, one approach involves increasing the number of segments used to calculate the random decrement signal. Another method consists in extending the duration of pulses while maintaining a constant number of segments and increasing the horizon of the Hankel matrices, leading to similar convergence of modal parameters. However, it is noted that increasing the duration of segments and the horizon of the Hankel matrix also achieves convergence but at a higher computational cost. Choosing the correct parameters for structure monitoring ensures that the obtained frequency-features reflect genuine changes in the monitored structure over time. This approach minimizes the influence of random variations that may occur when applying the necessary algorithms for feature computation. Regarding real deployments, it is concluded that obtaining comparable modal

characteristics of the RDS is feasible by adjusting the segments duration based on in situ resource constraints.

ABSTRACT: When performing vibration tests on bridges, engineers face the challenge of extracting the global dynamic properties of these structures from the vibration responses measured at several degrees of freedom. In this paper, the new subspace-based poly-Reference Complex Frequency (SpCF) technique is applied to the vibration measurements of a large span bridge. The advantage of the SpCF with regard to other modal or system identification techniques is that it provides robust estimates for the modal properties, which leads to very clear stabilization diagrams. In order to assess the performance of the new SpCF, its estimates for the modal properties of the aforementioned bridge are compared to those of the poly-reference Least Squares Complex Frequency (pLSCF, also known by its commercial name polymax), which is deemed as a standard technique in experimental and operational modal analysis.

1 INTRODUCTION

When performing output-only modal identification engineers face the challenge of extracting the modal properties of the tested structures from the vibration data in an accurate and robust fashion. Several time-domain system identification techniques exist for this purpose as, for instance the Ibrahim Time Domain (ITD) (Ibrahim & Milkulcik 1997, Ibrahim 1984 & Fukozono 1986), the Poly-reference Least Squares Complex Exponential (pLSCE) (Vold et al. 1982), the Eigen-system Realization Algorithm (Juang & Pappa 1985) and the Stochastic Subspace Identification (SSI) (Peeters, B. & De-Roeck 1999).

Alternatively, identification methods formulated in the frequency-domain such as the Poly-reference Least Squares Complex Frequency (pLSCF) (Peeters et al. 2007) and poly-reference Complex Frequency (pCF) (Amador & Brincker 2023a, b & c) can also be utilized to estimate the modal properties from vibration data. Whilst the former are applied to a time-domain function like the impulse response or the correlation function, the latter operates on a frequency-domain function such as the Frequency Response Function (FRF) or the Half Spectrum (HS).

The advantages of using subspace driven time-domain methods like the ERA and the SSI with regards to their Least Squares counterparts such as the ITD and pLSCE, is that former tend to provide clearer stabilization diagrams, facilitating the extraction of the physical modal properties from the numerical ones and, in turn, leading to a more robust modal parameter estimation.

DOI: 10.1201/9781003483755-181

Another benefit of utilizing subspace driven identification methods is related to the fact that they can provide very robust and accurate estimates even when applied to vibration data containing the measurement of several sensors.

The idea of using subspaces of the system matrices in the identification process is widely used in time domain system identification. Recently, this idea was extended to the frequency domain in the formulation of the Subspace-based pCF (SpCF) described in Amador & Brincker 2023d. In this paper, the performance of the recently introduced SpCF method is assessed by means of the Operational Modal Analysis (OMA) of a large span bridge, namely the Port Mann stay cable bridge located in Vancouver, British Columbia, Canada. The bridge has been continuously monitored since it was opened to traffic in 2012 by means of 54 accelerometers. In order to assess the performance of the SpCF, its estimates for the modal properties of the Port Mann bridge are compared to those of the pLSCF, which is regarded by many as standard in frequency-domain modal analysis.

2 BACKGROUND THEORY: THE SPCF APPROACH

The FRF matrix of a structural system with general viscous damping containing the information of N_i inputs, N_i outputs and n vibration modes, and sampled with a time step, Δt, can be modeled by the so-called frequency-domain state-space model with an arbitrary forward time shift, as (Amador & Brincker 2023a, b & c)

$$z^r \boldsymbol{H}(z) = \boldsymbol{C}(\boldsymbol{I}z - A)^{-1} B \tag{1}$$

where r denotes a discrete-time forward shift or a time delay ($\tau = r\Delta t$) and $\boldsymbol{H}$(z) stands for the FRF in z-domain; $\boldsymbol{A}$, $\boldsymbol{B}$ and $\boldsymbol{C}$ are the discrete-time state matrix, the input matrix and the output matrix, respectively; $\boldsymbol{I}$ denotes the identity matrix and $z = e^{j\omega\Delta t}$ is the z-domain variable expressed as a function of the imaginary unity, $j = \sqrt{-1}$, and the angular frequency, ω (in rads/sec). From the eigenvalue decomposition of the discrete-time state matrix

$$\boldsymbol{A} = \boldsymbol{\Psi}\boldsymbol{\Lambda}\boldsymbol{\Psi}^{-1} \tag{2}$$

it can be proven that relations between the eigenvectors $\boldsymbol{\Psi}$ and eigenvalues $\boldsymbol{\Lambda}$, and the invariants of the classic modal model is given by (Amador 2015)

$$\boldsymbol{\Psi} = \begin{bmatrix} \boldsymbol{\Phi} \\ \boldsymbol{\Phi\Lambda} \end{bmatrix}, \ \boldsymbol{\Phi} = C\boldsymbol{\Psi}, \boldsymbol{\Gamma}^T = \boldsymbol{\Psi}^{-1} B \tag{3}$$

where $\boldsymbol{\Phi}$ denotes the mode shape matrix, $\boldsymbol{\Gamma}$ the modal participation matrix, and $(\cdot)^T$ stands for the matrix transpose. Writing down Eq (1) for r ranging from 0 to a maximum time shift n and combining the resulting equations in single matrix expression, gives

$$\boldsymbol{H}_0(z) = \boldsymbol{O}(\boldsymbol{I}z - \boldsymbol{A})^{-1}\boldsymbol{B} \tag{4}$$

with

$$\boldsymbol{H}_i(z) = \begin{bmatrix} z^i \boldsymbol{H}(z) \\ z^{i+1}\boldsymbol{H}(z) \\ \vdots \\ z^{i+n}\boldsymbol{H}(z) \end{bmatrix} \tag{5}$$

and

$$\boldsymbol{O} = \begin{bmatrix} \boldsymbol{C} \\ \boldsymbol{CA} \\ \vdots \\ \boldsymbol{CA}^n \end{bmatrix} \tag{6}$$

standing for the so-called *Observability* matrix. Eq. (4) can be written for two discrete consecutive frequency lines ω_a and ω_b ($\forall \omega_a > \omega_b$) spaced from each other by a single discrete frequency step $\Delta\omega$, giving

$$\boldsymbol{O}^{-1}\boldsymbol{H}_1(z_a) - \boldsymbol{A}\boldsymbol{O}^{-1}\boldsymbol{H}_0(z_a) = \boldsymbol{B} \tag{7}$$

$$\boldsymbol{O}^{-1}\boldsymbol{H}_1(z_b) - \boldsymbol{A}\boldsymbol{O}^{-1}\boldsymbol{H}_0(z_b) = \boldsymbol{B} \tag{8}$$

Combining Eqs. (7) and (8), and writing the resulting expression for all frequencies lines in the range of 0 (DC) to N_v (Nyquist frequency), gives

$$\boldsymbol{O}^{-1}\boldsymbol{Q} = \boldsymbol{A}\boldsymbol{O}^{-1}\boldsymbol{P} \tag{9}$$

where the system matrices Q and P are given by

$$\boldsymbol{P} = \left[\left(\begin{Bmatrix} z_1^0 \\ \vdots \\ z_1^n \end{Bmatrix} \otimes \boldsymbol{H}(z_1) - \begin{Bmatrix} z_0^0 \\ \vdots \\ z_0^n \end{Bmatrix} \otimes \boldsymbol{H}(z_1) \right) \quad \cdots \right.$$

$$\left. \left(\begin{Bmatrix} z_{N_v}^0 \\ \vdots \\ z_{N_v}^n \end{Bmatrix} \otimes \boldsymbol{H}(z_{N_v}) - \begin{Bmatrix} z_{N_v-1}^0 \\ \vdots \\ z_{N_v-1}^n \end{Bmatrix} \otimes \boldsymbol{H}(z_{N_v-1}) \right) \right] \tag{10}$$

$$\boldsymbol{Q} = \left[\left(\begin{Bmatrix} z_1^1 \\ \vdots \\ z_1^{n+1} \end{Bmatrix} \otimes \boldsymbol{H}(z_1) - \begin{Bmatrix} z_0^1 \\ \vdots \\ z_0^{n+1} \end{Bmatrix} \otimes \boldsymbol{H}(z_1) \right) \quad \cdots \right.$$

$$\left. \left(\begin{Bmatrix} z_{N_v}^1 \\ \vdots \\ z_{N_v}^{n+1} \end{Bmatrix} \otimes \boldsymbol{H}\left(z_{N_f}\right) - \begin{Bmatrix} z_{N_v-1}^1 \\ \vdots \\ z_{N_v-1}^{n+1} \end{Bmatrix} \otimes \boldsymbol{H}(z_{N_v-1}) \right) \right] \tag{11}$$

with $\otimes$ denoting the *Kronecker product*. The derivation of the SpCF technique (Amador & Brincker 2023d) is accomplished by factoring the Q matrix as follows

$$\boldsymbol{Q}_{\mathrm{RE}} = [\,\mathbf{Re}(Q) \quad \mathbf{Im}(Q)\,] = O\Upsilon \tag{12}$$

with $\boldsymbol{Y}$ standing for the *Frequency-domain Controllability* matrix (Amador & Brincker 2023d). Replacing $\boldsymbol{Q}$ by $\boldsymbol{Q}_{\mathrm{RE}}$ and $\boldsymbol{P}$ by $P_{\mathrm{RE}} = [\,\mathbf{Re}(P) \quad \mathbf{Im}(P)\,]$ in Eq. (9), gives

$$P_{\mathrm{RE}} = OA\Upsilon \tag{13}$$

The key step towards the derivation of the SpCF is to estimate matrices $\boldsymbol{O}$ and $\boldsymbol{Y}$. This is accomplished by taking the SVD of $\boldsymbol{Q}_{\mathrm{RE}}$, giving

$$Q_{\mathrm{RE}} = USV^H \tag{14}$$

where $\boldsymbol{U}$ and $\boldsymbol{V}$ are orthogonal matrices containing the singular vectors and $\boldsymbol{S}$ is diagonal matrix containing the singular values of $\boldsymbol{Q}_{\mathrm{RE}}$, with $(\cdot)^H$ denoting the complex conjugate transpose (Hermitian) of a complex matrix. From Eq. (14), estimates for $\boldsymbol{O}$ and $\boldsymbol{Y}$ can be computed using the i^{th} subspace of $\boldsymbol{Q}_{\mathrm{RE}}$ as

$$\begin{aligned} \hat{\boldsymbol{O}}_i &= U_i S_i^{1/2} \\ \hat{\Upsilon}_i &= S_i^{1/2} V_i^H \end{aligned} \tag{15}$$

where $U_i = [u_1 \quad \cdots \quad u_i]$, $V_i = [v_1 \quad \cdots \quad v_i]$, and $S_i = \mathbf{diag}([s_1 \quad \cdots \quad s_i])$, with $\mathbf{diag}(\cdot)$ denoting the diagonal matrix operator, $\boldsymbol{u}_{\mathrm{k}}$ and v_k the column vectors of $\boldsymbol{U}$ and $\boldsymbol{V}$, and s_k designating the diagonal elements of $\boldsymbol{S}$. Once the estimates $\widehat{O}_i$ and $\widehat{\Upsilon}_i$ are computed from Eq. (15), the estimate for the discrete-time state matrix is computed from i^{th} subspace of $\boldsymbol{Q}_{\mathrm{RE}}$, as

$$\widehat{A}_i = \widehat{O}_i^{+} P_{\mathrm{RE}} \widehat{\Upsilon}_i^{+} = S_i^{-1/2} U_i^H P_{\mathrm{RE}} V_i S_i^{-1/2} \tag{16}$$

with $(\cdot)^+$ denoting the pseudo-inverse of a matrix. The estimate for the output matrix $\widehat{C}_i$, on the other hand, is found by retrieving the first N_o rows of $\widehat{O}_i$. Next, the estimates for the modal properties can be computed, firstly, by taking the eigenvalue decomposition of $\widehat{A}_i = \widehat{\boldsymbol{\Psi}}_i \widehat{\boldsymbol{\Lambda}}_i \widehat{\boldsymbol{\Psi}}_i^{-1}$. Then, by making use of relations (3), the mode shape matrix is estimated as

$$\widehat{\boldsymbol{\Phi}}_i = \widehat{C}_i \widehat{\boldsymbol{\Psi}}_i \tag{17}$$

Finally, the continuous-time poles can be retrieved from the main diagonal of $\widehat{\boldsymbol{\Lambda}}_i$ as described, for instance, in (Brincker, R. & Ventura 2015).

3 APPLICATION EXAMPLE: OMA OF THE PORT MANN STAY CABLE BRIDGE

In addition to providing clear stabilization diagrams, the subspace driven system identification techniques possess the ability of handling the information of several sensors at once. This follows from the fact that the SVD condenses and reduces physical information in the big system matrices in a much smaller subspace, leading to very robust identification and, thereby, to very clear stabilization diagrams. In order to assess this characteristic, the SpCF is applied to the vibration responses of the Port Mann bridge depicted in Figure 1, which has been continuously monitored since 2012 by means of 54 acceleration sensors placed on the footing, pylons and floating decks, as indicated in Figure 2.

The Port Mann Bridge is a 10-lane large span cable-stayed bridge spanning the Fraser River in Vancouver, British Columbia. The cable-stayed central span is one of the longest in the world measuring 850-meter-long. The North and South main span superstructure consists of steel field sections, pre-cast deck panels and stay cables. The North and South approaches are both span-by-span superstructures with pre-cast segment decks. 144 cable stays extend from each 535-foot-tall tower. The vibration responses of the bridge are continuously acquired by a vibration monitoring system with a sampling rate of 200 Hz. The vibration responses of the bridge are stored in datasets containing 40min worth of data. The dataset utilized to assess the performance of the SpCF technique was acquired on the 9$^{\mathrm{th}}$ of April 2015. For this purpose, the acceleration response histories in such a dataset were de-trended, filtered with an 8th order lowpass Chebyshev Type I filter and resampled with a sampling frequency of 2 Hz.

Finally, the HS matrix was estimated with a frequency resolution of 513 frequency lines by taking the Fourier Transform of the positive part of a Correlation Function matrix previously computed from the filtered response histories with 1024 time lags. The estimation of the HS

Figure 1. Port Mann Cable-stayed bridge spanning the Fraser River in Vancouver, British Columbia, Canada.

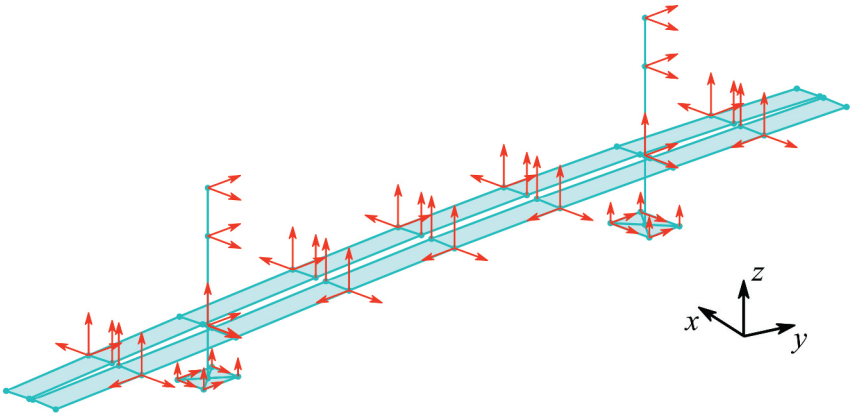

Figure 2. Sensors' locations and measurement directions adopted in the continuous vibration monitoring of the Port Mann bridge in Vancouver, British Columbia, Canada.

matrix was carried out by applying an exponential window with a decay rate of 99,9999% to the positive part of the CF function to minimize the leakage effects and the spurious influence of the higher correlation lags on the estimated frequency function.

Once estimated, the HS matrix with dimension 54 x 35 x 513 was used as primary data both by the pCF and the pLSCF algorithm. The identification of the modal properties of the Port Mann bridge was carried out with a HS matrix with only 35 columns conveniently chosen to be related to the responses of the floating deck and pylons, which possess higher amplitudes of vibrations. This allowed, on the one hand, to reduce the size of the HS matrix and, thereby, the computational time needed to run the pLSCF and SpCF algorithms, and on the other hand, to improve the accuracy of their estimates for the global modal properties of the bridge.

Next, the pLSCF and SpCF methods were applied to estimated HS matrix. The pLSCF technique, also known by its commercial name PolyMAX (Peeters et al. 2007), is known for being a very accurate and robust frequency domain identification algorithm, and therefore, it is regarded as a standard modal identification approach by the modal analysis community and is commercialized in several modal identification software.

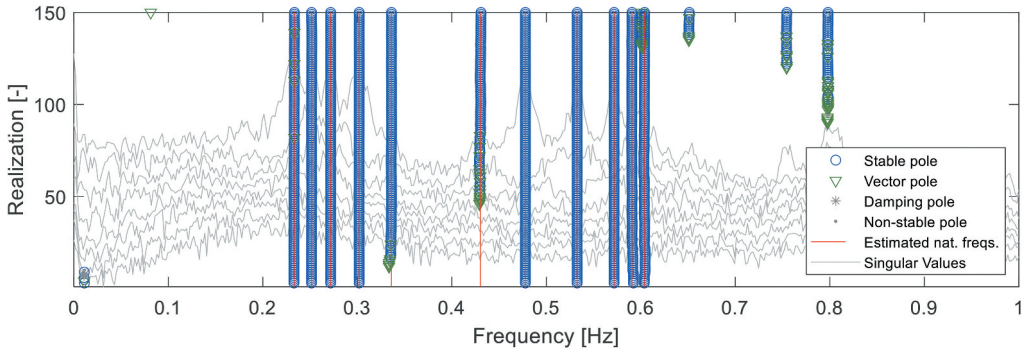

Figure 3. Stabilization diagram constructed with the SpCF technique from the vibration responses of the Port Mann bridge by performing 150 realizations of the system matrices constructed with a maximum model order $n = 4$. The vertical solid lines indicate the identified vibration modes and the background gray lines (plotted solely for validation purposes) are the singular values obtained from the SVD of the full spectral matrix at each frequency line.

Figure 4. $f_9 = 0.572\ Hz, \xi_9 = 0.412\ \%$

$f_{10} = 0.591\ Hz, \xi_{10} = 1.357\ \%$

Figure 5. First ten vibration mode shapes identified with the SpCF technique.

Thus, the pLSCF algorithm is used as reference in the application example presented in this paper to assess the performance, robustness and accuracy of the SpCF approach. Aiming at sorting the physical modal properties from the numerical ones, stabilization diagrams were constructed by performing 150 realizations of the system matrices of both techniques which were assembled with a maximum model order $n = 4$. The stabilization diagrams constructed with the pLSCF and SpCF techniques are shown in Figures 3 and 4, respectively, wherein the vertical solid red lines indicate the natural frequencies automatically identified with the Hierarchical Clustering Algorithm (HCA) described in Amador 2015.

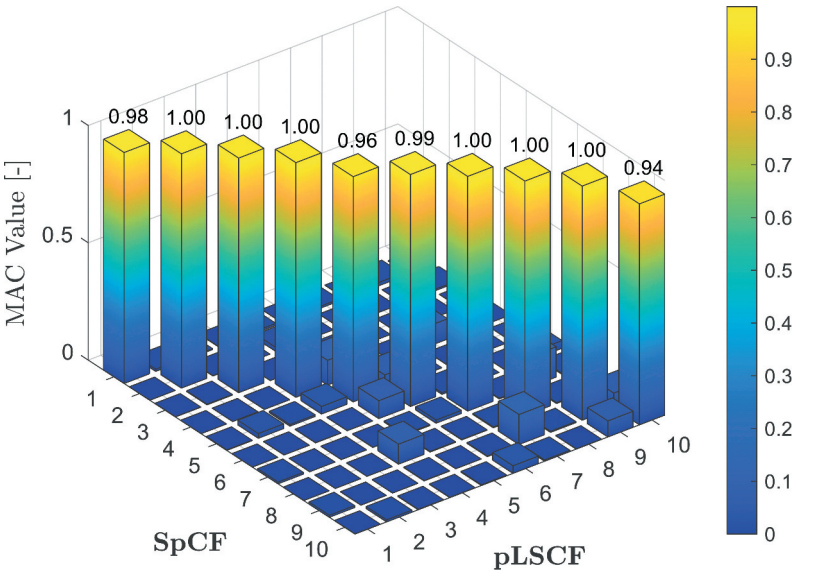

Figure 6. Modal Assurance Criterion (MAC) between the mode vectors estimated with the pLSCF and SpCF techniques.

By comparing the plots shown in such figures, it becomes clear that the SpCF provided clearer stabilization diagrams, which facilitated the identification of the first eleven vibration modes of the Port Mann bridge. The estimates for the natural frequencies and damping ratios of the first ten vibration modes obtained with both techniques are shown in Table 1. The results presented in this table show that the SpCF method provided estimates for the modal properties of Port Mann bridge that match fairly well those obtained with the pLSCF algorithm. The first ten vibration mode shapes automatically identified with SpCF approach by means of the stabilization diagram depicted in Figure 3 are shown in Figure 5.

The results presented in Figure 5 illustrate the ability of the SpCF method of providing accurate estimates for the mode shapes, even when it is applied to the vibration responses of a high number of sensors. The mode shape vectors estimated with the SpCF approach are compared to their counterparts estimated with the pLSCF technique in Figure 6. Similar to the other modal properties, this figure shows that the mode shapes estimated with the SpCF technique are very well correlated with those estimated with the pLSCF approach.

4 CONCLUSION

This paper assesses the performance of the new SpCF system identification technique in handling the vibration responses of a high number of sensors at once. For this purpose, the SpCF algorithm was applied to the vibration data of a large span stay cable bridge containing the responses measured with 54 accelerometers. In order to assess its performance, the SpCF

identification results were compared, in terms of stabilization diagrams and MAC, to those of the pLSCF algorithm, which is deemed as a standard system identification method due to its ability of providing clear stabilization diagrams. By comparing the diagrams constructed with both techniques, it became clear that the SpCF approach provided clearer stabilization diagram than that of the pLSCF approach, which in turn, led to a robust identification of the first ten vibration modes of the Port Mann bridge. In addition to this robustness, the SpCF approach also provided estimates for the modal properties of the Port Mann bridge which are very well correlated with the estimates obtained with the pLSCF method.

ACKNOWLEDGMENTS

The author acknowledges the funding received from DTU Offshore - Danish Offshore Technology Centre (DOTC) - to develop, formulate and implement the SpCF technique.

Development of a novel bridge deck-to-pier connection for improved tsunami resilience

ABSTRACT: Tsunami events have caused significant coastal damage in the past two decades, including the widespread failure of bridges. The 2011 East Japan tsunami revealed a common bridge failure mode: superstructures disconnecting from piers due to weak deck-to-pier connections unable to withstand uplift forces. This study proposes a novel deck-to-pier connection to enhance bridge resilience to tsunami. The connection consists of a mechanical bar that increases vertical displacement capacity, dissipates tsunami energy through material hysteresis, and yields before damage to critical bridge elements. By concentrating tsunami damage into a replaceable element, the post-event repairs are quick and economical to undertake, reducing bridge downtime. A series of experimental tests, conducted on a 1/3 scale pier cap and bridge deck specimen, investigate the connection and bridge system response. This study validates the design philosophy, and investigates bar materials suitable for coastal environments, including mild steel, stainless steel and glass fibre reinforced polymer.

1 INTRODUCTION

Bridges frequently serve as vital connections between coastal communities, particularly for isolated areas with limited transportation networks. The functionality of these structures is essential for recovery efforts during and in the immediate aftermath of a natural hazard, as demonstrated by the 2004 and 2011 tsunami events.

Reconnaissance conducted after the 2011 East Japan tsunami found that over 300 bridges were significantly damaged in this event (Akiyama et al. 2012). Many of these bridges were found with damage consistent with large uplift forces acting on the superstructure: damage to the connection between the bridge deck and pier, decks found flipped upstream or next to the piers and damage to the top of the shear keys on the piers (Kawashima 2012; Shoji, Hiraki & Ezura 2012; Unjoh 2012).

Subsequent research highlighted the large forces acting on bridge sub- and superstructures during tsunami inundation (e.g. Azadbakht & Yim 2015). Researchers identified that the magnitude of these actions depends on several parameters, including the wave height and velocity (Istrati et al. 2018), the wave type and how it breaks (Araki, Ishino & Deguchi 2010) and amplification from local bathymetry and topography (Yeh, Robertson & Preuss 2005). Similarly,

DOI: 10.1201/9781003483755-182

many factors were found to influence how the bridge responds, such as the substructure and span arrangement, which affect load distribution (Motley et al. 2016) and the type of girders used, due to the air entrapment effect, which can generate additional buoyancy forces (Azadbakht & Yim 2016; Istrati & Buckle 2019; Seiffert, Ertekin & Robertson 2015).

Bridges typically have different force-resisting mechanisms for lateral and vertical actions, so the relative magnitude of these actions can significantly affect the response and the level of damage induced on the structure. An investigation by Robertson et al. (2007) revealed that bridges are often inadequately designed for the uplift forces generated by wave loading. Furthermore, Yeh, Sato and Tajima (2013) identified that the initial wave loading can weaken critical force-resisting components, resulting in significant damage during the return wave loading.

In response to the evident scale of damage caused by these waves, solutions have been proposed to mitigate the effects of tsunami inundation on bridge structures. Researchers have investigated including perforations in the superstructure to allow the air and water to move vertically through the deck. An experimental study by Cuomo, Shimosako and Takahashi (2009) found that air relief slots in the bridge deck could reduce the uplift forces for small wave amplitudes. However, these slots were found to be inadequate for larger waves. Additionally, an experimental study by Lukkunaprasit et al. (2011) on a 1:100 scale bridge indicated that the peak uplift force could be reduced by up to 25%.

Another approach proposed to mitigate tsunami damage involved optimising the bridge superstructure for hydrodynamic loads. Zhang, Hoshikuma and Usui (2012) proposed installing a fairing on the side of the bridge deck to improve the hydrodynamic flow during tsunami inundation. Their experimental testing concluded that this could minimise the horizontal force but would increase the uplift force for some fairing geometries. Both proposed solutions require further experimental validation and development to verify their practicality in the design of bridges.

However, these solutions do not fully address the inability of a bridge system to resist the large uplift forces induced by tsunami inundation. Therefore, this research proposes a novel deck-to-pier connection to accommodate these tsunami forces. This paper presents an overview of the development of this novel connection and experimental testing conducted to verify the design and detailing of this connection.

2 NOVEL BRIDGE DECK-TO-PIER CONNECTION

This research proposed a novel bridge deck-to-pier connection. The connection consists of mechanical bars designed to elongate under tsunami uplift actions, allowing the bridge deck to displace vertically and rotate. This design philosophy aims to limit forces induced onto the bridge substructure, dissipate tsunami wave energy, and delay the washout failure of the deck. While these bars are designed for uplift forces, the lateral component of the tsunami force will be resisted by concrete or steel shear keys.

The bars are not constrained vertically, so once the tsunami flow has subsided, the stabilising effect of the deck's weight will provide re-centring force, and the bridge deck will return to its initial position. Due to the large lever arm between the mechanical bars and the deck's centre of rotation, the bars will yield at low rotations. Therefore, any significant deck rotation due to tsunami inundation will result in residual deformations, requiring the bars to be replaced. However, when the superstructure is appropriately designed for rotations, the post-event repairs will likely be limited to bar replacement and minor concrete repairs.

Three bar materials were investigated for their feasibility to be used in this connection: galvanised mild carbon steel, stainless steel and glass fibre reinforced polymer (GFRP). These materials were chosen based on their material properties and suitability for coastal environments. Both carbon and stainless steel exhibit ductile post-yield behaviour with large displacement capacities, while GFRP is elastic until rupture. The use of glass fibres means the bar is lightweight and non-corrosive, and the longitudinal arrangement of these fibres results in a low shear capacity and a brittle failure mechanism.

3 LARGE SCALE EXPERIMENTAL TESTING

3.1 *Prototype and specimen design*

The chosen prototype bridge configuration represents a typical medium-span New Zealand bridge, as depicted in Figure 1. The prototype comprises a cast in-situ reinforced concrete substructure and a precast, post-tensioned concrete superstructure. Two 30m spans are simply supported on a 1.5m diameter circular pier and pier cap beam. The bridge deck comprised five standard super-tee beams in accordance with details outlined in Research Report 364 (New Zealand Transport Agency 2008).

Wave heights for the coastal Christchurch location were obtained from Power (2013) and were used in conjunction with the AASHTO Guide Specifications (AASHTO 2022), to determine the tsunami forces. All concrete elements were designed for these forces in accordance with NZS 3101 (Standards New Zealand 2006).

A 1/3 scale model of the prototype structure was used in the experimental testing phases. This structure consisted of a deck unit with three tee beams cast integrally. A precast pier cap and foundation, which supported the deck, were post-tensioned to the strong floor to minimise unintended displacements of these elements.

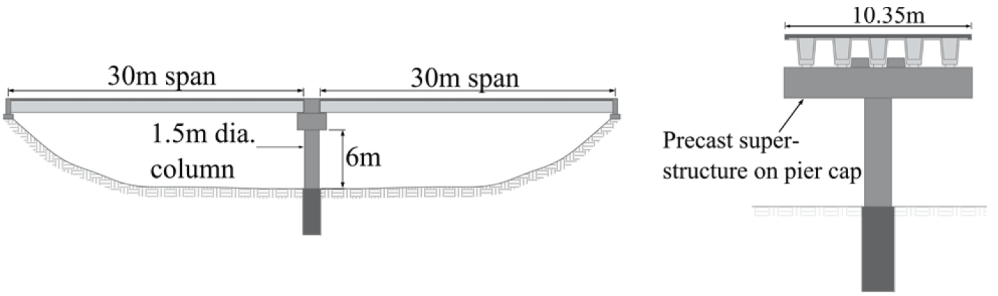

Figure 1. Prototype bridge structure: (left) Longitudinal profile, (right) Elevation profile.

3.2 *Connection detailing*

The bars were debonded within Drossbach ducts located within the pier cap and deck, as shown in Figure 2. The positioning of these ducts within the flange of the tee beam was selected to avoid clashes with the heavily reinforced and typically post-tensioned base of the beam web; however, the ducts could be moved for different geometries. Additionally, positioning the ducts within the flange of the beam was viable due to the diaphragm spanning between adjacent webs, which provided additional transverse stiffness to the bridge deck.

Anchorages were located at the top of the deck and the base of the pier cap. These consisted of flange nuts and washers installed snug-tight for the carbon steel and stainless steel bars and a 300mm sleeve anchorage, which the GFRP was epoxied into (Figure 3). The anchorages were designed to be easily accessible, facilitate the replacement of the bars, and enable corrosion monitoring. For this experimental testing, the washers and nuts were positioned flush with the base of the pier cap (and the top of the deck). For future application, it is recommended to embed these into a grout pocket to minimise the effect on the roadway.

3.3 *Design recommendations for countering tsunami demands*

Design changes should be considered to minimise the damage induced on bridge structures due to tsunami inundation and to effectively integrate the proposed connection alongside standard bridge details.

Unlike typical bridge design, which primarily considers downward forces, tsunami inundation applies upward forces on the bridge deck and, therefore, can induce tension along the top of the deck. This tension force will typically require additional steel reinforcement to be included within the beam flange to satisfy design requirements.

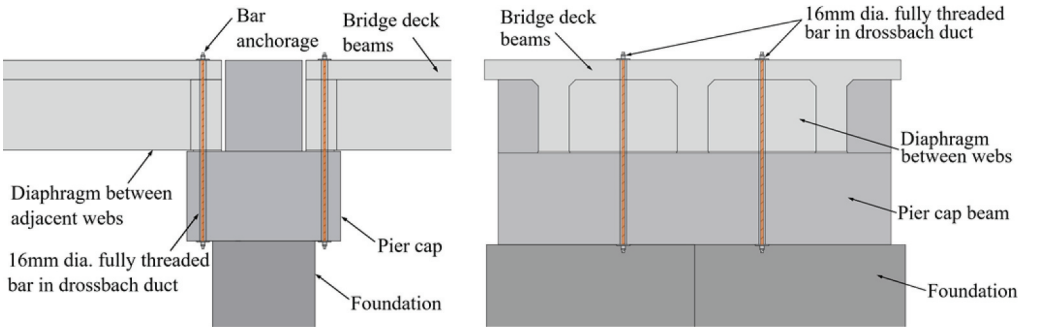

Figure 2. Schematic of the bars anchorage detailing within the deck and pier cap of the specimen structure (left) side view (right) cross-sectional view at pier.

Figure 3. Bar anchorages below the pier cap: installed washer and nut/flange nut (left) the carbon steel bar, (middle) the stainless steel bar and (right) internal sleeve with the epoxied GFRP bar before installation.

The mechanical bars should be designed considering both uplift loads and overturning moments. A capacity design process should be used to ensure that the bars yield before the superstructure and the substructure elements. It is recommended to check a minimum of three critical cases:

1. The start of the initial wave inundation, when uplift force acts on the offshore edge of the bridge deck, creating an overturning moment about the onshore elements. Downward force should be considered if the wave height exceeds the superstructure height for all three cases.
2. Halfway through of the initial wave inundation, when uplift force is distributed across the entire underside of the bridge deck, creating an upwards deck motion.
3. The start of the return wave inundation, when uplift force acts on the onshore edge of the bridge deck, creating an overturning moment about the offshore elements.

It is advisable to consider the duct size relative to the size of the bar. A large duct allows for large deck rotations and lateral displacements before the bar is engaged, while a small duct may be easier to implement alongside existing reinforcing. Depending on the positioning of the ducts, additional reinforcing (U-bars or similar) may be required to tie the ducts into the main reinforcing cage in both the pier cap and the deck diaphragm.

The shear keys and diaphragm should be designed to the maximum lateral demands induced by the tsunami while also considering seismic lateral demands if applicable. In addition, the shear keys should be of sufficient height considering the maximum expected superstructure uplift. A shear key with angled sides in the transverse direction will allow more rotation and potentially be damaged less than a shear key with straight sides. The gap between the shear key and the edge of the bridge beam influences how much the deck can translate under tsunami inundation and, thus, how much shear load is transferred to the structural fuse bars.

3.4 *Experimental test set-up*

This experimental study was set up to simulate both the vertical and horizontal force components of the tsunami force. Four hydraulic actuators positioned beneath the bridge deck were used to simulate the vertical component of the force, while two actuators attached to the strong wall simulated the horizontal force (Figure 4). The vertical actuators were positioned offset from the centreline of the deck to induce an overturning moment and associated rotation on the bridge deck. The two east vertical actuators were connected to the deck to apply the initial wave loading, and to simulate an anticlockwise rotation of the bridge deck. The return wave loading was applied using the west set of actuators, via a clockwise rotation. Potentiometers were positioned on the deck to measure displacements, while load cells and strain gauges were attached to the bars to capture the applied loads and strains.

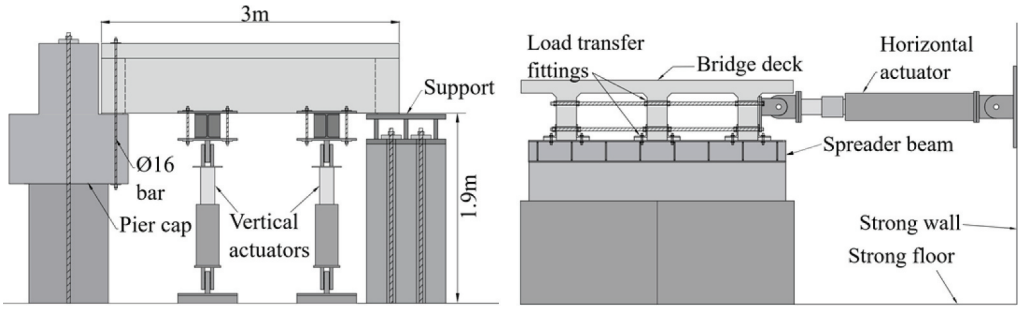

Figure 4. (Left) Schematic of the side view of the testing set up from the west, showing vertical actuators only (right) Schematic of the cross-sectional view of the testing set up, showing horizontal actuators only.

3.5 *Experimental testing programme*

The testing programme aimed to validate the predictions of the bridge deck-to-pier connections response under tsunami loading. Given the potential variation in the ratio of the vertical and horizontal force component magnitudes, as Istrati et al. (2016) noted, the angle of incidence of tsunami waves can vary significantly. This variability can lead to differences in the bridge structural performance, so an envelope of loading cases was developed to capture all likely actions. The envelope consisted of horizontal-only actions (0°) to vertical-only actions (90°) and included an intermediate case consisting of combined horizontal and vertical actions (45°), as shown in Table 1.

The vertical loading was applied so as to initiate rotation of the deck. A design ultimate limit state rotation of 0.02 radians was selected for the loading protocol. This rotation exceeded the yield rotation capacity for the steel and stainless steel bars and was less than the rupture rotation capacity of the GFRP bars.

The horizontal loading was applied, assuming that the shear key would allow lateral displacement of the deck before it was engaged. The applied lateral displacement resulted in a small amount of shear load applied to the bars.

One loading protocol was developed for each test phase and considered the initial and return wave loading. Figure 5 outlines the loading protocol displacement history for the uplift loading case.

4 EXPERIMENTAL RESULTS

An experimental study was undertaken to validate the theoretical predictions and assess the system response under representative tsunami loads. This section outlines the findings from eight tests conducted in Phases 1 – 3 (refer to Table 1). The bridge deck-to-pier connection response, in terms of overturning moment versus rotation, is presented for all three bar

Table 1. Summary of the testing programme (loading direction is taken from the horizontal)

Phase	Direction	Test ID	Test
1:Uplift loading	90°	P1-1	Carbon steel
		P1-2	Stainless steel
		P1-3	GFRP
2:Lateral loading	0°	P2-1	Carbon steel
		P2-2	Carbon steel
3:Combined loading	45°	P3-1	Carbon steel
		P3-2	Stainless steel
		P3-3	GFRP

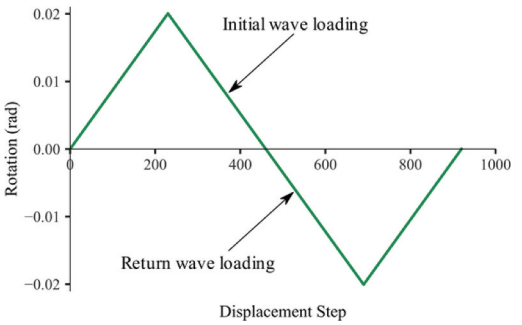

Figure 5. Loading protocol displacement history for uplift loading.

materials investigated in Figure 6. As expected, minimal damage was observed to the pier cap or deck for these eight tests, indicating that damage was effectively concentrated into the bars.

Under the overturning-only loading scenario, the carbon steel and stainless steel bars were subjected to displacements that exceeded their yield limit, resulting in large energy dissipations and residual deformations. The plastic deformation induced on the bars from the initial wave loading meant larger rotations were required to engage the bars under the return wave loading. As such, less bar capacity was activated under the return wave loading for the same rotation (Table 2), which was particularly significant for the carbon steel bars.

On the contrary, the glass fibre reinforced polymer bars (GFRP) exhibited primarily linear elastic behaviour for the overturning only loading scenario. The elastic behaviour of these bars resulted in lower residual displacements and a more optimum return wave response (3.1% degradation compared with 25% and 13.2% for carbon steel and stainless steel, respectively). Additionally, a small amount of slip (0.1-0.2%) was observed in the anchorage.

Applying shear load to the carbon steel and stainless steel bars effectively created a post-tensioning force, activating more bar capacity than the overturning-only loading scenario. However, the shear load weakened the GFRP bars, and one bar prematurely ruptured in the

Table 2. Maximum overturning moment capacity achieved for each loading case.

	Carbon Steel		Stainless Steel		GFRP	
	UP*	LAT/UP	UP	LAT/UP	UP	LAT/UP
Initial wave capacity (kNm)	225.5	229.1	320.8	345.6	222.5	211.5
Return wave capacity (kNm)	169.2	166.9	278.3	276.7	218.2	184.8
Degradation (%)	*25.0*	*27.1*	*13.2*	*19.9*	*3.1*	*12.6*

*Note: UP refers to the uplift-only loading, and LAT/UP refers to the combined lateral and uplift loading. Degradation refers to the reduction in load obtained in the return wave loading compared with the initial wave loading when both are limited to 0.02 radian rotation.

initial wave loading. This bar rupture reduced the total overturning moment capacity by 5.0% for the initial wave loading and 15.3% for the return wave loading, compared with the scenario with no lateral loading. These results have highlighted the need to design shear keys to limit the maximum lateral displacement of the deck. Implementing a well-designed shear key will minimise the shear forces induced on the bars, which is particularly important when utilising the GFRP bars.

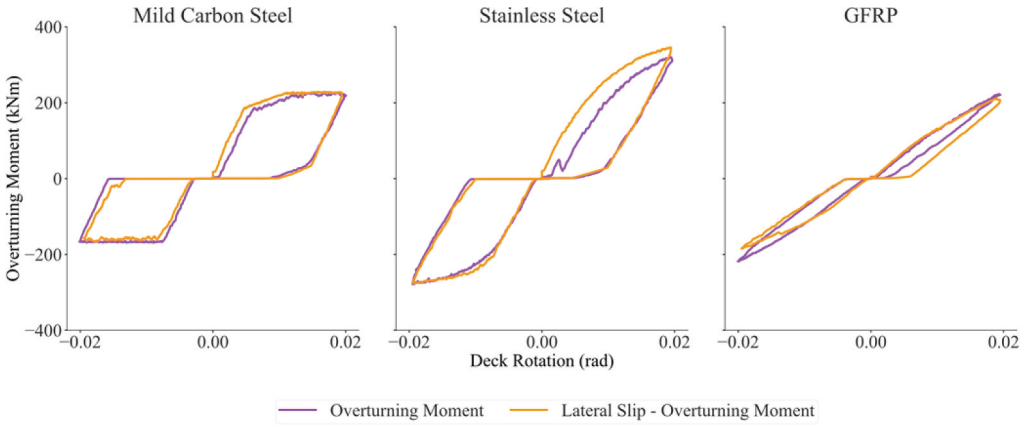

Figure 6. Comparison of the moment-rotation response for all three bar materials investigated.

5 CONCLUSION

The 2011 East Japan tsunami highlighted the vulnerability of bridges to the uplift forces induced by tsunami waves. Reconnaissance indicated that the connection between the deck and the pier was susceptible to uplift forces, and, in many cases, these connections failed, causing the bridge deck to wash out in the tsunami flow.

This research proposes a novel bridge deck-to-pier connection to increase resilience against tsunami inundation. The connection utilises mechanical bars that elongate under tsunami loading, allowing the deck to displace vertically and rotate. By designing the bars properly, damage can be concentrated into these elements, to minimise damage to critical bridge components, including the bridge substructure. Following a tsunami event, repairs are likely limited to replacing the bars and minor concrete repairs.

An experimental study was conducted to validate the theoretical predictions and assess the bar response under typical tsunami loads. Three loading protocols, considering a range of likely tsunami wave angles of incidence, were proposed in this experimental study and could be used for future large-scale experimental programmes. This study highlighted that carbon steel and stainless steel bars effectively dissipated tsunami wave energy but exhibited residual deformations in the initial wave loading resulting in a different return wave loading behaviour. In contrast, the glass fibre reinforced polymer (GFRP) bars had minimal residual deformations and thus had a more similar response under both the initial and return wave loading. However, one of the bars ruptured when shear force was induced on the bars via lateral displacements of the bridge deck. This bar rupture resulted in a reduced capacity for the return wave loading, highlighting the importance of the shear key being designed to limit lateral displacements of the deck.

These tests confirmed that tsunami force could effectively be concentrated into the bar and limit the damage induced on the bridge deck and pier. Based on this, it is anticipated that this proposed bridge deck-to-pier connection could minimise the bridge downtime following a tsunami event. Lastly, the experimental testing highlighted the need to consider the full effects of tsunami forces on a bridge and adapt the structure design accordingly.

ACKNOWLEDGEMENTS

The authors extend their gratitude to Precast NZ for their partial funding of the specimen and to Ramset Reid, BBR Contech, Pultron Composites, GPIl and Freysinnet for their material contributions. Special appreciation is directed to Busck Prestressed Concrete Ltd for precasting the specimens. Additionally, the authors acknowledge the invaluable support and assistance provided by the University of Canterbury's Structural Engineering Laboratory technicians.

The seismic response and resilience of nearby underground infrastructures

M. Dalmasso, M. Civera & B. Chiaia
Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino, Turin, Italy

ABSTRACT: To assess the seismic resilience of civil structures and infrastructures, a detailed investigation of their response to strong motions is required. However, while the effects of major and minor earthquakes on above-ground infrastructures (e.g. road bridges) are relatively well-known, fewer studies have addressed underground ones (e.g. shallow or deep tunnels). In fact, while many bridges are heavily instrumented, few tunnels are equipped with the sensor networks needed for proper structural health monitoring. On the one hand, it is well-expected that both underwater and mountain tunnels will suffer much less significant structural damage than bridges. Nevertheless, research works on their respective responses, analysing comparatively different kinds of tunnels under the same seismic input, are lacking. This is even more true for studies involving recorded data and quantitative measurements. Here, the dynamic responses of one shallow underwater tunnel, built using the immersed tube technique in soft soil, and one deep tunnel, excavated in sandstone and shale rock, are directly compared. These two infrastructures are located close to each other in the San Francisco Bay Area and endured a very close near-fault earthquake. The results show that the tunnel in hard rock guaranteed a higher seismic resilience than the underwater tunnel dug in soft soil.

1 INTRODUCTION

Underground structures and infrastructures have strong robustness to sustain seismic events; nevertheless, they are not immune to them. Depending on the nature of the surrounding soil, several damaging mechanisms may be caused by strong motions.

In loose, water-saturated granular soils such as sand, silt, or gravel, seismic liquefaction can occur. In this scenario, due to the intense shaking of the ground, the surroundings of the tunnel temporarily lose their strength and behave like a liquid. In turn, without external constrictions, the tunnels may suffer uplifting due to their buoyancy in the liquified soil. This is a typical issue of underwater tunnels. Instead, based on the current reports found in the scientific literature, the direct effects of the strong motion on the tunnel structural elements themselves seem to be very limited. Hence, soil-structure interactions seem to be the main cause of potential damage and/or collapse.

The main failure causes are different for what concerns deep tunnels, excavated in rocks or hard soil. Based on the aftermaths of the Mw=7.6 Chi-Chi Earthquake of 21 September 1999 on 57 investigated cases, post-earthquake surveys (Wang et al., 2001) evidenced structural damage in 49 of them. Differently from their underwater counterparts in soft soils, both direct and indirect failure mechanisms were found to be involved. The systematic investigation highlighted the nine most common failure mechanisms as: sheared-off lining, crack development near the opening, bottom cracks, slope failure induced by tunnel collapse, inclined cracks, longitudinal cracks, transverse cracks, extended cross cracks, and wall deformation. Thus, not only site conditions (such as active fault displacement, rock rupture, weathering and decompression) and slope failures at the tunnel openings but also direct damage can be encountered. In this latter case, the tunnel shaking-induced damage is directly dependent on the structural form and building materials, such as e.g. the quality of the reinforced concrete tunnel linings

DOI: 10.1201/9781003483755-183

(Fantilli et al., 2023). Similar effects were observed in Japan (Asakura & Sato, 1996) and the rest of the world (Sharma & Judd, 1991).

To assess the seismic fragility of underground infrastructures some methods have been introduced. For instance, one is based on fragility curves for existing structures, adopting a stochastic approach exploiting the Hazus database (Marano et al., 2011). Another is based on the results of the 3D Incremental Dynamic Analysis (IDA), which takes into consideration bi-directional ground motions and coefficients of the structural components pertinent to the infrastructure (Ma et al., 2024).

However, despite all the scientific literature available on the topic, a side-by-side experimental comparison of the seismic response of deep and shallow tunnels does not seem to have been reported yet. To this aim, this short study directly compares two case studies, located in the San Francisco Bay Area, during the same near-fault seismic event.

2 CASE STUDIES

The two case studies analysed here are the Transbay Tube, also known as the Bay Area Rapid Transit (BART) Transbay Tunnel, and the Caldecott Tunnels (specifically, the third and fourth bores). These infrastructures are all instrumented with permanent Structural Health Monitoring (SHM) systems. They have been chosen based on their proximity, both to each other and to the epicentre of the seismic event of interest, the Mw=4.4 Berkeley Earthquake of 04 January 2018. Their respective locations are reported in Figure 1; considering the position as per the longitude and latitude assigned to the respective stations in the Centre for Engineering Strong Motion Data (CESMD) database[1] (CE58580 for the Transbay Tube, CE58359 and CE58540 for the Caldecott Tunnels), the distances are only 10.78 km and 3.71 km. Hence, the two infrastructures are expected to be highly excited by the very near-fault earthquake.

Figure 1. Locations of the epicentre (Berkeley Earthquake of 04 Jan 2018, Mw=4.4, 02:39:37 PST, 37.8552N 122.2568W Depth 12.3 km), indicated by ☆, and the two infrastructures, highlighted in red, with shakemap MMI contours superimposed in green. Modified from https://earthquake.usgs.gov/earthquakes/eventpage/nc72948801/map.

2.1 *The Transbay Tube*

The Transbay Tube is used here as an example of an underwater tunnel. It connects Oakland (on its East end) to San Francisco (West side), running beneath the waters of the San Francisco Bay. This infrastructure became operational in 1974, operating alongside the San Francisco-Oakland Bay Bridge, which instead opened in 1936. The construction of the tunnel employed an innovative immersion tube technique. Initially, a trench was dug into the bay's

1. https://www.strongmotioncenter.org/

seabed, and then tubular steel and reinforced concrete segments were submerged and subsequently covered with layers of rocks, sand, and gravel.

The tunnel reaches a maximum depth of -41 meters below sea level and spans a distance of 5.8 kilometres. At its terminus, it connects through two boring tunnels. Importantly, this connection is engineered with robust joints designed to allow the tunnel to withstand significant seismic activity without breaking, ensuring safety during earthquakes. In between, the tunnel consists of 57 segments, each averaging 100 meters in length, 7.3 meters in height, and 15 meters in width. Each segment comprises two separate train tunnels, with a pedestrian gallery in the centre intended for emergency purposes.

In the early 2000s, the Transbay Tube underwent seismic retrofitting to reduce movement in case of liquefaction of the surrounding sand and gravel. This retrofitting involved compacting the sand and gravel and utilising concrete-encased supports. Regarding the geological conditions of the infrastructures, Figure 2 reports the official stratigraphy as obtained by soil characterization tests. Generally speaking, the bay soil stratigraphy includes an uppermost layer of marine clay denominated as Young Bay Mud (YBM), overlying Old Bay Clay (OBC) or alluvial sands (Metropolitan Transportation Commission, 2015).

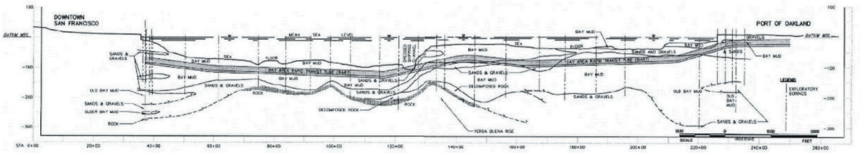

Figure 2. Interpreted geotechnical cross-sections of the Transbay tube alignment across San Francisco Bay. modified from (Parsons Brinckerhoff Quade & Douglas, 1965).

The sensor setup is the one of the CE58580 station, reported in full detail in Table 1. The * symbol indicates the sensors considered for the following analysis.

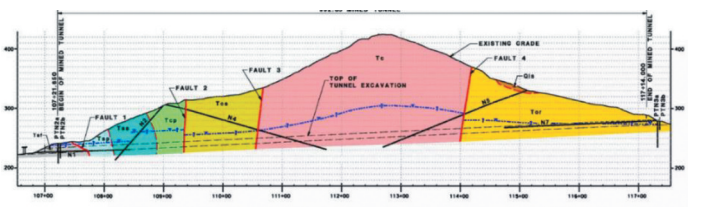
In this regard, to keep this analysis brief yet as complete as possible, it was decided to consider a subset of four other output channels, deemed as the most interesting ones, and focusing only on the transversal response of the infrastructure.

From other ongoing studies (Dalmasso et al., 2024), it was assessed that channel 22, due to its minimal proximity to the (underwater) surface, suffered the largest transverse maximum acceleration. Hence, this channel was selected as representative of the most critical subsection. Channels 2 and 8 are included to account for the behavior of the San Francisco end, before and after the sliding seismic joint. Finally, channel 39 is also included as representative of the opposite end (Oakland side).

2.2 *The Caldecott Tunnels*

The third and fourth bores of the Caldecott Tunnels serve here as examples of deep tunnels. In detail, they belong to the State Route 24 tract that crosses the Berkeley Hills, East of Oakland. The fourth bore was initiated in 2010, finished in late 2012, and opened to traffic on November 16, 2013. It added two 3.7 m traffic lanes to the already-existing three bores. It was excavated with the innovative New Austrian Tunneling Method (NATM). Its typical cross-section is 15.2 m wide, for a total length of 1036 m. Following the standard procedure observed by Caltrans for "critical" structures along vital transportation routes such as SR 24, the seismic design of the Bore 4 relied on the Safety Evaluation Earthquake (SEE), considering a 1,500-year return period seismic event for the design, as well as a less severe Functional Evaluation Earthquake (FEE), considering a 300-year return period seismic event (Thapa et al., 2013). The requirements were set such that the fourth bore should remain fully operational (no or minimal damage) in case of the FEE event and can be reopened within 72 hours in case of the SEE event. These are discussed in more detail in (Yang et al., 2008). Regarding the other three pre-existing tunnels, Bore 3 were built in the early 1960s and instrumented since 1979.

The geologic profile of the mountain is reported in Figure 3. As can be seen, the tunnels intersect four major and three minor faults (all of them inactive) (Jacobs Associates, 2009), which may represent the most critical points. Overall, all strata represent weak, highly fractured, and sheared sedimentary rock formations.



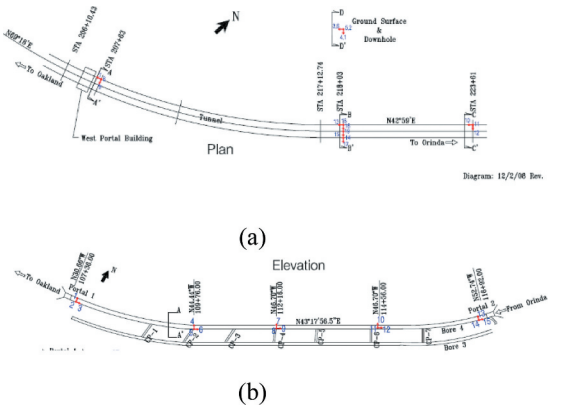


Figure 3. Geologic profile of the Caldecott Tunnels fourth bore. Retrieved from (Jacobs Associates, 2009).

Regarding the sensor layouts, the infrastructure presents two CESMD stations, CE58359 and CE58540, deployed respectively in the older Bore 3 and the newer Bore 4. These include 19 and 21 output channels respectively, shown in Figure 4. In both cases, again for conciseness' sake, it was decided to consider only a subset of accelerometers, located at different cross-sections and oriented in the direction transversal to the tunnel direction. For CE58359, due to the limited number of instrumented cross-sections (only three), all of them were analysed, thus considering channels 9, 12, and 16 (for better comparability with respect to the other options, channels 15 and 17).

For CE58540, it was considered that numerical and, especially, experimental evidence found in the scientific literature highlights two majorly at-risk locations for deep tunnels: the intersections with (active) faults and the portals at both ends. These aspects are confirmed by

the specific structural design considered for Bore 4 (Wilson et al., 2014). Applying these general considerations to the specific case under investigation, channels 1 and 13, located at the two ends of Bore 4, were selected for in-depth analysis. Instead, no channel is exactly located at any fault; furthermore, from the geological recordings mentioned above, they are all considered to be inactive. Thus, channel 7 was considered, due to its mid-length position.

3 RESULTS

In this section, the seismic responses of the selected case studies to the Berkely 2018 event are reported and discussed. These are reported as a side-by-side comparison to better highlight similarities and differences.

More specifically, Figures 5.a and 5.b report the seismic response at the selected output channels in the time and frequency domain. Notably, the accelerograms of stations CE58359, CE58540, and CE58580 have been time-synchronized, thus showing the different times of arrival. Finally, the Arias Intensity build-up curves, also known as Husid diagrams, are portrayed in Figure 6.

(a) (b)

Figure 5. Comparison of the acceleration time series (a) and Fourier spectra (b) at the selected output channels for the shallow underwater and deep underground tunnels.

The record length of the Transbay Tunnel is 65.835 seconds, composed of 6584 points equally spaced by $\Delta t = 0.01$ seconds. On the other hand, the signals recorded for Bore 3 span 58.0 seconds and are composed of 11600 points, while for Bore 4 there are 12255 for a recorded length of 61.275 seconds. Both cases are equally spaced by $\Delta t = 0.005$ seconds.

A key observation from Figure 5.a is the smaller amplitude of accelerograms for Caldecott Tunnel Bore 4 (maximum acceleration registered 0.08 m/s^2) compared with the other two cases (maximum acceleration registered 0.47 m/s^2 and 0.37 m/s^2 for Transbay Tube and Bore 3, respectively). Additionally, the acceleration peaks occur at different times for the three infrastructures. Indeed, the first structure that experiences the maximum acceleration is the Caldecott tunnel Bore 3, then Bore 4 and lastly the Transbay Tube. However, this is consistent with the distances from the epicentre; the delay between the peak acceleration between Caldecott Tunnel Bore 3 and the Transbay Tube is 2 seconds, while it is only 0.7 seconds between the two bores of the mountain tunnels. Interestingly, the seismically-induced oscillation of the Caldecott Tunnel Bore 4 becomes depleted in a much shorter time than the other two infrastructures.

In the frequency domain, signal spectra are analyzed for specific intervals corresponding to the seismic motion of each structure. For the Transbay Tube, it has been considered recorded signals between 28.3 and 43.0 seconds, for Bore 3 it has been considered the signals included between 25.0 and 34.0 seconds and lastly for Bore 4 signals comprehended between 27.5 and 39.5 seconds. Of course, also, in this case, the amplitudes of the Fourier spectra of the Bore 4 are smaller compared with the ones of the other two cases. Aside from a few general observations regarding the energy distribution in the lowest frequencies (below 5 Hz), this visualization of the recorded outputs doesn't provide any immediately discernible specific insights.

The analysis in the time-frequency domain, not fully reported here due to space constraints, enables to see more clearly how the duration of the recording in all the Transbay Tube and the Caldecott Tunnel number 4 is included in the range between 30 and 45 seconds. For the Bore 3, the duration is contained in the range between the 20 and 30 seconds. On the other hand, the frequency content is variable, considering the three different structures, but also considering different channels of the same structure. However, in all cases, this is always mainly contained under 10 Hz. Another distinction between the cases is the amplitude behaviours. For instance, the amplitude of channel 2 of the Transbay Tube decreases much faster than the one recorded at channel 39 of the same infrastructure.

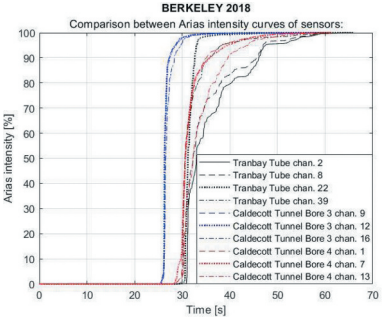

Figure 6. Comparison of the Husid diagrams for all the available transverse output channels of the shallow underwater and deep underground tunnels.

The Husid diagrams offer some interesting perspectives. In fact, they allow us to visualise how the Arias intensity (AI), defined by (Arias, 1970) as

$$\mathrm{AI} = \frac{\pi}{2g}\int_{o}^{t_{max}} a(t)^2 dt \tag{1}$$

cumulates over time. In turn, the AI is a well-known index of the seismic energy, related to the squared ground acceleration at time t, the total duration t_{max}, and the gravitational acceleration g. In this sense, Husid diagrams are extensively employed to estimate the seismic significant duration, as generally done in terms of D_{S595} (Trifunac & Brady, 1975) as the time elapsed between the two instants when 5% and 95% of the total energy is reached. From Figure 6, it can be seen how the D_{S595} duration of the event increases with the distance from the epicentre (it must be remarked that the Caldecott tunnel number 3 is much shorter than the BART Transbay Tube, hence, these effects are much less evident).

However, even considering this geometric attenuation due to the increased distance travelled by the seismic waves, the Husid diagrams offer some hints about the expected dynamic behaviour of the two underground infrastructures.

First, in both cases, the behaviour is similar to the dynamic response induced by an impulsive force since the earthquake epicentre is very close to the two infrastructures, which are both well confined by the surrounding ground. That does not allow for large free vibrations after the initial shock. From Figure 6, this is particularly noticeable for the Caldecott Tunnel bore 3 (in dark blue) at all cross-sections.

In general terms, the response of the Transbay Tube is overall in line with the expected dynamic behaviour of long submerged tunnels under strong motions of similar magnitude - see e.g (Dikmen, 2016) - as also reported in other recent works (Dalmasso et al., 2024).

Conversely, the two bores excavated in the hard rock show, as expected, a lower total duration, which is significant and more evident in the case of Bore 3.

These small yet noticeable differences, fully detailed in Table 2, could explain the different seismic robustness of underwater and mountainous tunnels, excavated (respectively) in soft and hard soils. Please note that all channels are reported, from the top down, in order of increasing distance from the epicenter.

Table 2. Significant duration and Arias Intensity of the selected output channels, ordered from the end closer to the epicentre to the one farther away.

Channel (BART)	D_{S595} [s]	AI [m/s]	Ch. (Bore3)	D_{S595} [s]	AI [m/s]	Channel (Bore4)	D_{S595} [s]	AI [m/s]
39	8.250	0.0021	9	2.355	0.0049	1	8.405	2.93e-4
22	2.370	0.0094	16	3.620	9.84e-4	7	10.410	1.02e-4
8	15.940	0.0029	12	2.575	6.17e-4	13	13.460	6.95e-5
2	16.440	0.0017						

The seismic durations of the channels related to the Transbay Tube are generally (with a few exceptions at specific locations) longer than those of the two bores of the Caldecott Tunnel. On the one hand, this could be a negative aspect since, as it is well-known, a longer seismic event results in more structural damage, all other things being equal (Jeong & Iwan, 1988).

Furthermore, one should consider that, since the infrastructure is considerably long, the seismic duration is higher than 10 seconds for channels 2 and 8, located farther from the epicentre, and lower than 10 seconds for channels 22 and 39, situated closer. Interestingly, for channel 22, there is an outstanding small value, likely due to its minimal proximity to the underwater surface. In a surprising turn, the Caldecott Tunnel exhibits different seismic durations between Bore 3 and 4. Nevertheless, there is a consistent trend within channels of the same bore, due to their much shorter length.

The two bores of the Caldecott tunnel, in general, are subjected to an Arias Intensity one order of magnitude lower than that of the Transbay Tube. This aspect, combined with the Transbay Tube's longer significant duration, can be seen as an explanation of why the deep mountain tunnels can be expected to be at a much lower risk. However, the dissimilarities between the two bores of the Caldecott Tunnel, despite their very close proximity, do not allow us to ascertain which one should be considered at major risk.

All these observations, however, are limited to one strong motion of a particularly close seismic event; thus, their generalization to other (near-fault or not) earthquakes will require further studies on a larger dataset.

4 CONCLUSIONS

This brief contribution reported a comparative analysis of the recorded seismic response of two deep and one shallow tunnels, recorded during the same near-fault seismic event. This side-by-side comparison was made possible by the recent seismic event of Berkeley 2018, which was recorded by the three nearby stations. This study highlighted some major aspects, namely:

- The Caldecott Tunnel Bore 4 experienced an acceleration that is an order of magnitude lower than the one of the Transbay Tube and, most interestingly, the nearby Bore 3.
- The seismic duration of the Transbay Tube is variable in its length, differently from the bores which have almost constant seismic duration. The arias intensity in the Transbay Tube is also higher than the cases of the bore tunnels.
- Therefore, in conclusion, the seismic resilience of the two bores excavated in hard rock can be guaranteed to be higher than that of the underwater tunnel dug in soft soil. This well-known aspect can be explained, at least partially, by their shorter significant duration and lower Arias Intensity, even when accounting for the slightly different distances for near-fault earthquakes.

These preliminary investigations will serve as a basis for future studies in the field of tunnel vibration-based monitoring under strong seismic motions.

ABSTRACT: In the modern transportation networks, such as metropolitan infrastructures, advanced technologies play a crucial role in enhancing efficiency. Infrastructure management is paramount for safety and sustainability. The integration of IoT and digital technologies in smart infrastructures poses challenges in the evolving digital landscape, particularly in ensuring the security and integrity of monitoring data. This study explores the potential applications of blockchain technology to enhance data authenticity and security in real-time subways monitoring. By leveraging blockchain, the study aims to establish a secure digital twin, ensuring the accuracy and integrity of acquired data. The technology's decentralized and tamper-resistant nature makes it well-suited for safeguarding critical monitoring data, offering a reliable foundation for proactive maintenance strategies. The findings indicate a promising avenue for blockchain in fortifying data management and information security in infrastructure assessment. For these reasons, blockchain could represent a valid solution to the modern challenges involved in the lifecycle management of infrastructure such as subways.

1 INTRODUCTION

In recent years, the development of our cities has increasingly focused on maximizing the use of existing built space. In this perspective, the creation of ever-expanding and efficient metropolitan networks allows us to harness technological advancements while respecting environmental criteria and the demand for effective and rapid transportation means.

Similarly, one of the significant challenges of this century is related to the adaptability of our infrastructure to the ongoing climate changes. The application of Internet of Things (IoT) technologies in recent years has resulted in the generation of numerous data, the analysis of which is crucial for the management and implementation of smart cities (Xiaoming, 2022). It becomes indispensable to acquire data with the absolute certainty of its accuracy and security, a necessary objective given the strategic and economic importance that infrastructures such as subways have demonstrated for our cities and societies.

Blockchain technology, originally arising from the financial sector, has recently exhibited such versatility that its application has extended to various fields. Currently, there are three types of blockchains (Swan, 2015):

Type 1.0 associated with cryptocurrencies;

Type 2.0 typically linked to economic, marketing, and financial applications;

Type 3.0 associated with other applications.

The proliferation of IoT devices has ushered in an era of unparalleled connectivity, enabling seamless communication and data exchange. However, this interconnectedness also amplifies concerns related to data security, integrity, and authenticity. Blockchain technology,

DOI: 10.1201/9781003483755-184

characterized by its decentralized, distributed ledger system, provides an innovative framework to address these challenges. IoT systems simplify a real-time data collection and provide automatic and remote control mechanisms, for this they generate massive volumes of data that require network connectivity and power, processing and storage resources to transform these data into information. (Lokshina et al, 2019).

The proliferation of increasingly widespread IoT sensors has led to the generation of large amounts of data that not only need to be protected but also properly managed, maintained, and archived. In the perspective of a vision of interconnected structures and infrastructures aimed at implementing the resilience of our cities, the so-called smart cities (A. R. Javed et al., 2022).

With this scenario in mind, the need to track and certify data becomes indispensable. For this reason, it is crucial to envision consent systems, typical of blockchain technology, that can seamlessly integrate with Big Data management. We can speak about Big Data when the quantities are on the order of petabytes (Al Nuaimi et al., 2015).

Moreover, the application of blockchain technology would not only certify data related to structural monitoring but can also be extended to the broader concept of project monitoring, encompassing cost management and maintenance planning. This would result in the creation of a system characterized by a high level of traceability of actions and transparency, enabling the reduction of the complex bureaucratic processes that typically characterize the management of such infrastructure projects.

The study has therefore set the ambitious goal of identifying a possible architecture that not only ensures data security but also enables its transparent and efficient use at all levels and throughout the entire lifecycle of the infrastructure.

2 BLOCKCHAIN TODAY

Today, blockchain technology has found substantial application in both financial realms, with established projects like Bitcoin and Ethereum, and in the industrial sector. Several companies utilize blockchain for data security and traceability. The strength of this technology lies in its versatility, allowing seamless integration and ensuring interoperability with various data types, especially evident in applications related to Digital Twins used by industries for product development (Götz et al., 2020).

Numerous works in the literature explore the possibility of developing models that integrate blockchain frameworks for applications in Digital Twins and IoT sensors. In the construction industry, the adoption of blockchain has been slower, with many potential applications yet to be explored and evaluated. Certainly, integration with Building Information Modeling (BIM) models has allowed for optimal utilization of BIM methodology, originally designed to facilitate collaboration and information transmission among different processes and stakeholders in the design phase (Krämer et al., 2018).It is noteworthy that for BIM methodology to achieve its maximum potential, data sharing and processing are required by both technicians and stakeholders, who play distinct roles and have different data needs. The success of decision-making processes is precisely determined by the quality of data and the type of communication established. Consequently, over the years, models have been developed that involve the integration of blockchain technology, ensuring the security and traceability, and providing tracking throughout the project's lifecycle, which extends beyond its construction phase.

One of the less-explored applications, which will be examined in the following paragraphs, is the possibility of tracking the various stages that data undergoes. When referring to data, it encompasses not only physical data but any type of information, such as the occurrence of maintenance processes, the entities involved, quantities, and materials utilized.

With the development of new sensors and connected technologies such as 5G, the implementation of Information and Communication Technology (ICT) in Building Information Modeling (BIM) processes has become feasible. Similar to industrial processes, frameworks have been initiated to facilitate integration not only with BIM models but also with sensors that enable real-time data collection from the structure, enhancing decision-making processes

in emergency situations or refining maintenance procedures in consideration of the real-time evolution of the structure. (Pasini et al., 2016).

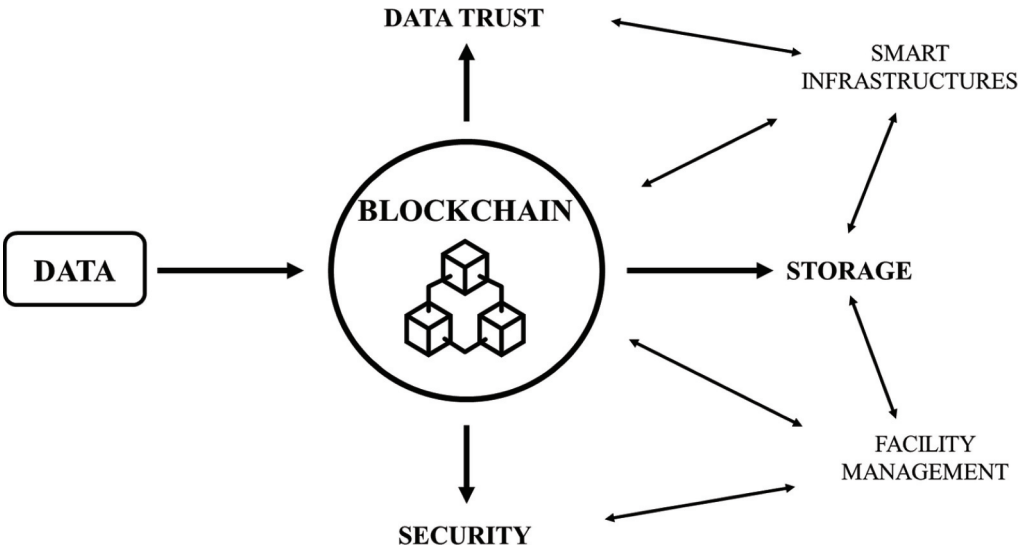

Figure 1. Potential uses of blockchain for data management.

In this context, various authors concur in asserting that blockchain technology presents undeniable advantages when applied to the construction sector.

Consider, for instance, a system combining Cloud computing, IoT, and BIM, which not only requires ensuring data interoperability but also its integrity and accuracy. Tracking the various stages that the data undergoes throughout the project is crucial, along with addressing the significant issue of security, especially concerning critical structures and infrastructure like subways. Such challenges could be effectively tackled with the utilization of blockchain technology would serve as an immutable method to store data and information and use and reuse it at different times. (Kshetri, 2017).

Otherway some of these applications may be affected by one of the still partially unresolved issues of blockchain related to scalability. The term scalability refers to the ability to handle a growing number of transactions without compromising performance. Factors influencing this capacity can be identified by the consensus mechanism used, the block sizes representing the amount of exchanged data, and the number of nodes. That is, the extent, also understood as the physical extension, of the network; each node corresponds to a computer.

Next-generation blockchains have partially addressed these challenges by adopting solutions such as sharding. Sharding is a technique that allows the subdivision into smaller and more easily manageable parts (Zamani et al., 2018).

Alongside sharding, complementary solutions are usually implemented, involving the creation of secondary blockchains alongside the main one with specific tasks; in this case, they are referred to as sidechains (Lohachab et al., 2022).

In any case, it is evident that blockchain technology and the applications arising from it require the resolution of what is defined in the literature as the 'blockchain trilemma,' which involves scalability, decentralization, and security. The trilemma highlights how it is currently impossible to simultaneously implement all three aforementioned characteristics, each of which in turn affects the consensus system (Buterin, 2015), as highlighted by Figure 2.

The trilemma underscores how the implementation of one of the three fundamental characteristics can impact one or even both of the remaining features. Over the years, various solutions have been developed to address this ongoing and evolving trilemma.

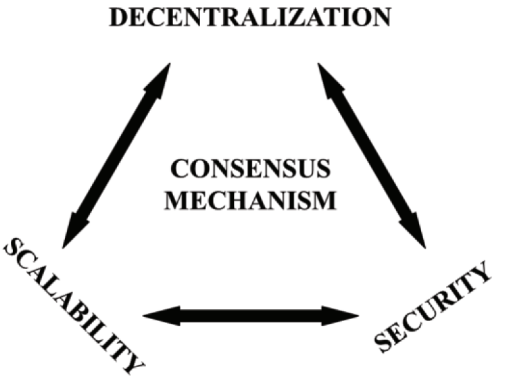

Figure 2. Blockchain's trilemma.

In this regard, the development of new blockchain architectures has significantly improved scalability without excessively sacrificing security or decentralization (Bano et al., 2017).

In the end blockchain could ensure the possibility of access to individual data without the interlocutor gaining access to the entire database. This capability has made the development of blockchain for structure management throughout its lifecycle.

Methodology

The work has focused on defining a potential architecture for implementing a framework that maximizes the benefits of IoT sensors, integrated into a digital twin benefiting from blockchain technology. This study stems from the authors' belief that a digital twin, to be considered as such, not only needs to provide an effective view of the studied infrastructure based on well-defined physical and environmental parameters but also must allow the implementation of functions for efficient facility management while ensuring data management, whether related to a physical-mechanical or economic parameter.

The work has been based on two specific questions:

How is the state of the art of blockchain technology and the level of application it has reached in the construction industry.

What possible architecture to adopt to perform optimally according to the needs presented by such infrastructures?

The work involved an extensive review of existing literature and a deep exploration of blockchain technology-related literature. This enabled an understanding of potential positive aspects while simultaneously identifying possible implementations to address some challenges in applying this technology.

In the Figure 3, you can observe the workflow followed by the team. It is evident how the requirements of these infrastructures have been connected with the characteristics expected of

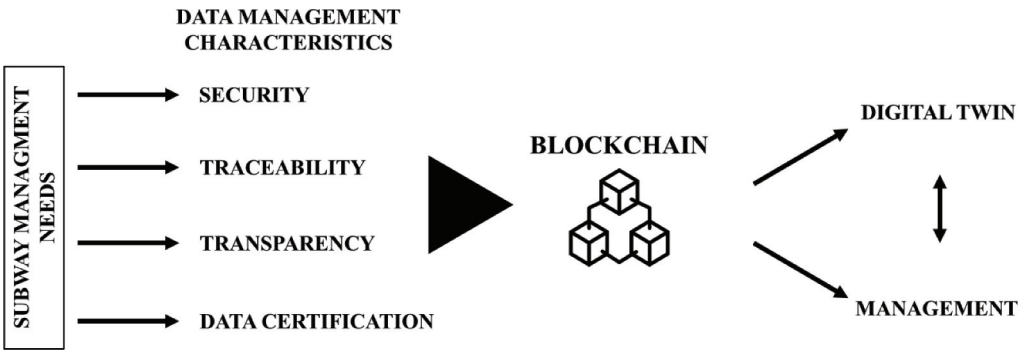

Figure 3. The correlation between the needs of a subway infrastructure and the utilization of blockchain for its management.

a system to be considered efficient from a data management perspective. Starting from data management, the application of blockchain technology has been initiated, with the ultimate focus being the potential implementation in digital twin and LCA systems.

3 APPLICATION

The application of Blockchain technology in the management of subway monitoring systems, as well as in the management and scheduling of maintenance procedures, and handling relationships with various suppliers, presents an innovative approach. The creation of a blockchain framework leveraging recent developments, such as technologies that do not require mining, is a significant step forward. Traditional mining procedures have been associated with substantial computational efforts, resulting in both economic and environmental burdens, particularly in early applications.

Recent advancements have given rise to blockchains like IOTA (Alshaikhli et al., 2022), specifically designed for managing and transmitting data from IoT sensors. The entire infrastructure could be equipped with structural or environmental sensors, collecting data on various parameters under investigation. In this scenario, the operator could decide between two strategies.

The first strategy involves acquiring data from sensors and certifying it. This can occur immediately or by setting a specific delta time to collect data packets that are then certified together.

The second strategy involves connecting, using technologies like 5G, to obtain a digital twin containing the collected data and certifying the final result only afterwards.

As shown in the diagram in Figure 4, the two strategies diverge on the subject of certification. The first proposed solution suggests certifying raw data, allowing not only for archiving but also for safeguarding them from potential tampering. On the other hand, the second strategy involves certifying the digital twin.

Certifying the model not only provides the ability to validate the current state of the infrastructure but also validates various post-processing operations to which the data are subjected.

Both strategies can be executed through manual or automated certification operations.

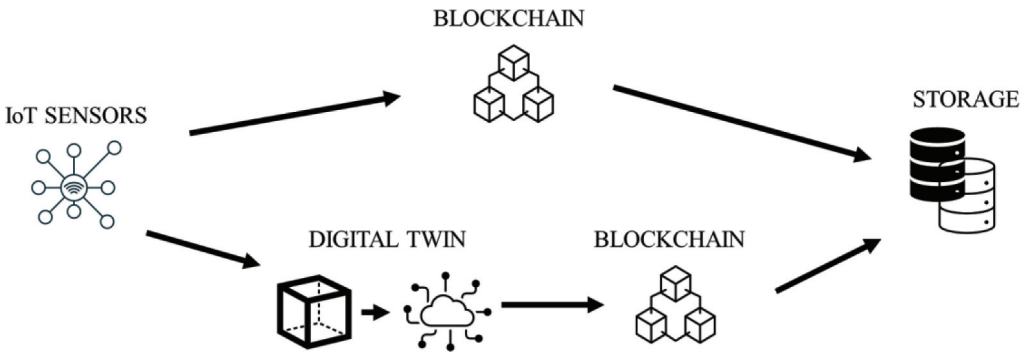

Figure 4. Two possible application of blockchain for data security.

Subsequently, the protected and certified data could be shared with all parties involved in various operations. The framework architecture allows data owners to share data with selected entities, ensuring data compartmentalization among individual users. This procedure ensures traceability and confidentiality levels among different users that the current BIM methodology may not completely guarantee.

Simultaneously, creating a blockchain linked to the structure enables the transmission of useful information for various processes. With a single cryptocurrency, it becomes possible to make payments for services and transmit technical instructions, materials, quantities, and more, all in one transaction, this possibility is provided by smart contracts. (Ghiani, 2021).

To create a smart contract the first step is the parties define the corresponding objectives for each party and agree on the expected outcomes.

In the next step all specifications and contract clauses are written in computer logic language and coded in a programmatic way.

All specifications and contract clauses are then written with computer logic and coded in a programmatic way. Then the smart contract will be sent to the Blockchain, that will be executed on its own when specific criteria are activated. When a consensus is achieved from the majority, the transaction will be added to the ledger, the smart contract will be executed, and the results will be registered (Cachin et al. 2017).

Through the consensus mechanism, it is possible to guarantee the transparency of operations, which is typical of blockchain technology. The application of this procedure allows administrations to establish economic and operational relationships based on a dedicated cryptocurrency. This cryptocurrency acts as a guarantor of a broader system involving operating companies, infrastructure managers, and technicians.

Figure 5. Example of smart contract.

In a way, the cryptocurrency takes on the role of a digital certification for adhering to specific technical, economic, and environmental characteristics. This ensures a quality system among the involved companies, allowing them to demonstrate compliance and adherence to established standards.

In the end with this solution it is possible obtain a system with different characteristics:

Strong security;

Data trust;

Traceability;

Transparency;
Quality control.

The diagram below (Figure6) illustrates the identified architecture intended for use in implementing a framework that can ensure multiple functionalities, proving to be both dynamic and efficient across different territorial and managerial contexts.

The diagram shows how the solutions involve using blockchain in two different time steps. This is because it is believed that the optimal solution should not only have the certification of pristine data, which could also be used in legal disputes, but also utilize the blockchain to certify and protect the digital twin. This solution allows for the creation of a data background and provides a mechanism to have an always updated and verified digital twin that can be used to track various events and interventions that the structure has undergone over the years.

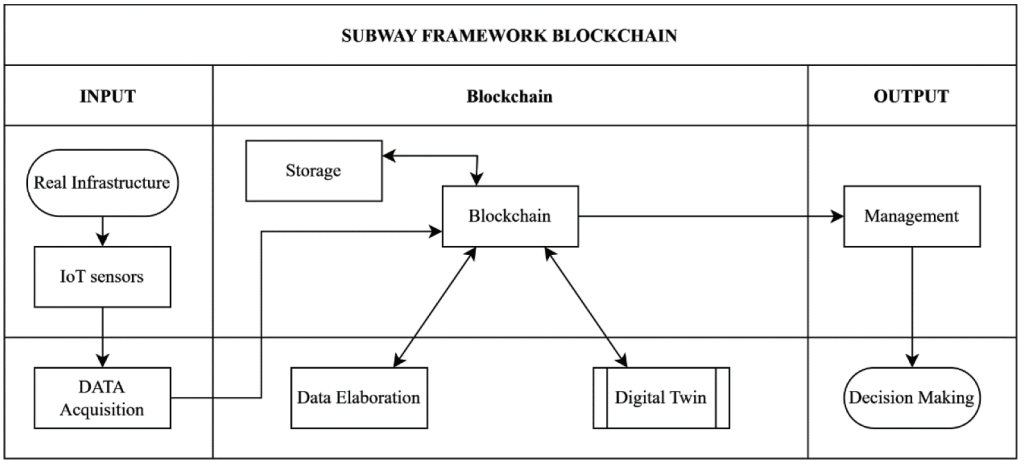

Figure 6. Framework's architecture to use blockchain for subway infrastructures.

The use of a certified model containing all the information, verified and transparent, related to the entire life of the structure is not to be underestimated. In this way, the life cycle analysis process could benefit from it, including the verification of any environmental criteria introduced in the years following the construction and commissioning of the subway.

4 CONCLUSION

This work has allowed for a clear definition of milestones and requirements necessary for the development of a framework aimed at the optimal combination of blockchain technologies with the capabilities of IoT. The obtained results and the defined architecture of the framework will lead to developments, through the use of an open-source ecosystem, resulting in a blockchain that is usable and adaptable to all the needs involved in the physical and economic management of infrastructures such as subways.

It is believed that the use of blockchain can maximize the utilization of existing tools, still underutilized to date, provided by the BIM methodology. Additionally, it serves as a valuable tool to ensure the security and transparency of all operations, both during the construction phase and management phase throughout the entire lifecycle.

D. Hajializadeh
School of Sustainability, Civil and Environmental Engineering, University of Surrey, Guildford, Surrey, UK

ABSTRACT: This paper introduces a novel probabilistic framework for assessing the resilience of highway bridges using a machine learning (ML) algorithm, specifically an ensemble learning tree-based model. By leveraging ML's computational power, the study explores the impact of various parameters on the resilience of concrete box-girder bridges under extreme events, with a particular focus on seismic hazards. Sixteen input variables, including ground motion intensity, concrete and steel strengths, and deck width, are investigated for their influence on the bridge's resilience. Results highlight the importance of features such as peak ground acceleration and the number of bridge columns per bent, offering valuable insights for informed decision-making in the resilience assessment of bridges. The study pioneers an embedded feature identification technique to identify key structural-based resilience identifiers, providing a comprehensive understanding of the resilience drivers in bridge infrastructure.

1 INTRODUCTION

Highway bridges, as integral components of transportation infrastructure, play a pivotal role in ensuring communication efficiency and traffic flow across various regions. However, their vulnerability to catastrophic events poses a significant threat to network functionality, impacting emergency responses and socio-economic recovery. Past seismic events underscored the susceptibility of bridges to severe seismically-induced damages, leading to disruptions in vital transportation routes and, in some cases, catastrophic consequences (Kawashima et al. 2011, Schanack et al. 2012). As urbanization and population growth continue, the need to enhance the seismic resilience of bridges becomes increasingly paramount. The seismic performance of bridges is a multifaceted indicator, involving complex interactions between structural engineering, geotechnical considerations, and regional seismic hazards. Analyzing and understanding the seismic resilience of bridges requires a comprehensive approach that goes beyond traditional structural assessments. This paper delves into the realm of analytical seismic resilience identifiers for bridges, aiming to establish a framework that enables a holistic understanding of a bridge's ability to withstand and recover from seismic events. The outcomes offer insights for targeted optimization of resilient design, rapid recovery processes and sustainable retrofit decisions.

Resilience, defined as the transport network's ability to withstand extreme events, operate during such conditions, and promptly recover upon a disruption, is a paramount consideration in the context of extreme events (Department for Transport 2014, Henry & Emmanuel Ramirez-Marquez 2012, Hajializadeh & Imani 2020). Yet, resilience's complexity and varying definitions pose challenges for decision-making. In the engineering sector, resilience often focuses on post-event rebound capability, quantified by recovery rates or area metrics. Existing models, however, lack flexibility and may overlook uncertainties.

DOI: 10.1201/9781003483755-185

In recent years, advancements in structural engineering, materials science, and data analytics have provided new opportunities to assess and improve the seismic resilience of bridges. This paper explores these developments and seeks to identify key analytical parameters that can serve as resilience indicators for bridges. By doing so, we aim to contribute to the ongoing discourse on enhancing the earthquake resistance of critical infrastructure and mitigating the societal impacts of seismic events.

This study introduces a novel ensemble learning-based resilience model, leveraging machine learning's computational power to discern the impact of structural features on bridge resilience. Unlike classical models, ensemble learning accommodates complex relationships without predetermined functional forms or parameter distributions. By incorporating uncertain configurational features, this research enhances the realism and reliability of resilience estimations, providing a pioneering framework for seismic resilience identification in bridge engineering. Through this exploration, we aspire to offer valuable insights that contribute to the ongoing efforts to enhance the seismic resilience of bridges and, consequently, the overall resilience of transportation networks in earthquake-prone regions.

2 ANALYTICAL SEISMIC RESILIENCE OF BRIDGES

The presented research in this study focuses on the seismic behavior of two-span continuous concrete box-girder (2SCC-BG) highway bridges to build a cohort of case study bridges. The analysis encompasses three distinct design periods: pre-1971, 1971–1990, and post-1990, considering two bridge configurations with rigid diaphragm and seat abutments.

Analytical finite element models are developed for this bridge type across the specified design eras. Box-girder bridges feature integral diaphragms at the bents, serving as solid connections. Bridges constructed before 1971 exclusively transmit negative moments, whereas those built between 1971 and 1990, as well as those constructed after 1990, transfer both positive and negative moments across the interface of the deck and bent columns. Multi-span continuous concrete box-girder bridges incorporate circular columns, their diameter and reinforcement dependent on the number of columns per bent, influenced by the bridge width. Longitudinal and transverse reinforcement ratios dictate the number and spacing of #11 longitudinal reinforcing bars and #4 stirrups in the finite element models. Girders are generally sized according to acceptable depth-to-span ratios, specifically 0.055 for cast-in-place reinforced concrete boxes and 0.04 for prestressed concrete boxes. The superstructure integrates with the diaphragm abutment, transferring all forces and moments. Seat abutments utilize 14 in. x 14 in. elastomeric bearing pads, introducing a 2.5 in. gap at the abutment seat. Single column bents feature a moment transfer connection and are upheld by a pile cap, supported by a cluster of piles beneath it. Abutments consist of a 6 ft tall backwall, supported by Class 70 cast-in-driven-hole piles spaced at 7 ft intervals. The adopted values for concrete compressive strength and reinforcing steel yield strength are 4860 psi and 67.4 ksi, respectively.

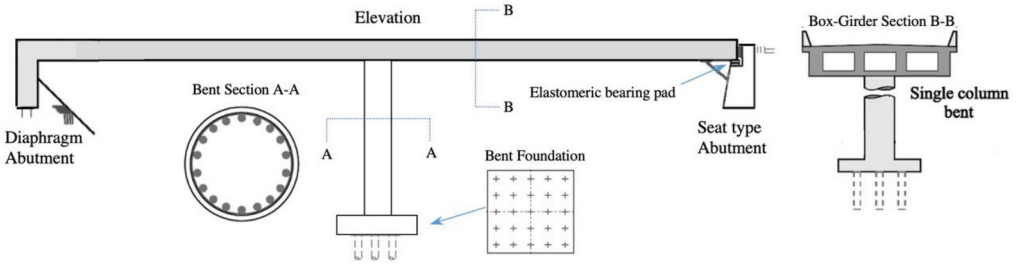

Figure 1. General layout of 2SCC-BG bridges.

The bridges are numerically modeled and analyzed using OpenSEES (McKenna et al., 2000). Figure 1 and Tables 1-2 present the details and characteristics of the modeled 2SCC-

BG bridges. The superstructure is simulated employing elastic beam-column elements with concentrated mass along the centerline, as these elements typically maintain elasticity during seismic events. Composite section properties are utilized in the calculation of deck element characteristics to account for the inclusion of box-girders.

Columns employ displacement-based beam-column elements with rigid links for moment and force transfer within the bent. Rigid links are employed to establish a connection between the column's top and the solid diaphragm. Modeling columns involves the use of discretized fiber-defined cross-sections, offering the distinct advantage of specifying material properties tailored to different locations within a member's cross-section. As an example, unconfined concrete properties are allocated to the cover concrete, while confined concrete properties are designated for the core fibers. Additionally, the exact positioning of longitudinal reinforcing bars and pre-stressing strands can be specified, with corresponding material properties assigned to each.

Transverse rigid elements and displacement beam-column elements model the solid diaphragm and columns, respectively. Translation and rotational springs at the column base represent foundation behavior. Longitudinal response of the abutment considers passive and active resistance, modeled with a hyperbolic soil model. These are represented through linear springs as zero-length elements positioned at the base of the column.

Earth pressures acting on the abutment may arise from the longitudinal response of the bridge deck, and these pressures are further heightened by the impact of the deck against the abutment backwall, particularly in the case of seat abutments. The abutment's reaction in the longitudinal direction differs from that in the transverse direction. Moreover, the longitudinal response encompasses two forms of resistance: passive resistance, occurring when the abutment wall compresses the backfill soil, and active resistance, arising when the abutment backwall moves away from the backfill soil. Passive resistance is contributed by both the backfill soil and the piles, while active resistance is solely provided by the piles. To capture the abutment's response, the hyperbolic soil model proposed by Shamsabadi and Yan (2008) is employed in this study. Zero-length springs, characterized by nonlinear soil behavior, are employed to depict the response of the abutment soil. The HyperbolicGapMaterial feature in OpenSEES is utilized to simulate the response of the backfill soil, based on the model proposed by Shamsabadi and Yan (2008).

For diaphragm abutments, there is no gap between the deck and the abutment backwall, while a gap is present in the case of seat-type abutments. The response of the piles is modeled using a trilinear approach based on the recommendations of Choi (2002). The reaction of elastomeric bearing pads in seat-type abutments is simulated by assigning an elastic perfectly plastic material to zero-length elements, capturing its force deformation response. In continuous bridge superstructures, the control of relative transverse movement between the deck and abutments is crucial, and this is achieved through the utilization of zero-length elements. These elements are defined by the nonlinear force deformation response proposed by Megally et al. (2002), effectively capturing the behavior of shear keys. This study employs the contact element approach proposed by Muthukumar and DesRoches (2006) to model the impact between the deck and abutment backwall, specifically in the case of seat-type abutments. A 4.5% Rayleigh damping is implemented in the time history analysis conducted on the bridge model subjected to a pair of ground motion records.

This study addresses excitations' uncertainty by utilizing Baker's suite of ground motions, which comprises 160 motions compiled by Baker et al. (2011) for the PEER Transportation Research Program. The motions, sourced from the PEER Next Generation Attenuation Project ground motion library (Chiou, et al. 2008), are representative of shallow crustal earthquakes with magnitudes ranging from 4.3 to 7.9. The Baker set includes two sets of 120 broad-band ground motions, reflecting response spectra distribution for moderately large earthquakes at small distances. Additionally, it encompasses a set of 40 ground motions characterized by strong velocity pulses, indicative of sites experiencing near-fault directivity effects.

This study encompasses uncertainties in structural geometric and material parameters, alongside uncertainties associated with ground motions. Parameters susceptible to variation, capturing uncertainties across three significant design eras for the bridge class, are identified. Employing Latin Hypercube Sampling, a set of statistically significant yet nominally identical 3D bridge models is developed by sampling across the parameter range. In total, one hundred

and sixty analytical bridge models are generated to match the number of ground motions in the Baker suite, and these models are then randomly paired to establish bridge model-ground motion pairs. For each scenario, a non-linear time history analysis is executed, and the peak component demands are documented to ascertain the correlation between the peak demands and the ground motion intensity measure.

In this investigation, the susceptibility of various bridge components is examined. Employing finite element models for bridges, pertinent peak demand measures like column curvature ductility, bearing and abutment deformations are documented. Subsequently, probabilistic seismic demand models are formulated, and the fragility analysis procedure is applied to generate analytical fragility curves for both individual bridge components and the entire system (Figure 2).

Table 1. Properties of bridge modelling.

Bridge parameters	Distribution	Units	Distribution Parameters
Concrete compressive strength	Normal	ksi	μ=5.0, σ=0.63
Reinforcing steel yield strength	Lognormal	ksi	μ=4.21, σ=0.08
Span length	Empirical	ft	μ=114.8, σ=40.5
Deck width	Empirical	ft	μ=67.2, σ=42.2
Vertical under clearance	Empirical	ft	μ=18, σ=3.7
Abutment concrete pile effective stiffness	Lognormal	kip/in	μ=80 σ=00.3
Damping ratio	Normal	-	μ=0.045, σ=0.0125
Shear modulus of elastomeric bearing pads	Uniform	ksi	[80-250]
Abutment backwall height	Uniform	ft	[3.5-8.5]
Gap between deck and seat type abutment backwall	Uniform	in	[0-1.5]
Restrainer cable length	Uniform	ft	[8-20]
Mass factor	Uniform	-	[1.1-1.4]

Table 2. Component capacities adopted in this study.

Engineering demand parameter	Eras	Units	DS1	DS2	DS3	DS4
Column curvature ductility	Pre 1971	NA	0.8	0.9	1.0	1.2
	1971-1990	NA	1.0	2.0	3.5	5.0
	Post 1990	NA	1.0	4.0	8.0	12.0
Deck displacement	All	Inches	1.0	3.0	10.0	15.0
Foundation rotation	All	Radian	1.5	6.0	NA	NA
Foundation displacement	All	Inches	1.0	4.0	NA	NA
Bearing displacement	All	Inches	1.0	4.0	NA	NA
Abutment passive displacement	All	Inches	3.0	10.0	NA	NA
Abutment active displacement	All	Inches	1.5	4.0	NA	NA
Abutment transverse displacement	All	Inches	1.0	4.0	NA	NA

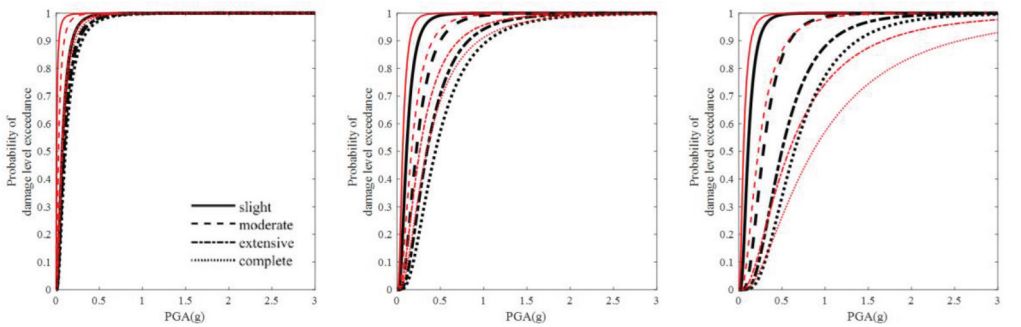

Figure 2. Fragility curves of the investigated bridges – black and red lines correspond to rigid and seat abutment accordingly.

The probabilistic seismic analysis of structures involves the development of seismic demand models, often presented as probability distributions describing structural responses contingent on a seismic intensity measure. These demand models represent the likelihood of structural demand given the intensity measure and are referred to as probabilistic seismic demand models.

Fragility curves are the most common approach considered in bridge risk assessment for diverse bridge components, depicting engineering demand parameters (EDPs) such as column curvature ductility as a function of intensity measures for diverse hazard scenarios (e.g. fatigue (Aloisio et al., 2023) and flooding (Pucci et al., 2023)). In the seismic risk assessment context, often modeled through a single-variable linear regression (Equation 1), fragility curves estimate median values with variability expressed through dispersion (β_{DM}) (Equation 2), a methodology introduced by Shome et al. (1998) and applied extensively in bridge performance analyses (Gardoni et al., 2003; Padgett and DesRoches, 2008; Zhong et al., 2008; Ramanathan, 2012; Soleimani et al., 2017a). Modified seismic demand models tailored to specific bridge characteristics have also been proposed (Soleimani, 2017; Soleimani et al., 2017b; Soleimani & Liu, 2021).

$$\ln(\mu_{DM}) = \ln(a) + b\ln(IM) \tag{1}$$

$$\beta_{DM} = \sqrt{\frac{\sum_{i=1}^{n} [\ln(DM_i) - (\ln(a) + b\ ln(IM_i))]^2}{n-2}} \tag{2}$$

Seismic fragility involves convolution of demand and capacity models, with analytical fragility curves expressing the probability (Equation 3) for a bridge component's performance given seismic intensity. To estimate bridge system fragilities, a joint probabilistic approach and Monte Carlo simulations are often employed (Nielson and DesRoches, 2007). Limit states are characterized by mean (S_C) and dispersion (β_C) values, assumed to be lognormal, akin to Probabilistic Seismic Demand Models (PSDMs). However, this lognormal assumption may not universally apply, prompting the need for a more generalized machine learning (ML)-based framework.

$$P[S_D \geq S_C|IM] = \Phi\left(\frac{\ln(\mu_{DM}/S_C)}{\sqrt{\beta_{DM}^2 + \beta_C^2}}\right) \tag{3}$$

In this study, $P[S_D \geq S_C|IM]$ is used to formulate normalized bridge performance indicator ($\bar{Q}(t)$) as shown in Equation 4, which in turn used to quantify resilience. A performance indicator represents bridge following a seismic event, in which structural capacity decreases, depending on the failure absorption patterns, varying intensity of hazard and structural specifications. Typically, failure absorption patters are simplified as a sudden drop in performance, categorized as slight, moderate, extensive, and complete damage states (FEMA, 2009). Upon duration of stabilization following full failure absorption and depending on the recovery resources available, the performance indicator is restored to a new/original level. For the purpose of this study, the asset's behavior is formulated post-failure absorption with sudden drop in performance, corresponding to four damage states of slight, moderate, extensive and completed. Whilst acknowledging a wide range of possible recovery trajectories for different types of bridges and context, for the purpose of demonstration of the concept, recovery trajectories as recommended by (HAZUS-MH, 2011) with mean recovery times ($m_{t,d}$) and standard deviations ($\sigma_{t,d}$) for each damage state are used in this research. The area of remaining performance indicator is used as resilience indicator in this study.

$$\bar{Q}(t) = \sum_{d=1}^{nDs} (1 - P[S_D \geq S_C|IM]) \times \Phi\left(\frac{t - m_{t,d}}{\sigma_{t,d}}\right) \tag{4}$$

3 ENSEMBLE LEARNING-BASED METHODOLOGY

In recent years, the field of structural engineering has increasingly turned to machine learning as a powerful tool for predicting and evaluating the seismic response of structures. The emergence of ensemble learning as a promising paradigm has added a new dimension to this

approach (Yang et al. 2010, Harrou et al. 2019, Li et al. 2019), leveraging the strengths of multiple individual models to enhance predictive performance and generalization. This study explores the application of ensemble learning methods, particularly focusing on the widely used Random Forest algorithm, in the analysis of seismic resilience identifiers for bridges.

Ensemble learning methods, introduced by Dietterich (2000), are recognized for their unbiased nature and their ability to capture complex relationships between input and response variables. Their popularity stems from the reduction of model variance with low bias, making them effective in addressing challenges such as weak predictors, small sample size, and overfitting of training data. The unique approach of ensemble learning in combining multiple individual learners contributes to enhanced prediction quality relative to single regression models, thereby reducing overall prediction error.

A cornerstone of the ensemble learning methodology is the decision tree algorithm proposed by Breiman et al. (1984), which efficiently addresses large datasets, complicated data structures, and missing values. While individual decision trees provide intuitive insights into the relationships between input variables and outputs, they are sensitive to minor changes in the training dataset. The ensemble method, encompassing multiple decision trees generated in parallel or sequentially, overcomes this sensitivity and prevents overfitting, improving accuracy and generalization ability (Ishwaran and Kogalure 2010, Yang et al. 2010, Zhou 2021).

Random Forest, a prominent ensemble learning technique, constructs multiple regression trees in parallel, with no interaction between them (Liu et al. 2012). This technique is particularly well-suited for the complex and multidimensional nature of seismic resilience assessment in bridge engineering. By aggregating predictions from diverse individual trees, Random Forest enhances robustness, reduces overfitting, and provides valuable insights into the intricate interplay of factors contributing to the seismic resilience of a bridge (Hastie et al., 2009).

Our methodology employs Random Forest to analyze a comprehensive set of seismic resilience indicators for bridges, encompassing structural characteristics, material parameters, and seismic data. The ensemble learning approach allows the integration of information from various sources, extracting nuanced patterns not apparent through traditional analytical methods.

The interpretability of Random Forest enables the identification of influential factors contributing to the seismic resilience of bridges. This understanding allows engineers and policymakers to prioritize interventions and design strategies, ultimately enhancing the overall resilience of bridge structures in seismic-prone regions.

In this study, a random allocation of 80% to training and 20% to testing is employed. Sixteen input variables are selected to encompass material, geometric, and structural properties, along with PGA, for predicting bridge resilience. Subsequently, the seismic resilience is estimated for the testing dataset using the models trained with Random Forest.

4 SEISMIC RESILIENCE INDICATORS

This section presents the critical evaluation of the impact of input bridge characteristics on predicting the resilience index. Beyond gaining insights into the most influential parameters in

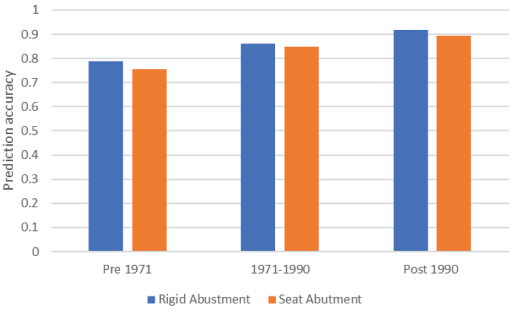

Figure 3. Evaluation of the predictive model (prediction accuracy).

defined bridge resilience indicator, identifying input variables with minimal relevance allows for their exclusion, reducing model complexity and optimizing efficiency. Figure 3 presents the prediction accuracy of the developed predictive model for all three eras and two groups of rigid and seat abutment cases.

To gauge variable importance, the EL algorithm, a random forest, permutes variables to track averaged changes in prediction errors and node impurities throughout the tree-splitting process. Figure 2 illustrates variable importance measured using EL algorithms (logarithmic scale). These scores indicate the contribution level of each variable to outcome prediction, with higher scores indicating more significant contributions.

As can be seen from Figure 4, overall, the most predictive parameters are Peak Ground Acceleration (PGA) and the number of column bents, whereas soil type (sand or clay), girder type (prestressed or reinforced concrete) and column diameter are less predictive. The impact of PGA is attributed to fragility curves' importance in resilience index calculation. While both PGA and structural parameters influence fragility curve shapes, structural characteristics exhibit a more gradual impact compared to the pronounced effect of PGA. Additionally, the recovery projection patterns used in this study are solely a function of damage state, which could be enhanced by formulating recovery projections based on diverse structural forms and characteristics, albeit beyond this study's scope.

Further examination in Figure 4 reveals that reinforcement ratio and superstructure depth consistently rank among the top five influential features. Foundation translational stiffness is prominent for bridges from the pre-1971 and 1971-1990 eras. Column height significantly influences bridges with rigid diaphragm abutments, particularly those designed in earlier eras, while bridges with seat abutments showcase greater sensitivity of column height in earlier era designs. Conversely, deck width holds more influence for bridges with seat abutments compared to those with rigid diaphragms.

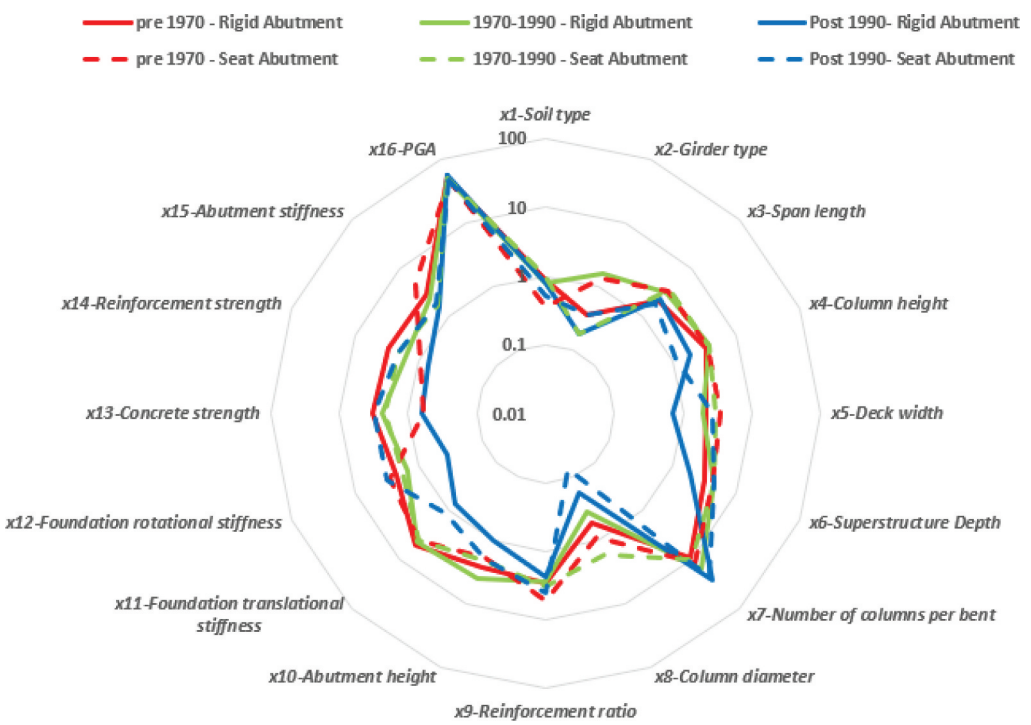

Figure 4. Features ranking based on their level of importance measures in predicting bridge resilience.

These observed distinctions may be linked to increased vulnerability, particularly of columns, in bridges designed in earlier eras compared to more recent, seismically advanced structures. Differences in results between bridges with seat and rigid abutments may be attributed to their structural performance under seismic excitation, with rigid abutments moving synchronously with the superstructure, while seat abutments and superstructures move independently.

5 SUMMARY AND CONCLUSIONS

This research delved into the potential utilization of ensemble learning (EL)-based machine learning (ML) algorithm using random forest, to predict the seismic resilience of bridges reliably. Sixteen parameters were scrutinized as input variables for developing EL-based models, which play a crucial role in the analytical development of probabilistic seismic demand and fragility curves used to quantify bridge seismic resilience.

To assess the predictive performance of the EL-based model, the accuracy is presented showing a consistent level of good accuracy for different bridge groups.

Furthermore, the study measured the feature importance of the considered variables and provided a ranking based on their contribution to predicting seismic resilience. Ground motion intensity (PGA) and the number of bridge columns per bent emerged as the most influential features in all scenarios, while the type of superstructure girder and soil had the least impact on predictions. This insights into influential parameters can inform decisions in bridge resilience assessment and aid in developing concise models.

The research presented EL-based methodology, shedding light on the application of ML algorithms in seismic resilience assessments of bridges. Future studies can address limitations by testing the generalization of findings to other bridge types, such as I- and T-girder bridges, and exploring the sensitivity of bridge resilience to different ground motion characteristics beyond the considered PGA in this study.

Dynamic measurements for assessing bridge response to foundation scour

M. Aimar, M. Civera, B. Chiaia, S. Foti, A. Quattrone & D. Sabia
Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino, Turin, Italy

ABSTRACT: Hydraulic actions are considered one of the main causes of bridge collapse worldwide. Among them, foundation scour plays an important relevant role. However, the assessment of foundation conditions is a difficult task, especially for existing bridges. Indeed, a complete characterization is often hindered by the limited accessibility and, in some cases, by the lack of available information on both the structural and the geotechnical design. On the other hand, an effective identification of foundation scour can be crucial for an accurate prediction of the long-term bridge performance, also for the planning of possible retrofit interventions. This paper presents the results of an experimental study carried out on a road bridge in Piedmont, severely affected by foundation scour and under strict surveillance by the Metropolitan City of Turin. Dynamic measurements were collected on the superstructure and the foundations. This enables to get an insight into the modal response of the deck and to detect asymmetries in the foundation behavior due to the presence of scour. This study demonstrates the potential of in situ measurements as a tool for the characterization of scour conditions of existing bridges and thus for the improvement of the resilience of transportation infrastructures.

1 INTRODUCTION: FOUNDATION SCOUR IN RIVER BRIDGES

The particular case study of interest, which will be detailed in the remainder of this paper, regards a riverside tract of a long road bridge. Indeed, even when bridges and viaducts just run alongside the river bank, without crossing it, they can be heavily affected by the time-varying conditions of the water-soil-foundation interactions.

In this regard, foundation scour is, by far, the most common cause of collapse for river bridges (Borlenghi et al., 2022) Recent examples of severely scoured bridges in Italy can be found in (Pizarro et al., 2020) and (Aimar et al., 2024).

Therefore, the scour phenomenon requires particular attention from geotechnical, structural, and hydraulic engineers, especially since its complex dynamics are not yet totally understood and easily predictable (Borlenghi et al., 2022; Ciancimino et al., 2021, 2022; Foti et al., 2023).

To this aim, this short contribution presents some preliminary results from dynamic identifications carried out on the deck and foundation caps of one segment of a very long road bridge, located in Inverso Pinasca (Piedmont, Northwestern Italy) and subject to heavy scour due to an ongoing change in the Chisone river course.

2 THE INVERSO PINASCA BRIDGE

The Inverso Pinasca bridge is part of a large set of renewal works performed between 2004 and 2005 to improve the road connection between Turin (the 2006 Winter Olympic Games host city) and Séstriere (a main ski resort) on the SP 166 road through the Chisone Valley. This route is inserted in an Alpine environment, with most of the traffic occurring during the winter season due to the influx of ski and mountain tourists. In

DOI: 10.1201/9781003483755-186

particular, the small village of Inverso Pinasca (circa 600 inhabitants), as the Italian name *Inverso* (inverse) suggests, lies on the southern side of the valley, shadowed by the mountains. The majority of the other villages are situated on the northern (sunnier) side of the Chisone River. The bridge object of this study follows this southern bank before crossing the river after the village.

Figure 1. Side view of the Inverso Pinasca bridge in its full length, as captured during preliminary in situ surveys (February 3rd, 2023).

2.1 *Details of the tract of interest: Foundations and superstructure.*

The whole bridge (left side of Figure 2) measures 1849.90 m from end to end. The superstructure consists of four continuous decks, divided by expansion joints (that make all segments act as detached, independent units) and lying on 45 piers. the deck width is constantly 14.6 m, with one lane per direction.

The tract of interest is highlighted in red in Figure 2. It has a mixed profile, with rectilinear and curvilinear sections. These are located (as mentioned earlier) between the Chisone River on their East side and the small town of Inverso Pinasca on the West side.

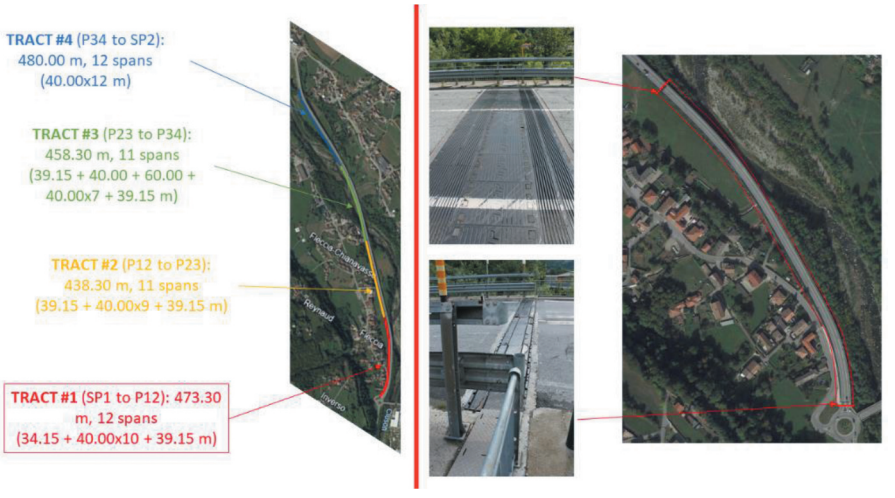

Figure 2. The four segments of the bridge continuous deck, with the one of interest (tract #1) highlighted in red and zoomed in on the right side. The two joints at its South and North ends are also portrayed.

The superstructure lies on deep foundations, with 8 piles per pile cap. These piles are particularly large (1.5 m in diameter), with a depth varying at each pier but included in a minimum of 14 m (pier P1, corresponding to the Southern abutments) and a maximum of 33 m (P24, out of the tract of interest here).

2.2 *Site-specific risks*

The area where the bridge lies is relatively seismically active, if compared to the rest of the Piedmont region. However, in absolute terms, it is classified as a low seismic hazard area, with an expected Peak Ground Acceleration (PGA) of 0.133 g (class 3S according to the local implementation of the Chapter 7 of the Italian NTC 2018 (Ministero delle Infrastrutture e dei Trasporti, 2018), considering a 10% probability of exceedance in 50 years). It is also worth noting the state-of-the-art seismic design of the bridge, where all bearings rest on seismic isolators.

From a hydrogeologic perspective, the area is free from landslide hazards, with only some slow ground movements on the north bank (hence, on the opposite side of the Chisone River) and no avalanche hazard due to the relatively warm climate year-round at the valley bottom.

Instead, the whole length of the infrastructure is classified by the Istituto Superiore per la Protezione e la Ricerca Ambientale (ISPRA)[1] as a high flood hazard area. The last major flood (October 2000, when the bridge of interest was yet to be constructed) caused the collapse of a nearby river crossing. Therefore, from a multi-risk assessment point of view, the potential scouring of the bridge piers can be identified as the main potential source of danger.

2.3 *Current scouring state*

The repeated alluvial events that affected the Chisone valley since the construction year (for instance, in 2010 and 2016) induced a migration of the main channel of the river, which has gradually shifted towards the orographic right, in correspondence with the bridge piers. The migration has resulted in strong undermining of the pier foundations in correspondence with a portion of the bridge, namely the one between P8 and P11. The modified shape of the streambed resulted in the exposure of the top part of foundation piles and general scour of piers, with depths up to 3.8 m for pier P9 (computed from the bottom surface of the pier cap) and 3.5 m for pier P10. It has to be remarked that the scour hole is not symmetrical because of the presence of a scarp more or less around the longitudinal axis of the bridge. Therefore, only half of the foundation is exposed. Furthermore, the scour hole below pier P8 has been partially refilled with coarse soil to prevent further erosion in this portion.

A map of the surveyed piers is reported in Figure 3, with the respective photo documentation of the scouring state as of mid-2023.

3 THE DYNAMIC IDENTIFICATION CAMPAIGN

The aim of the dynamic identification campaign was two-fold. On the one hand, it focused on the estimation of the modal parameters of the superstructure. Furthermore, it targeted peculiarities in the soil-structure system response to have an indirect insight into the influence of scour on the dynamic response, in terms of asymmetric features in the behavior. For this purpose, the survey focused on a portion of the bridge including parts affected and not affected by scouring. Indeed, the relative response can directly provide indications about the scour influence.

The setup included 13 PCB 3701G3FA3G uniaxial capacitive sensors, mainly located along the external longitudinal beams of the deck (Figure 4). The asymmetric location was mainly dictated by the accessibility of the beams on the river side, due to the presence of the scarp. In

1. https://idrogeo.isprambiente.it/app/pir

addition, 5 PCB 356B18 triaxial capacitive sensors were located on the longitudinal beams, in correspondence with the piers, to track the complete motion and to capture the influence of the seismic bearings.

Furthermore, high-sensitivity (10 V/g) PCB 393B04 piezoelectric sensors were located on the top of the foundation pad, both in uniaxial vertical or multiaxial configuration, to track the motion of the pier. The considered piers were P7, P8 and P9, each characterized by a different scour magnitude (Figure 5). For all the piers, a minimum sensor layout was adopted, consisting of four vertical sensors on the corners plus one/two horizontals, to track the relative asymmetries in both the vertical response and the horizontal response. However, being P9 the most deteriorated pier, a dense layout was adopted for this.

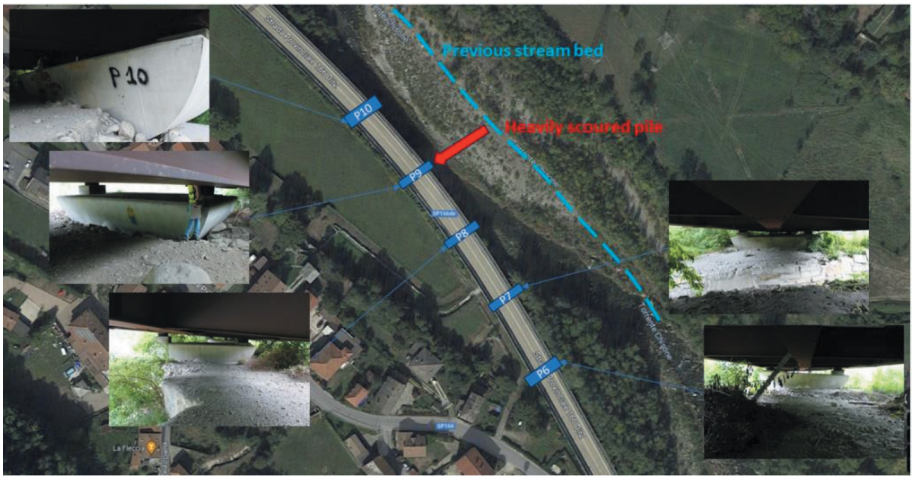

Figure 3. The current (mid-2023) scouring state at the pier foundations of interest. The most critical one (P9) is indicated by the red arrow. The blue dashed line represents the river course as of 2004 (during construction).

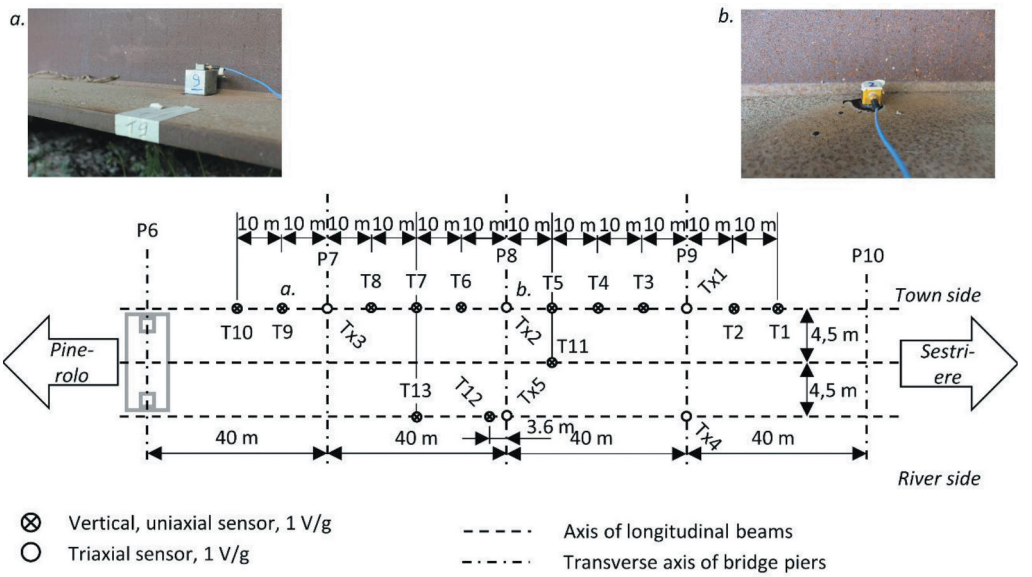

Figure 4. The sensor layout for the bridge deck, including a picture of the capacitive uniaxial (a) and piezoelectric triaxial (b) Accelerometers.

The acquisition was carried out through a 40-channel, LMS Siemens SCADAS acquisition device, using a 256-Hz sampling rate.

The limited number of channels and of high-sensitivity sensors compared to the inspected locations forced to perform the measurements through multiple setups. In all the setups, the

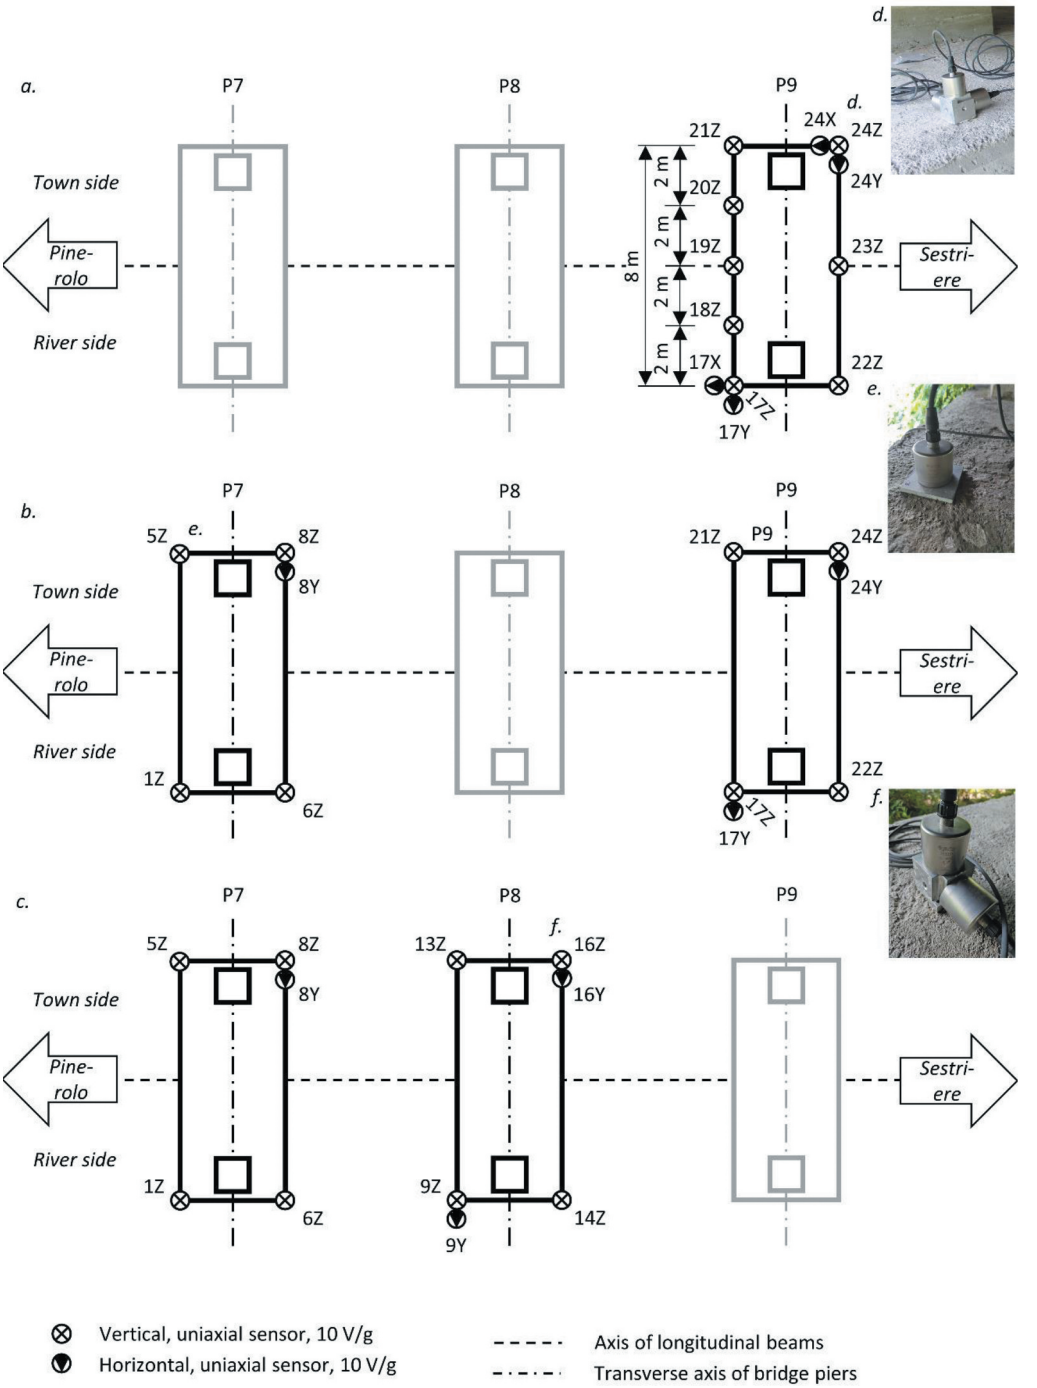

Figure 5. The first (a), second (b) and third (c) sensor layouts for the pier caps, including a picture of the high-sensitivity accelerometers in uniaxial (e), biaxial (f), and triaxial (d) configuration.

sensors on the deck and part of those installed on pier P9 were kept unchanged, also to provide a reference for the normalization and harmonization of measurements, whereas the high-sensitivity sensors were located to measure each couple of piers (i.e., P7-P9, P7-P8 and P9 only; see Figure 5). The rationale behind this strategy is to address the relative response of each couple of piers, with different scour conditions, to have an insight into the effect of scour.

4 PRELIMINARY RESULTS

The results described in this section refer to the first insights gained from a preliminary analysis of the gathered acquisitions, in terms of the response of the bridge deck and pier foundations.

4.1 *Insights from the bridge deck*

From a preliminary analysis of some of the signals acquired from the sensors deployed on the bridge deck, the main vibrational modes of the bridge deck in the tract under investigation seem to be a first vertical flexural mode at circa 2.20 Hz and a torsional one at 2.44 Hz. These values are averaged over six different ambient vibration acquisitions, analysed with the Automated Operational Modal Analysis code described in (Civera et al., 2022; Mugnaini et al., 2022). Both modes appear to have a relatively high damping, with the damping ratio ξ being larger than 2.5% in both cases. This is most likely due to the presence of seismic isolators at all bearings.

Furthermore, the detailed analysis of all modes highlights an asymmetry between the town- and the river-side. That is to say, the peak relative displacement (corresponding e.g. to the antinode at midspan for mode #1; see Figure 6.a) was found to be higher on the side of Inverso Pinasca, in all acquisitions. Considering six signals and the first mode shape, this difference in peak amplitude can be estimated at 28.51 ± 2.08 % ($\mu \pm \sigma$), thus, almost a third. Considering that all the sensors start from their zero, the slight transverse inclination of the deck should not have a direct influence. However, some numerical simulations of the uncalibrated FE model of the deck only (Figure 6.c) show that the leftward curvature of the deck naturally induces some higher vibration amplitudes on the riverside, as was also well expected. Nevertheless, these asymmetries could be (at least partially) also exacerbated by the absence of the scoured ground on the riverside (due to the loss of stiffness). Therefore, these aspects will need further studies to be properly investigated and understood.

4.2 *Insights from the pier caps*

For a quick assessment of the foundation response, this study estimated the RMS vertical acceleration (here, labelled as a_z) recorded at the vertices of each pier cap, consistently with the approach adopted in (Foti & Sabia, 2010). For a more reliable estimate, a_z was computed from 10-s long time windows extracted from the recorded data, each corresponding to the passage of a vehicle on the bridge deck. Figure 7 shows the estimated a_z for piers P7 and P9, that is, the ones with the least and the most scoured foundations. Results are clustered according to the side of the load application. Furthermore, they highlight the trend on the upstream side and the downstream side, to investigate asymmetries both in the town-river direction and along the longitudinal axis of the bridge. Finally, for each pulse considered, a_z data are normalized with respect to their average value, to remove the influence of the load entity on their magnitude.

In all the cases, a larger a_z is observed at the side corresponding to the load application, as expected. However, some relevant differences can be observed when comparing the dynamic behavior of P9 and P7. On the one hand, the spatial distribution of a_z is similar when vehicles pass on the town side, in terms of asymmetry. Instead, for loads

on the riverside, a_z is quasi-uniform in P7 (as the normalized value is almost close to the unit) whereas larger variations are observed for P9. This means that, for the same loads, the vibration levels in P9 are highly asymmetric compared to P7, due to the stiffness variations induced by foundation scour. On the other hand, in P9, a_z is significantly larger downstream than upstream. Notably, this is observed both on the town side and on the river side, for all the considered load pulses and application locations. Instead, this discrepancy is smaller in P8 (not reported here) and almost negligible in P7. This result was somewhat unexpected, as the erosion mostly acts along the longitudinal axis of the bridge and should not produce relevant differences in the response between upstream and downstream. Instead, this evidence may indicate that stiffness variations in the soil-structure system due to scour also occur along the flow direction of the river – and not only in the transverse direction, as it may be expected from the available information. This may be a consequence of the curvature of the main river channel, which results in a complex morphology of the scour hole.

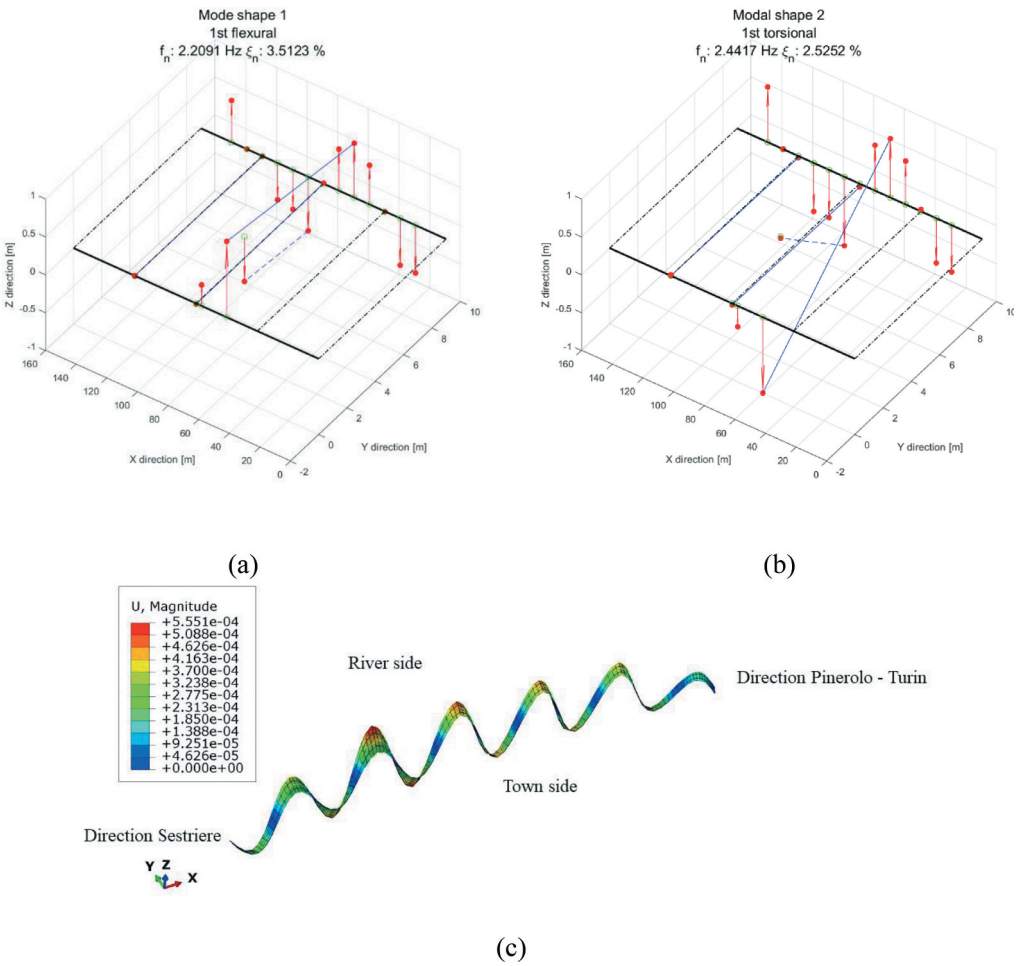

Figure 6. (a-b) The mode shapes identified from the deck bridge dynamic response (example taken from the ninth acquisition). The blue lines connect the modal displacements captured by the accelerometers located on the town side of the deck with their counterparts on the other side (or at mid-width for T5-T11). The black lines represent the deck layout in its undeformed shape. (c) First flexural mode, according to a preliminary simulation (uncalibrated, deck only) run on Abaqus 2019.

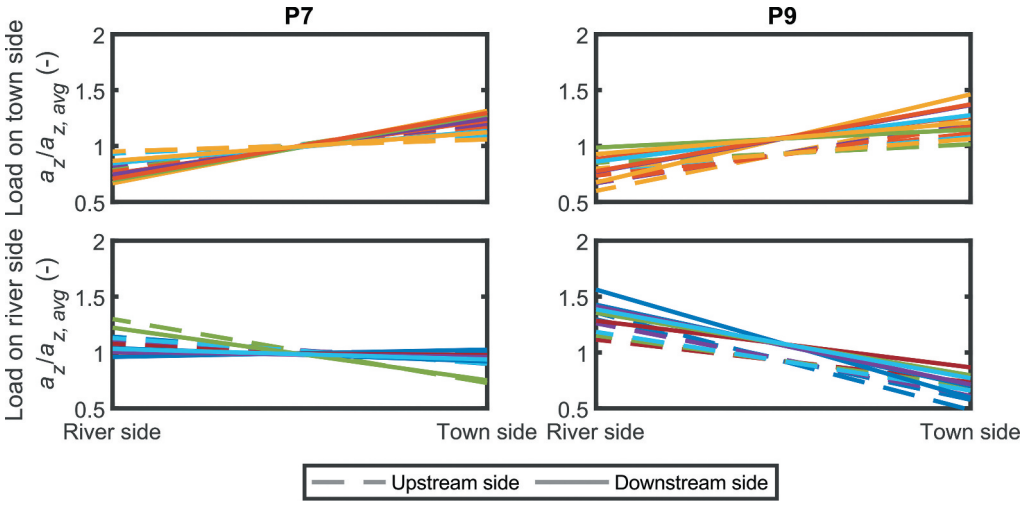

Figure 7. Estimated normalized acceleration RMS at the pier caps, for P7 and P9 and for loads applied on the town side or the river side. Results are clustered according to the considered side of the pier cap (i.e., downstream and upstream). Each color corresponds to a specific load (i.e., vehicle moving on the deck), with the continuous line representing the vibration level observed downstream and the dashed line representing the response on the upstream side.

5 CONCLUSIONS AND FUTURE WORKS

This study described the experimental campaign carried out to investigate the dynamic response of a multi-span bridge near to Turin, which is affected by foundation scour. The survey addressed both the deck and the foundation response over a portion of the bridge, which includes scoured and unscoured piers. The rationale behind this strategy is to address the relative response of nearby portions of the bridge, with different scour conditions, to have an insight into the effect of scour. Preliminary results from the processing of experimental data demonstrated the presence of asymmetric behavior on both the deck modal shapes and the piers vibration magnitude, which can be attributed to the inhomogeneity of the distribution of soil stiffness due to scour. Ongoing studies, to be reported in the near future, are focusing on more detailed assessment of scour effects on the bridge pier caps and deck. As the local administrative entity (Città Metropolitana di Torino) is currently planning for hydraulic and geotechnical countermeasures, future works will report as well the dynamic behaviour of the target infrastructure before and after interventions.

ACKNOWLEDGEMENTS

This work is part of the research activity developed by the authors within the framework of the 'PNRR': SPOKE 7 "CCAM, Connected Networks, and Smart Infrastructure" - WP4. The Authors would like to thank the institution of Città Metropolitana di Torino, especially Marco Benso, Matteo Tizzani, and Giovanni Luca Zagardo, for their precious help and support.

Seismic design modifications for damage prevention in skewed bridges

T. Amaya & H. Santa María
Department of Structural and Geotechnical Engineering, Pontificia Universidad Católica de Chile, Santiago, Chile
CIGIDEN, Research Center for Integrated Disaster Risk Management, Macul, Santiago, Chile

ABSTRACT: The seismic design of bridges is vital for safety and functionality, especially for skewed bridges with asymmetrical geometry. This study assesses the impact of seismic design criteria on the seismic performance of Chilean skewed bridges. Fragility curves for bridges designed under the current design criteria are compared with those prior to 2010. Nonlinear analytical models, of typical Chilean bridges are subjected to ground motions records to obtain the damage probabilities of the bridges. The fragility assessment reveals that changes in design criteria alter component damage probabilities, with a more pronounced effect observed for skewed bridges compared to straight bridges. Additionally, current seismic design criteria reduce superstructure displacement and rotation but increase substructure stresses. Insights from this study contribute to the evaluation of seismic performance and offer recommendations for reinforcing vulnerable bridges.

Keywords: seismic fragility, bridge seismic design, seismic fragility curves, skewed bridges

1 INTRODUCTION

The seismic design of bridges is crucial to ensuring their safety and functionality. A comprehensive understanding of how seismic design requirements impact the bridge seismic response is essential for accurate analysis and successful design. This is particularly important when dealing with skewed bridge structures, in which their asymmetrical geometry may alter their seismic performance. The 2010 Mw 8.8 Maule Earthquake in Chile caused extensive damage to many bridges across the country (Kawashima et al., 2011) with the most common types of damage resulting from large displacements of the superstructure, a phenomenon particularly observed in skewed bridges. In response to the observed bridge damage, new seismic design criteria were introduced (MOP, 2020). These changes include the extension of seat support lengths, addition of diaphragms, higher design forces for vertical seismic bars, adjustments to interior and exterior shear key specifications, as well as modifications in the anchorage of elastomeric bearings. Notably, for skewed bridges, there are specific considerations that require a greater number of connecting elements between the superstructure and substructure, depending on the geometry of the bridge deck (MOP, 2020). While several authors (Aldea et al., 2021; Wilches et al., 2019, 2021) have explored the impact of seismic design on the behavior, damage mechanisms, and fragility of Chilean bridges, there is not enough research analyzing how seismic vulnerability varies with the skew angle. Particularly, there is a lack of studies on how changes in seismic design requirements influence the response of skewed bridges under different conditions of bridge deck geometry.

The objective of this study is to assess the impact of changes in the seismic design criteria on the seismic vulnerability of Chilean skewed bridges. For that aim, a typical Chilean bridge is

DOI: 10.1201/9781003483755-187

considered as a case study. The benchmark bridge is analyzed considering different values of the skew angle (0, 15 and 30 degrees) and two seismic design conditions: seismic designs before 2010 and those adopted afterward. The influence of the seismic design criteria is evaluated by comparing fragility curves and the nonlinear seismic response of the different cases of bridges.

2 METHODOLOGY

2.1 *Case study*

This study considers the typical bridge structure obtained after a statistical analysis (Wilches et al., 2019) of available information on Chilean bridges, which corresponds to a simply supported bridge with prestressed concrete girders. The bridge comprises two spans with a continuous slab, each measuring 27 meters in length and 13 meters in width. The superstructure consists of four prestressed concrete girders, supported by elastomeric bearings on a central pier of three columns and seat-type abutments at each end. For this bridge, three skew angle cases were considered: the scenario of a straight bridge (0 degrees) and angles of 15 and 30 degrees. For these bridges, two different design conditions were analyzed: one using the design requirements enforced before 2010 (Ministerio de Obras Públicas, 2002) (referred to as Seismic design 1) and another with the design requirements after 2010 (MOP, 2020) (referred to as Seismic design 2). The bridges with Seismic design 1 are equipped with exterior shear keys and unbonded elastomeric bearings under the main girders. In contrast, the bridges with Seismic design 2 incorporate both interior and exterior shear keys, alongside bonded elastomeric bearings. Additionally, in Seismic design 2, the design forces of shear keys and seismic bars, as well as the length of the seat support increase. Furthermore, for skewed bridges, Seismic design 2 mandates a larger number of interior shear keys when the specified condition of excessive displacements is met. This condition, depicted in Figure 1, relates the aspect ratio of the bridge deck to the skew angle of the bridge.

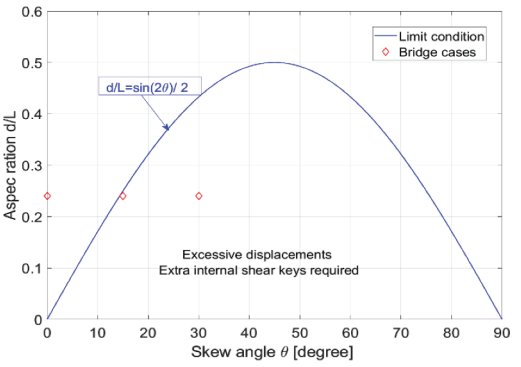

Figure 1. Aspect ratio (d/L) vs skew angle.

2.2 *Numerical models*

Three-dimensional analytical models were developed for the bridges using OpenSees (McKenna, 2011). Figure 2 shows the modelling approach of the bridges. The superstructure was modeled using elastic beam-column elements. The columns were modeled using displacement-based beam-column elements with fibers sections. The foundations of piers and abutments were modeled using linear springs. Unbonded elastomeric bearings were modeled using Flat Slider Bearing elements (McKenna, 2011); and bonded elastomeric bearings were modeled using Elastomeric Bearing (Bouc-Wen) elements (McKenna, 2011). The interaction between the deck and abutments was simulated by incorporating nonlinear springs. The passive soil pressure was modeled using a hyperbolic backbone curve (Shamsabadi et al., 2009),

while pounding between the deck and abutments was simulated using an impact material (McKenna, 2011). Interior and exterior shear keys were modeled using a trilinear constitutive following (Silva et al., 2003). The properties of reinforced concrete were represented using the Hysteretic material (McKenna, 2011), while the gap between shear keys and girders was simulated with the ElasticPPGap material (McKenna, 2011).

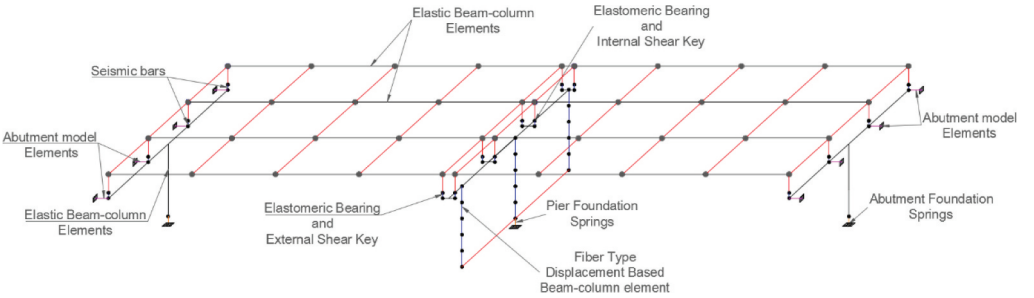

Figure 2. Nonlinear numerical model.

In this study, we obtain fragility curves for the bridges employing the Multiple Stripe Analysis method (Baker, 2015). The chosen intensity measure (IM) corresponds to the spectral acceleration at a period of 0.6 seconds, which represents the average of the fundamental periods of the bridges. To obtain the fragility curves, seismic records were carefully selected through a probabilistic seismic hazard assessment (PSHA). In this study, the bridges are assumed to be located at site latitude 33.097◦S, longitude 71.547◦W. The seismic hazard curve at the site is estimated through PSHA using the SeismicHazard platform (Candia et al., 2019). A total of 11 pairs of seismic records were selected across 8 intensity levels, covering return periods ranging from 72 to 4975 years. The seismic hazard curve, along with the corresponding intensity levels, is shown in Figure 3. The seismic records were selected from the Siberrisk database (Castro et al., 2022). The record selection process was guided by the conditioned spectrum (Baker & Asce, 2011) corresponding to each intensity level.

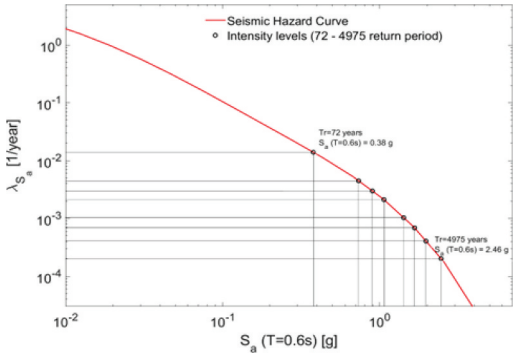

Figure 3. Seismic hazard curve.

2.2.1 *Damage states*

This study uses different engineering demand parameters (EDPs) for superstructure and substructure elements in constructing the fragility curves. Three damage states (DS) are considered, each with specific numerical values detailed in Table 1.

For bridges equipped with unbonded elastomeric bearings (Seismic design 1), DS1 is reached when the residual displacement of the elastomeric bearings exceeds 50 mm. DS2 occurs when the maximum displacement of the bearings surpasses the displacement corresponding to the maximum capacity of the shear keys, set at 160 mm. DS3 is defined by transversal displacement exceeding the length of the seat support in the transverse direction. For bridges equipped with bonded bearings (Seismic design 2), two damage states, DS1 and DS2, are associated with the shear strain of the bearings. These damage states are reached when the shear strain exceeds 150% and 200%, respectively. These numerical values were adopted based in previous research studies (Alam et al., 2012; Zhang & Huo, 2009). The third damage state is defined by the transverse collapse of the superstructure.

For the substructure, the EDP relies on the displacement ductility of the columns. The thresholds for damage states related to column displacement are established using values derived from Billah & Allam (Muntasir Billah & Shahria Alam, 2015). In addition, we considered an extra damage state associated with the potential collapse of the bridge in the longitudinal direction.

In this study, we develop fragility curves individually for superstructure and substructure damage. Additionally, we establish fragility curves representing bridge damage as a system, where both substructure and superstructure damage contribute to the overall system damage. The damage probabilities of the bridge as a system are calculated using Equation 1. Where P_{sys} is the probability of damage of the entire bridge and P_{EDP} is the probability of damage of the superstructure or substructure of the bridge.

$$P_{sys}(DS_i|IM) = 1 - \prod_{EDP_j}\left(1 - P_{EDP_j}[DS_i|IM]\right) \quad (1)$$

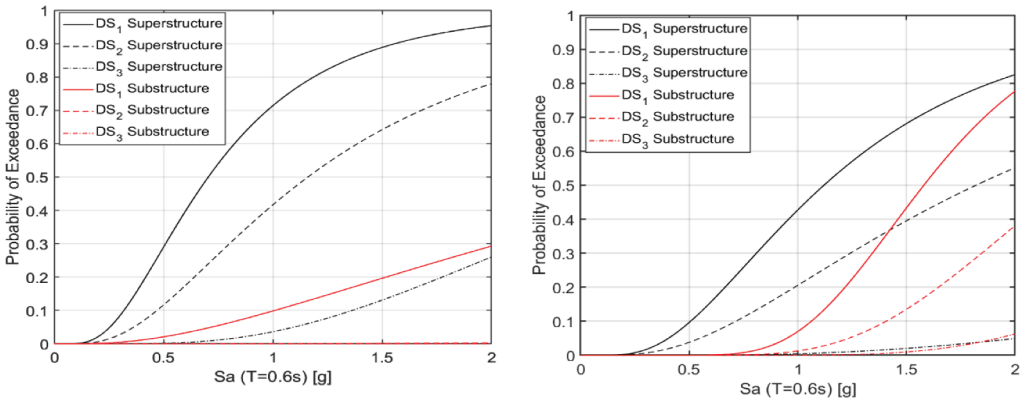

Table 1. Bridge EDP and damage state values.

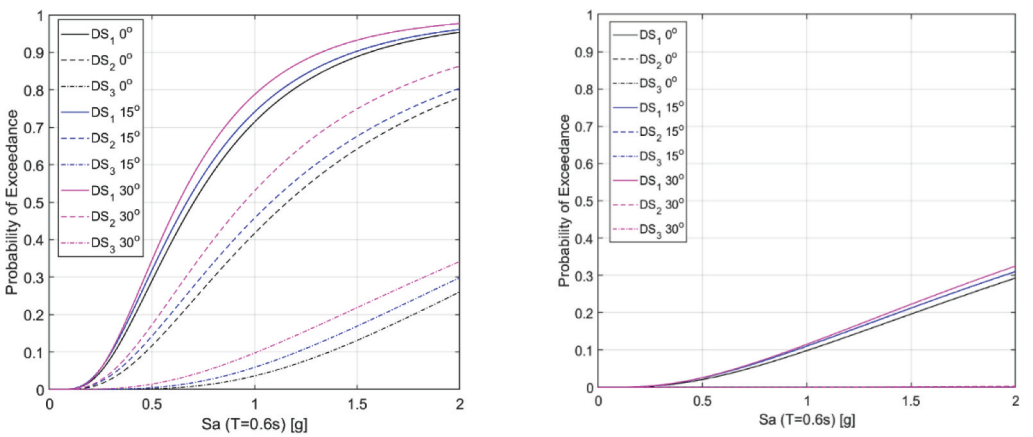
Bridge elements	EDP	Damage state 1 (DS1)	Damage state 2 (DS2)	Damage state 3 (DS3)
Superstructure	Unbonded elastomeric bearing	50 mm (RD)	160 mm (MD)	Transversal collapse *
Superstructure	Bonded elastomeric bearing	150 % (SS)	200 % (SS)	Transversal collapse *
Superstructure	Unseating	—-	—-	Longitudinal collapse *
Substructure	Column (μ_d)	1.22	1.78	4.8

RD: Residual displacement
MD: Maximum displacement
SS: Shear strain
μd: Displacement ductility
*: Numerical value variable depending on bridge and seismic design.

3 RESULTS

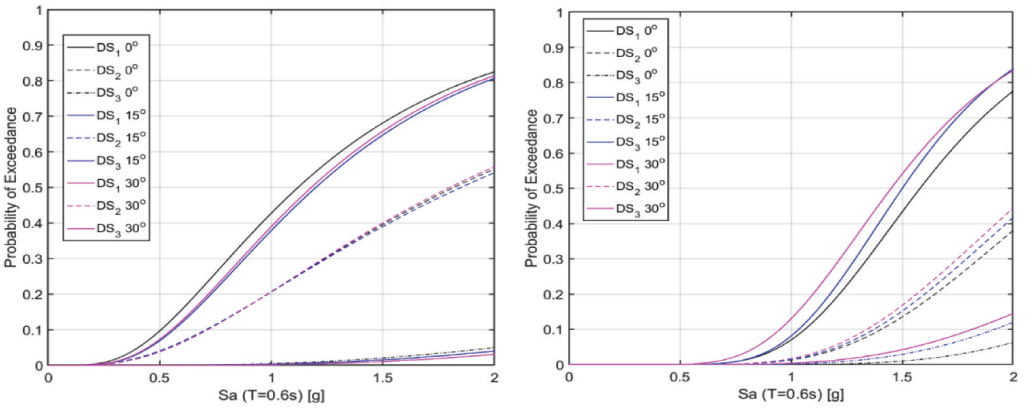


In order to compare the effect of the changes of the seismic design criteria on the damage probabilities of the bridges, Figure 4 depicts the superstructure – substructure fragility curves of the straight bridge (0 degrees) designed with the two seismic design configurations. Figure 4a and 4b present the fragility curves related to Seismic design 1 and Seismic design 2, respectively. These fragility curves illustrate changes in the bridge's damage mechanisms in response to the altered design requirements. In the bridge designed under Seismic design 1 (see Figure 4a), there is a notable prevalence of high probabilities of superstructure damage, while the probabilities of substructure damage are relatively low. In contrast, in the case of the bridge designed with Seismic design 2 (see Figure 4b), the probabilities of superstructure damage decrease, compared to Seismic design 1, but there is a noticeable increase in the probabilities of substructure damage.

a) Seismic design 1 b) Seismic design 2

Figure 4. Superstructure – substructure fragility curves for straight bridge.

Figure 5 compares the fragility curves for the superstructure and substructure for bridges employing Seismic design 1 and the three skew angles. As the skew angle increases, the probabilities of superstructure damage also increase. For instance, in Figure 5a, at an intensity of 1.5 g and considering DS2, the superstructure damage probabilities are 64%, 68%, and 75% for skew angles of 0◦, 15◦, and 30◦, respectively. Consistent patterns are observed across all three damage states. Notably, the increasing skew angle enhances the tendency for planar rotation in the bridge deck, ultimately amplifying superstructure displacement. This underlines the crucial role of skew angle in influencing superstructure response under seismic conditions. For substructure damage (see Figure 5b), the fragility curves remain similar for all skew angles. As mentioned before, under Seismic design 1, substructure damage is minimal, emphasizing the predominant impact of skew angle on the superstructure.



a) Superstructure b) Substructure

Figure 5. Superstructure – substructure fragility curves, Seismic design 1.

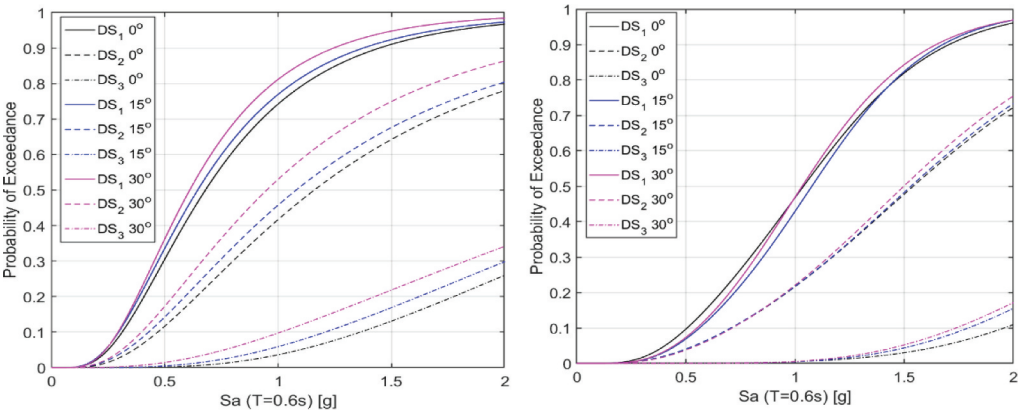
Figure 6 shows the superstructure – substructure fragility curves for the bridges with Seismic design 2 and the three skew angles. For this design condition, two primary observations emerge. Firstly, the probabilities of superstructure damage (see Figure 6a) are lower compared to the Seismic design 1 condition and remain consistent across all three skew angles. The introduction of additional internal shear keys, as a design requirement, effectively restricts the

displacement and rotation of the bridge deck, consequently reducing the superstructure damage probability. On the other hand, in Figure 6b, it is observed that as the skew angle increases, the probabilities of substructure damage also increase. For instance, at an intensity of 1.5g and considering DS1, the damage probabilities are 43%, 50%, and 54% for skew angles of 0◦, 15◦, and 30◦, respectively. Similar trends are noted for all three damage states. This phenomenon arises because, while the inclusion of additional interior shear keys limits superstructure displacements, it concurrently enhances the transmission of forces from the deck to the substructure, thereby escalating the probabilities of substructure damage.

a) Superstructure b) Substructure

Figure 6. Superstructure – substructure fragility curves, Seismic design 2.

Figure 7 illustrates the system fragility curves for the bridges designed with the two seismic design configurations. For the Seismic design 1 condition (see Figure 7a), as the skew angle increases, the probabilities of damage also increase. For instance, in Figure 7a, at an intensity of 1.5g and considering DS3, the damage probabilities are 13%, 17%, and 22% for skew angles of 0◦, 15◦, and 30◦, respectively. In contrast, under the Seismic design 2 condition (see Figure 7b), the probabilities for all three damage states are lower compared to the Seismic design 1 case, and there are smaller differences among the various skew angle cases. For example, in Figure 7b, at an intensity of 1.5g and considering DS3, the damage probabilities are 3%, 4%, and 5% for skew angles of 0◦, 15◦, and 30◦, respectively.



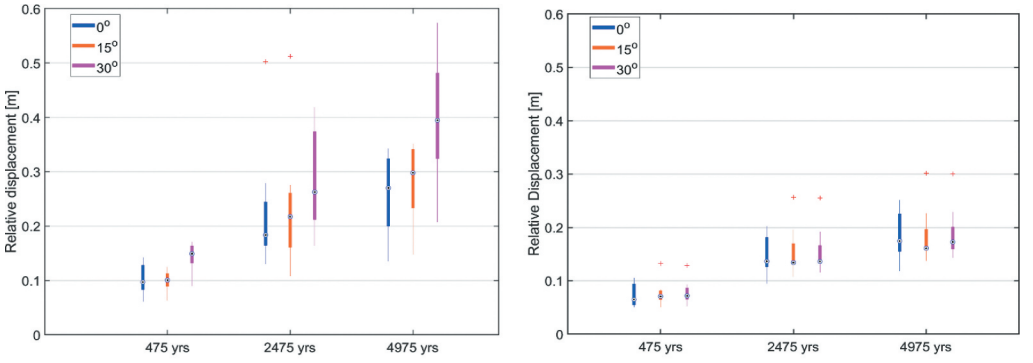


Figure 7. System fragility curves, Seismic design 1 and Seismic design 2.

To analyze the effect of both design conditions on the rotational response of the bridge decks, Figure 8 compares the maximum relative transverse displacement response. Box plot graphs are presented depicting responses to seismic records corresponding to three return periods. Under the Seismic design 1 condition, a clear effect of the skew angle is observed, where higher angles exhibit a greater tendency for rotation. In contrast, for the Seismic design 2 condition, rotations are lower and more controlled with the increase in the skew angle. These results, along with the previously presented fragility curves, indicate that the current seismic design criteria are effective in controlling the skew angle effect. They effectively limit the displacement and rotation of the superstructure, resulting in lower probabilities of damage for the bridges.

a) Seismic design1 b) Seismic design 2

Figure 8. System fragility curves, Seismic design 1 and Seismic design 2.

4 CONCLUSIONS

The analysis presented in this study examines the impact of changes in the seismic design criteria on the seismic fragility of Chilean skewed bridges, using a representative Chilean bridge as a case study. Three skew angle scenarios (0, 15, and 30 degrees) were considered, and seismic design provisions before and after the 2010 Maule Earthquake were evaluated. Nonlinear three-dimensional models were developed in the OpenSees software, and fragility curves were generated using the Multiple Stripes Analysis method. The results indicate that the change in the design criteria reduces superstructure damage but increases substructure damage. In the Seismic design 1 condition, skew angle primarily influences superstructure damage probabilities, whereas in the Seismic design 2 condition, the influence is more pronounced in substructure damage probabilities. The system fragility curves demonstrate that the revised seismic design criteria effectively decrease overall bridge damage probabilities and mitigate the skew angle effect. Additionally, the current design requirements were found to reduce deck rotation effects in the bridges.

Collapse of Cau Cau Bridge: Forensic engineering study

M.A. Valenzuela
Pontificia Universidad Católica de Valparaíso, Valparaíso, Chile

M. Márquez
Dirección de Vialidad, Ministerio de Obras Públicas, Santiago, Chile

ABSTRACT: The city of Valdivia is located in the Los Rìos Region, in southern Chile, crossed by several rivers, among which is the navigable Cau Cau river, which divides Isla Teja from the Las Ánimas sector. The Ministry of Public Works tendered the design and construction of the Cau Cau Bridge, which provides a new road alternative to access both the city and the coast of the region and allows the passage of boats, including towards the city shipyard. The awarded proposal consists of three structures: a 110-meter-long northern access viaduct, the main bascule bridge, 165 meters in total and a 70-meter main span, and the 88-meter southern access viaduct. The Cau Cau Bridge is the first mobile structure built in Chile. On February 24, 2015, during the startup stage of the construction phase, and while the lifting operation of the decks is being carried out, one of the hydraulic lifting devices in the southern sector fails, finally generating that the bridge was not opened to service. This paper provides the forensic engineering study carried out by the principal after the failure produced in one of the deck leaves, with a critical analysis of the management protocol carried out, the hypotheses of the causes, analysis of the manufacturing process, assembly and construction process of the deck, study of the oleo hydraulic and mechanical systems and the modeling of the structural system, in order to determine the origin of the failure. The conclusions of the investigation and the lessons learned for the process of design and construction of singular bridges in Chile and their application in other projects are delivered.

1 INTRODUCTION

The Construction of the Cau Cau Bridge and Access Project aims to design a new road connection to optimize traffic in the road network of the city of Valdivia, located in the Valdivia Province, Los Ríos Region.

Specifically, for the traffic coming from the northern sector of the city heading west, which previously had to circulate through the center of the city of Valdivia.

With this new road connection, the volume of vehicular traffic through the center of Valdivia is reduced, utilizing existing roadways.

Due to the city of Valdivia being surrounded by a network of watercourses (Valdivia, Cruces, and Cau Cau rivers to the west, Calle Calle river to the north, and Angachillas, Tornagaleones, and Futa rivers to the south), the construction of bridges is necessary to provide connectivity to different areas through existing roads.

Therefore, to connect the Las Ánimas sector, i.e., the northern side of Valdivia, with Isla Teja and provide feasibility for this new road connection, a bascule-type bridge over the Cau Cau River was designed, considering it is a navigable river.

The Cau Cau River is a natural barrier that prevents the integration of both riverbanks (Las Ánimas and Isla Teja), as well as the development of both sectors, due to the lack of road connectivity (Figure 1). Therefore, within the Communal and Regional Development, the project, in addition to improving the connection of productive sectors to and from Niebla

DOI: 10.1201/9781003483755-188

and reducing congestion in downtown Valdivia, enables the development of the Las Ánimas sector, which has proposals for urban expansion in both housing and facilities, sectors awaiting this new project.

The New Regulatory Plan for Valdivia establishes a new urban boundary and incorporates some changes in land use for sectors located both north and south of the river. Areas for housing development, facilities, productive activities, and harmless industry are designated. The previous point will generate increased use of the road to be developed, as the densification of the area could increase.

This development respects the wetland areas of the zone as a tourist attraction. Additionally, the bridge itself will be another tourist attraction due to its bascule operation, increasing pedestrian demand and walks in the northwest sector of Valdivia, as it is the first bascule bridge designed and built in Chile. Furthermore, the New Regulatory Plan leaves a reserve for a road strip that would directly connect Route 205 with the Cau Cau Bridge in the future, providing an even more direct connection to Isla Teja and Niebla.

The characteristic of the Cau-Cau Bridge being a movable bridge also considers communal and regional development regarding the anticipated growth in future fluvial activities since there is no height restriction for vessel passage, unlike existing bridges Pedro de Valdivia and Calle Calle, which limit the height to 10 m. The Cau Cau Bridge is the only option for the passage of vessels with a height greater than 10 m.

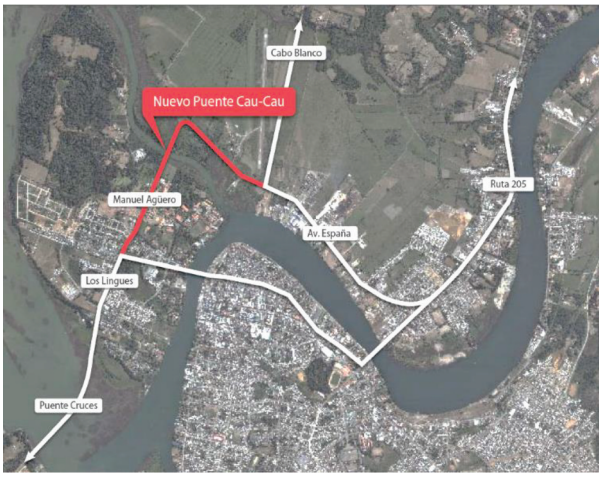

Figure 1. Cau Cau bridge location.

2 DESCRIPTION

The project involves the construction of a bascule bridge over the Cau Cau River and the improvement and paving of the accesses (NSM, 2011) (MOP, 2011).

The bridge consists of a movable span with a length of 70 m and a clearance of 7 m, composed of a bascule bridge with two leaves of 35 m each and two spans of 15.5 m, including 10 m counterweight spans (Figure 2).

The movable structure to be built over the Cau Cau River is of the bascule type. This bridge type allows the movement of the deck by rotation about a horizontal axis through a hinge and hydraulic lifting systems. The crossing conditions at the Cau Cau River require the use of a bascule bridge with two leaves.

In the proposed arrangement, the hinge joints have been placed, spanning the strict 70 m width of the riverbed, to minimize the required structure. This design integrates the bridge pier and abutment into a single element accessible from the shore for the installation of lifting machinery.

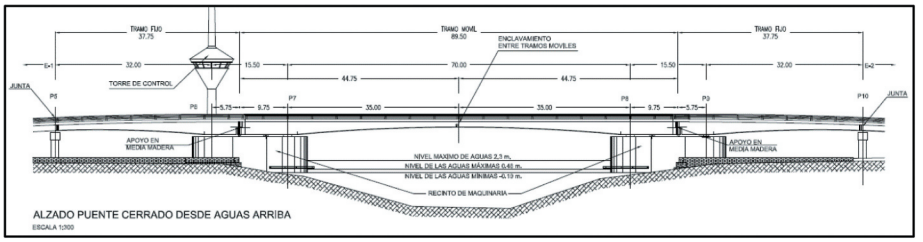

Figure 2. Bascule section view.

The cross-section of the span is metallic and consists of two main beams with a double "T" section, spaced 6.5 m apart, and a deck with a metallic orthotropic slab formed by transverse beams spaced 3.5 m apart, extending into lateral cantilevers of 3.84 m. The main beams have a variable depth, with 3.0 m at the supports and 1.5 m at the center of the span, with a parabolic variation between them (Figure 3).

The cross-section of the movable bridge and viaducts has two roadways, each 4.0 m wide, and sidewalks, 1.77 m and 3.27 m wide on each side. At the ends, there is space for the accommodation of corresponding safety barriers, resulting in a total deck width of 14.20 m. The deck has a 2.5% camber from the centerline of the roadways, and the two side sidewalks have a 20% camber towards the roadways.

The pavement surface of the movable span consists of a 6.0 mm thick epoxy resin-based coating, sprinkled with fine aggregate to enhance vehicle adherence, with significantly lower weight compared to a standard asphalt pavement layer.

Additionally, the project includes two fixed spans (north and south viaducts). The north viaduct is 142 m long, with one span of 32 m and five spans of 22 m each, all simply supported. The south viaduct is 120 m long, with one span of 32 m and four spans of 22 m each, all simply supported.

The superstructure of the viaducts is structured with 3 steel beams, a variable thickness in situ reinforced concrete upper slab, and a 5 cm thick asphalt riding surface. The deck is supported on the infrastructure through neoprene plates, located at the ends of each beam, and is anchored to it through anchor bars.

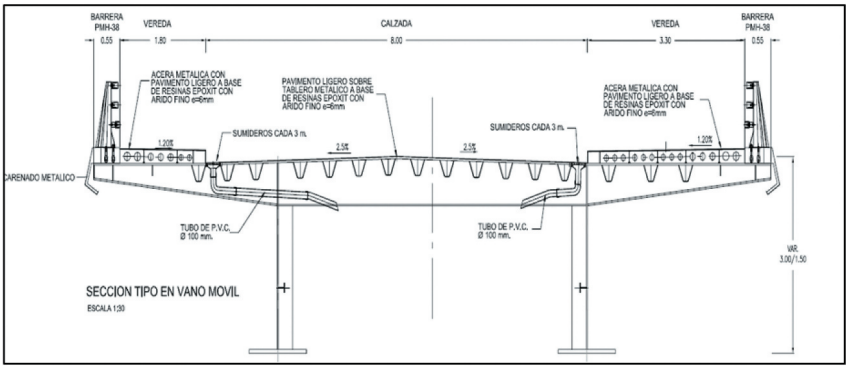

Figure 3. Cross-sectional profile of the bascule section.

The infrastructure of the viaducts comprises 2 abutments and 7 piers. The abutments are of the solid wall type with wings parallel to the roadway and foundation through in-situ pre-excavated and concrete-filled piles of 35 m, while the piers consist of 3 pile-piles, where the piles are pre-excavated and concrete-filled in situ with an average length of 35 m.

The bascule bridge is designed with a double system of mechanical devices (Figure 4). On one hand, the main machinery applies the necessary force to ensure movement around the

pivot axis and secure stability during the opening phase. On the other hand, there are interlocking systems between both movable spans and between the movable span and the access viaduct. These elements must be released to allow the opening movement and must be reactivated once the structure is closed.

The main machinery consists of hydraulic jacks (each with a capacity of 750 tons) capable of producing a moment around the pivot axis by applying forces against the compensation span and the foundation of the abutment-pier to complete the imbalance pair not covered by the counterweights. The entire bridge movement and interlocking system are hydraulic, including pumps, valves, filters, and systems with smooth braking at the end of both opening and closing movements.

Two hydraulic jacks are employed on each side, connected to the deck on the inner side of the beams where the counterweights are located. In the closed bridge position, they extend to 12.40 m, and in the open bridge position, they contract to 7.0 m.

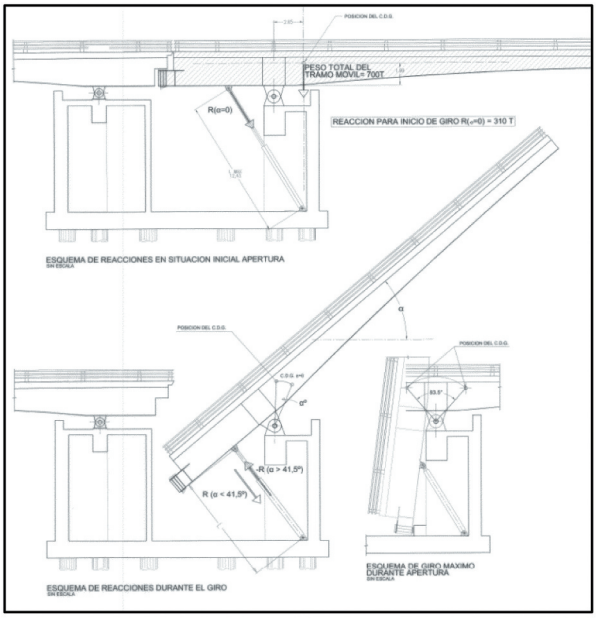

Figure 4. General overview of the tilting system.

Finally, the project includes access works, sanitation, road safety, landscaping, lighting, river defenses, and a control tower.

3 EVENT

The overall failure of the Cau Cau Bridge occurred on February 24, 2015, during the testing process to prepare the bridge for operation. It happened while the south leave was being raised slightly, which needed to be lifted first to subsequently lift the north leave of the bridge.

The failure occurred particularly in the southeast leave of the bridge, and it unfolded chronologically as follows:

The startup test began with the lifting of the south leave to 11°, intending to open it and then proceed to lift the north leave to its maximum angle of 82°.

The lift of the south leave started at 12:07:10 hrs. with an initial pressure of 372 psi at 0°, then, after 6 seconds, reaching a pressure of 2420.5 psi at 11.08°. This position was maintained while awaiting the start of the lift of the north leave.

After 10 seconds, a first sharp sound emanated from the south leave compartment. Five seconds later, a second noise occurred, followed by a strong impact of the southeast cylinder against the concrete support base 1 second later.

Over the next 4 seconds, there was a transverse oscillation of the bridge deck, during which the weight of the bridge deck was fully taken by the west cylinder of the south leave, stabilizing the leave's opening at 10°.

The descent of the south leave, according to the information available, was manually performed from the V12 valve of the safety system until reaching the resting position at 0°. The descent of the leave was completed at 12:26:28 hrs.

Figure 5. Final position of leaves after the collapse.

4 FORENSIC ENGINEERING

In light of the previously described event, the Highway Directorate of the Ministry of Public Works has decided to contract technical consulting services for forensic investigation. In this regard, the consultancy services were awarded to SECON, a firm with an interdisciplinary team encompassing structural, mechanical, and metallurgical areas, supervised by the Inspection Office of the Highway Directorate. The contract's objectives included: Determining the causes and origin of the failure; Reviewing the temporary lifting project; Proposing solutions to the detected failures; Following the engineering forensic protocol, a final diagnostic report on the failures and proposed solutions was requested.

In 2010, Chile experienced its most intense earthquake, and referencing this event until 2020, several structures failed, many due to extreme events (Valenzuela et al., 2020), with the collapse of the Cau Cau Bridge being part of this category. From these experiences, the Highway Directorate of the Ministry of Public Works developed a program of protocols and a methodology for forensic investigation. Thus, the investigation activities on the Cau Cau Bridge have been integrated into current protocols (Valenzuela & Márquez, 2023), (PIARC, 2023).

In particular, the investigation on the Cau Cau Bridge included the review of information gathered from records provided by the Highway Directorate, on-site inspection visits, laboratory sample evaluations, and the examination of all other pertinent volatile and non-volatile data.

The methodology employed for this study consisted of three phases.

Review and evaluation of background Information.

This involved the examination of the following: Documents from the project bidding phase (specifications, blueprints, studies, and schematics); Documents from the construction phase (projects, blueprints, schematics, photographs); Documents related to previous bridge failures; Information regarding the failure on February 24, 2015; Documents related to the temporary lifting system of the bridge.

On-Site Inspection

Multiple on-site visits were conducted to verify the current state of the bridge structure, its operational conditions, and the state of the failed component (rod-cylinder-fork joint). Additionally, a detailed inspection and dimensional verification of the piece were performed during its transportation for study. Samples of the failed component were extracted by certified laboratories for material testing, and inspections of southeast arm cylinder pieces were carried out at the supplier's facility.

Failure Analysis

The analysis and study of the bridge failure were conducted, considering three areas of focus:

Evaluation and Analysis of the Oleo Hydraulic System: This encompassed an assessment of the oleo hydraulic system, spanning from the proposal stage during project and bidding phases to its construction and utilization in the lifting system.

Mechanical System Evaluation (Metallurgical): This involved assessing the quality of materials used in the manufacturing of the lifting cylinders, along with their respective forks. Laboratory tests and microscopic examinations of the material involved in the failure were conducted, in conjunction with a review of blueprints and quality documents related to the lifting cylinders.

Structural Analysis: This phase entailed the modeling and analysis of components with failures using Ansys for mechanical elements and Sofistik for structural analysis. These tools were employed to verify hypothetical failure scenarios prior to the results of the metallographic analyses performed on the failed components.

5 FORENSIC STUDY RESULTS

The SECON team (Contreras, 2015) and the Inspection Office concluded, based on the review of records and results of the technical inspection, the following relevant aspects concerning the failure:

5.1 *Background analysis*

As part of the supplementary background information, failures or issues preceding the collapse of the bascule system were considered. Among the most relevant are:

Bascule Mechanism and Modification of the Locking System between the Fixed and Mobile Systems.

The bascule mechanism operates through two hydraulic jacks acting in parallel. In the initial closed configuration (0°), the hydraulic jacks start pulling (i.e., in tension) with maximum force until, at an intermediate position (approx. 41.5°) when the center of gravity is located above the fixed hinge, the jacks begin pushing (i.e., in compression) until the final open position (83°). The locking mechanism in the center of the bridge consists of two hydraulic latches that are activated once the bridge is in the closed position. Initially, a similar locking system with a hydraulic latch for the rear span, at the junction with the fixed section, was considered in the project but was eliminated during the bidding stage. Although this rear latch system is not necessary for the structure's balance, it is customary to have this system to prevent issues at the joint between the fixed and mobile spans, which could later impact service conditions.

Modifications During Construction

Several structural adjustments were necessary during construction due to construction errors and/or modifications.

- Incorrect Assembly of the North and South Bascule Spans
  Due to errors during execution, the North and South bascule spans were mistakenly installed interchangeably. Since the deck is not symmetrical (i.e., the structure's axis does not align with the roadway axis), structural adjustments were required to avoid disassembling both spans and placing them in their correct positions. The adopted solution involved continuously welding

longitudinal stiffeners with a thickness of 8 mm and variable height, onto which an 8 mm upper plate was welded. This resulted in noticeable upward vertical deformation at the center of the mobile span and appreciable differential deformation between both ends of the deck (transversely). These deformations at the central joint (interlocking between mobile spans) affect the behavior of the hydraulic latch interlocking system due to the misalignment of both spans. All solutions adopted to adjust the deck's geometry led to an increase in the deck's self-weight and a shift in the center of gravity position of the structure.

- Cutting of Fixed Support Lugs
  The construction procedure adopted for the assembly of each bascule span involved lateral positioning parallel to the river and subsequent vertical axis rotation to its final position. To achieve this, the decision was made to cut the lugs of the fixed supports, subsequently welding them once the deck span was in its final position. The full-penetration welding during the cooling process resulted in the loss of verticality of the lugs. The non-verticality of the anchor lugs affected the proper functioning of the fixed hinge (e.g., wear due to friction, pin and hinge binding, etc.).

Adjustment in the Position of the Mobile Hinge

Interference points between the pistons and the fixed structure of the chamber and deck were identified. To address these interferences, it was decided to shift the pull point of the lifting system (upper hinge of the cylinder) to a position closer to the fixed hinge. This involves a modification in the forces to be applied by the lifting system, consequently affecting the stresses/strains in the deck and the rotation angle corresponding to the indifferent equilibrium position, in relation to the original project.

5.2 *Metallographic and structural analyses*

The following observations were carried out:

- The stresses generated in the failure zone are well below the yield values of the materials.
- Based on the results from three structural models subject to loads from their self-weight, imbalanced loads on the cylinders, and lateral displacements of the deck, it was concluded that the stresses that could have occurred in the failure zone are well below the specified material yield stress.

The rupture occurred due to inadequate and defective execution of secondary welding. Conclusions from metallographic studies include:

- The material specified for the fork, AISI-SAE 1045, does not comply with ASTM A29 standards, as the steel's microstructure indicates that it was cast and not shaped as required by the standard.
- Quality procedures in the welding of the stem-fork joint were not followed (Figure 6), and the failure initiated in the Heat-Affected Zone (ZAC).
- Filler welding was performed on the fork before thread manufacturing and machining.

Figure 6. Sample of the welding applied on the fork – lug.

6 FINAL COMMENTS

Upon completing the forensic engineering work, the Directorate of Highways of the Ministry of Public Works establishes the following lessons learned:

- Specific Bidding Projects for Unique Bridges: Before tendering unique bridge projects, especially when dealing with first-time experiences in certain structural typologies or their magnitude, it is necessary to enhance the capabilities of the professionals involved in the process. This involves forming technical-legal teams for their development, starting from the pre-investment phase and throughout the investment phase (design, construction, and operation/maintenance). This consideration extends not only to the capacities of the client but also to those of the contractors and consulting services for the Inspection Fiscal.
- The work carried out around Forensic Engineering on the Cau Cau Bridge allowed obtaining information crucial for decision-making regarding projects developed after the failure event, ultimately leading to the bridge's operational status.
- Among the elements contemplated for repair or modification based on the consultant's recommendations are:

  a) Orthotropic Deck - The deck has deformations due to the metallic overlay installed because of the incorrect assembly of the bridge leaves.
  b) Fixed Joint - The fixed joints exhibited significant damage due to errors in project execution.
  c) Cylinder - It recommends removing the remaining three cylinders and replacing them to avoid the risk of failure.
  d) Hydraulic-Oil System - The cylinders should be replaced, and the hydraulic-oil system should be improved.
  e) PLC (Programmable Logic Controller) - The control and emergency system must be reinforced.
  f) Central Latch - The central latch underwent modifications compared to its original design

- Comparative Review with Other Bascule Structures in Specialized Disciplines:

Based on visits conducted to various European bascule bridges, certain elements subject to updating due to advancements in the state of the art in the field were identified. The visited bridges include: Porta D'Europa Bridge, Barcelona, Spain; Leixoes Bridge, Porto, Portugal and Estacio Bridge, Murcia, Spain. Main issue to improve in Cau Cau Bridge are: bearing, dumpers, interlocking, control ITS – monitoring and instrumentation, sidewalks and stock.

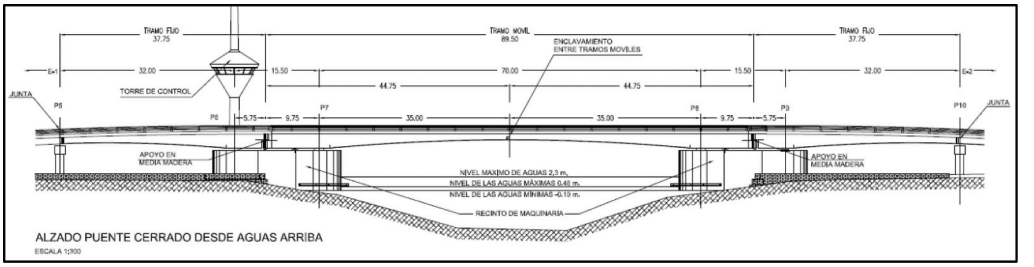
ABSTRACT: As a consequence of the failures experienced by the Cau Cau Bridge, Chile, the Ministry of Public Works of Chile entrusted the performance of a series of tests to this structure, which included invasive and non-invasive tests, load tests and various experimental and numerical analyzes to generate a detailed structural diagnosis.

This paper reports the main results of non-invasive tests carried out on the reinforced concrete elements of this structure. Special geophysical tests using high-frequency Ground Penetration Radar, the use of traditional non-invasive methods, as well as the use of remote sensing methods based on high-range Terrestrial Laser Scanning for 3D modeling in conditions with and without loading are highlighted and detailed.

Results show the advantages related to the great precision, speed and reliability of the use of these non-invasive methods as support for an opportune structural diagnosis of bridges.

1 INTRODUCTION



The Cau Cau bridge is located in the city of Valdivia, Chile. This structure is movable and is located over the Cau Cau River, connecting the Las Ánimas sector with the Isla Teja sector (See Figure1). It was built by the company AZVI CHILE S.A. between 2012 and 2015.

Figure 1. Location of Cau Cau Bridge, in the city of Valdivia, southern Chile.

DOI: 10.1201/9781003483755-189

The bridge consists of a movable span with a length of 70 m and a clearance of 7 m, composed of a bascule bridge with two leaves of 35 m each and two spans of 15.5 m, including 10 m counterweight spans (Figure 2). The movable structure to be built over the Cau Cau River is of the bascule type. This bridge type allows the movement of the deck by rotation about a horizontal axis through a hinge and hydraulic lifting systems. The crossing conditions at the Cau Cau River require the use of a bascule bridge with two leaves. Figure 3 shows the cross section of the structure (MOP, 2011).

Figur 2. Bascule section view.

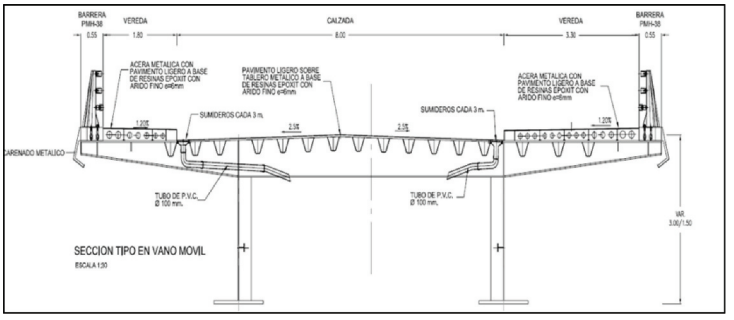


Figure 3. Cross-sectional profile of the bascule section.

The overall failure of the Cau Cau Bridge occurred on February 24, 2015, during the testing process to prepare the bridge for operation. It happened while the south leave was being raised slightly, which needed to be lifted first to subsequently lift the north leave of the bridge. A strong impact of the southeast cylinder against the concrete support base occurred, originating a stop in the process and the subsequent problems. The failure is well described in several studies and documents (Contreras, 2015; VMB Ingeniería Estructural, 2016; RiNA, 2018).

This paper exposes the non-invasive structural auscultations carried out on the Cau Cau bridge, as well as tele-detection strategies applied by means of terrestrial LiDAR for the precise geometric definition of the bridge including load testings and measurements with this 3D technique. The main objective is to determine the homogeneity of the concrete and its mechanical properties, in addition to the identification and checking of the arrangement of the reinforcement with respect to the project plans. Specifically, it is of interest for repairing strategies, the evaluation of the resistance and homogeneity of the concrete in the different elements monitored, based on the results of the compression tests carried out on concrete and results obtained from ultrasound and sclerometric testings. On the other hand, the distribution of the reinforcing is characterized based on high frequency Ground Penetrating Radar (GPR) results, and comparing these surveys with the project specifications (RiNA, 2018).

2 LIGHTLY INVASIVE AND NON-INVASIVE SURVEYS PERFORMED AND RESULTS

2.1 *Lightly invasive auscultation. Assessment of resistance and homogeneity of concrete*

Reinforced bars scanner was used for the identification of in situ concrete test tubes. Those tubes were tested at Materials Laboratory in Universidad Austral de Chile. In the particular case of extracting tubes at height, an articulated man-lift platform was used. Prior to lifting the platform, the system is fixed in a horizontal position, ensuring that it will not move at the time of extraction (Figure 4).

Figure 4. Extracting concrete tubes for compressive testing.

Additionally, ultrasonic and sclerometric tests were applied to the tubes, in order to calibrate results with obtained compressive resistances. With this, it is possible to explore other areas of the structure and to obtain mechanical properties without excessive lightly invasive tests (Figures 5a b).

Figure 5. (a) Ultrasonic testings for the tubes at laboratory. (b) Ultrasonic testings in the structure.

Sclerometric tests were carried out at 136 points in different structural elements of the bridge. It should be noted that according to the NCh1565 standard (INN, 1979), this procedure is not applicable to the determination of concrete resistance, so in this case it was applied

only to estimate levels of homogeneity in concrete. It is indicated in the regulations that the errors of the method range around 20 to 25%.

Strengths obtained in laboratory are above the project specifications for all the auscultation areas (H-30 concrete), obtaining the maximum resistances in the approach slabs and viaducts, while the minimum resistances were obtained in the piers. The above could indicate that the quality of the concrete used in the piers is comparatively lower than those used in the other areas.

Regarding the ultrasound results, it was observed that the average values obtained in the northern and southern sectors are similar to each other. In the case of the southern sector, the deviation exceeds 10% of the average for this element. Average time values for the viaduct are in the order of 2700 m/microsec), for indirect tests.

Sclerometric tests showed average values of 702 kg/cm2 for the viaduct, with dispersions up to 50 kg/cm2, that can be excessive.

2.2 *Non-invasive geophysical surveys. Reinforcement identification and detection of pathologies*

To characterize the arrangement of reinforcement in the defined areas of the bridge, two complementary non-invasive methods were used: reinforcement scanner and Ground Penetrating Radar.

The reinforcement scanner or pacometer was used to characterize the presence of reinforcing steel in the structure, mainly determining the spacing and direction of the reinforcing bars, managing to estimate in certain areas the thickness of the mechanical recover of the concrete. It should be noted that one of the main limitations of this device is that as the mechanical recover increases, precision can be poor in determining its thickness, also making it difficult to detect the diameters and location of the reinforcing bars. On the other hand, in cases where the mechanical recover very low and/or the reinforcement is very dense, the identification of individual bars can be difficult or non-precise.

To solve difficulties related with penetration capacity and resolution, medium and high frequency Ground Penetrating Radar (GPR) was used to identify with more precision the location, spatial distribution and recovering of the reinforcement. This technique constitutes the state-of-the art for the non-invasive auscultation in reinforced concrete structures. For the bridge, two frequencies (antennas) were used: 800 MHz and 2700 MHz. The first for the identification of deep reinforced bars and deep detection of cavities and concrete pathologies (up to 1,2 m). The second, for detailed shallow identification of bars and detailed pathologies (up to 60 cm). When executing field surveys, the main considerations that must be taken into account are related with the calibration of acquisition and visualization parameters, which must be adjusted based on the characteristics of the element to be explored. Considering that the penetration capacity of the emitted electromagnetic wave varies depending on the characteristics of the medium, it is necessary to carry out previous tests to calibrate the speed of wave propagation in the medium to be explored (or the dielectric parameter). This calibration was carried out on the interior wall of the south engine room, which has a thickness of 50 cm. (see Figure 6a). Based on this, the propagation velocity of radar waves in the medium (reinforced concrete) was adjusted in such a way that the reflection associated with the opposite face of the wall coincides with the known thickness of the element. Based on this, the propagation speed of the medium obtained was 90 m/microsec. This value is absolutely consistent with typical velocities in concrete with similar humidity conditions.

Post-processing involves, in general terms, the application of 1D filters, 2D filters, static correction, migrations and gain adjustments. Obviously, the application of these post-processing tools will be particular for each radargram (2D image obtained with GPR), and will be applied depending on the objective of the study. It should be noted that unlike the reinforcement scanner, GPR allows the generation of a continuous survey of the element (2D image), determining in the same profile the general distribution of the mechanical recover and the distribution of the steel bars. In some cases, despite the application of different filters, corrections and gains, it is not possible to visualize the object(s) of interest, which indicates that the raw radargram does not contain the necessary information due to the unfavorable conditions of the exploration medium. The results obtained are conditional on the correct interpretation of the reflections or anomalies that are displayed in a post-processed radargram.

Figure 6. (a) Calibration of the GPR. (b) Field surveys with high frequency GPR.

Results of the radargrams post-processed showed adequate distribution of the reinforcement, as well as bar recover, without evidence of pathologies inside the analyzed concrete areas. Figures 7a b show typical radargrams obtained, in this case, for piers and walls of the engine area respectively.

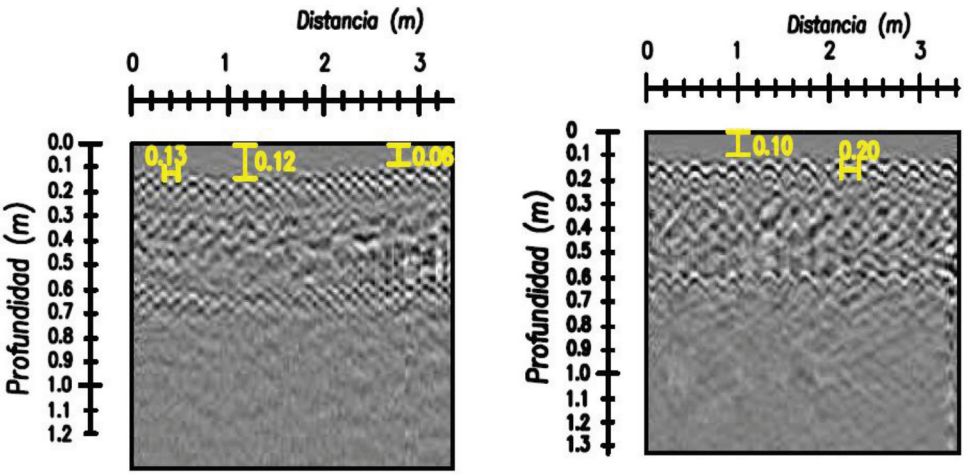

Figure 7. (a) Radargram showing a 2D postprocessed image of the northern pier. (b) Radargram showing a 2D postprocessed image of the engine walls.

2.3 *Remote-sensing techniques*

Remote sensing field surveys were carried out with the objective of generating a high-definition point clouds of the northern and southern sectors of the bridge. For this, a RIEGL VZ-2000 high range Terrestrial Laser Scanner (TLS) was used. The survey was organized in several field campaigns, which consisted of a differentiated survey for each sector of the bridge (North and South). In addition, two campaigns were considered to raise each of the engine rooms associated with the bridge. This technique, permits the generation of high definition complete 3D geometric models of the bridge, including difficult access areas. The georeferenced and multi-adjust post-processing for each position, permits the generation of the complete model, including the engine areas, permitting and adequate link of the interior and exterior areas. This point clouds, constitutes 3D DEMs (Digital Elevation Models) of the structure in detail, permitting load test verifications by means of DoD

(differences of DEMs) as well subsequent generation of structural modellings. Figures 8a b illustrates the TLS field surveys.

Figure 8. (a) Field survey with TLS of the access. (b) Capturing the 3D geometry of the bridge.

As a result, it was possible to obtain calibrated 3D models. Figure 9 shows part of the complete 3D model of the bridge, as well as Figure 10 shows a DEM obtained for calibration model with real load tests. The three control points are observed for the vertical deflection measurements for each loading condition.

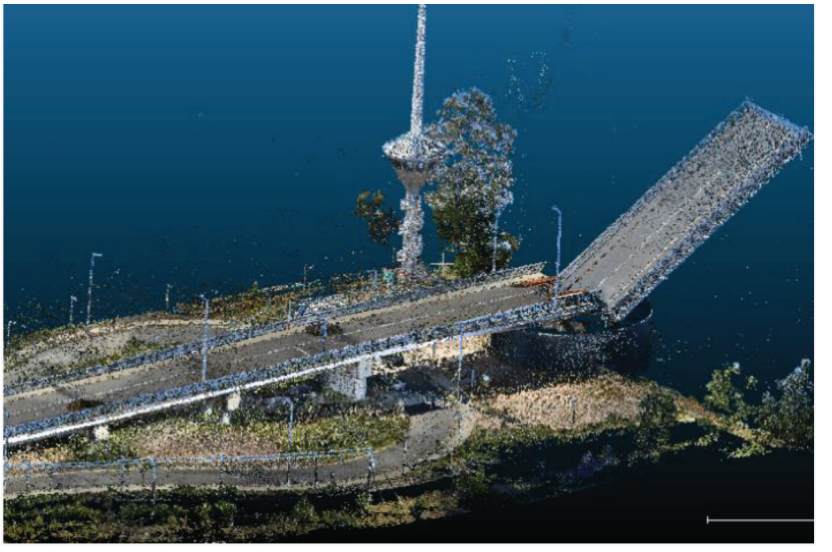

Figure 9. 3D model of the obtained with a high resolution high range terrestrial laser scanner. Real colors of the point cloud were generated with a high definition camera installed in the TLS.

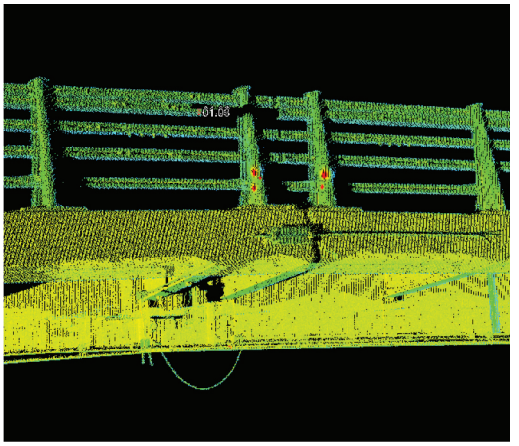

Figure 10. DEM for the measured deflections obtained with real load cases.

3 CONCLUSIONS

Several lightly invasive and non-invasive auscultation surveys were performed in the Cau Cau bridge. Main conclusions are:

- The use of lightly invasive testings are mandatory for calibration of models, especially for the definition of mechanical properties. For the bridge, results of resistance are above the specifications of the original project.
- Non-invasive surveys were highly useful for identification of real distribution of steel bars. GPR technique is fast and economical technique that permits generation of 2D images inside the concrete with a high definition and precision. The bar spacings and related information obtained are consistent with results obtained with pacometer, and also tend to be consistent with what is indicated in the planimetry and technical specifications.
- 3D modelling by means of remote sensing by means of TLS permits the generation of complete geometric 3D models of the structure, as well as calibration with real load tests, resulting in a fast and more precise technique compared with traditional topographic methods.

A study on machine learning for creating crack images of RC columns

H. Yasukawa & H. Naito
Tohoku University, Sendai, Miyagi, Japan

H. Fujioka & S. Fujikura
Utsunomiya University, Utsunomiya, Tochigi, Japan

ABSTRACT: A reversed cyclic loading test was conducted on a RC column specimen to examine the effectiveness of vibration measuring and machine learning for damage evaluation of RC columns. In the loading test, 11 acceleration sensors were placed on the surface of the column to obtain frequency responses at concrete cracking and spalling of the cover concrete. It was determined that an unsupervised learning model can evaluate the damage levels and locations, based on intact data measured before the loading test. Moreover, a following supervised learning method indicated the possibility of creating crack images on RC columns, from frequency responses measured with sensors.

1 INTRODUCTION

Civil structures (e.g. roads, railways, power plants, dams) are essential for modern living. However, a lot of civil structures are aging in Japan. In addition, some structures have serious damage resulting from natural disasters, such as large earthquakes, floods, landslides, avalanches. Non-destructive inspection and evaluation of civil structures are needed to detect damages and evaluate their safety performance.

Many studies on non-destructive testing and structural health monitoring have been conducted. These methods are useful to detect invisible damages (e.g. cracks, voids, delamination) within concrete structures (Maccan et al., 2001). The effectiveness of an impact echo method for detecting damage in concrete structures has been demonstrated (Cheng and Sansalone, 1993). Moreover, the possibility of an impact echo method for evaluating not only the damage location but also the damage sizes has been researched (Huang et al., 2010). In addition, it has been determined that electromagnetic wave methods are also useful to detect cracks, voids, and delamination near the surface of concrete structures (Barreira et al., 2007).

Deep learning (DL) has been used in non-destructive evaluation of structures (Avci et al., 2021). Its merits include accurate diagnosis and reducing inspection duration and labor. However, it has difficulty in collecting a large amount of training data, since civil structures might have various damage depending on the situation. Anomaly detection methods based on an autoencoder have been useful to evaluate damage levels and locations without labeled training data (Chow et al., 2020, Fujisaku et al., 2023). Furthermore, generative AI has created the possibility of creating crack images in concrete structures. Dung et al. (2019) has performed a crack image classification task with a convolutional neural network. Engineers can discuss reasonable maintenance plans from the evaluated damage conditions and structural performances based on the created crack images. Generative AI crack images provide innovative inspection and maintenance of civil structures, though experimental data and further examinations are needed.

In this study, a reversed cyclic loading test was conducted on a RC column specimen. In the test, 11 acceleration sensors were placed on the surface of the column for obtaining vibration

DOI: 10.1201/9781003483755-190

characteristic data at each loading step. An unsupervised learning method for evaluating damage levels and locations was examined. Moreover, a supervised learning method was also used for creating crack images in the RC column.

2 REVERSED CYCLIC LOADING TEST

A reversed cyclic loading test was conducted on a RC column specimen. The details of the specimen are shown in Figure 1. Diameters of the longitudinal and transverse bars were 16 mm and 6 mm, respectively. The transverse bars were arranged at an interval of 60 mm. The design yield

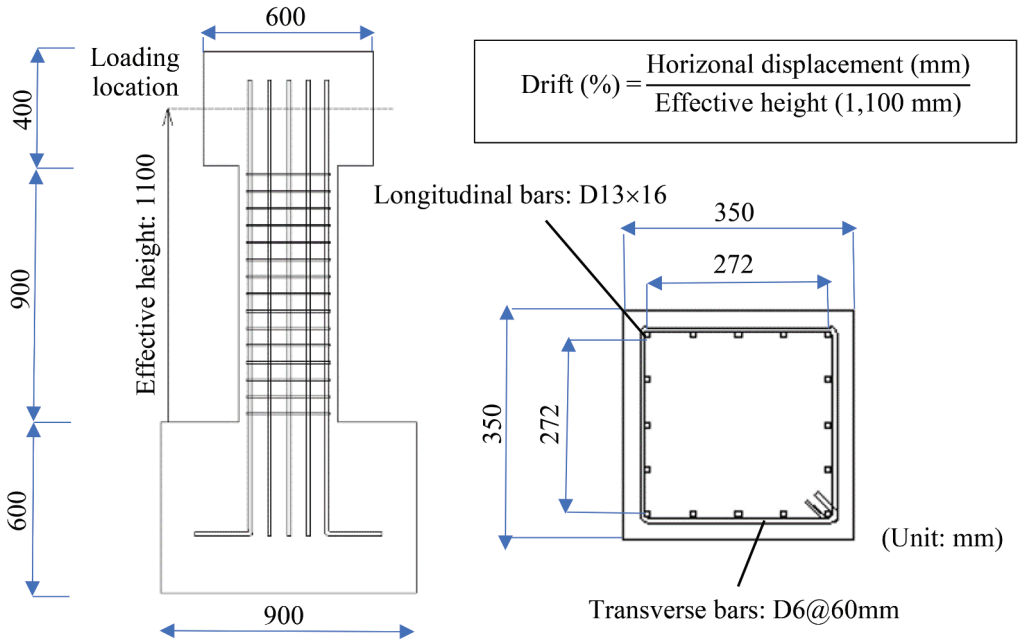

Figure 1. Details of the RC column.

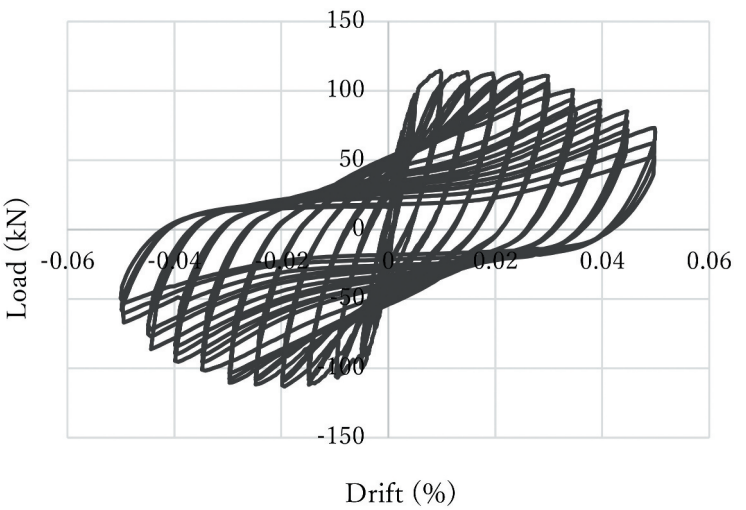

Figure 2. Load-drift relationship.

strength of bars was 295 N/mm^2. Material properties of concrete were obtained from test cylinders with a diameter of 100 mm and a height of 200 mm. The compressive strength and elastic modulus of the concrete were 35.3 N/mm^2 and 28,500 N/mm^2, respectively.

An axial force of 122 kN was applied to the top of the column. A lateral load was applied at the height of 1100 mm from the bottom of the column, as shown in Figure 1. The loading steps were set to drifts of +/–0.25 %, +/–0.5 %, +/–1.0 %, +/–1.5 %, . . ., and +/– 5.0%, where the drift was defined as the horizontal displacement divided by the effective height of 1100 mm. The number of cycles were three at each loading step.

Figure 2 shows the relationship between load and drift obtained in the loading test. In addition, crack images observed at the drift of 3.0 % are shown in Section 4, Figures 8, and 9. The column failed in flexural mode. In particular, the horizontal load decreased over the drift of 3.5 %, when the cover concrete spalled.

3 ANOMALY DETECTION USING UNSUPERVISED LEARNING

3.1 *Vibration monitoring*

In this section, the effectiveness of vibration monitoring and unsupervised learning for damage detection was examined. Forced vibration testing with a portal electric-magnetic vibrator was conducted on the column at each loading step (Naito et al., 2019). The excitation and measurement locations with acceleration sensors are shown in Figure 3. The sensors were placed on the south surface (S200 to S850) and the north surface (N225 to N675) for obtaining frequency response functions in the loading test.

The vibrator had a mass of 1.8 kg, a diameter of 95 mm, a height of 62 mm, the maximum excitation force of 50 N, and a frequency range of 100 to 20,000 Hz. Using the vibrator, white noise force was applied at the height of 850 mm from the bottom of the column. The excitation force was controlled at a power spectral density (PSD) of 0.5 $(m/s^2)^2$ /Hz over a frequency range of 1,000 to 20,000 Hz. The root mean square of acceleration amplitude (RMS) was 97.6 m/s^2.

Frequency response functions were obtained from the acceleration records with the sensors, using a Fast Fourier transform (FFT). The frequency responses had the range of 1,000 to 20,000 Hz with a resolution of 97.7 Hz. As a result, the deep learning models, described in a later section, used 194 parameters of one-dimensional data as features.

3.2 *Anomaly detection*

An autoencoder based on a neural network was used for damage evaluation. The structure of the autoencoder is shown in Figure 4. The model was built and trained with Keras and TensorFlow in Python. The input data f_i (i = 1 to 194) was given from the frequency responses and compressed through three hidden layers. Decoding was carried out in the same process. A Rectified Linear Unit (ReLU) was used as activation functions of the hidden layers. Sigmoid function was used in the output layer. The optimizer was Adam. The model was trained with a batch size of 16. Early stopping was employed in the training process. The training was terminated when the validation loss did not improve for three epochs.

The autoencoder was trained on frequency responses obtained from the intact column before loading. The autoencoder can reconstruct test data well when it is similar to the training data. However, the autoencoder cannot reconstruct test data from the damaged column since the data is different from the training data. Damage evaluation was based on anomaly scores calculated from the reconstruction error with an additional process. Moving averages of the input f_i (i = 1 to 194) and the output g_i (i = 1 to 194) with a width of 10 parameters were taken (Fujisaku et al., 2023). The anomaly score e was defined as,

$$e = \frac{\sum_{i=1}^{194} |f_i - g_i|}{\sum_{i=1}^{194} f_i} \tag{1}$$

3.3 *Results and discussions*

396 intact frequency responses were obtained from each sensor before the loading test. Moreover, 5 frequency responses were obtained from each sensor at each loading step. The autoencoder was trained on the intact data for each sensor location. As an example, Figure 5 shows comparisons between input and reconstructed output data of S200. The intact data before loading was reconstructed well, whereas the test data obtained at the drift of 3.0 % was not reconstructed.

Figure 6 shows the relationships between anomaly score and drift for the 11 sensor locations. Where, the anomaly score was normalized by the threshold determined as the average of anomaly score of the intact data. The anomaly scores were evaluated from averaging 5 measurement trials at each loading step.

From the results, the anomaly scores of S200 increased as the drift increased, as large flexural cracks occurred around the bottom of the column. Moreover, the cover concrete spalled over the drift of 3.5 %, resulting in high anomaly scores of S200.

The anomaly scores of S300 and S400 were also increased during the negative loading rather than the positive loading. This indicates that large cracks on the tensile/south surface during the negative loading increased the anomaly scores of S300 and S400. On the other hand, the anomaly scores were lower when the cracks were closed during the positive loading.

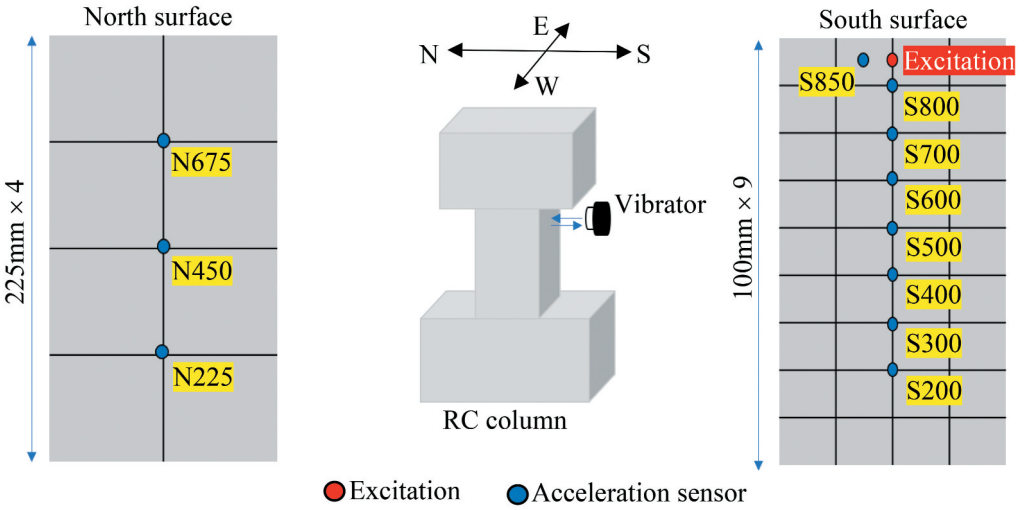

Figure 3. Excitation and measurement locations.

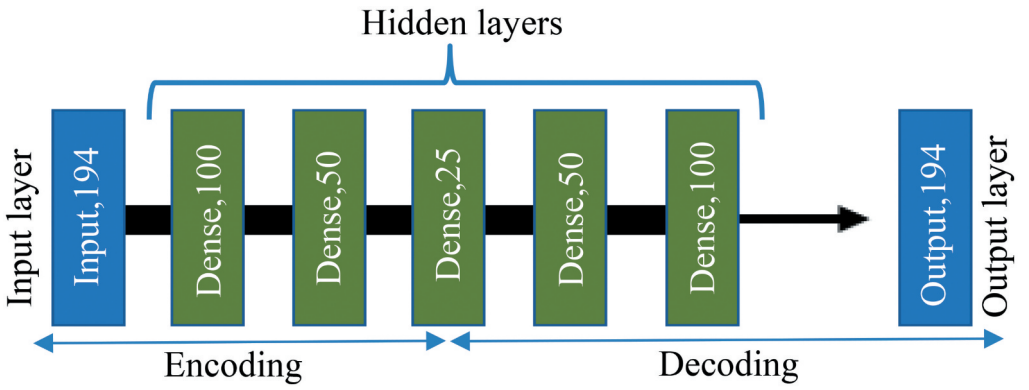

Figure 4. The structure of the autoencoder.

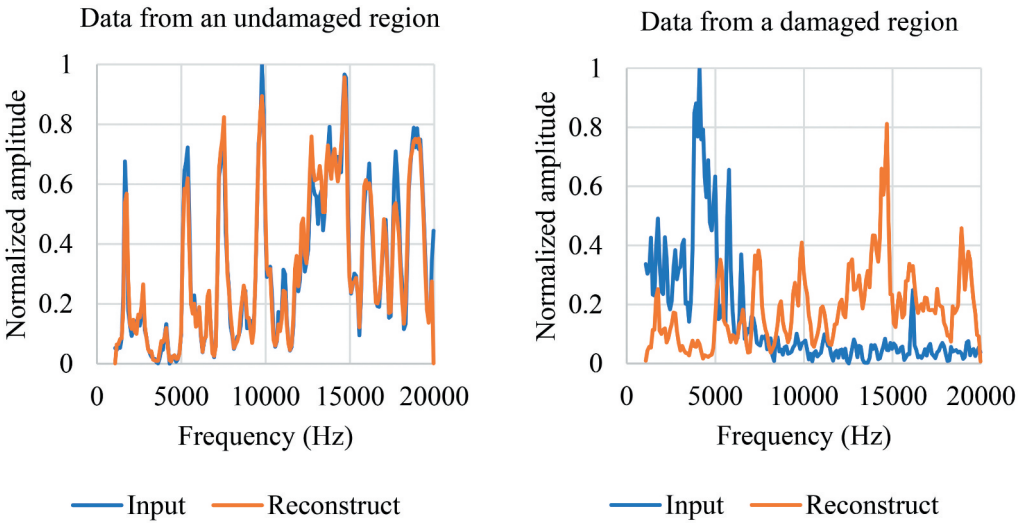

Figure 5. Comparisons between input and reconstructed data through the autoencoder.

Around the top of the column, the anomaly scores of S600-S850 were low. Slight cracks appeared around the sensor locations through visual observation. This indicates the autoencoder cannot detect slight flexural cracks.

From the results, the anomaly detection method based on an autoencoder is useful to detect damage (e. g. large flexural cracks, spalling of cover concrete) in RC columns. The proposed method detects serious damages but does not register slight cracks that do not affect structural performance.

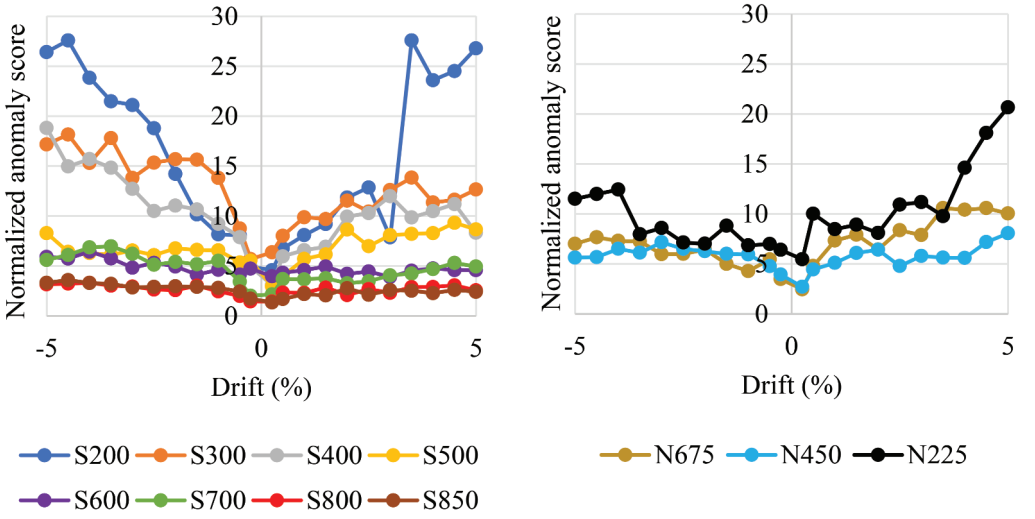

Figure 6. Relationship between anomaly score and drift of the column.

4 CREATING CRACK IMAGES USING SUPERVISED LEARNING

4.1 *Convolutional neural network*

The effectiveness of anomaly detection based on an autoencoder was shown in Section 3. However, the method does not provide detailed information on the cracks (e. g. crack widths,

lengths, angles, and crack density). In response, supervised learning was used for creating crack images in the damaged RC column.

The structure of a convolutional neural network (CNN) is shown in Figure 7. The model was built and trained with Keras and TensorFlow in Python. The one-dimensional data of frequency responses were also given in the input. The input with 194 neurons was broken down into one-dimensional convolutional layers through 10 filters with a kernel size of 3 and a stride of 2. In all layers except the output layer, batch normalization was applied between convolutional layers and activation functions, where Exponential Linear Unit (ELU) was used as the activation function. In the output layer, Sigmoid function was used as the activation function. The optimizer was Adam, with a learning rate of 0.0001 to 0.001. The model was trained for 200 epochs with a batch size of 16.

For labeling the data in the supervised learning, 2-dimensional crack images observed on the south and north surfaces at each drift were given in another input layer, as shown in Figure 7. The crack images observed around the sensor locations were converted to the sizes of 175 × 150 pixels. The crack images obtained at the drifts of 0.5 to 3.0 % were used in the training process, since the cover concrete spalled at the drift of 3.5 %. In addition, the data obtained from the sensor S850 was not used in the examination.

The datasets of two cases were compared. In the case of A, all frequency responses and crack images obtained in the loading test were given to train the CNN. In the case of B, the data obtained at the tested drift was removed from the dataset of Case A. These datasets contained the frequency responses and crack images from all sensor locations, except for S850. The amount of training data of Cases A and B were 580 and 550, respectively.

4.2 *Results and discussions*

Figures 8 and 9 illustrate the crack images at the drift of 3.0 % using the trained CNN. In Case A, the created images agreed with the experimental images. This result indicates the possibility of creating crack images based on vibration monitoring and supervised learning subject to a large amount of training data.

On the other hand, the created images in Case B were unclear around the bottom of the column, due to lack of training data at the tested drift. In particular, the data obtained at the drift of 3.0 % were very different from those of the drift of 0.5 to 2.5 %, since large cracks occurred at the drift of 3.0 % in the loading test. However, the trained model in Case B provided fine images around the middle and top of the column, even with limited training data.

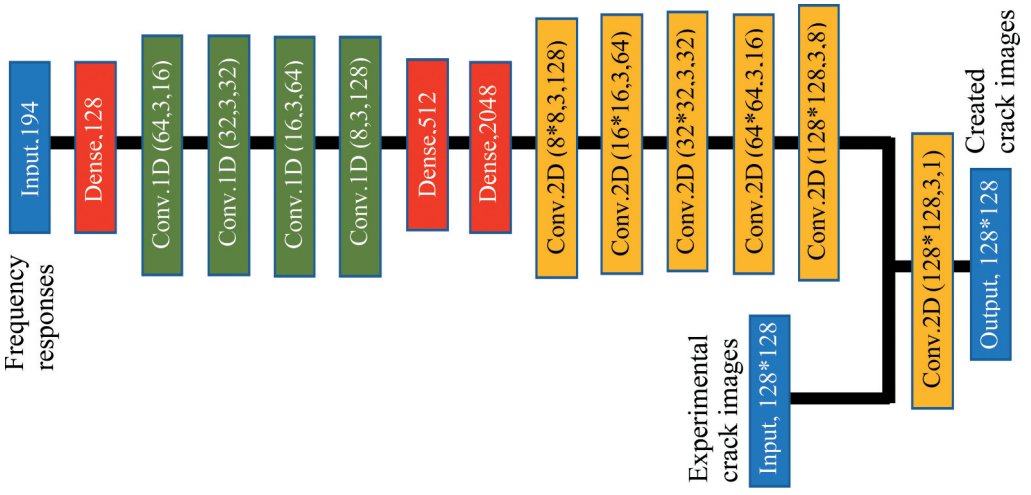

Figure 7. The structure of the convolutional neural network.

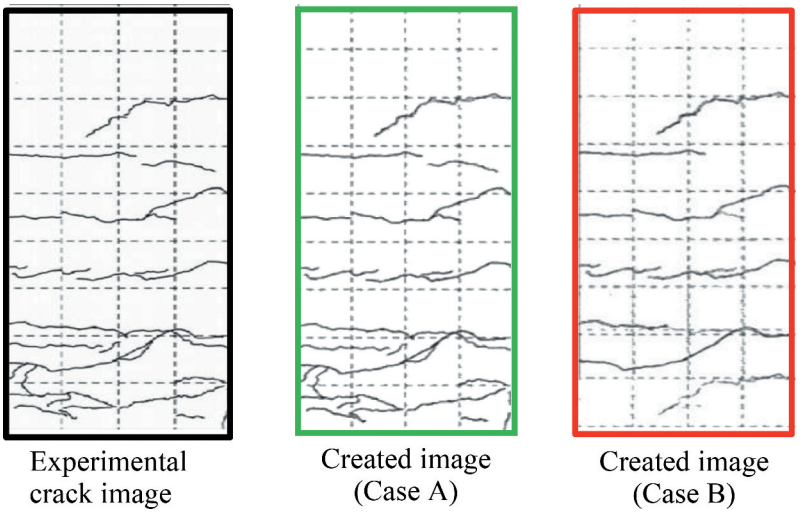

Figure 8. Created crack images on the south surface.

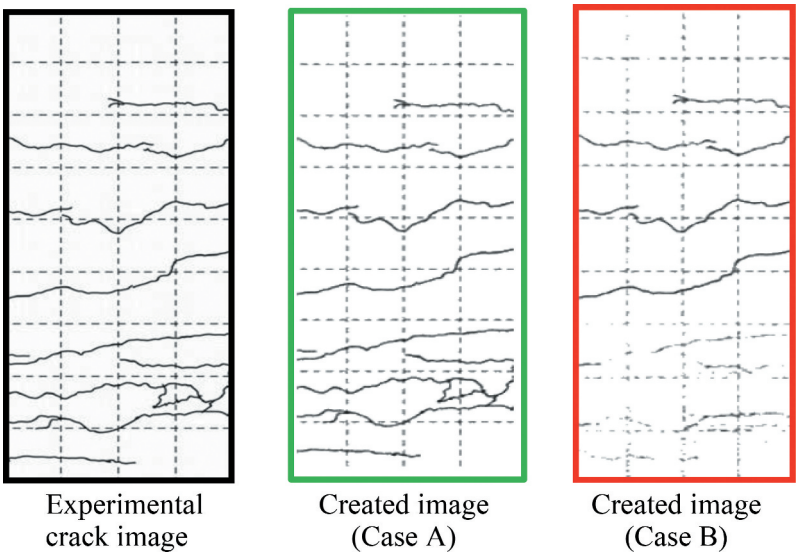

Figure 9. Created crack image on the north surface.

5 CONCLUSIONS

In this study, the effectiveness of vibration monitoring and machine learning for detecting damage of RC columns was examined. Anomaly detection (unsupervised learning) and creation of crack images (supervised learning) were conducted on a RC column specimen subjected to a reversed cyclic loading. From these examinations, findings were observed as indicated:

(1) A damage detection method using an autoencoder was proposed. Anomaly scores were evaluated on the RC column specimen before and after the loading. From the results, the anomaly scores decreased when large flexural cracks and spalling of cover concrete occurred in the column. Moreover, the anomaly score was not sensitive to a slight crack.

(2) A convolutional neural network was built for creating crack images in the RC column. The trained model created crack images accurately. The possibility of machine learning for creating crack images was shown, though requires a large amount of training data.

These findings were obtained from the loading test and vibration monitoring on the RC column specimen. Additional experiments and calculations are needed to improve the methods for damage detection and creating crack images. Moreover, numerical simulations (e.g. concrete cracking analyses, wave propagation analyses) would be useful to obtain a large dataset for training deep learning models. The authors are considering the use of simulation tools and transfer learning in a further study.

In addition, these supervised and unsupervised machine learning were examined for each sensor independently. This means the machine learning methods can be used not only for structural health monitoring with multiple sensors but also for conventional non-destructive inspection (e.g. hammering testing, impact echo method) with using a single sensor. In particular, the unsupervised method is thought to be helpful for improving non-destructive inspection of concrete structures in site.

ACKNOWLEDGEMENTS

Mitigation of unwanted effects in drive-by acceleration data for bridge monitoring

M. Casero & A. González
University College Dublin, Dublin, Ireland

K. Feng
Queen's University Belfast, Belfast, UK

ABSTRACT: Drive-by bridge health monitoring is hindered by the adverse effects of the road surface. In this paper, noisy accelerations are simulated for the unsprung mass of a quarter-car crossing a beam with a rough road profile at two different speeds. The fast Fourier transform, and the transfer function are applied to extract real and imaginary parts of the response of the contact point with the bridge, thus mitigating the impact of vehicle-related factors. The responses for the two speeds are subtracted in the spatial domain to isolate the bridge component within the resulting power spectral density, effectively removing the influence of the road profile. Damage is characterized by comparison with a database of power spectral densities derived from the contact point response of a moving constant force. The methodology exhibits great accuracy in identifying the damage caused by a localized crack of size 10% to 30% of the beam depth.

1 INTRODUCTION

Road vehicles can be equipped with devices that measure the response of underlying road and bridge infrastructure to evaluate its structural condition as they travel along. While their use in monitoring road condition, particularly roughness, is widespread, their application to bridges is limited. Existing proposals for applying drive-by to bridge monitoring heavily rely on theoretical tests, lacking substantial support from field campaigns (Malekjafarian et al., 2022). Often, experiments are confined to laboratory results using scaled models of vehicles and bridges, which fail to accurately replicate real-world conditions and tend to result in quasi-static scenarios. Field implementations are rare, and they primarily involve simple means to extract bridge frequencies from vehicle accelerations, such as the fast Fourier transform (FFT) or power spectral density (PSD). This information is then used to detect potential changes in bridge behavior. The following paragraph reviews successful instances of drive-by systems tested on bridges in the field and their outcomes.

Lin and Yang (2005) successfully estimated the 1st bridge frequency from trailer accelerations for vehicle speeds up to 35 km/h. Yang and Chang (2009) employed empirical mode decomposition on the acceleration data from a tractor-trailer vehicle driving at 10 km/h to enhance the visibility of bridge frequencies, including higher modes. Elhattab et al. (2018) utilized frequency-independent underdamped pining stochastic resonance to identify the 1st bridge frequency from measurements taken from a three-axle truck driving at up to 53 km/h. Singh and Sadhu (2022) proposed a time-frequency method based on a Wavelet packet transform of the vehicle measurements to decouple vehicle-bridge interactions. Yang et al. (2022) suggested parking the monitoring vehicle on the bridge, excited by random traffic, to obtain the first four bridge frequencies of the bridge while avoiding the impact of the road profile. With the advancement of smartphone technology, the use of smartphones for measuring

DOI: 10.1201/9781003483755-191

accelerations in drive-by systems is gaining popularity (Shirzad-Ghaleroudkhani and Gul, 2021). In contrast, Liu et al. (2023) measured tire pressure and related it to the relative displacement between the axle and contact point, as the latter is more sensitive to bridge frequencies and less influenced by vehicle dynamics.

The literature review underscores acceleration as the preferred response in field implementations due to the simplicity and affordability of its collection, but successful results are typically limited to detecting frequency changes in medium and long-span bridges (Li et al., 2023). The goal of this paper is to expand on the current capabilities of drive-by technology, by using acceleration data to detect, locate, and quantify damage in the form of an equivalent stiffness loss in a short-span bridge. Here, the main challenge lies in separating the bridge component from the usually larger vehicle and road components, which heavily influence the measured acceleration, even more so in shorter bridges. The methodology section outlines a five-step damage detection algorithm that mitigates road and vehicle components in drive-by measurements. The results section demonstrates the accuracy of the algorithm across 1800 different damage scenarios and measurements contaminated with two noise levels (1% and 5% noise). Finally, the conclusions section highlights the main findings of this work and suggests avenues for future research.

2 METHODOLOGY

2.1 *Vehicle-bridge interaction model*

The algorithm's functionality is illustrated using a quarter-car (QC) vehicle model. The sprung and unsprung masses are assumed to be 8900 and 1100 kg respectively, therefore the gross vehicle weight (GVW) equals 98 kN (Cebon, 1999). The suspension and tire stiffness are specified as 2×10^3 and 3.5×10^3 kN/m, respectively, with adopted viscous damping of 40 kNs/m for the suspension and 4 kNs/m for the tire. These properties yield vehicle frequencies of 1.89 and 11.35 Hz. The QC traverses a planar simply supported discretized bridge model featuring a -15 m span length and a 0.75 m depth. The bridge model consists of 150 discretized beam elements, each with a length of 0.1 m, cross-sectional area of 11.25 m^2, and a uniform 2nd moment of area (I) of 0.5273 m^4. Typical properties of reinforced concrete are assumed for the bridge material, with a modulus of elasticity of 35 GPa and a unit weight of 2500 kg/m^3. The road profile is characterized as class 'A' per ISO standards, with a geometrical spatial mean equal to 0.1×10^{-6} m^3/cycle. In its healthy state, the first two longitudinal modes of vibration of the bridge correspond to frequencies of 5.66 and 22.62 Hz. Bridge damage is introduced following the stiffness loss model proposed by Sinha et al. (2002) for a crack. The reduction in the 2nd moment of area is maximum at the crack location where $I = (1 - (1 - \lambda)^3) \times 0.5273$ m^4, with λ representing the ratio of the crack depth to the cross-section height. The value of I increases linearly up to 0.5273 m^4 at a distance of 1.125 m on either side of the crack.

2.2 *Drive-by algorithm for locating and quantifying reductions in bridge stiffness*

The five-step damage detection algorithm proposed in this paper capitalizes on the sensitivity of the PSD of the bridge response to the location and severity of the damage. To successfully isolate the bridge component contained within the axle acceleration, it is crucial to consider the transfer function (TF) between the vehicle and the contact point with the bridge, together with the spatial invariant nature of the road profile.

2.2.1 *Steps 1 and 2: Acceleration measurement at two speeds, and conversion to frequency domain*

First, the vehicle traverses the bridge at two different constant speeds, and the vertical acceleration at the QC is recorded. Two potential measurement locations, namely the unsprung and the sprung masses of the QC model, are initially considered. Speeds of v_1 = 5 m/s and v_2 = 10 m/s are used to illustrate the proposed methodology. The FFT is applied to the acceleration time history to calculate the real and imaginary parts of the signal in the frequency domain.

2.2.2 *Step 3: Removal of PSD content associated with vehicular components*

In Step 3, the TF is applied to estimate the contact point response from the measurements at the vehicle. In general, the TF is the ratio between two responses, i.e. the acceleration of the unsprung mass and the acceleration of the contact point in the frequency domain. Consequently, the contact point response can be calculated using the TF without direct measurement. Practical challenges in directly measuring the contact point response make the use of the TF a viable solution. The TF can be obtained by driving the vehicle over a stretch of road with a known profile. For the simulations in this paper, the theoretical TF between the QC and the contact point is utilized.

The PSD of the contact point is reconstructed from the real and imaginary parts resulting from the application of the TF to the vehicle acceleration. It is anticipated that the PSD of the contact point will alleviate the impact of the vehicle component contained in the original measured/simulated signal. The effectiveness of the TF in removing the vehicle content from the PSD can be visualized in Figure 1 for the vehicle moving at 5 m/s over smooth (Figure 1a, b) and class 'A' (Figure 1c, d) road profiles. Figure 1a, c and Figure 1b, d use the acceleration of the sprung and unsprung masses respectively, as the measurement location in the vehicle. Figure 1a, b illustrates the amplification of the amplitude of the PSD around the 1st bridge frequency (5.66 Hz) after applying the TF in the absence of a road profile. The plots also show a good match between the PSDs of the estimated and true contact point responses. In Figure 1a, b, the estimated contact point PSD contains only the bridge component in the absence of the road profile. When the rough road profile is introduced (Figure 1c, d), the estimated contact point PSD contains both the bridge and road components. The unsprung mass is preferred over the sprung mass due to its easier accessibility in a vehicle; hence, the following steps will exclusively focus on the unsprung mass response.

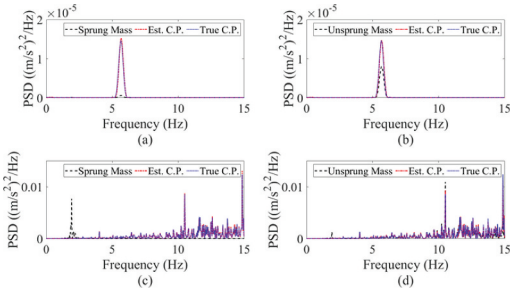

Figure 1. True vs estimated contact point PSDs via sprung mass and unsprung mass acceleration with: (a, b) a smooth road, (c, d) a class 'A' road, at 5 m/s.

2.2.3 *Step 4: Removal of the PSD content associated with road frequencies*

The real and imaginary parts of the FFT of the acceleration signal of the unsprung mass of the QC traveling over the bridge at 5 and 10 m/s are given in Figure 2 for reference. The real ($a_{CP}(f)$) and imaginary ($b_{CP}(f)$) parts at the contact point resulting from the application of the TF in Step 3 are also shown in Figure 2.

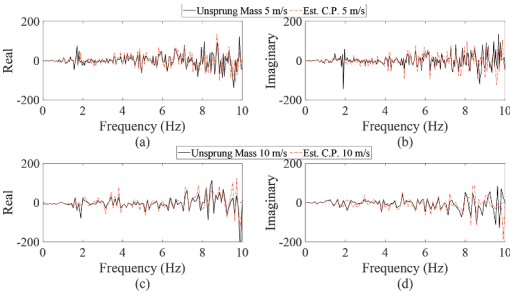

Figure 2. Real (a, c) and imaginary parts (b, d) of the unsprung mass and contact point responses at 5 m/s (a, b) and 10 m/s (c, d) in the frequency domain.

The real and imaginary parts presented in Figure 2 are expressed in the temporal frequency domain, preventing direct comparisons at different vehicle speeds (Figure 2a, c). To facilitate comparison in the spatial frequency domain (cycle/m), the values in the temporal frequency domain are normalized by the vehicle speed, and the amplitudes of the real and imaginary parts are multiplied by $1/v^4$, where v is the vehicle speed in m/s. Regardless of the vehicle speed, the representation of the road profile in the spatial frequency domain should be the same. Therefore, subtracting the real and imaginary parts of the contact point at two different speeds in the spatial frequency domain is expected to eliminate or significantly mitigate the road component. The outcome of this subtraction is depicted in Figure 3a, b for the real and imaginary parts. The subtracted real and imaginary parts are then transformed back into the frequency domain to improve the visualization of the relevant peak frequencies (Figure 3c, d). The peak corresponding to the 1st bridge frequency is marked with vertical dashed lines in Figure 3a, b (1.13 cycle/m) and Figure 3c, d (5.66 Hz).

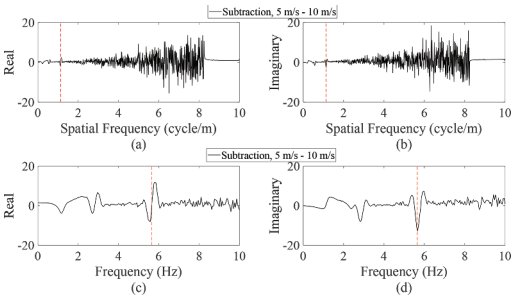

Figure 3. Subtracted real (a, c) and imaginary parts (b, d) of the contact point in the spatial frequency (a, b) and frequency (c, d) domains.

To enhance the visibility of the 1st bridge frequency, the PSD associated with the real and imaginary parts shown in Figure 3c, d is calculated. When carrying out this calculation, it is possible to use either vehicle speed as reference (v_i), i.e., $i = 1, 2$ and $j \neq i$ in Equation 1.

$$PSD_{bridge}(f) = \left(a_{CP}(f)|_{v_i} - \frac{v_i^2 \times a_{CP}(f)|_{v_j}}{v_j^2} \right)^2 + \left(b_{CP}(f)|_{v_i} - \frac{v_i^2 \times b_{CP}(f)|_{v_j}}{v_j^2} \right)^2 \quad (1)$$

Figure 4 displays the final estimated PSD, labeled as "Est. Bridge", which contains solely the estimated bridge component of the contact point acceleration. This is juxtaposed with the estimated PSD associated with the total acceleration of the contact point, labeled as "Est. C. P.", which includes both bridge and road components, as directly obtained via the TF. Additionally, the figure incorporates the PSD of the unsprung mass acceleration ("Unsprung mass"), the true PSD linked to the irregularities of the road profile ("True R.P.") and the true PSD associated with the bridge component of the contact point acceleration ("True Bridge") for comparative analysis. Figure 4a showcases an estimated 1st bridge frequency of 5.76 Hz using v_1 = 5 m/s as a reference, indicating an error of 1.77%. The estimated amplitude of the peak is 1.59×10^{-5} g^2/Hz with a relative error of –2.45% compared to its true amplitude of 1.63×10^{-5} g^2/Hz. The "Est. Bridge" curve in Figure 4b uses v_2 = 10 m/s as reference, yielding a bridge frequency of 5.71 Hz and amplitude of 5.17×10^{-5} g^2/Hz, with relative errors of 0.88% and 46.88% respectively. Even though the bridge frequency is slightly more accurate in the last instance, the zoom-in windows in Figure 4 reveal that the overall shape of the PSD is closer to the true one in Figure 4a, suggesting more accurate results are obtained when making the conversion using the lower of the two speeds. Figure 4 demonstrates that the proposed approach, involving the TF and subtraction at two speeds, estimates a PSD containing peaks associated with the bridge frequencies only. Therefore, this estimated PSD should closely resemble the PSD extracted from a P-load model with the same GVW as the vehicle

and traveling over a numerical model of the bridge at the same speeds. Here, P-load model refers to a constant force traversing the bridge, where vehicle dynamics and the road profile are disregarded, and there is no interaction between the vehicle and the bridge.

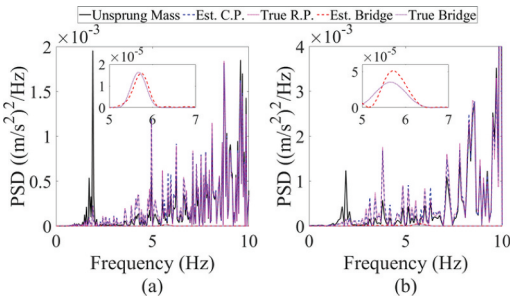

Figure 4. Estimated PSD of acceleration of the contact point, estimated and true PSD of bridge component, and true PSD of road irregularities, for speeds of: (a) 5 m/s, (b) 10 m/s.

2.2.4 *Step 5: Damage detection through comparison with P-load database*

Steps 1 to 4 encompass the manipulations necessary to extract pertinent information from the acceleration signals measured in the field (or numerically simulated in this paper). After completing these steps, the algorithm compares the estimated PSD of the bridge, as shown in Figure 4, with a database of PSDs derived from a numerical model of the bridge subjected to a P-load with the same GVW as the vehicle. To enable a comparison between the P-load and the estimated PSD from Step 4, the database must be built by subtracting the PSD from P-load crossings at the same vehicle speeds used in Steps 1 to 4. The use of a P-load model offers a dual advantage: (1) only the static weight of the vehicle needs to be known (dynamic parameters are unnecessary), and (2) the computational time required is significantly reduced compared to the use of a full vehicle model. In the numerical model, the location and severity of the damage are varied to cover a broad spectrum of scenarios. In particular, the severity varies from $\lambda = 10\%$ to $\lambda = 30\%$ in 1% increments, while the location ranges from 0 to 15 m in 0.1 m increments. By comparing the estimated PSD of the bridge component of the contact point (referred to as "Est. Bridge") in Figure 4 to each of the PSDs in the database, it is possible to determine the damage location and severity of the optimal solution. The latter is given by the PSD from the P-load database resulting in the minimum least squares difference with respect to the "Est. Bridge" curve. The least squares are calculated for a portion of the PSD covering ±0.5 Hz around the peak frequency.

3 RESULTS

The algorithm undergoes testing for 1800 different damage scenarios using the bridge, QC vehicle, and road models described in the preceding section. These scenarios are randomly generated by sampling locations between 0 and 15 m and severities (λ) ranging from 10% to 30% with millimetric precision. Understandably, the algorithm's sensitivity diminishes as the damage gets smaller, and scenarios with severity λ below 10% are excluded. Given that field measurements will be affected by noise, the simulated acceleration signals are contaminated with an additive noise model. This involves randomly sampling values from a normal distribution with a zero mean and a standard deviation equal to a percentage (i.e. 1% or 5% in this test) of the standard deviation of the noise-free acceleration, which are then added to the noise-free acceleration response. Subsequently, Steps 2 to 4 of the proposed methodology are applied to the noisy acceleration to estimate the PSD of the bridge component of the contact point. A database of PSDs is established based on a P-load and a bridge model containing the severity and location range under investigation to select the optimal solution as per Step 5. It

is acknowledged that there is an inherent error as a result of the discretization selected for the solution space to be explored by the P-load model. In this paper, PSDs due to a P-load model are obtained in increments of damage severity with 0.75 cm steps and increments of damage location with 0.1 m steps.

The errors in the estimation of the damage location and severity are depicted in Figure 5a, b for 1% noise, and in Figure 5c, d for 5% noise. In these plots, the true location and severity of the tested damage are represented along horizontal and vertical axes, respectively. The color scheme indicates the error magnitude in terms of severity (in cm) and localization (in m). Errors are computed as the estimated value of the location (or severity) of the damage minus the true values.

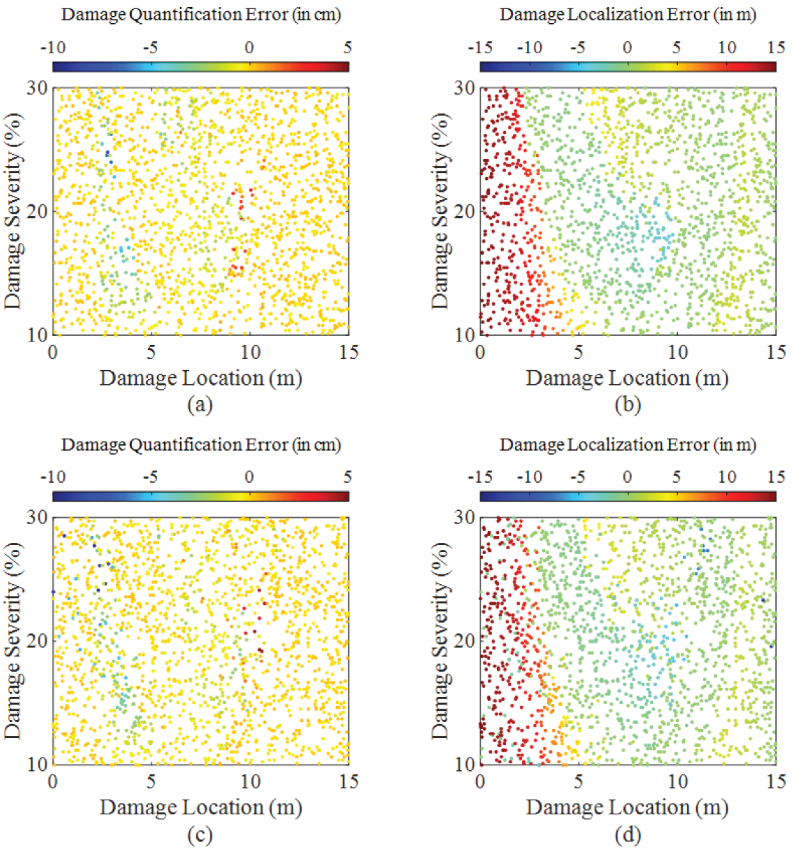

Figure 5. Algorithm prediction errors: with 1% noise: (a) severity and (b) localization; and 5% noise: (c) severity and (d) localization.

The algorithm demonstrates a high level of accuracy in predicting damage severity under both levels of noise (Figure 5a, c). The similar distribution of errors across both noise levels attests to the robustness of the algorithm. For example, when grouping the 1800 random damage scenarios into two severity ranges (10% to 20% and 20% to 30%) and three location ranges (0-5 m, 5-10 m, and 10-15 m), each group consisting of approximately 300 simulations, the largest average error for severity prediction is observed in the group defined by the 0-5 m location range and 10% to 20% severity range. These errors are –0.69 cm (with a standard deviation σ of 1.15 cm) and –0.76 cm (σ = 1.18 cm) for the 1% and 5% noise levels, respectively.

The performance worsens for smaller damage severities and locations closer to the left-hand support, indicated by dark-colored markers in Figure 5b, d. Figure 6a shows the histogram of the localization errors for the two noise levels. While most of the localization errors cluster

around zero, the histogram reveals a right-hand side tail with large errors, corresponding to the observations in Figure 5b, d. When the damage is situated near the left-hand support, the algorithm occasionally chooses a location close to the right-hand support as the optimal solution. In a few isolated cases with 5% noise, the opposite scenario arises, where damage on the right-hand side of the bridge is incorrectly identified at the left-hand side. Figure 6b plots the localization error versus the true location, highlighting a distinctive linear pattern for damage scenarios near the supports. For both noise levels, several points are distributed along the top dashed line, meaning that they share the same damage location estimated as 15 m, i.e. the location of the right-hand support of the bridge. Hence, scenarios on the left-hand side of the dashed line correspond to those at the right-hand side tail of the histogram in Figure 6a. A similar pattern starts to emerge for the 5% level of noise, with two values at the left-hand side of the histogram that can be seen on the bottom right-hand side corner of Figure 6b. Broadly speaking, when the damage is located within the first and last quarters of the span, the algorithm may misidentify the damage location significantly. On the other hand, when the damage is closer to the midspan, the magnitude of the localization error tends to decrease.

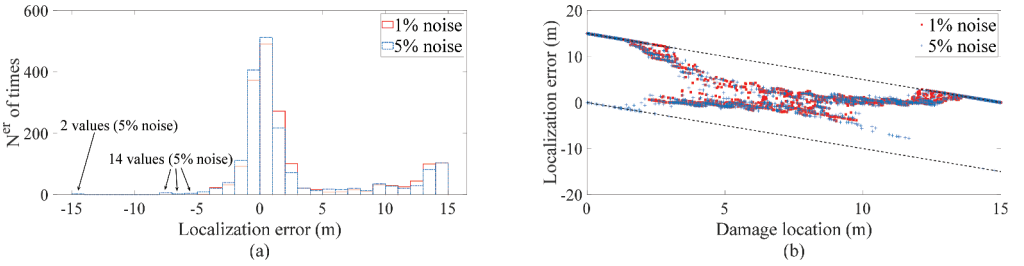

Figure 6. (a) Histogram of damage localization errors, (b) Pattern of localization errors.

The error pattern in damage localization is primarily attributed to two factors: (1) the estimated PSD from the QC tends to exhibit a smaller amplitude than the PSD for the P-load case corresponding to the same damage location and severity, and (2) the amplitude of the PSD in the P-load database for damage near the left-hand support is marginally greater than the PSD in the P-load database for a damage scenario with the same severity, but located near the right-hand support. Figure 7 illustrates an instance of this situation. The estimated PSD of the bridge component of the contact point using the QC is represented for two damage scenarios: (D1) a crack with severity of λ = 10.27% (7.7 cm crack) positioned at 2.267 m from the left-hand support (labelled '7.7 cm @ 2.267 m Est. Bridge'), and (D2) a crack with severity of λ = 10.27% (7.7 cm crack) located at 14.583 m from the left-hand support (labelled '7.7 cm @ 14.583 m Est. Bridge'). Several PSDs

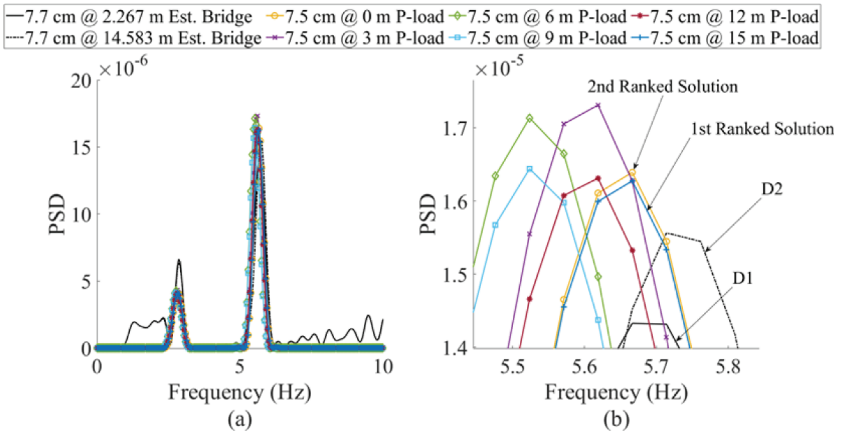

Figure 7. (a) Estimated PSDs for two damage locations vs PSDs from P-load database, (b) zoom-in plot.

from the P-load database for a similar severity (7.5 cm) but different locations (0, 3, 6, 9, 12, and 15 m) are also represented (i.e. '7.5 cm @ 0 m P-load', '7.5 cm @ 3 m P-load', . . ., '7.5 cm @ 15 m P-load'). In the zoom-in window, Figure 7b, it is evident that the PSD of the P-load database for the damage located at 15 m (i.e. '7.5 cm @ 15 m P-load'), or the 1st ranked solution, closely resembles both D1 and D2, even when these two damages are located in opposite ends of the span. The curve '7.5 cm @ 0 m P-load' bears a strong resemblance to '7.5 cm @ 15 m P-load', but has a slightly higher amplitude than the 1st ranked solution for the 15 m location (i.e. the right-hand support). Differences between P-load curves with the same severity, but symmetric locations with respect to midspan (i.e. 0 and 15 m, 3 and 12 m, or 6 and 9 m), become more pronounced for damages located farther from the supports.

4 CONCLUSIONS

The dynamic response of a point that is part of a vehicle-bridge dynamic interaction system can stem from three potential sources: the bridge, the vehicle, and the road surface. Vibrations directly measured on the bridge typically reflect the bridge component, while vibrations measured on the vehicle mainly contain vehicle and road components. Existing literature presents experimental evidence highlighting the successful extraction of bridge frequencies from vehicle accelerations. However, effective field tests are restricted to medium and long-span bridges with good road profiles. In essence, the amplitude of the bridge vibrations within drive-by measurements must be sufficiently high to avoid being overshadowed by vehicle and road components. Also, longer bridges result in lengthier drive-by records, enhancing frequency resolution. Hence, short-span bridges are less conducive to drive-by assessments, a major downside considering the prevalence of these spans in the bridge inventory. To address this limitation, this paper has proposed a methodology that not only extends the applicability of drive-by technology to a broader span range, but also facilitates the localization and quantification of damage. The methodology relies on the accurate removal of vehicle and road components before extracting the PSD associated with the bridge frequency. Successful numerical testing has been conducted for a 15 m bridge span with 1800 different simulated damage scenarios under two noise levels (1% and 5%). The best results have been achieved for the quantification of damage, with a mean error of –0.32 cm (σ = 0.83 cm) for the 1% level of noise and –0.37 cm (σ = 1.04 cm) for the 5% level of noise, taking all 1800 simulations into account. However, some difficulties have been identified regarding the localization of the damage near the supports. This issue arises from the fact that cracks of the same severity in symmetrical locations relative to midspan produce similar effects. Therefore, if the algorithm predicts damage close to either support, the bridge owner would be advised to inspect both. Experimental testing on a real bridge is imperative to comprehend additional potential challenges stemming from the implementation of this novel drive-by methodology in the field.

Smartphone-based monitoring: Improving the bridges braking force model

M. Breveglieri & G. Feltrin
Empa -Swiss Federal Laboratories for Materials Science and Technology, Dübendorf, CH

ABSTRACT: Smartphones can be used to collect real-world information to address the lack of data on the frequency and magnitude of heavy vehicle braking events which was encountered during project AGB 2011/003 (Updated Braking Forces for Road Bridges). The current research aims to obtain a large database of deceleration profiles and to accurately estimate the frequency of braking events per road type by instrumenting a fleet of heavy vehicles in order to improve the previously developed model. For this purpose, Android applications have been developed to collect acceleration, gyroscope and GPS data. Preliminary tests were conducted to validate the use of smartphones against a high-precision system to ensure the accuracy of both acceleration and GPS measurements. The results of a pilot test, conducted by instrumenting one heavy vehicle before the start of the 22-vehicle test campaign, are presented here. This pilot test demonstrates that the smartphone can provide accurate results, resulting in a significant cost reduction compared to traditional measurement systems.

1 INTRODUCTION

While in modern design standards vertical traffic force models are based on probabilistic evaluations targeting a predefined reference return period, braking force models are still derived from a deterministic ad-hoc characterization of the braking process with simplified vehicle configurations. As a consequence, the return period of the braking force is unknown and probably not consistent with that of the vertical load model. The research project AGB 2011/003, entitled "Updated Braking Forces for Road Bridges" (Martins et al., 2016), aimed to improve the assessment of braking forces on road bridges through the development of a novel stochastic procedure.

As long as direct experimental validation is not possible one must rely on computational prediction with "realistic" models. The accuracy of the results of a stochastic model depends on the assumptions made by the model and the reliability of the input data. The model developed in AGB 2011/003 relies on three main types of data: traffic data, the braking deceleration profiles to be assigned to each vehicle, and the frequency of heavy braking events on the motorway.

The traffic data on Swiss highways provided by the Federal Road office are very extensive and of good quality, therefore traffic configurations were extracted starting from the automatic road traffic count station, and the Weight in Motion station located at two locations on the highway (Sjaarda et al., 2000). A key challenge was the limited availability of data on the frequency and magnitude of heavy vehicle braking events. The frequency of heavy braking events on motorways, primary roads and secondary roads was determined mainly based on data from a Dutch field test - AOS Field Operational Test, (FOT-Net partners, 2016) with instrumented vehicles. The system originally gathered for testing electronic accident prevention systems, recorded the most significant positive and negative acceleration peaks in the direction of travel within a 2-minute interval, furthermore, the vehicle's position was only recorded via GPS every 2 minutes. However, these data partially fulfilled the requirements for

DOI: 10.1201/9781003483755-192

determining the frequency of heavy braking events. The braking deceleration profiles (magnitude of the braking) were extracted from field tests with instrumented passenger cars in the USA - 100-Car Naturalistic Driving study, NDS, (Dingus et al., 2006). Nevertheless, these data are not optimal for accurately representing the deceleration profiles of heavy truck braking events (Martins et al., 2016).

Since the conclusion of project AGB 2011/003 (Martins et al., 2016) the UDRIVE project (Bärgman et al., 2017; Barnard et al., 2016) focused, among other issues, on the frequency of heavy braking events per road category (urban, interurban and motorway). On motorways, one event per 5,500 km was recorded, increasing to approximately one event per 200 km on interurban roads and one event per 50 km on urban roads. Comparisons with a study of long-distance drivers in the USA (Hickman & Hanowski, 2011) reveal similar frequencies on motorways (1 event per 8,000 km), considering only safety-relevant events with a braking deceleration limit of 5.0 m/s². Adjusting the UDRIVE data to a 4.0 m/s² limit would reduce the highway frequency to approximately one event per 8,000 km, a sevenfold deviation from the AGB 2011/003 project. This reduction in frequency has a direct effect on the characteristic value of the braking force, decreasing it by around 20 % for a return period of 1,000 years (Eurocode reference period for loads on road bridges). Despite enhancements to the database from international field tests, notable disparities between the AOS and UDRIVE project evaluations highlight the limited data and substantial uncertainty surrounding the frequency of severe braking events, necessitating further investigation. In addition, results from countries such as the USA, Canada, or Australia cannot be directly extrapolated to Swiss conditions.

2 AIM OF THE RESEARCH

The research aims to improve the knowledge of the frequency and magnitude of braking events of heavy vehicles in order to improve the results of the model developed in (Martins et al., 2016) for the assessment of braking forces on road bridges. This includes the use of smartphones for data collection, specifically acceleration, gyroscope and GPS data. The present work also demonstrates how smartphones can be used as monitoring devices as an alternative to high-quality measurement systems to address existing gaps in the field of evaluation of braking forces on road bridges. Smartphones were chosen for their cost-effectiveness. While the characteristics of sensors embedded in smartphones may not be comparable to those of high-precision professional instruments, for this study, such high-quality features are deemed unnecessary, as explained in (Feltrin & Breveglieri, 2024). In the present work, the preliminary results of a pilot project conducted before the test campaign with 22 heavy vehicles are presented.

3 METHODS

3.1 *Instrumentation*

Modern mid-range smartphones are equipped with a three-axis accelerometer, a three-axis gyroscope and a GPS receiver. As part of this research, three different Android apps were developed. The first app was programmed to collect data from the GPS receiver to locate the truck's position on its daily route and therefore the location of braking events. The data acquisition rate was set to 1 second. For each acquisition, a time stamp, longitude, latitude, and elevation of the vehicle position, a measure of the position inaccuracy, speed, and bearing angle of the vehicle were recorded. The speed and direction of travel are determined directly from the GPS sensor. The second app was programmed to collect data from the accelerometer sensor. The recording of an event was triggered and stopped as soon as the acceleration in the direction of travel exceeded a threshold of 2 m/s^2. Data acquisition was extended to include readings taken before and after the thresholds were crossed, i.e. buffer both before and after the event.

In order to minimize false triggering, the acceleration in the direction of travel was first filtered with a digital low-pass filter to trigger the measurement. The upper cut-off frequency of the filter was 2 Hz. The filtered acceleration was only used to trigger the measurement. The unfiltered acceleration, i.e. the direct reading from the sensor, was recorded.

A time stamp, the sensor time and the accelerations in three mutually perpendicular directions were recorded. The time stamp is provided by the smartphone's internal clock and is used for synchronization with the data from the other recording programs. The sensor time corresponds to the time of the accelerometer's internal clock and was recorded to avoid time jumps due to periodical clock synchronizations of the smartphones, which would lead to a time distortion of the braking deceleration. The sampling rate was set to 50 Hz.

The recording program calibrates to zero by recording accelerations on the three axes for 10 seconds, calculating average values, and storing them as calibration values. These values are then subtracted from recorded accelerations to compensate for gravity and sensor inaccuracies. Calibration assumes a flat surface, with tilt verified by observing the calibration vector. The angular rotation (gyroscope data) is continuously recorded in three mutually perpendicular axes with a third application. As the rotation rate is primarily used to correct the direction of travel from the position measurement and this has a sampling rate of 1 Hz, the sampling rate of the angle measurement is 10 Hz. The timestamp, like in the acceleration app, is provided by the smartphone's internal clock, and by the sensor time.

3.2 *Validation of the measuring system*

As part of the ongoing project, several tests have been carried out to assess the quality of the data provided by the smartphone's sensor. These tests typically included comparing the data recorded by the phone with a high-quality measurement system in different driving and laboratory conditions as further explained in (Feltrin & Breveglieri, 2024). The investigation was not limited to checking the quality of the acceleration time histories but was also extended to the GPS receiver data. Figure 1 shows the setup of the last performed validation test carried out by instrumenting a Volvo school tractor from Planzer AG (Dietikon, CH). The tractor was equipped with two pairs of capacitive uniaxial accelerometers (PCB), strategically placed to measure both vertical and horizontal (along the main axis) accelerations. Two PCB accelerometers connected to a HBM amplifier and data acquisition system, were used as reference measurements in all the verification tests. The first pair was fixed to the chassis between the tractor axles, while the second pair was mounted inside the side box of the tractor, attached to a heavy steel plate (Figure 1). The smartphone was mounted on the same plate. The MEMS sensor installed in the phone is a 6-axis motion sensor from TDK, specifically the ICM42605M. This sensor is capable of recording both acceleration and angular velocity (gyroscope data) in all three axes. A GPS receiver, linked to the same recording system that records deceleration, was positioned on top of the cab to ensure good GPS signal reception and to be used as a reference measurement.

The test consisted of driving 29 km and intentionally braking to trigger the accelerometer measurement. The driver was instructed to vary the braking strength during the test. 32 braking events were recorded during the test. From the test results it was observed that there was a consistent difference in acceleration variance between the frame and the side box, attributed to the driver compartment suspension system. The difference could be minimized by applying a transfer function calibrated using the side box as input and the frame as output. Figure 2 shows an acceleration comparison between the reference system measurement at different position and the phone for an illustrative deceleration profile. The deceleration profile of the phone after applying the identified transfer function (PhoneCorr) is also shown. To reduce acceleration noise, all signals were filtered with a Chebyshev Type II low-pass filter with a stopband frequency of 4 Hz. Figure 2 clearly illustrates the disparity between the frame and side box measurements, regardless of whether the data is from the phone or the reference system. It also highlights the similarity between the reference system and phone profiles when installed in the same location, and finally, the effectiveness of applying a transfer function to

correct for the phone acceleration trajectory. In terms of frequency content, no significant difference was observed between the sensors used for frequencies below 4 Hz. A direct comparison of the peak values for all braking events reveals that the error attributed to the phone, when compared to the frame measurement, can be around 0.8 m/s² for braking events exceeding 7 m/s². For braking events in the range of 2 m/s², the error is approximately 0.4 m/s², corresponding to percentage errors of approximately 10 % and 20 %, for hard and soft braking respectively. When comparing the phone to the accelerometer located at the same position in the side box, the absolute error is within the range of 0.1 m/s², with percentage errors below 2 % for accelerations greater than 4 m/s², and is not influenced by the magnitude of braking. This test demonstrates that the phone can provide reliable results, and the source of error can be mainly related to the installation position. Figure 3 presents the measurement comparison between the phone and the GPS receiver of the measurement system.

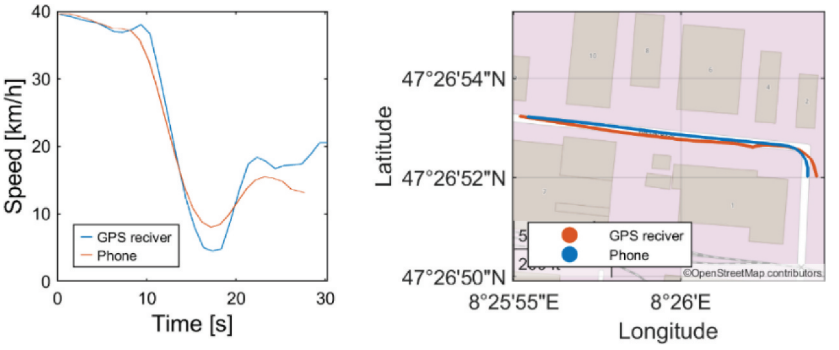

Figure 3. GPS receiver data comparison during a braking event.

4 PILOT TEST

4.1 *Aim of the test*

Before starting the test campaign, which involved 22 heavy vehicles (launched in June 2023) a preliminary pilot test was conducted. This aimed to assess the device's performance over an extended duration, identify potential measurement challenges inherent in such systems, and refine both data collection and analysis processes. To this end, a 5-axle articulated truck was instrumented. After sharing preliminary results with the logistics company, was decided to install the phone directly on the chassis frame, housed in a protective box (Figure 4). This approach eliminated the need for dynamic characterization for each vehicle used in the monitoring program and ultimately could provide better data. The collected data were transmitted at the end of each day to an SFTP server. Remote access software (TeamViewer GmbH) was installed on the phone facilitating phone management and addressing any potential system issues. To avoid drift accumulation in accelerometer and gyroscope measurements, and to reduce the possibility of missing data measurements due to application crashes, all applications were restarted and recalibrated at the beginning of each work week. For the present pilot study, a SAMSUNG Galaxy XCover Pro, a phone released in Q1/2020, with 8 GB RAM, and an 8-core Exynos 9611 chipset, running Android 13 SDK 31, was used. The same phone was used during the test presented in section 3.2.

Figure 4. Smartphone installation.

5 DATA ANALYSIS

5.1 *Raw data fusion and preparation*

The collected files are processed daily to systematically minimize potential errors. The first step is to merge the files containing the respective raw route data (GPS), and gyroscope angular velocities (gyroscope) and organize them according to the time stamp, to correct the traveling direction, i.e. bearing. At higher vehicle speeds, the accuracy of the bearing information is typically good. As the speed of the vehicle decreases, the accuracy of the direction of travel also decreases as the effect of the geolocalisation error increases. When the vehicle is stationary, the GPS latitude and longitude readings may inaccurately indicate movement, resulting in a characteristic loop-like wandering in confined spaces that produces inaccuracies leading to sudden sharp changes in direction. Despite the small relative distance between points, the loop-like wandering over time accumulates and affects also the calculation of the distance traveled. It is therefore essential to correct not only the bearing, which is relevant to determine the road category, but also the latitude, longitude and speed inaccuracies in such cases. The two files containing the data of the route and angular velocities are then merged into a single file. The direction correction algorithm isolates segments with speeds below 12 km/h, detects abrupt direction changes, and iteratively refines the route by approximating the points to be corrected with spline polynomials until a better approximation of the direction is achieved. The distance traveled is also calculated from the corrected coordinates (latitude and altitude) and height above sea level. An additional column is added with the average acceleration calculated from the changes in speed.

Braking event periods are indicated by assigning a number in a new column based on the lexicographical order of the files containing the raw data for the braking events. This "marking" is used to make a first approximate assignment of the braking event to the geographic position of the vehicle. An additional column is introduced to indicate whether the vehicle is stationary. A speed of less than 5 km/h and an angular change of less than 0.5° is chosen as the standstill criterion. In addition, the standstill criterion must be maintained continuously for at least 5 seconds.

The timestamp in GPS data makes it possible to identify the acceleration file corresponding to a braking event. All acceleration files undergo signal filtering using the low-pass filter mentioned above and synchronization with GPS data. This synchronization aligns the GPS-derived speed with the speed calculated by integrating the accelerometer signal in the direction of travel. While acceleration integration provides only the change in speed and lacks pre-braking speed information, synchronization allows estimation of both the initial and final post-braking speeds. To address potential inaccuracies associated with accelerometer zero (constant acceleration not equal to zero when the vehicle is stationary), an objective function is applied. This function shifts the acceleration signal in the vertical plane to minimize the error between the speed calculated by the accelerometer and the speed measured by GPS, thereby aiming to reduce small biases in the accelerometer measurement.

5.2 *Evaluation of the distance traveled according to road classes*

The assessment of driven kilometers for each road class type relies on the OpenStreetMap (OSM) geographic database. The OSM database primarily comprises geometric objects with attributes consisting of a key and a value assigned to each object. The road classes selected for the project include "Class 1- Motorway" (key: Motorway /_link, Trunk /_link), Class 2- Main Roads (key: Primary /_link), Secondary /_link), Class 3- Local Roads (key: Tertiary, Residential and Class 4-Other (key: Unclassified, Service and Living street). The road category is determined based on the current geodetic coordinates of the vehicle, by sending a query to the OSM server requesting road segments in the immediate vicinity. Due to positional inaccuracies, a single distance criterion can lead to errors. To address this, the road category determination is extended to include direction of travel, vehicle speed, and perpendicular distance in a unified objective function. The direction of travel narrows the selection to road sections that are aligned with the direction of the vehicle, while the vehicle speed helps to exclude inappropriate road categories.

The most accurate method is to determine the road class for each vehicle coordinate and calculate the distance traveled per road class accordingly, but this approach suffers from significant computation times that are hardly feasible. However, not all waypoints need to be evaluated suggesting the use of a larger sampling period and then identifying the point where the change occurred within that sampling interval, nevertheless this approach was also to be found computationally inefficient, as explained in (Feltrin & Breveglieri, 2024). In the same study, it was shown that incorporating additional trip information into the computational procedure to identify potential road class changes is the most convenient strategy in terms of computational efficiency. For this reason, an algorithm has been developed that checks the speed and direction of the vehicle over the distance traveled to identify the point of possible class change. A significant decrease in speed or a major change in the direction of a vehicle could indicate a change in road. On the other hand, if no slowdown or major change in direction is observed, it is possible to skip to the next point. Therefore, starting from a waypoint with known road class, the algorithm selects a new waypoint according to the sampling period and checks for speed and direction changes at the current waypoint to determine if the vehicle may have changed road class. If the check is negative, the algorithm proceeds to a new waypoint. If positive, the road class of the current waypoint is determined. If the road class of the current waypoint matches the road class of the last waypoint, the waypoints in between are marked with the current road class and the algorithm proceeds to a new waypoint. If the road class of the current waypoint does not match the road class of the last waypoint, a binary

search is used to find the waypoint with the road class change. Accordingly, the waypoints between the last waypoint and the current waypoint are marked with the initial road class and the waypoints after the current waypoint are marked with the new road class. This procedure greatly reduces the number of queries to the OSM database.

6 RESULTS

The pilot test lasted three months, during which the trucks traveled 21,317 kilometers across Switzerland in Figure 5 (left). The roads traveled during the 56 days of monitoring, taking into account the interruption of the system. An analysis of the kilometers traveled by road class showed that 16,938 km were on motorways (Class-1), 3,456 km on main roads (Class-2), 905 km on local roads (Class-2) and 18 km on other roads (Class-4). In percentage terms, these constitute 79 %, 16 %, 4 %, and 1 %, respectively, highlighting the majority of kilometers driven on motorways. Figure 5(right) shows a daily journey of 618 kilometers, with the motorway in purple, major roads in cyan, and local roads in red. Colored dots mark the locations of braking events (deceleration greater than 2 m/s^2), using the same color code as the road classification. A closer look at the figure reveals that the majority of braking events occur on local and major roads, with a limited number on the motorway. For example, on Road Class 1 ("Motorway"), the average speed over 478 km was 73.3 km and 6 braking events were recorded (1 event every 80 km). In comparison, on Road Class 2 ("Main Roads"), although only 105 km were covered, a higher number of braking events occurred: 29 (1 event every 4 km).

Figure 6 Provides a summary of the key data recorded during a braking event, including acceleration, speed calculated from acceleration integration (blue), and GPS data (yellow). The event shown is geolocated within the same figure and occurred on a main road. The green triangle marker indicates the direction of travel, and the green section highlights the point of higher acceleration. The highest recorded deceleration peak reached 6.3 m/s² and was observed on a main road. When plotting the distribution of acceleration peaks for each road class in Figure 7, it becomes evident that despite the maximum value, the majority of accelerations are close to the selected threshold value and barely exceed the 4 m/s² threshold used in AGB 2011/003.

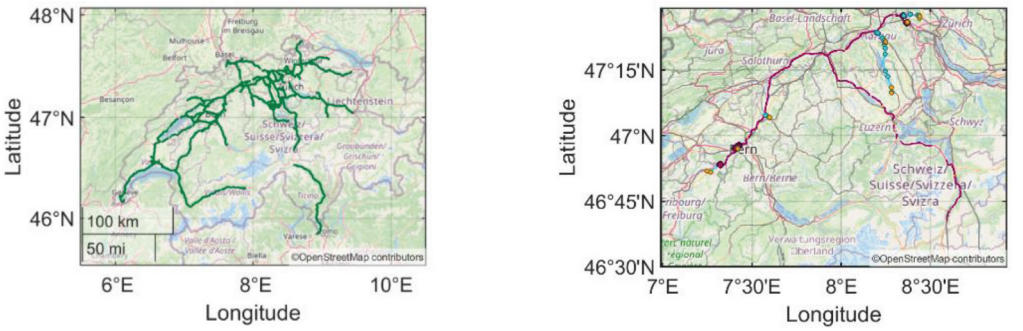

Figure 5. Route traveled by truck during the pilot test (left), explanatory daily route (right).

This suggests a lower magnitude than initially considered in the completed project (Martins et al., 2016). In addition, the braking rate from the pilot study is significantly lower, with no recorded braking events exceeding 4 m/s² on a motorway. Therefore, a direct comparison with AGB 2011/003 is not possible. Using a threshold of 3 m/s², the braking rate is one event per 1540 km, which is more in line with the UDrive project than AGB 2011/003. However, more data is needed to draw conclusions on both braking rate and braking magnitudes. The magnitude or intensity of braking events is not determined solely by the value of the maximum deceleration. Other factors, such as the duration of the braking and a plateau value of the

acceleration representing its average, among other parameters, are representative of the magnitude of the event, as discussed in (Feltrin & Breveglieri, 2024). A lower magnitude affects the forces acting on the bridge, which are calculated by multiplying the mass of each truck by its deceleration profiles assigned during the definition of the braking kinematics (Martins et al., 2016). Therefore, it affects the empirical probability distribution of the forces generated by the simulations. The frequency of braking events, on the other hand, influences the estimation of parameters. As described in Martins et al., 2016), the frequency of braking events allows the quantile of the probability distribution of the braking force in terms of the order statistic to be estimated as the k^{th} order realization of the braking force. It also allows to associate the characteristic value of the braking force with a given return period.

7 CONCLUSIONS

This paper provides an overview of the Android smartphone-based monitoring system developed to record braking events along with their geolocation data. The system is designed to collect data from a fleet of heavy vehicles operating on Swiss roads for about nine months, with the scope to improve the model developed by (Martins et al., 2016) to calculate the braking forces on road bridges. The aim is to address the lack of knowledge on braking frequency (defined as braking events per kilometer driven on different road classes) and braking deceleration characteristics. The paper describes the monitoring strategy, data processing methods and relevant preliminary tests.

The validation test performed to compare the phone measurements with a high-precision reference system showed that the accuracy provided by the smartphone is appropriate for the purpose of this research. In terms of acceleration, the deviations are mainly related to the installation of the phone rather than the accuracy of the phone's accelerometer. The GPS data provided, although not as good as in the case of the reference system, do not adversely affect the data processing procedure for the calculation of the distance traveled and the geolocalisation of the braking event.

The phone's GPS receiver has been enhanced with information from the OSM database to identify road classes and morphology. The use of OSM was fundamental to assess the truck's travel distance on different road classes, taking into account expected variations in braking rates for different road types.

A pilot study was carried out to test the monitoring system and data processing over several months before the start of the monitoring campaign, demonstrating the long-term stability of the smartphone and the feasibility and efficiency of the data processing procedure. The results of the pilot study showed a braking rate significantly lower than assumed in (Martins et al., 2016) and braking magnitudes hardly exceeding 4 m/s². If these results are validated during the fleet monitoring campaign, it is expected to have a significant impact on the calculated braking forces, resulting in lower values compared to the original stochastic model calculations and the current Eurocode standards.

ACKNOWLEDGMENTS

The authors would like to thank the Swiss Federal Roads Office for their financial support and the logistics company Planzer AG (Dietikon, Switzerland) for its extraordinary personal and technical support during the monitoring campaign.

Bridge damage classification using multiple responses of vehicles and 1-D convolutional neural networks

Z. Li, Y. Lan & W. Lin
Department of Civil Engineering, Aalto University, Espoo, Finland

ABSTRACT: Bridges exposed to extreme environmental conditions are susceptible to damage and even failure during service life. Traditional monitoring techniques may necessitate the installation of numerous sensors on the bridge, which can be time-consuming and costly. Instead, the indirect method typically employs several accelerometers attached to the passing vehicle, which is more economical and more accessible to operate. To promote the development of the indirect method, this paper proposes a novel vehicle vibration-based method for classifying bridge damage of varying severity using cutting-edge deep learning techniques. Initially, the framework for damage classification based on the responses of a single vehicle and 1-dimensional convolutional neural networks (1-D CNNs) is appropriately designed and introduced. Then, the proposed approach is evaluated using a steel continuous beam and a model truck in the laboratory, which is utilized to simulate a vehicle-bridge interaction (VBI) system in engineering applications. The experimental results indicate that the bridge's damage severity can be predicted by the CNN with high accuracy, thereby validating the inclusion of bridge damage information in the passing vehicle's responses. Furthermore, it is determined that employing multiple responses from the vehicle facilitates the improvement of damage classification accuracy. Heavier vehicles are conducive to the transfer of more bridge-damaged information and are therefore recommended in engineering.

1 INTRODUCTION

Bridge structures play a vital role in European transportation systems, yet their aging and deterioration pose significant challenges. Over the past decades, the need for structural health monitoring (SHM) of bridges has become increasingly apparent. Traditional monitoring heavily relies on visual inspections by experienced engineers, but this approach becomes impractical for newly constructed bridges spanning tens or even hundreds of meters. In the 21st century, a promising and expedient solution to bridge health monitoring has emerged through the vibration-based approach (Hou and Xia, 2021). This method involves monitoring the modal parameters throughout the bridge's service life, offering insights into potential damage occurrences. However, the conventional approach mandates the installation of a large number of sensors, including temperature sensors, accelerometers, strain gauges, etc. directly on the bridge (referred to as the direct method) to establish a sensing network. Undoubtedly, this solution incurs a high cost and is typically reserved for significant projects rather than short- and mid-span bridges.

Over the past two decades, researchers worldwide have developed the indirect method, involving the installation of sensors on passing vehicles rather than directly on bridges (Malekjafarian et al., 2022; Wang et al., 2022; Xu et al., 2024; Yang et al., 2024). This approach is characterized for its economic efficiency and convenient applications. Numerous numerical simulations and experiments have demonstrated the viability of extracting bridge modal parameters from vehicle responses (Feng et al., 2023; Li et al., 2023a). However, practical

DOI: 10.1201/9781003483755-193

engineering observations reveal that modal parameters of bridges may not be highly sensitive to damage due to the influence of operational conditions, such as temperature effects and ongoing traffic. Consequently, bridge health monitoring based on changes in modal parameters may face essential challenges.

In recent years, artificial intelligence (AI) has made significant strides across various domains, notably enhancing bridge health monitoring. Traditional direct methods initially employed intelligent techniques such as supervised deep learning (DL) and transfer learning (TL), yielding robust results in bridge health monitoring. When applying the indirect method, vehicle responses typically include vehicular information, road roughness, and bridge vibrations, with the latter being particularly challenging to identify (González et al., 2023). DL techniques are good at extracting essential features, making them valuable for identifying bridge information from passing vehicle responses. Malekjafarian et al. (2019) developed a machine learning approach using vehicle accelerations to detect and quantify bridge damage. Two strategies, involving time-domain or frequency-domain responses from multiple vehicle runs, successfully identified damage occurrences and provided references for damage severity. Corbally and Malekjafarian (2022) improved this method by incorporating contact-point (CP) frequency responses into artificial neural networks (ANNs), demonstrating superior performance in identifying bridge damage. The proposed method underwent robust testing with variations in vehicle speeds, ambient temperatures, and road roughness levels. In 2023, Li et al. (2023b) emphasized the importance of considering both low and high-frequency responses of passing vehicles for extracting bridge damage-sensitive features. Furthermore, their findings verified that short-time vibrations during vehicular passage contain valuable information for determining the bridge's health state (Li et al., 2023c). To overcome the challenges that DL techniques typically require a large number of samples, a physics-guided framework was proposed by Lan et al. The results verified the effectiveness of the proposed method in damage indication, quantification, and localization (Lan et al., 2024). Despite these advancements, most studies have simplified vehicles into a quarter-car model during training (Corbally and Malekjafarian, 2023). The vehicle's response along with one degree of freedom (DOF) is considered. In practice, vehicles have multiple DOFs, and each can contain bridge-related information (Li et al., 2023d). Therefore, for improved accuracy in the training process, responses from multiple positions of the vehicle need to be considered.

This paper introduces an innovative approach to damage classification using 1-dimensional convolutional neural networks (1-D CNNs) to advance the monitoring process. Sensors are strategically positioned on various locations of a passing vehicle, collecting its accelerations as it traverses the bridge. Subsequently, the time-domain vehicular accelerations obtained from multiple positions are transformed into the frequency domain. These frequency-domain responses are then employed as inputs across different channels of the 1-D CNN for damage severity classification. To illustrate the effectiveness of the proposed method, an experimental study involving a U-shape beam and a scaled truck is conducted. The subsequent sections of this paper are structured as follows: Section 2 delves into the theoretical foundation of employing 1-D CNNs for damage classification within the indirect method. Section 3 outlines the laboratory experimental setups for the vehicle-bridge interaction (VBI) system and introduces artificial damage cases. Results and discussions are offered in Section 4. Finally, Section 5 provides the conclusion of this paper, summarizing the key findings and potential avenues for future research.

2 THEORY FOUDATION

2.1 *Vehicle's multiple responses*

This paper introduces a novel approach using multiple responses of the vehicle, distinguishing itself from existing studies. Assuming a vehicle equipped with N accelerometers, denoted as $\ddot{z}_i$ for the accelerations measured by the ith sensor, this study advocates optimal sensor placement aligning with the 3-D vehicle's seven degrees of freedom, as detailed in the reference (Li

et al., 2023d). However, practical challenges arise in accurately localizing the vehicle body's gravity center and capturing vibrations from the vehicular wheels, particularly given the intricate suspension systems. As an initial study, this paper employs a pragmatic solution, utilizing only two accelerometers strategically placed on the front and rear axles, denoted as $N = 2$.

Further, in order to remove the influence of unrelated information about the bridge, only when the vehicle is on the bridge will the vehicle's accelerations be recorded. This can typically be achieved by installing GPS sensors on the passing vehicle (Lan et al., 2023). Signals collected by the vehicle could be truncated according to location information. Assume that the vehicle's rear wheels enter the bridge at T_{in} and its front wheels leave the bridge at T_{out}, and only the vehicle's accelerations within T_p will be utilized, where T_p is the vehicle's passing time and is shown in Eq. (1),

$$T_p = T_{out} - T_{in} \tag{1}$$

2.2 *1-D CNNs*

In contrast to traditional 2-D CNNs tailored for image analysis, 1-D CNNs specialize in handling single-dimensional inputs. While standard images possess three channels—R, G, and B—the proposed method incorporates multiple signal channels derived from diverse positions on the moving vehicle. The architecture of 1-D CNNs encompasses convolutional layers, 1-D max-pooling/average pooling layers, and fully connected layers. The computations within the convolutional layers can be expressed by Eqs. (2) and (3) (Abdeljaber et al., 2018),

$$x_k^l = b_k^l + \sum_{i=1}^{N_{l-1}} \mathrm{CONV}\left(w_{ik}^{l-1}, s_i^{l-1}\right) \tag{2}$$

$$y_k^l = f\left(x_k^l\right) \tag{3}$$

where x_k^l means the input of the lth layer. b_k^l represents the bias of the kth neuron at layer l. CONV $(\cdot)$ denotes the 1-D convolution without zero padding. w_{ik}^{l-1} is the 1-D kernel from the ith neuron at layer $l-1$ to the kth neuron at layer l. f means the activation function. Typical activation functions include rectified linear unit (ReLU), Sigmoid, and Tanh.

1-D max-pooling/average-pooling layers efficiently down-sample the data by selecting the maximum/average value within a defined neighborhood. Interested readers can find further details in the reference (Murray and Perronnin, 2014). The resulting output is flattened into one dimension before being connected to fully connected layers. The ultimate output of the fully connected layer corresponds to the different damage severities in this paper.

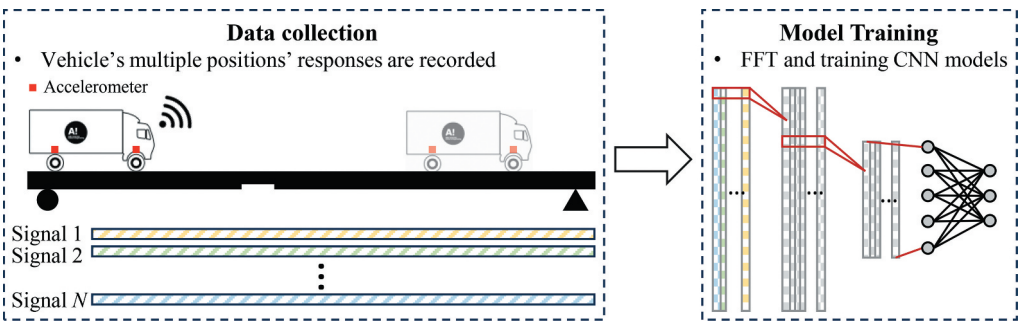

Figure 1. Data collection and model training.

3 LABORATORY EXPERIMENTS

3.1 *Vehicle models*

This paper employs a meticulously scaled model truck to simulate real-world engineering vehicles. Figures 2 and 3 illustrate the truck, its system and installed accelerometers. The employed truck model is the Tamiya Mercedes-Benz 1850L, with a scale ratio of 1:14. The truck's self-mass, denoted as T0, is 4.305 kg, and to simulate heavy vehicles, an additional mass of 5.157 kg is added (referred to as T5). A guide-wire system ensures the truck follows a straight path without colliding with the beam's flange. The bottom view of the scaled truck is depicted in Figure 3, showcasing its scaled suspension system, engine, connecting shaft, and more. Driven by a 540-brushed electric motor powered by a Tamiya Ni-MH 7.2 V–3000 mAh battery, the vehicle introduces engine noise that inevitably affects acceleration data collection in engineering. Two Brüel & Kjær accelerometers (type 4371) are attached to the front and rear axles (Figure 3), with a sampling frequency set at 10 kHz. The vehicle, remotely controlled, exhibits slight speed variations across runs due to battery constraints. However, to allow for optimal vibrations, the wire tension is deliberately kept loose, resulting in slightly varied passing traces during multiple beam crossings.

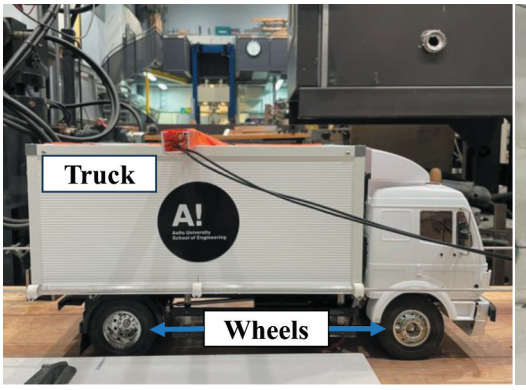

Figure 2. Model truck (lateral).

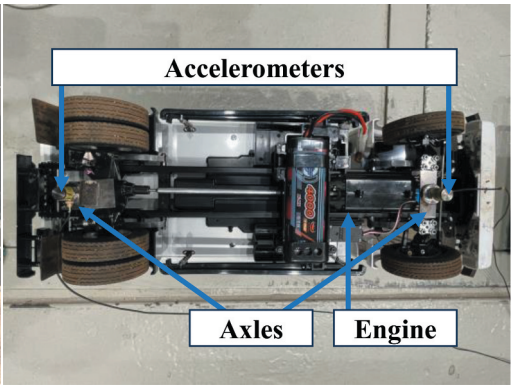

Figure 3. Model truck (bottom).

3.2 *Bridge model*

In this experiment, a single continuous beam with three supports is employed for the bridge configuration, as shown in Figure 4. The utilized beam is a UPE 300 with a cross-sectional area of 5660 mm^2, a span length of 5.7 m, a support length of 0.15 m, and a mass of 248.64 kg. To maintain a relatively constant speed as the truck traverses the beams, acceleration and deceleration runways are positioned at the beam ends. For comparison purposes, accelerometers are also installed at the bottom of the beam to capture its vibrations concurrently with the truck's passage. Additionally, to clearly identify the beam's modal frequencies, impulse excitation using an impact hammer is applied. Employing FFT analysis, the natural frequencies of the beam are obtained, as illustrated in Figure 5, revealing the first two frequencies as 30.75 and 42.53 Hz.

3.3 *Damage scenarios*

In practical engineering, the occurrence of damage can lead to a decrease in a bridge's natural frequencies. An effective experimental method for simulating damage involves adding mass to the bridge, a process known to cause a reduction in natural frequencies (Cerda et al., 2014).

Figure 4. Bridge model.

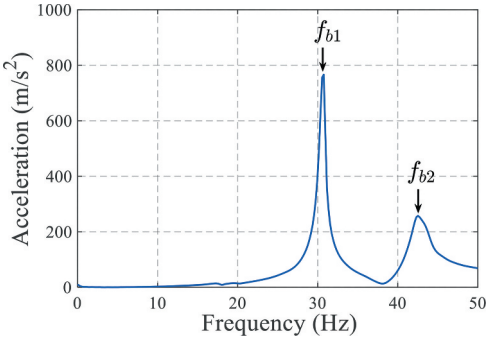

Figure 5. Bridge frequency spectrum.

This approach offers the advantage of easy recovery, allowing the beam to return to an undamaged state when necessary. In this study, various masses are applied to the bridge to simulate different artificial damage scenarios. Damage degrees are represented by the ratios of added masses to the beam's mass. For example, when there are two 5 kg masses and two hooks (4 kg) added to the beam's two spans, the damage degree is (5+5+4)/248.64 =5.6%. Table 1 summarizes all scenarios (S0-S6), where S0 means an undamaged bridge, while scenarios S1-S6 represent varying degrees of damage.

Table 1. Damage scenarios.

Scenarios	S0	S1	S2	S3	S4	S5	S6
Added mass/kg	0	5	10	15	20	25	30
Damage degree	0	5.6%	9.6%	13.7%	17.7%	21.7%	25.7%
T0 runs	50	49	50	42	51	51	47
T5 runs	57	56	57	56	57	56	57

4 RESULTS AND DISCUSSIONS

4.1 *Model training and testing*

In this study, runs of T0 or T5 are divided into two groups. 70% of runs are utilized for training and the rest are for testing. As outlined in Section 2, the vehicle's time-domain signals on the bridge are transformed into the frequency domain. To mitigate contamination from environmental noises, only vehicle frequency-domain responses within 100 Hz are utilized for training, as validated in previous work (Li et al., 2023c). Zeros padding is applied to align input time-domain signals, resulting in an FFT frequency resolution of 0.0763 Hz, yielding 1310 response points within the 0-100 Hz range. The training is conducted on an Aalto University workstation equipped with Intel Core i7-9750 CPUs, 16 GB RAM, and an NVIDIA GTX 1650 graphic card for tensor computation acceleration. All code is implemented in Python 3.9 with the PyTorch package. The model architecture, detailed in Table 2, employs hyperparameters including a learning rate of $1e^{-4}$, Adam optimizer, cross-entropy loss, batch size of 16, and 200 epochs.

4.2 *Damage classification using 1-D CNNs*

When utilizing the vehicle's frequency-domain responses within 0-100 Hz for training, loss curves for T0 and T5 vehicles have been plotted in Figures 6 and 7. Notably, for both T0 and T5 vehicles, employing responses from two axles yields smaller losses compared to using responses from only one axle. The difference is relatively minor for T0, as the lighter vehicle

Table 2. Architecture of the 1-D CNNs.

Layer	Pooling	Output shape	Batch normal	Activation
Conv1d	–	1310×20	Yes	ReLU
Conv1d	–	1310×20	Yes	ReLU
Conv1d	Max	655×20	Yes	ReLU
Conv1d	–	655×40	Yes	ReLU
Conv1d	–	655×40	Yes	ReLU
Conv1d	Max	327×40	Yes	ReLU

Fully Connected	–	7	No	–

* Conv1d: 1-dimenasional convolutional layer, ReLU: Rectified linear unit

may not induce strong vehicle-bridge interaction responses, resulting in less bridge information transferred to the vehicle. Despite including responses from another axle in the training, the model's ability shows marginal improvement. In contrast, for the heavier T5 vehicle, the inclusion of responses from two axles significantly reduces the loss. This is attributed to the incorporation of valuable bridge damage information in the vehicle's axles' responses, enhancing the model's damage classification capabilities.

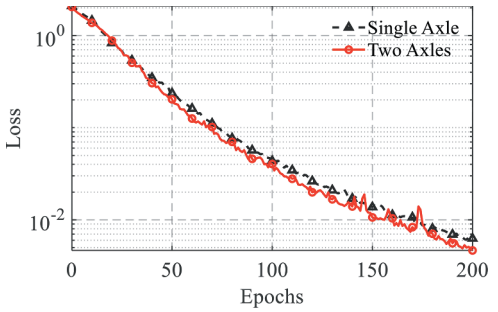

Figure 6. Loss curve using T0 vehicle.

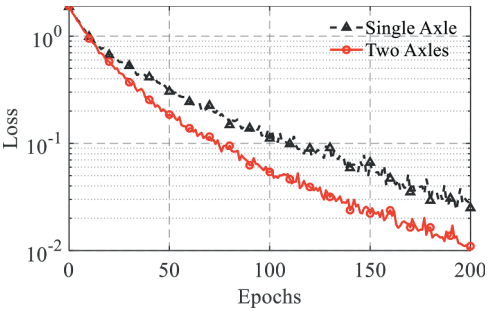

Figure 7. Loss curve using T5 vehicle.

To evaluate the capability of the trained model, some criteria listed in Eq. (4) are utilized,

$$Accuracy = \frac{TP + TN}{TP + FP + TN + FN}, Precision = \frac{TP}{TP + FP}, Recall = \frac{TP}{TP + FN} \tag{4}$$

where True Positive (TP) refers to a sample belonging to the positive class being classified correctly; True Negative (TN) refers to a sample belonging to the negative class being classified correctly; False Positive (FP) refers to a sample belonging to the negative class but being classified wrongly as belonging to the positive class; False Negative (FN) refers to a sample belonging to the positive class but being classified wrongly as belonging to the negative class. The damage classification accuracy using T0 and T5 are plotted in Figures 8 and 9.

We can see that for both T0 and T5 vehicles, employing responses from both axles yields higher accuracy compared to using responses from a single axle. Notably, with T0, accuracy stabilizes below 80% after 50 epochs. Conversely, Figure 9 illustrates that when a heavier vehicle is employed, accuracy consistently exceeds 95%. Consequently, in practical engineering

applications, it is advisable to recommend the use of heavier vehicles, as they can gather more damage-related information about the bridge.

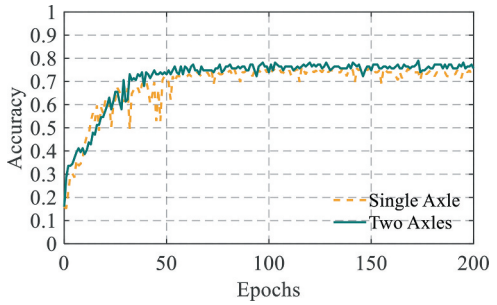

Figure 8. Damage classification accuracy (T0).

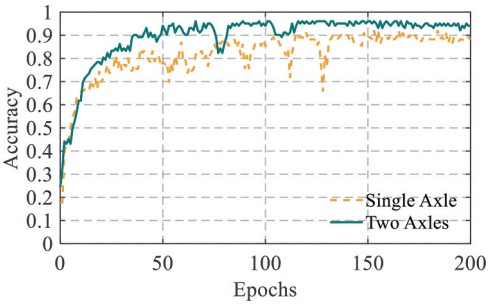

Figure 9. Damage classification accuracy (T5).

To assess the predictive capabilities of the trained DL model for damage severity classification, we employ the confusion matrix (CM), a widely used tool, to show the best bridge damage classification results. Figures 10 and 11 illustrate the CMs for T0 and T5, respectively.

From Figure 10, we can see that with the use of a light vehicle, the overall damage classification accuracy reaches 79%. Across most damage scenarios, ***Recall*** values range between 50% and 95%, though certain instances, such as S3, exhibit low ***Recall***, indicating inaccuracies in predicting damage severity. Contrastingly, when employing a heavier vehicle, as shown in Figure 11, ***Recall*** values can consistently approach or exceed 90%, with some cases achieving 100% ***Precision*** and ***Recall*** values. The overall accuracy of damage classification across all scenarios increases significantly to 96.1%. Therefore, we can conclude that in practical engineering, heavier vehicles are recommended for the indirect bridge health monitoring using responses of passing vehicles.

4.3 *Further discussions*

In this study, we employ a scaled truck and a U-shaped beam to simulate real VBI scenarios. The road roughness, primarily caused by the wheels' tread, is relatively good compared to practical engineering cases. To alleviate the influence of road roughness, various techniques, such as CP responses and residual CP responses between wheels or connected vehicles, can be

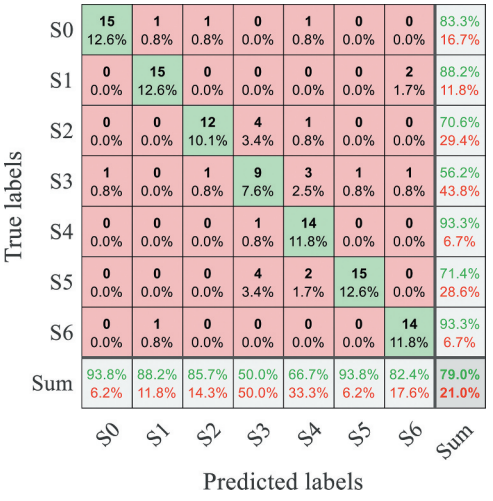

Figure 10. Damage classification results (T0).

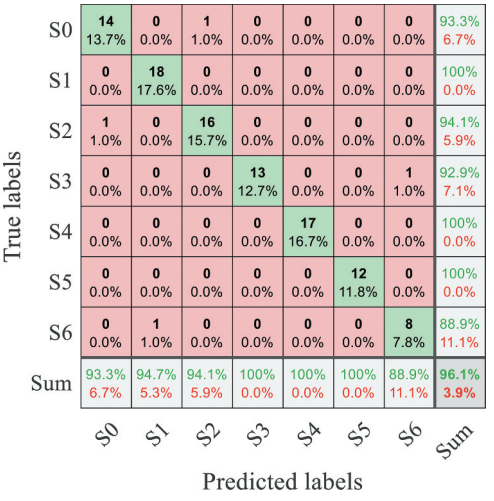

Figure 11. Damage classification results (T5).

examined. Furthermore, it is noted that as an initial investigation, this paper mainly explored the superior capability when responses of multiple positions of the vehicle are utilized. To overcome the challenges that labeled damaged data are difficult to obtain in engineering, semi-supervised or unsupervised DL techniques deserve further studies.

5 CONCLUSIONS

This paper proposed a bridge damage classification strategy using responses of the passing vehicle's multiple positions and 1-D CNNs. Firstly, the fundamental theories about CNNs are introduced. Then, the proposed method was verified via a scaled truck and continuous beam in laboratory experiments. The experimental results indicate that the bridge's damage severity can be predicted by the CNN with high accuracy, and some concluding remarks are drawn below:

(1) The passing vehicle's responses on multiple positions can contain bridge damage information. Therefore, in the DL model training process, the responses from more DOFs are supposed to be included to increase its damage classification capability.
(2) Heavier vehicles can make the VBI interaction responses stronger. Through this, more bridge damage-related information can be transferred to the passing vehicles' vibrations, resulting in boosted damage classification accuracy.

Even though there are some key findings, some important influence factors, such as ongoing traffic and very poor road roughness, have not been checked. Our future studies will include these factors and further unsupervised DL models before engineering applications.

ACKNOWLEDGEMENT

This research was fully sponsored by the Jane and Aatos Erkko Foundation in Finland (Grant No. 210018). The support for the vibration tests provided by the staff of the laboratories in the Department of Civil Engineering and the Department of Mechanical Engineering at Aalto University was greatly appreciated.

T. Katika
Institute of Communication & Computer Systems (ICCS), Athens, Greece

ABSTRACT: In this paper, a crowdsensing and Indirect Structural Health Monitoring (iSHM) strategy is presented within the framework of the FUTURAL project. This development was based on the hypothesis that regular "health" inspections are not a realistic option in terms of cost and time. This iSHM strategy takes advantage of the dynamic responses of instrumented vehicles that monitor the "health" of roads or bridges as they pass, based on data collected by on-board IoT sensors or smartphones, which can be temporarily installed on shared mobility vehicles according to user preferences or permanently installed in inspection vehicles covering a specific route. For other structures, with an extra focus on building health assessments, visual input/feedback will be collected from users' smartphones. The proposed solution will allow monitoring of multiple buildings at a territorial level.

The solution will be verified in rural areas in Spain (Durangaldea) and Austria (Pongau).

1 INTRODUCTION

In European Union, the architecture, engineering, construction, and operation (AECO) sector is a significant industry. It contributes up to 9% of the EU's gross domestic product (GDP) and 18 million direct jobs, i.e., more than 6% of all employment in Europe. However, this crucial sector for the global economy is lagging in the adoption of Information and Communication Technology (ICT) and digital transformation when compared to other industries such as telecoms or the manufacturing sector.

New ICT technologies can help the AECO sector catch up with other sectors and the adoption of digital technologies can significantly improve effectiveness and efficiency. In particular, considering the construction operation and maintenance procedures, the implementation of automatic processes through sensors and monitoring systems, along with the development of algorithms for predictive maintenance and the identification of critical events, can greatly improve the performance in the sector contributing to the implementation of better maintenance and intervention strategies.

In the past, monitoring was meant to provide information to support condition assessment and check the safety of the structure. Currently, the objective of monitoring is not only to assess the current condition, but also to forecast the future performance to optimize in terms of cost-effectiveness the allocation of available resources, all by taking advantage of today's technological capabilities provided by IoT sensors and connected environments.

2 QUICK ASSESSMENT OF THE STRUCTURAL CONDITION AFTER EVENTS

As explained in Gkoumas et al. 2023, technologies and their applications for measuring and managing civil structure full-scale performance are targeted at serviceability -in respect of

DOI: 10.1201/9781003483755-194

vibrations, resilience -in respect of structural health monitoring and sustainability -in respect of optimised design.

Some traditional SHM technologies are piezoelectric impedance transducers, magnetoelastic stress sensors, and synthetic aperture radar. Traditional discrete monitoring sensors are still relevant in monitoring bridges at critical locations, where the development of cracks or large stresses are expected. Moreover, despite some of these technologies being considered obsolete, modern iterations of the same devices might be found in the market, offering high performance.

On the other hand, distributed sensing technologies, such as fiber optics and smart sensing materials, represents one of the latest evolutions in the SHM field. Although large companies have been somewhat reluctant to use new technologies, fiber optics have many advantages, such as geometric adaptability, the possibility of being embedded in concrete, capability of measuring a variety of perturbations (e.g., strain, acceleration, temperature, etc.), high signal-to-noise ratio, and resistance to harsh environments. They are probably the best option to monitor long structures, such as tunnels, and some of the most recent sensors can be easily installed on existing structures with tape or glue.

Other recent innovations are related to noncontact sensing, which is particularly useful in situations where traditional human inspection operations are complex or unsafe. Examples are: (1) digital image correlation, where cameras are used to detect displacement, deformations, stresses, and crack propagation; (2) infrared, where the variation in the surface temperature of the material is used to identify phenomena such as delamination, detachment, and cracks; (3) Light Detection and Ranging (LiDAR) sensors that can be mounted on vehicles or drones to scan the infrastructure even under low light conditions to identify deformations/displacements that may have occurred; and (4) indirect structural health monitoring (iSHM).

3 ISHM AS NEW PARADIGM SHIFT

iSHM (Fan et al. 2024) (Calderon Hurtado et al. 2024), in its current state, still deals with several challenges that need to be overcome to bring it into practice. It represents a paradigm shift, from the current situation where most monitoring is by human inspection to the time when most monitoring will be indirect, with all the instrumentation in passing vehicles (i.e., for bridge and road applications). Gkoumas et al. 2023 identified three main points: (i) iSHM with a single vehicle is difficult; (ii) direct monitoring with a fleet of vehicles is feasible, and (iii) iSHM with a fleet of vehicles is the future. In this regard, OBrien proposed mining data from a fleet of instrumented passing vehicles. He described a 3-step process, as follows: (a) processing of accelerations measured on the vehicles using an inverse Newmark-beta method to determine moving reference deflections under vehicle axles, as explained in Keenahan et al., 2020; (b) using off-bridge deflection data to calibrate the vehicles of the fleet, exploiting the fact that they all pass over the same road profile; (c) using on-bridge data to determine a moving-reference influence line, that is, deflection at a (moving) point on the bridge due to a unit (moving) load. He showed, through simulations, that the moving reference influence line was damage-sensitive and was an effective way of aggregating data from a wide variety of uncontrolled passing vehicles from the general traffic. They concluded that a fleet-based approach has great potential as an effective means of iSHM in the future. The next step was to prove this concept by instrumenting vehicles in full-scale field trials. Other approaches, also reported in Gkoumas et al. 2023, such as the one presented by Dr. Cantero (Sarwar et al. 2021), rely on a data-driven approach. They proposed a deep autoencoder ML model to process signals from passing vehicles and obtain a damage indicator that allowed the detection of bridge damage. In summary, experience shows that it is feasible to detect changes in structural behavior indirectly by analyzing signals from accelerometers embedded in specialized vehicles crossing bridges at low speeds. They also concluded that numerous vehicle passages are required to obtain robust results. In other words, Machine Learning (ML) techniques can be used to process indirect measurement signals and identify significant deviations in vehicle responses that could indicate severe infrastructure damage processes, which can be applied relatively easily across the entire road network to support existing bridge maintenance strategies.

We can conclude that iSHM appears to have potential if vehicles can be instrumented at a low cost and the massive amount of data generated is collected centrally. Algorithms also need to be developed to make a practical application feasible, for which the combination of data methods with numerical models, as well as indirect measurement data on cars with some direct measurement data on the bridge, does not seem to have been exploited to its full potential in a way that can fill the gaps that separate approaches inevitably have.

4 RECENT RELEVANT PROJECTS

4.1 *Mitica project*

The European Commission Joint Research Centre (JRC) established an exploratory research project MITICA (Monitoring Transport Infrastructures with Connected and Automated vehicles) to investigate the opportunity to use novel methods for infrastructure motoring, aiming at the efficient maintenance of the European aging road infrastructure.

The discussions taken during the workshop held at the JRC in Ispra (Italy) on 6&7 of June, 2022 highlight the high interest within the academic and technical community to developing vehicle assisted iSHM. During the workshop, a special focus was placed on innovative indirect structural health-monitoring approaches. These rely on vehicle-bridge interactions and the deployment of sensor-equipped vehicles to monitor existing bridge infrastructure, including results from the JRC MITICA Project.

This report aims to serve as a reference document in the area of iSHM using passing vehicles, for both scholars and policymakers.

4.2 *Good vibration project*

Good Vibration project aims to implement a modal-based indirect structural health monitoring of bridges through opportunistic data coming from smartphones placed in vehicles crossing the bridge. The project is being studied at the MIT Senseable City Lab, whose mission is to study the interactions between the physical and digital layer of cities, seeking opportunities that could bring benefits to communities.

The project specifically focuses on bridge structural health monitoring and the possibility of applying the paradigm of crowdsensing to the monitoring of bridge infrastructure worldwide.

The research then focused on mode shape estimation and semi-controlled data acquisition, realized within a three-year partnership with Anas S.p.A., the Italian national road maintenance and construction company. In particular, this methodology involves transforming each time history into a space-frequency map. Such reshaping is realized by applying the so-called synchrosqueezed wavelet transform, which guarantees better performance than other wavelets in terms of frequency smearing, as explained by Daubechies et al. 2011. Synchrosqueezing transforms single-bridge trips into maps containing bridge dynamics, vehicle dynamics, and noise. All maps were combined to obtain a final average map. Averaging allows us to highlight bridge structural behavior, reducing the effects of noise and vehicle dynamics. All trips, indeed, share the same bridge dynamics content, while the vehicle and noise are different for every trip. This methodology explains the power of big data in this application: the more maps are averaged together, the less noisy the final map will be. After synchrosqueezing is applied, the Most Probable Modal Frequencies algorithm is exploited to estimate a bridge's natural frequencies, which appear on the space-frequency map under the form of statistical wavelet ridges. Mode shape reconstruction is based on a similar concept: cutting the map in correspondence of the modal frequency and the intensity of the statistical ridges, which represents the amplitude of the bridge motion at each spatial location. Because the data acquisition is not synchronous, only the absolute mode shapes can be estimated.

The app, installed on the smartphones of a pilot group of Anas road operators (the Italian Autonomous Roads Corporation), requires no interaction with the user and acquires data in an autonomous manner. The minimization of battery consumption and data transmission has been achieved thanks to a geofencing algorithm, which densifies data collection when the smartphone

is localized in the proximity of a bridge of interest. According to the data pipeline, the Anas fleet collects data, transfers them to an Anas database, and then transfers them to MIT for processing.

The case studies involved in the campaign are all located in Italy, three near Rome, and one in the Dolomites, close to Cortina. The latter, called "Ponte Cadore," was the object of further experiments. A 272 m single span bridge, built as a hyperstatic structure with two pins and two diagonal supports, in 2013 Anas performed a monitoring campaign that involved a dynamic testing. In 2021, another experimental campaign was deployed to study the effects of vehicle dynamics, sensor performance, and GPS accuracy on the effectiveness of drive-by monitoring. The campaign consisted of Ambient Vibration Testing (AVT), to verify the dynamic properties of the bridge, and data collection was performed via two e-scooters on which both a smartphone and a professional wireless accelerometer were installed. Such a rich dataset, combined with more than 1000 passages recorded through the app by Anas personnel in 2022, allowed us to test the performance of drive-by monitoring according to the choice of sensor diagnostic vehicles. The first analyses pointed out outstanding results from e-scooters, which were able to identify more mode shapes than cars. This outcome opens interesting horizons for the use of micro-mobility in urban environments to scan the health of bridge infrastructure.

4.3 *Im-safe*

IM-SAFE EU project[1] supports the preparation of the mandate for CEN which aims at improving standardisation of the assessment of structural performance and of the proactive maintenance practices for the European transport infrastructure so that optimal use is made of information from inspection, monitoring and testing. The project focuses on bridges, tunnels, and other large infrastructures in road and railway networks.

The rapid growth of large-scale civil infrastructure and increasing dependence of society on the availability of transport networks has driven political and societal pressure to keep transport infrastructure available and to provide the required service level without unforeseen investments to maintain the desired performance. There is a general consensus that effective and cost-optimal maintenance is only possible with appropriate policies and rational decisions. Such policies and decisions should be considered and supported by timely, available, meaningful, and accurate information. In this respect, the monitoring of structures is expected to become a key enabler of proactive maintenance strategies to ensure the safety of the transport infrastructure during its entire service life.

One of the most interesting outputs of the IM-SAFE project is the online knowledge database, which contains a large number of examples in which data-informed approaches that involve monitoring of structures have been implemented at various stages of the maintenance decision-making[2].

5 FUTURAL PROJECT

Within the FUTURAL project, which held its Kick-off Meeting in Athens last June 2023, and in particular within the developments leading to the Smart Solution for Resilience to Shocks, the indirect measurement from vehicles in pilot cases of bridges in the rural areas of Durangaldea (Spain) and Pongau (Austria) is currently proposed.

In December 2023, work started on the pilot structure in Durangaldea, a 3-span road bridge with high piers, and a central span resting on half-joint (or dapped-end) supports, which require repair. This bridge is also vulnerable in its foundation because of torrential runoff under the structure, as well as being located in an area prone to a violent natural phe-

1. IM-SAFE-Project. European Union's Horizon 2020 research and innovation programme under grant agreement No 958171.
2. IM-SAFE Knowledge Base. IM-SAFE-Project. European Union's Horizon 2020 research and innovation programme under grant agreement No 958171.

nomenon called debris flow. Thus, because this structure is a critical node of the transport network of Durangaldea, providing access to the main communication routes, and is particularly vulnerable to climatic and natural phenomena, it was chosen as a pilot case for the development of ISHM algorithms for its control before, during, and after significant events.

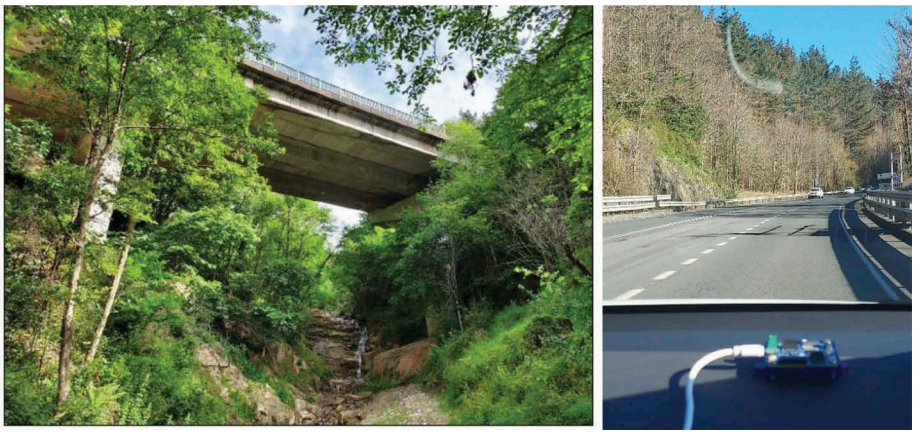

Figure 1. Image of the bridge on BI-633 road in Berriz (rural area of Durangaldea, Bizkaia, Spain) and image of the accelerometer onboard the car, attached to the dashboard, crossing the BI-633 road bridge in Berriz (rural area of Durangaldea, Bizkaia, Spain).

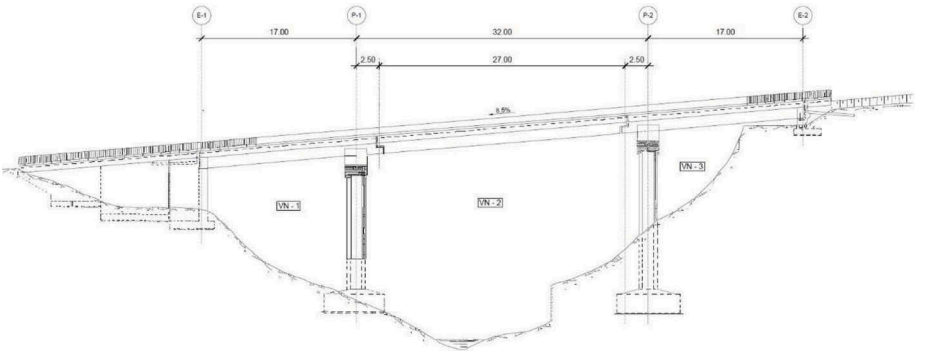

Figure 2. Elevation view of the bridge with the length of its spans. Image courtesy of the Provincial Council of Bizkaia.

For in-vehicle measurements, we chose to use "Steval-stwinkt1b" development kit from ST Microelectronics, which includes a IIS3DWB ultra-wide bandwidth (up to 6 kHz), low-noise, 3-axis digital MEMS accelerometer. ARM Cortex-M4 based STM32 microcontrollers allow us to train and run embedded extrapolation and outliers algorithms for low power microcontrollers (Later in the project, we will test other algorithms running on a cloud system, which will enable the processing of large amounts of data coming from other types of devices, such as smartphones or sensors without advanced local processing capabilities). In any case, low-cost and low-power edge computing, devices are considered an advance towards a low latency distributed processing with lower remote communication data rate requirements.

In this first phase of development, we are working with promising results on an anomaly detection system on the same signals recorded by the on-board accelerometer. To perform the first analyses, 6 measurements have been carried out with IIS3DWB vibrometer from ST Microelectronics at a 26KHz high sampling rate (so that a high number of analysis points are ensured even if the recordings are of short duration) with the vehicle crossing the bridge in the downward

sense and 6 measurements with the vehicle crossing the bridge in the upward sense (all of them with controlled speed between 70-75Km/h).Then, after duly cutting the signals between the acceleration peaks generated by the vehicle hitting the expansion joint at the entrance and exit of the bridge, a Machine Learning algorithm (Nanoedge Studio software is used to train an Edge Computing algorithm for STM32 microcontroller) is trained on the time series (with 4 signals in the downward sense and an anomalous record, just to define a "normal" class) obtaining that:

1. When comparing (asking the trained algorithm) with another record in the downward sense (of the two reserved for testing) it turns out that it is practically equal to the "normal" one (99% match).
2. When comparing (asking the trained algorithm as in the previous case) with a record in the upward sense, it turns out to be 90% similar (going down the car goes slightly faster, with the entrance and exit strokes stronger due to defects in that area of the expansion joint, which is to be replaced in 2024). This is expected to improve, or simply become more uniform, by training with more signals and/or without distinguishing between going up and down.

3 & 4. When asking for two anomalous records, it detects that both are 100% anomalous.

No bridge damage has been synthetically recreated in this early phase of FUTURAL, so in this first test the anomalous records are a passage of the car over another bridge and the passage of the vehicle over the road (without a bridge). In a more advanced stage of the developments, the sensitivity to damage will be tested after affecting the signals by a damage ratio obtained from computational models.

As example, Figure 3 includes some results with 99% of coincidence when asking the algorithm, trained with signals in the downward direction of car traffic, for another signal (not used in the training) in the same direction (all at about 72-75Km/h car speed). Similar results when asking the algorithm trained with signals in the downward direction of car traffic for a signal in the opposite direction (at about 70 km/h car speed; asking for an anomalous record (car driving on the road without a bridge); and asking for an anomalous record (car crossing another bridge). This are preliminary tests (feasible damage scenario will be generated at a later stage of development).

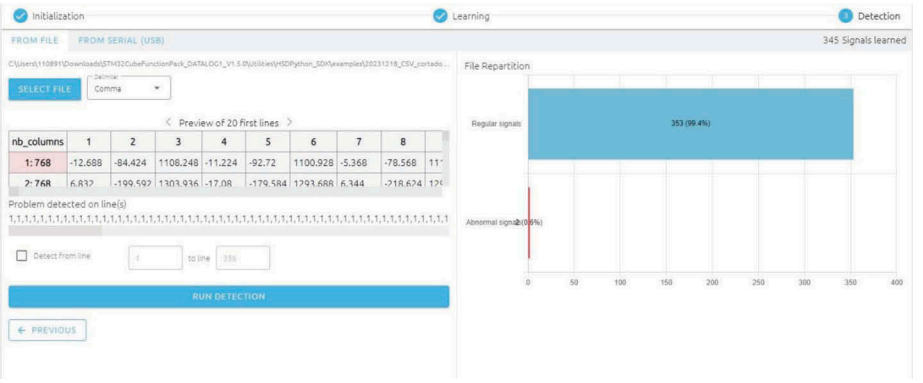

Figure 3. Image of the result for point 1 above.

It is important to note that not all processing is currently done on-chip. For this, it needs to be modified with an accelerometer to allow for less sampling and regulation of consumption, which will be studied further as knowledge of the pilot case improves.

Further work leading to a Smart Solution for Resilience to Shocks in FUTURAL, which will not be completed until the end of 2025, in addition to the study of the sensitivity of this application to a reasonable damage scenario, will comprise the development of other algorithms for off-chip processing, which would be usable for other types of devices without the capability to incorporate complex algorithms at the edge, such as self-developed Internet of

Things (IoT) sensors or smartphones, among others. For this, an alternative to be studied could be the future implementation of a deep autoencoder model for damage assessment of road bridges using vehicle responses as discussed in Gkoumas et al. 2023, along the lines of the work by Sarwar et al. 2021, cited above.

As concluded by other works, already referred to, another key step in the process will be to collect a good database of car crossings. This data can also be enriched with in-situ sensor measurements (permanent or temporary) on the bridge, with one of the focal points of the FUTURAL Smart Solution for Resilience to Shocks being to rely on multi-sensor information, combining both accelerations measured by onboard sensors with different bridge and weather event measurements to drive a cost-effective and connected solution for structural assessment before, during and after significant natural events.

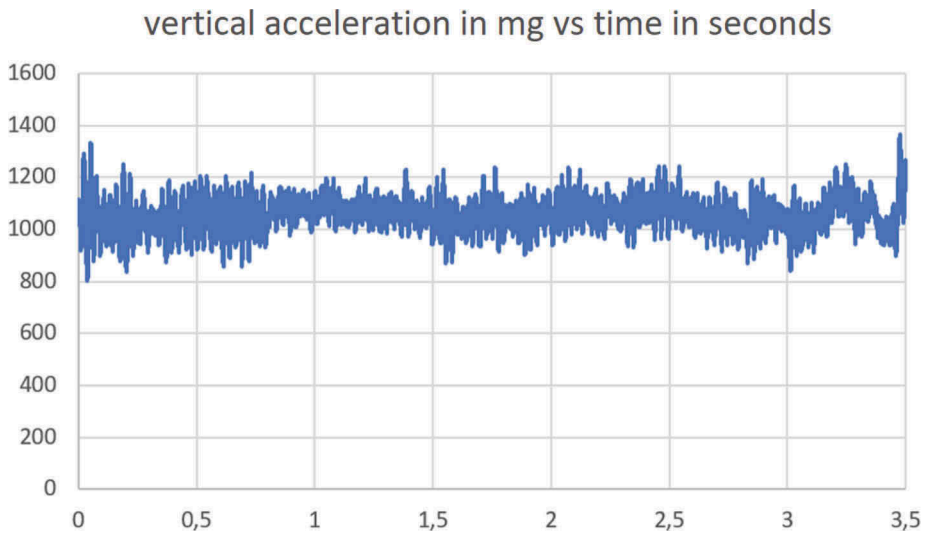

Figure 4. Image of a sample acceleration record from the tests described above.

Last but not least, it will be necessary to automate the cutting of the signal, leaving only the part corresponding to the bridge for local analysis (preprocessing) or server (postprocessing), for which the most desirable option would be the incorporation of a GPS to the onboard sensor, whatever it may be. Likewise, it is necessary to enable data communication from the sensor to the Cloud, being the GPS metadata also crucial to locate each bridge measurement in the transport network (here a GIS-based platform could be of support for a contextualization of the data and results).

6 CONCLUSIONS

Current challenges in this field are:

- Short duration of signals
- Interference from the pavement-induced vibration
- Accounting for Environmental and Operational Influences
- Quantification of Damage
- Experimental Verification of Drive-by Concepts

Enablers of iSHM are:

- vehicle communication
- on-board sensing and computing

– the management of big data, the integration with existing infrastructures monitoring (providing additional reference signals for better indirect assessment)
– the implementation of advanced algorithms and machine learning data processing

Moreover, standardization of both hardware, communication protocols and data, just like in the other environments adopting new digital technologies (e.g. smart cities), can ensure the iSHM future development with effective integration and interoperability of components and processes from different developers. However, acceleration measurements are the standard, and the processing can be derived to a device-independent Cloud system, this the device only must ensure sufficient quality of the measurement and its communication. Nevertheless, the inclusion of devices with complex processing capabilities, such as the ST development kit tested in this initial phase of FUTURAL, are considered a great advantage (reducing the processing and storage requirements for a crowdsensing platform).

In the future, local monitoring systems will possibly be integrated into smart cities digital platforms. This would allow the interaction with smart infrastructures that collect and process physical measurements and data, and then transfer relevant information to centralized systems, contributing to the functioning of urban system as a whole.

When talking about digital twins (DT) of the entire critical infrastructure or even the entire city, the consequences regarding resources for data elaboration, maintenance or storage, could in the end, affect the sustainability of the system. Also, the cost in terms of CO_2 emissions for maintaining a DT for many years at the level of system of systems. This cost maybe needs to be measured with the advantages the digital transformation is bringing. The only answer at this moment is to promote different scales for different needs (i) regarding local and global, these could be relevant at different scales, local at the bridge scale, global at network scale; (ii) regarding the amount of data collected nowadays, it is huge, and we should reflect on what data are actually needed before collecting them; (iii) the use of DT is often downscaled to the integration of a FEM and/or BIM model: considering DTs as a tool for optimizing future management rather than a tool used to perform damage detection.

ABSTRACT: This paper proposes the use of a Bayesian approach to detect bridge bearing damage using simulated acceleration measurements collected from a fleet of notional instrumented vehicles. On-bridge vehicle accelerations are used to update bridge and vehicle properties. Four different bridge damage states are considered with different bearing damage conditions. The results show that bridge properties, i.e., second moment of area and bearing stiffnesses, can be inferred accurately from the acceleration measurements using a Bayesian updating approach. The fleet monitoring concept with the Bayesian approach is computationally efficient when a large quantity of measurement is involved.

1 INTRODUCTION

An increasing number of road bridges, particularly in Europe, are aging and deteriorating which has resulted in a number of recent failures, e.g., Malahide Estuary bridge collapse in 2009; Genoa bridge collapse in 2019. The safety of these pieces of critical infrastructure is important to prevent future fatal collapses or operational interruptions. Regular bridge condition monitoring, ensuring timely maintenance or repair, is necessary to achieve this goal. Recent practice heavily relies on visual inspection, which tends to be infrequent, expensive, disruptive to traffic and potentially unsafe for those involved. Electronic monitoring using sensors installed on bridges can be costly and time-consuming. This method is often applied on longer bridges. However, for large numbers of medium and short-span bridges, it becomes infeasible due to the high cost of set-up, operation and maintenance. An alternative solution is 'drive-by' or 'indirect' monitoring, which uses sensors installed in passing vehicles. This is potentially much more cost effective and becomes accurate when data from a large fleet of passing vehicles is combined. So called 'fleet' monitoring has the potential to generate the paradigm shift from visual to electronic monitoring of bridges, enhancing the capability for early damage detection and effectively extending infrastructure life.

'Drive-by' monitoring has been generating increasing interest in recent years (Malekjafarian et al. 2022). The concept was first proposed by Yang et al. 2004, 2005 and validated by passing an instrumented vehicle over a real bridge (Lin et al. 2005). It is expected to be time efficient, scalable, and hence to greatly reduce cost as sensors are mounted on in-service vehicles passing over bridges on a daily basis. It has the potential to monitor a large stock of bridges as

DOI: 10.1201/9781003483755-195

vehicles pass through the network. Dynamic data collected from instrumented vehicles can provide information on bridge condition via vehicle/bridge dynamic interaction mechanisms. However, drive-by monitoring also involves a number of significant challenges (Malekjafarian et al. 2022): (1) extracting bridge information from vehicle vibration is difficult as the signal is dominated by the influence of road roughness, (2) high vehicle speed on short-span bridges results in very small segments of data (1 or 2 seconds), (3) light vehicles induce insufficient bridge excitation, and (4) environmental effects and variation in vehicle configuration significantly influence the measurements. These challenges can be overcome if a sufficiently large quantity of data is collected from a fleet of in-service vehicles passing over the target bridge.

'Drive-by' damage detection relies on the extraction of bridge damage-sensitive features from measurements containing information on the vehicle and the road profile, as well as the bridge properties. The bridge features can be dynamic properties, such as natural frequency, mode shape or damping, or other pseudo-static features, such as deflection under load. Key frequencies in the data include bridge and vehicle natural frequencies, moving vehicle pseudo-frequencies, and road profile frequencies, as first identified by Yang et al. 2004. The method has now been validated by Yang and others (McGetrick et al. 2010, Kim et al. 2011), including some limited field experiments (Siringoringo et al., 2012). Siringoringo et al., 2012 identifies the first natural frequency, at a driving velocity below 30 km/h, with a maximum estimation error of 11.4% – insufficient to detect low levels of damage. Changes in estimated mode shapes can also indicate bridge damage but it works only with low-speed data (Yang et al. 2014, Malekjafarian et al. 2014) and has not been validated in the field.

Apart from modal-based detection, OBrien et al. 2014 measure dynamic axle force using the Moving Force Identification method and use the inferred force signals to identify global bridge stiffness loss. The results show good potential to use this low-cost method to detect global damage in short to medium span bridges. OBrien et al. 2015 simulate the time-shifted difference in inferred apparent profile from Traffic Speed Deflectometer data and use Cross Entropy optimization to detect damage effectively. Keenahan et al. 2020 introduce the fleet monitoring concept to calculate road profile from vehicle acceleration without prior knowledge of vehicle properties. OBrien et al. 2023 detect bridge bearing damage using measurements from a fleet of vehicles through a moving reference influence function. The above studies show that increasing data collected from many vehicles can significantly improve the accuracy of drive-by and fleet bridge condition monitoring.

An alternative approach to infer vehicle/bridge properties is Bayesian updating, using data collected from sensors mounted on passing vehicles. While the accuracy of drive-by monitoring is sensitive to vehicle speed, pavement roughness, vehicle weight and environment-induced bridge property variation, the Bayesian approach is robust. It results in probabilistic estimations which are updated as data is added continuously. For this reason, fleet monitoring following the Bayesian approach is effective and computationally efficient relative to deterministic methods such as optimisation. Wilson et al. 2006 predict patterns of statistical spatial repeatability using a fleet of truck models inferred from dynamic tyre force measurements. That study shows that the fitted models inferred from the Bayesian framework agree well with the 'true' distributions. Kumar et al. 2021 use Bayesian inference to estimate tyre model parameters and then uses these parameters as inputs to reconstruct vehicle bridge interaction forces that can indicate bridge damage.

The latest Bayesian approaches expressed above focus on calibration of multiple parameters of a fleet using tyre force/pressure measurements. Changes on Vehicle-Bridge-Interaction forces can indicate changes in bridge condition. The Bayesian updating can be done both as vehicle and bridge properties simultaneously using inertial on-board measurements, eventually providing bridge condition information. This paper explores the fleet monitoring concept using the Bayesian approach for bridge damage detection. Vehicle sprung mass and bridge properties such as spring stiffness of the bearings, are updated probabilistically using data simulated by a fleet of vehicle models. The method can quantify bridge bearing damage at different levels.

2 NUMERICAL MODELING

2.1 *Vehicle-bridge interaction model*

A coupled vehicle and bridge model is used in this paper. A fleet of quarter car models is simulated passing over a 20 m simply supported finite element (FE) beam, with a smooth profile, as shown in Figure 1. This vehicle–bridge interaction model has been used by many other authors (Elhattab et al. 2016, Malekjafarian et al. 2019). The bridge has a modulus of elasticity of $E = 35\times10^9$ N/m^2, density, ρ = 37,500 kg/m^3, second moment of area, I_{bridge}=1.259 m^4 and a bridge damping ratio of 3%. Rotational springs are added at each beam support to represent the bridge bearing stiffnesses, $K_{rot,1}$ and $K_{rot,2}$ (Kliewer et al. 2017, OBrien et al. 2023). A fleet of vehicles is generated based on the mean and standard deviation of vehicle properties presented in Table 1.

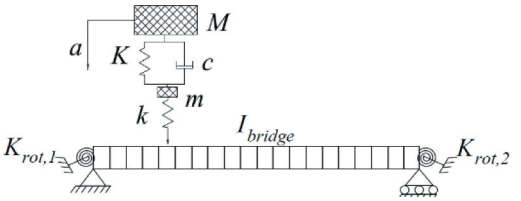

Figure 1. Quarter-car and bridge model.

Table 1. Vehicle properties.

Parameter	Symbol	Unit	Mean	St. dev.
Sprung mass	M	kg	4,450	445
Unsprung mass	m	kg	420	42
Suspension stiffness	K	N/m	500,000	50,000
Tyre stiffness	k	N/m	1,950,000	195,000
Suspension damping	c	Ns/m	20,000	2000

Bearing damage is deemed to be in the form of a loss of bearing spring stiffness. The values of K_{rot} ranges from zero (free to rotate) to infinity (fully fixed). To test the bearing damage level of the bridge model, one vehicle is simulated crossing this bridge with different values of $K_{rot,1}$ and $K_{rot,2}$. Then, the area under the deflection curve of the bridge is used to verify changes

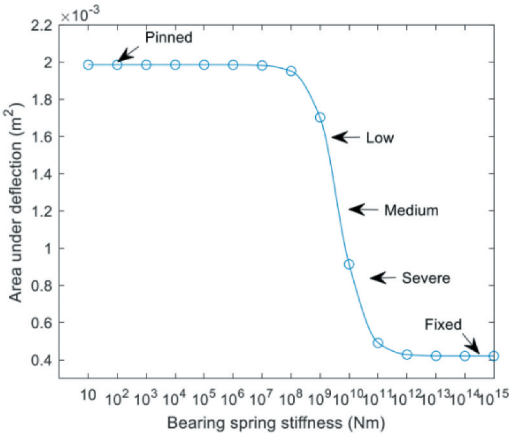

Figure 2. Area under the deflection curve with different values for K_{rot}.

in the bridge condition. The parameters, $K_{rot,1}$ and $K_{rot,2}$ start from 0 Nm/rad and increase to 10^{15} Nm/rad, where the supports behave as effectively fully fixed. The area under the deflection curve with different stiffness values are shown in Figure 2. Here, $K_{rot,1}$ is equal to $K_{rot,2}$ and represented by K_{rot}. It shows that there is no obvious change in the area under the deflection curve if K_{rot} is less than 10^7 Nm/rad. After 10^7 Nm/rad, the area starts to reduce. For higher values (over 10^{11} Nm/rad), the areas do not show significant further change.

3 DETECTION OF BRIDGE BEARING DAMAGE USING BAYESIAN UPDATING

3.1 *Bearing damage*

A Bayesian updating method is introduced in this section to detect bridge bearing damage. Four different bearing damage states are considered and corresponding vehicle accelerations are generated: $K_{rot,1} = K_{rot,2} = \{0, \ 10^9, \ 10^{10}, \ 10^{12}\}$ Nm/rad. All the vehicle properties can be found using data from the approach (off-bridge) section except vehicle sprung mass (Keenahan et al. 2020). The vehicle sprung mass, bridge 2nd moment of area, I_{bridge} and bridge bearing stiffnesses $K_{rot,\ 1}$ and $K_{rot,\ 2}$, are inferred from these 'measured' accelerations using the Bayesian approach. Here, it is assumed that all 20 elements of the bridge have the same 2nd moment of area, equal to I_{bridge}.

3.2 *Data likelihood*

A simple independent Gaussian error model is used to calculate the deviations of the observed bridge deflections from the true values. The Gaussian error model is formulated in terms of the probability of a specific deflection (Wilson et al. 2006, Obrien et al. 2023):

$$\begin{aligned} p(\boldsymbol{w_n}|M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2}\ ) &= \prod_{i=1}^{P} p\big(w_n(y_i; M_n)|W_n(y_i; M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2}\ )\big) \\ &= \prod_{i=1}^{P} \frac{1}{\sqrt{2\pi\sigma_2^2}} \exp\left(-\frac{1}{2\sigma_2^2}\big(w_n(y_i; M_n) - W_n(y_i; M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2})\big)^2\right) \\ &= \big(2\pi\sigma_2^2\big)^{-0.5P} \exp\left(-\frac{1}{2\sigma_2^2}\sum_{i=1}^{P}\big(w_n(y_i; M_n) - W_n\big(y_i; M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2}\big)\big)^2\right) \end{aligned} \tag{1}$$

where $W_n(y_i\ ;\ M_n,\ I_{bridge},\ K_{rot,1},\ K_{rot,2}\ )$ is the expected bridge deflection observed from the n^{th} vehicle with M_n crossing the bridge with true properties, I_{bridge}, $K_{rot,1}$, $K_{rot,2}$. The term, $w_n(y_i\ ;\ M_n)$ is the observed bridge deflection signal which is calculated from the 'measured' accelerations using the Inverse Newmark-beta method. The Inverse Newmark-beta method to calculate the apparent profile directly from 'measured' accelerations was proposed by Keenahan et al. 2020. It is assumed that each vehicle's observations are independent:

$$\begin{aligned} p\big(\boldsymbol{w}|\boldsymbol{M_{1:N}}, I_{bridge}, K_{rot,1}\ , K_{rot,2}\ \big) &= \prod_{n=1}^{N} p\big(\boldsymbol{w_n}|M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2}\ \big) \\ &= \big(2\pi\sigma_2^2\big)^{-0.5NP} \exp\Big(-\frac{1}{2\sigma_2^2}\sum_{n=1}^{N}\sum_{i=1}^{P}\big(w_n(y_i; M_n) - W_n\big(y_i; M_n, I_{bridge}, K_{rot,1}\ , K_{rot,2}\big)\big)^2 \end{aligned} \tag{2}$$

3.3 *Priors*

A prior distribution, $p(M_n|\varphi_M)$, is introduced for each vehicle mass. It is the distribution of vehicle masses across the population of vehicles. For each vehicle class, the mass distribution is assumed to be the same – histograms of vehicle weights have been shown to be repeatable at a given site. This distribution is taken to be normal and φ_M is its mean and variance. It is

assumed that these priors are independent for each vehicle, so the prior for all masses $\boldsymbol{M}_{1:N} = (M_1, \ldots M_N)$ is:

$$p(\boldsymbol{M_{1:N}}|\varphi_M) = \prod_{n=1}^{N} p((M_n|\varphi_M)). \tag{3}$$

Bridge properties, such as I_{bridge}, $K_{rot,1}$ and $K_{rot,2}$ are constant values across an interval. Their distribution is assumed to be uniform over an interval $(a,\ b)$, with density:

$$p(x) = \frac{1}{b-a}, a \le x \le b. \tag{4}$$

3.4 *Posterior distribution*

A posterior distribution for the bridge section is introduced. By Bayes' Law, this is given in terms of the likelihood and prior terms by:

$$\begin{aligned} &p\left(\boldsymbol{M_{1:N}}, I_{bridge}, K_{rot,1}\ , K_{rot,2}|\boldsymbol{w}\right) \\ &\propto p\left(\boldsymbol{w}|\boldsymbol{M_{1:N}}, I_{bridge}, K_{rot,1}\ , K_{rot,2}\ \right)\left(\prod_{i=1}^{N} p((M_n|\varphi_M))\right)p\left(I_{bridge}\right)p\left(K_{rot,1}\right)p\left(K_{rot,2}\right) \end{aligned} \tag{5}$$

3.5 *MCMC algorithm and calculation results*

The question now is the issue of computing Equation (5). The proposal here is to do it by Monte Carlo sampling, specifically Markov Chain Monte Carlo (MCMC) which is suitable for complex and high dimensional distributions. A fleet with 30 different vehicles is simulated crossing the bridge and sprung mass accelerations of these vehicles are generated as 'true' accelerations. Additive White Gaussian Noise of 2% is added to the measurements to allow for inaccuracy. Then these accelerations are used as input into the MCMC algorithm to back-calculate the bridge and vehicle properties. The MCMC process can determine the bridge second moment of area, I_{bridge}, the bearing damage levels $K_{rot,1}$, $K_{rot,2}$ and vehicle sprung mass value, M at the same time.

The calculated K_{rot} and I_{bridge} of the four damage states considered, are shown in Table 2. For the second and third state, both the bearing spring stiffness values, K_{rot} and bridge property, I_{bridge} can be calculated with good accuracy. However, for the first and fourth damage state, only the bridge property, I_{bridge} can be calculated. The calculated bearing spring stiffness values are different to the true ones. As shown in Figure 2, if the value of K_{rot} is less than 10^8, the bearing damage condition is low, and it is very close to the healthy state. It is also worth noting that the areas under the deflection curves are almost the same. Similarly, for higher values of K_{rot}, the bearings are approaching being fully fixed and the areas under the deflection curves will not change as the value of K_{rot} increases. The calculated sprung masses values for the second damage state are shown in Figure 3 and the calculated sprung masses are very close to the true masses.

Table 2. Calculated bridge properties by MCMC.

Damage states		1	2	3	4
$K_{rot,1}$ (Nm/rad)	True	0	10^9	10^{10}	10^{12}
	Calculated	4.3×10^7	1.28×10^9	1.06×10^{10}	6.0×10^{12}
$K_{rot,2}$ (Nm/rad)	True	0	10^9	10^{10}	10^{12}
	Calculated	1.0×10^7	1.01×10^9	1.00×10^{10}	1.8×10^{12}
I_{bridge}(m^4)	True	1.26	1.26	1.26	1.26
	Calculated	1.22	1.22	1.24	1.23

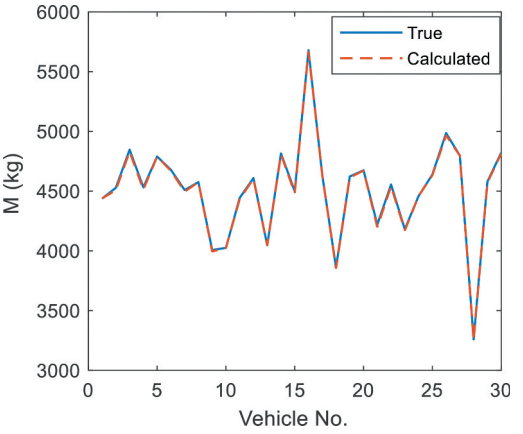

Figure 3. True and calculated sprung masses of the 30 vehicles, from MCMC for damage state 2.

4 CONCLUSION AND FUTURE WORK

This paper uses a Bayesian approach to detect bridge damage using a fleet of instrumented vehicles. Here, the on-bridge vehicle accelerations collected from a fleet of simulated vehicles are used to determine the bridge properties, vehicle sprung masses and the spring stiffnesses of the bearings. Four different bridge damage states are considered with different bearing damage conditions. The results show that the bridge properties and spring stiffnesses can be calculated with good accuracy using this Bayesian approach. The calculated bearing spring stiffnesses can be used to determine the bearing damage condition.

It is acknowledged that the road surface profile on the bridge, assumed to be smooth in this paper, may have a significant effect. It would be desirable to demonstrate the ability to detect lower levels of damage. For future work, bridges with non-smooth profiles will be investigated. The results in this research are based on simple numerical models and there will be challenges for real vehicles in the field. Accuracy will be improved by considering larger fleets of vehicles.

Indirect bridge condition monitoring using feature selection strategy

R. Ghiasi, R. Corbally & A. Malekjafarian
Structural Dynamics and Assessment Laboratory, School of Civil Engineering, University College Dublin, Dublin, Ireland

ABSTRACT: Bridge damage detection (BDD) techniques have been widely explored over the last years driven by the advances of computational intelligence technologies. Drive-by monitoring approaches, using sensors in a vehicle, provide a promising framework for BDD. In this context, the aim of this paper is to present a novel automated methodology for damage detection based on the extraction of features from the vibration responses measured on a passing vehicle using filter-type feature selection scheme. Feature extraction is performed in the time domain and then feature selection (FS) is applied to increase the relevance of the feature set by choosing the most important features based on their ability to discriminate between different classes of data. Finally, a cascade forward neural network (CFNN) is used to classify damage severity. The method was tested using a finite element (FE) model of concrete beam-and-slab bridge by considering vehicle bridge interaction (VBI). Results show that when the Pearson correlation coefficient (PCC) is used as a feature selection algorithm and an CFNN as a classifier, 94% accuracy can be achieved for identifying the level of cracking in bridge.

1 INTRODUCTION

Transportation networks require ongoing inspection and maintenance of their physical infrastructure assets to ensure that they remain functional. Bridges are critical components, and it is essential that they are inspected and maintained appropriately to ensure that vehicles can travel in a safe and efficient manner. As transport networks age and the infrastructure deteriorates over time, inspection of large bridge stocks and prioritization of maintenance budgets towards specific structures becomes more and more challenging. For this reason, there is a clear need for quick and efficient techniques for ongoing monitoring and inspection of bridges.

Drive-by bridge monitoring approaches utilize in-vehicle sensors to monitor bridge condition based on measurements taken as the vehicle traverses the bridge. The drive-by concept was initially proposed by Yang et al. (2004) where it was theoretically demonstrated that the fundamental frequency of a bridge can be extracted from the vibration of the traversing vehicle. Given that bridge frequency is sensitive to damage, this represented a method of monitoring changes in bridge condition over time, without the need to install sensors on the bridge, or the need for manual visual inspections. Since the concept was initially proposed, there have been numerous developments in the use of drive-by bridge inspection techniques. Different damage mechanisms can affect bridge vibrations in different ways so there have been various efforts to examine how drive-by techniques can be used to identify these changes, e.g. for scour (Fitzgerald et al., 2019), cracking in the deck (McGetrick & Kim, 2013, Malekjafarian et al., 2018) or changes in boundary conditions (Mei & Gül, 2019, Cerda, 2014) amongst others. Drive-by techniques have also been used for different applications, including calculation of bridge modes shapes (Corbally & Malekjafarian, 2022a), bridge damping (Keenahan et al., 2014), estimation of vehicle properties and investigation of pavement characteristics (McGetrick et al., 2017, McGetrick et al., 2013).

DOI: 10.1201/9781003483755-196

More recently there have been a number of developments where researchers have explored the use of Machine Learning approaches to account for environmental or operational factors which may influence the measured bridge properties during any given vehicle passage (Sarwar & Cantero, 2021, Li et al., 2023, Corbally & Malekjafarian, 2023). The adoption of machine learning techniques for drive-by bridge monitoring is becoming more prominent, as discussed by Malekjafarian et al. (2022). The advantage of utilizing machine learning approaches lies primarily in their ability to identify and learn trends in the measured signals which can be attributed to different bridge conditions, and also to external influences such as temperature or vehicle speed (Locke et al., 2020, Corbally & Malekjafarian, 2022b). This paper presents a new approach which adopts a cascade forward neural network (CFNN) to classify the severity of bridge damage based on measured vibrations from a vehicle passing over a bridge. Damage-sensitive features are automatically extracted from the measured vibrations, and those with the greatest importance are selected to differentiate between different classes of damage, before the CFNN is adopted to classify the damage severity. The methodology is demonstrated using a finite element (FE) model of concrete beam-and-slab bridge, where the ability of the algorithm to identify cracking is tested.

2 METHODOLOGY

The proposed framework comprises five stages, elaborated in detail in Figure 1. The framework starts with data collection and signal processing, and then sensitive features are extracted and selected in steps 3 and 4. Finally the damage state is predicted in step 5. The detail of each step is explained in the below paragraphs.

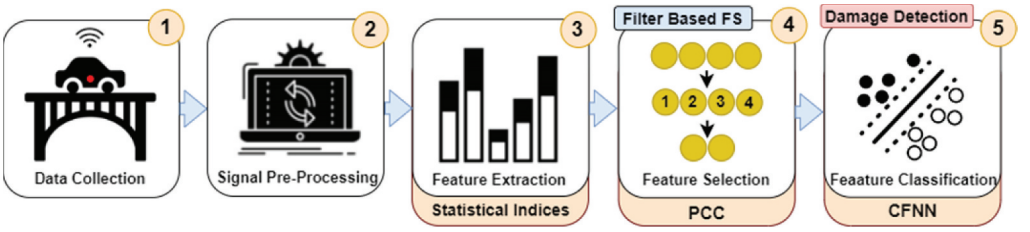

Figure 1. Proposed framework for indirect monitoring of bridge.

After collecting acceleration responses on the vehicle's axle and the body, in Step 2, the recorded sensor acceleration responses undergo a cleansing and filtering process. For this purpose, a band-pass filter (BPF) is used to reduce the effect of noise and environmental variables on the response (Corbally & Malekjafarian, 2022b). In this study, a 3rd order Butterworth BPF (5–25 Hz) is applied to all data channels prior to feature extraction step. The chosen band retains the frequencies of primary interest, removes drift/error, the influence of pavement and other unwanted noise (Corbally & Malekjafarian, 2022b).

In the third step (Features Extraction), to reduce the length of the data and extract meaningful information from the responses, statistical features of signals are extracted from the raw acceleration signal measured on the vehicle. These features (such as Root mean square, Variance, Mean, Shape factor, Crest factor, etc.) are computed in the time domain and provide a summary of the statistics of the signal over a time window with a specified number of sample points (Buckley et al., 2023).

When the feature set is extracted, a filter-based feature selection method called Pearson correlation coefficient (PCC) (Saidi et al., 2019) is used to reduce the dimensionality of the problem. The PCC quantifies the linear relationship between a feature and the target variable. Ranging from -1 to 1, a high absolute PCC indicates strong correlation, guiding the selection of informative features for enhanced model performance (Saidi et al., 2019). It's important to note that the target variable in this work represents the specific damage classes. This metric

offers a concise and interpretable means of optimizing feature subsets that are used as the input vector to the damage classification algorithm.

In the final step (Features Classification), the classification algorithm using a CFNN (Fathnejat et al., 2014) is trained based on 80% of the data. CFNN is a robust classification algorithm that leverages a series of interconnected layers to extract hierarchical representations from input data (Fathnejat et al., 2014). By systematically forwarding information through hidden layers to an output layer, the CFNN excels at discerning intricate patterns and relationships within features (Torkzadeh et al., 2016). In this paper, the output of CFNN is damaged states of the desired bridge.

The evaluation metric used to reflect the overall performance of the classification model is balanced accuracy classification score (Ritto et al., 2022), which is measures the average accuracy obtained from both the minority and majority classes.

3 NUMERICAL MODELING

The methodology is tested using a quarter-car vehicle model, passing over a finite element representation of bridge. The quarter car model, as shown in Figure 2, consists of two degrees of freedom, with two lumped masses, representing the vertical motion of the (i) vehicle body (M_v=8,900 kg) and (ii) the axle (including the wheel) (M_w=1,100 kg). The two masses are connected using a spring and dashpot representing the stiffness (k_v=2x10^6 N/m) and damping (c_v=40,000 Ns/m) properties of the vehicle suspension and the axle degree of freedom is connected to the bridge using a spring to represent the tire stiffness (k_T=3.5x10^6 N/m). While the quarter-car is a simplified representation of the actual behavior of a vehicle, it has been widely adopted to represent the two primary modes of vibration of a vehicle, i.e. 'bounce' of the vehicle body and axle 'hop'.

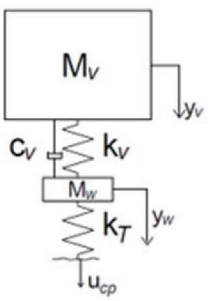

Figure 2. Quarter-car vehicle model.

A typical beam-and-slab bridge, as shown in Figure 3, was modelled with a 'Class A' pavement representing a smooth road surface in good condition. The FE model of the bridge consisted of 25 no. beam elements, with the second moment of area ($I_0 = 1.156$ m^4) and mass per unit length ($m = 17,384$ kg/m) of the cross section shown in Figure 3 assigned to each element along with a Young's modulus of $E_0 = 35$ GPa. Rayleigh damping of 2%. Damage to the bridge was modelled as cracking at a single location longitudinally along the bridge, following the method proposed by Sinha et al. (2002), whereby a localized reduction of stiffness is introduced at the crack location, and propagates away from the crack longitudinally across the affected zone.

A series of vehicle passages across the bridge were simulated, with the speeds were randomly generated for each passage by sampling from a normal distribution with a mean value of 20 m/s and a standard deviation of 1.7 m/s. 200 passages across the healthy bridge were simulated, and the acceleration response (without any artificial noise) on the vehicle's axle, and on the body of the vehicle were saved for each passage. Similarly, 100 passages were simulated across the bridge in each of three different damage cases, representing (i) 10%, (ii), 20% and (iii) 30% cracking at midspan.

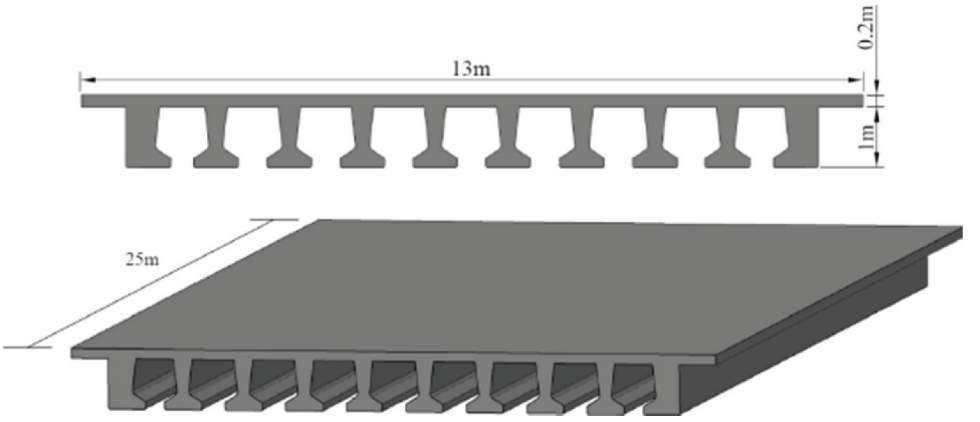

Figure 3. Cross section and 3D view of bridge deck.

4 RESULTS

4.1 *Feature extraction and features selection*

After acquisition of the acceleration response of the vehicle over the bridge and applying BPF, the third step of the proposed framework is to extract the damage-sensitive features from the raw data. According to the number of accelerometer sensors considered for the vehicle (3) and the number of features extracted from each response (10), the final features matrix has 30 columns. This matrix is input of the feature selection step.

Figure 4 shows the ranking of the top 10 features based on the PCC algorithm. In this diagram, the horizontal axis shows PCC values for different features. As can be seen in the figure, the response recorded by both sensors is necessary to achieve the desired accuracy, meanwhile, most of the selected features (7/10) are from the sensor that is installed on the body. This shows that the use of this sensor is necessary to detect damage in the bridge. In

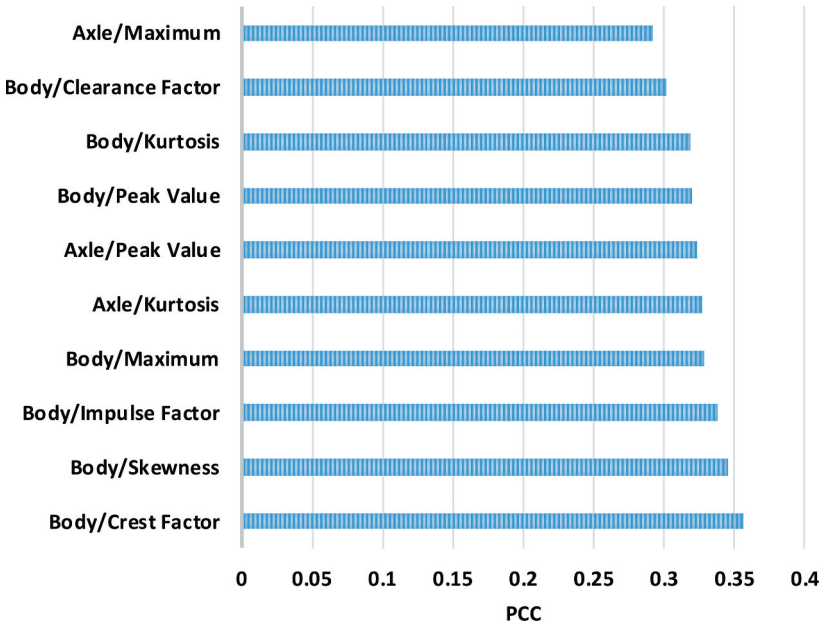

Figure 4. Feature subset selection using PCC.

order to check the selected features, the scatter plot of two pair of them are shown in Figure 5 and Figure 6 which are grouped by damage state of bridge.

It is apparent from Figure 5 and Figure 6 that the selected features in different damage classes have different distribution intervals, and they can be used as features which are sensitive to structural damage in the bridge. However, the sensor placed on the body of the car, exhibits the changes of different damage modes within a more specific range. One possible explanation for this is the filtering out of minor changes in acceleration response induced by pavement roughness through the use of a suspension system.

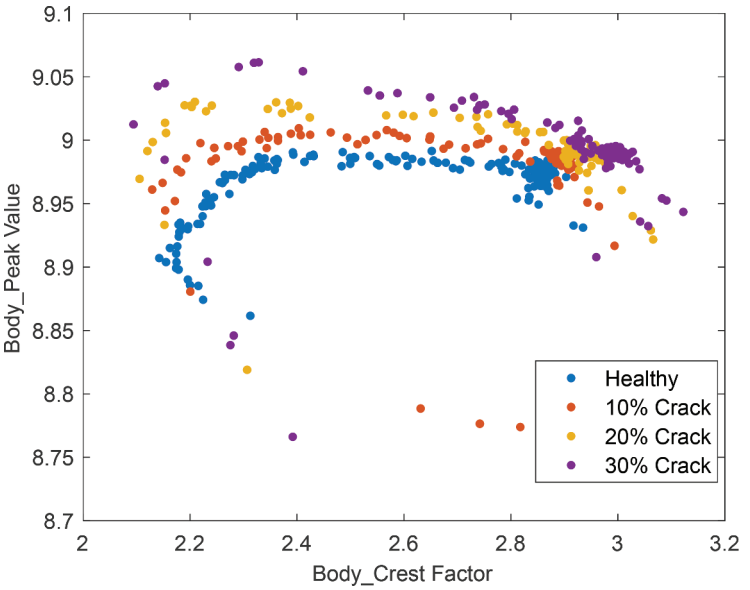

Figure 5. Scatter plot of crest factor and peak value of body sensor grouped by damage state.

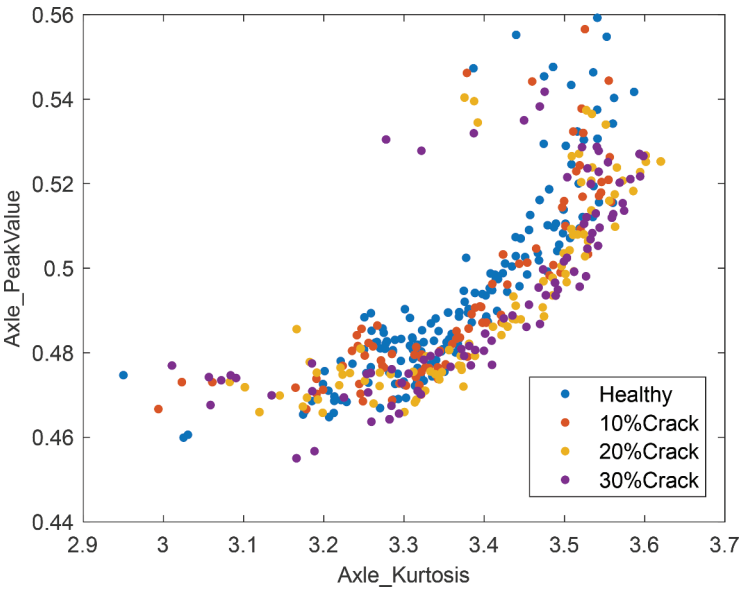

Figure 6. Scatter plot of kurtosis and peak value of axle sensor grouped by damage state.

4.2 *Feature classification*

In the last step, the top 10 features selected in the previous step are used as input to the classification algorithm. CFNN is trained on 80% of the dataset and tested on the remaining 20% of the data. In addition, 2 hidden layers, each with 10 neurons, are considered as inner layers of the network. The maximum epoch is set to 50, and Levenberg-Marquardt is chosen as the training function. The classification results are shown in Figure 7. The overall classification accuracy of the algorithm is 94% and the true positive rates (TPR) is above 92% in all classes. Furthermore, the false negative rates (FNR) in all classes are below 7.1% that shows reliability of the proposed framework. These results have been obtained by considering only 10 selected features and this indicates a 66% reduction in the dimension of the input data to the CFNN algorithm.

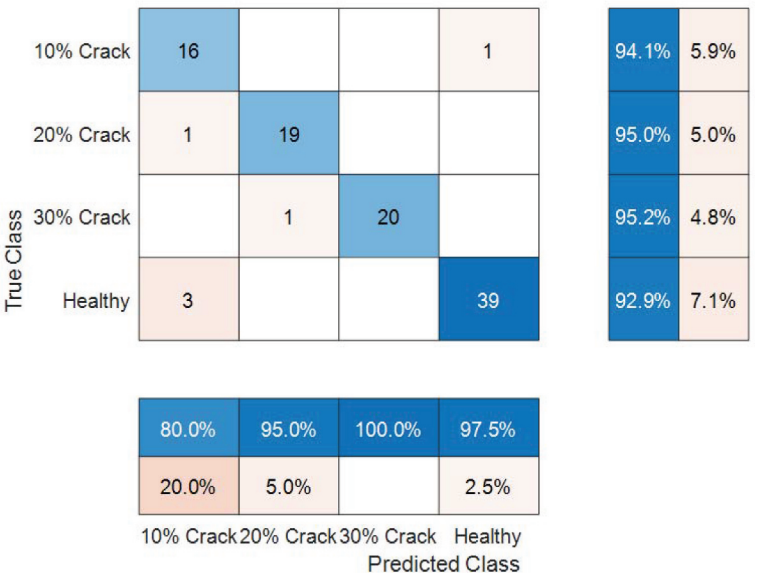

Figure 7. Confusion matrix for CFNN.

The performance progress of CFNN is displayed in Figure 8. This figure does not indicate any major problems with the training. The validation and test curves are very similar, and overfitting has not occurred.

According to the results shown, it can be concluded that the proposed data-driven framework has a high accuracy when detecting damage in a bridge using the responses collected by the moving vehicle. Drive-by monitoring scheme significantly reduces the number of sensors and the overall cost required for the SHM of bridges.

5 CONCLUSIONS

In this paper, a data-driven framework for structural health monitoring of bridges using drive-by monitoring was presented. After recording the acceleration response simulated from a numerical of vehicle-bridge interaction model using the sensors mounted on the moving vehicle, statistic indicators were extracted from the raw data and then sorted based on their ability to distinguish between different damage states.

The results showed that the sensor placed on the body of the vehicle has a clear sensitivity to bridge damage. In addition, by using a subset of features as input to the CFNN algorithm, 94% classification accuracy was achieved. Also, the PCC that was used as the feature selection method in this paper, has reduced the number of input data to the classification algorithm by 66%.

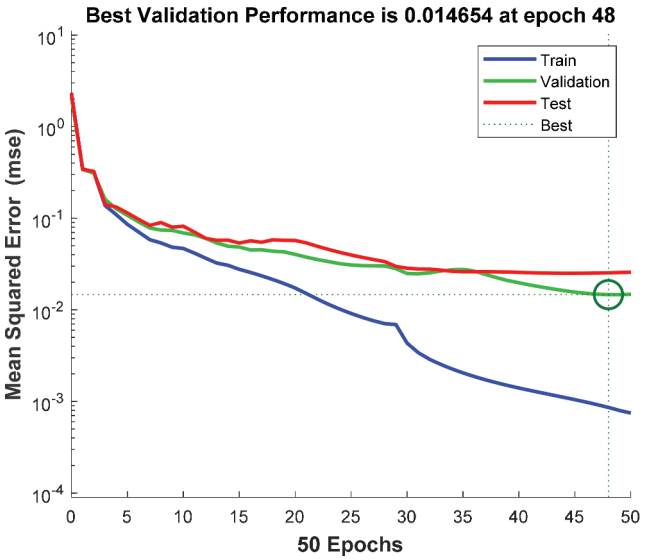

Figure 8. Performance progress for CFNN.

The results of the implementation of the proposed framework on the numerical model of a real concrete bridge indicate that the drive-by monitoring scheme can be implemented on real structures, although the effect of environmental variables on the accuracy of the algorithm should be investigated.

Crowd-sensing drive-by monitoring for bridge frequency identification

Yifu Lan, Zhenkun Li & Weiwei Lin
Aalto University, Espoo, Finland

ABSTRACT: The drive-by inspection methods have garnered significant attention in recent years, owing to their advantages in mobility, cost-effectiveness, and efficiency. However, in practical applications, even simple extraction of bridge frequencies from an ordinary/commercial vehicle proves to be challenging; components associated with road roughness and vehicle dynamics typically dominate the vehicle vibration response. Current research typically attempts to alleviate these influences by minimizing variability (e.g., driving in the same lane, using the same speed, etc.), and by employing custom vehicles, though such practices are often difficult to implement. Recent advancements have pivoted towards "crowd-sensing" or "fleet monitoring" approaches, which undoubtedly introduce greater variability, thus potentially making the aforementioned strategies less preferable. In light of this, this paper presents a novel coherence-based approach applied to crowd-sensing drive-by monitoring systems which leverage data from multiple vehicles. The fundamental idea is to identify bridge frequencies as common vibrational components across a variety of vehicles driving over it. It encourages the introduction of variability in drive-by measurements to filter bridge frequencies. The proposed method is explored through numerical experiments, incorporating Monte Carlo methods. The results highlight the method's efficacy in eliminating the influences of road roughness, environmental noise, and vehicle parameter variations, with accurate identification of bridge frequencies. From the perspective of the method, this paper also illustrates the advantages of crowd-sensing drive-by monitoring and its practical feasibility in engineering problems.

1 INSTRUCTION

Bridge frequency plays a vital role in understanding essential characteristics of bridges (Nagayama et al. 2017). However, traditional methods of frequency measurement, which typically involve installing sensors directly on bridges, are fraught with challenges. These include substantial labor costs, risks related to onsite work, disruptions to traffic flow, and the expenses associated with sensor upkeep (Abdulkarem et al. 2020). An alternative is the drive-by method, which has seen a surge in interest and research activity recently. This technique utilizes vehicles as moving sensors, gathering dynamic data of bridges through the vehicle-bridge interaction (VBI) (Yang et al. 2004). It necessitates minimal equipment on the vehicle, presenting an effective and cost-efficient means of obtaining critical information about bridges (Lan et al. 2023, 2024).

However, in practice, even the seemingly simple task of extracting bridge frequencies can be quite challenging. Current research on drive-by monitoring mostly focuses on developing and validating methodologies in numerical studies, controlled laboratory environments, and small-scale structures using specialized vehicles (Malekjafarian et al. 2022). Drive-by measurements using ordinary/commercial vehicles on normal bridge structures are prone to large uncertainties (Nagayama et al. 2017). The amplitude of spectral peaks related to bridge frequencies may be low, and interference signals caused by road roughness components or

DOI: 10.1201/9781003483755-197

vehicle dynamics could mask the signals of interest. Non-bridge frequency peaks often combine with weak bridge frequency peaks (or are entirely absent), leading to misleading frequency identification (Lan et al. 2022). Therefore, discerning bridge information from the complex and variable signal components in vehicle responses is a key issue.

In light of this, considerable research has been conducted to eliminate the vibration components of the interference and extract the bridge frequency from the vehicle response. For instance, Yang et al. (2021) proposed to utilize the contact point (CP) response between the bridge and the vehicle to measure the bridge frequency; it was found to be independent of the vehicle frequency. This approach then removes the influence of surface irregularities by deducting the CP responses from two adjacent axles or trailers, allowing the bridge frequency to be deduced from the residual response. Nevertheless, practical implementation of such techniques often requires axles or trailers to follow identical trajectories and may necessitate the use of specialized vehicles or additional equipment like shakers (Yang et al. 2020, 2021, 2022). Unfortunately, these are not always available, and integrating such methods into commercial vehicles for daily monitoring proves even more challenging.

On the other hand, recent advancements have pivoted towards "crowd-sensing" or "fleet monitoring" approaches. Such methods can significantly reduce maintenance costs, as they do not require special arrangements for monitoring, including the custom vehicles (Mei & Gül 2019). Vibrational data of bridges can be automatically collected as vehicles pass over them, enabling the regular monitoring of numerous bridges within a region. Furthermore, due to its crowdsourcing nature, this technique offers robustness against operational effects and human errors. However, the crowd-sensing measurements will inevitably introduce greater variability (Mei et al. 2019; Mei & Gül 2019), potentially making the above strategies less desirable. There is a need to propose algorithms for crowd-sensing drive-by monitoring.

One idea is the application of cross-spectral estimation. Nagayama et al. (2017) utilized cross-spectral density function estimation techniques to extract bridge frequencies as common vibrational components in the responses of two ordinary vehicles. The effectiveness of this method was validated through field tests. Lan et al. (2023) obtained bridge frequencies as common signals among different sensors mounted on a truck model through laboratory experiments. In the cross-spectra obtained using these methods, peaks unrelated to the bridge frequencies were weakened. However, their performance is influenced by factors such as speed, road roughness, and vehicle weight; they are not always successful. In this regard, Lan et al. (2023) proposed a Coherence-PPI (Prominent Peak Identification) algorithm, a method that uses a Bayesian framework to further filter bridge-related peaks from a large number of coherences, allowing the identification of bridge frequencies under uncertainties such as road roughness. They verified the method by using multiple drive-by measurements of a city bus. The algorithm results demonstrate that more diverse vehicle parameters and more passing measurements are beneficial for filtering bridge frequencies. This also inspires the application of the algorithm to multi-vehicle tasks (i.e., crowd-sensing drive-by monitoring).

This study introduces a crowd-sensing drive-by monitoring algorithm for extracting bridge frequencies based on coherence and a Bayesian framework, which is a modification of the previously proposed Coherence-PPI algorithm by the authors. The underlying idea is to identify bridge frequencies as common vibrational components among different vehicles. Instead of using multiple runs of a single vehicle as input in previous studies, it utilizes runs by different vehicles as input (crowd-sensing measurements). To validate the proposed algorithm, a numerical study was conducted. The crowd-sensing measurements were simulated using vehicles with random parameters, and the effectiveness and robustness of them under various conditions (e.g., road roughness and environmental noise) were investigated using methods that include the Monte Carlo approach.

2 ALGORITHM

This algorithm is a revision of the previously proposed Coherence-PPI algorithm by the authors (Lan et al. 2023), modified for crowd-sensing measurements. It comprises three parts, namely coherence computation, threshold determination, and selection of prominent peaks

(PPs) and frequency identification. It is worth noting that some contents of the algorithm are simplified here. For a detailed description, one can refer to the original text.

2.1 *Coherence computation*

This step presents the methodology used for calculating coherence in crowd-sensing measurements. Generally, there are four main contributors to vehicle vibration: bridge vibration, road roughness, vehicle dynamics, and environmental noise. In the frequency spectrum, the peaks that correspond to bridge vibrations often appear less distinct in comparison to others. Yet, to some extent, they are deemed to exhibit a commonality across different passages. Peaks related to road roughness and vehicle dynamics tended to vary with different trajectory, speed, etc. Environmental noise is random. The coherence between the two signals is mathematically expressed as (Bendat & Piersol 2011):

$$C_{xy}(f) = \frac{\left|G_{xy}(f)\right|^2}{G_{xx}(f)G_{yy}(f)} \tag{1}$$

where $G_{xy}(f)$ is the cross-spectral density of signals x and y, $G_{xx}(f)$ is the power spectral density of signal x, and $G_{yy}(f)$ is the power spectral density of signal y.

For multi-vehicle passages on the same bridge, coherences are calculated for every possible pairing of them (see Figure 1). If there are n vehicle passages, then the total number of coherences is $N = C_n^2 = \frac{n(n-1)}{2}$. The coherence for any two runs, denoted as $\{X_i\}$, is computed using Equation 1. In this context, $\{X_i\}$ is a vector, and $[X]$ is a matrix consisting of N coherence vectors. It should be noted that due to varying speeds of different vehicles, their time-domain lengths differ. Thus, it is necessary to ensure that the input signals for algorithm are of equal length. In this regard, a 3-second time segment is selected from each signal to ensure they have equal frequency domain resolution.

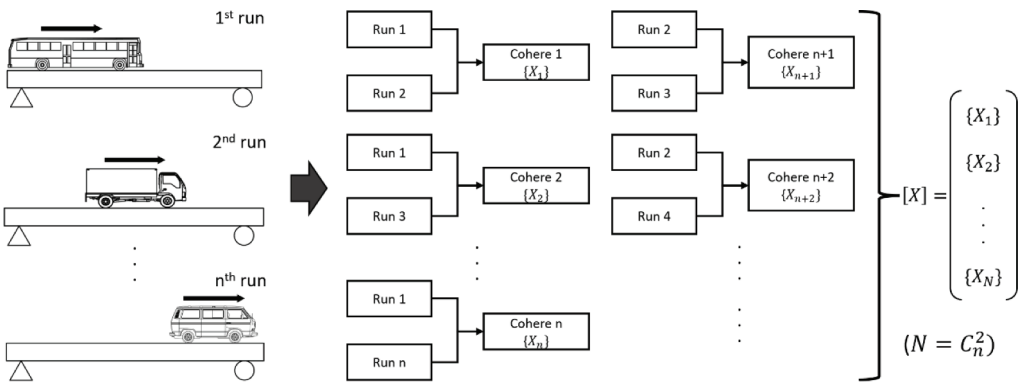

Figure 1. Coherence computation process.

2.2 *Threshold determination*

This step aims to determine the threshold that maximizes the occurrence of bridge-related frequencies. The Bayesian theorem (Bernardo & Smith 2009) provides a mathematical framework. Event B is defined as the attainment of the target frequency, and event H represents the occurrence when the coherence value is greater than or equal to a certain value (i.e., the threshold). The likelihood $P(H \mid B)$ signifies the probability that, when the target frequency is known, its corresponding coherence value is greater than the threshold. The prior $P(B)$ is the probability of attaining the target frequency in the absence of a threshold, whereas the evidence $P(H)$, is the probability that the coherence value is greater than the threshold. The

posterior $P(B \mid H)$, that is, the probability that the target frequency can be obtained when the threshold is given, can be calculated as:

$$P(B|H) = \frac{P(H|B) \cdot P(B)}{P(H)} \tag{2}$$

Building on earlier studies (Nagayama et al. 2017; Lan et al. 2023a, 2023b), bridge-related peaks are more likely to correspond to high percentile coherence values; that is, given the bridge frequency θ, it is more likely to correspond to a high percentile of coherence value t_0:

$$P[H(t_0)|B_\theta] > E(P) \tag{3}$$

The distribution of all coherence values may approximate a normal distribution. Considering that $P(B)$ is a constant, it suggests that choosing a larger threshold value for coherence is reasonable (Lan et al. 2023).

According to the 3-sigma rule in statistics, in a normal distribution, approximately 68% of observations fall within one standard deviation of the mean ($\tau = 0.84$), 95% within two standard deviations ($\tau = 0.975$), and 99.7% within three standard deviations ($\tau = 0.9985$). In this study, a threshold of $\tau = 0.84$ can be chosen.

2.3 *Selection of PPs and frequency identification*

This step counts the probability of each frequency interval above the threshold. The frequency range from 0 to 50Hz is divided into 100 intervals (θ_1,θ_2...,θ_{100}), with each representing a 0.5Hz interval. The interval, θ, containing the bridge frequency will exhibit the maximum probability value. During the procedure, the peaks in coherence that exceed the threshold, denoted as P_i, along with their corresponding frequencies F_i, are recorded. They are used to form a new matrix, [P], which can be thought of as a prominent peak matrix:

$$\begin{bmatrix} P_1 P_2 \dots P_n \\ F_1\ F_2 \dots F_n \end{bmatrix} = [P] \tag{4}$$

Then, the occurrence of these prominent peaks (PP) within each frequency interval is counted. The interval of the maximum occurrences is indicative of the bridge's fundamental frequency.

3 VBI MODEL

To validate the algorithm and to study the impact of various factors, a numerical study will be conducted. The following presents the construction of the VBI model used for the simulations in this work. A 2-DOF quarter-car model is utilized to simulate the rear axle system of a vehicle, and at the same time, an Euler-Bernoulli beam model is used to represent the simply supported bridge, as shown in Figure 2. This simplification aligns with that used in the study by Liu et al. (2023), who demonstrated that overlooking the impact of front suspension vibrations on the rear axle system is akin to introducing a certain level of noise into the results, which they deemed acceptable. This study adopts an unusually high noise level (10%), contrasting with previous studies that often considered 5% as a high noise level (Li et al. 2023). The adoption of the 2-DOF quarter-car model offers a compromise between model complexity and computational efficiency. This is particularly beneficial for implementing computationally intensive methods such as Monte Carlo simulations. For the bridge, each node in this finite element (FE) beam model is characterized by 2 DOFs: vertical translation and rotation. The beam model comprises n elements and $n + 1$ nodes, resulting in a total of $2n$ DOFs, not including the vertical constraints at the ends of the bridge. The bridge has a total length of L, and it features uniform flexural rigidity, denoted as EI, and a consistent mass per unit length, represented by m. Additionally, the damping characteristics of the bridge are approximated using mass-stiffness proportional Rayleigh damping.

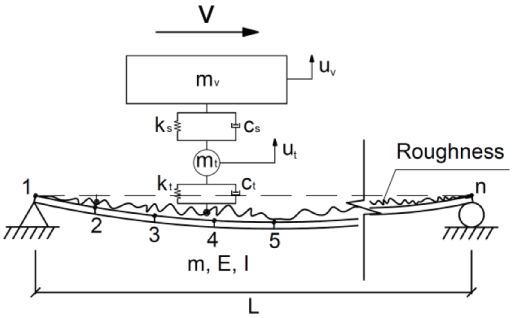

Figure 2. VBI model.

The fundamental equations governing the VBI system are as follows:

$$[M_v]\{\ddot{y}_v\} + [C_v]\{\dot{y}_v\} + [K_v]\{y_v\} = \{F_{cv}\} \tag{5}$$

$$[M_b]\{\ddot{y}_b\} + [C_b]\{\dot{y}_b\} + [K_b]\{y_b\} = \{F_{cb}\} \tag{6}$$

For the vehicle, $[M_v]$, $[C_v]$, and $[K_v]$ signify the vehicle's mass, damping, and stiffness matrices, respectively, and $\{y_v\}$ is the displacement vector. The time-varying interaction force on the vehicle is $\{F_{cv}\}$. For the bridge, $[M_b]$, $[C_b]$, and $[K_b]$ denote the bridge's mass, damping, and stiffness matrices, respectively, and $\{y_b\}$ is the bridge's nodal displacement vector. The force acting on the bridge is represented by $\{F_{cb}\}$.

The subsystem matrices and response vector for the vehicle model are as follows, where the body and axle masses are denoted by m_v and m_t, the suspension and tire damping by c_s and c_t, and the suspension and tire stiffness by k_s and k_t, respectively. The vertical displacements of the vehicle body and axle are denoted u_v and u_t, respectively.

$$[M_v] = \begin{bmatrix} m_v & \\ & m_t \end{bmatrix} \tag{7}$$

$$[C_v] = \begin{bmatrix} c_s & -c_s \\ -c_s & c_s + c_t \end{bmatrix} \tag{8}$$

$$[K_v] = \begin{bmatrix} k_s & -k_s \\ -k_s & k_s + k_t \end{bmatrix} \tag{9}$$

$$\{y_v\} = \begin{bmatrix} u_v & u_t \end{bmatrix}^T \tag{10}$$

The Newmark-Beta method is used to obtain the dynamic responses of the vehicle through the VBI process. The parameters β and γ of the Newmark-Beta method are selected as 0.25 and 0.5, respectively.

In this study, road roughness is simulated according to ISO 8608 (Múčka 2018), using a Power Spectral Density (PSD) function that characterizes roughness for different classes. Five roughness classes are defined, with coefficients: Class A ($0 - 2^5$), B ($2^5 - 2^7$), C ($2^7 - 2^9$), D ($2^9 - 2^{11}$), and E ($2^{11} - 2^{13}$) in units of $10^{-6}m^3$. A standard zero-mean real-valued stationary Gaussian process simulates the surface roughness profile, summing harmonic waves with specific spatial frequencies and random phase angles to construct the profile.

This noise is introduced into the signal using the formula given in Equation 11 (Xu et al. 2022). In this equation, $\ddot{u}_p$ represents the acceleration data of the vehicle that has been polluted. The term E_p denotes the level of environmental noise, N_s is a variable following the standard normal distribution, and $\sigma_{\ddot{u}_v}$is the standard deviation of the vehicle's acceleration response, denoted by $\ddot{u}_v$. In this study, noise is set to be 10%.

$$\ddot{u}_p = \ddot{u}_v + E_p N_s \sigma_{\ddot{u}_v} \tag{11}$$

4 NUMERICAL STUDY

4.1 *Simulations and algorithm results*

In this section, the simulation of crowd-sensing measurements over a bridge will be demonstrated using vehicles with random parameters. The bridge parameters are: m = 2000 kg/m, $EI = 6.06 \times 10^{1\circ}$ N·m^2, L = 45 m. The random parameters will be selected within a normal distribution based on the rear axle parameters of a bus. For example, the parameters of a bus can be: $m_v = 1.0 \times 10^4$ kg, $m_t = 1.0 \times 10^3$ kg, $c_s = 1.0 \times 10^4$ N·s/m, $c_t = 0$, $k_s = 4.0 \times 10^5$ N/m, $k_t = 3.5 \times 10^6$ N/m, and v = 7.5 m/s. The randomly generated vehicle parameters for the $i-th$ passage can be represented as follows:

$$Para_i^* = normrnd(Para, \sigma) \tag{12}$$

where *normrnd* is the normal distribution function, *Para* denotes the baseline bus parameters, which is the above-mentioned m_v, c_s, etc., and σ is the standard deviation of the normal distribution. In this study, it is taken as one-quarter of the original parameter (i.e., *Para*/4).

Under Grade "E" road conditions (poorest), it is evident from the responses obtained using vehicles with baseline parameters (see Figure 3a) that, although some peaks in the spectrum appear to be related to the bridge frequency, it is challenging to determine the bridge frequency. By contrast, in the algorithm results obtained from 100 random vehicle measurements (see Figure 3b), the bridge frequency can be clearly identified as the most prominent peak even under the poorest road roughness. Measurements obtained from multiple vehicles can filter the bridge-related components in the signal, because the distinct characteristics of each vehicle infuse variability into the non-bridge components of the signals. This proves the effectiveness of the proposed algorithm. It is noteworthy that this work only considered the scenario of a single vehicle on the bridge at a time. The case of multiple vehicles simultaneously on the bridge merits further exploration in future research.

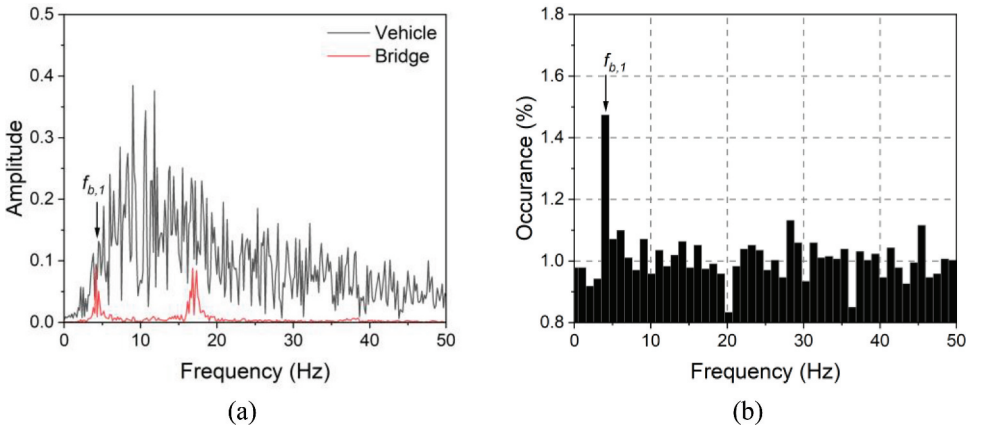

Figure 3. Frequency identification results: (a) frequency spectrum; (b) algorithm output.

4.2 *Effect of vehicle runs and Monte Carlo simulations*

This study also explored the effect of the number of vehicle passages on the results. Under the same conditions and using random functions as above, the algorithm results for different vehicle passages are illustrated in Figure 4. When results are obtained from a smaller number of vehicle passes, the peaks associated with the bridge frequency may not be well identified. Therefore, an adequate number of runs should be ensured to achieve statistical significance in the results; in this study, 50 passages were found to be sufficient.

This section also employs Monte Carlo simulations to validate the robustness of the proposed algorithm. The fundamental concept of Monte Carlo simulations is to utilize randomness to solve problems that could, in principle, be deterministic (Z.Mooney 1997). Utilizing

VBI simulations, random samples are produced, where each set of 50 samples (equating to 50 vehicle passages) is used as a single algorithm input, denoted as $[X]q$ (q=1, 2, 3…), with the corresponding output being $P_q(B_\theta \mid H_\tau)$. When the algorithm is run 2000 times for each road roughness, the Monte Carlo result for that roughness level should be $\frac{1}{2000}\sum_{q=1}^{2000} P_q(B_\theta \mid H_\tau)$. From Figure 5, it is evident that the algorithm performs effectively and similarly across various road roughness. This demonstrates the robustness of the proposed algorithm and its insensitivity to road surface conditions, which is considered one of the most critical factors affecting drive-by methods.

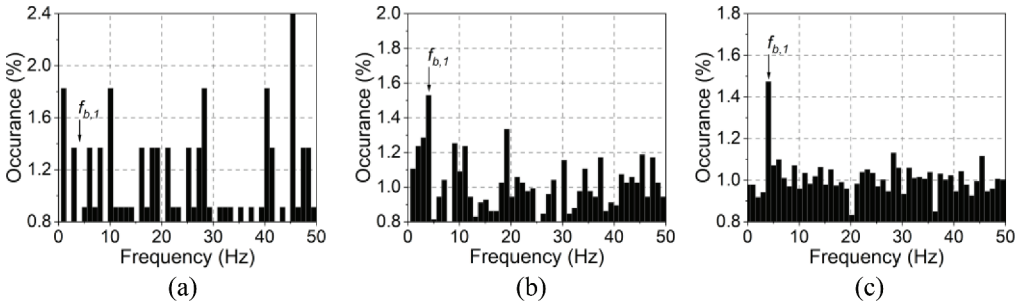

Figure 4. Algorithm outputs for different vehicle runs: (a) runs = 10; (b) runs = 50; (c) runs = 100.

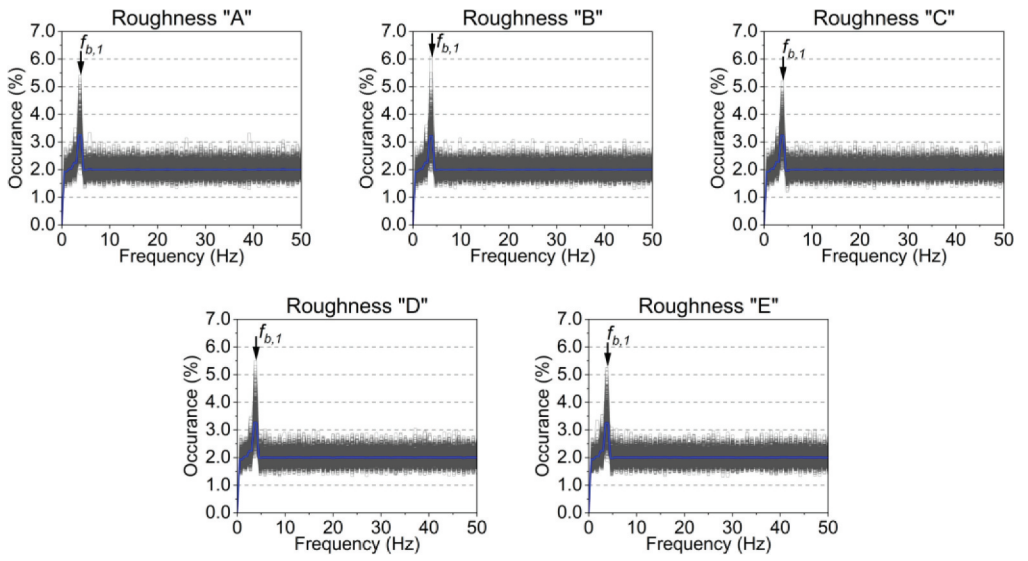

Figure 5. Monte Carlo results.

5 CONCLUSION

This study presents a crowd-sensing drive-by monitoring algorithm for extracting bridge frequencies. It is a modification of the Coherence-PPI algorithm previously proposed by the authors, adapted for multi-vehicle measurements. To validate the proposed algorithm, a numerical study was conducted, where the crowd-sensing measurements were simulated using vehicles with random parameters. According to numerical studies, several conclusions can be drawn:

(1) Under the influence of road roughness and environmental noise, the algorithm based on crowd-sensing measurements successfully identifies the bridge's fundamental frequency.

(2) The frequencies identified by the algorithm are statistical results, where numerous measurements enhance clarity and ensure reliability in frequency estimation.
(3) The robustness of this method has been examined using the Monte Carlo approach. The algorithm's outcomes are unaffected by the level of road roughness.

Despite the findings summarized above, field tests are required to assess the performance of this method in practice.

ABSTRACT: Bridge displacement provides valuable information for bridge health monitoring. However, direct displacement measurement techniques are always costly to apply to large numbers of short and medium span bridges. To overcome these difficulties, indirect displacement estimation approaches have been developed as an alternative. Such indirect approaches use bridge acceleration, which can reduce the cost and be more convenient. However, the direct double integration of bridge acceleration can lead to low-frequency drift in the estimated bridge displacement caused by the unknown initial condition and measurement noise. This study focuses on the bridge displacement induced by the vehicle load in a simple vehicle-bridge interaction (VBI) system. The bridge displacement, which has been shown to have a non-zero mean and is mainly contributed by the low-frequency bridge vibration, is estimated using the bridge acceleration combined with the bridge mode shape. Tikhonov regularization is used to suppress the negative influence of the measurement noise. The proposed method is validated by a laboratory experiment.

1 INTRODUCTION

The health monitoring of common short- and medium-span bridges is a critical issue in civil engineering (Sofi et al. 2022). As reported by the American Society of Civil Engineers (ASCE) infrastructure maps in 2021 (ASCE 2021), more than 46,000 bridges in the United States are considered structurally deficient. In China, more than 1 million bridges will have been built by 2023 (China Govern Report, 2022), and a large number of them have been in service for more than 50 years with rapidly increasing traffic. Excessive deterioration of these bridges would cause potential risks to the normal operation of transportation systems (Milillo et al. 2019). Therefore, it is necessary to obtain monitoring data to reduce these risks.

Among various types of monitoring indicators, bridge displacement under vehicle load is an important indicator for bridge weight-in-motion (WIM) (Kim et al. 2022) and damage detection (Ge et al. 2023). To measure bridge displacement, scholars have proposed many methods, which can be generally classified into two categories: direct and indirect. The direct method directly measures bridge displacement using advanced instruments such as the linear variable differential transformer (LVDT) (Peddle et al. 2011), the laser Doppler vibrometer (LDV) (Garg et al. 2019), and the millimeter wave radar (Michel et al. 2021). While these instruments can provide an accurate measurement, they are always expensive. For example, a set of industrial millimeter wave radars can cost more than $0.2 million. Considering the large number of short and medium span bridges, the expected cost is unacceptable (Li et al. 2023).

DOI: 10.1201/9781003483755-198

In contrast to direct measurement, indirect measurement can be more economical, where the bridge displacement is estimated indirectly from the monitoring data of common monitoring sensors. A common method is to use an accelerometer (Gindy et al. 2007). The time history of the bridge displacement can be obtained by double integrations of the acceleration. However, in real engineering, the measured bridge acceleration signal contains unknown environmental and measurement noise (Gindy et al. 2008; Nagayama & Zhang 2017). In addition, the initial state of the bridge is also unknown. Therefore, the direct double integration would produce an unrealistic drifting displacement.

To solve this problem, an optional method is proposed by Park et al. (Park et al. 2005) to estimate the high-frequency displacement using the bridge acceleration processed by the Tikhonov regularization (Golub et al. 1999). Essentially, this study assumes that the high-frequency displacement should be a stationary zero-mean time series signal. The zero mean was then set as the regularization element to remove the potential interference from noise. In addition, the zero-mean assumption can solve the unknown initial condition problem through the regularization process. However, for medium and short span bridges, the vehicle load-induced bridge displacement is mainly contributed by low frequency rather than high-frequency displacement. As Biggs verified in (Biggs, 1964), for a simple vehicle-bridge interaction (VBI) system (Kim et al. 2005), the low-frequency displacement of an observation point on the bridge approximates the corresponding static deflection curve under the moving vehicle gravity (Frýba 2013) and is non-zero mean.

To estimate the non-zero low-frequency bridge displacement, Shin et al (Shin et al. 2012) used the measured strain and theoretical mode shapes. Park combined the methods proposed in (Park et al. 2005) and (Shin et al. 2012) and proposed a new regularization element (Park et al. 2013) as a data fusion method. This regularization item is a non-zero mean and is essentially the sum of the displacements that are estimated from the mode shapes. Similar to the method proposed in (Park et al. 2005), the new regularization element provides a baseline of the target displacement and helps to remove the negative influence of measurement noise.

A shortcoming of the method proposed in (Park et al. 2013) is that the vertical distance between the observation point and the neutral axis in the cross-section, as a key parameter, is unknown. Considering that in actual engineering, the cross-section is not homogeneous, the distance is difficult to estimate.

In this study, a new method was proposed to estimate the low-frequency bridge displacement from the noisy low-frequency bridge acceleration in VBI systems. In this study, we theoretically analyzed the characteristics of low-frequency and high-frequency bridge acceleration in a VBI system. Then, based on these characteristics, the Tikhonov regularization method in (Park et al. 2013) was modified to estimate the bridge displacement from low-frequency acceleration. Instead of strain gauges, accelerometers were used to obtain the mode shapes of a target bridge and to build the regularization item. Moreover, instead of measuring the distance between the observation point and the neutral axis, the new method switches to measuring the vehicle speed, which can be obtained cheaply and easily with a common radar. Then the low-frequency bridge displacement is estimated. The proposed method was validated through a laboratory experiment. Compared with the methods in the above research, the new method inherits the advantage of indirect measurement methods and solves the difficulties in application.

In Sec. 2, characteristics of the bridge dynamics in the VBI system were illustrated. The algorithm of the Tikhonov Regularization was also introduced. In Sec. 3, the proposed method was validated with laboratory experiments.

2 METHODOLOGY

2.1 *Dynamics of a simple VBI system*

A typical VBI system consists of a moving vehicle, a bridge, and the interaction between the tire and the surface of the bridge. The dynamic equations of a simple VBI system with

a single-degree-of-freedom sprung mass and a simply supported beam are listed as follows. For the vehicle (Yang & Lin 2005),

$$m_v\ddot{u}_v(t) + k_v[u_v(t) - u_w(t)] = 0 \tag{1}$$

where, $u_v(t)$ and $\ddot{u}_v(t)$ are vertical displacement and the acceleration of the vehicle. $u_w(t)$ is the vertical displacement of the contact point. The model does not include road roughness, considering its limited influence on bridge dynamics (Chang et al. 2010).

For the bridge,

$$\bar{m}\ddot{u}_b(x,t) + EIu_b''''(x,t) = \{k_v[u_v(t) - u_w(t)] - m_v g\}\delta(x - vt) \tag{2}$$

where, $u_b(x, t)$ denotes the vertical displacement of the bridge at x at time point t. $\bar{m}$ is the unit mass, E is the elastic modulus, I is the moment of inertia. g is the acceleration of gravity, a prime denotes differentiation to coordinate x.

When the vehicle mass is much smaller than the bridge mass, Eq. (2) can be simplified as Eq. (3), in which the interaction force is simplified as a moving force.

$$\bar{m}\ddot{u}_b(x,t) + EIu_b''''(x,t) = -m_v g\delta(x - vt) \tag{3}$$

The solution to Eq. (3) is shown as Eq. (4. a),

$$u_b(x,t) = \sum n\frac{\Delta_{st,n}}{1 - S_n^2}\left\{sin\frac{n\pi x}{L}\left[sin\frac{n\pi vt}{L} - S_n sin\omega_{b,n}t\right]\right\} \tag{4.a}$$

where S_n denotes the non-dimensional speed parameter, and $\omega_{b,n}$ is the bridge natural frequency, and can be formulated as follows.

$$\Delta_{st,n} = \frac{-2m_v gL^3}{n^4\pi^4 EI} \tag{4.b}$$

$$S_n = \frac{n\pi v}{L\omega_{b,n}} \tag{4.c}$$

$$\omega_{b,n} = \frac{n^2\pi^2}{L^2}\sqrt{\frac{EI}{\bar{m}}} \tag{4.d}$$

The bridge displacement $u_b(x, t)$ in Eq. (4.a) can be divided into $u_{b,N}(x, t)$ (shown as Eq. 5 (a)) and $u_{b,D}(x, t)$ (shown as Eq. 5(b)).

$$u_{b,N}(x,t) = \sum n\frac{\Delta_{st,n}}{1 - S_n^2} sin\frac{n\pi x}{L}\left(-S_n sin\omega_{b,n}t\right) \tag{5.a}$$

$$u_{b,D}(x,t) = \sum n\frac{\Delta_{st,n}}{1 - S_n^2} sin\frac{n\pi x}{L} sin\frac{n\pi vt}{L} \tag{5.b}$$

$u_{b,N}(x, t)$ is a summation of multiple sinusoid waves whose frequencies are the bridge natural frequency $\omega_{b,n}$. Similarly, $u_{b,D}(x, t)$ consists of multiple sinusoid waves whose frequencies are the driving-force frequencies $\omega_n = \frac{n\pi v}{L}$.

This study focuses on the $u_{b,D}(x, t)$. As Paultre et al. presented in (Paultre et al. 1992), for the general cases of highway system, the ratio between ω_1 and $\omega_{b,1}$ is always smaller than 0.15. Therefore, ω_n is always much smaller than $\omega_{b,n}$. Then, the $u_{b,N}(x, t)$ is defined as the high-frequency part and the $u_{b,D}(x, t)$ is defined as the low-frequency part. Yang and Lin illustrated in

(Yang & Lin 2005) that the contribution of the low-frequency displacement $u_{b,D}(x, t)$ to the whole displacement $u_b(x, t)$ is much higher than the contribution of the high-frequency components $u_{b,N}(x, t)$.

2.2 *Application of Tikhonov regularization in displacement estimation*

To estimate high-frequency vibration of the bridge, Park et al (Park et al. 2005) used the Tikhonov regularization method. Bridge displacement is estimated from measured bridge acceleration following Eq. (6):

$$\min_u \prod = \frac{1}{2}\left\| L_a\left(L_c u - (\Delta t)^2 \bar{a}\right)\right\|_2^2 + \frac{\lambda^2}{2}\|u\|_2^2 \tag{6}$$

where L_a is a diagonal weighting matrix with all diagonal entries of 1 except the first and last entries, which are equal to $\frac{1}{\sqrt{2}}$. L_c is the second-order differential operator matrix of the discretized trapezoidal rule. u here denotes the high-frequency bridge displacement $u_{b,N}(x, t)$. Δt is the sampling time interval. $\bar{a}$ is the vector of the measured bridge acceleration at x.

However, for the low-frequency displacement $u_{b,D}(x, t)$, the first driving-force component contributes the most (He et al. 2017). Unlike the high-frequency vibration, as derived from Eq. (5. b), $u_{b,D,1}(x, t)$ is a half-period sinusoid curve which has a non-zero mean. Therefore, Park et al (Park et al. 2013) modified Eq. (6) as

$$\min_u \prod = \frac{1}{2}||L_a(L_c u_i - (\Delta t)^2 \bar{a}_i||_2^2 + \frac{\lambda^2}{2}||u_i - D_i\{\bar{\varepsilon}\}||_2^2 \tag{7}$$

where u_i is the displacement vector at the i-th measuring point on the bridge, $\bar{a}_i$ is the bridge acceleration, D_i is the transfer matrix from multiple strain vectors to the u_i. $\{\bar{\varepsilon}\}$ is the strain responses at all of the measuring points. $D_i\{\bar{\varepsilon}\}$ denotes the estimated displacement from measured strain which is non-zero-mean vector.

2.3 *Low-frequency displacement estimation from low-frequency acceleration*

To make an estimation of the non-zero mean low-frequency bridge displacement, bridge low-frequency acceleration was utilized. It can be inferred from Eq. (5. b) that,

$$\{\bar{a}_{low}\} = -\frac{\pi^2 v^2}{L^2}\begin{bmatrix} sin\frac{\pi x_1}{L} & \cdots & n^2 sin\frac{n\pi x_1}{L} \\ \vdots & \ddots & \vdots \\ sin\frac{\pi x_r}{L} & \cdots & n^2 sin\frac{n\pi x_r}{L} \end{bmatrix}\begin{Bmatrix} \frac{\Delta_{st,1}}{1-S_1^2} sin\frac{\pi v t}{L} \\ \vdots \\ \frac{\Delta_{st,n}}{1-S_n^2} sin\frac{n\pi v t}{L} \end{Bmatrix} \tag{8}$$

and

$$\{u_{b,D}(t)\} = \begin{bmatrix} sin\frac{\pi x_1}{L} & \cdots & sin\frac{n\pi x_1}{L} \\ \vdots & \ddots & \vdots \\ sin\frac{\pi x_r}{L} & \cdots & sin\frac{n\pi x_r}{L} \end{bmatrix}\begin{Bmatrix} \frac{\Delta_{st,1}}{1-S_1^2} sin\frac{\pi v t}{L} \\ \vdots \\ \frac{\Delta_{st,m}}{1-S_m^2} sin\frac{m\pi v t}{L} \end{Bmatrix} \tag{9}$$

Therefore, by assuming that,

$$\{u_{b,D}(t)\} = T\{\bar{a}_{low}\} \tag{10}$$

Where T is the transfer matrix from multiple acceleration vectors to the u_i. Substituting Eq. (8) and (9) into Eq. (10), one can obtain that

$$T = -\frac{L^2}{\pi^2 v^2}\begin{bmatrix} sin\frac{\pi x_1}{L} & \cdots & sin\frac{n\pi x_1}{L} \\ \vdots & \ddots & \vdots \\ sin\frac{\pi x_r}{L} & \cdots & sin\frac{n\pi x_r}{L} \end{bmatrix}\begin{bmatrix} sin\frac{\pi x_1}{L} & \cdots & n^2 sin\frac{n\pi x_1}{L} \\ \vdots & \ddots & \vdots \\ sin\frac{\pi x_r}{L} & \cdots & n^2 sin\frac{n\pi x_r}{L} \end{bmatrix}^{+} \tag{11}$$

where + denotes the transfer of a generalized inverse matrix. The new objective optimization function is proposed as Eq. (12).

$$\min_{u_{i,b-low-Fre}} \prod = \frac{1}{2}||L_a\left(L_c u_{i,b,D} - (\Delta t)^2 \bar{a}_{i-low}\right)||_2^2 + \frac{\lambda^2}{2}||u_{i,b,D} - T_i\{\bar{a}_{low}\}||_2^2 \tag{12}$$

where $\bar{a}_{i-low}$ is the low-frequency bridge acceleration at the i-th monitoring point, $\{\bar{a}_{low}\}$ is the acceleration vector of multiple monitoring points, T_i is the i-th row of the transformer matrix T. The solution of (12) is

$$u_{i,b,D} = \left({L_{ac}}^T L_{ac} + \lambda^2 I\right)^{-1}\left({L_{ac}}^T L_a \bar{a}_{i-low}(\Delta t)^2 + \lambda^2 T_i\{\bar{a}_{low}\}\right) \tag{13}$$

where

$$L_{ac} = L_a L_c \tag{14}$$

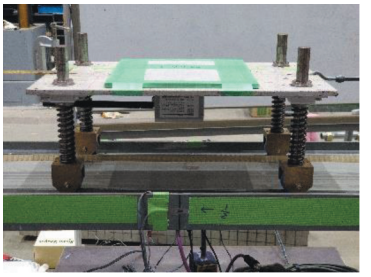
Instead of measuring the distance between the observation point and the central axis, the new regularization formulation measures the moving vehicle's speed, which is supposed can be easily obtained with an inexpensive speed radar. In addition, we assumed that vibration mode shapes in Eq. (8) can also be measured with the multiple accelerometers. In this study, we only consider the simple scenario of a single vehicle traveling on the bridge. More complex scenarios, such as multiple lanes with multiple vehicles, or the potential bending torsional coupling effect of some bridges, are not considered.

3 EXPERIMENT VALIDATION

The VBI system used for the experiment consists of three beams for the bridge and a vehicle model. These three beams are simply supported steel beams (Figure 1) with a constant H-section. The span length of the center beam is 5.4 m. The remaining two spans are designed as acceleration and deceleration spans to keep the vehicle moving at a constant speed on the center beam. Figure 2 shows the vehicle as a sprung mass system moving along a pair of tracks installed on the bridge. The track surface has a very good road roughness condition

Figure 1. Experimental beams.

(ISO 8608:2016). A servomotor and a fixed pulley were installed at each end of the bridge. To form a driving system, the motor was connected to the vehicle with a nylon cable. The sprung mass of the vehicle was 11.83 kg.



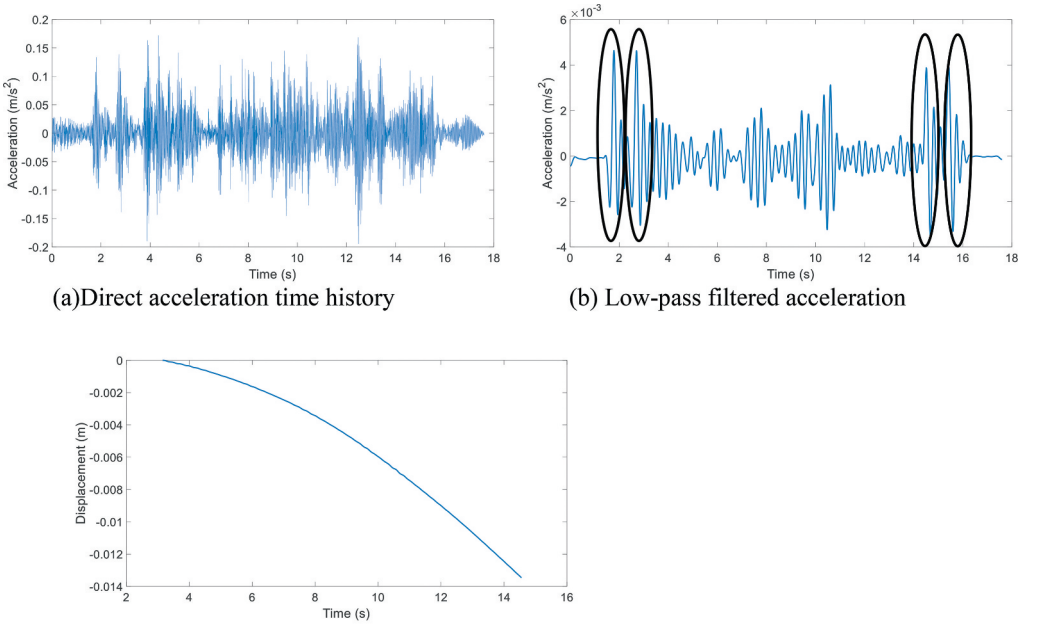


Figure 2. Moving vehicle model.

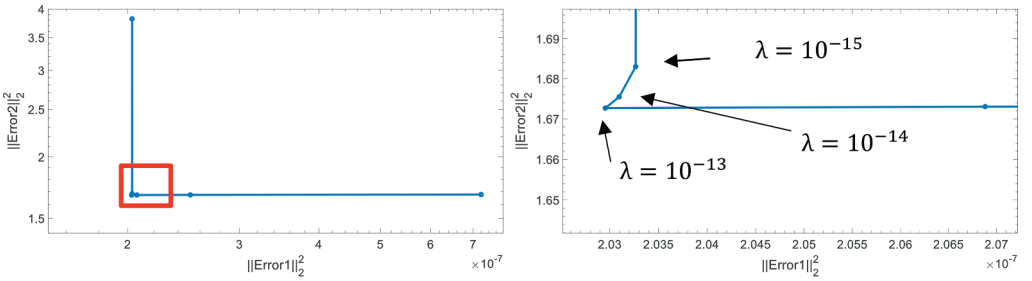
(a)Direct acceleration time history



(b) Low-pass filtered acceleration

(c) Displacement obtained from double integration of low-frequency acceleration.

Figure 3. Dynamic responses of the mid-span bridge with the speed of 0.43 m/s.

The proposed displacement estimation method was verified by an experiment with 0.43 m/s. The direct time histories of the mid-span bridge acceleration and the low-frequency acceleration (extract with a l-Hz low-pass filter) are shown in Figure 3 (a) and (b), respectively. In Figure 3 (b), four instants involving the entry and exit of the beam are marked. The vertical displacement of the mid-span, which is calculated through double integration of the direct beam acceleration, is shown in Figure 3(c). An apparent drift occurs for the obtained displacement.

Since the displacement corresponding to the second driving force mode is zero for the mid-span, and the amplitude of the third driving force mode is 1.2% of the amplitude of the first driving force mode according to Eq. (5. b), only the first driving force mode was included in the displacement estimation. Consequently, only the first bending mode was included in the construction of the relevant matrices from Eq. (8) to Eq (11).

(a) L-curve (b) Zoomed L-curve at the turning point

Figure 4. Determination of the λ with L-curve method. (The rectangle-marked L-curve is zoomed and illustrated in (b)).

The L-curve method is used to determine the value of λ. As shown in Figure 4 (a) and 4 (b), it is supposed that the most appropriate would lies within the range from 1×10^{-14} to 1×10^{-13}. Therefore, the ridge trace (Friendly 2013) figure is used. The minimum value of λ was set to 1×10^{-14} and linearly increased to 1×10^{-13} with the step of 1×10^{-14}. The directly estimated bridge displacement was shown in Figure 5. Then, the estimated displacements at 1, 2, … 10 seconds were selected as multiple targets. Figure 6 illustrates the change of these displacements with the ten values (from 1×10-14 to 1×10-13) of λ. It should be noted that the slope of these curves shows a notable change when λ is equal to 2×10^{-14}, which means that when λ is close to 2×10^{-14}, the estimated target tends to become stable. The final validation was done by comparing the detrend-ed (with MATLAB (Mathworks 2021)) estimated low-frequency displacement with the measured displacement. It can be seen that among all these λ values, the estimated displacement with 2×10^{-14} best matches the measured displacement (shown in

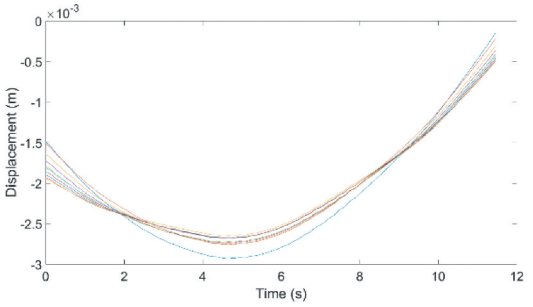


Figure 5. Directly estimated bridge displacement at mid-span for different λ ranges from 1×10^{-14} to from 1×10^{-13}. (Each curve denotes an estimated displacement corresponding to a λ.).

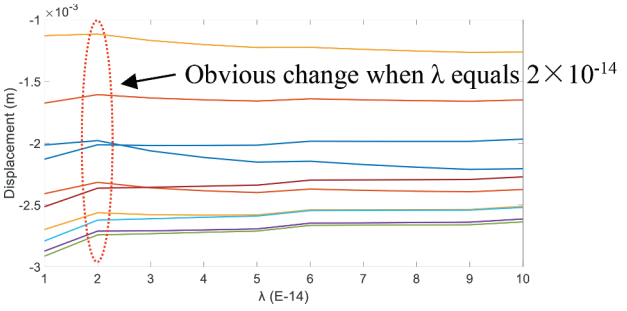

Figure 6. Ridge trace figure corresponding to different values of λ. (Each curve denotes an estimated displacement corresponding to a λ. It should be noted that all these displacement curve has an obvious change when λ equals 2×10^{-14}, marked with an ellipse).

Figure 7). Therefore, the proposed method has been validated for low-frequency bridge displacement estimation.

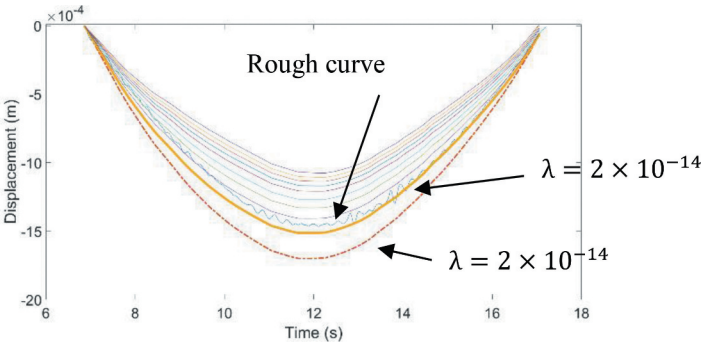

Figure 7. De-trend estimated bridge displacement at mid-span for different λ. (The dash-dot curve is corresponding to 1×10^{-14}, and the 2×10^{-14} curve has the largest width. The rough curve is the measured low-frequency displacement, and the first curve above the rough curve is corresponding to 3×10^{-14}).

4 CONCLUSIONS

This study proposed a novel method to estimate low-frequency bridge displacement from measured noisy low-frequency acceleration. In this study, the characteristics of low-frequency and high-frequency bridge vibrations in a simple VBI system were analyzed. Based on these characteristics, Tikhonov regularization was used to estimate the non-zero mean low-frequency bridge displacement under a moving vehicle. A laboratory experiments were then performed to validate the proposed method. The detailed conclusions are summarized as follows:

(1) The dynamic bridge responses in the simple VBI system consist of bridge frequency-related responses and driving force-related responses. The former is high frequency with zero mean displacement, and the latter is low frequency with non-zero mean displacement.

(2) The low-frequency bridge acceleration can be separated from the directly measured bridge acceleration with a low-pass filter. For the laboratory experiment, low-frequency bridge acceleration contains noise and it is hard to obtain the accurate displacement through double integrations.

(4) The key regularization parameter λ can be determined with the L-curve method, if necessary, combined with the ridge trace figure. The laboratory experiment results show good results for low-frequency bridge displacement estimation with the proposed method.

Compared with the direct methods in previous study, the proposed method inherits the low-cost advantage of the indirect method. Moreover, in comparison to the existing indirect method, this method uses the low-frequency acceleration, which not only streamlines the monitoring system, but also overcomes the difficulty of estimating the neutral axis distance. Therefore, this method is expected to be more applicable in actual engineering.

ABSTRACT: In the coming years, numerous bridges in Germany are reaching the end of their designed service life of over hundred years. However, due to diverse factors, it is crucial to extend their lifespan. Hence, a cost-effective and scalable solution is necessary to monitor and evaluate their condition. Drive-by Monitoring, which employs sensors on the passing vehicle to assess the bridge properties or condition, is one potential approach. Two extensive drive-by measurement campaigns have been carried out by the Institute of Structural Mechanics and Design (ISM+D), resulting in data for over 3000 kilometres of railway and numerous bridge crossings. The objective of this work is to construct and apply a framework for the automated analysis, management, and storage of this data. Attaining a high degree of automation for the application is crucial, which is why an application using various algorithms has been developed.

1 INTRODUCTION

DB InfraGO AG, a subsidiary of Deutsche Bahn AG (DB AG), operates over 25,000 bridges in Germany (Knapp 2019). With a service life of around 120 years, 40% of the railway bridges are over 80 years old (Knapp 2019, Geißler et al. 2019). This age structure shows that the structural condition of many railway bridges is affected by the challenges associated with the naturally ageing infrastructure. Combined with increasing traffic loads, additional challenges arise. Furthermore, bridges are neuralgic and important points for a robust and continuous transport of goods. Network-wide, continuous monitoring will therefore play an important role in the future to prioritise the renewal process.

Structural Health Monitoring generally addresses this issue. Due to the large number of bridges in combination with poor accessibility or required track closure permits and limited financial, human and time resources, the application of conventional methods, in particular direct monitoring where sensors are installed on the structure, is difficult (Geißler et al. 2019, Yang & Yang 2018). Alternative methods, such as indirect or drive-by monitoring, where sensors on the passing vehicle are used to monitor the bridges, can provide a solution (Malekjafarian et al. 2022). Drive-by Monitoring is a cost-effective and efficient method that can be scaled up across the network, especially if the equipped trains are used for regular services (Yang & Yang 2018, Malekjafarian et al. 2022). For example, DB AG already uses such an indirect system on 14,000 kilometres to monitor track geometry (Lorenzen et al. 2023).

However, the amount of data generated by network-wide continuous drive-by monitoring is enormous and needs to be managed and analysed. So, the main objective of this paper is to develop a tool that facilitates the management and analysis of drive-by monitoring data with a user-friendly graphical interface. Two drive-by measurement campaigns have been carried out by the authors. As a result, data are available for more than 3000 kilometres of railway and many bridge crossings. With the help of these two measurement campaigns a framework for the management and automatic analysis of this data is developed and implemented.

DOI: 10.1201/9781003483755-199

A high to complete degree of automation of the application is important. To be accessible from anywhere and with any device, a browser-based solution using a web framework is preferred. Python was chosen as the programming language as several data analyses are required.

As the data is generated by sensors installed on a train, location is a key element and therefore a map visualising the line travelled will be highly valuable. So, automatic mapping of the line on the railway network is required. The sensors record continuously, and their data is divided into predefined time intervals. New algorithms are needed to divide the data into specific data packages. In the scope of this work the focus lies on monitoring of railway bridges, so the data should be cut accordingly and assigned automatically to the bridge crossed. There are several possible solutions. If GPS is also recorded, it can be used to track the train on the railway network. Another possibility is to use the starting point of the measurement campaign, detect the first bridge crossing and then use the known network to assign the bridges. As described above, further bridge characteristics should be derived for (predictive) monitoring purposes.

The initiation for this work is design and development centred since a highly automated application is desired. To demonstrate the relevance of this topic, a motivation was provided in this Section 1. The next section outlines the available data, its structure and description. Section 3 then presents the concept of the proposed solution. With that in mind, the following section details the implications of the concept. This is followed by the evaluation and implementation of the concept, finishing with a conclusion and outlook in the last section.

2 DATA SETS

2.1 *Field measurements*

As reported by Rupp et al. (Rupp 2023), the ISM+D collected drive-by monitoring data as part of the ZEKISS research project (ZEKISS 2023), funded by the German Federal Ministry for Digital and Transport. The ISM+D, supported by German Federal Railways (DB), used the advanced TrainLab (aTL) to collect data while travelling on the German rail network.

The aTL is a laboratory train used by DB to test new technologies for the railway sector. Two trains have been deployed for this purpose. The technical basis for these trains is the ICE-TD, which was used for passenger transport until 2017. The trains consist of two middle and two end carriages and have a total length of 107 metres. The four carriages have conventional bogies, resulting in 16 axles and therefore 32 wheels (Advanced TrainLab 2023).

In the measurement campaign, a uniaxial acceleration sensor was mounted on each axle box using specially designed brackets (see Figure 2), giving a total of 32 sensors (Rupp 2023). Uniaxial piezoelectric accelerometers of the type PCB-(M)622B01 (manufactured by PCB Synotech GmbH, located in Hückelhoven, Germany) with a sensitivity of 100 mV/g (±5 %), a broadband resolution of 0.00005 g, a measuring range of ±50 g and a frequency range of 0.58 - 6,000 Hz (±5 %) were used. The sensor cables were installed under the car bodies and routed through specific doors via the windows to Quantum MX1601B amplifiers (manufactured by Hottinger Brüel & Kjaer GmbH, located in Darmstadt, Germany) (Rupp 2023). Figure 1 shows the placements of the sensors. The sensors were used to record the vertical accelerations of the wheelset. The sampling frequency was 5000 Hz. This high frequency was chosen to ensure one data point per centimetre as the train can travel at speeds of up to 200 km/h. The contact time between the train and the bridges is therefore extremely short (Rupp 2023).

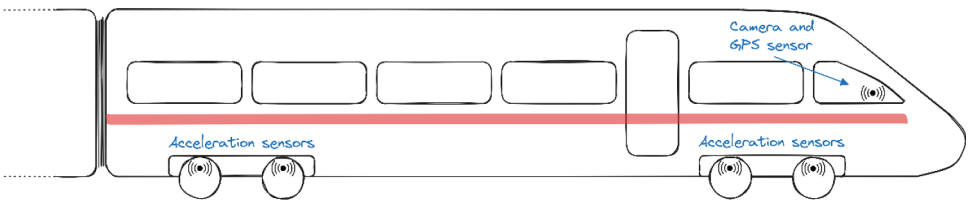

Figure 1. Sketch of the train with the locations of the sensors.

Additionally, two GPS sensors were installed to record the GPS position and speed of the train. The GPS antenna was also used to synchronise the train measurements with the monitoring system installed on the bridges. One sensor was placed in one of the middle carriages and the other in the front, as shown in Figure 1. The sampling frequency of the sensors was 1 Hz. The GPS signals allow the train to be located on the railway network. With the localisation of the train, the acceleration signals are also positioned, so that relevant bridge crossings can be assigned to specific measurement packages. In addition, a camera was placed in the driver's cab. The camera captured 30 frames per second enabling the recording of external influences as well. The camera was synchronised with the GPS sensors (Rupp 2023).

Figure 2. Acceleration sensor mounted on the axle box.

With the high sampling frequency of the acceleration sensors and other data collected such as GPS and images, a lot of data needs to be stored. The following section shows the structure of the drive-by monitoring data. The continuous measurement of the acceleration sensors is sliced into pre-defined data packages of 30 seconds with a file size of 120 megabytes. The measurement points MP1xx and MP2xx contain the acceleration signals from the axle boxes of both sides.

2.2 *Open data of Deutsche Bahn*

As stated in section 1, the objective is to facilitate and automate the management and analyses of collected drive-by monitoring data. A crucial aspect of this entails the mapping of the travelled line and the corresponding measurement data to the existing lines within the rail network, including any crossed bridges. For this task, the DB's accessible open data (Deutsche

Bahn 2023) of the rail network can be used. The data packages of interest are the coordinates of the different lines and bridges. The following two tables show the data description.

Table 1. Data description of the shapefile "lines" inside the data set "Geo-Line-Network".

Field	Description	Type	Format (example)
LINE_NO	Four-digit line number of DB	Number	2650
[. . .]	[. . .]	[. . .]	[. . .]
GEOMETRY	List of points of a polygon line consisting of longitude and latitude; WGS 84 (EPSG: 4326)	Number	9.383436, 54.743787

The data is stored in the shapefile format, which is widely used for vector-based geodata due to its simplicity. To extract the coordinates, the GeoPandas package (GeoPandas 2023) in Python can be used. The bridge information is retained in a csv file, which can be easily managed using Python.

Table 2. Data description of the table "bridges" inside the data set "Geo-Bridge".

Field	Description	Type	Format (example)
LINE_NO	Four-digit line number of DB	Number	2650
[. . .]	[. . .]	[. . .]	[. . .]
GEOGR_LAT	Geographical coordinates: Latitude ETRS 89 (EPSG: 4258)	Number	54.77366638
GEOGR_LON	Geographical coordinates: longitude ETRS 89 (EPSG: 4258)	Number	9.43702642
[. . .]	[. . .]	[. . .]	[. . .]

Both tables contain coordinates used as reference when mapping and assigning measurement data to lines and bridges. To make this comparison possible, this data must be stored in a framework. Consequently, an algorithm needs to be developed to perform this task.

3 CONCEPTUAL OVERVIEW

The user interface should be simple and straightforward as shown in Figure 3. The only action required from the user is to upload the data or reference the corresponding folder. The application processes the data for management and storage as well provides a visual output for the user. Since geolocation of the data plays a key role, a map visualises where the data has been collected and which bridges have been crossed. This is shown in section 5.

4 IMPLEMENTATION

To effectively implement the above concept, a general architecture illustrated in Figure 4 has been formulated. This design facilitates the separation of distinct tasks into different services. For example, the graphical user interface (GUI) acts as the frontend, which can be separated from the storage and management of data in the backend. Additionally, as the application is intended to be browser-based, the selection of a web framework is necessary. Therefore, Django (Django 2023) was chosen due to its fast and easy configuration process, together with the variety of built-in features. Django uses built-in models and default databases (DB1, . . .) to handle incoming data, with a clear separation of GUI and business logic, as intended in the architecture in Figure 4. There are several well-known companies that also use Django, such as Instagram, Spotify, YouTube, or Dropbox (GeeksforGeeks 2023).

Besides the general architecture, the matching of the measured line with existing lines and bridges is a very important step. This can be implemented through algorithms that compare

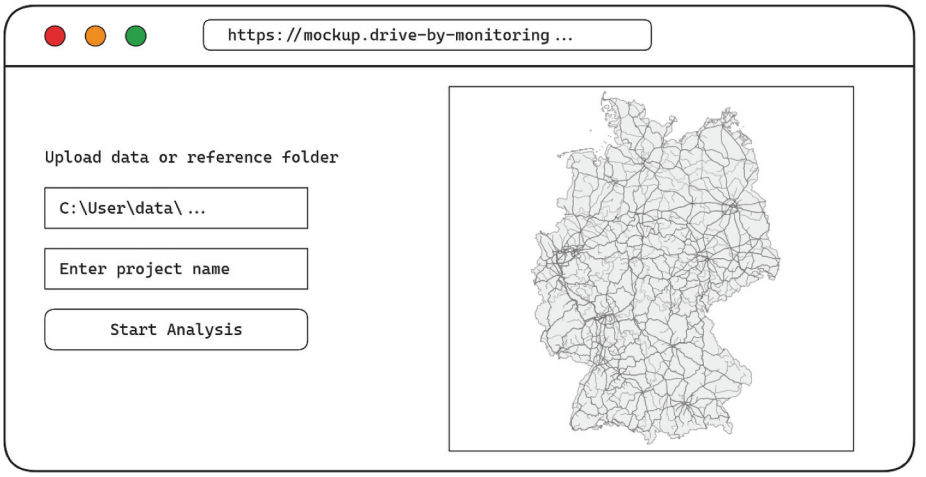

Figure 3. Mockup of the user interface of the application. Source of the railway network: Hbf878 2020.

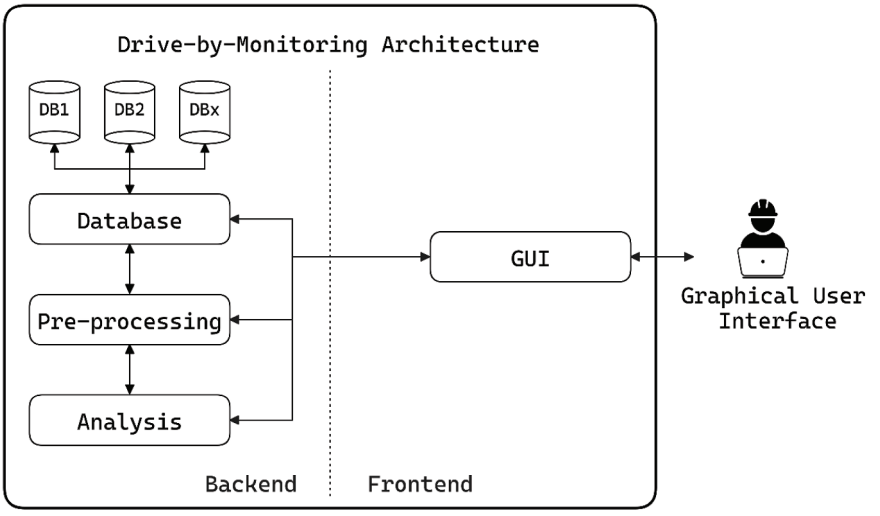

Figure 4. General architecture of the developed application.

coordinates. All signals were recorded using the catmanAP software and stored in a binary file. The Python package AP reader (Bohmann 2023) is used to extract data and features. A plausibility check of the GPS sensor is performed to rule out any malfunctions. The consecutive coordinates are checked for proximity and a general geographical location in Germany. The next step is to compare the coordinates of the measured line with those of existing lines and bridges in the open data of DB, as explained in subsection 2.2.

The travelled line of the measurement campaign is number 2650. It starts in Cologne and ends in Dusseldorf. Opening the shapefile provided by Deutsche Bahn and searching for the line number delivers the coordinates as follows.

```
LINESTRING Z (6.974548 50.940881 0, 6.97595 50.940729 0,
6.977346 50.940555 0, 6.980121 50.940159 0, 6.982896
50.939762 0, [...]

2650
```

Extracting the data from the very first measurement package gives the first coordinates as follows.

```
GNSS_Latitude 50.9407245
GNSS_Longitude 6.9748565
```

As directly visible, the coordinates appear to be close to each other. However, this is only the case if the line number of the trip is already known or provided as input. Requiring minimal user input while analysing the data independently is the main aim of this application. Therefore, when a new measurement package is entered as input, the algorithm must perform a thorough search of the entire open data set and make comparisons between each coordinate. This is achieved using the Euclidean distance metric (2) and searching for the minimum distance. The two points m (measured coordinates) and e (existing coordinates) are defined through their coordinates consisting of latitude and longitude (1). Note, that the coordinates in the open data set of DB are swapped.

$$m = (m_{lat}, m_{lon}) \; and \; e = (e_{lat}, e_{lon}) \tag{1}$$

$$d(m,e) = \sqrt{(e_{lat} - m_{lat})^2 + (e_{lon} - m_{lon})^2} \tag{2}$$

In Python, this can be implemented with the 'spatial algorithms' package of SciPy (SciPy 2023) which provides many fundamental distance computation algorithms. The function 'cdist' computes the distance between each pair of the two inputs. Based on these calculations the minimum distance can be determined and each measured coordinate can be associated with a line number. In this way, the measured line can be matched with existing line numbers of the railway network.

Nevertheless, the acceleration sensors generate 75,000 coordinate points at a minimum sampling frequency of 2500 Hz. Given the presence of latitude and longitude, there are 150,000 data points to check. However, the GPS sensor operates at only 1 Hz, so the remaining data points are repeated to match the acceleration data. Reducing the data set to just these unique coordinates significantly reduces the data set to just 31 coordinates. Despite this, it is still necessary to compare these 31 coordinates with every coordinate in the open data set of DB.

Another crucial objective is to identify the bridges that have been crossed and link them to a respective measurement package of the bridges. This will help the user to analyse measurements of specific bridges (e.g., in the context of Structural Health Monitoring). The DB csv file (see subsection 2.2) contains relevant data that can be easily used in Python. Since the line number is already known from the previous analysis, only the bridges belonging to this line are compared with the measured GPS signals. This process is analogous to comparing lines. However, it is not beneficial to search for the smallest Euclidean distance since a measurement package may include crossings of several bridges. Therefore, the distance in metres is calculated using the Haversine formula. The Haversine formula computes the distance on the surface of a sphere between two points based on their latitude and longitude (Chopde 2013). Using a threshold of 30 metres, bridges within a radius of 30 metres of the measured coordinates can be identified and assigned to the corresponding measurement package. The threshold of 30 metres has initially been chosen due to the train's maximum velocity of approximately 200 km/h or 55.56 m/s. This means that at this speed, a GPS signal (sampling frequency 1 Hz) is recorded every 56 metres. So, the set threshold makes sure that no bridge is left out. This can be verified by counting the number of bridges on the existing line and comparing it with the overall number of identified crossed bridges through the implemented algorithm. The evaluation has shown that the minimal

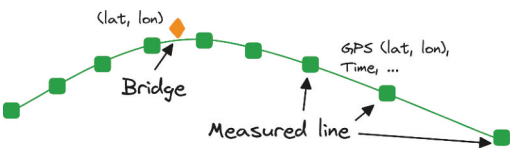

Figure 5. Identifying bridge crossings.

distances between the measured coordinates and the bridges is in average around 10 metres, confirming that the threshold is sufficient.

Figure 5 displays a location of a bridge and the measured line. The exact time of a crossing can be calculated using the train's velocity that is recorded as well.

5 EVALUATION

As there is sufficient data collected from the measurement campaign, the framework and the algorithms can be extensively tested. Figure 6 shows a specific measurement package on a map. The algorithm overall derived the line number 2650 from the measured GPS signal. In the first few measurements, line numbers 2660, 2654, or 2652 were calculated. Since the trip started in Cologne and there are different lines branching out, it is possible that other lines are closer to the measured GPS signals. Nevertheless, also different lines can be travelled during one measurement. A visual based verification of the algorithm is possible by displaying the measured line on a map (Figure 6).

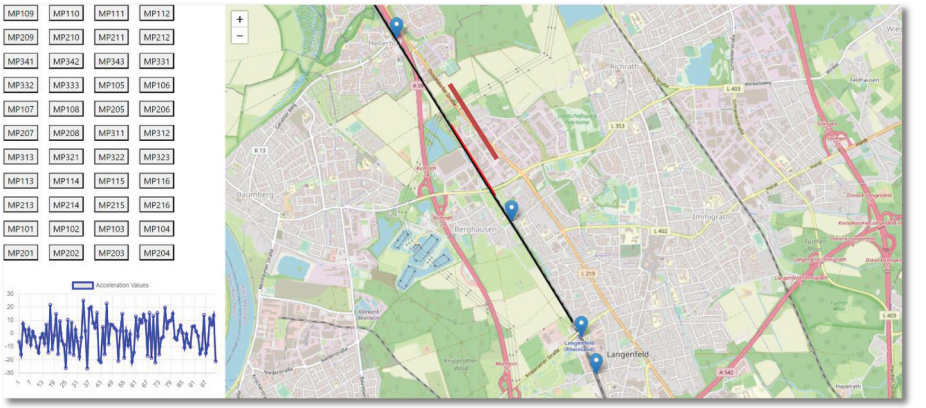

Figure 6. Browser-based visualisation of one measurement package (dark red) on a map and its acceleration measurements (MP. . .). The markers are the bridges on the line.

Bridges or bridge crossings can also be assigned to packages. For example, for the ninth measurement package the algorithm found two bridges, that were crossed during the time frame of this package. It's the eighth and ninth bridge on the line 2650 with the coordinates (50.95305818, 7.00128504) and (50.95377379, 7.00427725) respectively. The bridges in the provided open csv file have neither names nor IDs. The first coordinate of the ninth package is (50.95294117, 7.00122367) and the last (50.95391750, 7.00740033). A comparison shows that the algorithm correctly assigned the bridges to the ninth package. A visualization in a map makes a comparison even simpler. However, it is visible that the eighth bridge is near the first coordinate of the current package. Therefore, it will also be close to the last coordinate of the previous package. Due to the limited accuracy of the GPS signal and other uncertainties, the bridge is assigned to both packages. Furthermore, a sufficient distance before and after the bridge is required for subsequent analysis of the measured acceleration signals of the bridge crossing.

6 CONCLUSION AND OUTLOOK

As demonstrated in the previous section, the use of a browser-based map visualisation is a very efficient way of displaying location-based data. The algorithms used to calculate the line travelled and identify bridges crossed are also effective.

However, matching the line and then deriving the line number is a computationally expensive process, taking approximately four minutes to complete. This could be optimised by locating the first measured GPS signal in the railway network, then comparing the subsequent

measured coordinates with the coordinates of lines near the initial location. Alternatively, an input field could be included for the user to specify the line travelled. This would result in a slightly different user interface. However, if such measurement campaigns were to be carried out nationwide and on a daily basis, a fully automated solution would be required.

Furthermore, it is important to note that a browser-based solution would require the data to be uploaded or sent to the framework. Since file sizes are relatively large, the process may take some time depending on the internet connection. Local software applications could address this issue, or the presented algorithms could be carried out directly on the edge device collecting the measurement data. The derived information could be stored as meta data and referenced to measurement packages.

Additionally, further analysis services, such as those presented in Rupp et al. (Rupp 2023), can be smoothly and easily integrated. Furthermore, the proposed solution can be integrated into the digital twin framework developed within the ZEKISS research project, see e.g., Brötzmann et al. (Brötzmann 2022).

ABSTRACT: Fatigue cracks in steel bridges can lead to catastrophic failure and cause significant risks to public safety. These cracks can grow, propagate, reduce the structure maximum design capacity, and ultimately lead to a sudden failure. Fatigue cracks in steel bridges are primarily induced by the cyclic loading from constant traffic loads over time. Therefore, monitoring fatigue on steel bridges is essential to ensure structural safety. Operational modal analysis (OMA) is a non-destructive testing technique that can be used to monitor fatigue-induced damage through changes in modal parameters. When the fatigue crack grows the stiffness of the beam will reduce. This study implements OMA on a simply supported steel beam with changing stiffness. The natural frequencies and mode shapes of the beam are obtained through OMA, and combined with a model to predict the stress/strains at any point of the structure. The case study shows how maximum stresses and the natural frequencies that are affected by the crack growth are varying due to changes in stiffness. The result demonstrates that by combining OMA with fatigue assessment, the risk of fatigue failure in steel bridges can be significantly reduced.

1 INTRODUCTION

Fatigue crack is a critical issue for metallic structures. Especially for steel bridges that are subjected to the cyclic loading from constant traffic over time. Fatigue can reduce structure load-bearing capacity and overall service life (Azaïs et al., 2019; Kirkegaard et al.,1991; Leander, 2013; Avci et al., 2021). Also, weld imperfections often increase stress concentration that serve as potential initiators for fatigue cracking. If an initiated crack is subjected to cyclic loads, the crack will grow for each load cycle even if the stress level is far below the yield stress. When the crack has propagated beyond a threshold level, early failure may occur.

Recently growing attention has been obtained by Operational Modal Analysis (OMA) (Brincker and Vantura, 2015; Amador and Brincker, 2021, Alibrandi et al. 2023) and vibration based SHM (Lysgaard et al., 2020; Diord et al., 2017; Peeters De-Roeck, 2001; Alibrandi, 2022;). The underlying idea of these technologies is to enable engineers to assess the structural condition of different structural systems by simply extracting the system's physical properties - which are intrinsically related to the stiffness or strength of the system - from the vibration responses continuously acquired in a vibration-based monitoring campaign. Due to

DOI: 10.1201/9781003483755-200

the non-destructive character of these structural assessment techniques, they have become very popular amongst the structural engineering community and have increasingly been used in damage and structural condition assessment of modern society's civil infrastructure. This paper aims to illustrate the detectability on a case where the total fatigue life was seriously reduced due to un-expected stress concentration. It explores how a crack in a large steel bridge can be detected from the drop of the natural frequency. Additionally, it examines the timeframe available to the bridge owner for reaction when the natural frequency decline reaches a magnitude detectable through operational modal analysis (OMA).

2 FATIGUE ASSESSMENT

2.1 *Considered structure*

A support beam in a large bridge structure is illustrated in this study. As shown in Figure 1, the force F is applied on the bridge super structure, and as a result the dominating mass of this problem is not the mass of the beam, but the mass m of the part of the structure that is introducing the force F. As illustrated in Figure 1, a crack with the length a is introduced at the bottom of the beam, so that when vibrations occur on the bridge the associated fatigue will make the crack grow to a point that the crack growth might lead to a final failure.

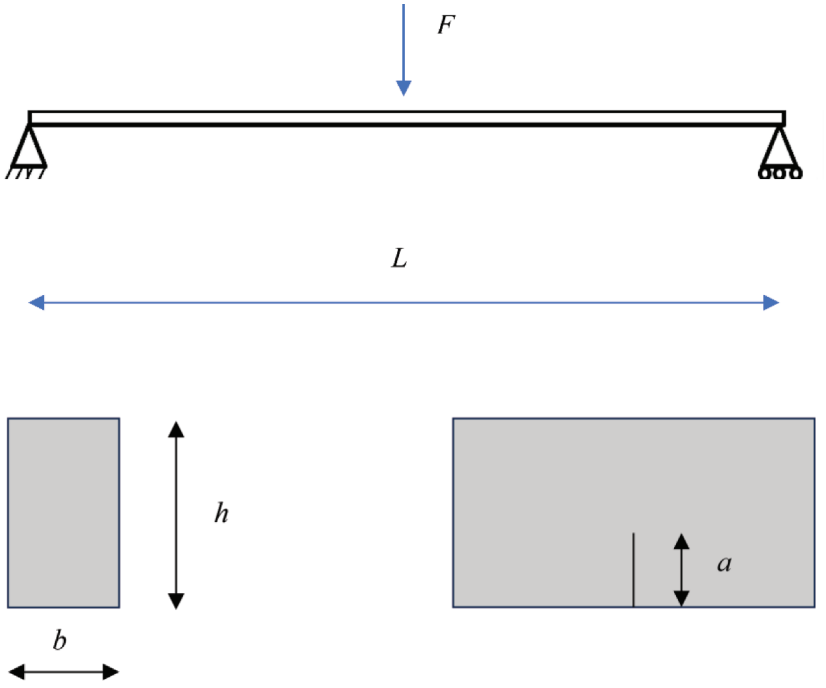

Figure 1. Top: Beam structure with a beam length L loaded with a point load F in the middle. Bottom: beam depth h,beam width $b$and a crack with length a in the middle of tension side of the beam.

2.2 *Stress and deformation*

Ignoring the crack, the stress in the beam is described by the bending moment that is given by

$$M = \frac{1}{4}FL \tag{1}$$

And the maximum stress at the bottom of the beam is then obtained dividing Eq. (1) by the resistant moment $W = \frac{1}{6}bh^2$

$$\sigma_0 = \frac{M}{W} = \frac{3}{2}\frac{FL}{bh^2} \tag{2}$$

The deformation in the middle of the considered beam is

$$u = \frac{FL^3}{48EI} \tag{3}$$

where EI is the bending stiffness, E is the Youngs Modulus and I is the geometrical moment of inertia. This defines the compliance for the crack length equal to zero

$$C_b = u/F = \frac{L^3}{48EI} \tag{4}$$

2.2 *Stress intensity*

The stress distribution around the crack is described by the stress intensity factor

$$K_I(a) = \sigma_0\sqrt{\pi a\, f(a/h)} \tag{5}$$

where the function $f(a/h)$ is given by

$$f\left(\frac{a}{h}\right) = 1.12 - 1.39\frac{a}{h} + 7.3\left(\frac{a}{h}\right)^2 - 13\left(\frac{a}{h}\right)^3 + 14\left(\frac{a}{h}\right)^4 \tag{6}$$

see Kåre Hellan (1984). In Figure 2 this solution is shown as a function of the crack length comparing with a similar solution from the reference Engineering Library.

2.3 *Fatigue crack growth*

The approach of the fracture mechanics describes the functional relationship between the crack depth a with the size and number of load cycles, where linear elastic behavior of the material is assumed. The fatigue crack growth is generally divided into three regions: (A) the crack growth process is governed by a threshold below which no crack growth occurs, (B) the crack growth is described by a linear relationship between log (ΔK) and log (da/dN), (C) fatigue crack growth interferes with fracture. The Paris law describes the second region. By assuming constant load amplitude, region (B) becomes

$$\frac{da}{dN} = A(\Delta K)^m \tag{7}$$

where ΔK is the intensity factor range, m, A are the Paris constants, and da is the extension of the crack over N load cycles. The intensity factor range is the difference of the maximum and the minimum of the stress intensity factor in one single stress cycle. For simplicity we will assume a constant stress cycle with amplitude σ_1, so that the intensity factor range is given by

$$\Delta K(a) = 2\sigma_1\sqrt{\pi a\, f\ (a/h)} \tag{8}$$

The number of load cycles extending the crack from a to + da is then given by

$$dN = \frac{da}{A\Delta K(a)^m} \tag{9}$$

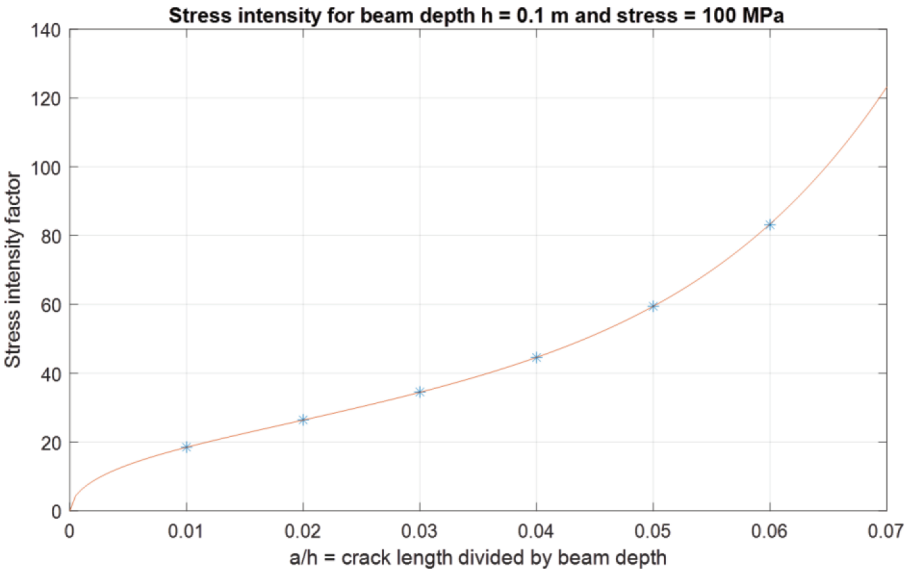

Figure 2. Stress intensity factor as a function of the crack length. The solution given by reference Kåre (1984) (red curve) is compared to solution from reference Engineering Library (blue asterisks).

2.4 *Fatigue failure*

When the fatigue crack grows, the stress intensity factor increase correspondingly until a critical crack length is reached where

$$K_I(a_c) = K_c \tag{10}$$

with K denoting the critical stress intensity factor, and where for the final failure, the stress intensity factor $K_I(a_c)$ is the sum of the stress intensity factor for the mean stress given by Eq. (5) and the half of the intensity range $\Delta K(a_c)$ given by Eq. (8)

The number of cycles N to fracture can then be obtained from the integration of Eq. (9) to yield

$$N = 2A \int_{a=a_0}^{a=a_c} K_t(a) - m_{da} \tag{11}$$

where a_0 is the initial crack length.

2.5 *Time To React (TTR)*

When the fatigue crack grows the stiffness of the beam will reduce, i.e. we will see an increasing compliance. It can be shown that the added compliance can be calculated as (Rincker, 2022)

$$\Delta C = \frac{2}{F^2} \int_{a_0}^{a+\Delta a} K_I^2/E \, da = \frac{\pi}{2Eh^2} \int_{a_0}^{a+\Delta a} a f(a/h)^2 \, da \tag{12}$$

As mentioned, we assume the beam to be a smaller part of bridge carrying the load F from the main structure, but also the main structure will introduce an associated mass m to move together with the mid point of the beam. Thus, neglecting the beam mass by assuming that it is small compared to m we have the following expression for the natural frequency f_b of the beam before a crack is introduced

$$f_b = \frac{1}{\sqrt{C_b m}} \tag{13}$$

After introducing the crack the natural frequency is

$$f_a = \frac{1}{\sqrt{(C_b + \Delta C)m}} \tag{14}$$

and we can define the dimensionless frequency ratio

$$\frac{f_a}{f_b} = \sqrt{\frac{C_b m}{(C_b + \Delta C)m}} = (1 + \Delta C / C_b)^{-1/2} \tag{15}$$

3 CONSIDERED CRACK EXTENSION CASES

For the illustrative purpose, we assume a beam case with the following material properties:

- Yeilding stress: 250 MPa
- Youngs modulus: 210 GPa
- Critical intensity factor: 50 MPa x $m^{1/2}$, see Wikipedia
- Paris constants: m = 3 and A = 10^{-8} mm/cycle, see Milović et al (2011)
- Initial crack lengths: a_0 = 2, 1, 0.5, 0.25 and 0.125 mm
- geometry of the considered beam: h = 1 m, b = 0.1 m and L = 10 m

Two cases are considered: one where the mean stress σ_0 is zero or close to zero, so it can be neglected, and one where the mean stress σ_0 is 10 % of the yielding stress. In both cases we focus on studying the errors occurred in the design process or fabrication, which has reduced

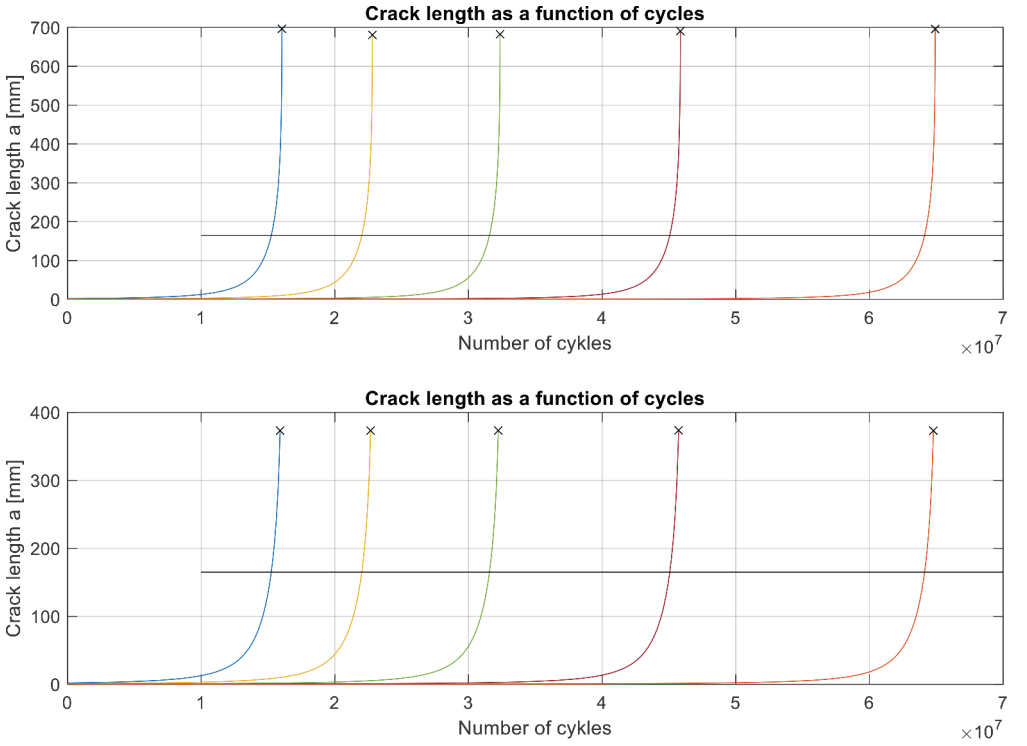

Figure 3. Crack length as a function of cycles for different initial crack length's (from the left) a_0 = 2, 1, 0.5, 0.25 and 0.125 mm. Top plot gives the results for zero mean stress, and the bottom plot for a means stress that is 10 % of the yielding stress. The horizontal line in both plots indicates the crack length for which the natural frequency of the beam has dropped 0.1 %.

the fatigue life to 10 % of the target life-time that is set to 20 years. The natural frequency of the beam including the mass from the structure loading the beam is set to 1 Hz.

Figure 3 Shows the crack propagation for different crack lengths, top plot for the zero mean stress and bottom plot for the mean stress equal to 10 % of the yielding stress. The horizontal line in both plots indicates the crack length for which the natural frequency of the beam has dropped 0.1 %, that is a = 165 mm.

From the theory of the crack extension, we see that the curves are the same for the two mean stress cases. The only difference is when the mean stress is large, which causes the final failure to happen earlier. This is due a higher value of the mean stress intensity factor.

We can now read the values of the curves, and calculate the number of cycles it takes to propagate the crack from a =165 mm to a_c. The results are given in Table 1 and 2 where results are also given for a frequency drop of 0.2 %, 0.5 % and 1 %.

Table 1. Time to react (TTR) for different frequency drop for the case of zero mean stress.

Freq. drop [%]	Crack [mm]	TTR [h]	TTR [days]
0.10	165	221.1	9.2
0.20	238	120.8	5.0
0.50	357	43.9	1.8
1.00	470	14.4	0.6

Table 2. Time to react (TTR) for different frequency drop for the case of a mean stress = 10 % of the yielding stress.

Freq. drop [%]	Crack [mm]	TTR [h]	TTR [days]
0.10	165	183.3	7.6
0.20	238	83.1	3.5
0.50	357	6.1	0.3
1.00	470	0.0	0.0

4 DISCUSSIONS

To detect a frequency drop of 0.1 %, we would need at least an uncertainty on the estimated natural frequency of that range. A frequency uncertainty of 0.1 % is normally difficult to achieve using classical OMA. However, in this case we have many test instruments, and thus, it is natural to assume that averaging these tests, we might easily reduce uncertainty to 0.1 %.

In addition to the uncertainties on the estimates for the natural frequencies, over time, changes in the environmental conditions may easily increase the uncertainty to something like 1 %. That is why we have considered four values in Tables 1 and 2 for the frequency drop in the range from 0.1 % to 1 %.

As shown in Table 1, in case when the mean stress is small, we will have time to react for all the considered frequency drops. For the smallest drop, we have plenty of time to react – about a week. For biggest drop we still have time to react – about 7 hours.

Similarly, as shown in Table 2, if we can detect reasonable small frequency drops, then we still have time to react for a larger mean stress – in case of a frequency drop of 0.5 % we have 6 hours to react. That is still a reasonable time, and it should be considered realistic to achieve an uncertainty smaller than 0.5 % for real life OMA.

SHM for railway bridges: Real time analysis of the train transit and thermal data

G. Ascari, A. Dalle Fratte & A. Terraneo
Akron srl, Bovisio-Masciago, Italy

P. Scali
Euroferroviaria, Roma, Italy

ABSTRACT: Fundamental aspects in railway bridges are the extreme stiffness and the relative influence of the impact of the train transits as compared to the variations resulting from the thermal phenomena. Within the framework of structural monitoring of railway bridges, an innovative approach in the monitoring techniques for the measurement of the relevant parameters of the structures is presented. This method allows to separate the effects of the train transit alone from the measurement of the parameters in certain rest conditions (environmental noise and thermal effects), already during the acquisition phase (edge computing) in near-real time. This approach enables to create two distinct datasets in terms of stresses, strains and displacements. Those, together with the measurement of the mass and speed of the trains transiting on the bridge, and considering the high frequency of train transit, allow the immediate use of the monitoring data for the construction of a dedicated dataset in terms of cause-effect (e. g. curvatures, bending moment, shear stresses), which can be used to verify the behavior of the structure comparing it with what expected. The differentiated measurement and the innovative calculation processes allow detailed analysis of a single-track deck or, in the case of double-track decks, the distinction of the transit direction (with evaluation of torsional phenomena) or of simultaneous transit on both tracks (greater flexural effects). The presented monitoring solution (hw & sw) allows to extract engineering parameters directly during the acquisition phase, assimilating and effectively treating each train transit as a single load test.

1 INTRODUCTION

In the context of the study of the health and maintenance of railway bridges, a fundamental issue concerns the difference in the analysis approach of the variation of the measured parameters due to thermals effects and caused by external forcing.

The main attention is generally focused on how the external forcing affect the structure behavior, not considering that the effect that the thermal variation has on the same parameters is generally an order of magnitude higher.

Therefore, it becomes fundamental the separation of the acquired dataset in the data related to the rest conditions of the structure (thermal variations and environmental noise effects) and related to the effects of the forcing alone (e.g. train transits, but also applicable to wind gusts, earthquakes, other).

The topic presented in the article addresses an in-depth analysis of the thermal effects and the critical issues related to the correction of the acquired data from the thermal component, and suggests a monitoring system solution that separates the two datasets (rest conditions and external forcing) in real time during the acquisition phase, using advanced edge computing functions.

DOI: 10.1201/9781003483755-201

2 THERMAL EFFECT ON THE STRUCTURES

The analyses on several databases acquired for different monitored structures on an annual basis, led to the observation that the variation of the parameters such as deformation, displacement measure at the bearings and tilt due to the thermal effect alone is generally an order of magnitude higher than the variation of the same parameters due to the effect of an external forcing, such as the train transit.

In order to correctly evaluate how the external forcing alone affects the structure, a procedure that corrects the data from the thermal effect is necessary. During the short-term daily cycle and within the long-term seasonal cycle, the parameter being measured is at different values depending on the temperature and thermal inertia. There are different common methods to correct the data from the thermal component, such as linear and multivariate regression methods.

However, there are some critical issues that affect the correction and the results. In fact, in the analysis of the temperature effects it cannot be avoided to take into consideration the effects of the possible different insolation determined by the position and the geometry of the structure.

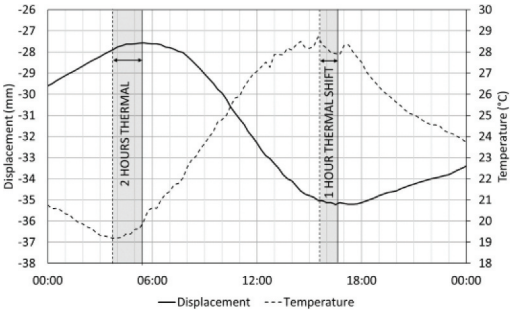
3 CRITICAL ISSUES

The main critical issues concerning the correction of the acquired data from the thermal component are the thermal shift, the thermal inertia, the oversampling and the overfitting.

3.1 *Thermal shift*

The thermal shift consists in the presence of a temporal shift between the daily absolute maximum/minimum peak values of the temperature with the absolute maximum/minimum values of the parameter being measured. The parameters such as deformation, displacement at the bearings, tilt, respond differently depending on the increasing (heating) or decreasing (cooling) temperature of the temperature gradient during the daily heating and cooling phases.

This phenomenon is not only referable to a shift in the deformation response with respect to the temperature variation, but also to different ways of heating of the structure. The thermal shift value is variable during the year and during the individual heating and cooling phases in a single daily cycle (Figure 1).



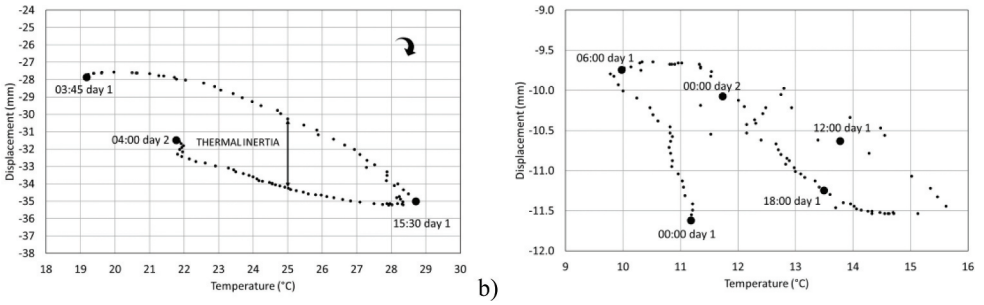


Figure 1. Thermal shift during the heating and the cooling phases in a daily cycle for a displacement sensor. The graph shows a displacement curve and a temperature curve. It is possible to notice the difference in the width of the shift during the heating and the cooling phases. The shift value is calculated between the minimum value of the temperature and the maximum value of the displacement for the heating phase and the maximum value of the temperature and the minimum value of the displacement for the cooling phase.

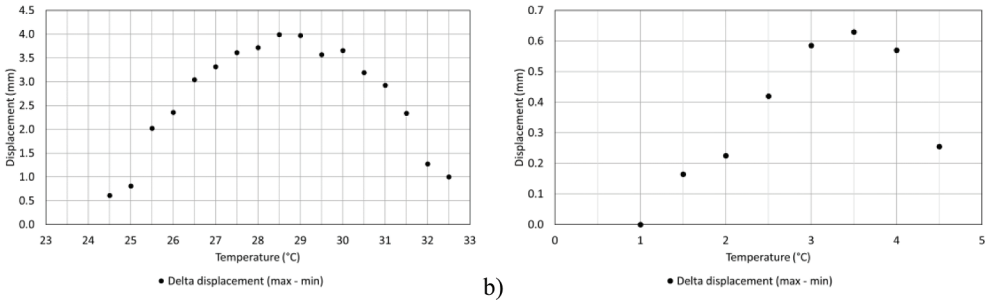
3.2 *Thermal inertia*

The phenomenon of thermal inertia, or the different heating/cooling rates of the structure, determines a non-linearity of the measured parameter in relation to the temperature variation during a daily cycle. The relationship between the parameter being measured (e.g. deformation or displacement) and the temperature outlines a single or double ring "elliptical" path during the daily thermal cycle. In this cycle, at a same temperature value, the corresponding measured parameter is different depending on whether it is measuring during the heating phase or the cooling phase (Figures 2a).

a) b)

Figure 2. a) thermal inertia in a thermal daily cycle (minimum – maximum – minimum); b) thermal inertia in the 24 hours, for an irregular daily cycle.

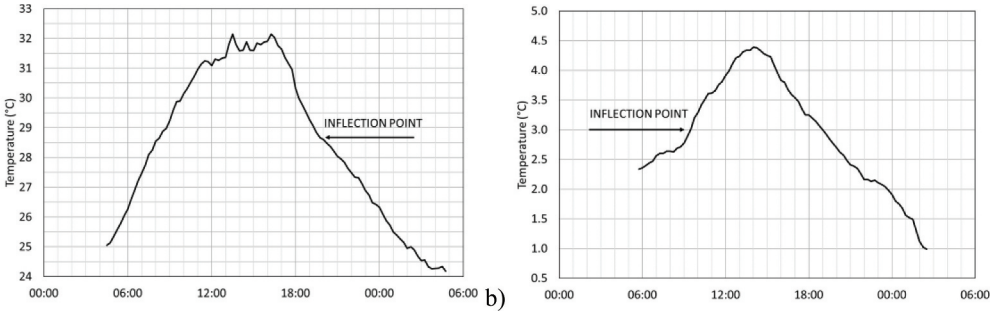
However, the daily cycle doesn't outline a regular sinusoidal trend. On days in which sudden temperature variations occur or in which the temperature variation does not follow the normal hysteresis daily cycle of minimum-maximum-minimum, the resulting correlation curve (temperature-parameter) may have a highly irregular trend. In these cases, the issue of thermal inertia becomes more complicated, also impacting on the methods chosen to correct the thermal curves. Therefore, the simple regression methods (linear or multivariate) for the correction of the thermal component may not be enough nor effective (Figure 2b).



3.3 *Variation of the inertia during a thermal cycle*

Thermal inertia is one of the main factors that make the correction with a simple linear regression method ineffective. The thermal inertia value varies over the daily cycle, depending on the average daily temperature. Therefore, its effect has repercussions both in the short term and in the long term, complicating the mathematical laws that describe the phenomenon. An in-depth analysis of the maximum daily values of thermal inertia is proposed.

A sufficiently high number of daily thermal cycles (minimum – maximum – minimum) were consider, in order to confirm the observations. The temperature values (acquired up to the second decimal) has been rounded to 0.5 °C. For each half degree of temperature, the maximum value and minimum value of the parameter being measured (displacement) were considered and the delta (maximum value minus minimum value) was performed (Figures 3a, b).

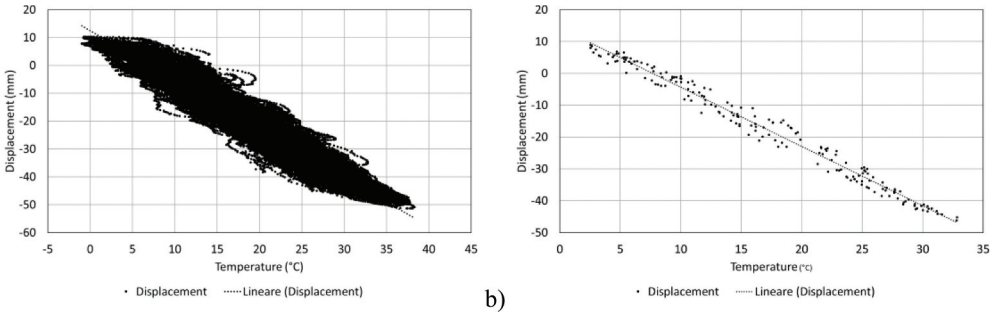


It is shown that the maximum value of delta has a correspondence with the average temperature of a thermal cycle (minimum – maximum – minimum) and with the inflection point of the temperature curve, assimilated to a sinusoid curve (Figures 4a, b).

The analysis was performed for warm and cold periods. The validity of the observation is confirmed, although for lower average temperatures the thermal inertia values are lower (due to the daily temperature range, which is generally more limited in cold periods).

a) b)

Figure 3. Delta (maximum displacement value minus minimum displacement value) for each value of temperature (rounded to a step equal to 0.5 °C) during an entire thermal cycle during a) the warm period and b) the cold period.



a) b)

Figure 4. a) temperature curve used for the analysis shown in Figure 4a, and inflection point at about 28.5 °C, corresponding to the average daily temperature; b) temperature curve used for the analysis shown in Figure 4b, and inflection point at about 3.0 °C, corresponding to the average daily temperature.

3.4 *Oversampling and overfitting*

Regardless of the method used for thermal correction, it is necessary to analyze the phenomena related to oversampling. By averaging the data acquired over different time intervals (1, 6, 12, 18, 24, 48, 96 hours) it can be noticed that the dispersion of the data is decreased (Figures 5a, b), and consequently, also the correlation index (Table 1, Figure 6).

The use of a large amount of data in static structural monitoring (e.g. sampling rate equal to 15 minutes) leads to a low usability of "simplified" thermal models. Consequently, it is easy to incur into overfitting problems, i.e. a high forecast error caused by the complexity of the model. Overfitting occurs when the model cannot be generalized and overfits the training dataset.

a) b)

Figure 5. Cross correlation graphs between the temperature and the displacement values for a) a two years database and sampling frequency of 15 min and b) for a two years database and averaging on 96 hours.

The graph in Figure 6 represents the variation of the correlation coefficient between temperature and displacement (for two different sensors) as the time grouping changes (from sampling rate equal to 15 minutes up to data averaged over 96 hours). A two-year database was considered for the analyses.

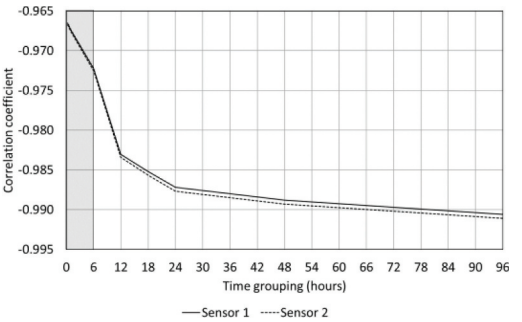


Figure 6. Variation of the cross-correlation values (Table 1), for increasing time averaging.

Table 1. Correlation coefficient variation for different degree (time) of data averaging.

Averaging degree	Correlation	coefficient
	Sensor 1	Sensor 2
15 min	-0.967	-0.967
1 hour	-0.967	-0.968
6 hours	-0.972	-0.973
12 hours	-0.983	-0.983
18 hours	-0.985	-0.986
24 hours	-0.987	-0.988
48 hours	-0.989	-0.989
96 hours	-0.991	-0.991

The improvement of the correlation coefficient using a database averaged over longer periods depends on the elimination of the thermal shift (after the first 6 hours, as the shift is generally shorter) and on the smoothing of the peculiar effects of each individual daily cycle.

In order to better fit the data by grouping the data on a time basis, a sufficiently long acquisition period is necessary, in order to perform a correct analysis of seasonal thermal cycles and to have a significant quantity of points to validate the observations. It is also necessary to correctly estimate the appropriate reactivity period to obtain the precision of the expected data.

4 REAL-TIME MEASUREMENT AND CALCULATION OF THE TRAIN TRANSITS EFFECTS ON THE BRIDGE

4.1 *Separation of train transit effects from thermal effects*

Given the critical issues for the correction of the effect of the thermal component in the post-processing phase, the best solution is to operate directly during the acquisition phase, using advanced edge computing functions that are performed directly on the field computer. The particular acquisition and processing mode functions developed for the monitoring system allows the separation of the acquired dataset in the data related to the rest conditions of the

structure (thermal variations and environmental noise effects) and related to the effects of the forcing alone (e.g. train transits, but also applicable to wind gusts, earthquakes, other).

In Figures 7, 8a and 8b it is shown an example of separation of the two datasets acquired on a pre-compressed concrete railway double track bridge. The acquired data are from two different strain gage installed on the same beam, one in the intrados position and the other in the extrados position. In Figures 9a e 9b it is shown the analysis on a daily curvature, calculated as difference in modulus between the intrados and extrados strain values measured on the same beam, divided by the distance between the two installed sensors.

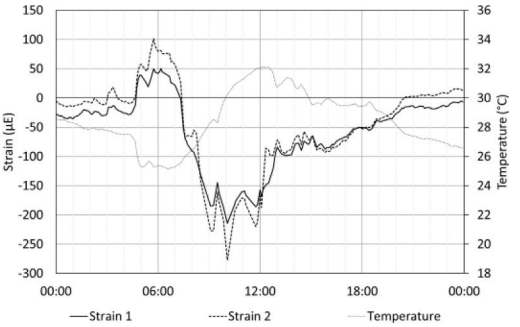

Figure 7. Daily variation of the value of two different strain sensors and temperature in rest conditions.

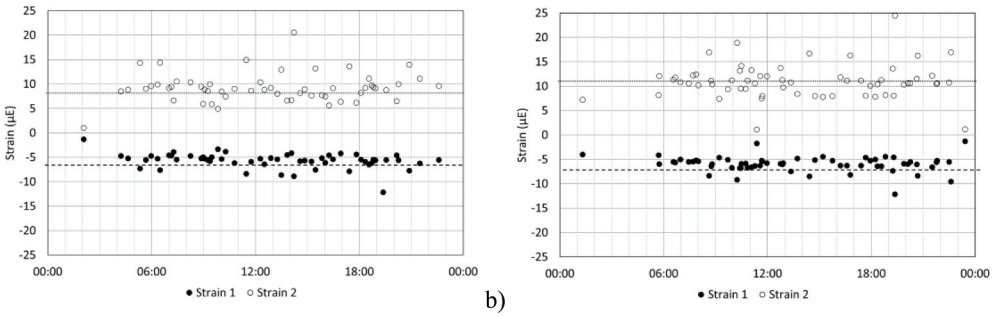

Figure 8. Daily variation of the value of two different strain sensors in forcing conditions. The graph on the left is related to the train transit on track 1 (a), the graph on the right to the train transit on track 2 (b).

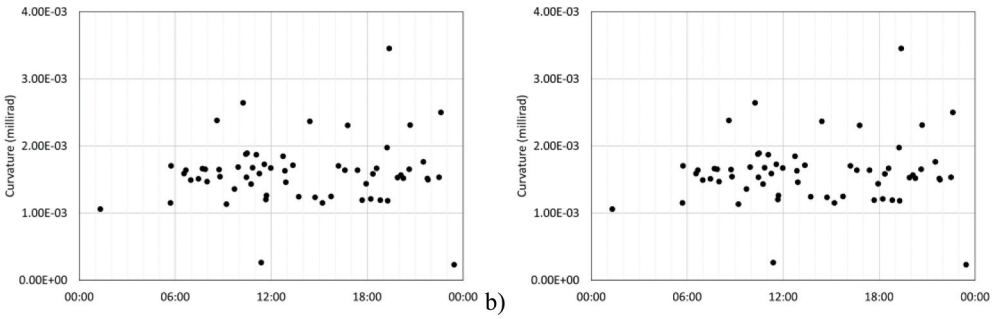

Figure 9. Daily value of curvature, calculated as difference in modulus between the intrados and extrados strain values measured on the same beam, divided by the distance between the two installed sensors. The graph on the left is related to the train transit on track 1 (a), the graph on the right to the train transit on track 2 (b).

4.2 *Value occurrence analysis*

From the dataset relating to the thermal component and from the dataset relating to the effects of the train transit component, it is useful to perform an analysis of the recurrence of the values, in particular the maximum daily values, in order to identify a "threshold" level for the identification of an evolution in the behavior of the structure in response to both the thermal and the forcing effects (e.g. railway trains in transit).

Regarding the variation of the parameter due to the thermal effect, it is necessary to have an entire annual monitoring cycle, to outline the upper and the lower limits of the variation range. Regarding the variation of the parameter due to the sole effect of the forcing (train transit), a population of a few hundred trains will be enough to validate the upper limit.

It is therefore possible to use this analysis to outline the thresholds for a diagnosis of the occurrence of an anomaly in the behavior of the bridge, in terms of variation in the distribution of the maximum daily recurrence peak values and use this parameter as a possible indicator to monitor the health of the monitored structure.

4.2.1 *Analysis for the thermal effect*

In this paragraph it is presented the analysis of the occurrences of the values during rest conditions, as effect of thermal variation and environmental noise (Figure 10a), and the range of variability of the monitored parameter during an entire seasonal cycle (Figure 10b), obtained as maximum and minimum daily values.

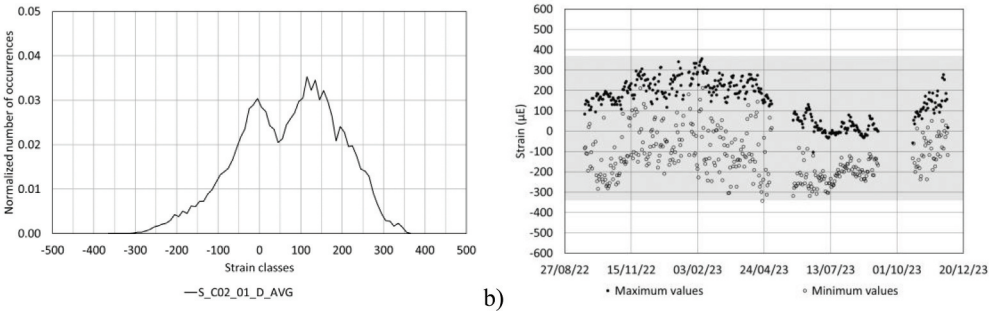

Figure 10. a) analysis of the occurrences of the values (strain) during rest conditions; b) range of variability of the monitored parameter during an entire seasonal cycle (rest conditions), obtained as maximum and minimum daily values.

4.2.2 *Analysis for the external forcing: Train transits*

Below, it is presented the analysis of the occurrences of the values during forcing conditions, as effect of train transit. Important information is already available from the acquisitions

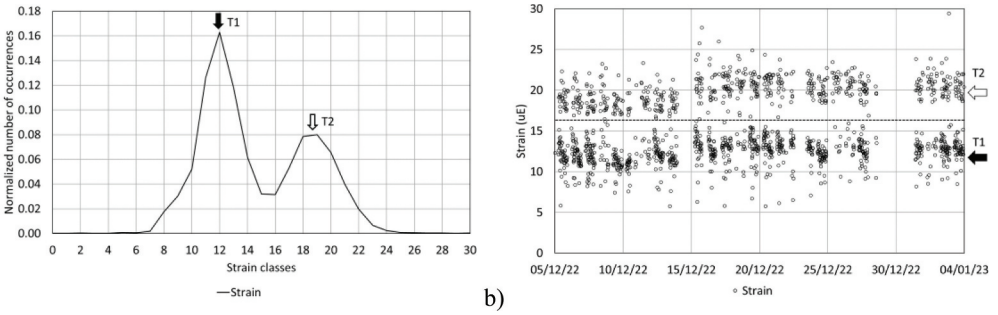

Figure 11. Analysis of the occurrences of the values (strain) during train transits (a). It can be noticed the presence of two defined picks related to the transit of two different type of train (b).

dedicated to train transits regarding the presence of two distinct families of behavioral response effects, due to two different types of trains, T1 and T2, characterized by different masses (Figures 11a, b).

The analysis of the variations in the maximum daily peak values on a database of one year of acquisition for a strain parameter is presented below (Figure 12a), with the separation of the analysis for the two families of values related to the transits of the two different types of trains. From the graph obtained, a trend can be outlined, which seems to have a link with the variations of the parameter with the thermal variation, albeit on a very small scale (around approximately ± 1 uE for the first family of trains and approximately ± 1.5 uE for the second family of trains). The same type of analysis was carried out using the curvature value, calculated as difference in modulus between the intrados and extrados strain values measured on the same beam, divided by the distance between the two installed sensors (Figure 12b).

Considering that the correlations between the calculated peak values and the average temperature and the correlation between the peak values and the daily averaged variation of the parameter in rest conditions are very low, it is assumed that the variation of the pick values and of the pick of curvature values during the train transits is affected by a variation in the elastic modulus of the constituent material (concrete) with the variation of the average daily temperature during the seasonal cycle.

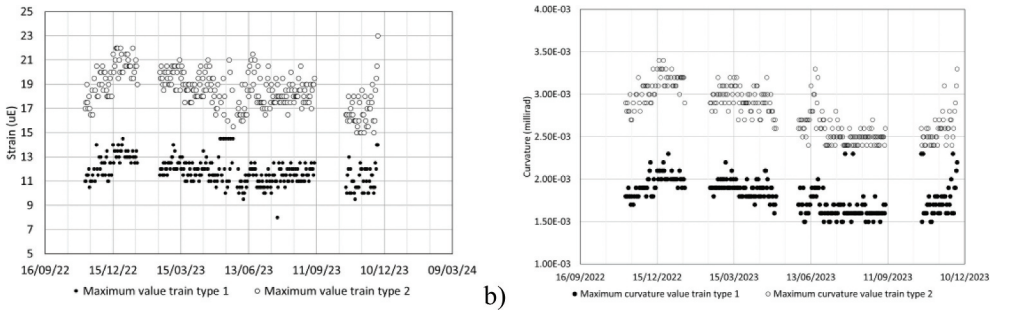

Figure 12. a) variations in the maximum daily peak values on a database of one year of acquisition for a strain; b) variations in the maximum daily peak values of the curvature on a database of one year of acquisition.

5 CONCLUSIONS

This work presents a monitoring system solution that allows the real-time separation of thermal effects from the effects of forcing agents on a structure. The variation of parameters such as deformation, displacement at the bearings and at the joints and tilt, due to the thermal effect alone is generally an order of magnitude higher than the variation of the same parameters due to the effect of external forcing, such as the train transits. Therefore, the analysis of the behavior of a bridge in terms of prediction of the parameters being measured and analysis of possible damage requires a considerable training period (generally in the order of at least 2 seasons).

The monitoring solution presented allows the separation of the the measurements of the structure parameters in rest conditions from the measurements related to the transit of trains. With this method it is possible to use the transits of railway trains of an operating railway line as a continuous series of load tests. The system also provides the possibility to calculate the transit speed of the trains and, using a dynamic weight in motion system, the dynamic force-effects correlation. The use of hardware and software solutions that allow real-time analysis not only of the parameters being measured, but also of calculated parameters (e.g. curvature), also allow the consolidation of measurement information in engineering parameters.

Given the generally high frequency of transits on railway lines, it is possible, directly from the monitoring acquired data, to classify the type of trains in transit, to determine the cause-effect relationship both on measured parameters and directly on engineering parameters (virtual channels obtained from algorithms applied to the acquired data), to calculate the repetitiveness of the effects on the bridge structures through the analysis of the occurrences (Gaussian curves) and to verify the coherence of the forcing/effects relationship over time.

The information thus calculated and analyzed allows, in a short period of time from the activation of the SHM system, the definition of more efficient alert or alarm thresholds, definable based on the behavioral models (FEM) of the structure.

ABSTRACT: Drive-by methodologies have emerged as a feasible and cost-effective monitoring solution for accurately and early detect damage on railway bridges while minimizing train operation interruptions. This study presents a novel approach for drive-by damage detection in high-speed railway (HSR) bridges. The methodology relies on acceleration records collected from multiple bridge crossings by an operational train equipped with onboard sensors. Log-Mel spectrogram features derived from the acceleration records are used together with sparse autoencoders for computing statistical distribution-based damage indexes. Numerical simulations were performed on a 3D vehicle-track-bridge interaction system (VTBI) model implemented in Matlab® to evaluate the robustness and effectiveness of the proposed approach. The model considers several damage scenarios, vehicle speeds, and environmental and operational variations (EOVs), such as multiple track irregularities and varying measurement noise. The results showed that the proposed approach can successfully detect and localize damages, as well as characterize their severity, especially for very early-stage damages.

1 INTRODUCTION

The significant technological advancement in railways regarding increased train speeds has enabled a rapid, safe, and environmentally friendly alternative to air transport for connecting various cities worldwide. In comparison to conventional railway lines, high-speed lines present more strict requirements concerning track geometry, not permitting sharp curves or steep gradients. As a result, bridges and viaducts occupy a substantial percentage of the railway network, allowing trains to overcome topographical obstacles more smoothly (Kang *et al.*, 2018). With this rise in the number of bridges and the higher demands in terms of train safety operation, there is an urgent need for implementing SHM systems capable of identifying damages in these structures. Nonetheless, implementing such systems represents a high and prohibitive cost for smaller-scale structures, rendering comprehensive railway monitoring infeasible. In the face of this reality, researchers have been exploring the possibility of implementing monitoring systems and using vehicles that regularly travel on tracks as mobile sensors able to detect damage in structures (Malekjafarian *et al.*, 2015, 2022). These monitoring strategies are called drive-by monitoring and represent a significant advancement in cost compared to traditional SHM techniques, since, in theory, a single instrumented vehicle would be capable of monitoring the entire extension of a railway (Locke *et al.*, 2020).

DOI: 10.1201/9781003483755-202

Aiming the accurate damage detection, studies have been conducted using various non-modal techniques for feature extraction, mainly based on signal processing and optimization-based parameter identification. Cepstral analysis has recently gathered interest among researchers and recent studies (Li, Morgantini, *et al.*, 2023) indicate the significant potential of these features on structural damage detection, particularly the Mel-frequency cepstrum (MFC). Despite the significant amount of research on damage detection investigating the application of cepstrum features, most of the studies are still focused on wayside applications (Zhang *et al.*, 2011) or in areas other than bridge SHM (Abdul & Al-Talabani, 2022). Therefore, the use of Mel-frequency damage features in drive-by monitoring is relatively recent. Pioneering work in this direction was conducted by Mei et al. (2019), where MFCC extracted from acceleration measured onboard of road vehicles were used as indicators for damage detection on bridges. Souza et al. (2022) first introduced the use of MFCC as damage features in a high-speed railway context, successfully demonstrating the sensitivity to damage, noise robustness, and capability of MFCC-derived damage indexes to offer reliable insights into damage location and severity under distinct track conditions and speeds.

Studies that include the use of AE in conjunction with drive-by methods are rare and all are related to road vehicles. To the best of the authors' knowledge, only three papers have been published regarding this approach (Calderon Hurtado *et al.*, 2023; Li, Lin, *et al.*, 2023; Liu *et al.*, 2020). The application of AE associated with MFSC in the context of drive-by monitoring of railway bridges is still, to the best of the found knowledge, unreported in the literature. Given this evident gap, this study introduces a novel drive-by damage detection method for HSR bridges, considering the analysis of multiple instances of train crossings over a bridge, during which onboard sensors are installed on the carbodies and bogies of a service train. The vehicle dynamic responses were evaluated on a 3D vehicle-track-bridge interaction system (VTBI) model implemented in Matlab®. The acceleration records are transformed into the time-frequency domain using Log-Mel spectrogram features extracted via a proposed adapted Mel-frequency scale. Then, these 2D image-like processed data are leveraged to compute statistical distribution-based damage indexes through the application of a deep learning algorithm, specifically a sparse autoencoder. The proposed numerical methodology considers several damage scenarios, vehicle running speeds, and EOVs, particularly distinct track irregularity conditions and varying levels of measurement noise. The main original contributions of this research work are:

- The development of a drive-by damage detection methodology to assess the presence of localized damage in high-speed railway bridges, capable of identifying its localization, type, and severity, with robustness regarding EOVs.
- The use of adapted Mel-frequency damage-sensitive features in association with a deep learning technique (sparse autoencoders) constituting a statistical distribution-based damage index.

2 PROPOSED DRIVE-BY DAMAGE DETECTION METHOD

The railway bridge damage detection methodology presented in this paper consists of a four-step process. In this process the sensitive damage features extracted from a indirect SHM system and its derived damage index are able to provide consistent and robust information regarding of the damage detection, localization and severity. Figure 1 depicts an overview of the proposed method, whose stages are discussed in detail on the following subsections.

2.1 *Data acquisiton*

The proposed method for detecting damage is numerically assessed through simulated data representing the dynamic responses of the vehicle components. These responses were derived from dynamic analyses performed using the 3D VTBI model implemented in Matlab®. For each baseline and damage scenario, the dataset is generated under batches of crossing events of the same train over the bridge. All carbodies and bogies of the train are instrumented, and therefore the datasets consist of their vertical acceleration responses associated with the train speed (v), as well as the damage location and irregularity profile characteristics.

2.2 *Feature extraction*

The feature extraction process is of paramount importance in damage detection systems. It must eliminate the influence of environmental and operational factors from the dynamic responses to enable the conversion of raw time series data into alternative damage-sensitive information. This section details the steps to derive the cepstral features from the sampled signals acquired from the drive-by monitoring system.

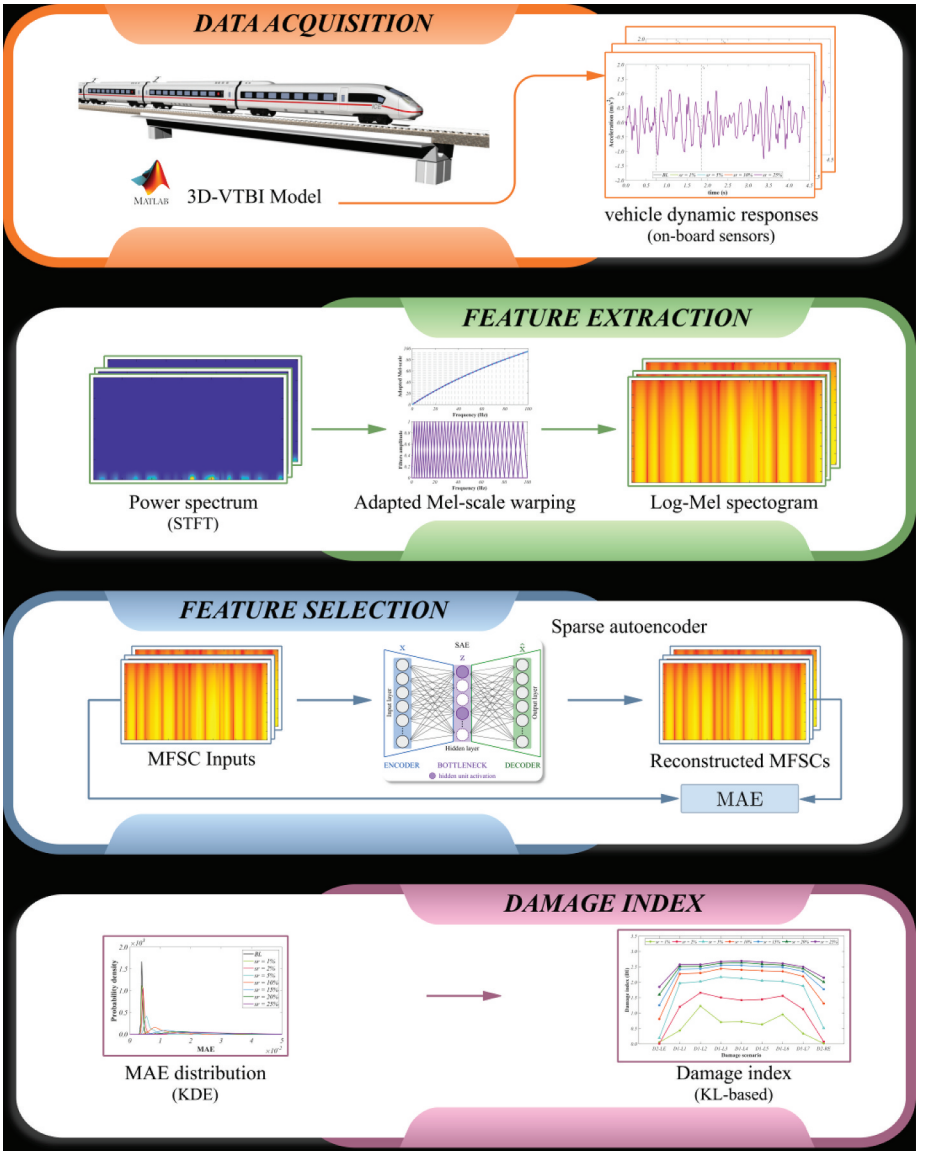

Figure 1. Flowchart of the proposed drive-by damage detection methodology for railway bridges.

2.2.1 *Short-time Fourier transform*

The STFT is used to preprocess the vehicle acceleration responses and to manage non-linear factors within the railway environment. This technique allows performing time-frequency analysis and involves applying the Discrete Fourier Transform (at b equally spaced frequency

bins) to each of the N overlapped short-time frames of a sampled signal $x[n]$. As a result, a power spectrum matrix $\mathbf{P}$ of size $b \times N$ is accomplished, which captures the signal's magnitude spectra over time.

2.2.2 *Log-Mel spectrogram features*

Spatiotemporal content of MFSC is used to train deep sparse autoencoder architectures tailored for railway bridge damage detection rather than time-series representations or linear frequency spectrograms. After evaluating the power spectrum $\mathbf{P}$, frequency warping is employed to enhance the signal's characteristics in the Mel-frequency scale by triangular filters whose centers are equally spaced into the Mel-scale. To make the Mel warping suitable for cepstral feature extraction in the context of SHM applications, the authors propose adapting the Mel warping approach. Instead of the frequency warping used in speech analysis, a linear weighting procedure is taken, using a scale that emulates the Mel scale trend up to a cutoff frequency f_c. In this study, it was adopted a uniform distribution of the triangular filter centers along the adapted Mel-frequency scale $\widetilde{m}$ given by:

$$m = 2595log(1 + f/700) \tag{1}$$

2.2.3 *Feature selection*

Several SHM approaches have been developed using Deep Learning (DL) for its ability to process and successfully analyze large amounts of data. These models involve the use of complex abstractions to represent data information, employing both linear and nonlinear mapping techniques across multiple processing layers. Among the available DL algorithms, Sparse Autoencoder (SAE) stands out as a promising alternative in bridge SHM systems. In this work, the SAE models are trained by inputs generated from the carbodies' and bogies' responses while crossing the target bridge under healthy conditions, i.e., baseline scenarios. Therefore, the model is not expected to reconstruct unseen data referring to damage scenarios since it has not learned them. To leverage this aspect, mean absolute error (MAE) is used to measure the reconstructed error, which can be expressed by

$$MAE = \frac{1}{n}\sum\nolimits_{i=1}^{n} |x_i - \widehat{x}_i| \tag{2}$$

where x_i and $\hat{x}_i$ are the corresponding ith components of the SAE input and output vectors, respectively.

2.2.4 *Damage index*

In cases where batches of crossing instances are considered, MAE exhibits substantial variation due to the varying sensor positions and train speeds. Nevertheless, MAE distributions can be used for damage diagnosis by assessing the dissimilarity between those obtained from a series of passages over a healthy bridge (baseline) and over it under a damaged.

The probability density distributions of MAE values for each damage scenario are determined using kernel density estimation (KDE) in this study. A KDE presents a smooth curve, enhancing the visualization of probability density function details while incorporating the locations of all sample points. A Damage Index (DI) is then calculated based on the KL divergence to measure the dissimilarity between two KDE for damage identification and severity assessment. The KL divergence is a metric rooted in information theory that quantifies the loss of information while approximating a probability distribution $p(r)$ with another distribution $p'(r)$, both with the same set χ of outcomes and is given by

$$KL(p'|p) = \sum\nolimits_{r\in\chi} p'(r) log\left(\frac{p'(r)}{p(r)}\right) \tag{3}$$

From Eq. (2) and Eq. (3), the adopted DI in this work can be written as follows:

$$DI = log\left(KL\left(KDE^{(u)}|KDE^{(d)}\right) + 10\right) - 1 \tag{4}$$

where $KDE^{(u)}$ and $KDE^{(d)}$ are the MAE estimated distributions for a baseline scenario and for a damage scenario, respectively. To derive Eq.(4), a log-linearized relationship is taken as the KL divergence provides either a nonnegative real value or infinity.

3 RESULTS AND DISCUSSION

3.1 *Case study*

Figure 2 shows the case study used in the present work for performing the dynamic analyses. The bridge deck consists of an idealized prestressed box-girder with a span of L_B =50.4 m, and the instrumented vehicle considered is the third-generation German high-speed train, the ICE3 Velaro, composed of eight cars. The total length of the ballasted track was assumed to be 497.4 m, consisting of the section over the bridge extended by the entry and exit lengths, each 223.5 m long. Therefore, the running distance for the vehicle is 303.9 m.

The bridge deck is modeled as a simply supported Euler-Bernoulli beam using 3D finite elements (FE), with bearing supports modeled using linear springs. In the ballasted track model, left and right rails (subscript *Lr* and *Rr*, respectively) are also modeled using 3D beams FE discretely supported at rail-sleeper junctions. The model incorporates three layers of spring-dashpot assemblies, which characterize the elasticity and damping of rail pads and fastenings, ballast, and subgrade.

Figure 2. Case study used in the present work for the numerical simulations.

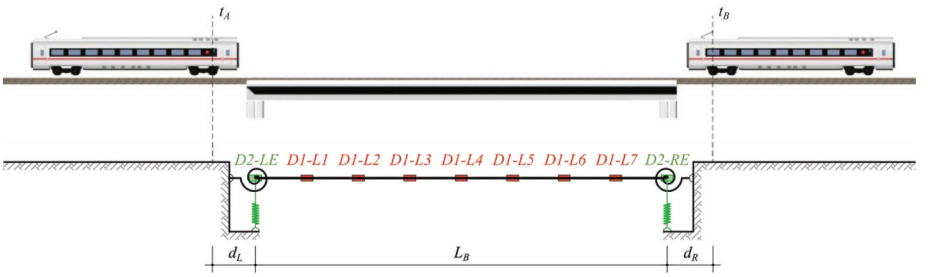

Figure 3. Types of damages and their location on the application case.

3.2 *Simulated scenarios*

Baseline (healthy condition) and damage scenarios were simulated to evaluate the proposed damage detection methodology, considering a wide range of train speeds (for the consideration of batches of crossing events) and three different track irregularity profiles to

verify the robustness of the proposal regarding track conditions. The damage scenarios were chosen based on two of the several possible failure states in a HSR bridge infrastructure: i) Type D1, characterized by a local reduction of the bridge deck flexural stiffness ($E_B I_{By}$)

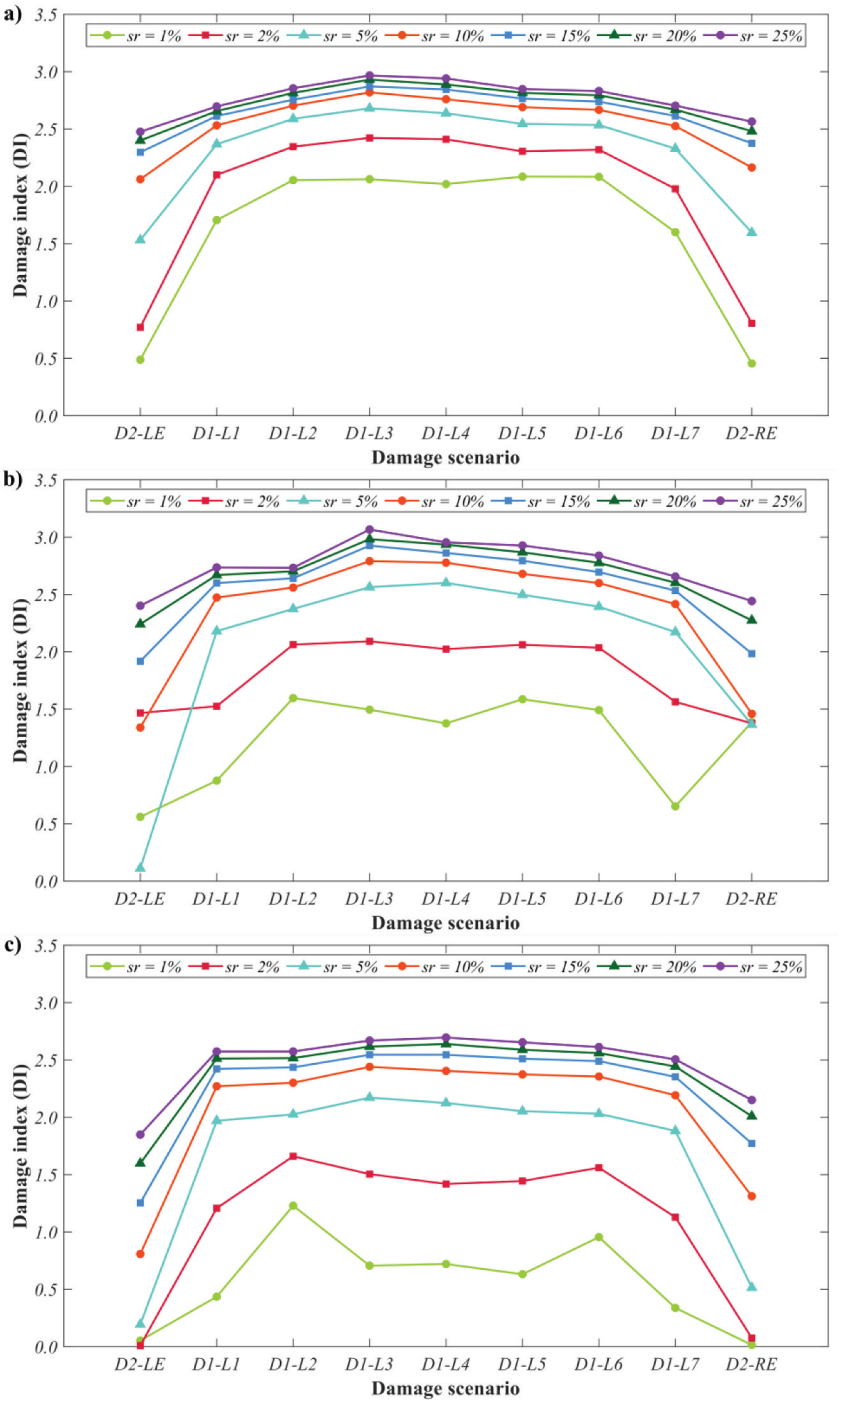

Figure 4. Damage index based on the bogie responses for the different damage scenarios considered in this study, and for different track conditions: a) NC, b) LD, and c) HD.

at a cross-section of the structure, and ii) Type D2, related to a loss of the vertical stiffness in a bearing device (K_{Bz}).

All the simulated damage scenarios consider only one damage location; nevertheless, different locations of damage were evaluated as illustrated in Figure 3. Damages type D1 were assessed at sections with a length of 1.5 m located at the first, second, third, …, seventh eighths of the span and labeled as D1-L1, D1-L2, …, D1-L7, respectively. The damage scenarios designated by D2-LE and D2-RE refer to those where the vertical stiffness reduction was considered in the bearing devices of the bridge located at its left and right ends, respectively. The stiffness reduction (sr) levels assumed for all damage scenarios were sr =1 %, 2 %, 5 %, 10 %,15 %, 20 % and 25 %.

A total of 45 simulations were conducted for baseline states, combining the range of 15 train speeds (v =180, 190, 200, …, 320 km/h) with three types of track conditions: track irregularities not considered (NC) and track irregularity profiles of quality low disturbance (LD) and high disturbance (HD), generated according to German track irregularity PSDs. For the damage scenarios, 1029 simulations were carried out for the damages type D1 and 294 for the damages type D2, combining the same three types of track conditions as for the baseline scenarios with the range of 7 train speeds (v =190, 210, 230, …, 310 km/h) and the damage location and severity.

3.3 *Damage index performance*

This section presents the efficiency of the proposed drive-by damage detection methodology by using a DI (Eq.(4)) based on the KL divergence between KDE distributions for baseline and damage scenarios fitted on the vehicle responses from batches of crossing events of the same train.

Figure 4 illustrates how the DI values vary significantly for various bridge conditions, as calculated from signal records of onboard sensors on the bogies, regardless of the track operational conditions. For the baseline, the magnitude of DI is highly near zero and, therefore, omitted. The robustness of the proposed method is displayed by the sensitivity of DI magnitude in distinguishing different damage severity, even and mainly for the lower levels. This aspect is particularly appealing when it comes to early-stage damage identification. The reason why the difference in the magnitude of the damage indices between cases with greater severity becomes less distinct is explained by the KDE of the MAE distribution. As the severity of the damage increases, the KDE curves of the MAE distributions tend to assume a similar shape, resulting in divergence values with respect to the baseline scenario that are less discrepant.

The results demonstrate the ability of MFSC to highlight the most significant energy content observable (here by the adapted Mel-frequency scale). In addition, in combination with the temporal-spatial resolution of the STFT, MFSC-based features successfully address the well-documented challenge of identifying damage in regions close to the bridge's supports under operational conditions. Similar results were obtained for the DI values calculated from signal records of onboard sensors on the carbodies.

4 CONCLUSIONS

The present work introduced a novel approach for HSR drive-by bridge damage detection utilizing adapted Mel-frequency damage-sensitive features in association with deep learning algorithms (sparse autoencoders) to produce a statistical distribution-based damage index. The suggested methodology for indirect SHM in the railway field uses vehicle responses from multiple instances of a service train crossing the target bridge, which were simulated using a 3D VTBI model implemented in Matlab®.

The trained SAE models can effectively and accurately represent the feature space related to vehicle responses for healthy conditions and generate reconstructed Log-Mel spectrogram with error distributions whose KL divergences display sensitivity to the damage in the bridge. Mel-spectrogram features, in turn, can convert the temporal representation of the vehicle acceleration signals into a comprehensive representation of frequency, time, and intensity (power) in higher dimensions. This characteristic renders Mel-frequency cepstral features very compatible with autoencoder architectures. The results indicate that the proposed approach

provides a damage index that can successfully identify the presence of localized damage along the span and at their ends. It can also distinguish its severity (mainly for early-stage damages), regardless of train speed, sensor position, and environmental and operational variations such as track irregularities and artificial noise. Such results suggest the potential of applying Mel-frequency damage-sensitive features associated with machine learning algorithms in the drive-by assessment of high-speed railway bridges based on their existing conditions.

ABSTRACT: Bridges are a neuralgic point for robust rail transport. Increasing rail traffic over the next years, combined with new vehicle developments, will lead to increased loads, especially in bridge transition areas. This requires regular network-wide monitoring to ensure safety standards and is associated with high maintenance costs.

DB Systemtechnik GmbH has successfully deployed the Continuous Track Monitoring (CTM) system, which uses sensors on scheduled trains to monitor indirectly and continuously railway tracks. This paper uses a case study to analyse how this concept can be extended to the monitoring of bridge transitions without modifying the CTM. By comparison with sleeper responses measured directly in the transition area of a tied arch bridge, it is shown that the CTM can reliably capture both the magnitude and time span of recurrent changes in track bedding or ballast deterioration, allowing optimised maintenance planning, thereby reducing costs and increasing reliability.

1 INTRODUCTION

The development of trains, marked by increasing speeds and new innovative axle configurations intensifies the demands on railway infrastructure (Karimi 2020). This challenge is acute in the transition zones of railway bridges, where abrupt stiffness changes and differential track settlements result in amplified dynamic wheel loads. These forces accelerate the deterioration of ballast and track settlements (Pannese et al. 2020, Wang & Markine 2019). This deterioration often manifests as white spots, indicating a need for frequent maintenance interventions to maintain track geometry (Lichtberger 2005). The transition between soft embankment and very stiff abutments and bridges with interruption of the ballast bed, as found in bridges with open decks, are particularly affected.

The ballast layer, a crucial element for track geometry and maintenance costs, can account for up to 30 % of total superstructure maintenance costs (Lichtberger 2005). In the Netherlands, the frequency of maintenance in transition zones is up to eight times higher compared to open tracks (Wang & Markine 2019, Wang et al. 2018). As a result, maintaining these transition zones represents a significant financial effort, with annual costs reaching approximately $ 200 million USD in the USA in 2012 and $ 110 million USD in Europe in 1999 (Pannese et al. 2020, Wang et al. 2018). Infrastructure managers are responding to this situation in new

DOI: 10.1201/9781003483755-203

bridges by designing the transition zones accordingly (no inclined support structure terminations, cement wedges, drag plates), but for a large number of existing transition zones, major interventions are associated with large investments. Despite its critical importance, the majority of differential track settlements at bridge transitions are currently assessed through visual inspection, which may be ineffective in the early stages (Pannese et al. 2020).

The increased rail traffic on our current infrastructure intensifies existing challenges, particularly limiting the time available for crucial inspections and maintenance (Lorenzen et al. 2023). This situation underscores the importance of regular monitoring to control track alignment and prevent potential disruptions or derailments (Falamarzi et al. 2019). Addressing this need, the Continuous Track Monitoring System 2.0 (CTM 2.0), developed by DB Systemtechnik GmbH, has been a key innovation. This system, which has been in operation for more than two decades and has been installed on regular trains, enables continuous monitoring of railway infrastructure. It plays a key role in early fault detection and improves maintenance planning (Lorenzen et al. 2023).

As already mentioned, the CTM system has been in use successfully for a long time, but only for the originally developed case of track geometry monitoring. The objective of this paper is to extend the scope of the measurement system. Therefore, it will be investigated whether and how the measurement data of the CTM 2.0 system can be used to monitor bridge transitions and in particular white spots throughout the network during regular train operations. By analysing the track geometry as determined by the CTM 2.0 together with sleeper responses directly measured and recorded by a long-term monitoring system.

2 CONTINUOUS TRACK MONITORING SYSTEM 2.0

The CTM is an indirect measurement system that uses acceleration sensors on axle boxes to continuously monitor track quality. The system consists of sensor boxes with sensors, measuring amplifiers, data recorders, positioning systems and data transmission devices (see Figure 1). The modular design and the use of standard industrial components ensures that the components can be easily replaced or improved individually. The system is also designed to be installed on regular scheduled trains. In this way, regular traffic is not interrupted for monitoring purposes and maintenance costs of CTM are kept to a minimum.

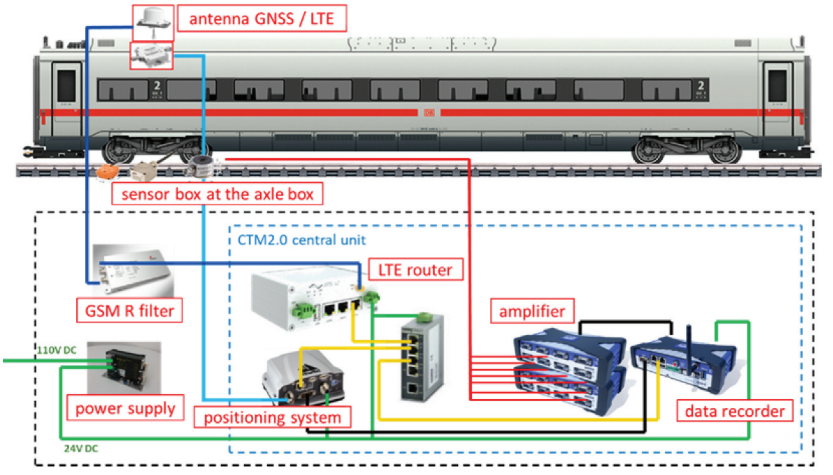

Figure 1. Principle of the CTM 2.0 measuring system.

Unlike the first generation CTM 1.0, the second generation CTM 2.0 transmits all acceleration data directly from the vehicle to the office. In addition, the position and speed are continuously recorded to determine the location of each measurement point and to match the

results to the corresponding tracks. Longitudinal track irregularities are calculated in the office by analysing the accelerations measured at the axle boxes within the wavelength limits of the European standard EN13848 (DIN EN 13848 2019). Finally, the results can be compared with those of other inspection vehicles. The validation of the CTM 2.0 shows an exact match with other inspection vehicles. Furthermore, the CTM measurement uncertainty of the vertical track geometry is less than 0.5 mm considering 20 test drives (Wolter 2021).

This system (see Figure 1), developed by DB Systemtechnik GmbH, has now been in use for more than two decades for the assessment of the track geometry of the superstructure. During this time, it has been continuously improved on the basis of operational experience and feedback from infrastructure managers. This has resulted in the ability to meet the wide range of requirements of vehicle owners, measuring system operators, and infrastructure managers. Ensuring that the system does not affect vehicle operation or require additional maintenance is essential for vehicle owners. For system operators, the system must be self-sufficient and fully autonomous. Automated monitoring reports and results must be provided for integration into existing maintenance databases. Infrastructure managers need to have valid and comparable results that can be evaluated against infrastructure operator standards (Wolter & Liu 2021).

DB Netz AG currently has a fleet of CTM measurement systems of different generations in operation, which are used by DB Systemtechnik GmbH to continuously monitor more than 14,000 kilometres of track in Germany on behalf of DB Netz AG. The results obtained are regularly made available to DB Netz AG to improve track maintenance. The monitoring data make it possible to detect faults at an early stage, facilitate the specific planning of repair work and allow the quality and sustainability of repairs to be checked. Figure 2 shows the lines operated by DB Netz AG on which the CTM track measurement systems are used for continuous monitoring.

Figure 2. Map of lines that are continuously monitored with CTM track measurement systems.

3 CASE STUDY: TIED-ARCH STEEL BRIDGE

3.1 *The tied-arch steel bridge*

The structure (see Figure 3) in this case study is a double-track tied-arch steel bridge with a span of 77.5 m. As part of the ZEKISS research project, this bridge was instrumented with various acceleration and strain sensors and monitored for over a year from January 2022 to March 2023. The CTM 2.0 monitoring area also includes this bridge.

During an on-site visit at the beginning of May 2021, a white spot was detected in the superstructure of the bridge transition (see Figure 3a). Strong pumping of the sleepers in this area was also observed during train crossings. This white spot is the result of a defective drainage in the backfill area, which can be noticed as well by vegetation in the superstructure (see Figure 3a). The defect was rectified during a maintenance operation (see Figure 3b). Another relevant maintenance operation was the ballast tamping of the analysed line section in Sept./ Oct. 2021.

For these reasons, the investigation of the temporal evolution of this spot was a monitoring task. So, an acceleration sensor was instrumented on a sleeper (see Figures 3c). A capacitive accelerometer from PJM was used, which has a measurement range of ±10 g and can record accelerations in the low frequency range. The position of the acceleration sensor can be obtained from the blueprint of the bridge (see Figure 4). The white spot is located behind the bridge in direction of travel 2. The position of the bridge on the line is marked for comparison with the indirect monitoring.

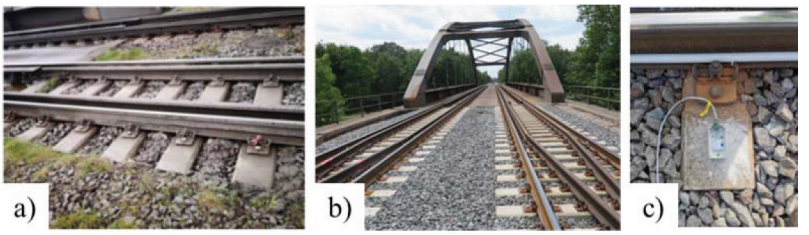

Figure 3. a) white spot in the transition area with vegetation, b) same spot after repairing the drainage, c) installation of the acceleration sensor on the sleeper.

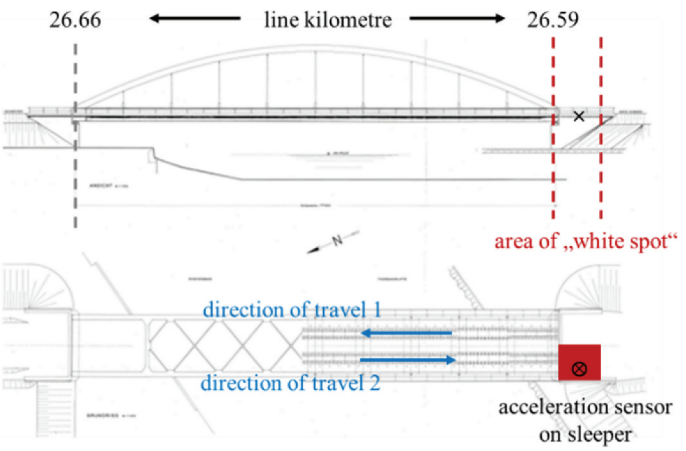

Figure 4. Blueprint of the bridge; red: area of white spot, blue: direction of travel, black circle: position of the acceleration sensor.

Over 85,000 crossings were recorded and analysed. Figure 5 shows the max.-min.-spans of the measured accelerations (range between minimum and maximum acceleration values) of all crossings for each month in a violin plot. The edges indicate a kernel density function fitted to the data. A temporal trend over time is visible. The mean value of the max.-min.-spans which is marked by a dash increases while the outliers of the max.-min.-spans (see dots in Figure 5) have no particular pattern. These values probably result from hard impacts due to non-round wheels. This tendency can be clearly seen by comparing the empirical probability distributions

of the max.-min.-spans for different time periods (see Figure 6). A significant increase in the empirical probability of large max.-min.-spans can be seen towards the end of the measurement campaign.

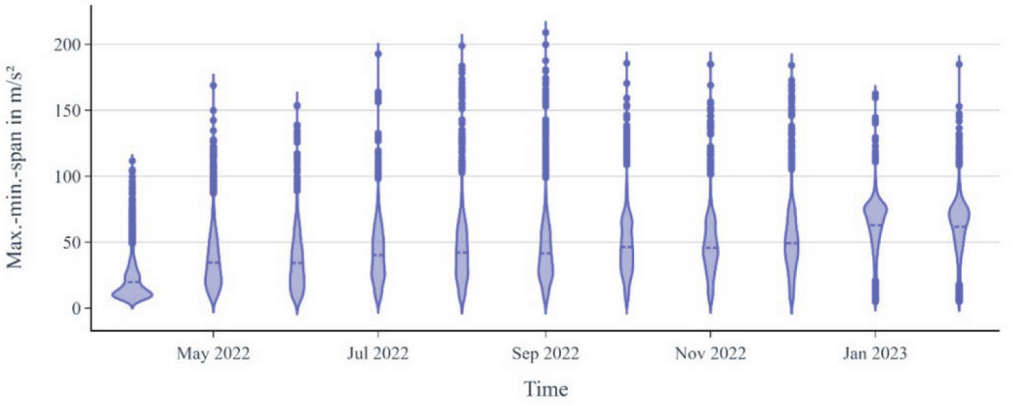

Figure 5. Max.-min.-spans of sleeper acceleration (measured with sensor on sleeper) plotted over time (85,188 train crossings).

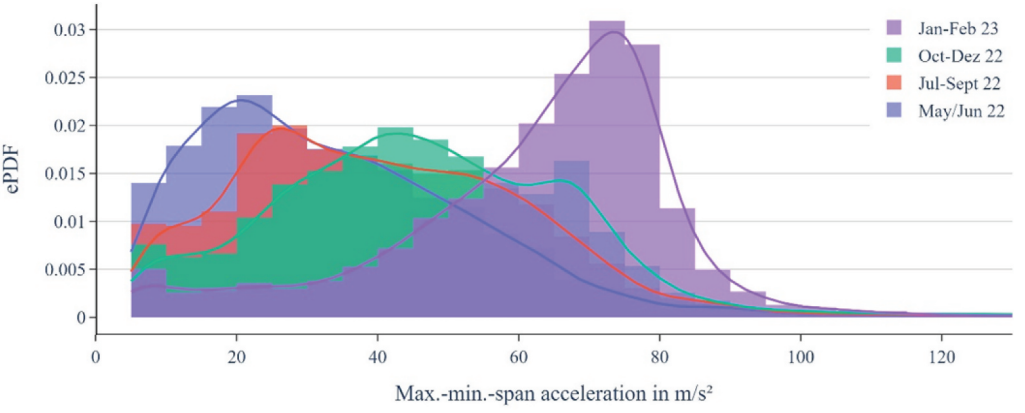

Figure 6. Empirical probability density function (ePDF) of the max.-min.-spans for four time periods.

This observation is analysed below by directly comparing the signal of vertical accelerations of the sleeper from the period May 2022 with March 2023 under the passenger train BR4010 (axle loads approx. 12 t). This vehicle is in May 2022 actually faster (approx. 180 km/h) than in March 2023 (approx. 140 km/h). However, the accelerations in March 2023 are about 3 times higher (compare Figures 7, 8) The displacement signals integrated from the accelerations also increase from about 1.0 mm (May 2022) to about 2.4 mm (March 2023). The detailed view shows a small peak in the displacement curve, which probably occurs when the sleeper touches the bottom of the void (Sysyn et al. 2020). This peak is about 0.2 mm in May 2022 and about 1.5 mm in March 2023.

3.2 *Evaluation of the CTM 2.0 measurements*

A total of 71 crossings in direction 2 are available for analysis of the white spot in the period from August 2020 to March 2022. As an example, the vertical track geometry according to DIN EN 13848 (DIN EN 13848 2019) of the left axle box can be plotted for all available

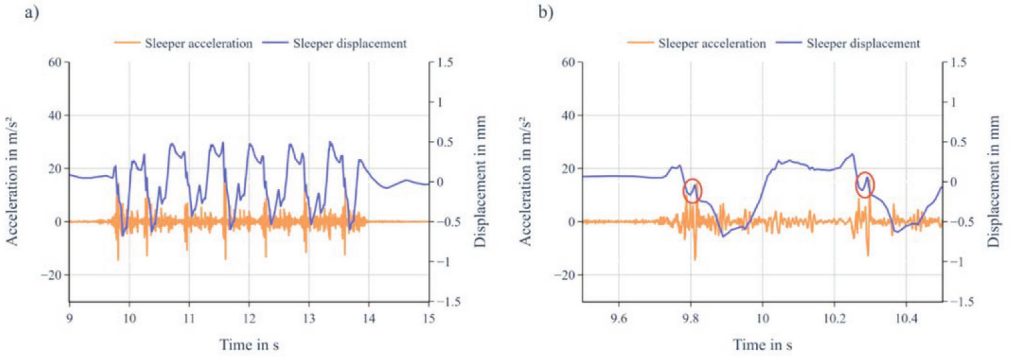

Figure 7. a) acceleration and displacement signal of sleeper (BR4010, 180 km/h, May 22), b) detailed view.

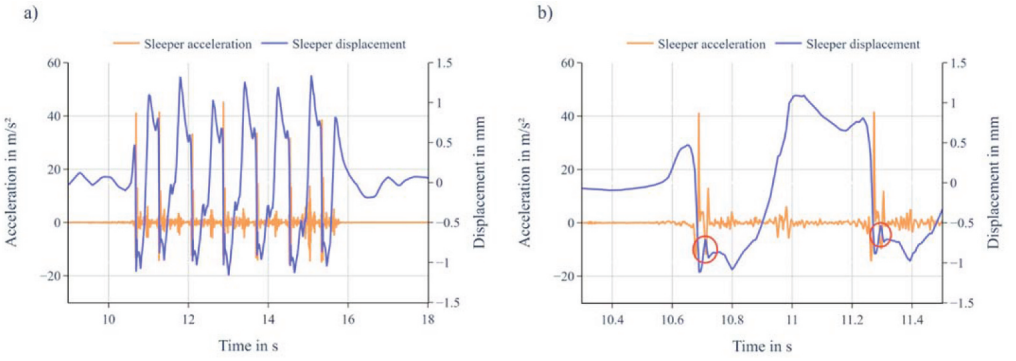

Figure 8. a) acceleration and displacement signal of sleeper (BR4010, 140 km/h, Mar 23), b) detailed view.

crossings over the line kilometre (see Figure 9). The vertical track geometry is the z-direction of a cartesian coordinate system, where the x-direction indicates the direction of travel of the train. It therefore indicates the deviation perpendicular to the running surface (height of rail running surface from smoothed vertical position) (DIN EN 13848 2019). The blue colour indicates the crossings between August 2020 and October 2021, and green shows the crossings between November 2021 and March 2022. With the CTM's positioning system, the bridge (see Section 3.1) can be located in the grey area. The white spot is hatched in red (see also Figure 4). Figure 9 reveals that the vertical track geometry is highest in the transition areas. The most prominent peak is in the area of the white spot. Large variations in the track geometry can as well be observed there.

In direction 1 in total 80 crossings are available, which can be visualised in an equivalent manner for comparison purposes (see Figure 10). Looking at the bridge transitions in this direction of travel (1), there are also peaks visible indicating increased stresses. However, the variation and magnitude of the peaks is much smaller compared to the white spot in opposite direction (2).

In both directions, two characteristic profiles of the vertical track geometry with different peak values are visible. In the following the different profiles can be explained by tamping operations in Sept./Oct. 2021.

In order to analyse the white spot, the area highlighted in red (see Figure 9) is extracted for further investigations. The max.-min.-spans of the vertical track geometry are derived in a similar way to the evaluation in Section 3.1, but now for the CTM system and no longer for the accelerometer on the sleeper. In addition, the corresponding max.-min.-spans of the

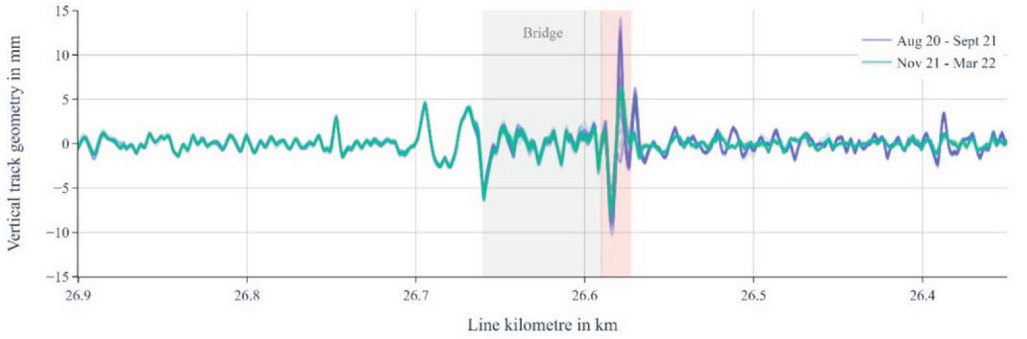

Figure 9. Vertical track geometry (measured with CTM's left axle box) according to DIN EN 13848 of all available 71 crossings plotted over the line kilometre (direction of travel 2); grey: location of the bridge, red: area of white spot.

Figure 10. Vertical track geometry (measured with CTM's left axle box) according to DIN EN 13848 of all available 80 crossings plotted over the line kilometre (direction of travel 1); grey: location of the bridge.

opposite direction (1) are extracted for comparison as well. All of these max.-min.-spans can be plotted over time (see Figure11). The colours in Figure 11 are chosen according to Figures 9 & 10 to emphasise the respective changes in the vertical track geometry. A clear increase in the max.-min.-spans over time can be seen, interrupted in form of steps. These steps are caused by tamping operations, which initially leads to an improvement in the bedding of the track. The bedding is then reduced over time due to the stresses on the track bed in the transition areas, which is reflected in an increase of the max.-min.-spans. The different colours chosen, as in Figures 9 & 10, now allow the different characteristic track geometry profiles to be associated with the tamping operations. This is plausible as tamping significantly and permanently changes the track geometry, which must be reflected in the measurement. In direction 2, the profiles only differ from the white spot onwards. This can probably be explained by the partial tamping of the fault with a single fault tamping machine, as the white spot was already known to DB Netz AG.

It can be observed that a change in the track bedding or a deterioration of the superstructure in areas of bridge transitions leads to an increase of peaks in track geometry profiles, so that the different extreme values can be interpreted as strong indication of a changed bedding behaviour. This change is particularly evident in white spots and can be seen in the measurement data in the much stronger increase in the extreme values compared to the opposite direction (1) without a white spot. The max-min-spans of the vertical track geometry is therefore well suited for monitoring changes in bridge transition areas.

The day of the on-site visit (see Section 3.1) is also marked (dashed black line in Figure 11) and is relatively close to the next tamping operation. The values in this period are high, indicating that the observations on the bridge (strong pumping of the sleepers) are consistent with the evaluation of the CTM. The period that overlaps with the monitoring of the tied arch bridge is marked in grey. The start of the bridge monitoring is therefore shortly after a tamping operation. This is also consistent with the analysis of the sleeper acceleration measurements in the white spot. Thereby it was found that the accelerations and displacements of the sleeper were low at the beginning and increased monotonically during the measurement campaign. The time between tamping operations could be recorded and the deterioration of the bedding be determined, as with the CTM one cycle before. Both the time span (slightly more than 1 year) and the magnitude of the changes (about a factor of 3) correspond between the indirect monitoring (CTM) and the measurement on the sleeper. A more detailed comparison of the two measurements was not conducted because the overlap of the measurement periods is small.

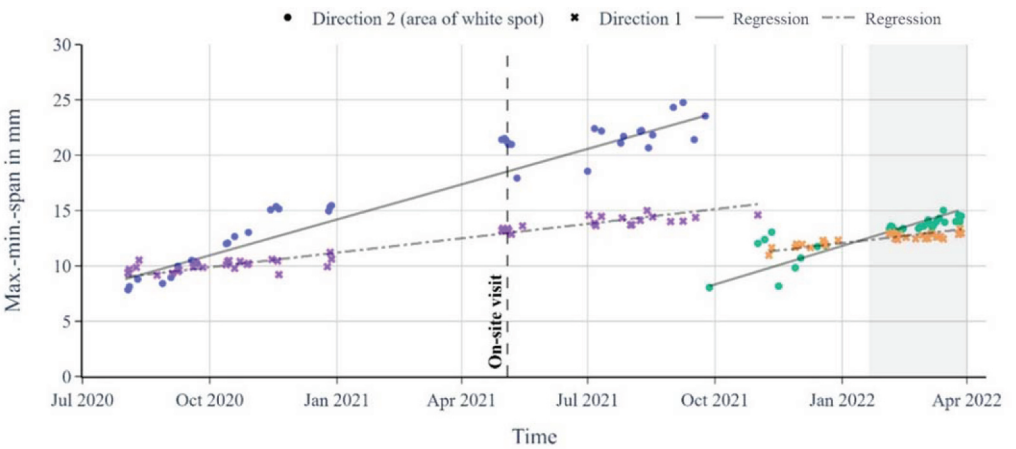

Figure 11. Max.-min.-spans of the vertical track geometry (left axle box) over time; colours chosen according to Figure 9 & 10, grey: period which overlaps with the tied-arch steel bridge monitoring.

4 CONCLUSION

In this paper, the CTM 2.0 system from DB Systemtechnik GmbH, which can be installed on regular scheduled trains, has been investigated to show its potential for monitoring bridge transitions. Using a case study of a transition zone of a tied-arch steel bridge, it was shown for the first time that the CTM 2.0 system can effectively monitor ballast deterioration in bridge transition areas, which had not been evaluated yet. No adjustments to the system are required as the track geometry measurement that is conducted anyway was used. The paper proposed the use of max.-min. spans for monitoring, which made it possible to reliably capture the changes that occur over time. The comparison with a direct measurement on a sleeper shows that both the magnitude and the time span of the recurrent changes in track bedding can be consistently obtained.

In future it could be possible to optimise tamping operations or maintenance with indirect measurements, by defining limit values based on metrics such as empirical variance, gradients, etc. White spots or voids could be detected in the form of outlier detection, as the changes here are much more significant. However, further measurements or a larger data set are required to make a more detailed comparison between the direct sleeper monitoring in the area of the white spot and the indirect monitoring (CTM), as the overlap of the measurement periods in this case is very small. Especially for the definition of the limit values an analysis

with a data set representative for the rail network must be carried out. At the same time, this data set can be used to create possible prediction models for the optimisation of the planning of tamping operations.

It can be concluded that the CTM system has the potential to monitor bridge transitions and in particular white spots throughout the network during regular train operations in a cost-saving manner, thereby increasing the safety and reliability of train operations.

Drive-by monitoring to assess railway bridge accelerations

S.R. Lorenzen, M.M. Rupp & C. Hübler
TU Darmstadt – Institute of Structural Mechanics and Design, Darmstadt, Germany

ABSTRACT: This study explores the use of drive-by monitoring as an alternative to conventional bridge-mounted sensors for monitoring maximum accelerations in railway bridge structures, a key factor in maintaining track ballast stability. Given the extensive rail network and the ongoing development of railway vehicles, traditional methods using bridge sensors require considerable effort, highlighting the need for a more efficient approach. This work analyses data from two field tests, using an ICE 4 train on a bridge with a 19.5 metre span and an ICE TD on a 16.4 metre span bridge, with synchronised acceleration measurements taken from both the train's axle boxes and the bridge's main girders. This allows for a direct comparison between the new drive-by approach and a conventional bridge sensor-based approach. Results indicate that axle box acceleration sensors in a drive-by approach are effective in monitoring bridge accelerations.

1 INTRODUCTION

Railway bridges have a considerable service life, with the average lifespan in Germany reaching 122 years (Knapp 2019). During this time, railway vehicles undergo numerous evolutionary stages, resulting in significant increases in axle loads and speeds (Karimi 2020). These changes pose challenges to these bridge structures beyond the original design expectations. Particularly problematic situations occur when changes in axle spacing and speed induce resonances in the bridge structures where no resonant excitations were expected (Firus *et al.* 2018, Matsuoka *et al.* 2021). This scenario can cause substantial accelerations and deflections in the structures. To ensure the stability of the track ballast, the maximum vertical acceleration of ballasted bridge structures is limited to 3.5 m/s² by the Eurocode (German Institute for Standardisation Registered Association 2021). However, Austrian regulations also allow accelerations of 6 m/s² for existing ballasted bridges (Austrian Standard Institute 2014).

Due to the large number of bridges in the network, combined with the continuous development of vehicles, conventional monitoring methods using sensors on the bridge structure would require a tremendous amount of work. A cost-effective alternative for monitoring acceleration limits could be the implementation of drive-by monitoring. The concept of drive-by monitoring was proposed about 20 years ago (Yang *et al.* 2004). Since then there has been a lot of research and development. An overview of the research conducted in this area can be found in (Yang and Yang 2018, Malekjafarian *et al.* 2022 and Souza *et al.* 2023). However, to the best of our knowledge, despite its practical importance, the topic of acceleration assessment has not yet become a focus of the community.

This paper analyses data from two field tests, where synchronised acceleration measurements were conducted on the main girders of the bridge and the axle boxes of the train. An ICE 4 was used on a bridge with a 19.5 metre span, and an ICE TD on a bridge spanning 16.4 metres.

DOI: 10.1201/9781003483755-204

2 FIELD MEASUREMENTS

2.1 *ICE 4 on Schmutter Bridge*

The first measurement campaign was initiated during the introduction of the ICE 4 in 2017. A comprehensive background, detailed description and analyses of the measurement data can be found in Firus *et al.* 2018, Firus 2021 and Lorenzen 2023. The Schmutter Bridge (see Figure 1) is a single-span, double-track, simply supported structure, with a span of 19.5 metre, consisting of two separate steel box girders coupled via track ballast. It was equipped with 44 accelerometers, positioned at 1.95 metre intervals along 11 structural axes (see Figure 2). Seven accelerometers were not available for all crossings; these are marked in white, while all others are marked in red. For this study, we focused on the four acceleration sensors located on axis 6 (labelled as A6, B6, C6, & D6), each with a measurement range of ± 5 g. These sensors were connected to HBM MX840B amplifiers and recorded data at a frequency of 1200 Hz.

The test train, a 12-car ICE 4, was equipped with 8 accelerometers on the axle boxes of cars 8 and 9 (labelled T_1 to T_8), each with a range of ± 100 g (see Figure 3). These sensors were connected to HBM 1-ML801B amplifiers to acquire data at 2400 Hz.

During the campaign, a total of 52 crossings were performed, 26 in each direction. Axles were detected by photoelectric sensors positioned at both ends of the bridge, to facilitate tracking of average speed (see Figure 4). A constant speed was a valid assumption considering the train driver's adherence to the set speed instructions and the minimal speed variations in the area. Axle spacing, axle loads and the traveled speeds are detailed in Firus 2021.

To synchronise the data between bridge and train, coils and magnets were attached to the rails and the train. This setup triggered the measurement system whenever the magnets passed over the coils.

The first bending frequency of the bridge structure, identified with covariance-driven stochastic subspace identification (SSI-COV) using free decay signals, showed significant amplitude dependence, fluctuating between approximately 5.1 Hz and 5.8 Hz (Lorenzen *et al.* 2022a and Lorenzen 2023). To ensure a consistent comparison of the frequency content and to retain the dominant vibration mode, while eliminating transient signals, both the train acceleration data and the bridge measurements were filtered using a 4th order Butterworth filter with a cut-off frequency of 8 Hz.

Figure 1. Schmutter bridge with a crossing ICE 4.

2.2 *ICE TD on Garather Bach Bridge*

In 2022, the second measurement campaign analysed in this study involved the ICE TD train on the Garather Bach bridge (see Figure 5). This bridge was equipped with a permanent monitoring system as part of the ZEKISS research project. Detailed discussions of these measurements and data analyses from the bridge are available in Lorenzen *et al.* 2022b, Lorenzen 2023 and Lorenzen *et al.* 2023 with specific focus on the ICE TD measurements in Lorenzen 2023 and Rupp *et al.* 2023.

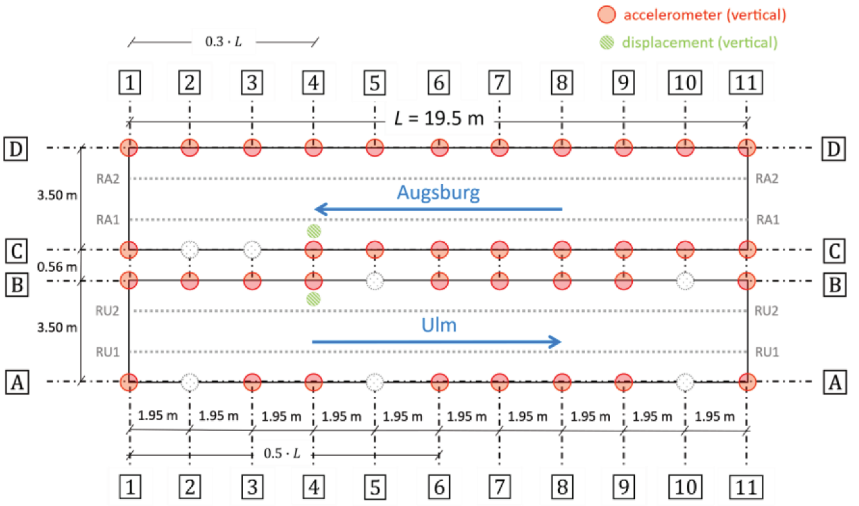

Figure 2. Sensor setup installed on the schmutter bridge.

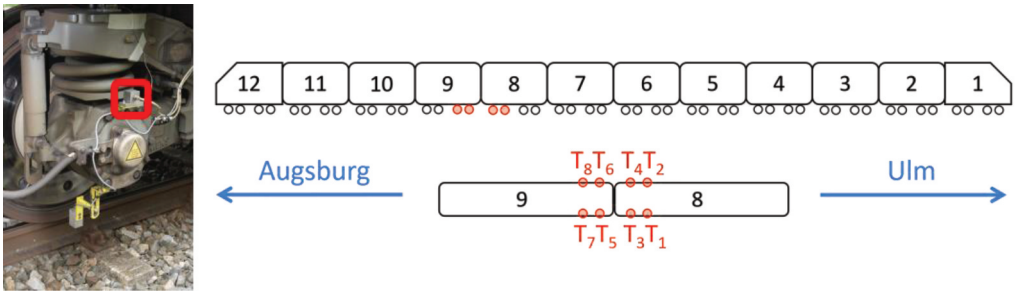

Figure 3. Sensor setup installed on the ICE 4.

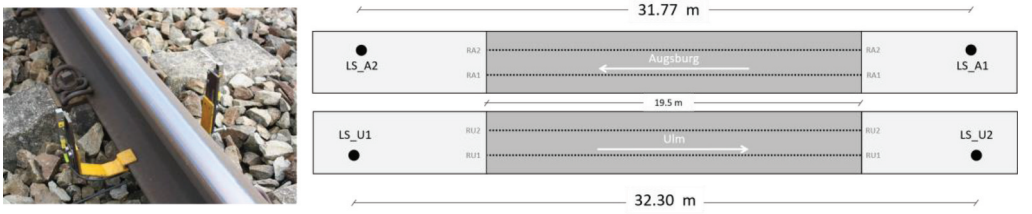

Figure 4. Photoelectric sensors for axle detection.

The Garather Bach bridge is a single span, single-track, simply supported steel trough bridge with a ballasted superstructure and has a span of 16.4 metres. Our study focused on two acceleration sensors (A2 & A7; see Figure 6) each with a measurement range of ± 5 g. These sensors, connected to HBK MX1601B measuring amplifiers, recorded data at a frequency of 1000 Hz. To track the train's axles, strain gauges G1 and G5 were used on the rails, also connected to HBK MX1601B amplifiers. The signals were sampled at 5000 Hz.

In addition to the bridge instrumentation, the 4-car ICE TD train was equipped with 32 accelerometers (labelled as T_{1L} to T_{16L} & T_{1R} to T_{16R}), each with a ± 100 g range, mounted on the axle boxes as shown in Figure 7. These devices were connected to a HBK QuantumX MX1601B and 3 QuantumX MX840B amplifiers, with a sampling rate of 5000 Hz. Five accelerometers failed during the test; they are marked in grey and were excluded from the analysis (see Figure 7).

Figure 5. Garather Bach bridge with a crossing ICE TD.

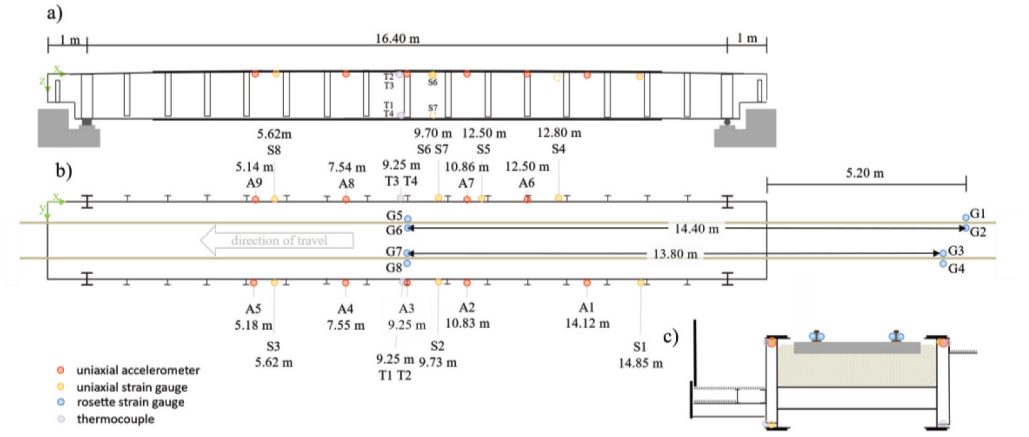

Figure 6. Permanent monitoring setup installed on the Garather Bach bridge. a) side view b) top view c) cross section.

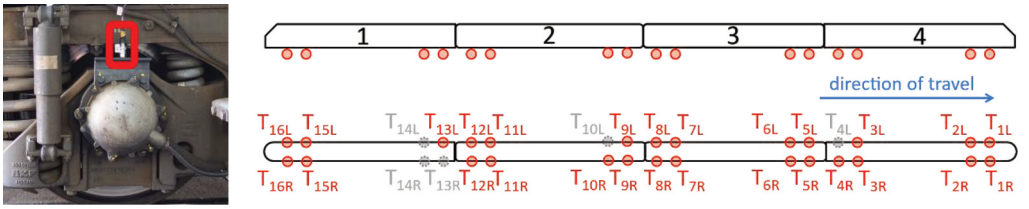

Figure 7. Sensor setup installed on the ICE TD.

During the measurement campaign, 13 crossings were recorded. However, one crossing was carried out at less than 10 km/h and the bridge accelerations are extremely low, so only 12 crossings were analysed.

To determine the train's position, two 1-GPS-USB-18Hz (HBK) Multi-GNSS receivers were connected to the measurement computer. A GPS module of the same type was installed on the bridge. By using the satellite timing from these GPS receivers, we synchronised the data from the train and bridge systems.

Like the Schmutter bridge findings, the first bending frequency of the Garather Bach bridge, identified with SSI-COV using free decay signals, showed significant amplitude dependency, ranging between approximately 5.6 Hz and 6.5 Hz (Lorenzen *et al.* 2022b and Lorenzen 2023). As in the previous section, we applied the same methodology for data consistency. Both the train and the bridge accelerations were filtered using a 4th order Butterworth filter with a cut-off frequency of 8.5 Hz. The cutoff frequency is therefore 0.5 Hz higher than before, the reason for this is that the bending frequencies are slightly higher for this bridge. This approach was chosen to ensure a uniform comparison of frequency content, while preserving the dominant vibration mode and eliminating transient signals.

3 METHOD FOR COMPARISON OF AXLE BOX WITH BRIDGE ACCELERATIONS

Due to track irregularities, the data collected by the acceleration sensors on the axle boxes is speed dependent. Owing to the brief contact period, it is reasonable to assume that the train's speed remains approximately constant during these intervals. Consequently, each sensor is subject to identical speed-dependent effects. The solution to this issue is to use the residual signal, which is obtained by subtracting the phase-shifted signal of a preceding axle from the signal of the current axle (see Figure 8).

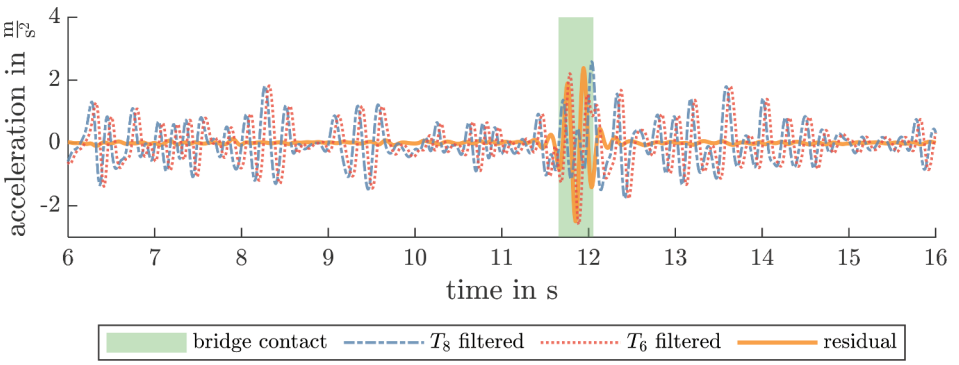

Figure 8. Filtered signals T_8 and T_6 (ICE 4), along with the residual signal, showing the contact time on the bridge during a crossing towards Augsburg.

In the first field test (see Section 2.1), only four axles were instrumented, and the residual was always calculated with respect to the axle immediately in front in direction of travel. In the second field test (see Section 2.2), the first axle was also instrumented, so the first axle residual was always used. The first axle residual is advantageous as the bridge vibration is still minimal.

To compare the accelerations, the maximum absolute value of the accelerations of the residual signals is compared with the maximum absolute value of the bridge accelerations during the contact period of each axle.

For a quantitative evaluation, we calculated the percentage error between the residual signal from the acceleration measurements on the train and the measured bridge accelerations. Denoting the maximum absolute acceleration on the train as $\max(|a_{\text{train}}|)$ and on the bridge as $\max(|a_{\text{bridge}}|)$, both being positive real numbers, the percentage error $E_{\%}$ is defined as:

$$E_{\%} = \frac{\max(|a_{\text{train}}|) - \max(|a_{\text{bridge}}|)}{\max(|a_{\text{bridge}}|)} \cdot 100\% \tag{1}$$

We consider $\max(|a_{\text{bridge}}|)$ to be the true or target value. We did not use the absolute value of the difference to preserve the sign, thereby indicating whether the values are overestimated or underestimated. For the summary of all crossings, the absolute values of the percentage errors were also calculated as follows:

$$|E_{\%}| = \frac{|\max(|a_{\text{train}}|) - \max(|a_{\text{bridge}}|)|}{\max(|a_{\text{bridge}}|)} \cdot 100\% \tag{2}$$

Before presenting the results, it should be noted that, due to the characteristics of the sensors, a larger relative error is to be expected at lower accelerations. In addition, the determination is based on the residual signal. This means that, depending on the phase shift of the signals, which in turn depends on the axle spacing and the speed travelled, the bridge vibration is either amplified (with opposite sign) or attenuated (with the same sign). Furthermore, if the ratio of travel speed to bridge frequency is too high, it is no longer guaranteed that the sensor will be close to the centre when the maximum amplitude occurs, and will therefore not detect the maximum acceleration, but only a fraction of it.

4 RESULTS

4.1 *ICE 4 on Schmutter Bridge*

In our analysis of the ICE 4 passages over the Schmutter Bridge, we found that it was not possible to derive valid residual signals for the pairings of T_5 with T_7 and T_4 with T_6. This issue arose due to the high dissimilarity between the signals, which prevented effective cancellation of accelerations when subtracting the phase-shifted signals. However, for all other residual signals, we calculated the percentage error $E_{\%}$ according to Equation (1). The errors were compared with the sensor on the same side as the corresponding train sensor. For crossings towards Ulm, this includes T_3 - T_1 and T_5 - T_3 paired with A6, and T_4 - T_2 and T_8 - T_6 paired with B6. For crossings towards Augsburg, this involves T_6 - T_8 and T_2 - T_4 with D6, and T_1 - T_3 and T_3 - T_5 with C6. The results are separated for the directions towards Ulm and Augsburg. Figure 9 shows how the results relate to both train speed and bridge acceleration (see Figure 9).

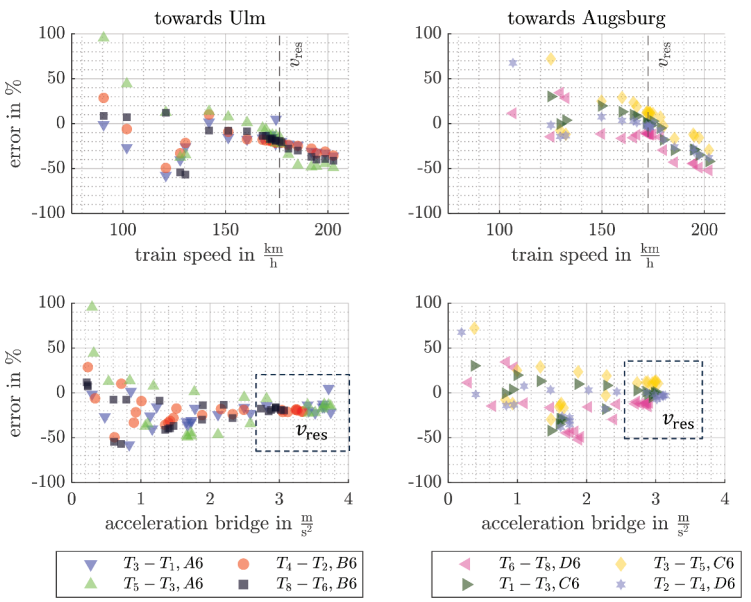

Figure 9. Percentage error in acceleration at the Schmutter bridge, separated by direction of travel.

For both directions, our analysis revealed a negative correlation between the percentage error and the train speed. The train resonance speed, indicated by a dashed line labelled as v_{res}, shows that the error is small near the resonance condition. The minimal errors observed at resonance inducing speeds correspond to high accelerations where small errors are also prevalent. Crucially, in the context of our study, the small errors at high accelerations, close to the threshold, are of primary importance, whereas larger errors at lower accelerations are considered less relevant.

The results are summarised quantitatively in Table 1. The mean values and standard deviations of the percentage error (see Eq. (1)) and the absolute values of the percentage error (see Eq. (2)) are displayed separately for the direction towards Ulm and towards Augsburg.

Table 1. Summary of mean and standard deviation of percentage errors and absolute values of percentage errors from residual signals of axle box accelerations on ICE 4 in comparison to sensor readings on Schmutter bridge.

	Ulm		Augsburg	
	mean in %	std. in %	mean in %	std. in %
percentage error	-18.6	21.2	0.4	40.9
absolute values percentage error	23.8	15.1	21.7	34.6

4.2 *ICE TD on Garather Bach Bridge*

For the second measurement campaign, the percentage error for all axles was determined for the 12 crossings according to Equation (1). The sensors on the left side in direction of travel (T_{iL}) were compared with the bridge sensor A2 and the sensors on the right side in direction of travel (T_{iR}) with the bridge sensor A7. The results are plotted separately for each axle as a function of bridge acceleration (see Figure 10). The plots are arranged line by line according to the coaches, i.e., the first column corresponds to the first axles, the second column to the second axles and so on.

It can be seen that the bridge accelerations tend to be underestimated by the sensors of the first bogie axles (columns 1 and 3) and overestimated by those of the second bogie axles (columns 2 and 4). For high amplitudes, the best results are obtained with the second bogie axles. As the amplitudes of the bridge vibration during the passage of the first and second axle of a bogie are very similar, this behaviour is probably caused by the phase shift relative to the bridge vibration.

The results are summarised quantitatively in Table 2. The mean values and standard deviations of the percentage errors and the absolute values of the percentage errors are displayed separately for the left and right sides.

5 CONCLUSION

To ensure ballast stability, allowable accelerations on bridge structures are regulated by technical standards. However, monitoring actual accelerations using bridge instrumentation is labourious. A more economical approach is the use of sensors on trains. This study aimed to explore, for the first time, the extent to which bridge accelerations can be estimated using train-mounted sensors. Our investigation involved field tests with two different bridges and trains. Both structures could be resonantly excited by the trains, leading to particularly high structural responses potentially critical for ballast stability. However, the tests have shown that there is no destabilisation of the ballast in the supporting structure.

The study of the percentage error between accelerations measured with sensors on the bridge and on the train showed that the error decreases with increasing amplitude. Therefore, in resonance scenarios, our findings indicate that estimating bridge acceleration based on axle

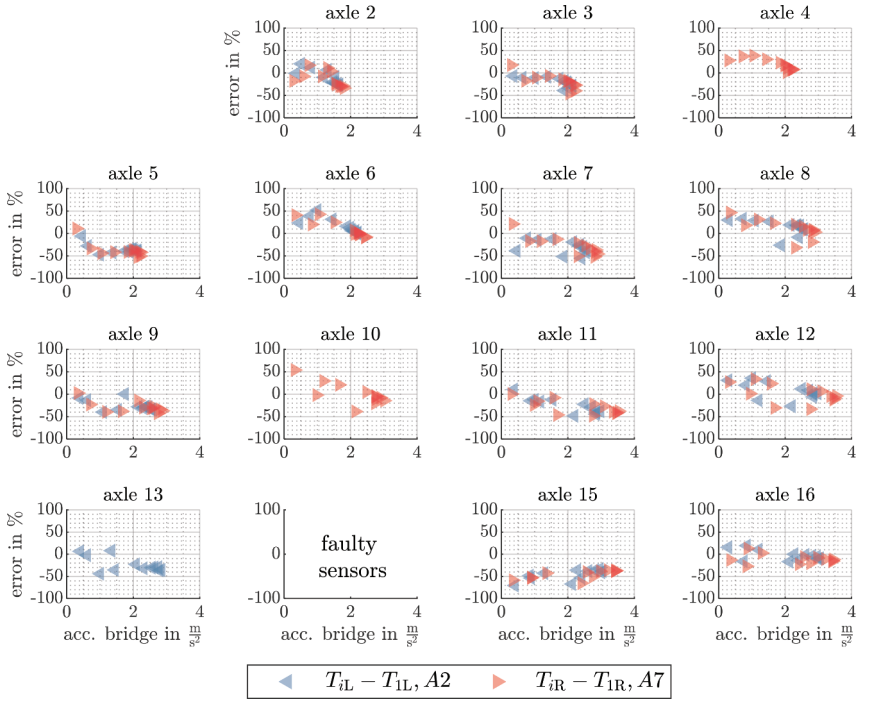

Figure 10. Percentage error for the left and right sensors compared to the bridge sensors separately for each axle.

Table 2. Summary of mean and standard deviation of percentage errors and absolute values of percentage errors from residual signals of axle box accelerations on ICE TD in comparison to sensor readings on Garather Bach bridge.

	left		right	
	mean in %	std. in %	mean in %	std. in %
percentage error	-15.0	24.2	-15.0	25.5
absolute values percentage error	24.2	15.0	24.3	15.4

box accelerations is within an acceptable range for assessing the bridge's accelerations. This holds significant practical value, as it encompasses critical states.

For future studies, it would be beneficial to examine the influence of the relationship between the periods of bridge vibrations and contact times.

ABSTRACT: Bridge dynamic properties can be extracted through the analyses of crowdsourced smartphone-vehicle trip (SVT) data collected during routine trips over bridges. The key advantage of crowdsourced SVT data is the ease in generating large volumes of data at very low costs compared to modern structural health monitoring (SHM) systems. By default, these SVT datasets generally contain measurements from over a dozen sensors embedded within the smartphone. Such SVT metadata are presumed to capture important variables that influence the inherent quality of the vibration data and the resulting accuracy of dynamical property estimates. However, the quantitative relationships between key metadata variables such as vehicle speed or trip direction are not well understood in real-world scenarios. This paper studies how the estimates of the absolute valued mode shapes (AMS) are affected by metadata variables of smartphone-vehicle trip (SVT) datasets. This study considers SVT data collected on two bridges (i) the Golden Gate Bridge in California, and (ii) the Gene Hartzell Memorial Bridge in Pennsylvania and focuses on the influence of vehicle speed and vehicle travel direction. A better understanding how such variables impact the estimation of bridge dynamic properties is critical to the future design and implementation of effective crowdsourcing campaigns.

1 INTRODUCTION

Over the past two decades, researchers have studied methods using sensors in moving vehicles to monitor bridge dynamical properties (Yang and Chang, 2009). The motivation for these "indirect bridge monitoring" methods are rooted in their potential advantages over traditional structural health monitoring (SHM) systems that consist of a distributed sensor network installed directly on the structure (Brownjohn et al., 1992; Smyth et al., 2003; Lynch and Loh, 2006). Indirect modal identification methods for bridges have been developed to determine bridge modal properties by analyzing measurements from sensors that are not installed on the

DOI: 10.1201/9781003483755-205

structure, instead, the sensors are attached to a moving vehicle (Yang et al., 2004; Lin and Yang, 2005).

Early successes were primarily demonstrated in controlled experimental tests or synthetic data, which does not fully represent real-world conditions. Additionally, the integration of mobile sensor networks, particularly leveraging ubiquitous devices like smartphones, has become a focal point in this research field (McGetrick et al., 2015; Yang et al., 2020; Gonzalez et al., 2012; Eshke-´ vari et al., 2019; Eshkevari and Pakzad, 2019; Eshkevari et al., 2020, 2022; Gkoumas et al., 2023; Malekjafarian et al., 2022; McGetrick et al., 2017; Matarazzo et al., 2018; ?; Yang et al., 2020). Although smartphones possess less accurate sensors overall, studies have shown their successful application in SHM.

Recent investigations into indirect methods using smartphone sensors in real-world scenarios, considering factors like operational traffic loading and typical bridge trips, have yielded promising results. Notably, accurate estimates of bridge modal frequencies have been obtained from data crowdsourced during smartphone-vehicle trips (SVT) (Matarazzo et al., 2022). However, crowdsourced SVT data fall into three classes—controlled, partially-controlled, and uncontrolled—based on the analysts' oversight and influence on data collection. The impact of SVT data quality variations, considering trip metadata such as vehicle speed or smartphone model, remains unclear.

In some instances, crowdsourced SVT metadata may signal poor data quality, and including such datasets could adversely affect SHM results. This becomes particularly crucial when dealing with large data volumes, reaching tens of thousands of datasets. For example, crowdsensing platforms with monthly data streams on this scale could greatly benefit from preprocessing tools that filter out noisy or less impactful datasets. This study aims to assess the quality of individual datasets in relation to the overall population, exploring their classification to develop tools that enhance the accuracy of estimation results in SHM.

This paper studies how the absolute mode shapes (AMS) estimates are affected by metadata variables of smartphone-vehicle trip (SVT) datasets. This study considers SVT data collected on two bridges (i) the Golden Gate Bridge in California, and (ii) the Gene Hartzell Memorial Bridge in Pennsylvania. This study focuses on the influence of vehicle speed and vehicle travel direction.

2 SMARTPHONE-VEHICLE TRIP (SVT) DATA COLLECTION

This study analyzes smartphone-vehicle trip (SVT) data collected on the Golden Gate Bridge in California and the Gene Hartzell Memorial Bridge in Pennsylvania. The Golden Gate Bridge (GGB) is located in San Francisco is amongst the world most renowned bridges. It is a suspension bridge with total length of 2740 meters and its main span spans a length of 1280 meters. The GGB accommodates an annual average daily traffic (AADT) volume exceeding 100,000 vehicles. This means even a low rate contribution to the crowdsourced data from vehicles would yield an abundance of SVT data per day. In total 152 SVT datasets were collected in two batches as part of the *Good Vibrations* project Lab (2023). The first batch includes 102 trips collected in a controlled environment, which means variables such as vehicle speed and orientation of smartphone is controlled. The other part was provided by UBER from its ride-hailing fleet, which consists of 50 trips made by a diverse set of drivers and vehicles therefore it is considered as uncontrolled dataset.

The Gene Hartzell Memorial bridge (GHMB) is located in Pennsylvania. This bridge was built in 2001 and is a steel truss bridge with overal lenth of 540 meters and main span length of 180 meters. GHMB is on the PA route 33 and has an AADT of around 59,000 vehicles. For the GHMB 332 SVT datasets were three different batches. 102 trips are collected with vehicles passing with an average speed of 19.6 m/s with little deviation. Another batch of 98 trips are collected with vehicle velocity of 22.2 to 36.1 m/s. With the aid of Pennsylvania department of transportation, another data collection batch was conducted to collect 132 more trips with lower vehicle velocity ranges. The trips are collected using seven different vehicles of the research team. The GHMB has two lane on each travel direction and during

the data collection, the right lane of the northbound was closed by officials and was only used by the research team's vehicles. The rest of the bridge stayed open to normal daily traffic. For this campaign the vehicle speed of the trips ranges between 4.5 to 13.5 m/s.

Each SVT dataset contains over a dozen measurement channels such as acceleration in three directions, vehicle speed, GPS, GPS accuracy, etc. The accelerometer triaxial accelerometer measurements (X,Y, and Z-directions) were sampled at 100 Hz and GPS (latitude, longitude) were sampled at a rate of 1 Hz.This study focuses on vehicle speed and GPS channels and their influence on the estimation of the absolute value mode shapes (AMS) of the bridge.

3 EXTRACTION OF ABSOLUTE MODE SHAPES

The bridge modal properties of interest in this study are the mode shapes. It is assumed that bridge modal frequencies have already been identified. It is important to note that the collected SVT datasets are asynchronous. A methodology proposed in Cronin et al. (2022) is implemented to estimate the *absolute value mode shapes* (AMS) – it is not yet possible to extract mode shape phase information from asynchronous sensor measurements – hence the *absolute value*. The methodology builds an aggregated frequency-space map using wavelet transforms and determines AMS from frequency-banded portions of this map.

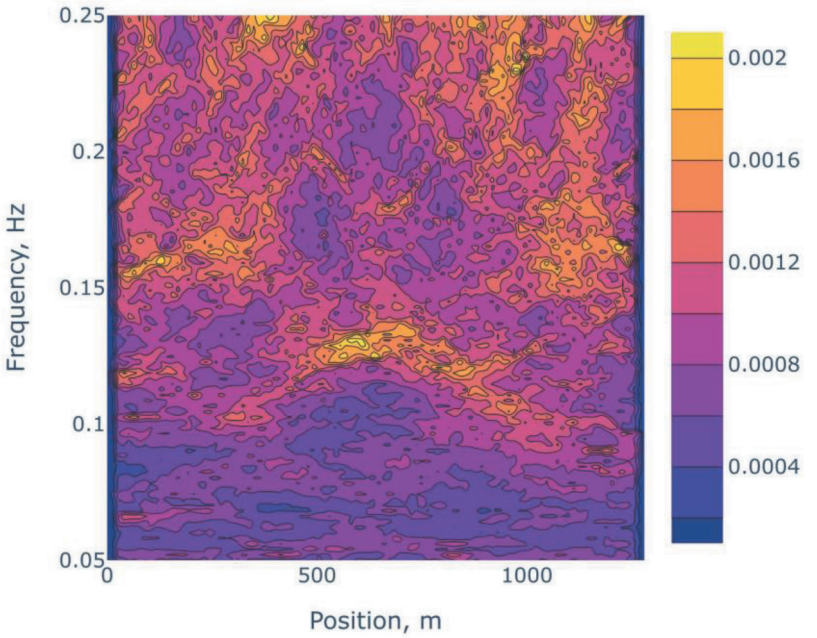

Figure 1. Aggregated frequency-space map for the GGB SVT data. Lighter colors (yellows) indicate a larger power (magnitude) in the frequency spectrum.

The overall idea behind the methodology is to aggregate the magnitude of the acceleration signal's frequency contents spatially. This is achieved using the synchrosqueezed wavelet transform to break down the collected acceleration time series into their time-frequency components. Using the GPS data from the phones, the vehicle's position is known at each time step. With these two pieces of information, magnitude and position, the aggreagtion process can begin. The signal magnitude at each position and frequency is aggregated across the entire SVT dataset, yielding a map of the frequency, position, and magnitude. Figure 1 shows an aggregated frequency-space map for the controlled GGB dataset collected by the research

team (102 trips). The first three modes are prominent in the collected dataset, and the ridges can be seen at frequencies 0.106, 0.132, and 0.169 Hz.

Cronin et al. (2022) recovers the absolute mode shapes for the first three modes from this dataset with all MAC values above 0.95, indicating high accuracy. With respect to Figure 1, the absolute modes shapes would be the section slices of the space-frequency map at the natural frequencies of the bridge. Figure 1 also highlights an imperfection in localizing time-frequency components and separating closely spaced frequencies. For example, the first and second modes are closely spaced, leading to smearing between the frequency bands and the"U" shaped ridge at the center span. This smearing artifact is not exclusive to wavelet transforms, but is an overall difficulty across all time-frequency transforms.

4 OBSERVATIONS ON THE INFLUENCE OF SPEED AND TRAVEL DIRECTION

This study empirically observes how the absolute mode shape estimates can vary based on two key variables: vehicle speed and direction of travel. The influence of vehicle speed on modal frequency estimation have been studied, e.g., peak shift in the power spectral density of the signal. Formal relationships between vehicle speed and mode shapes are not yet known. The direction of travel is an important variable whose effect on modal property estimates has not been well studied. As crowdsourcing campaigns continue, the bridges studied will include those with more complex, unsymmetric geometries and it is in these cases where such direction may be most pronounced. Interaction effects or other latent variables are not considered in this study.

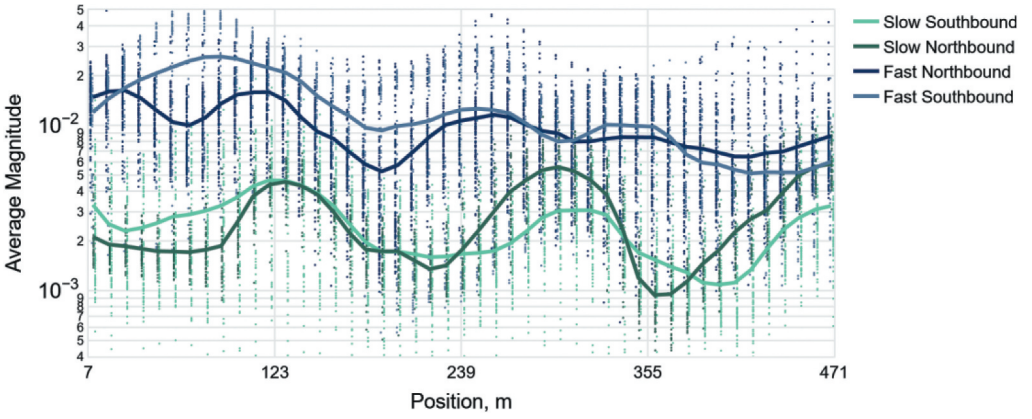

Figure 2. Absolute mode shape of the third vertical mode of the Gene Hartzell Memorial Bridge (GHMB) considering individual trips. Individual points are color-coded into four categories: 1) slow southbound (light green), 2) slow northbound (dark green), 3) fast northbound (dark blue), and 4) fast southbound (light blue).

First, the GHMB dataset is considered. Figure 2 shows a few scatter plots corresponding to the absolute mode shape for the third vertical mode of the bridge. The magnitudes of these scatter plots are unscaled and come directly from the aggregated frequency-space map. Nonetheless, the average of all the points (all trips in a dataset) is the average absolute mode shape, i.e., AMS estimate. Each individual point represents the magnitude of one trip at that location on the bridge, and at any one location, there is a distribution of magnitudes. The solid lines represent the average of the respective direction-speed subset. Figure 2 shows that the faster speeds (in either direction) are associated with larger mode shape magnitudes, and the slower speeds are associated with smaller magnitudes. One possible explanation is that faster vehicle

speeds are correlated with higher amplitude signals recorded by the smartphone accelerometers, yet it is inconclusive whether this is an apparent result for all modes. There are no clear visual trends with regard to southbound versus northbound trips.

Figure 3 attempts to expose general trends with respect to speed for multiple bridges and modes (different colors). Due to variations in the scale and mean of each estimate, the MAC value would not be able to accurately assess consistency in mode shapes. Instead, the cosine similarity between the AMS of of a single trip and the true AMS based on fixed sensor reference data is calculated and used as a proxy metric for quality. Finally, cosine similarities equal to one indicate a good match (like MAC value).

The trendlines in the plot show simple linear regression fits to highlight potential trends and relationships between AMS accuracy and speed. Most of these fits show lines with decreasing slopes, which suggest a decline in cosine similarity with increases in speed. The exception is the first horizontal mode for the GGB (GGB-C-H1). The GHMB dataset, red scatter in Figure 3, spans the widest range of speeds and the most samples of the controlled datasets; the regression line was highly significant ($F = 80.15$, $p < .0001$), suggesting a negative dependency of sample quality on speed. While maintaining an inverse relationship, the fits for the GGB modes are not significant ($p > .05$). The fit for the horizontal GGB mode has a positive slope, suggesting that mode shape accuracy improves with vehicle speed, which is inconsistent the hypothesis of faster speeds reducing quality of mode shape estimates. Overall, these results are preliminary and provide limited quantification on how vehicle speed can affect quality of some specific mode shapes. Complications arise from large difference in the range of vehicle speeds considered in the GGB and GHMB applications, 20-70 km/hr vs. 20-120 km/hr, as well as the nonuniform sampling of the speeds.

In summary, while we can confirm speed is a quality predictor, this observation is not statistically significant for GGB modes. The quality of an individual SVT is affected by a wide range of features including bridge length, traffic speed, length ratio, road profile roughness, expansion joints, to name a few. In our analysis, we found evidence of speed affecting a metric

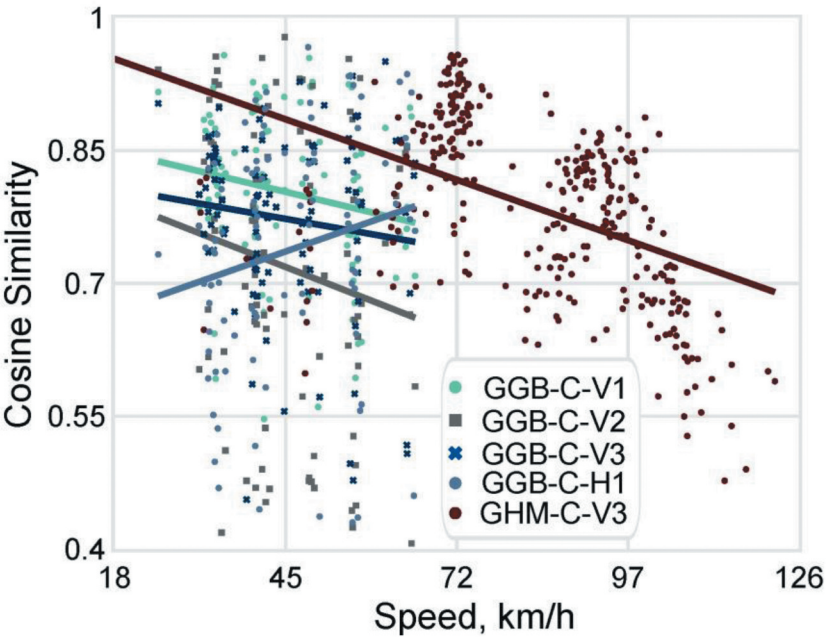

Figure 3. An analysis of the effect of speed of each SVT from GGB and GHMB case studies. Cosine similarity is a distance metric comparing the relative error between a fixed sensor reference and the AMS estimate from a single pass of over the bridge.

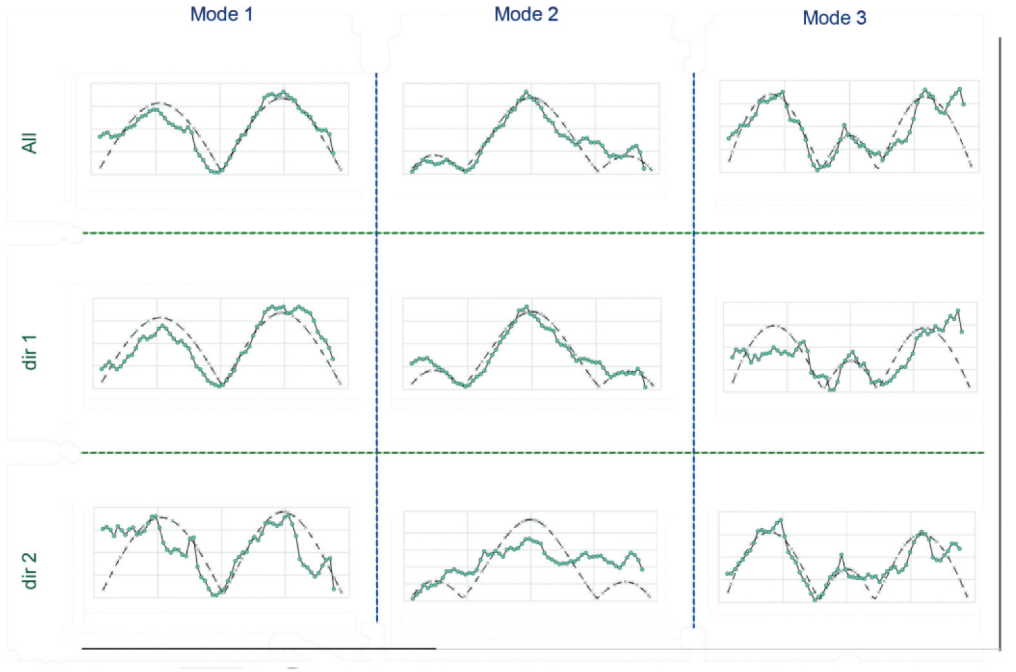

Figure 4. The effect of direction of travel on the GGB identified modes. Row 1 uses all of the data (102 trips). Row 2 presents the aggregation from only the northbound trips (dir 1), and Row 3 is the aggregation of only southbound trips (dir 2).

of mode shape quality, yet further investigation is needed to establish empirical rules for predicting the quality of individual SVT data based on trip metadata and features.

Figure 4 presents the first three vertical modes of the Golden Gate Bridge from the controlled dataset split by direction ("dir 1" = Northbound and "dir 2" = Southbound). Additionally, the full dataset aggregated mode shape is presented as a dashed line. While there do not appear to be any observable trends, significant differences between the datasets are apparent. For the first two modes, traveling in direction 1 appears to produce AMS that is closer to the overall result. For the 3rd mode, traveling southbound results in closer AMS.

5 CONCLUSION

This work analyzed over 400 crowdsourced smartphone-vehicle trip data collected on two bridges, the Golden Gate Bridge (GGB) and the Gene Hartzell Memorial Bridge (GHMB), to observe potential relationships between vehicle speed, travel direction, and the accuracy of absolute value mode shapes (AMS). Interaction effects were not considered. In analyses of the GHMB data, higher speeds were associated with larger AMS magnitudes, and the slower speeds were associated with smaller AMS magnitudes. While notable and consistent, these amplitudes did not appear to have an effect on AMS quality. In-depth analyses considering five modes identified on both bridges attempted to quantify trends between AMS quality and speed. Significant linear regressions on four modes (third vertical mode from GHMB and first three vertical modes from GGB) suggested a negative dependency of quality on speed. Importantly, the opposite relationship was observed for the horizontal mode from GGB – increasing speeds generally improved AMS accuracy. Finally, analyses of the first three vertical modes of the GGB showed significant visual differences between northbound trips and southbound trips.

In summary, these analyses identified notable differences between datasets collected at slow speeds versus high speeds. While there was some evidence to suggest AMS estimate quality decreases with speed, further analyses are needed to better establish generalized empirical laws. Differences due to travel direction were observed; however explicit trends could not be identified. Furthermore, it is possible such differences are caused by a different variable that was not controlled in this study.

Simplified stage construction and creep analysis of a segmental precast concrete bridge

A. Guarnieri, F. Bontempi & F. Petrini
University of Rome La Sapienza, Italy

ABSTRACT: In this work, a simplified methodology is developed for evaluating the evolution of strain/stresses or forces/deflections during the construction process of a segmental concrete precast bridge erected using a balanced cantilever method. The focus of the study is on modeling the entire construction process in stages (most significant) and the prestressing system, considering creep effects in a finite element model. During construction, the superstructure adopts a cantilever static scheme that change into a supported continuous beam upon the last stage. An original method for calculating creep phenomena has been implemented, involving the definition of a 'weighted' creep factor, which allows bypassing the limitations of the more common commercial codes in modeling such phenomena. Once the conceptual framework of the problem modeling is defined, it becomes possible to transfer all the acquired knowledge to more sophisticated models that use 2D or 3D elements and can address more complex local issues.

1 INTRODUCTION

For concrete bridges, the partition of the deck into segments becomes necessary for spans exceeding 50m, and the use of segments prefabrication proves to be a cost-effective solution in terms of launching equipment costs for long extensions and spans up to 120m. The construction methodology adopted in this work is well known as "Balanced Cantilever Method (BCM)" where the structure is erected by cantilevering through the initial construction of two cantilevers supported by an adequate prestressing system Barras et al. (2003). The typical cross – sections used in this type of construction are single-cell or multi-cell box girder, appropriately equipped with upper and lower ducts for prestressing tendons and eventually deviators in the case of external post - tensioning *Suntharavadivel (2005)*. The static scheme can vary (with continuous beam or frames static schemes) depending on economic, environmental, and construction needs, but reference will be made here to the case of a continuous deck on multiple supports with a parabolic tapering (a suitable solution for spans greater than 70m). The BCM involves constructing the deck starting from the piers and symmetrically progressing cantilever-wise from both sides, progressively placing various segments (each ranging from 3 to 6 meters in length) until they meet in the midspan where closure occurs through the installation of a cast-in-place stitch segment (this process is applied to all central spans). The portion of the deck coming from the abutment, of shorter length, can be erected either using an asymmetric cantilever technique or can be temporarily supported by a provisional structure until the structural continuity of the bridge is restored. In prefabrication, the placement of segment pairs generally occurs every 7 days, and in the work presented here, prefabricated segments positioned using ground cranes will be considered: their use does not impose additional load on the structure during the segment placement phase, and the weight of the segment does not bear on it until they are fixed through temporary prestressing bars. Post - tension in the cantilever construction phase is applied to the top slab with a strong eccentricity to generate a bottom positive moment that counteracts the upper negative moment induced by the self-weight in the cantilever diagram. At the end of construction, after the casting of the stitch segment, structural continuity will be restored by using post - tensioned continuity

DOI: 10.1201/9781003483755-206

tendons, which can be placed either inside the bottom slab or internally within the box girder through external prestress. These tendons will be tasked with making the entire deck integral and providing a moment opposing that generated by permanent nonstructural and service loads. The use of segments also needs the restoration of shear continuity through "dry" joints Petrangeli (1996) that exploit the presence of "shear keys" between two successive segments. The use of shear keys is combined with the use of epoxy resins applied to the face of one of the two segments before temporary anchorage and, in addition to serving as a waterproofing function, can offer decent tensile strength during the construction stage Shamass et al. (2016). In conclusion of this brief introduction, it is important to emphasize that one of the most significant aspects of this construction method concerns geometric issues Petrangeli (1996), as cantilever lengths of different spans will have different vertical displacements. The investigation of differential displacements between the ends of the two cantilevers (the one from the abutment and the one from the pier) is crucial for designing initial elevations and any altimetric calibrations of the various segments to avoid misalignments during the casting of the stitch segment.

2 CASE STUDY

The proposed deck is sized from the beginning with reference to the spans that typically characterize this design solution, emphasizing that the focus of the study is not so much on the correct sizing of all structural elements and the search for the most economically advantageous solution but on the simplified procedure that can be implemented in many commercial and non-specific bridge finite elements software.

2.1 *Bridge description*

The structure consists of a continuous beam with three spans on four supports, featuring single-cell box girder with variable height, ranging from 5.0 m at the central support on piers to 2.0 m at the mid-spans (Figure 1) through parabolic tapering. The initial construction stage involves erecting two symmetrical central cantilevers each of length 90.0 m and two side cantilevers each of length 18.0 m, employing cantilever diagram during construction stages (Figure 1, left side). Subsequently, structural continuity will be restored through the casting of three stitch segments, each with a length of 0.60 m, and the insertion and prestressing of continuity tendons (Figure 1, right side). The materials assumed involve the use of C40/50 class concrete and low-relaxation 7-wire stabilized strands with a diameter of 15.7mm (0.6") and Young's modulus E=201.000 MPa. In the conception of the cross sections Florida Department of Trasportation (2002), consideration has been given to the space occupied by the strands, their respective anchorage plates *Tensa (2023),* and the possible tendon layout, in order to consider sections that could be as closely adherent to reality as possible. This is because the space requirements of the prestressing elements involve appropriate thickening that significantly increases the self-weight of each segment that must be considered.

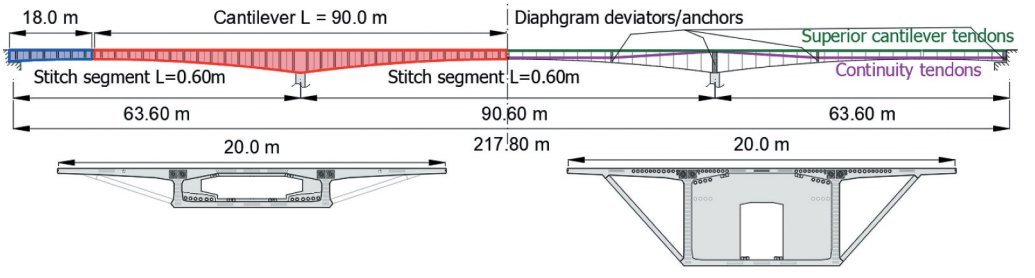

Figure 1. Longitudinal section of the bridge above, with the dimension of cantilever beams on the left and the disposition of tendons on the right. below, the cross-section of the box girder, with the midspan section on the left (2.0 m deep) and the section on the piers on the right (5.0 m deep).

2.2 *Stage construction process*

Leaving aside the prefabrication phase, construction begins when the first segment is transported to the construction site, and lifting operations commence from below, placing it at the top of the piers using a crane or mobile crane. After positioning, altimetric calibration of the supports of the pier head segment is carried out, previously arranged on the pier, and a temporary fixed support is created using prestressed loop tendons to provide a certain rotational stiffness in case of load asymmetries. Successive pairs of segments are transported to the site, and before proceeding with the placement, an epoxy resin layer (with a working time of 1-2 hours and a drying time of about 1 hour) is applied to one of the two faces of each pair of conjugate segments (there are two pairs). Its purpose is to lubricate, waterproof, and possibly, with the use of specific resins, provide tensile capacity for the joints Shamass et. al (2016). At this point, the pair of segments is positioned symmetrically on both sides of the structure. Using positioning bars passed through specific anchorage blisters, a temporary centered prestressing is applied to obtain a uniform compression of 0.2 – 0.3 MPa and allow the resin to take hold. After tensioning the positioning bars, the segment can support itself on the already constructed part of the structure, and the launching equipment can be released, allowing workers to proceed with the tendon placement operations. Once the resin has set, stressing of the upper prestressing tendons, previously inserted into the dedicated ducts in the upper slab, is carried out. If the resin used allows it, any tensile forces on the joint induced by the upper prestressing can be permitted during the construction stages, provided that the tensile strength of the concrete $\sigma_{t,limc}= 0.25 \cdot f_{ck}^{0.5}$ *Ministero delle Infrastrutture e dei Trasporti (2018)* is not exceeded. Once prestressing is complete, the positioning bars can be removed. If the resin does not allow for tensile stresses, temporary prestressing can be maintained until the lower continuity tendons are prestressed. This process is repeated for all subsequent segments to be inserted. Upon reaching the midspan of the span, it is necessary to create the closing segment that joins the decks coming from the two cantilevers (or from the abutments), making the bridge continuous. This is done by initially leaving a space of about 0.6 – 1.0 m between the last two segments and performing a cast-in-place pour. To connect the cantilever from the abutment with that from the pier, an altimetric correction of the supports must be provided before casting the stitch segment since, given the two different lengths, the displacements at the ends will be different. The last operation to be carried out in the construction stage is related to the stressing of the continuity tendons. These tendons will be positioned as the construction progresses and can be either internal (in which case they pass within the lower slab) or external (in which case they are placed inside the box and pass through deviators created with thickenings or actual diaphragms with variable thickness, usually from 0.4 to 1.0 m). Of these two configurations, modern construction techniques prefer the second because external post - tension (with tendons passing inside the box girder) allows for a complete inspection and repair in case of degradation, a critical aspect in post-tension with injected tendons *Suntharavadivel (2005)*. External post - tension also has the advantage of negligible friction losses, with the possibility of covering long distances with continuous tendons, as well as significant economic benefits in case of errors. It is advisable, during the prefabrication phase, to provide additional ducts in various deviators so that additional prestressing can be supplied over time if needed. During the construction, the bridge has fixed supports on piers and abutments, and at the end of the construction, a continuous beam over four support is reached with removal of temporary rotational constraints realized with the loop tendons mentioned above. In the upcoming analysis, the mentioned stages have been reproduced adopting appropriate simplifying assumptions:

1. Frictional phenomena are neglected, and bilateral tendons stressing is assumed
2. Relaxation and shrinkage effects are disregarded due to the use of stabilized strands and controlled 28-day curing (they can, however, be implemented in the procedure to be illustrated)
3. It is assumed that low tensile stresses are allowed during the construction stages
4. The effect of injecting the upper cables is neglected

5. A construction time of 98 days is considered (7 days for each pair of segments) for a total of 14 pairs, excluding the first one at the top of the piers
6. Each segment undergoes the initial loading step at an age of 28 days

Point 1 is considered plausible since the only tendons subject to friction are the upper ones. However, by introducing double side stressing, it ensures that both ends of the i-th pair of segments are subjected to the same compressive force. The occurrence of internal friction within the tendon does not affect the state of stress since the cable is pseudo-straight and does not have to transfer loads based on its curvature. Point 4 is considered plausible because the upper tendons primarily work during assembly to support the self-weight of the segments. The injection of these ducts, which occurs after the release of the beam's weight, does not provide substantial contributions to bearing additional loads, as these will be entirely supported by the continuity tendon.

3 FINITE ELEMENT MODEL AND ANALYSIS SETUP

The software used in this work is STRAND7©, which is not specific for bridge analysis. This paper aims to assist owners of this code or similar ones in the study of these types of bridges or similar structures, considering the possibly similar software limitations shown below. In STRAND7©, it is not possible to implement the evolution of creep phenomena (quasi static solver) simultaneously with the "assembly" of various elements in the non linear stage construction solver. Typically, what is done is taking the output of the stage construction solver and using it as an initial step for the creep analysis of the solver at each step. However, this approach tends to overestimate the effects of creep, as the load would be applied entirely in the initial step without considering the actual aging of concrete loaded at 7-day intervals. Importantly, it also does not account for the variation of boundary conditions after the first 98 days of assembly. This approach affects the initial tensile force to be given to the various tendons in the bridge design. An alternative procedure will be proposed to address these issues with good approximation while maintaining an acceptable solution accuracy.

3.1 *Phase 1 – Non linear construction stage analysis*

In the construction stage analysis Zucca et al. (2018), *Geethu (2016)* with STRAUS7©, it is possible to insert and/or remove elements and modify internal (link elements) or external constraint conditions during various construction stages, considering both geometric and material nonlinearities. The model used for this purpose involves the use of Beam-type elements (with flexural stiffness) for various segments and Truss-type elements (with only axial stiffness) to simulate the tendons. Since the tendons are eccentric, they are connected to the centroid of the Beam elements using rigid links. The tapering of segment elements and the behavior of sliding filaments in the tendons are achieved through the specific command now present in the majority of FEA software. Regarding the support conditions, a distinction is made between side cantilevers and central cantilevers. Side cantilevers lies directly on the abutment, and the support conditions will be simulated with a fixed support preventing vertical translation, horizontal translation, and rotation in the plane during the construction stage. Subsequently, after entering service, the external constraints on rotation and horizontal translation will be removed, simulating a roller support. It should be noted that the operation of removing external constraints can be performed on both solvers. For the central cantilevers, there is greater complexity due to the necessary presence of internal constraints (connection between pier and superstructure) that cannot be removed when transitioning from one solver to another. This modeling issue is addressed by using master-slave link elements for internal connections that do not change from the construction stage to service conditions. These link elements enforce the selected degrees of freedom to have the same displacements. In the case of the first pier-superstructure connection (chosen as a fixed point of the structure), relative horizontal and vertical translational displacements are fixed (hinge support). In the second connection, only

the relative vertical displacement between abutment and superstructure is fixed (roller support). The simulation of the temporary rotational constraint during construction is introduced by inserting an external constraint that blocks rotation in the plane. In the real case, any bending moment generated by potential load asymmetries is countered by the flexural stiffness of the pier. In the assumed modeling, the rotational constraint is external and does not transmit bending actions to the pier. However, if the construction is executed correctly, these actions

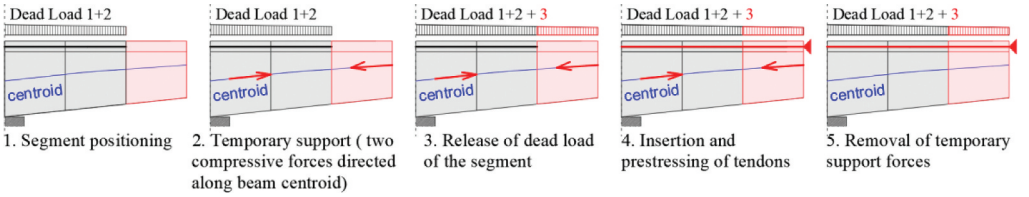

Figure 2. Modeling of the process from segment positioning to tendon stressing.

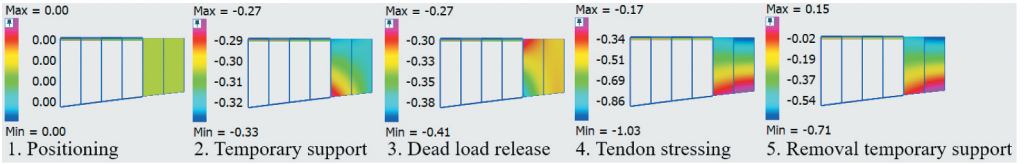

Figure 3. Example of stage construction analysis for segment number three, stresses in MPa.

are not significant enough in this stage to explicitly require rotational continuity between the pier and the superstructure. The adopted simplification is deemed appropriate, and in service, the rotational constraint will be removed, restoring the hinge and roller behavior ensured by internal constraints. Having defined the boundary conditions, the next step was to define the construction stages that would be most critical for the controls on compressive and especially tensile stresses limits. Except for the first segment, a sequence of identical actions was defined for all subsequent segments until the casting of the stitch segment. The construction stages analysis begins with the placement of the first segment (beam element), assumed to be attached to the crane until prestressing occurs (resulting in zero self-weight on the structure). The upper prestressed tendon (truss element) is inserted, stressing is applied to the segment through an assigned pre-stress load on the tendon, and the crane is released (applying the self-weight to the structure). At this point, the first segment is positioned at the top of the pier (or abutment) and temporarily clamped with a fixed support. The placement of subsequent segments occurs similarly but with some additional steps. After placing the initial elements in stage zero, all subsequent ones will need to be placed on a deformed configuration compared to the initial modeling, with nodes of the model having undergone mutual displacements due to initial loads. This implies that, upon inserting additional elements in subsequent stages, these will be pre-deformed compared to the initially modeled configuration, introducing states of stress that are not real. To avoid this behavior, various software options provide more or less complex solutions. In the case of STRAUS7©, the morphing and rotate cluster options have allowed the insertion of elements into the deformed configuration with an initial rigid rotation equal to the rotation of the node to which the new element is attached, without introducing states of pre-stress. From the second segment onwards, the construction stages involve placing the segment on the structure (self-weight not yet acting), inserting temporary anchorages (this phase occurs immediately after applying epoxy resins, ensuring minimal compression and the ability to release the cranes), simulated by a load centered on the centroid of the newly inserted and the preceding element, releasing the self-weight, inserting and tensioning the upper prestressing tendons (Figure 2). The process is repeated until the insertion of the

stitch segment and the insertion of the continuity tendons, which, at the end of the staged analysis, will be inserted but unloaded. It is useful to repeat the analysis twice to evaluate the elastic differential vertical displacement that occurs between the ends of the cantilevers and assign this value as a positive vertical settlement of the hinge on the abutments, thus reproducing the altimetric calibration of the supports before the closure casting. Figure 3 illustrates the evolution of the stress state for the third segment.

3.2 *Phase 2 – Analysis of creep phenomena and long-term behavior*

The study of creep phenomena with STRAND7© Tahmasebinia et al. (2019) occurs by using the solution obtained from the staged solver as the initial input for the time-stepping analysis. Two issues need to be addressed: the first involves the variability of boundary conditions affected by creep, starting with a cantilever scheme and eventually transitioning to a continuous beam scheme. The second arises from the solver constraint in which all loads from construction stages are applied from the initial step *Geethu (2016)*. The first problem is circumvented by observing that during the first 98 days of construction, creep phenomena tend to move the ends of the cantilevers away from those of the side spans with elongations of the stitch segment and the continuity tendon (this occurs only in the model since creep phenomena are introduced downstream of the construction and not during). As a result, a no-tension constitutive relationship is assigned to the three stitch segments, while the continuity tendon is assigned a zero elastic modulus, which will activate after 98 days along with its respective prestressing load. Once the time-stepping analysis is launched, in the first 98 days, the stitch segments will be non-reactive (concrete in tension); creep will act on the cantilever scheme. However, after 98 days, the entire elastic modulus, along with its corresponding tension load, is assigned to the continuity tendon. Temporary external constraints are removed by releasing rotations, resulting in the entire deck being compressed, just like the stitch segments, which, working in compression, contribute stiffness to the structural system. From this point onwards, all creep deformations and additional loads (permanent non-structural and service loads) will develop on the static scheme of a continuous beam over multiple supports. The second problem involves a significant overestimation of creep deformations. This aspect has led to the adoption of a methodology that will be explored in the following section, aiming to find a solution that still overestimates creep effects (underestimating them poses a significant challenge in older bridges) but minimizes the difference with the real solution as much as possible.

3.2.1 *Creep analysis*

The creep model used for the analysis is that of UNI EN 1992-1-1 Appendix B. The creep coefficient is defined as:

$$\Phi(t_f, t_i) = \beta(t_f, t_i)\beta(t_i)\beta(f_{cm})\Phi_{RH} = \left(\frac{t_f - t_i}{\beta_H + (t_f - t_i)}\right)^{0.3} \cdot \frac{1}{0.1 + t_i^{0.2}} .\beta(f_{cm})\Phi_{RH} \tag{1}$$

where $\beta(t_f, t_i)$ represents the time development function starting from $t_f = t_i$ varying between 0 and approximately 1, while the remaining terms that depend on various factors (Relative Humidity %, mean compressive strength of concrete at 28 days f_{cm}, concrete age at the time of loading t_i, effective thickness h_0) provide the modulus of the creep function. The time and age dependence of the concrete at the time of loading are regulated by the first two terms. In nowadays software creep analysis is generally conducted through step-by-step analysis Petrangeli (1996), which, for concrete matured for at least 28 days, is such that:

$$\varepsilon(t_f, t_i) = \frac{\sigma_0}{E_{28}}[1 + \Phi(t_f, t_0)] + \sum_i \frac{\Delta\sigma_i}{E_{28}} 1 + \Phi(t_f, t_i)] \tag{2}$$

The search for the exact solution through step-by-step integration requires that the various load steps $\Delta\sigma$ be introduced stage by stage with different concrete ages t_i for each element. However, using the already assembled superstructure as the initial step, the load is applied integrally and instantaneously. For instance, considering the first element, at the end of construction, the concrete age t_f will be 98 days + 28 days with $t_f - t_i = 98$ days. For the last element, t_f will be 0 days + 28 days with $t_f - t_i = 0$ days (construction is completed at the installation of the last element), while in this case, all elements will be evaluated at $t_f = 98$ days. To mitigate the overestimation of deformations resulting from such software limitations, the following approach is proposed:

$$\varepsilon(t_f, t_i) = \sum_i \frac{\Delta\sigma_i}{E_{28}}(1 + \Phi(t_f, t_i)) = \frac{\Delta\sigma_{tot}}{E_{28}}\left(1 + c \cdot \Phi\left(t_f, t_i^*, \beta_H^*\right)\right) \tag{3}$$

Setting aside the parameter 'c' (that is introduced only to scale creep coefficient Φ) for now, which will be used later, fictitious values for the age of the concrete at the first load 't_i' and the parameter 'β_H' are sought for each concrete element. These values are assigned to the various concrete elements during the analysis phase to enforce the equality of deformations (of the chosen control fibre) between the real curve that represent the correct strain evolution of the chosen control fibre according with (2) and the approximated one according with (3) at the point 't_f.' If equality is assumed at infinite time, it is easily demonstrated that the influence of 'β_H' is null (and therefore the real value will be used). The only parameter to be identified is 't_i^*', which can be obtained simply by reversing the expression for $\beta(t_i^*)$, as follows:

$$\beta(t^*) = \frac{\sum_i \beta(t_i)\Delta\sigma_i}{\Delta\sigma_{tot}} = \frac{1}{0.1 + t^{*0.2}} \tag{4}$$

The use of this formulation, however, still leads to a certain overestimation of creep deformations compared to the real solution, coinciding with the approximate one only at infinite time.

A more complex approach involves applying (3) while varying the three parameters t_i, β_H and c, imposing a condition: the sum of the absolute percentage errors on deformations between the approximate curve and the real curve, evaluated at $t_{fc} = 98$ days, $t_\infty = 10{,}000$ days, t_a, and t_b, where the latter two are arbitrarily chosen points such that the first is close to t_{fc} and the second is a long-term value (>1000 days), is minimized. Through a target search using a simple spreadsheet, the point of minimum of the target function sum of errors $f_{\%}(t_i, \beta H, c, t_a, t_b)$ is sought, resulting in a curve that is closer to the real one. There is another possibility, not considered here as it strongly underestimates deformation compared to the real one, which involves imposing equality between the real and approximating functions at the end of the construction point t_{fc} as a function of the sole variable t^*. Although intuitive, it is essential to emphasize that the evolution of the stress state in terms of $\Delta\sigma_i$ is obtained from the stage analysis by choosing a control fiber (whose correct strain evolution is showed in Figure 4 according with (2)) for each element, where the stress variation is acquired for use in equation (3). In addition, although the approximate solution is entirely incorrect from 0 to 98 days, this is of little importance since the critical conditions to be verified are the short-term ones (maximum stresses check) and the long-term ones (decompression). If these two conditions are verified, all those in between will also be satisfied. Figure 3-4 illustrate the real strain-time curves and those obtained through the three types of approximations seen earlier. With the defining curves for each element of the structure, it is possible to start the stepwise analysis, introduce permanent actions following the installation of the stitch segments and the tensioning of the continuity tendons, and study their effects over time. In this study, the creep coefficient weighted at infinite time was employed (Figure 4 - 5 red curve), obtaining a response that overestimates creep deformations but was still considered plausible, having neglected the effects of steel relaxation and residual shrinkage after the 28-day curing

period for each element. Figure 6 shows the evolution of vertical displacements and bending moments over time on the bridge in question. The purple arrows in Figure 6 (above) represent the differential displacement between the ends of the cantilevers and are zeroed by imposing a vertical settlement on the supports of the abutments, reproducing the previously mentioned altimetric calibration.

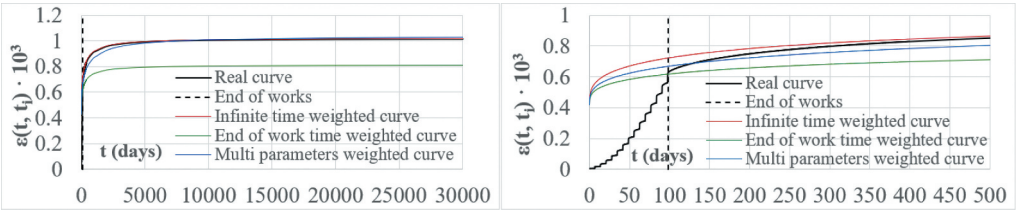

Figure 4. Strain – time curve comparison for segment 1, the multi parameter weighted curve was obtained with c = 0.985, t* = 85 days, β_H = 5628, t_a = 128 days, t_b = 5628 days.

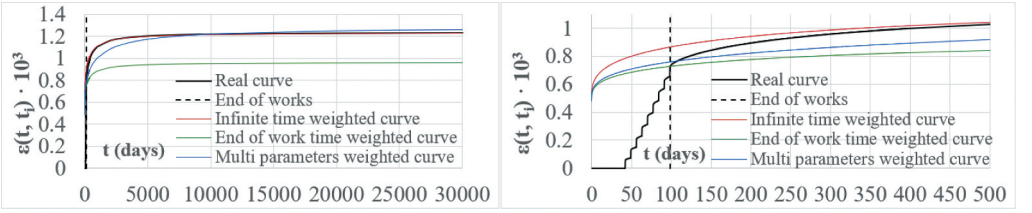

Figure 5. Strain – time curve comparison for segment 7, the multi parameter weighted curve was obtained with c = 0.967, t* = 41 days, β_H = 3245, t_a = 113 days, t_b = 7000 days.

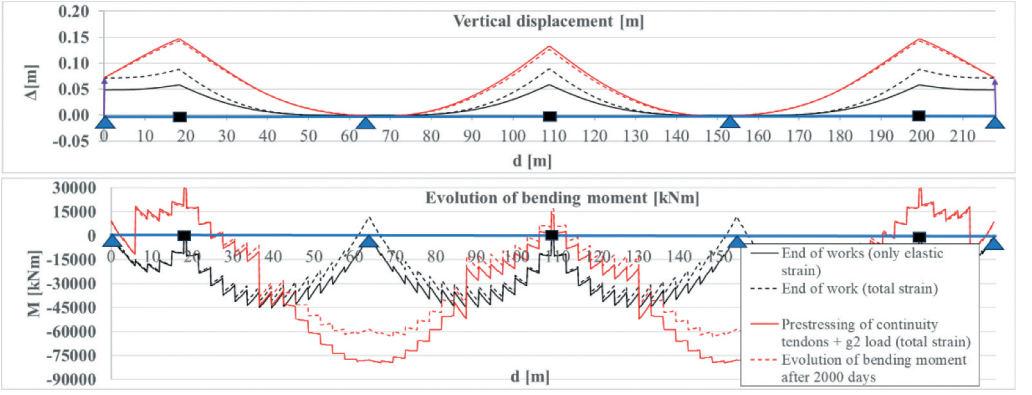

Figure 6. Evolution of vertical displacement (above) and bending moments (bottom) from 98d to 2000d.

4 CONCLUSION

Through the adopted computational model for the study of this bridge, the global quantities involved in the construction of the deck during all construction stages were

analyzed and evaluated. The purpose of the entire work was to understand the construction process of the specific bridge, distinguishing between negligible operations and those that must be considered and consequently analyzed. The next step was to translate these stages from reality to the FEA model, where an attempt was made to reproduce a sequence of actions and conditions that approached the real behavior as closely as possible. It is essential to understand how this work aims to lay the groundwork for a simplified modeling of bridge structures subject to non-negligible construction stages with creep effects. This allows for a good approximation of the evolution over time of bending moments and displacements (Figure 6) even with non-specialized software. Although phenomena such as shrinkage and relaxation have been neglected in the model, there is nothing preventing their addition to the analysis, given the model's setup. Once the workflow is understood, it will be possible to transfer all the acquired concepts to more sophisticated models that use 2D or 3D elements, enabling the analysis of more complex issues such as local statics and kinematics, D-Regions, etc.

ACKNOWLEDGEMENT

This paper is derived from the master's thesis work of the first author under the supervision of the second and third authors.

ABSTRACT: The rise in prestressed reinforced concrete bridges surpassing their projected lifespan has spurred increased attention from infrastructure managers and authorities toward monitoring and maintenance. Accurate understanding of bridge degradation is pivotal for efficient planning and prioritizing maintenance. According to several guidelines, the prestressing system, central in risk assessment and maintenance, demands careful evaluation. Said guidelines also suggest employing non-destructive, semi-destructive, and destructive tests to assess this system's condition. Though numerous innovative investigation techniques exist, their efficacy remains debated, necessitating further exploration. This study focuses on validating the efficacy of three non-destructive tests (NDTs): Digital Radiography, Ground Penetration Radar, and Reflectometric Impulse Measurement Test, conducted on the Alveo Vecchio viaduct—a decommissioned bridge repurposed as a testing site. Classification analyses between NDTs results and observed defect intensity during controlled beam demolition offer insights into their accuracy. This research contributes substantially to understanding the precision of non-destructive tests.

1 INTRODUCTION

The growing concern among infrastructure managers and control authorities revolves around the increasing number of prestressed concrete bridges surpassing their lifespan. Ensuring the safety of these bridges requires accurate monitoring and assessment of their prestressing systems (Bonopera et al., 2020). To this end, Non-Destructive Evaluation (NDEs) are commonly employed to inspect the prestressing systems of post-tensioned PC bridges. However, the validation of the accuracy of those commonly deployed Non-Destructive Tests (NDTs) continues to pose unresolved challenges within the scientific community.

This study conducts a metrological validation of Digital Radiography (DR), Ground Penetration Radar (GPR), and Reflectometric Impulse Measurement Test (RIMT) (Kashif Ur Rehman et al., 2016), assessing their efficacy in detecting defects within the prestressing system of a PC bridge's girders (Innocenzi et al., 2022). Specifically, this NDTs theoretically allows to identify grouting voids in ducts, assess the integrity of steel wires, and determine their positioning along the girders (Lim & Cao, 2013).

The metrological validation was conducted on the Alveo Vecchio Viaduct, which was repurposed as an open-air laboratory following its decommissioning. Four beams of the viaduct

DOI: 10.1201/9781003483755-207

were subjected to NDTs, after which they were demolished for defect survey. This operation involved: (i) extracting the prestressing system, (ii) opening metallic ducts, and directly (iii) examining duct, grout, and strand defects along the prestressing cables. A metrological validation of the NDTs was carried out by using a classifier based on the Bayesian network (BN) (Thulasiraman & Swamy, 1992) and calculating proper metrics related to the confusion matrices (CMs) obtained by the classification (Murphy, 2013).

2 CASE STUDY

Previously part of the Italian A16 highway, in 2005 the Alveo Vecchio viaduct was decommissioned due to a landslide that caused a pier's displacement and a span's collapse. In 2019, the viaduct was readapted as an outdoor research laboratory within the research agreement between the Ministry of Infrastructure, Autostrade per l'Italia S.p.A., and the University of Trento. This collaboration aims to develop inspection protocols, validate NDT techniques, and evaluate monitoring systems to ensure the performance and safety of existing highway bridges. Further details on the outdoor laboratory and the ongoing experimental activities are provided by Tonelli et al. (2020, 2023).

Specifically, the Alveo Vecchio viaduct consists of two decks, each consisting of three 32.5-meter spans made of prestressed reinforced concrete. Four prestressed concrete beams connected by a reinforced concrete slab characterized each deck. Every prestressed beam is realized with 14 post-tensioned cables of 12-Ø7mm steel wires. Figure 1 shows a detailed graphical representation of the viaduct.

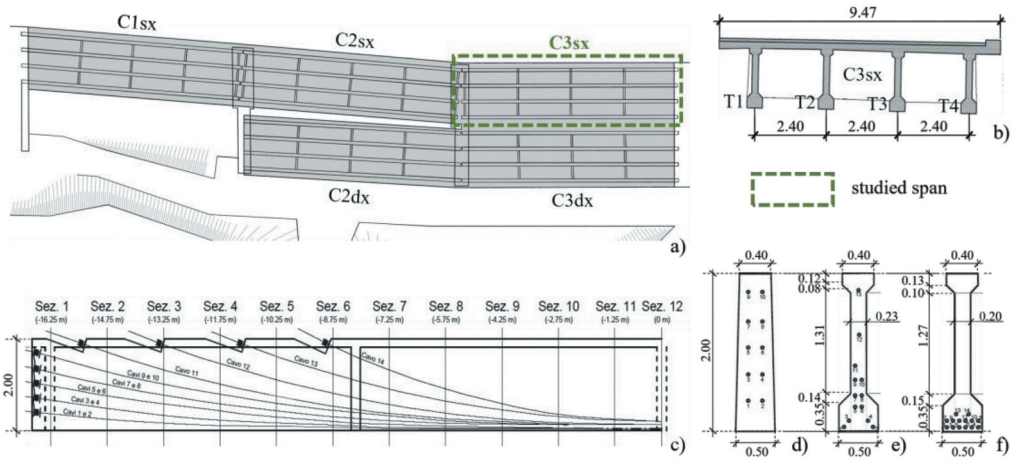

Figure 1. Alveo Vecchio viaduct. (a) Top view, (b) cross-section, (c) cables layout longitudinal section, (d) cross section 1, (e) cross section n. 6, (f) cross section n. 12. All measurements are expressed in meters.

3 METHODOLOGY

This research aims to validate Digital Radiography, Ground Penetrating Radar, and Reflectometric Impulsive Measurement Tests through an in-depth evaluation of their efficiency in identifying defects in prestressing systems of concrete bridge beams. The validation process is organized as follows: (i) performing NDTs on the C3sx span of the Alveo Vecchio Viaduct, (ii) demolition of the prestressing system to identify the actual defects in the cables, and finally, (iii) using a classifier to analyze the ability of NDTs to predict the actual state of the prestressing system.

During the state demolition and surveying phase, steel duct defects (voids, perforations, and lack of integrity), injected grout defects (fracturing and injection voids), and steel wire

defects (corrosion, section reduction, and breaks) were classified. This paper focuses on the defects of grout injection voids (G.V) and steel wire corrosion (S.C). In fact, among the most related defects concerning the considered NDTs, G.V and S.C are the most significant defects in prestressing systems.

To perform the metrological validation of NDTs, each cable was segmented into 10 cm-long sections, and both NDT results and observed defects were classified according to intensity. This segmentation facilitates organizing the experimental results into ordered vectors, creating categorical ordinal variables suitable for analysis by classification methods. Those variables are categorical variables with a logical order.

Table 1 outlines the ascending classes based on the intensity of NDT results, classifying DR into three levels of defects and RIMT into two types of defects with different intensity classes. GPR intensity is defined in three classes. Table 2 shows the classes for cable defects, defining 6 classes for G.V and 13 classes for steel strand corrosion. To allow more reliable classification, these classes were later made binary: 0 for no defect and 1 for the presence of a defect, as highlighted in Table 2.

Table 1. Classes of NDT outcomes and relative quantitative intensity scale.

Test ID	Description	Intensity scale
RIMT.V	Reflectometric Impulse Measurement Test for injection voids identification	0-1, 1-2, 2-3, 3-4, 4-5
RIMT.C	Reflectometric Impulse Measurement Test for strands corrosion identification	0-1, 1-2, 2-3, 3-4, 4-5
RD.V	Digital Radiography	0, 1, 2
GPR.C	Ground Penetration Radar	0, 1, 2

Table 2. Classes of cable defects and relative quantitative intensity scale.

State ID	Description	Intensity scale
G.V	Percentage of grouting voids	**0** := [=0%]; **1** := [<25%, <50%, <5%, <100%, =100%];
S.C	Corrosion of steel strands	**0** := [0/12]; **1** := [1/12, 2/12, 3/12, . . ., 12/12];

This paper focused on the analysis of NDT performance in predicting defect conditions in cables using a BN-based classification method, as represented in Figure 2.

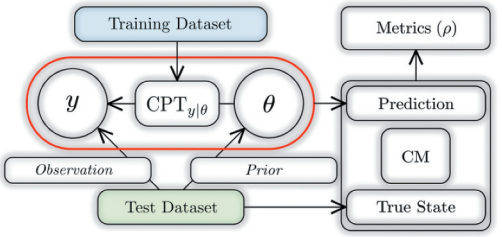

Figure 2. BN-based classifier framework.

The proposed framework is similar to the Naïve Bayes classification method (James et al., 2021). Unlike Naïve Bayes, the proposed BN-based classifier involves training on the likelihood ($y|\theta$) rather than directly on the a posteriori distribution ($\theta|y$), which also considers the prior condition of the dataset. Note that y denotes the NDT outcomes, and θ represents the defect classes of the cable; both are classified as categorical ordinal variables. The BN-based classifier was trained on the 75% of the total dataset. Within this phase, the conditional probability table ($\mathbf{CPT}_{y|\theta}$), which represent the likelihood term, was obtained by normalizing the

contingency table concerning the NDT outcomes, y. Therefore, each column reports the conditional probability of y given the knowledge of θ.

Next, moving to the testing phase, the prediction of the defect state for each element in the test dataset was performed using the Bayes theorem considering the sample's prior distribution. A matrix form of this expression is

$$\mathbf{CPT}_{\theta|y} = [\mathrm{diag}\{\mathbf{CPT}_{y|\theta}\,\boldsymbol{p}_\theta\}]^{-1}\,[\mathbf{CPT}_{y|\theta}\,\mathrm{diag}\{\boldsymbol{p}_\theta\}], \tag{1}$$

where $\mathbf{CPT}_{\theta|y}$ is the posterior conditional probability table, $\mathbf{CPT}_{y|\theta}$ is the classifier likelihood and $\boldsymbol{p}_\theta$ is the sample prior probability mass vector.

The prediction of the defect state, θ_P, was determined as the maximum a-posteriori, θ_{MAP}, as per Equation (2).

$$\theta_P(y_j) = \theta_{MAP}(y_j) = \underset{\theta_i}{\mathrm{Argmax}}\{[\boldsymbol{CPT}_{\theta|y}]_{i,j}\}\ \forall y_j \tag{2}$$

Subsequently, for each element in the dataset, the cable defect prediction, θ_P, was compared with the actual cable defect, θ_T. As a result of this, the confusion matrix was computed (Murphy, 2013). The evaluation of classification performance, based on CMs, involved the accuracy metric ACC, (Fawcett, 2006), the positive predictive value PPV, (Powers, 2008), the negative predictive value NPV, (Powers, 2008), and Matthews correlation coefficient MCC, (Matthews, 1975). Specifically, ACC is defined as the percentage of correct predictions out of the total number of predictions. PPV and NPV measure the performance of NDTs in identifying cable defects (true positive) and no defects (false positive), respectively. Finally, the MCC measures the overall prediction quality of NDTs. The values of the metrics considered are between 0 and 1. A high value means that NDTs perform well.

4 RESULTS

This section presents the results of the metrological validation analysis. First, the state defect prior distribution is defined on the grounds of the following parameters: (i) beam type (external or internal), (ii) cable type (anchored in the head of the beam or anchored in the slab), (iii) location of the segment along the longitudinal axis of the beam (within 2.5 m of the anchorage, within 2.5 m of the spacing, or outside the above regions). The selected parameters represent the intrinsic factors of the prestressing system that influence cable defects. Therefore, all cable segments were divided into 12 groups based on the above definitions, characterized by a specific prior distribution. The prior distribution is calculated on the total dataset.

The results are gathered in confusion (CM) and normalized confusion matrix (nCM). Note that nCM reports the false negative rate and false positive rate of the classification. CM and nCM are graphically described in Figure 3.

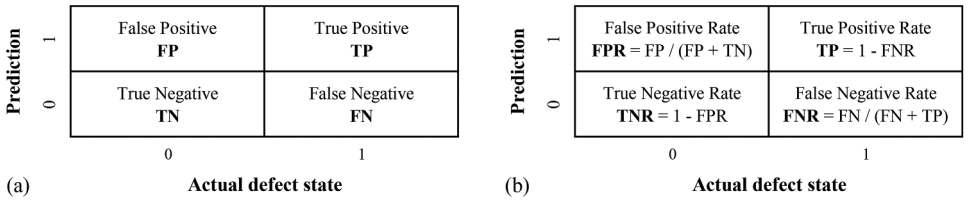

Figure 3. Binary confusion matrix definition. (a) confusion matrix; (b) normalized confusion matrix.

Based on CMs, the ACC, PPV, NPV, and MCC are discussed. The results are presented in two different forms: (i) a single elaboration with fixed dataset subsets for the training and the test phases; (ii) a statistical analysis resulting from 1000 elaboration with different training

datasets and test datasets. This latter result is presented in the form $\mu \pm \sigma$, where μ and σ are the mean and the standard deviation, respectively.

4.1 *Injection voids defects*

The present subsection reports the results of the metrological validation analysis on the injected void defects. As for the defects related to injected grout, our focus was mainly on NDT outcomes with DR.V (Figures 4 and 5), RIMT.V (Figures 6 and 7), and GPR.C (Figures 8 and 9) described in Table 1.

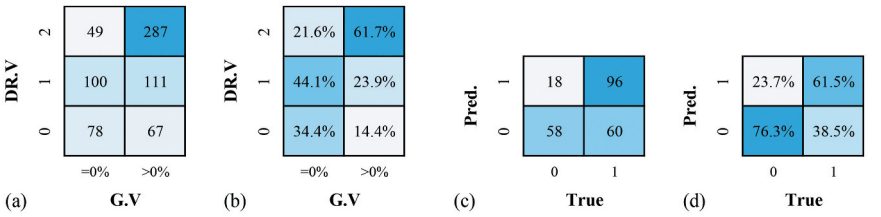

Figure 4. DR.V performance with respect to G.V detection. (a) CT; (b) $\boldsymbol{CPT}_{y|\theta}$; (c) CM; (d) nCM. ACC = 0.664, PPV = 0.842, NPV =0.492, MCC = 0.355.

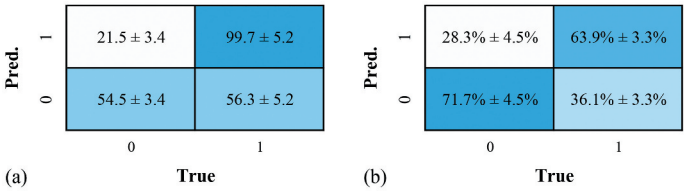

Figure 5. Statistical analysis of DR.V performance with respect to G.V detection. (a) CM; (b) nCM. ACC = 0.665 ± 0.026, PPV = 0.823 ± 0.024, NPV = 0.493 ± 0.028, MCC = 0.335 ± 0.052.

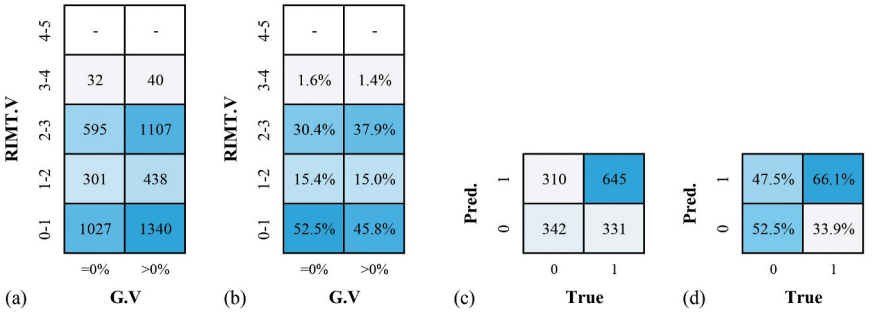

Figure 6. RIMT.V performance with respect to G.V detection. (a) CT; (b) $\boldsymbol{CPT}_{y|\theta}$; (c) CM; (d) nCM. ACC = 0.606, PPV = 0.675, NPV =0.508, MCC = 0.184.

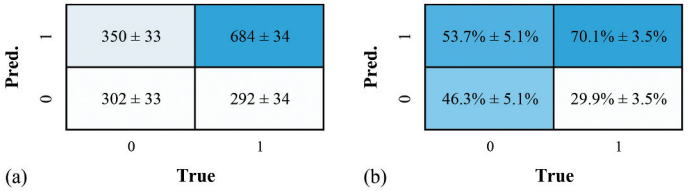

Figure 7. Statistical analysis of RIMT.V performance with respect to G.V detection. (a) CM; (b) nCM. ACC = 0.606 ± 0.010, PPV = 0.662 ± 0.013, NPV = 0.509 ± 0.014, MCC = 0.168 ± 0.025.

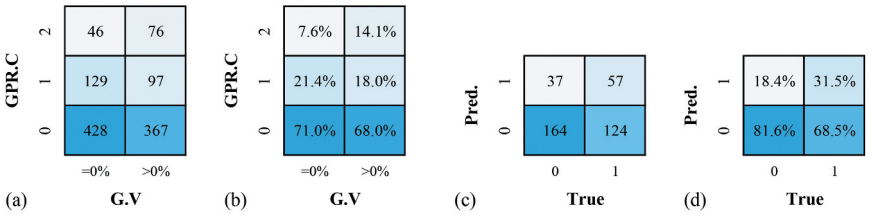

Figure 8. GPR.C performance with respect to G.V detection. (a) CT; (b) $\boldsymbol{CPT}_{y|\theta}$; (c) CM; (d) nCM. ACC = 0.575, PPV = 0.606, NPV =0.569, MCC = 0.152.

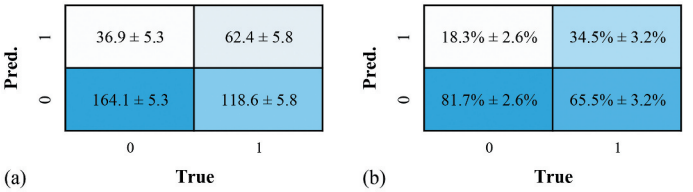

Figure 9. Statistical analysis of GPR.C performance with respect to G.V detection. (a) CM; (b) nCM. ACC = 0.593 ± 0.019, PPV = 0.629 ± 0.038, NPV = 0.581 ± 0.014, MCC = 0.184 ± 0.044.

4.2 *Steel wires corrosion defects*

The present subsection reports the results of the metrological validation analysis on the steel corrosion defects (S.C). As reported in the previous subsection, the same procedure used for injected grout defects is adopted. The analyses on steel corrosion defects focus exclusively on RIMT.C (Figures 10 and 11) and GPR.C (Figures 12 and 13).

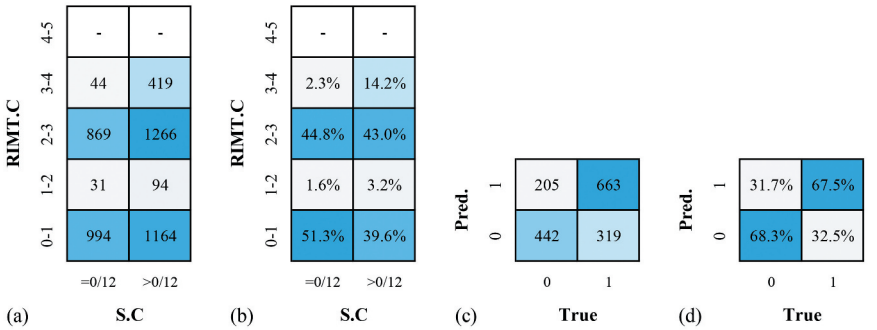

Figure 10. RIMT.C performance with respect to S.C detection. (a) CT; (b) $\boldsymbol{CPT}_{y|\theta}$; (c) CM; (d) nCM. ACC = 0.678, PPV = 0.764, NPV =0.581, MCC = 0.351.

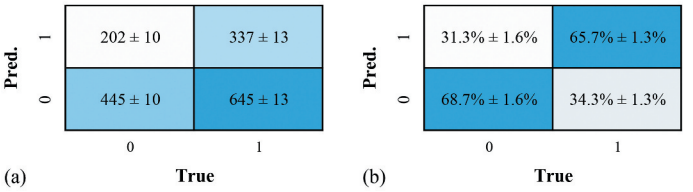

Figure 11. Statistical analysis of RIMT.C performance with respect to S.C detection. (a) CM; (b) nCM. ACC = 0.669 ± 0.010, PPV = 0.761 ± 0.010, NPV = 0.569 ± 0.011, MCC = 0.337 ± 0.021.

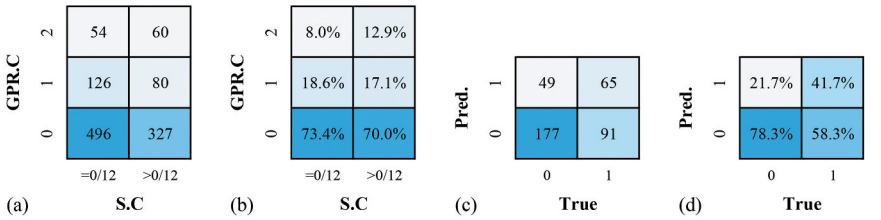

Figure 12. RIMT.C performance with respect to S.C detection. (a) CT; (b) $\boldsymbol{CPT}_{y|\theta}$; (c) CM; (d) nCM. ACC = 0.634, PPV = 0.570, NPV =0.660, MCC = 0.215.

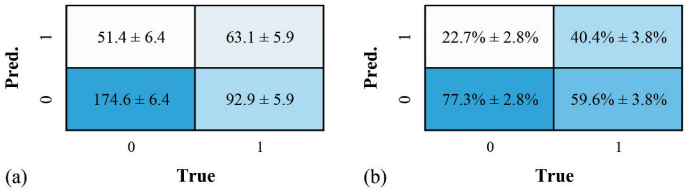

Figure 13. Statistical analysis of GPR.C performance with respect to S.C detection. (a) CM; (b) nCM. ACC = 0.622 ± 0.020, PPV = 0.552 ± 0.034, NPV = 0.653 ± 0.015, MCC = 0.190 ± 0.044.

5 DISCUSSION

The proposed metrological validation analysis results reveal a moderate efficacy of DR in detecting grout defects (ACC = 0.665 ± 0.026, MCC = 0.335 ± 0.052). The performance significantly improves (ACC = 0.714 ± 0.032, PPV = 0.808 ± 0.031, NPV = 0.604 ± 0.037, MCC = 0.423 ± 0.064) when excluding overlapped cables, specifically those anchored in the beam header. However, due to the inherent challenge of interpreting radiographic images for each overlapping cable, decoupling is not possible, impacting the overall performance of DR. RIMTs and GPR tests exhibit limited ability in predicting grout defects (MCC values less than 0.2).

Nevertheless, accounting for the a priori state distribution, RIMTs demonstrate a moderate capability in detecting steel corrosion defects (ACC = 0.669 ± 0.010, MCC = 0.337 ± 0.021). In contrast, the GPR can not predict corrosion defects (MCC = 0.190 ± 0.044).

Generally, the considered NDTs display relatively low Negative Predictive Values (NPV) (less than 0.6), indicating limited predictive ability when the test result is negative. Furthermore, given the relatively high false-negative rate values (greater than 30 percent), the prediction of the state appears moderately unreliable.

It is crucial to note that the results presented in this paper arise from the binary discretization of the classes shown in Table 2.

6 CONCLUSION

This study proposes a metrological validation of Digital Radiography tests, Ground Penetration Radar tests, and Reflectometric Impulse Measurement Tests in identifying defects within the system of prestressed concrete bridges. The metrological validation is based on the Alveo Vecchio viaduct outdoor research laboratory.

To perform the metrological validation, the NDT outcomes are compared in terms of observed defects along the cables after the bridge demolition. The investigation focuses on injected grout void defects and steel wire corrosion defects. The metrological validation of

NDTs is conducted employing a BN-based classification method, assessing informative performance metrics derived from confusion matrices.

The results indicate a moderate performance for DR in predicting injected grout defects and for RIMT in detecting steel corrosion defects. Conversely, GPR demonstrated poor performance for both considered defect states. Overall, the NDT methods under consideration exhibited a notable false-negative rate exceeding 30 percent, underscoring their limited capability in detecting cable defects.

ACKNOWLEDGEMENT

The studies presented here were carried out as part of the activities envisaged by a research agreement between the University of Trento and Autostrade per l'Italia SpA, and supported by Fondazione CARITRO Cassa di Risparmio di Trento e Rovereto (grant number 2021.0224), MIUR PON RI 2014-2020 Program (Project MITIGO, ARS01_00964), the Agreement between the High Council of Public Works (CSLLPP) and the ReLUIS Consortium implementing Ministerial Decree 578/2020 and Ministerial Decree 240/2022, and the Agreement between the Italian Department of Civil Protection (DPC) and the ReLUIS Consortium. The impact of post-tension modeling techniques on calculated concrete member stresses

K. Basnayake
Parsons Corporation, East Hartford, CT, USA

U. Attanayake
Department of Civil and Construction Engineering, Center for Structural Durability, Western Michigan University, Kalamazoo, MI, USA

ABSTRACT: Post-tensioning is a form of prestressing of concrete members to increase its tensile load capacity. The process includes (i) installing tendons inside plastic or steel ducts embedded in concrete, (ii) pulling tendons from one or both ends up to a predefined force after concrete attains a specified strength for the operation, and (c) anchoring the ends to maintain the required force in the tendons. Ducts are typically grouted to enhance durability and establish strain compatibility between tendons and the surrounding concrete. Due to wobbling effect and friction, the force along the tendon decreases during the jacking operation. Further, the force in the tendon is slightly reduced during anchoring. Different modeling techniques are used to represent the stress state in post-tensioned concrete members. One such technique is to embed the tendons in 2D or 3D structural elements representing the concrete member by excluding the influence of the ducts. This modeling techniques utilizes the gross cross-section area of the concrete member to calculate stresses. This can be a concern when empty ducts are present during multi-stage post-tensioning. A common technique implemented in commercial software is to model the concrete member using 1D line elements with the post-tensioning force applied as member loads. As a more precise technique, a refined 3D finite element model can be used to represent the geometry with empty ducts and the sequence of post-tensioning and grouting. However, this technique also presents several challenges including the simulation of tendon force variation along its length. Strain measurements recorded during post-tensioning of an instrumented tie girder of a tied network arch bridge are used to evaluate the impact of different modeling techniques on girder stresses. The paper describes different post-tension modeling techniques and their capabilities and limitations to represent the stress state of concrete members.

1 INTRODUCTION

Post-tensioning (PT) is a form of prestressing of concrete members to increase its tensile load capacity. During post-tensioning, the tendons are stressed and anchored at the ends of the concrete member after concrete attains the required compressive strength to withstand the applied force. The PT ducts are typically grouted to maintain strain compatibility between the surrounding concrete and the tendons, as well as to improve durability. The stresses in a post-tensioned member are calculated using the effective prestressing force after accounting for all the losses. Immediate losses (short-term losses) and time-dependent losses (long-term losses) are considered in the design of post-tensioned members. Immediate losses are recorded between the time of tendon stressing and the time when the prestressing force is transferred to the concrete at the anchorages. Friction between the tendon-duct interface, anchorage set, and elastic shortening of the concrete member contribute to immediate losses. The subsequent losses due to concrete shrinkage, concrete creep, and steel relaxation are considered as the time-dependent losses (PTI 2006).

DOI: 10.1201/9781003483755-208

In the structural analysis of post-tensioned members, the tendon is modeled using two approaches: (1) as an applied loading or (2) as a load resisting element. The load balancing method, primary moment method, and equivalent load through discretization of the tendon force method are three methods used when the tendon is modeled as an applied loading (Lin 1961, Aalami 1990, and Aalami 2000). Under these methods, the tendon is removed from its housing member and is replaced with the force it exerts on the housing member (PTI 2006). Even though the load balancing method is commonly used for the hand calculation of stresses in post-tensioned members, the method fails to account for the variation of prestressing force along the length of tendon (Aalami 2000). When the tendon is modeled as a load resisting element, the tendon is modeled as a distinct element linked to its housing member and an initial prestress force, after friction and anchorage set losses, is applied as a loading to the tendon. Any deformation in the concrete member due to long-term losses and elastic shortening are implicitly accounted for by the corresponding displacement in the tendon element.

2 POST-TENSION MODELING TECHNIQUES IN COMMERCIAL FINITE ELEMENT SOFTWARE

The beam, truss, plane stress, or solid elements can be used to model tendons as load resisting elements in refined finite models (Ellobody and Bailey 2008, Bažant et al. 2012. Huang 2012, and French et al. 2014). This technique can be implemented in commercial finite element software such as ABAQUS, ANSYS, SAP 2000, MIDAS FEA, and MIDAS Civil. The two primary challenges of modeling post-tensioning in refined finite element models are (1) modeling the interaction between concrete and tendon at various stages of post-tensioning, and (2) modeling the varying prestress force along the length of the tendon.

2.1 *Modeling concrete and tendon interaction*

During post-tensioning, the tendons remain unbonded to the surrounding concrete until the ducts are grouted. The unbonded tendon force is transferred to concrete through the end anchorages. Once grouted, any change in the tendon force is transferred from the tendon to the concrete through strain compatibility. Therefore, the contact interaction defined between the tendon and the concrete should reflect the bonded and unbonded stages. Several studies simulated post-tensioning procedures by defining a perfect bond between the tendon and the concrete member (Bažant et al. 2012, French et al. 2014, and Mohammed et al. 2017). This technique is valid once the ducts are grouted, but significantly misrepresents the force transfer mechanism between concrete and the tendon before grouting and does not represent the effective section area of the concrete member (concrete gross cross-section area minus the empty post-tensioned duct area). The following are the three techniques implemented in literature to model the behavior of a post-tensioned member with unbonded tendons:

a) The first technique uses surface-to-surface contact between the tendon and the concrete member (Ellobody and Bailey 2008, Huang et al. 2010, Huang 2012, Kang and Huang 2012, French et al. 2014, and Kang et al. 2015). A frictionless contact is defined in the tangential direction to define the interaction during post-tensioning. The tangential contact behavior is changed from frictionless to hard contact at the grouting stage to represent a perfect bond.
b) The second technique uses tube-to-tube contact elements (ITT21 and ITT31 elements) in the Abaqus element library (Huang et al. 2010, Huang 2012, and Kang and Huang 2012). The tube-to-tube contact elements are used to model the relative motion of two tubes representing the tendon and the duct along the line defined by the axis of one of the tubes (slide line). The post-tensioned duct embedded in concrete is modeled as the outer tube. The tendon is modeled as the inner tube. The slide line is defined for the inner tube. Frictional characteristics can be assigned to define the surface interaction between the inner and outer tube surfaces (Abaqus 2018).
c) The third technique uses springs to model the interaction between an unbonded tendon and the concrete member (Huang et al. 2010). The unbonded tendon is connected to

a virtual tendon embedded in the concrete member using spring elements at discrete locations to maintain the tendon profile. The virtual tendon is similar to the real tendon but is assigned with a very low elasticity modulus. The springs are assumed to be rigid with no axial and bending deformations.

2.2 *Modeling the varying prestress force*

The variation of the prestressing force with time due to concrete creep, concrete shrinkage, and elastic shortening is captured implicitly by the finite element model when the tendons are modeled as load resisting elements. However, modeling the variation of the prestressing force along the tendon length after friction and anchorage set losses is challenging, particularly in 3D refined finite element modeling. A few studies have modeled the friction and anchorage set losses in 2D finite element modeling (Vecchio et al. 2006, Huang 2012, and Huang and Kang 2018). Vecchio et al. (2006) used bond link elements to model the friction losses in an unbonded tendon in a 2D reinforced concrete beam. Huang (2012) and Huang and Kang (2018) proposed a two-dimensional nonlinear finite element formulation to model the prestress force variation along the length of a post-tensioned tendon after friction and anchorage set losses. In contrast to 2D finite element modeling, there are no methods implemented in literature to model the varying prestress force in 3D finite element modeling when solid elements are used to model the surrounding concrete and beam, truss, or solid elements are used to model the tendons. Even though a friction model can be used in the tube-to-tube contact elements to represent the interaction between the tendon and the duct, the activation of the friction in the tangential direction requires a contact between the inner and outer tubes to generate a normal force (Abaqus 2018). The common approach in 3D finite element modeling is to represent the prestressing force as a uniform force. Studies have followed different approaches to calculate the magnitude of this uniform force. For example, French et al. (2014) applied a stress equivalent to the jacking stress minus the friction losses averaged over the tendon length. Huang et al. (2010) applied an average stress after accounting for the prestress losses due to friction and anchorage set but the calculation method of the effective prestress and the average stress is not given in detail. The ADAPT-FELT program, a calculation tool used to compute losses in prestressed tendons, calculates an average initial stress which is the average of the stress distribution after friction and anchorage set losses (ADAPT 2017). Once the magnitude of the uniform force is established, the uniform force is applied as a predefined field of stress (Ellobody and Bailey 2008, French et al. 2014, Huang 2010, Bažant et al. 2012, and Mohammed et al. 2017) or a temperature range with an appropriate thermal expansion coefficient is defined to generate an equivalent prestressing force (Huang 2012 and Brenkus 2016).

3 ASSESSING STRESSES IN A POST-TENSIONED TIE GIRDER

3.1 *Instrumented post-tensioned tie girder*

The west tie girder of the network tied arch bridge in Michigan, USA, commonly known as the 2nd Avenue Bridge, shown in Figure 1, was selected for this study. The skeleton of the bridge was built off site in a staging area. The completed skeleton was transported using self-propelled modular transporters (SPMTs) and placed at the final alignment to complete the construction. As shown in Figure 1, the uniform prismatic portion of the tie girder is 188 ft long. The girder cross-section is 3.25 ft wide and 4 ft tall and has 12 PT tendons (TT01 to TT12). Each tendon has 19 - 0.6 in. Grade 270 Low-relaxation 7-wire strands. Corrugated plastic ducts with a 4.6 in. diameter were used as PT ducts. The tie girder was longitudinally post-tensioned in two stages (PT Stage 1 and PT Stage 2). The tendons for PT Stage 1 were stressed in two steps (PT Stage 1-1 and PT Stage 1-2) at the staging area prior to the bridge move. During PT Stage 1-1, only TT08 was stressed. During PT Stage 1-2, five tendons in the order of TT05, TT04, TT09, TT06, and TT07 were stressed. During PT Stage 2, the remaining six tendons in the order of TT03, TT10, TT12, TT01, TT02, and TT11 were stressed. The jacking force per tendon was 780 kips and the tendons

were stressed from the southwest (SW) end. The age of the west tie girder at PT Stage 1-1, PT Stage 1-2, and PT Stage 2 was 60, 167, and 280 days, respectively. The scope of this study is limited to evaluating the state of stress in the west tie girder until bridge move; i.e., only PT Stage 1-1 and 1-2 were considered.

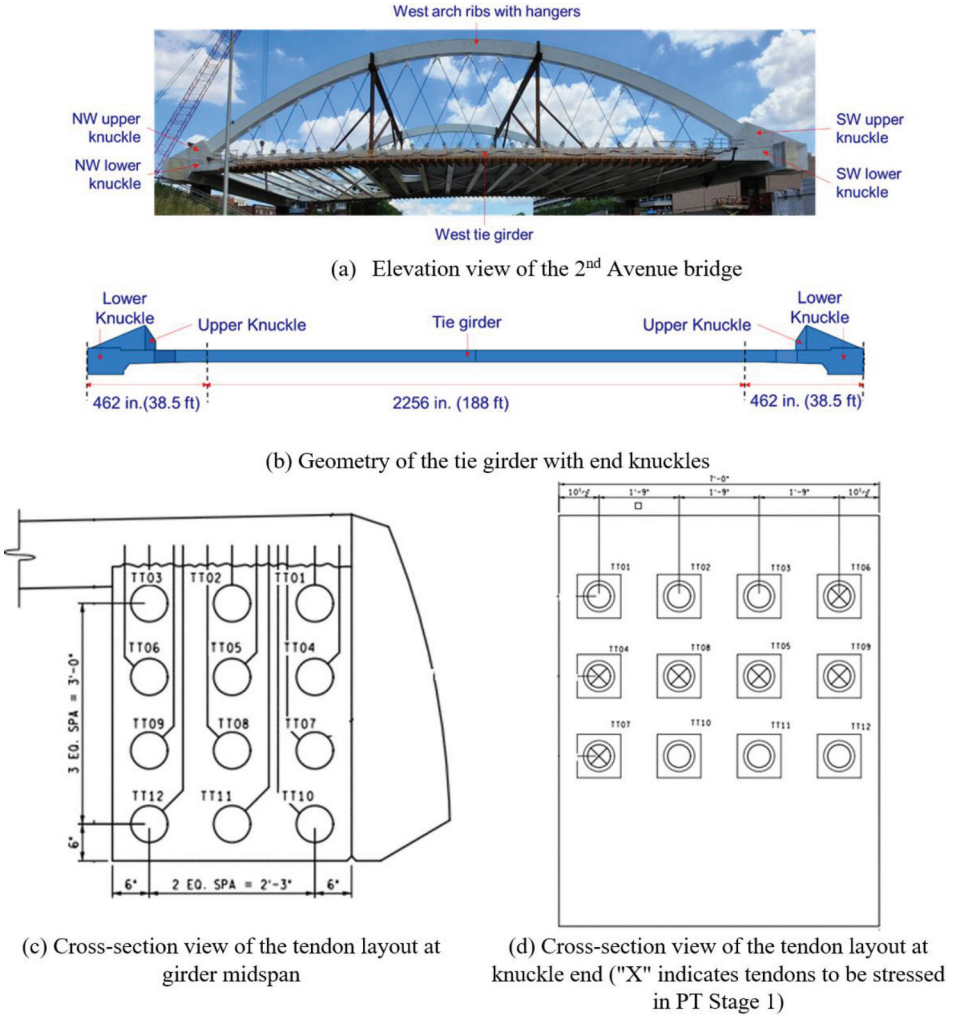

Figure 1. Details of the tie girder; (a) Elevation view of the bridge, (b) Geometry of the tie girder with end knuckles, (c) Cross-section view of the tendon layout at girder midspan, (d) Cross-section view of the tendon layout at knuckle end.

The typical practice is to use the gross cross-sectional area of tie girder to calculate stresses during post-tension application. However, this approach results in lower stresses since the space due to empty ducts are not included in calculations. Table 1 shows the difference between the stresses calculated at the tie girder midspan during PT Stage 1-1 and PT Stage 1-2 with gross and net cross-sectional areas. The stresses calculated using gross cross-sectional area resulted in 33% lower stresses at girder top and 5% lower stresses at girder bottom, at PT Stage 1-1. Compared to PT Stage 1-1, the stresses calculated using gross cross-sectional area resulted in 7% lower stresses in the girder at PT Stage 1-2. During the service life of the girder, the use of gross cross-sectional area has a less impact on the stresses calculated. However,

during the construction (such as during the PT Stage 1-1), the use of gross cross-sectional area to calculate the stresses in the girder can underestimate the actual stress developed at certain locations in the girder. Therefore, the correct representation of the effective cross-sectional area is important for calculating stresses during post-tensioning.

Table 1. Tie girder stresses considering the gross and net cross-sectional areas.

At Girder Section	PT Stage 1-1 Stresses			PT Stage 1-2 Stresses		
	Gross Area (psi)	Net Area (psi)	Deviation with Respect to Gross Area (%)	Gross Area (psi)	Net Area (psi)	Deviation with Respect to Gross Area (%)
Top	-75	-111	33	-2327	-2513	7
Middle	-399	-435	8			
Bottom	-723	-760	5			

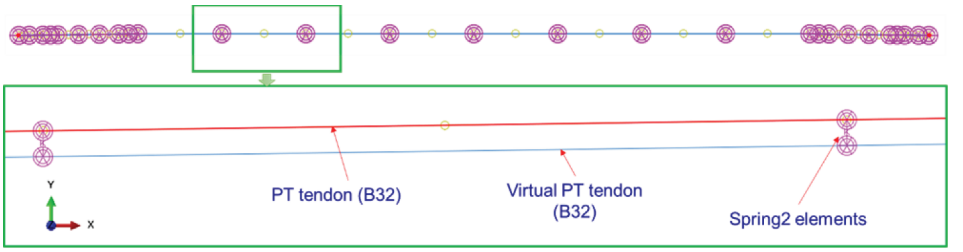
3.2 *Finite element model description*

A three-dimensional finite element model of the west tie girder with the end knuckles was developed using Abaqus Standard 2023 incorporating time-dependent concrete properties. The tendons were modeled using 1D elements with an equivalent circular cross-section to represent all the nineteen strands in a single duct. The tendon layout was maintained along the duct profile. Wedge plates were modeled at the end anchorages to transfer the force from the tendons to the concrete girder. The geometry of the grouted PT ducts were circular cylinders with a diameter of 4.6 inches. Mild steel reinforcement in concrete members was not modeled. The lower knuckles with the empty PT ducts and the upper knuckles were modeled with 10-node three-dimensional quadratic tetrahedral elements (C3D10). The tie girder, grouted PT ducts, and wedge plates were modeled using 8-node three-dimensional quadratic linear brick (hexahedral) elements with incompatible modes (C3D8I). The tendons were modeled with 3-node quadratic beam (B32) elements. Surface-to-surface tie constraints were used to connect incompatible mesh configurations. The time-dependent material properties were defined for concrete assuming material isotropy. The time-dependent variation of the concrete elasticity modulus and Poisson's ratio was defined using measured data and the field variables option in Abaqus.

3.3 *Post-tension modeling*

For accurate representation of the stress due to post-tensioning, the correct girder sectional geometry (area and section modulus), tendon eccentricity, and the tendon forces needs to be correctly modeled. The eccentricity of tendons along the plan and elevation profiles were controlled using spring elements, as proposed by Huang (2012) and shown in Figure 2.

In the finite element model developed in this study, the net area of the girder was modeled. The grouting sequence was modeled by activating the corresponding grout elements in parallel to the grouting operations. After grouting the ducts, both the concrete and the tendons contribute to the stiffness. Strain compatibility takes effect between tendons and the concrete



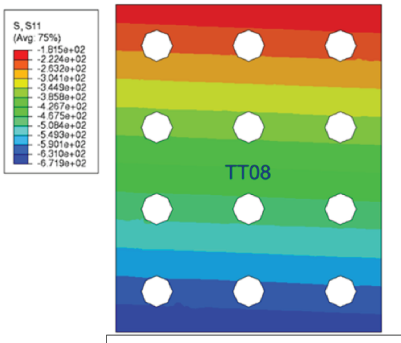


Figure 2. The modeling approach used to maintain the tendon eccentricity.

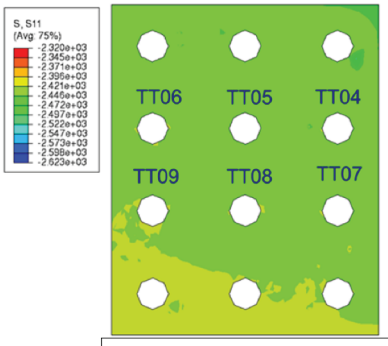
girder sections. Once the mesh representing the grout was activated, the virtual tendon was deactivated and tie constraints were used between the center nodes of the mesh representing the grout and the nodes along the tendon. Surface-to-surface interaction with tie constraints was used between the outer surface of the grout and concrete to represent the bonding between the grout and girder concrete.

The variation of the tendon force along the profile due to friction and anchorage set losses cannot be explicitly modeled in Abaqus. Therefore, the average force in each tendon after friction and anchorage set losses was used. Predefined temperature fields were assigned for each tendon such that the resultant force/stress in the tendon is equal to the average force/stress after friction and anchorage set losses. Anisotropic thermal expansion was assumed for prestressing steel. Since the elastic shortening of the girder took place when the average stress is applied to the tendon, the tendon force/stress decreased. Since this elastic shortening did not reflect the elastic shortening from the jacking operation, the exact value of the stress to be applied as a predefined field was decided after performing several iterations to achieve the expected average prestress in the tendon. The time-dependent concrete creep and shrinkage in the tie girder was modeled using the UEXPAN user subroutine with the creep and shrinkage behaviors defined as per CEB-FIP 2010 model. The stresses in the tendons were automatically calculated for elastic shortening due to sequential stressing of the tendons and long-term losses due to concrete creep and shrinkage. After grouting, strain compatibility exists between the tendon and the surrounding concrete. Any change in stress (due to creep, shrinkage, and stressing sequence) is directly transferred to the tendon from the concrete.



3.4 *Finite element model verification with theoretical values*

The model accuracy was verified using the stresses at the midspan of the tie girder due to PT Stage 1-1 and PT Stage 1-2. Figure 3 shows the midspan stress distribution at the end of PT Stage 1-1 and PT Stage 1-2. As shown in Figure 3(a), at the end of stressing TT08 for PT Stage 1-1, tensile and compressive stresses are observed at the top and bottom of the section, respectively. At the end of stressing TT04, TT05, TT09, TT06, and TT07 for PT Stage 1-2, uniform compressive stresses are observed at the midspan. The stresses were calculated manually at the end of each post-tensioning stage by considering tendon forces and eccentricities. The simulation results agreed with the theoretical calculations with zero or negligible deviations at the middle of the section and reasonable deviations at the top and bottom of the

	Average stress (psi) at the section

section. The deviation of stress at the top and bottom of the section could be due to slight difference in the tendon force eccentricity in the model.

3.5 *Comparison of the finite element model results with the measured data*

Time-dependent strains were extracted from the vibrating wire gage (VWG) sensors at the mid span and at the north end of the west tie girder. The measured strains were compared with the results from the finite element analysis until the bridge move. Figure 4 shows the measured and simulated total strain in the west tie girder. The simulated strains at TG-8 and TG-9 match with the measured strains, with the simulated strains showing a slight overestimation.

(a) At tie girder midspan (TG-8) (b) At tie girder north end (TG-9)

Figure 4. Measured and the simulated total strain in the west tie girder at (a) TG-8 and (b) TG-9.

4 SUMMARY AND CONCLUSIONS

The stress state of a post-tensioned member is governed by the magnitude of the effective prestressing force in the tendons and the concrete elasticity modulus at the time of load application. The effective prestress force is the remaining force after total prestress loss. Friction between tendon and duct, anchorage set, and elastic shortening due to sequential tendon stressing cause the immediate prestress losses that occur during the stressing and prestress transfer operations. Concrete creep, concrete shrinkage, and steel relaxation cause the time-dependent losses that occur throughout the service life.

In this study, the strains in a post-tensioned concrete tie girder in a network tied arch bridge was numerically simulated and the results were validated using the strain data collected from the girder during the bridge construction. The concrete elements and anchorage wedge plates were modeled with solid (hexahedral or tetrahedral) elements. The tendons were modeled with beam elements. The average tendon stress after short-term prestress losses due to the effects of tendon curvature, wobble effects, and anchorage set was applied as the initial prestress force. This initial prestress force was applied by defining predefined fields of temperature to cool down the tendon. The elastic shortening losses due to sequential tendon stressing and the concrete creep and shrinkage were captured in the model with the concrete deformation. The tendon eccentricity within the tie girder prior to grouting the PT ducts was maintained by connecting the PT tendon to a virtual tendon that was embedded in the concrete. This virtual tendon profile was similar in geometry to the real tendon but was assigned a lower elasticity modulus. The real and virtual tendons were connected at discrete locations along the tendon length using Spring2 elements that were assigned with higher stiffnesses in the perpendicular and transverse directions to the tendon. After grouting the PT ducts, the tendons were connected to the grouted PT ducts using tie constraints to maintain strain compatibility. The simulated strains were approximate to the measured strains in the tie girder, but with an upper bound.

The simulation techniques followed in this study can be used to model the stresses in a post-tensioned member and thereby overcome the drawbacks in typical post-tension modeling techniques of embedding the PT tendon in the concrete and using gross-section properties of the post-tensioned member without accounting for the presence of empty PT ducts. However, the techniques are applicable only for determinate structures which can deform and generate an average stress distribution along the member.

ACKNOWLEDGEMENT

This project was funded by the Michigan Department of Transportation (MDOT) through the Center of Excellence for Structural Durability at Western Michigan University. The authors would like to acknowledge the support of MDOT engineers and the members of the Z-Contractors. Authors appreciate the contribution of Harsha Amunugama, Srikanth Vemula, Sanjoy Bhowmik, Naveen Ranasinghe, and Uresh Wijesinghe for instrumentation and data collection.

Service life determination of post-tensioned hanger rods

A.P Ranasinghe & H.T Al-Khateeb
Jacobs Engineering, New Jersey, USA

ABSTRACT: Post Tensioned Hanger Rods are used in Cable Stayed and Tied Arch Bridges. As these bridges become old, it is important to have an idea of the service life of these Hanger Rods. This will enable a proper maintenance plan to be implemented in a timely manner. For new designs, provisions can be incorporated to enhance the service life of the Hanger Rods. The biggest challenge for the hanger rods is corrosion. The corrosion rate of metals will depend on the atmosphere of the rod and how well it is protected from moisture and other chemicals. Hot dip galvanizing of the rods is common. Such organizations like the American Galvanizers Association have published corrosion rates of Zinc and other metals. Their Zinc Coating Life Predictor can be used to predict the service life of the rods. Encasing the rods in steel pipes can increase the service life. Sealing the pipes or filling them with grout can further enhance it. This paper describes how the service life of hanger rods were calculate for a bridge in the California High Speed Rail Project.

1 INTRODUCTION

1.1 *Project information*

The California High Speed Rail (CAHSR) is the pioneer high-speed rail program in the nation, connecting San Francisco to Los Angeles in less than three hours at speeds over 200 miles (320 km) per hour. The second and third Construction Packages (CP 2-3) of the First Construction Segment include 65 miles (104 km) of rail through several counties. The project includes at-grade and aerial structures in addition to local and state route under-passes and overhead structures.

The State Route - 43 Underpass is a Network Tied Arch Bridge in this project. It has post-tensioned hanger rods, and their service life is an important parameter in preparing a maintenance manual for the bridge.

Post-tensioned hanger rods find application in Cable-Stayed and Tied Arch Bridges. As these bridges age, understanding the service life of these hanger rods becomes crucial. This knowledge facilitates the timely implementation of an effective maintenance plan. Moreover, in new designs, provisions can be integrated to improve the service life of the hanger rods.

The design life of the bridge structures in CAHSR Project is 100 years. The Post Tension Institute (PTI) arbitrarily assigns 75 years for the design life of hanger cables and rods. The above project required to determine the service life of the hanger rods using a more rational method. Hence the procedures presented in this paper were used to estimate the service life of the hanger rods of the above tied arch bridge in the (CAHSR) Project.

1.2 *Needs for galvanizing*

One of the biggest challenges for the hanger rods is corrosion. Corrosion of metals is a chemical process rooted in science. After the metals are processed, they tend to revert into their natural and low energy state of ore. The energy used to transform ore into metal is reversed if the metal

DOI: 10.1201/9781003483755-209

is exposed to oxygen and water. As the metal is exposed to these elements, the corrosion process begins, and oxides and other compounds are formed on the steel surface.

Steel is an efficient and durable construction material. It is readily available, cost effective, aesthetically pleasing, sustainable, and strong as a construction material. Like all metals, steel corrodes when exposed to the atmosphere. Therefore, it is important to consider corrosion protection. There are several corrosion protection methods including: Hot-Dip Galvanizing (HDG), Duplex Systems, Zinc Coatings, Protective Coatings, Special Steels, and Sacrificial Anodes.

The American Post Tension Institute (PTI) recommends the use of High Strength Steel Grade 150 deformed thread bars meeting ASTM A 722 "Standard Specification for High-Strength Steel Bars for Prestressed Concrete" Type 2 and Hot Dip Galvanized per ASTM A 123. In addition to its inherent corrosion resistance, HDG has other superior qualities such as lowest initial cost, durability, longevity, availability, versatility, sustainability, and aesthetics compared to other corrosion protection methods. Therefore, HDG of the hanger rods is common.

The corrosion rate of metals will depend on the atmosphere of the rod and how well it is protected from moisture and other chemicals. According to the American Galvanizers Association, the corrosion rate of metals will increase going from Rural, Suburban, Temperate Marine, Tropical Marine to Industrial environments. They have published corrosion rates of Zinc and other metals. This data can be used to predict the service life of the rods.

Encasing the rods in steel pipes offers an initial boost to their service life, while sealing the pipes or utilizing grout can further extend this duration. Within this paper, strategies aimed at bolstering the overall durability of these hanger rods are also presented.

2 STATE-OF-THE ART OF HOT DIP GALVANIZING

2.1 *Hot dip galvanizing process*

As per the American Galvanizers Association, Hot Dip Galvanizing is the process of dipping fabricated steel (i.e., steel hanger rods in this case) into a kettle containing molten zinc. While the steel fabrication is in the kettle, the Iron in the steel metallurgically reacts with the molten zinc to form a tightly bonded alloy coating that provides superior corrosion protection to steel.

(Weisenberger, 2014) has provided an excellent photo tour of a galvanizing plant in Arizona, USA that explains the HDG process quite well. Steel comes to the facility at various states of cleanliness and is sandblasted if necessary. Then all steel batches go through a series of tanks or "baths". The first bath is a caustic dip with Sodium Hydroxide that will remove oil, grease, and dirt. In order to neutralize the batch, it is soaked in water. The third tank is an acid bath which removes any oxidation. Sulfuric or Hydrochloric Acid is used for this "pickling" process. From the pickling tank the batch goes to rinse off the acid. The next and final bath before the actual zinc dip is a zinc ammonium chloride mixture, which acts as a fluxing agent. It also contains a chlorine salt that encapsulates the metal and prevents it from oxidizing again.

Following the flux, the batch is dipped in a kettle. The Zinc in the kettle is at 835 ^{O} F (446^{O} C) for 3.5 minutes. The batches are raised and lowered into the kettle to make sure the zinc gets into all the nukes and crannies, tapping them as necessary to remove excess zinc and skimming the top of the tank to make sure that no detritus adheres to the steel as it is removed from the top.

3 SERVICE LIFE PREDICTION OF POST-TENSION HANGER RODS

3.1 *Corrosion rate of zinc coating – Use of ZCLP*

If the corrosion rate of the zinc coating and its thickness is known, then the time to corrode the coating can be calculated. An updated tool now makes it easier for engineers to estimate the service life of zinc coatings and predict their performance (Krzywicki, 2024). The Zinc

Coating Life Predictor (ZCLP) is available on the American Galvanizers Association's website (zclp.galvanizeit.org). It can be used to predict the service life of hanger rods. The web-based ZLCP requires numerical input of six yearly average atmospheric parameters: annual precipitation, sulfur dioxide deposition rate, relative humidity, airborne salinity, air temperature, and sheltering condition (open air, rain-sheltered or indoor). The 'Resources" tab at the top of the website contains links to this data. The corrosion prediction calculations are based on models that were developed using statistical methods, neural network technology, and an extensive worldwide corrosion database.

3.2 *Limitations of available tools*

The ZLCP cannot be applied to coatings containing alloying elements larger than 1% or painted products. Additionally, yearly average wind direction can significantly affect corrosion rates for structure within one mile of the coastline. The tool does not incorporate data from accelerate corrosion tests such as salt spray tests due to the absence of real-world wet-dry circles. It assumes that the zinc coating is not subjected to significant damage or defects, which could accelerate corrosion and reduce performance.

3.3 *Corrosion rate of zinc coating using charts*

If the corrosion rate of the zinc coating and its thickness is known, then the time to corrode the coating can be calculated.

The challenge is to use an appropriate value for the corrosion rate of the zinc layer. It depends on many environmental and other factors as discussed earlier in this paper.

American Galvanizers Association has provided Service Life Charts based on decades of corrosion data collected from galvanized steel samples exposed to five defined environments in cities all over the world. The five defined environmental conditions are Rural, Suburban, Temperate Marine, Tropical Marine, and Industrial. Figure 1 shows the service life for different zinc coating thicknesses, in various environmental conditions and coating thicknesses.

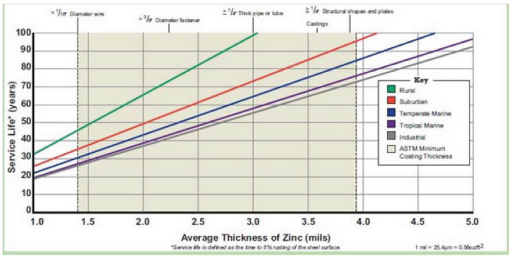

Figure 1. Service life chart for hot dip galvanized coatings.

The 9ASM Handbook, Corrosion,1987), provides corrosion rates of structural steel in various environments. One needs to select a location with similar environmental conditions where the hanger rods are used, and utilize the charts and tables provided for the service life calculations.

It should be noted that the corrosion rate provided in the charts generally assume that the hanger rods are in an open area. However, if they are enclosed by steel pipes, the enclosed hanger rods will be protected by the pipes provided there is no frequent condensation. In that case the hanger rods will be first protected by the steel pipes. However, if there is frequent condensation on the surface of the hanger cables, then the pipes cannot provide proper protection and that should be considered in the calculations. One conservative method of compensation is to ignore the protection provided by the pipes.

4 DESIGN EXAMPLE

4.1 *Bridge application details*

The hanger rods of the tied arch bridge consist of High Strength Steel Grade 150 deformed thread bars meeting ASTM A 722 and Hot Dip Galvanized per ASTM A 123. The 3" (75 mm) diameter hanger cables are encased in Schedule 40, 8" (200mm) diameter steel pipes. Steel pipes are not galvanized, and the bridge is located in an urban environment. There is minimal condensation inside the casing pipe. Minimum diameter of the hanger cables required for stress and fatigue is 2.975" (74mm). Estimate the service life of the hanger cables.

4.2 *Calculations*

From ASTM 123 the zinc coating for a 2.975" rod is 3.9 mils

From Figure 1, Service Life of a zinc coating 3.9 mils thick in an industrial environment = {95 Years}

Extra diameter of hanger cables = 0.5x(3"-2.975")
= 0.0125" (12.5mils)

From Table 2 of ASM Handbook, the corrosion thickness of steel in an industrial environment in 15.5 years = 5.3 mils

Number of years for the extra steel in the hanger able to corrode = (15.5x12.5/5.3) = {36 Years}

Thickness of Sch. 40 casing pipe = 0.322" (322 mils)

Number of years for the Sch. 40 casing pipe to corrode = (15.5x322/5.3) = {941 Years}

Service Life with no heavy condensation or moisture in the casing pipe = (95 + 36+ 941) = 1,072 Years

Service Life with heavy condensation or moisture in the casing pipe = (95 + 36+ 0) = 131 Years

4.3 *Important considerations for HDG*

The following are important considerations when HDG hanger rods are utilized:

a) Hydrogen embrittlement is of concern for steels of ultimate tensile strength of 150 ksi (1100 MPa). During the chemical reaction between steel, rust and the chemicals used in the pickling stages of the galvanizing process, hydrogen is produced and absorbed by the steel. The very small grain structure of high strength steel prevents the hydrogen from being expelled during immersion in the molten zinc. When placed under stress in use, the steel may become brittle and fracture. To prevent hydrogen embrittlement from occurring the hanger rods should be blast cleaned before they are sent to the galvanizer. Only mechanical pre-cleaning is allowed, and acid wash or acid pickling is not allowed.
b) Hanger rods should meet the requirements of PTI Recommendations Section 3.2.4 and be tested after galvanizing for, corrosion, ductility, strength, and fatigue as per Section 3.2.4.1.
c) Threads should be made after galvanizing. It is important to maintain correct zinc layer thickness. Less than the specified thickness will reduce the life span of the hanger rods. Larger than specified thickness can affect the tolerances. Though robust and difficult to damage, large galvanize coating thicknesses can be damaged during handling and installation. Also, very thick coatings are subject to damage during transportation. Galvanizing a trial batch of the hanger rods is recommended to ensure that the correct thickness is achieved.
d) Depending on the size of the molten zinc kettle, some hanger rods may need to be dipped one half at a time. This procedure is known as progressive dipping (Double Dipping). Uneven heating and cooling may cause warpage or distortion of the hanger rods.

e) Where the galvanized pipes are in contact with wet concrete, there will be an initial reaction of the galvanizing layer due to the reaction of the zinc with the wet concrete. The reaction will stop after the initial curing stages of the concrete. If the pipe is not galvanized, and comes in contact with the galvanized rod, and if wetted, a bimetallic corrosion may follow, and the zinc layer will be lost sacrificially. These possibilities might need to be considered as part of the overall design and durability.

4.4 *Testing of HDG hanger rods and anchorages*

The following tests should be done on the hanger rods and anchorages as per PTI Recommendations:

a) Quality control tests for hanger rods as per Section 3.2.4.1
b) Tests for steel pipes as per Section 3.5.2
c) Salt Fog Tests as per 4.1.4.1 and 4.1.4.2
d) Temporary corrosion protection as per Section 4.1.5
e) Anchorage Leak Test as per Section 4.1.6
f) Anchorage Fatigue Test as per Section 4.2

5 CONCLUSIONS

This paper presents a systematic approach to estimate the service life of hot dip galvanized steel hanger rods. It also provides some recommendations to properly galvanize hanger rods:

1) In order to prevent Hydrogen Embrittlement, blast cleaning or other mechanical cleaning of the hanger rods should be performed before they are immersed in the molten zinc kettle. Acid pickling or chemical cleaning normally associated with preparations prior to the galvanizing is not recommended.
2) The thickness of the rods will also affect the tolerance of the galvanized layer. Further there may be variations in the thickness of zinc over the length of the rod. Galvanizing a trial batch of rods is recommended to check thickness attained.
3) The rods should be first galvanized and then threaded.
4) The length of the rod will also require a check with the galvaniser in that the length of rod can be dipped in the bath, as there will be a limit to the size that can be immersed.
5) Do not allow the pipe casing to come in contact with wet concrete or the hanger rods.

The comparative analysis of post-tensioned tendons in ultra-high-performance box girders

M. Tsas-Orgilmaa
Mongolian University of Science and Technology, Ulaanbaatar, Mongolia

Han Sang Mook
Kumoh, National Institute of Technology, Gumi, South Korea

ABSTRACT: The UHPC (ultra-high-performance concrete) composite box girder consists of three segments of UHPC U-shaped girder, 50 mm UHPC depth deck plate and reinforced high-strength concrete (HSC) slab with 240 mm depth. The steel fiber 1.5% of volume fraction was added to the UHPC mixture to induce ductile behavior in the girder. The webs and deck plate of the box girder are not reinforced in the longitudinal direction and no stirrups. Totally 146 tendons inserted in upper and lower flanges of girder to induce flexural strength of composite box girder. Moreover, FBG (fiber bragg grating) sensors are used in lower flange to monitor stress-strain relationship of tendons. The objective of this study is to calculate the instantaneous prestress loss and compare it to the results of experiment and finite element analysis of 50 m UHPC post-tensioned composite box girder. The finite element analysis was used as a strong analytical tool for modeling of UHPC composite box girder. The commercial version of MIDAS FEA was used. The difference in instantaneous loss of tendons between analytical calculation and experimental result are 2-9%. The analytical calculation and FEA show good agreement with experimental result.

1 INTRODUCTION

There are two stages of stress loss considered in prestressed concrete structures. It includes instantaneous prestress loss which occurs during construction stage, time-dependent prestress loss which occurs during the service stage of the structure. The instantaneous prestress loss consists of loss due to elastic shortening, loss due to anchorage seating and loss due to friction. Time-dependent loss consists of loss due to creep, loss due to shrinkage, loss due to temperature effects and loss due to relaxation. The evaluation of final stress force of the prestressed strand is not easy after completion of the structure on site. Therefore, to overcome this drawback, several researchers developed a smart strand which was embedded fiber bragg grating (FBG) sensor in core of wire of the prestressing strand. It gives an opportunity to control the stress-strain relationship of presstressing strand for long term.

In 2015, (Kim, et al., 2015) adopted carbon fiber as the material for the core wire for the sensing strand. That kind of carbon fiber core wire is fabricated by adjusting its diameter to 5.3 mm so as to achieve a diameter of about 5.4-5.5 mm when the external nylon cover fiber is included. Moreover, the volume fraction of the carbon fiber is adjusted to be larger than 65%. The corresponding stiffness of the actually as-fabrictaed carbon core wire is approximately 163 GPa. The tensile test of core wire and strand verified that this smart strand demonstrates structural performance equivalent or superior to the traditional prestressed concrete wire strand. The measuring performance of the sensing strand was also verified to be capable of measuring strain up to a range of 13000-14000 microstrain. The sensing strand developed in this study exhibits consistent structural performance that allow it replace the traditional prestressed concrete wire strand, constitutes the most adequate method to measure the axial strain of the strand, and secures the reliability of the measured data.

DOI: 10.1201/9781003483755-210

In 2016, (Keunhee, et al., 2016) conducted a research on the distribution of prestressing forces for 24 types of 49 girders by using multi-strands in girders. In this study, a special device was conceived to deposit electromagnetic sensors onto each strand so as to measure the prestress force in each individual strand of the multi-strand system.The distribution of the mean prestress force per anchor head have means ranging between 164 KN and 200 KN, and standard deviations ranging between 5.1 KN and 8.4 KN. The prestress force per strand ranging between 144 KN and 220 KN is seen to cover a wider range than the mean of the prestress force per anchor head.

In accordance above studies, the FBG sensors are capable tool to measure the prestress force of prestressed concrete structures. The objective of this study is to calculate the instantaneous prestress loss and compare it to the experimental result and finite element analysis of UHPC post-tensioned composite box girder.

2 CALCULATION OF INSTANTANEOUS PRESTRESS LOSS

2.1 *Design 50 m UHPC composite box girder*

The 50 m span UHPC Composite box girder consists of UHPFRC U-shaped girder, UHPC deck slab 50x2500x50000 (thickness, width, and length) mm and HSC reinforced slab 240x2500x50000 (thickness, width, and length) mm. The 50 m span UHPFRC U-shaped girder consists of three segments, which were integrated at two joint sections such as scheme (17+16 +17) m. The 50 m span UHPC U-shaped girder is designed with prestressing tendons 2x7 and 6x22 tendons in the upper and lower flanges respectively. Lower tendons were indicated T1, T2, T3, T4, T5, T6 and upper tendons were indicated left T7 and right T7. After post-tensioning of tendons grouting was injected into sheaths and cured with heat treatment. The steel fiber 1.5% of volume fraction was added to UHPC to induce a ductile behavior in the girder.

The feature of the U-girder is not reinforced longitudinal and transverse direction except from 0 m to 4 m reinforcement of anchoring zone. The U-shaped girder was connected to the UHPC deck plate and high-strength concrete (HSC) slab by shear key and bar connectors.

2.2 *Cross section properties of U-shaped girder*

The properties of a cross-section such as an area, a first moment of area, a moment of inertia, coordinates of centroid and eccentricities of tendons were calculated for determining prestress loss caused in post-tensioned tendons. Figure 1 shows cross-section and simple cross-section and positions of tendons of U-shaped girder.

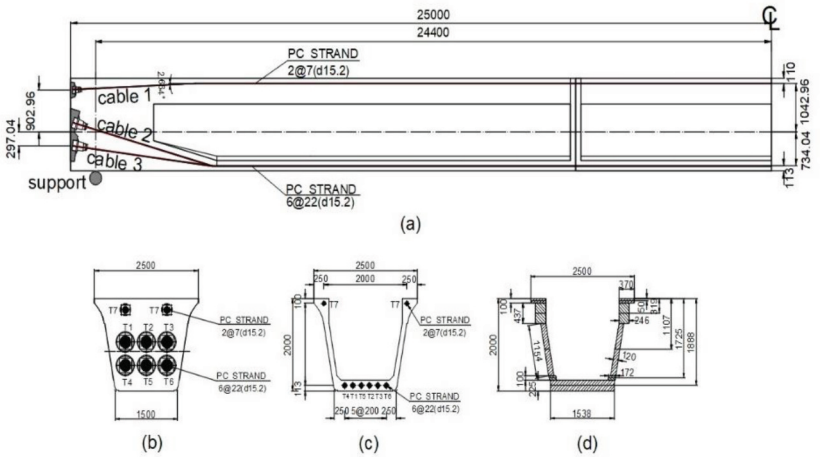

Figure 1. U girder profile and cross sections: (a) girder profile, (b) at support, (c) at midspan (d) transformed cross section at midspan (all dimensions in mm).

Calculated cross-section properties are:
Area of cross section: $A_{c,\,u} = 0.947 \cdot 10^6$ mm^2
First moment of area: $S_y = 1.092 \cdot 10^9$ mm^3
Moment of inertia: $I_{c,\,u} = 3.575 \cdot 10^{10}$ mm^4
Squared radius of gyration: $r^2 = 3.275 \cdot 10^4$ mm^2
Coordinates of centroid: $x_{c,\,u} = 0$; $y_{c,\,u} = 1152.96$ mm
Distance from the centroid to extreme top/bottom edge of U-girder: $y_1 = y_c = 1152.96$ mm, $y_2 = 847.04$ mm

2.3 *Calculation of instantaneous prestress loss of UHPC box girder*

The analytical computation of instantaneous loss of prestress is followed by the KCI Structural Concrete Design Code (KCI, 2012). The instantaneous loss of prestress comprises of loss due to elastic shortening loss, anchorage seating loss and loss due to friction as expressed in Equation 1.

$$\Delta f_{pim} = \Delta f_{fr} + \Delta f_{an} + \Delta f_{el} \tag{1}$$

Where, Δf_{pim}= instantaneous loss of prestress; Δf_{fr} = prestress loss due to friction; Δf_{an} = prestress loss due to anchorage seating; Δf_{el}= prestress loss due to elastic shortening.

2.3.1 *Friction loss*

The values of the curvature and wobble effect are $K = 0.0016$, $\mu = 0.18$ given respectively in (KCI, 2012).

The friction loss is determined by the Equation.2. It should be noted that the maximum frictional loss would be at the far end of the girder if jacking is from one end (KCI, 2012).

$$\Delta f_{fr} = f_{f0}(\mu\alpha + KL) \tag{2}$$

Where f_{f0} = transferring stress, N/mm^2; L = whole length of tendon, mm; α = inclination of tendon, in radians; μ = curvature effect; K = wobble effect.

According to the material property of seven wire strand yield strength of SWPC 7A (15.2mm) tendon is determined as $f_{py} = 1471$ N/mm^2 and the tensile strength is $f_{pu} = 1730$ N/mm^2. Based on (KCI, 2012) the transferring stress must not exceed maximum permissible stress in the strand immediately after transfer. The maximum permissible stresses are $0.82 \cdot f_{py} = 1206$ N/mm2 or $0.74 \cdot f_{pu} = 1280$ N/mm^2. Therefore, in this case $0.82 \cdot f_{py} = 1206$ N/mm^2 is assumed for transferring stress.

Jacking force for a tendon is determined by Equation 3.

$$P_j = f_{f0} \times A_p \tag{3}$$

Where: P_j= jacking force, KN; f_{f0}= transferring stress, N/mm^2; A_p – cross sectional area of a tendon, mm^2.

A summary of loss due to friction is shown in Table 1.

Table 1. Prestress loss due to friction.

	Unit	Tendon T7	T1, T2, T3	T4, T5, T6
Number of tendons (for a bundle)		7	22	22
Cross sectional area	mm^2	970.9	3051.4	3051.4
Inclination of tendon, α	degree	2.764	15.492	7.459
Curvature effect, μ	-	0.18	0.18	0.18

2.3.2 *Anchorage seating loss*

The loss due to anchorage seating is influenced by anchorage setting length l_{set}, and friction loss per length of tendon p.

Loss due to anchorage seating is determined by Equation 4.

$$\Delta P = 2p \times l_{set} \tag{4}$$

Where, ΔP = anchorage loss force in tendon, KN; p = friction loss per length of tendon, N/mm; l_{set} = anchorage setting length, mm.

$$p = \frac{P_j - P_i}{L} \tag{5}$$

Where, p = friction loss per length of tendon, N/mm; P_j = jacking force at prestressing section, KN; P_i = tendon force at midspan after friction, KN; L = whole length of tendon, mm.

Anchorage setting length is determined by Equation 6

$$l_{set} = \sqrt{\frac{\Delta l A_p E_p}{p}} \tag{6}$$

$$\Delta P = 2p \times l_{set} \tag{7}$$

Where, Δl = anchorage slip, mm; A_p = cross sectional area of tendon, mm2; E_p = elasticity modulus of tendon, N/mm^2.

A summary of loss due to anchorage seating is shown in Table 2.

Table 2. Prestress loss due to anchorage seating.

Characteristic	Unit	Tendon T7	T1, T2, T3	T4, T5, T6

2.3.3 *Elastic shortening of post-tensioned elements*

In this case of study, composite box girder has eight bundles of tendons. As each tendon is tensioned, there will be a loss of prestress in the previously tensioned tendons due to elastic shortening of the member. The elastic shortening is determined by Equation 8.

$$\Delta f_{el} = \frac{1}{2} \times n \times f_{cir} \tag{8}$$

Where, n = modular ratio, n = 4.48; f_{cir} = average compressive stress in the concrete along the length of the girder at the center of gravity of the tendon immediately after the prestress transfer.

Average compressive stress in the concrete along the length of the girder at the center of gravity of the tendon immediately after the prestress transfer is determined by Equation 9

$$f_{cir} = \frac{f_{cs}(\text{midspan}) + f_{cs}(\text{PS section})}{2} \tag{9}$$

Compressive stress of tendons after post-tensioning

$$f_{cs} = \frac{P_i}{A_c} + \frac{P_i}{I_c} e_p^2 - \frac{M_d}{I_c} e_p \tag{10}$$

Where, P_i = initial prestressing force (after anchorage seating loss); A_c = area of gross section of concrete, $^{mm}2$ $A_c = 0.947 \times {}^{10}6$ $^{mm}2$; M_d = bending moment due to self-weight, Nmm; I_c = moment of inertia of gross section of concrete, $^{mm}4$; $I_c = 3.575 \times {}^{1010}$ $^{mm}4$; e_p = eccentricity of center of gravity of tendons with respect to center, of gravity of concrete, mm.

Eccentricities of tendons are calculated in followings:

At support

e_{et} = 902.96 mm – for T7 tendons in top flange

e_{eb1} = 202.96 mm – for T1,T2,T3 tendons in bottom flange

e_{eb2} = 297.04 mm – for T4,T5,T6 tendons in bottom flange

At midspan

e_{ct} = 1042.96 mm – for T7 tendons in top flange

e_{cb1} = 734.04 mm – for T1,T2,T3, T4,T5,T6 tendons in bottom flange

A summary of loss due to elastic shortening is shown in Table 3.

instantaneous loss was 18% at right for T7. In the case of lower tendons, the maximum instantaneous loss was 22% at right and the minimum instantaneous loss was 14% at midspan.

3 EXPERIMENTAL STUDY OF 50 M UHPC COMPOSITE BOX GIRDER

The composite box girder was instrumented by embedded FBG optical wires for analyzing post-tensioned tendons which were inserted in lower flanges T2 and T5.

When applied load was increased over 5000 KN, the experiment was stopped due to actuator hydro pump capacity (Tsas-Orgilmaa.M, et al., 2018b). The final step of applied load was 5048.19 KN. The UHPC composite box girder was not occurred to failure. At transfer of

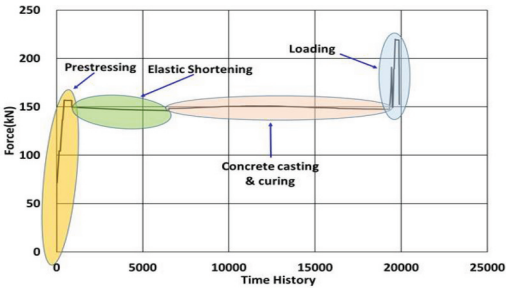

Figure 2. Force versus time history analysis of FBG (Kim, et al., 2018).

prestress force to tendons 184.5 KN jacking force was given for each tendon. The Figure 2 shows force versus time history analysis result. According to this record, 152 KN prestress force was given and decreased to 144 KN in T2 and T5 tendons due to instantaneous prestress loss. After prestress loss the force increased over 150 KN due to the placement of the UHPC deck plate and casting of HSC slab. During the four-point bending test, the force in the prestressing tendon increased to 220 KN and showed little flat values and dropped slightly to 151 KN.

The Figure 3 illustrated applied load versus strain analysis result of embedded FBG optical wires which were inserted in tendons T2 and T5. According to the applied load versus strain analysis the strain values were gradually increased until 2850 microstrain under 5048.19 KN load.

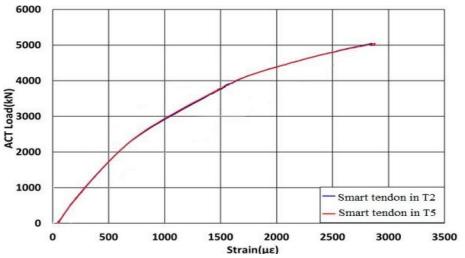

Figure 3. Applied load versus strain of tendon (Kim, et al., 2018).

4 THE NONLINEAR MODEL OF TENDONS

The MIDAS FEA was used to model UHPC composite box girder. Tendons of UHPC composite box girder were modeled as two node bar element. To achieve accurate results, the hexahedron element was used to create a 3D model of UHPC composite box girder. One hexahedron element must contain one bar element. Therefore, the dimension of mesh is 125 mm for tendons and solid UHPC.

The model assumed that the 2-node bar element is perfectly bonded in a solid 3D element. Post-tensioning force is given to both ends of tendons by jacking force. The value of given jacking force for each tendon is 152 KN. The model solved with 40 steps increments, 30 iterations in each increment by Newton Raphson method. The convergence criteria were such as energy norm -0.001. The nonlinearity of tendons was assumed as perfect elastic-plastic model under Von Mises yield criteria to describe the stress-strain relationship.

As a result of FEA solution by MIDAS FEA post-processing was done based on applied load on composite box girder, and strain and stress of tendons. Figure 4 (Tsas-Orgilmaa.M, 2019) shows curves of applied load versus strain/stress of tendons at midspan of girder. According to

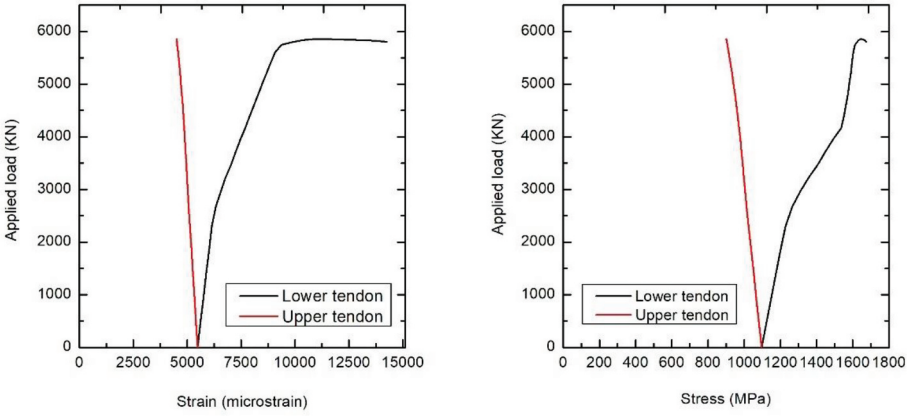

Figure 4. Applied load versus strain/stress of tendons at midspan (Tsas-Orgilmaa.M, 2019).

the applied load versus strain curve, the lower tendons work in tension. The ultimate point of applied load 5855.02 KN and strain reached 11434 microstrain. The failure point of model is determined at the point of 5807.69 KN applied load, strain reached 14238 microstrain.

5 DISCUSSION

Before applying external load to the composite box girder, the prestressing tendons has been tensioned with 152 KN jacking force. Thus each tendon has been previously given 5479 microstrain before the four-point bending test. After applying 5048.19 KN load, the strain of tendons reached 2850 microstrain. The total strain after sum up increase to 8329 microstrain. According to the finite element analysis, the strain of lower tendons under 5048.19 KN load reached 8529 microstrain. The standard deviation of finite element analysis an experimental result is 1.07 and the coefficient of variation is 10.2%. It shows very good result in strain of tendons.

According to the calculation of instantaneous prestress loss the jacking forces were at prestressing section 135.69 KN, at midspan 141.81 KN, at right 131.01 KN for T1, T2, T3 tendons and at prestressing section 136.79 KN, at midspan 143.31 KN, at right 134.65 KN for T4, T5, T6 tendons, respectively.

In the case of experiment, the jacking force was 144 KN. Based on the experiment and calculation of jacking force for a tendon, the difference between the experiment and calculation ranges 2-9% based on Table 4.

6 CONCLUSION

In the frame of the study, the instantaneous prestress loss was determined for 8 tendons of composite box girder, and the post-processing of finite element analysis of composite box girder was done in stress-strain applied load versus strain/stress of tendons and compared to the experimental results. The prestress loss after instantaneous prestress loss was determined from 14% to 26% at prestressing, at midspan, and at right for 8 tendons.

Based on the records of FBG optical wires, the difference of strain between finite element analysis and experimental result was determined as 2-9%. The standard deviation of finite element analysis for an experimental result is 1.07 and the coefficient of variation is 10.2%. It shows very good agreement in strain of tendons.

ACKNOWLEDGEMENT

The experimental part of this study was carried out at the Structural Engineering Laboratory of KICT, and the finite element analysis of 50 m UHPC composite box girder was done at UHPC Laboratory, as part of Ph.D candidate thesis at the Civil Engineering Department, Kumoh National Institute of Technology, Gumi, Korea. I would like to express my gratitude to my supervisor Professor Han Sang Mook and my colleagues who jointly conducted the experimental research.

Finite element analysis of over-height vehicle collisions on prestressed girder bridges

A. Samadzad, S. Cathey, M. Whelan, N. Braxtan & S. Chen
University of North Carolina at Charlotte, Charlotte, N.C., U.S.A

ABSTRACT: The accidental collision of over-height vehicles, especially construction equipment hauled on trailers and dump trucks with unintentionally raised beds, with bridge girders is an event that often occurs multiple times a year in many states within the U.S. The evaluation of bridges subjected to over-height impacts is typically informed by visual inspection, however some damage mechanisms having significant effects on the strength and durability of prestressed concrete girders may not be visually apparent and therefore can be difficult to assess. Furthermore, the damages resulting from an over-height vehicle collision, and subsequent repair and replacement implications, are dependent on the nature and speed of the offending vehicle and the characteristics of the bridge subjected to the impact force. In this paper, a framework for high fidelity finite element analysis of over-height vehicle collisions with prestressed concrete girder bridges is developed to provide a physics-based approach for predicting the damages from over-height vehicle impacts and the influence of the damage on the residual capacity. When coupled with field observations, high fidelity finite element analysis can provide a means for improving post-impact damage assessments and avoiding unnecessary repair and replacement actions while mitigating potential safety risks. The paper details the modeling strategies and constitutive models adopted to create finite element models of conventional prestressed concrete girder bridges, demonstrates the automatic generation of finite element models from key parameters of bridge plans, and presents simulation results for a representative bridge to examine the influence of over-height vehicle characteristics and speed on the predicted extent of damage.

1 INTRODUCTION

According to a recent analysis of a regional database of bridge failures in the United States, collisions are the second most common cause of bridge failures, with the failure typically occurring as a partial collapse (Cook et al. 2015). However, the majority of collisions of over-height vehicles and carried freight with bridges result in minor or moderate damage that can be repaired (Feldman et al. 1996), although often at significant cost and with potentially lengthy disruption to service. In 2020 alone, 14,630 vehicle collisions with bridges were reported throughout the United States (National Center for Statistics and Analysis 2022). Statistical analysis of a large database of bridge collision incidents in New York State indicated that over-height vehicle collisions are significantly more prevalent than vehicle collisions with abutments or piers. Furthermore, the majority of over-height collisions were attributed to trucks and trailers carrying construction equipment, materials, and other objects (Agrawal et al. 2011).

Experimental insight on the behavior of prestressed concrete girder bridges under lateral impacts has been extremely limited. The few exceptions include laboratory testing of model-scale partial width bridge spans to investigate the effect of intermediate diaphragm type and location (Abendroth et al. 1995) and a single experimental test of a full-scale girder subjected to lateral impact from a large concrete mass carried by a cart (Jing et al. 2016). The latter experiment was conducted with an independent girder and therefore does not reflect the contributions that end diaphragms, intermediate diaphragms, additional girders, and a complete deck would provide in an actual bridge, while the former experiment relied on quasistatic loading as a substitute to

DOI: 10.1201/9781003483755-211

impact loading. Due to technical and logistical challenges, risks, and significant costs associated with impact testing of full-scale bridge girders, finite element (FE) analysis has been the predominant tool for investigating the behavior of bridges under impact loads and understanding the effect of design features and impactor characteristics on the resulting severity of damage.

A significant portion of earlier research on the response of prestressed concrete girder bridges to over-height collisions centered on the role of intermediate diaphragms and effect of the diaphragm design on the lateral resistance of the bridge (Abendroth et al. 1995, Qiao et al. 2008). However, FE analysis that served as the basis for this early research was hindered by the technological capabilities of the time as reflected by coarse meshes, simplified constitutive models, idealized boundary conditions, absence of strain-rate effects, neglect of bent diaphragms and other bridge components that may contribute to the girder resistance, and simplified modeling of the impact through prescribed force time histories rather than explicitly modeling the impacting object with a contact model. A critical review prepared subsequent to much of this early research classified the effect of diaphragms during lateral impacts as "not fully addressed" and recommended that high-fidelity modeling be pursued to overcome the limitations of imposed by the computational simplifications (Cai et al. 2007).

Recently, the investigation of over-height vehicle impacts to bridge girders has experienced renewed interest with the support of high-fidelity FE analysis with advanced constitutive models. Xu et al. (2013) developed FE models for container, tipper, and tank trucks and simulated the collision of these vehicles with a prestressed concrete girder bridge model to investigate damage mechanisms and impact force characteristics as well as to develop a simplified model to predict the collision force time history. Oppong et al. (2021a) conducted parametric analysis of the collision of several construction objects as well as a tractor-semitrailer with reinforced concrete bridge girders to investigate variations in impact forces and girder damage. Simplified equations were developed to predict the impact force characteristics for concrete pipe and steel tank collisions. This work was extended to reinforced concrete bridge girders constructed with high-strength concrete and ultrahigh-performance concrete (Oppong et al. 2021b). The numerical simulations suggest that the mean impact force is greater for collisions with ultrahigh-performance concrete girders, but the lateral displacement and resulting damage is reduced.

2 AUTOMATED MODEL GENERATION AND MODELING APPROACH

This paper discusses the development of high-fidelity FE models of complete bridge superstructures to investigate the influence of bridge and impacting object characteristics on the severity of damage to prestressed concrete girders. LS-DYNA was selected by the authors as the FE analysis software package for the research and all simulations disclosed in this paper are conducted using the explicit time integration scheme.

2.1 *Automated model generation*

The construction of large, detailed FE models can be a time-consuming exercise and ensuring consistency in the modeling technique and assignment of model parameters is extremely challenging when a set of FE models are created manually. To address this challenge and to facilitate rapid development of parametric models, the authors have written an extensive library of MATLAB scripts to automatically prepare LS-DYNA keyword files using a defined structure of geometric and material properties that can be extracted from bridge plans. The library is capable of automatically generating keyword files for highly detailed FE models of prestressed concrete girder bridges, implementing the modeling approach and staged analysis sequence described in the subsequent sections, with no manual intervention or manipulation of the keyword files prior to the analysis.

2.2 *Description of finite element modeling approach*

The concrete in the girders is modeled using constant stress hexahedral solid elements with the Continuous Surface Cap Model (CSCM) used for constitutive modeling of the nonlinear, inelastic, and strain-rate dependent behavior of the concrete. CSCM has been found to provide realistic predictions for the behavior of reinforced concrete members subjected to impact loading (Adhikary

et al. 2005, Saini and Shafei, 2019). Automatic parameter generation for this constitutive model is available in LS-DYNA requiring only the mass density, maximum aggregate size, and unconfined compressive strength of the concrete. A database of 2D meshes for standard girder cross sections has been developed by the authors using HyperMesh to ensure high element quality while constraining the minimum edge size to prevent a small number of elements from establishing an unnecessarily small time step. These 2D meshes are then used to create the 3D meshes for the girders by replicating the node set and connectivity at uniform increments along the length of each girder. Prestressing strands are modeled using truss elements with a plastic kinematic material model implemented with yielding and isotropic hardening. Mild reinforcement is similarly modeled as a plastic kinematic material, although Hughes-Liu beam elements are used to ensure stability of shear reinforcement that is not fully embedded in concrete prior to the introduction of the deck. Both the prestressing strand and the mild reinforcement include strain-rate effects using the Cowper and Symonds model. The constrained beam in solid constraint is used to couple the strands and reinforcement to the concrete in the model. Sole plates at the bearing surfaces are modeled with shell elements assigned to shared nodes with the concrete elements in the girder. This effectively permits the ability to prescribe both translational and rotational boundary conditions using a single node at the bearing location.

The reinforced concrete deck is modeled with constant stress hexahedral solid elements. Shared nodes are used to couple the girders to the deck. End and continuous bent diaphragms are also modeled with constant stress hexahedral solid elements. Given the difficulty in generating a mesh for the bent diaphragms that would share nodes with the girder elements without introducing small or highly distorted elements, tied nodes to surface contact was used to couple the bent diaphragms to the girders. A similar approach is used to model cast-in-place reinforced concrete diaphragms. For simplicity, the authors adopt an elastic material model for the deck and bent diaphragms under an assumption that the bridge deck and bent diaphragms will experience little to no damage from lateral impact to the girder. For bridges with steel intermediate diaphragms, the channel member and connecting plates are modeled with shell elements. For bridges with X-brace with strut intermediate diaphragms, Hughes-Liu beam elements are used to model the individual members of each diaphragm. Steel intermediate diaphragms are modeled with the plastic kinematic material model and include yielding, isotropic hardening, and strain-rate dependency.

2.3 *Description of analysis sequence*

To accurately initialize the internal state of stress and initial camber in the complete bridge model, a staged development of the FE models that replicates aspects of the construction sequence is required. Specifically, prestressed concrete girder bridges are constructed of girders that are prestressed prior to placement at the site and then the diaphragms, deck, and remaining bridge components are placed or cast. Consequently, it is necessary to introduce the effects of prestressing in a model that initially consists of just the girders so that the bridge deck does not act compositely with the girders during the introduction of prestressing, as the contribution of the deck would significantly affect the stress, neutral axis location, and camber in the model. A schematic representation of the staged development of the FE model is presented in Figure 1. The staged initialization of the full bridge model is accomplished by using the full restart capability of LS-DYNA. Advantageously, the full restart feature only requires initialization of the bridge model once. Multiple impact analyses can be performed on the initialized model by consistently restarting from the d3dump file created at the conclusion of Step 2.

The introduction of prestressing force in this study was based on applying an equivalent temperature-induced shrinkage in the elements representing the prestressing strands. This general approach was detailed in Jiang and Chorzepa (2015), however the equation provided for the temperature change in this source does not account for elastic shortening. When elastic shortening is included in the strain compatibility, the temperature change, ΔT, associated with a desired prestressing force, f, in the model is:

$$\Delta T = \frac{f}{\alpha}\left(\frac{1}{E_s A_s} + \frac{1}{E_c A_c} + \frac{e^2}{E_c I_c}\right) \tag{1}$$

where α is the temperature coefficient, E_s is the modulus of elasticity for the strands, E_c is the modulus of elasticity for the concrete, A_s is the cross sectional area of the strands, A_s is the cross sectional area of the concrete, I_c is the moment of inertia of the concrete, and e is the eccentricity of the strands. The desired prestressing force introduced into the model can account for typical prestress losses, which can be estimated specifically for the age of the structure at the time of the simulated impact. The application of the prestress in the model is applied simultaneously with the introduction of body forces due to gravitational acceleration during a transient analysis with explicit time integration. This analysis extends over a multiple of the natural period of the girder associated with the fundamental mode for major axis flexure. Mass proportional damping is applied at this stage to suppress resonance of the vibrational modes during the application of the static loads. During the introduction of the prestress force, idealized boundary conditions are assigned at the bearing locations.

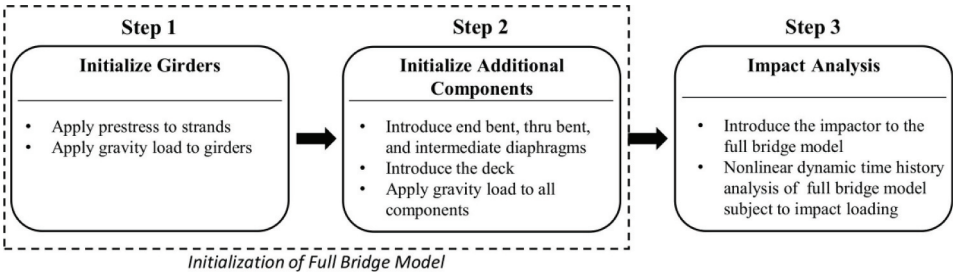

Figure 1. Staged development and analysis of prestressed concrete girder bridge models.

Following the initialization of the individual girders, the remaining bridge components are introduced to the model. During this second step of the initialization of the bridge model, the idealized boundary conditions are replaced with linear elastic translational and rotational springs to approximate the behavior of the elastomeric bearings. The springs are introduced in LS-DYNA using the linear elastic discrete beam material model and the spring stiffnesses are calculated for compressive, shear, flexural, and torsional behavior of the steel-reinforced elastomeric bearings using AASHTO-based guidance outlined in Whelan & Janoyan (2011). The second step of the model initialization introduces the body forces in the added components due to gravitation acceleration as well as establishes equilibrium of the model with the elastic boundary conditions. At the conclusion of this step, mass proportional damping is removed from the model, the impacting object and associated contact model are introduced, and transient analysis is conducted to simulate the damage to the bridge resulting from the collision.

2.4 *Details of bridge span used as a case study*

As detailed above, the developed library of scripts automates the development of high-fidelity models of prestressed concrete bridges, which will ultimately facilitate parametric analysis of the effect of bridge and impacting object characteristics on the severity of damage to prestressed concrete girder bridges. In this paper, a case study of a FE of a single bridge span created by the developed library of scripts is presented and preliminary results from impact simulations are discussed. The bridge span modeled in this paper is a representation of an actual design from the bridge inventory of the State of North Carolina with all geometric and material properties sourced from bridge plans.

The bridge span consists of six AASHTO Type IV girders spaced 2.46 m on-center and spanning 23.72 m. The span has a 10° skew, a crown point at the center of the cross section with symmetric 2% slope on each side of the crown point, and an out-to-out width of 14.5 m. The reinforced concrete deck is 210 mm thick. Each girder is prestressed with a total of 26 low relaxation grade 1860 (270) strands of 15.24 mm diameter. All strands in the girders are straight and bonded over the full length of the span. The compressive strength of the concrete in the girders is 41.4 MPa and the maximum aggregate size is 8 mm. The girders include additional longitudinal reinforcing steel at the ends and near the connection to intermediate diaphragms as well as shear

reinforcement along the span. The girders are supported by rectangular steel reinforced elastomeric bearings with one bearing being designed as an expansion bearing to accommodate thermal expansion. Intermediate diaphragms comprised of steel channels bolted to angle connector plates are present at the midspan of the girders. The span includes reinforced concrete partial depth end bent diaphragms and full depth continuous bent diaphragms. The mass density of all concrete materials in the model was taken as 2,400 kg/m^3, while the mass density of all steel materials in the model was taken as 8,000 kg/m^3. An edge size of 50 mm was used to develop the mesh for the FE model of this bridge span.

Figure 2 presents the bridge model as well as the vertical displacement in the model after the staged initialization. The positive displacement at the midspan of the girder predicted by the FE analysis was verified through comparison with the calculated camber as well as estimates provided on the bridge plans. It is noted that the negative displacements throughout the bridge deck are generated due to the introduction of the deck to the model after the introduction of prestressing to the girders, consistent with the construction sequence. The downward displacement reflects the deflection resulting from the self-weight of the deck and intermediate diaphragms.

3 IMPACT SIMULATIONS

A recently published study utilized high-fidelity FE analysis to examine the variation in impact forces and develop simplified equations to predict the peak and mean force of the impactor (Oppong et al. 2021a). In the authors' opinion, this study established a benchmark for high fidelity modeling of overheight collisions to bridge girders. However, the study was limited to reinforced concrete girders and, furthermore, the database of simulations used to develop the simplified equations was based on a single span length. Prior to conducting the current study, the authors replicated the results in the referenced paper to ensure that the modeling approach, assumptions, and parameters used were consistent with those used by the other authors. In the current study, the authors adopt the geometry and modeling strategies for the steel tank and concrete pipe impacting objects detailed in this referenced publication. The steel tank model is a closed ended hollow cylinder with an outer diameter of 2.19 m, a wall thickness of 15 mm, and a length of 2.29 m that is modeled with shell elements. The same plastic kinematic material model developed for the mild reinforcement in the bridge was assigned to the steel tank. The concrete pipe model is an open ended hollow cylinder with a wall thickness of 178 mm and the same outside diameter and length as the steel tank. Solid elements were used to model the concrete pipe with the CSCM constitutive model. Erosion settings for the concrete of the impactor and the girders were established such that erosion occurs when the damage exceeds 0.99 and the maximum principal strain exceeds 0.1. The automatic surface-to-surface contact card was used to model contact between the respective impactor and girder.

A set of simulations were performed with each impactor model to preliminarily investigate the variation in the impact force characteristics and damage to the girder with the impact location and impactor velocity. For each impactor, nonlinear transient analysis was conducted for impacts occurring at the quarter point, third point, and midspan of the bridge. The midspan location is

coincident with the location of the intermediate diaphragm. For each impact location, simulations were performed for impactor velocities of 72.4 km/h, 88.5 km/h, 104.6 km/h, and 120.7 km/h. All simulations were performed for a termination time of 300 ms to ensure that all significant dynamics were completed by the end of the analysis. Time histories for the lateral displacements at the respective impact location were used to confirm this. For all cases investigated, the top of the tank or pipe was located 330 mm above the base of the bottom flange of the girder. The total mass of the steel tank model is 2795 kg and the estimated contact area associated with the impact to the bottom flange of the girder is 2622 cm^2. The total mass of the concrete pipe model is 6171 kg and the estimated contact area associated with the impact to the bottom flange of the girder is 1690 cm^2. The output time interval for the contact force time histories was $1x10^{-5}$ s.

The typical variation in impact force time history across the impactor velocities is presented in Figure 3. The duration of the time histories plotted in this figure is truncated to 6 ms, as this is the time window over which the magnitudes of the impact forces are significant. The FE results presented in this figure were obtained with the steel tank model, but similar observations were made with the simulation data obtained with the concrete pipe model. As expected, the peak force and impulse increases as the velocity of the impactor increases. Figure 4 presents impact force time histories for collisions of the concrete pipe with a velocity of 104.6 km/h at the three different locations in the span. The results suggest that neither the peak force nor the impulse are sensitive to the location of the impact in the bridge span. Similar results were obtained for the other velocities as well as for the simulations performed with the steel tank model. The duration of the impact is also approximately twice as long as that presented in Oppong et al. (2021a). The longer contact duration may be the result of a more flexible girder, which is the result of the significantly longer span length of the bridge modeled in the current paper as well as the complete modeling of the superstructure.

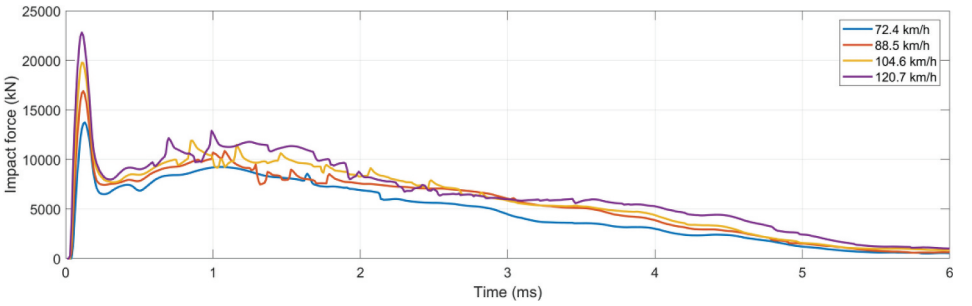

Figure 3. Impact force time histories for steel tank collision at midspan of the bridge.

As previously mentioned, Oppong et al. 2021a developed a set of prediction equations for the peak and mean impact forces developed by collisions of steel tanks and concrete pipes based on parametric analysis conducted with a reinforced concrete girder model. In this referenced paper, the mean impact force was defined as the impulse divided by the duration of the impact. In the current study, the peak impact forces were extracted from the force time histories and the mean impact forces were calculated by numerical integration. Figure 5 presents a comparison between the results from the 24 FE simulations and the predictions developed with the simplified equations. These preliminary results suggest that the prediction equation significantly overpredicts the peak forces from the steel tank when extended to this case study. However, the peak impact forces developed for the concrete pipe exhibit reasonably strong agreement with the prediction equation. Conversely, the mean impact forces, or impulse, developed by the FE simulations with the steel tank agree well with the prediction equation, while the mean impact forces from the simulations with the concrete pipe are significantly lower than the anticipated by the prediction equation.

Figure 6 presents the condition of the exterior girder at the end of the simulation for the four different velocities of the steel tank collision at the quarter point and the midspan. The fringe pattern depicted in the figure and indicated in the legend is the maximum principal strain. Some

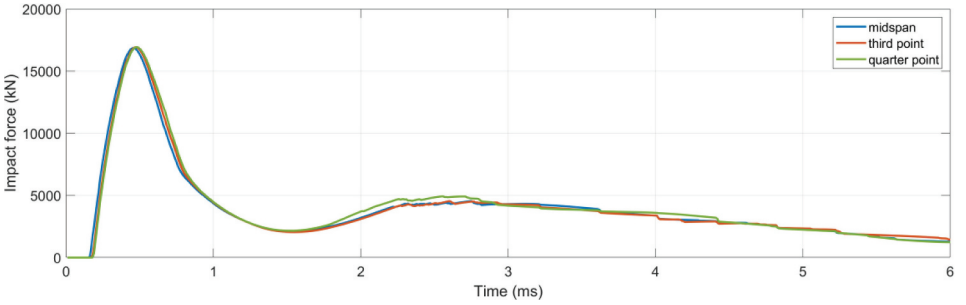

Figure 4. Impact force time histories for concrete pipe collisions with velocity of 104.6 km/h.

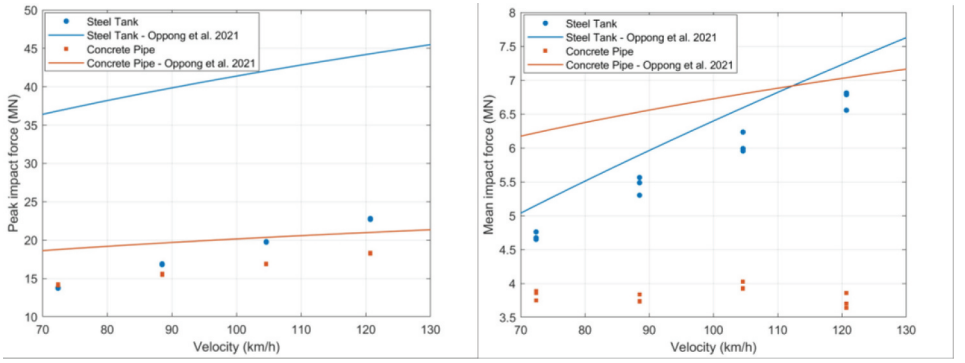

Figure 5. Comparison between FE results from high-fidelity bridge model and prediction equations: a) peak impact force; b) mean impact force.

erosion of elements can be observed for the greater levels of damage severity. The simulations predict damage in the form of spalling and loss of side cover at the contact area, lateral and torsional deformation of the impacted girder, localized loss of prestress and a significant crack extending up to the top of the web of the girder. In general, the damage patterns are consistent with expectations based on documented field observations (Feldman et al. 1996). While some differences are apparent in the damage produced at different impact locations, the FE results suggest that the velocity of the impactor has a more significant influence on the severity of damage than the impact location. In this limited preliminary study, the authors found that the presence of the steel intermediate diaphragm reduced the extent of lateral displacement for impacts at the midspan. Lastly, it is noted that the degree of damage apparent in the FE simulations is significant, however Oppong et al. (2021a) pointed out that the steel tank and concrete pipe impactor models generated significantly greater impact forces and greater damage than their other models of construction objects or the tractor semi-trailer model. Future extension of this work will expand the simulation database to include additional impactors as well as additional bridge models.

4 CONCLUSION

This paper presented a high-fidelity approach to modeling prestressed concrete girder bridges and simulating the collision of vehicles and construction objects. Preliminary results obtained from a set of 24 simulations performed with two different impactors, three different impact locations, and four different speeds suggest that the characteristics of the impact force time history are not affected by the location of the impact. Comparison of the impact force time histories with a set of prediction equations from the literature developed with a reinforced concrete beam model yielded mixed results. Based on this limited preliminary investigation, the severity of damage to the girder appears to be affected more significantly by the velocity of the impactor

than the location of the impact. Early evidence from the study indicates that steel intermediate diaphragms result in reduced lateral deformation for impacts occurring near the diaphragm.

ABSTRACT: A 265 ft (80.8 m) long post-tensioned concrete tie girder was being fabricated as a cast-in-place girder at an off-site location. The 3.25 ft (1.0 m) wide and 4 ft (1.2 m) deep section included 12 empty post-tensioning ducts and a congested reinforcement cage. A lack of workability was noticed during the placement of concrete delivered by one of the trucks. This necessitated a nondestructive investigation of the girder interior for indications of insufficient consolidation. Ultrasonic tomography was selected as a suitable technique. Wave signal propagation through the reinforced concrete section (with and without ducts) was simulated to evaluate the likelihood of detecting backwall reflections. Backwall reflection detection was required for the calibration of phase values for the classification of reflector types (i.e., the internal details and voids). The simulation showed the likelihood of visualizing only the empty ducts and longitudinal reinforcement located near the scanned surface with very light reflections from the empty ducts at the 2nd column located at a distance of 19.5 in. (495.3 mm) from the vertical surface. Based on the simulation results and the understating of girder details, data collection protocols were developed and executed. This paper describes structural details of the post-tensioned concrete tie girder, simulation results, data collection plan, findings, and the capabilities and limitations of the state-of-the-art technology for visualizing the interior of concrete sections with complicated details.

1 INTRODUCTION

An unbraced network tied arch bridge was constructed in Detroit, Michigan, as a replacement of the 2nd Avenue Bridge over Interstate (I) 94 freeway. This 265 ft (80.8 m) long and 96.5 ft (29.4 m) wide bridge has a skew of eighteen degrees (18°) making it a unique structure among the network arch bridges in the U.S. Figure 1 shows the structural components of the bridge. The structural assembly consists of two trapezoidal steel arch ribs connected at each end to post-tensioned concrete tie girders through the knuckles, post-tensioned concrete end diaphragms, steel floorbeams, lateral bracings, floorbeam diaphragm, and hangers. The bridge structure was assembled in a staging area near the bridge site. Subsequently, the assembled structure was moved into alignment by self-propelled modular transporters (SPMTs). Following the SPMT move and placement of the assembled structure on permanent bearings, the remaining construction activities were completed.

The east tie girder was fabricated on Thursday January 13, 2022, using a concrete mix with a maximum aggregate size of ¾ in. (19 mm). The concrete delivered in Truck #3 indicated a lack of workability during placement. Visula and photographic evidence of poor concrete workability was documented. In response, a nondestructive testing was initiated to investigate girder interior for indications of insufficient consolidation, if any. The placement of concrete delivered by Truck #3 extends from a location in between floorbeams L and M to floorbeam Q. The Truck #3

DOI: 10.1201/9781003483755-212

concrete filled the entire girder width and about ⅔rd of the girder height from the bottom (i.e. about 2.7 ft; 0.823 m). The floorbeam spacing is 14 ft (4.2 m), and the length of the specific girder segment is about 50 ft (15.2 m). The tie girder reinforcement detail is shown in Figure 2.

Since the deck and the sacrificial nose had not been completed at the time of tie girder condition evaluation, the girder top surface was roughened with exposed slab ties, as shown in Figure 3. The girder surface was accessible from all four sides for measurements, except at the floorbeam connections. The typical section depth and width of the completed girder is 4 ft (1.2 m) and 3.25 ft (1.0 m), as shown in Figure 3. The cross-sections T-T and V-V shown in Figure 3 represent tie girder details between and at the floorbeams, respectively. The plastic corrugated post-tensioning ducts in the tie girder have an internal diameter of 3.93 in. (100 mm).

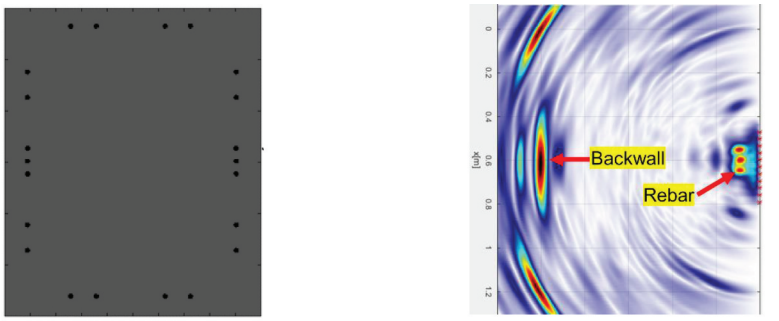
2 TECHNOLOGY FOR VISUALIZING THE INTERIOR OF THE TIE GIRDER

A group of authorities representing the bridge owner, contractor, designer, consultants, and nondestructive testing experts deliberated on available technologies to visualize the internal condition of the tie girder segment and detect any potential voids or lack of consolidation with a dense reinforcement cage and 12 empty ducts. The consensus was to try the A1040 MIRA (an ultrasonic pulse-echo device designed for imaging of the internal structure of concrete) to visualize the girder's interior. The device has an array of 48 dry-point-contact shear wave transducers (12 columns and 4 rows). Shear wave transducers are favorable due to lower signal attenuation and backscattering compared to longitudinal wave transducers. The data collected with different transmitter-receiver distances (aperture) in a single position results in better resolution and image accuracy. The principle approach for identifying and locating a defect is to inspect the reflected signal amplitude through the device data display. The data collected on a grid can be postprocessed using a special software to generate C and D scans in addition to A and B scans (Basnayake et al. 2021).

The device functionality was evaluated by calibrating and collecting data from two reference specimens. Also, the raw data (signals) were evaluated using a specialized software to verify the proper functioning of each channel and the equipment.

3 PLANNING FOR DATA COLLECTION AND ANALYSIS

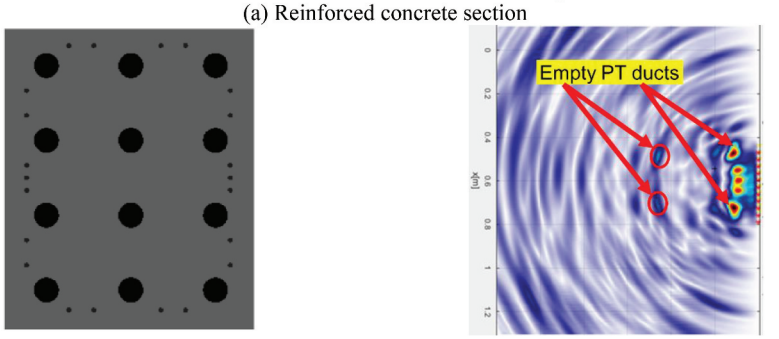
3.1 *Simulations to evaluate data collection procedure*



Prior to data collection, the measurement process was numerically simulated to verify the ultrasonic wave propagation and wave rebound within a concrete specimen. The measurement refinement and direction was decided based on the simulations of the concrete volume with obstacles. Since the quality of concrete in this model was assumed satisfactory, the obstacles impacting wave propagation in this case included rebars and empty post-tensioning ducts.

Signal propagation was simulated through a 3.25 ft (1.0 m) wide and 4 ft (1.2 m) deep reinforced concrete section (with and without ducts) to evaluate the likelihood of detecting backwall reflections. Backwall reflection detection is required for the calibration of phase values for the classification of reflector types (i.e., the internal details and voids). The simulation emulates a single MIRA scan on the right side vertical surface and at a depth of 23.6 in. (600 mm) from the top surface. The unit was placed with the excitation direction parallel to the ducts. The following observations were made from the simulation of three different cases:

(1) Reinforced concrete section: As shown in Figure 4(a), strong reflections are clearly visible from the longitudinal reinforcement located closer to the right-side vertical surface and directly in front of the unit. Also, a strong backwall reflection is visible at a distance of 3.25 ft (1.0 m) from the right-side vertical surface of the reinforced concrete section.
(2) Reinforced concrete section with 12 empty ducts: As shown in Figure 4(b), out of the 12 empty ducts, only the ducts and longitudinal reinforcement located near the scanned surface are visible. Very light reflections appear from the 2nd column of the empty ducts, which are located at a depth of 19.5 in. (495.3 mm) from the scanned surface.
(3) Reinforced concrete section with 12 grouted ducts containing post-tensioning strands: As shown in Figure 4(c), simulation shows backwall reflection only when the ducts are grouted. Light reflections appear from the grouted ducts closer to the scanned surface. Similar to the two previous simulations, longitudinal reinforcement located closer to the scanned surface shows strong reflections.



3.2 *Evaluation of data analysis procedure*

As shown in Figure 4(b), strong reflections were expected from longitudinal reinforcement and empty ducts located nearest the scanned surface when the unit was placed with the excitation direction parallel to the ducts. Weak reflections were observed from the second column of

Section details Signal reflections

(c)Reinforced concrete section with grouted ducts containing post-tensioning strands

Figure 4. Simulation results showing limitations of the depth of observation.

empty ducts that were located at a depth of 19.5 in. (495.3 mm) from the vertical surface. Since the simulation models did not include voids or anomalies, no other reflections were observed.

To further validate the simulation observations, measurements were performed on the mock-up knuckle. The mock-up knuckle was fabricated to evaluate the possible challenges in meeting the required construction quality. The details of the knuckle were known, and the concrete condition was visible over the saw cut surface. Figure 5 shows an isometric view, saw-cut surface, details closer to the scanned surface, and cross-section details of the lower portion of the knuckle.

Figures 6(a) and (b) show the reconstructed data at sections in between the stirrups and at a stirrup. As shown in Figure 6(a) (i) and (ii), the reflections are evident from three longitudinal reinforcement bundles and the duct nearest the scanned surface. The three reinforcement bundles include two bundles of #8 (25.4 mm) bars and one bundle of #7 (22.2 mm) bars, which were the primary reasons for strong reflections. As shown in Figure 6(b), signals are disturbed and shielded by vertical stirrups producing multiple reflections. As shown in Figure 6(a) (iii) and 6(b) (iii),

(a) Isometric view

(b) Saw-cut surface

(c) Details closer to the scanned surface

(d) Cross-section details

Figure 5. Lower part of the mock-up knuckle.

phase distribution is disturbed insignificantly away from the stirrups. Since the backwall reflection was not visible, phase values of the empty post-tensioning duct were used to calibrate the phase diagram after carefully evaluating the reflection of the duct at sections away from the stirrups.

3.3 *Planning for tie girder data collection*

Based on the observations made from the numerical simulations and mock-up data analysis, it was decided that data collection will be performed from the two sides and the bottom of the tie girder segments between two floorbeams. At the floor beam connections, however, data was collected only from the outside and bottom surfaces of the tie girder. Since shear waves have uncertain sensitivity to elongated objects (such as rebars or post-tensioning ducts), the recommendation is to survey twice with different orientations ("polarizations") of the device if objects in all directions are of importance. If and only if there is a preferred orientation of the objects, or if an object is sufficiently large with an upper side more or less parallel to the subsurface, one survey is deemed sufficient. Since the investigation involved unknown interior conditions, data collection refinement was decided to be at a 2 in. (50 mm) spacing parallel to the excitation direction and at a 4 in. (100 mm) spacing perpendicular to the excitation direction. A detailed plan for data collection and recording was developed. The plan included measurement grids, device orientation, starting position on the grid, and the sequence of data collection.

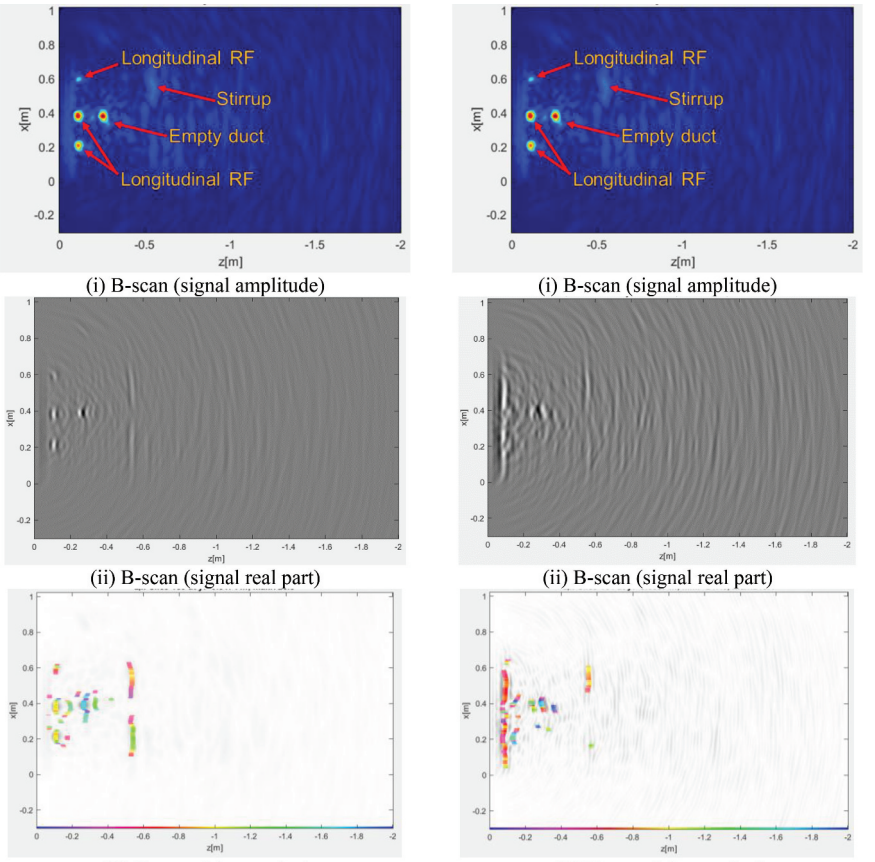

Figure 6. B-scans at a section (a) between vertical stirrups and (b) at a vertical stirrup showing signal strength, real part, and phase value distribution.

4 RESULTS AND CONCLUSIONS

The data from three sections, (i) the reference section between floorbeams C and D, (ii) Section 3 between floorbeams N and P, and (iii) Section 5 between floorbeams P and Q, were analyzed to develop signal strength and phase value plots. Data was collected with the excitation direction parallel and perpendicular to the ducts. Interior of the tie girder was characterized using 3D reconstructions. Observations at a large number of sections were documented and evaluated by comparing results from multiple sections with similar details. Figure 7 presents one of the formats used for documenting the analysis results.

The following conclusions are developed from this study:

- Simulation of shear wave propagation through this complicated and congested section demonstrated the capabilities and limitations of the tomography technology for visualizing the interior conditions of the tie girder.
- Data collection and analysis of the mock-up knuckle and the simulation of shear wave propagation through the tie girder helped to realize the challenges and advance the confidence on the nondestructive evaluation results.
- More reflections are observed from the outside surface scans. This could indicate voids closer to the outside surface. While drawing the 2-in. (50 mm) grid, many bugholes were

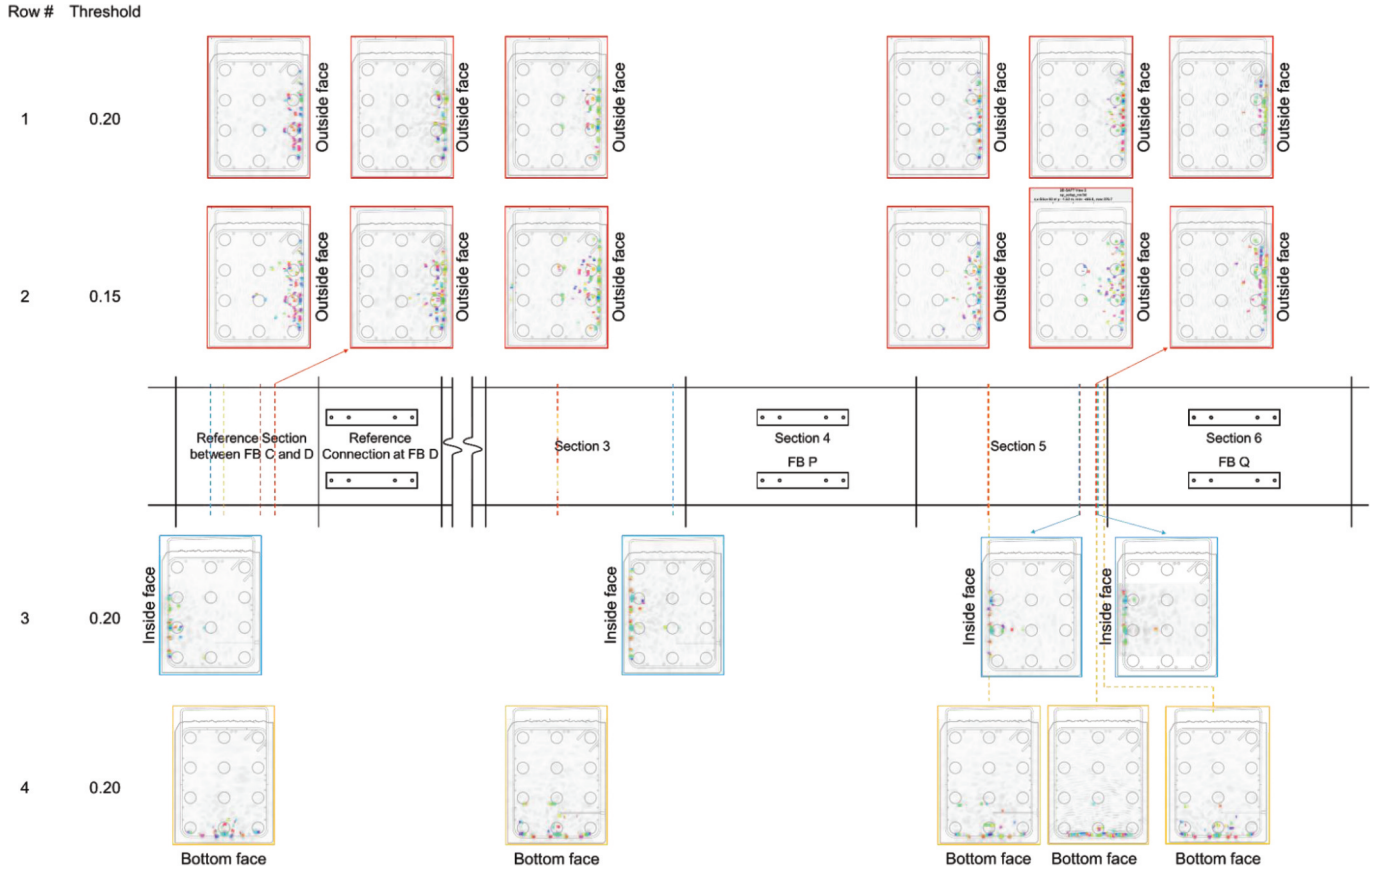

Figure 7. Summary of findings at the sections located between floor beams.

observed on the outside surface. Certain bugholes on Section 5 were as deep as 1 in. (25.4 mm). Compared to the outside surface, the inside and bottom surface quality of Section 5 is significantly better. Similar conditions are observed at the other cross-sections of the girder.

- Inside and bottom surface scans show strong reflections from the ducts and reinforcement nearest the scanned surface and weak reflections from the empty ducts at the second layer. This indicates that the concrete quality towards the inside and bottom surfaces is superior to the quality of concrete near the outside surface.
- After comparing all scans from outside surfaces and reducing the phase value threshold to 0.15, a section within Section 5 showed few additional reflections. One of the reflections is located at about 42.5 in. (107.95 mm) south of the south end of the floor beam Q anchor plates. These reflections are observed at only 15% signal strength: typically, an indication of weak reflections (small voids). In this case, however, this assessment might not be valid since weak reflections are also observed at the 4 in. (100 mm) diameter second column empty ducts. Since the length of the reflector is only about 3 in. (75 mm) along the tie girder length, its significance was considered to be minimal when compared to the overall section quality.
- After careful evaluation of all the observations and considering the meticulous process implemented for visualizing the interior of the girder, it was decided to move forward with construction. The project was successfully completed in 2023.

ACKNOWLEDGEMENT

This project was funded by the Michigan Department of Transportation (MDOT) through the Center of Excellence for Structural Durability at Western Michigan University. The authors would like to acknowledge the support of MDOT engineers and the members of the Z-Contractors. The authors would like to thank Dr. Klaus Mayer for simulating stress wave propagation through the tie girder cross-section to identify condition assessment limitations, sharing necessary tools, expertise, and time to address the project needs. A special thank is due to Eng. Jens Wöstmann (BAM) for performing analysis of a selected number of datasets and providing results to evaluate the data analysis process and assumptions. Authors appreciate the contribution of Srikanth Vemula, Sanjoy Bhowmik, and Uresh Wijesinghe for data collection.

Reliability analysis of end cracking in continuous prestressed concrete girders

A.M. Okeil
Department of Civil and Environmental Engineering, Louisiana State University, Baton Rouge, LA, USA

S. Ghimire
Enbridge, Inc., Houston, Texas, USA

ABSTRACT: Constructing bridges using precast prestressed concrete girders is extremely popular because of their durability and ease of construction. Establishing continuity between precast girders has its advantages and has been employed in many projects. It causes the development of positive restraint moments at intermediate supports as a result of long-term effects such as creep, shrinkage and thermal gradients. Prestressed concrete girder end cracking occurs if the positive restraint moments exceed the girder's cracking moment. In this study, the probability of girder end cracking in continuous prestressed concrete bridges is assessed using structural reliability concepts. This study focuses on two bridge configurations with different lengths and girder cross sections, which were assumed to be continuous over two spans. Design parameters such as dimensions, modulus of elasticity, modulus of rupture, area of prestressing steel and temperature gradient are first defined as random variables. A limit state function to assess the probability of girder end cracking is established based on the identified random variables for the serviceability limit state. The effects of creep, shrinkage, prestress, and temperature gradient were considered in the analyses. Monte Carlo simulations were then used to assess the probability of girder end cracking for an assumed girder age of 28 days. Results show that for this girder age, the probability of girder end cracking is high (68.2% – 91.8%); highlighting the vulnerability of prestressed concrete girder end cracking when used in continuous bridge spans as has been observed in the field. The vulnerability of girder ends to cracking is exacerbated by the fact that not the entire section is yet engaged in resisting restraint moments due to St. Venant's principal.

1 INTRODUCTION

Assessing the vulnerability of concrete girders to cracking is typically done deterministically. Practice has shown that cracking still occurs in situations where it is not expected (Hossain et al. 2020). Like other structural design quantities, many of the parameters involved in determining the cracking moment, M_{cr}, are not deterministic, which is a source of uncertainty in the assessed M_{cr} values. This implies that absolute safety or zero probability of failure cannot be achieved (Nowak and Collins 2000). Therefore, it is crucial to produce structural designs with an acceptable low probability of failure which translates into a reasonable safety level. Acceptable safety levels must meet societal expectations, which are achieved by strictly following code requirements that set minimum design requirements that must be met (e.g. minimum flexural capacity to meet gravity/wind/seismic load demands for strength limit states or allowable deflections for serviceability). Modern design codes such as the American Concrete Institute's (ACI) *Building Code Requirements for Structural Concrete – ACI 318-19* (ACI 2019) and American Association of State Highway and Transportation Officials (AASHTO) *Bridge Design Specifications (BDS)* (AASHTO 2020) are developed by considering the sources of uncertainty involved in design based on structural reliability concepts (Nowak and Collins 2000).

DOI: 10.1201/9781003483755-213

Many factors need to be considered in the design and construction of continuous bridges compared to simply supported bridges. One of these factors is the development of positive restraining moments at intermediate supports. Positive restraining moments are caused by time dependent factors such as creep, shrinkage, and thermal gradient, and are one of the main causes of girder bottom flange, or continuity diaphragm, cracking near the supports (Okeil et al. 2013). Cambering of girders due to long-term effects causes the bottom flanges of the girders to translate away from each other at the continuous supports. Positive moment reinforcement restrains this movement, which leads to tension, and hence the development of a positive moment. Creep is a time dependent physical property of concrete that leads to deformations under sustained loads (Hossain et al. 2014). Shrinkage is also a time dependent physical property that occurs due to the drying up of water molecules from the concrete mix in concrete structures in the absence of sustained. Thermal stresses are caused by changes in the ambient temperatures surrounding the structure, which is typically not uniform. Consequently, some structural components that are not free to expand or contract experience additional stresses due to these temperature changes.

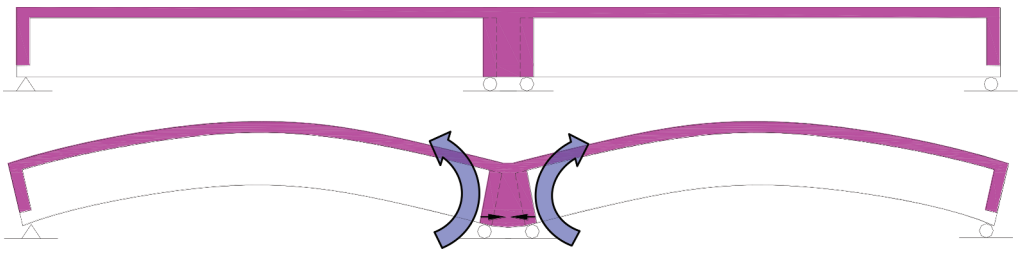

Figure 1. Positive restraint moment caused by long-term effects.

In this study, two continuous slab-on-prestressed concrete (PSC) girder bridge configurations with different lengths and girder cross sections are studied for the purpose of assessing the probability of cracking at girder ends due to positive restraint moments. A probabilistic limit state function is established based on random variables (dimensions, material properties, . . .etc.) for the serviceability limit state. The effects of creep, shrinkage, prestress, and temperature gradient were considered in the analyses. The probability of girder end cracking in continuous prestressed concrete bridges for an assumed girder age of 28 days is assessed using theory of structural reliability using Monte Carlo Simulations (MCS).

2 MOTIVATION

Slab-on-PSC girder bridges are considered one of the most popular alternatives for bridge construction in the United States and many other parts of the world. Ease of construction and superior durability due to their uncracked nature are only a couple of the reasons often sighted for their appeal to designers and bridge owners. Cracking, therefore, is not a welcome behavior for PSC bridges. In addition to loosing stiffness, cracked PSC girders are prone to rapid deterioration as a result of the exposure of internal reinforcement to the environment. This study is motivated by the need to understand the cracking vulnerability of PSC continuous bridges for the purpose of building new bridges with construction details that achieve the end goal of building longer span bridges that are safe and durable. The effect of thermal changes on PSC continuous bridges have been overlooked for a long time (Elbadry and Ghali 1986), but as recent studies have shown (Hossain et al. 2020), it has been found that temperature field changes result in thermal stresses that can be critical and cause cracking of PSC girders in bridges. Hence, it is crucial to develop a better understanding of the behavior of this popular bridge alternative by studying behavior under temperature gradient effects to reduce the probability of cracking, which may lead to shorter design life.

3 METHODOLOGY

Two continuous slab-on-PSC girder bridges with different lengths and girder cross sections are selected for this study. The bridges are first analyzed to obtain the internal force demands that typically develop in such bridge configurations. The RESTRAINT program (Mirmiran et al. 2001) that was developed as part of the National Cooperative Highway Research Program (NCHRP) project on establishing positive moment continuity (Miller et al. 2004) was modified to add the capability to account for temperature gradient effects on restraint moments in what will be referred to as mRESTRAINT-TG. mRESTRAINT-TG is capable of calculating the restraint moments caused by creep, shrinkage, and temperature gradients for a continuous slab-on-girder prestressed concrete bridges with various geometric configurations. Uncertainties inherent in the variables involved in these demands are then introduced. The resulting random variables are then introduced to a limit state function to assess the probability of cracking.

A random variable can be defined as a variable whose value can vary because of epistemic or aleatory uncertainties; i.e., not deterministic. Random variables are important for estimating the reliability of structures because there are many factors in the design and construction of structures whose outcomes are not deterministic. Random variables can be modeled as continuous or discrete random variables. For this study, all parameters such as concrete elastic modulus and modulus of rupture, area of prestressing steel and temperature gradient are modeled as continuous random variables. A limit state function mathematically defines the boundary of a desired and undesired performance of any structure (Nowak and Collins 2000). These boundaries are represented by an equation that in its simplest form is the difference between the structure's capacity to resist applied loads (R) and the applied load effects (L):

$$g(R, L) = R - L \tag{1}$$

where, $g(R, L)$ is the limit state function. If $g(\ )$ is greater than zero, it can be said that the structure did not fail, where failure is simply defined as not meeting design requirements. Conversely, if $g(\ )$ is less than zero it can be said that the structure failed at meeting the design requirements since it its capacity is less than the load demands it is subjected to. Since the aim of this study is to assess the probability of cracking due by positive restraint moments that develop due to thermal gradients in continuous PSC girder bridges, the limit state function for this study is taken as follows:

$$g(\ ) = M_{cr}\ - M_{TG} \tag{2}$$

where M_{cr} is cracking moment of the girder, and M_{TG} is restraint moment due to thermal gradient. In addition to M_{TG}, continuous beams are also subjected to thermally induced primary stresses (Priestley 1985). Since primary stresses occur due to the temperature gradient as a result of maintaining that structural sections remain plane, it does not generate additional moments and should be accounted for in this study. This primary stress effect occurs even in simply supported bridges. Creep and shrinkage also cause secondary restraint moments in continuous bridges. It should be noted that prestressing effects were ignored in this study since the sections at the girder ends are subjected to minimal compressive stresses because of the transfer length. After adding these effects, the limit state function becomes

$$g(\ ) = M_{cr} - M_{TG} - \text{primary stress effect} - M_{(\text{CR+SH})} \tag{3}$$

Monte Carlo simulation was used for calculating the probability of cracking due to positive restraint moments developed by thermal gradient. For the study, the probability of cracking was calculated for two scenarios. First, the cross-sectional properties were calculated using the gross section as is typically done. Another case was considered where the web of the cross section was ignored. The second case was considered in this study because finite element analyses showed that the cold joint does not fully engage the web of the girder. As can be seen in Figure 2, a gap develops between the continuity diaphragm and the girders' webs above the

bottom flange after the forces exceed the friction at the cold joint. Consequently, the stress distribution was found to be concentrated around the bottom flange positive moment reinforcement at the girder ends rather than the entire cross section (Hossain and Okeil 2014). This observation confirms St. Venant's principal (von Mises 1945). In other words, the web can only be engaged in resisting the restrain moments after a distance typically taken equal to the member's depth. Therefore, it was deemed necessary to assess the probability of failure for both assumptions, i.e. with and without the considerations of web. Figure 3 shows the cases described above that were considered in this study.

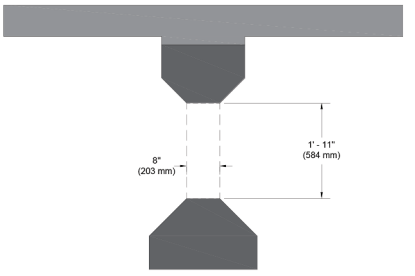
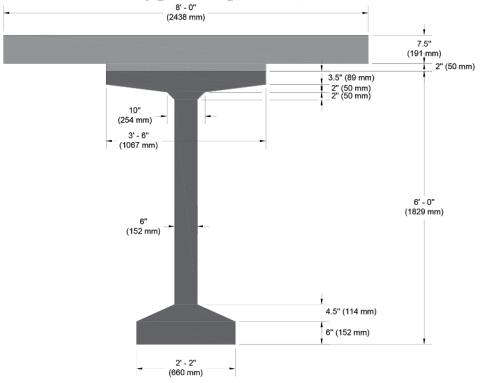
3.1 *Details of case study bridges*



The bridges selected for this study were assumed to be continuous over two spans with equal span lengths. A deck slab with an 8-in. (203 mm) thickness was considered in this study and the girders were placed at a spacing equal to 8 ft (2.44 m). To accommodate girder camber due to prestressing, a 1.0-in. (25 mm) haunch was also considered. A standard AASHTO Type-IV section was chosen for the first bridge to meet design requirements for a 100 ft (30.48 m) span length. Figure 4-(a) and (b) show the dimensions of AASHTO Type-IV girder with and without the web part respectively. The span length for the second bridge was taken equal to 120 ft (36.58 m), which required a larger standard section, namely AASHTO BT-72. As stated earlier, both bridges were analyzed twice, once with the full gross section properties and the other after eliminating the web contribution of the cross-sectional properties. Figure 4-(c) and (d) show the dimensions of the girder with and without web parts, respectively.

The analysis using mRESTRAINT-TG dissects the cross section into a sufficient number of layers, or fibers, for calculations of composite area, moment of inertia, non-composite area and temperature variations. The nominal values taken for modulus of elasticity of girder and deck were 5,422 ksi (37.4 MPa) and 3,834 ksi (26.4 MPa), respectively. The nominal value



taken for modulus of rupture is 0.678 ksi (4.7 MPa), and the nominal value of area of pre-stressing strand was 0.217 in^2 (140 mm^2). Figure 5 shows the temperature gradient model used in this study is based on AASHTO BDS for Zone 2.

4.2 *Calculation of probability of cracking*

The commercially available software MATLAB was used to generate random variables with the appropriate distribution types (e.g. normal or lognormal) for all random variables in the limit state function. More details about the statistical characteristics of the random variables can be found elsewhere (Ghimire 2014). Monte Carlo simulation was then conducted using

the generated random values to calculate probability of cracking of the girder based on the limit state function. The flowchart of the MCS used in this study is shown in Figure 6.

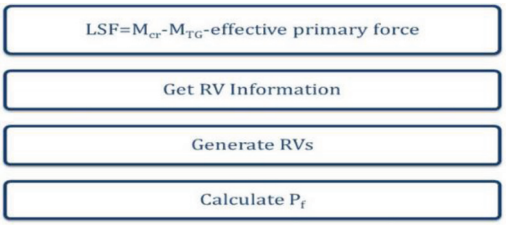

Figure 6. Flow-Chart for Monte-Carlo Simulation.

The probability of girder end cracking was first calculated for moment developed due to the temperature gradient only and later restraint moment developed due to creep and shrinkage was also added to probability of cracking. The girder's size and properties were all same for both cases. The nominal values of the restraint moment due to creep and shrinkage was taken from the mRESTRAINT-TG program for the 2 span bridge cases with AASHTO Type-IV and AASHTO BT-72 girders. The magnitude of the restraining moment due to creep and shrinkage is affect by the girder age at time of establishing continuity. Accordingly, it was assumed that girder age was 28 days when the continuity was established. As with all simulation methods, a sensitivity study was first conducted to determine a suitable number of simulations. Five different numbers of simulations were used to calculate the probabilities of cracking. The number of simulations used were 1,000, 10,000, 100,000 and 1,000,000.

4 RESULTS

The results presented in this section were obtained following the methodology described in the previous section. Table 1 and Table 2 list the results of the probability of cracking considering the restraint moment due thermal gradient, M_{TG}, only as a least critical scenario. It can be seen that the probability of cracking almost stabilizes at 1,000,000 simulations. For the 1st Bridge case (TYPE IV, L =100 ft), the probability of cracking when the web is considered is around 16.0%. When the web is not considered for the same bridge, the probability of cracking increases to about 29.0%. The difference in these results is because of the reduced girder section, and its geometric properties (e.g. area and moment of inertia), and hence the cracking moment, M_{cr}. The corresponding values for the 2nd Bridge (BT-72, L =120 ft), the probability of cracking increases when the web is considered is about 23.9% when the web is included in the analysis and 48% when the web is not considered.

It should be noted that these probabilities are higher than what is typically expected for strength limit states, which typically corresponds to a reliability index, β, equal to 3.5 (P_f = 0.0023). This is expected since the consequences of exceeding serviceability limit states are not as consequential as exceeding strength limit states that can lead to jeopardizing safety and economic losses (Wassef et al. 2014). As stated earlier, the results presented in Table 1

Table 1. Results from Monte-Carlo Simulations for 1st Bridge (TYPE IV, L =100 ft).

Number of simulations	Probability of Cracking (with Web)	Probability of Cracking (without Web)
1,000	14.5 %	26.6 %
10,000	14.6 %	26.7 %
100,000	15.1 %	27.5 %
1,000,000	15.9 %	28.5 %

Table 2. Results from Monte-Carlo Simulations for 2nd Bridge (BT-72, L =120 ft).

Number of simulations	Probability of Cracking (with Web)	Probability of Cracking (without Web)
1,000	22.9 %	47.4 %
10,000	23.5 %	47.4 %
100,000	23.8 %	47.9 %
1,000000	23.9 %	48.0 %

and Table 2 list the probability of girder end cracking when only restraint moment developed due to the temperature gradient is considered. Subsequent analyses were performed for the complete limit state function including the effects of creep and shrinkage. As a result of the increase of the restraint moment, the probability of girder end cracking will be even higher. The probability of cracking calculated for these cases increases to about 68.2% for the 1st Bridge case (TYPE IV, L =100 ft) and 79.0% for the 2nd Bridge case (BT-72, L =120 ft) if the web is considered and 77.7% and 91.8% for both cases, respectively, when the web is not considered. These probabilities are extremely high (β equal to –0.47 and –1.39) and exceed any values acceptable to code committees even for the less stringent serviceability limit states. These results confirm the aforementioned field observations of cracks at girder ends in a monitored bridge that used the positive continuity detail (see Figure 7). These bottom flange cracks can propagate into diagonal shear cracks in the web over time as they open and close on a daily basis with thermal cycles.

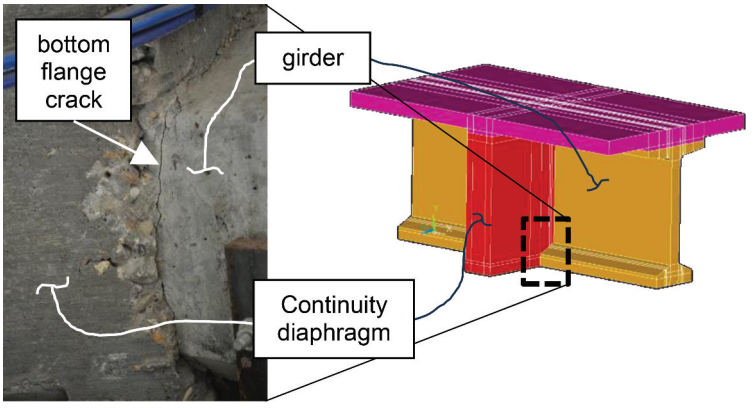

Figure 7. Bottom flange cracking in monitored bridge.

5 CONCLUSION

The following conclusions can be drawn from the results presented in this paper:

1. Temperature gradients can cause large restraint moments in continuous bridges and should be considered in the design of continuous slab-on-PSC girder bridges. Temperature gradients exacerbate the effect of creep and shrinkage leading to even larger restraint moments in continuous slab-on-PSC girder bridges.
2. Positive restraint moments may cause cracking at the girder ends. Results show that the probability of cracking that is more likely than not (>50%).
3. The study showed that the probability of cracking is affected by girder size as it was noted that the number increased with increase in size of girder. This may be because larger girders are more susceptible to temperature gradient effects.

4. In checking the cracking of the girder ends, it is recommended that the web portion be ignored as it not engaged in the moment resistance of the cross section due to the disturbed stress state as a result of lumping the force transfer in the bottom positive moment reinforcement in the bottom flanges (St. Venant's principal).

Accordingly, thermal gradients effects should be considered in the design of continuous slab-on-PSC girder bridges. A full parametric study is needed to study the probability of cracking over a wider range of parameters (span lengths, number of spans, temperature gradient models). Cracking mitigation measures should also be investigated to reduce the probability of cracking.

B. Wagner
Michigan Department of Transportation, Lansing, MI, USA

ABSTRACT: A unique network tied-arch bridge with free-standing, unbraced arch ribs was designed to carry the 2nd Avenue traffic over the Interstate Highway (I-94) in Detroit, Michigan. This 96.5 ft wide and 18° skew bridge with a 245 ft span is the first unbraced network arch bridge in Michigan, the fourth in the U.S., and the only unbraced and skewed network tied-arch bridge in the world. The bridge superstructure was assembled at a nearby staging area and moved into place on the permanent abutments using Self-Propelled Modular Transporters (SPMTs) and launching techniques. This design and construction method was selected for this site to minimize traffic disruption, improve safety, and allow 2nd Avenue to completely span over I-94 without intermediate supports to facilitate future widening and alignment shift of I-94 freeway and the adjacent interchange. Several alternative designs were considered; a) the use of post-tensioned concrete tie girders, (b) the use of internally redundant steel tie girders and (c) a multi-span bridge with a movable pier. During preconstruction planning, the contractor submitted a Value Engineering Change Proposal to erect the bridge in place by using a combination of cast-in-place concrete and spliced precast segmental tie girders. The paper describes the project and the technical basis for the selection and implementation of the post-tensioned concrete tie girders.

1 INTRODUCTION

The interstate highway (I-94 freeway) segment between the east of I-96/I-94 interchange to the east of Conner Avenue in the Metro Detroit area, shown in Figure 1, is being upgraded to eliminate safety concerns associated with the presence of narrow median shoulders, inadequate capacity with three driving lanes in each direction, and inadequate clearance for freeway entrance/exit ramps. In 1994, the Michigan Department of Transportation (MDOT) initiated an Environmental Impact Study (EIS) to evaluate possible ramifications due to this corridor improvement project. In December 2004, the Federal Highway Administration (FHWA) approved the Final Environmental Impact Statement (FEIS) for modernizing this freeway segment.

In December 2005, a Record of Decision (ROD) was issued allowing MDOT to proceed with the final design, property acquisition, and construction operations in support of modernizing the I-94 corridor. A detailed engineering report was completed by fall 2010 incorporating the critical information for moving the project forward. At the time of the ROD, it was anticipated that the full buildout could take 20 to 30 years due to funding constraints. However, numerous bridges carrying traffic over I-94 were beyond their original design life and had deteriorated to the point that they needed to be reconstructed prior to the corridor project. As a result, MDOT prioritized the worst condition bridges and began designing and constructing them as part of

DOI: 10.1201/9781003483755-214

Figure 1. I-94 corridor segments selected for improvements (courtesy: MDOT).

the I-94 Advanced Bridges program while still conducting stakeholder engagements to provide a platform to discuss potential approaches to enhance local connectivity and mobility across the freeway as well as potential bridge aesthetic criteria that could enhance the local communities.

The scope of the corridor modernization project includes upgrades to 6.7 miles of the freeway, service roads, bridges, and interchanges considering safety, capacity, local connection, and condition. The following are the specific activities included in the project to improve safety and mobility:

- Address existing traffic congestion while considering future travel demand.
- Address poor pavement and bridge conditions.
- Connect important routes in an effective and efficient manner.
- Improve neighborhood connectivity across I-94 and along service drives to enhance traffic circulation through the local road system.
- Provide improvements supporting multimodal transportation.
- Upgrade infrastructure to meet current design standards.

The freeway upgrade includes addition of a fourth lane in each direction; widening the median shoulders to better accommodate disabled vehicles and emergency responders; and

Figure 2. I-94 Freeway current and proposed designs (courtesy: MDOT).

Figure 3. Constellation pattern on abutment walls.

lengthening freeway entrance/exist ramps to improve safety, capacity, and travel time reliability. Figure 2 shows the generalized 1-94 current and proposed designs.

The modernization project includes upgrades to 67 bridge structures, including 6 railroad overpasses, 11 of which were reconstructed in advance of the freeway reconstruction. Figure 1 shows the locations of these advanced bridges with each bridge featuring one vehicle lane in each direction, wide sidewalks or shared use paths with protective barriers and ornamental railings, pedestrian lighting, bridge piers representing the barrel arch design, and abutment walls with constellation patterns (as shown in Figure 3).

2 THE 2ND AVENUE BRIDGE OVER I-94

2.1 *Site constraints*

The proximity of the site to M-10 and I-94 interchange, as shown in Figure 4, required a bridge without intermediate supports and adequate underclearance to span over eight traffic lanes, four wide shoulders, and two entrance/exit ramps. Also, the proposed future alignment of the I-94 freeway will not only be widened, but will be shifted approximately 40 feet to the north of the current alignment. Since the construction of this portion of the freeway will not be completed for several years, the bridge selected for this site is expected to accommodate not only the current alignment that will remain in place for some time, but also a future widened and shifted alignment.

The new alignment of the I-94 freeway and the 2nd Avenue had an impact on three properties in the area, as shown in Figure 5. The FEIS provided detailed information on the impacts of the project on these properties. The ROD outlined the decision-making process and the specific measures to be taken to mitigate the impacts of the project on the affected properties. Overall, these measures were designed to minimize the negative impacts of the 2nd Avenue bridge construction and the I-94 modernization project on the surrounding area.

Property No. 1 is the United Sound Systems Recording Studio (USSRS) building located at 5840 Second Avenue. It was a historically significant recording studio that was founded by James V. Siracuse in 1933. Due to its association with some of the most influential musical artists of the 20th century, particularly the earliest beginnings of the world-famous Motown Music, the USSRS was eligible for inclusion in the National Register of Historic Places (NRHP). To maintain the building and prevent its demolition, MDOT and the State Historic Preservation Officer (SHPO) discussed the possibility of relocating the USSRS. Ultimately, it was decided to move the property further north and take protective measures during the construction phase of the bridge. Property No. 2 is a two-story Prairie Style house at 5832 Second

Figure 5. Three properties impacted by the new bridge construction.

Avenue. This building was constructed in 1916 as a two-family dwelling. Upon reevaluation, it was determined that this house was also eligible for inclusion in the NRHP. However, due to changes in the I-94/M-10 interchange ramp, the 0.10-acre site was acquired and the house was demolished. Similarly, the 0.28-acre site located at 5821 Second Avenue, labeled as Property No. 3 in the figure, was also acquired by MDOT. Since this site was found to be an imminent public safety hazard, the house on the property was demolished earlier than anticipated. As a result, it was no longer eligible for listing in the NRHP.

From a bridge design standpoint, the presence of the USSRS required a revision to the proposed bridge alignment and more importantly, the use of a skewed bridge. Even though a skew less than 20 degrees normally requires a minor adjustment to the design detail of a conventional girder bridge, the need for a skew became a significant factor in the design of an arch bridge.

2.2 *Bridge configuration and construction methods*

The 2nd Avenue bridge is one of the advanced bridges with non-motorized facilities (i.e. wide shared use paths with protective barriers and ornamental railings), one vehicle lane in each direction, and pedestrian lighting. A network tied arch bridge was selected as a replacement of the 2nd Avenue Bridge over I-94 freeway. This 265 ft long and 96.5 ft wide bridge has a skew of 18° making it a unique structure among the network arch bridges in the U.S. Figure 6 shows the structural components of the bridge. The structural assembly consists of two trapezoidal steel arch ribs connected at each end to post-tensioned tie girders through the knuckles, post-tensioned end diaphragms, steel floor beams, lateral bracings, and hangers. The lateral bracings between the arches were excluded since the use of lateral bracings in a skewed arch bridge is not aesthetically pleasing because the entire bridge appears significantly warped when viewed from the driver's perspective. The Naruse Okumatsushima bridge in Japan is an example of a skewed network arch bridge with lateral bracings. The 2nd Avenue bridge is also equipped with color-changing and energy-efficient LED aesthetic lighting to provide a visual centerpiece for the entire corridor.

At the start of the project, MDOT and the design team identified the prime objective of constructing this signature bridge without impacting I-94 traffic for more than a few days – perhaps as short as a weekend closure (e.g. from 10 p.m. Friday to 5 a.m. Monday) to completely avoid rush hour traffic. MDOT and the design team held a series of confidential meetings with several industry-leading specialty contractors to solicit input on feasible means of moving the bridge into its final position. The design team evaluated several construction alternatives and ultimately selected one in which the bridge skeleton – essentially the entire arch span except the concrete deck – would be constructed in a nearby parking lot and moved into place using self-propelled modular transporters (SPMTs). An SPMT is a flatbed trailer with a large array of wheels used for transporting massive objects big or heavy for conventional trucks. Following the SPMT move and placement of the assembled structure on permanent bearings, the remaining construction activities were completed.

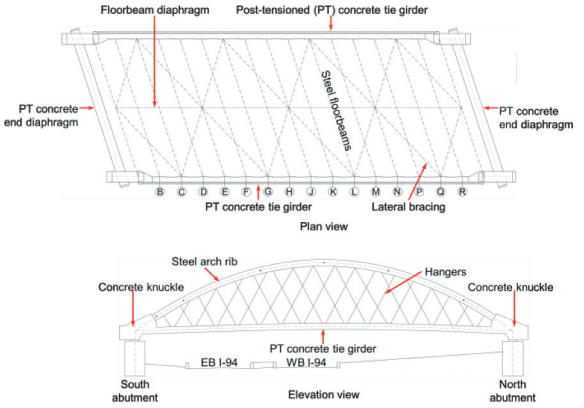

Figure 6. Major components of bridge superstructure.

3 SELECTION OF POST-TENSIONED CONCRETE TIE GIRDERS

For complex bridges such as this network tied arch span, the method and sequence of construction is extremely important to the design of the permanent bridge. The structure must be able to withstand any forces applied during construction and thus the designer must anticipate the most reasonable sequence of installation.

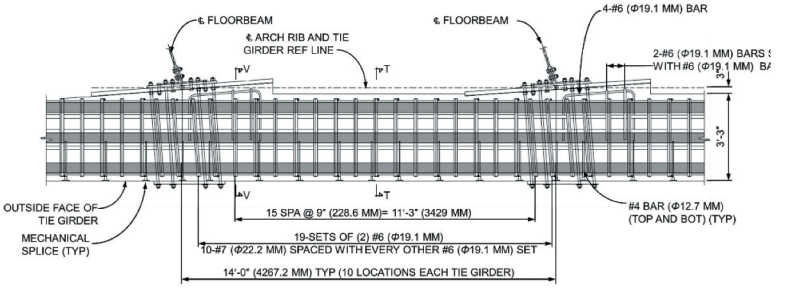
First and foremost, the design of the permanent structure must ensure adequate strength and stiffness, in accordance with the design codes and criteria, to resist gravity loads and environmental effects such as wind, temperature, and seismic ground motions. Initially, the bridge was designed as it will exist during in-service conditions without addressing the method of construction in fine detail. Following the selection of the most feasible construction sequence, the bridge was again analyzed and designed based on the assumed location of temporary supports and the order in which bridge components are added or made composite in the overall structure. The permanent bridge members were analyzed at each step of the assumed construction sequence to confirm that the bridge could resist the applied loads without creating overstress conditions or unacceptable deflections that could create fit-up problems at a future step.

Traditionally, tied arch superstructures have used steel members, typically box sections, to resist the thrust of the loaded arch rib. Modern tied arches utilizing steel tie girders have done so by using heavily bolted box sections which require holes and hatches to inspect the interior. These box sections typically consist of four plates that are bolted together at the corners with internal angles so that a crack forming in a single plate cannot propagate to the adjacent plate and lead to failure of the box. The need for redundancy of the box means that extra material is required beyond what is needed to carry design loads.

The clear-span options for the I-94 Advanced Bridges face an unusually difficult challenge in coping with a reduced vertical clearance beneath the bridge – a challenge that is especially acute at the 2nd Avenue bridge site due to the close proximity to the M-10/John Lodge freeway. The likelihood of over-height vehicle strikes makes it vital that a robust and redundant tie system be provided for the bridge. The increased depth of a steel tie girder and the potential for severe damage or plate failure due to a vehicle impact, made the steel tie girder undesirable for this project.

At the complex bridge meeting held on February 9, 2016, it was agreed among the design team, and MDOT that a traditional fracture-critical steel girder would be eliminated from consideration on the project and that only post-tensioned concrete tie girders would be considered for the arch bridges. Further discussions with MDOT, after the type studies were submitted, re-affirmed the selection of a post-tensioned concrete tie girder for the final design.

The tie girder reinforcement detail is shown in Figure 7. The plastic corrugated ducts in the tie girder have an internal diameter of 3.93 in. In addition, cross-section T-T and V-V details are shown in Figure 8, which illustrate the overall dimensions and number of ducts in each tie girder.



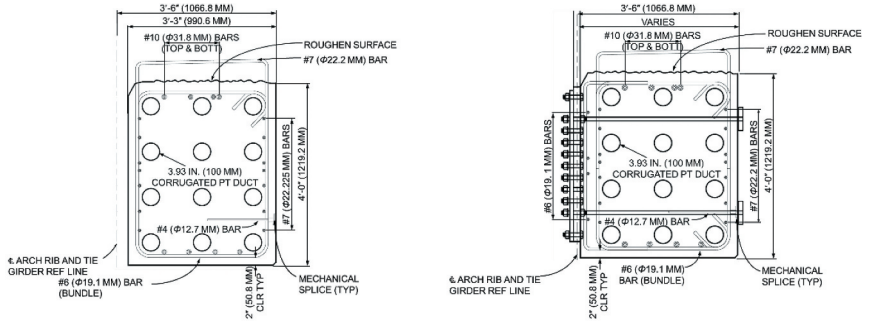


Figure 7. Typical tie girder reinforcement detail (plan view).

Section T-T: Section in between floor beams

Section V-V: Section at the floor beam

Figure 8. East tie girder section T-T and V-V as of 01/26/2022 (from SE knuckle towards NE knuckle).

A summary of the perceived advantages and disadvantages of the post-tensioned concrete and steel tie girder options includes the following:

Post-tensioned Concrete Tie Girders – Advantages:

- Post-tensioning keeps concrete in compression to reduce cracking, increase durability and extend service life.
- Internal redundancy is provided by using 12 ducts with 19 multi-strand post-tensioning tendons in each duct.
- May be constructed of precast, pre-tensioned concrete and spliced in the field or site cast.
- Post-tensioning can be performed in stages to balance applied loads during construction.
- Additional "empty" ducts can be provided for future use or replacement if desired.
- Damaged concrete and broken strands can be repaired in the event of a vehicle impact.

Post-tensioned Concrete Tie Girders – Disadvantages:

- Heavier lifting weight than steel – an important consideration for bridges built using ABC methods.
- Requires post-tensioning equipment and experience – somewhat limited in Michigan, but specialized assistance is available through the chosen supplier.

Steel Tie Girder – Advantages:

- Internally redundant steel box section can be designed using four separate plates bolted together at the corners.
- Lighter weight than a concrete tie girder.

Steel Tie Girder – Disadvantages:

- Member size is too small to provide internal access for inspection.
- Extra material beyond that needed by design is required to provide redundancy.
- Inspection handholes provide opportunity for moisture/debris accumulation and corrosion.

- Requires future re-painting.
- Repairs to steel are feasible, but difficult to recover loads that have been shed to other plates in the box section.

The design team also identified two feasible methods for constructing a concrete tie girder prior to moving the member into position spanning I-94. These methods are described in the following sections.

3.1 *Site cast concrete tie girder*

The term "cast in place" may be something of a misnomer in this case and perhaps a more accurate description of the two casting methods is site-cast and plant-cast concrete tie girder.

The site cast tie girder option consists of building conventional concrete forms on the available hard-surfaced parking lots near the bridge site and casting the tie girders using contractor forces. The advantages and disadvantages of site casting are as follows:

Site Cast Concrete Tie Girders – Advantages:

- Conventional casting that can be self-performed by contractor allows better control of project schedule and risk.
- Contractor can utilize forms for both tie girders in the same location.

Site Cast Concrete Tie Girders – Disadvantages:

- Requires additional field inspection due to the accurate geometry control required for fit-up of the floor system later in the process.
- Requires tighter than normal construction tolerances for use with ABC assembly.
- Any waviness or surface imperfections of tie girder would be highly visible in final product.

3.2 *Plant cast concrete tie girder*

The tie girders could be cast in smaller sections in a Precast/Prestressed Concrete Institute (PCI)-certified plant and then delivered and spliced in the field to complete the assembly of the tie girder. Possible splice details include either cast-in-place joints or match-cast shear key joints at the mating faces of the tie girder sections. The advantages and disadvantages of plant casting are as follows:

Plant Cast Concrete Tie Girder – Advantages:

- Concrete casting is performed by a PCI-certified plant using existing casting beds.
- Pretensioning of the precast sections would reduce shrinkage and handling stresses prior to assembly in the field.
- Smooth, reusable steel casting beds maximize visual quality of concrete.
- Plant cast operations can be conducted during cold weather.
- Tie girder can be cast in shorter sub-assemblies and spliced once they arrive onsite to form the complete member.

Plant Cast Tie Girder – Disadvantages:

- Plant cast knuckle section will be very heavy and awkward to ship to the site.
- Splicing of precast sections in the field would require connection details.
- Construction method is not typical for Michigan-based contractors.

4 SUMMARY AND CONCLUSIONS

After considering the advantages and disadvantages described in the previous sections of this document, the designers recommended the following structural details for the network tied arch bridges at 2nd Avenue over I-94:

- Arch Ribs: Unbraced, trapezoidal steel box section

- Floorbeams: Fabricated steel plate girders with steel wide flange stringers (as needed)
- Tie Girder: Site cast, post-tensioned concrete with section to provide accurate geometry control and floorbeam/hanger connection points.

The designers were confident that this combination of details would provide the best combination of constructability, reduced material lead times, shortened construction schedule, long-term durability and aesthetic appeal.

Assembly of the bridge skeleton was performed on temporary supports in a parking lot approximately 500 feet from the final location of the bridge. The assembly work faced many challenges, not the least of which was the COVID pandemic and related work delays and supply chain shortages. The bridge skeleton, weighing more than 2500 tons and nearly the size of a football field was ready to be moved into place by the start of July 2022. Nearly 70 truckloads of SPMTs and support equipment arrived onsite beginning on July 6 and the weight of the bridge was lifted by SPMTs approximately 10 days later. After some final adjustments, the bridge was driven from the staging area on July 19th and positioned directly behind the south abutment. Following the closure of I-94 and some final preparations, the bridge was launched over the top of the abutment on skid tracks and transferred to another set of SPMTs positioned down on I-94 on July 23rd. On Sunday, July 24th, the arch span was slowly driven across I-94 and landed safely on the other side by the end of the day. Figure 9 presents two views of the bridge move operation.

(a) (b)

Figure 9. Images of the skeleton supported on SPMTs during the move (a) at the staging area (July 19, 2022) and (b) during the move across I-94 (July 24, 2022).

The bridge move proceeded without an incident. The move was interrupted intermittently for a few minor elevation adjustments at one corner of the bridge or another during the

Figure 10. The 2nd Avenue network tied arch bridge in Detroit, MI, USA.

operation to maintain four corners of the bridge in the same plane at which they were cast to avoid damage to concrete or undue stresses on the bridge. Following completion of the bridge move and the transfer of the bridge to the permanent bearings, the structure received a thorough inspection by the designer and MDOT staff to ensure that it was safe to reopen I-94 traffic. The concrete bridge deck was placed and final adjustments made to the bridge prior to opening 2nd Avenue to traffic in mid-December, 2022. The completed bridge is shown in Figure 10.

ACKNOWLEDGEMENT

This project was constructed by the Michigan Department of Transportation and their support of innovative design and construction practices is very much appreciated. Z-Contractors of Shelby Township, MI, was the general contractor for the bridge and their willingness to expand their normal construction practices for a highly unusual bridge is highly commendable. The entire team would agree that this project could not have been completed without teamwork and collaboration.

Post-tensioning tendons under strand breakages: Modelling approach for bonded tendons

B. Vecino, C.M.C. Renedo, J. Naranjo-Pérez, I.M. Díaz & J.H. García-Palacios
E.T.S.I. Caminos, Canales y Puertos, Universidad Politécnica de Madrid, Madrid, Spain

ABSTRACT: Recently, numerous failures have been detected in external post-tensioning tendons due to brittle fracture in stress corrosion situations. Non-destructive testing (NDT) techniques related to vibration-based structural health monitoring (SHM) can be used to detect anomalies and the grade of damage in these structural elements and thus, prevent their collapse. This paper aims to propose and validate a modelling strategy of taut short external post-tensioning tendons. The authors have carried out a detailed finite element (FE) model of the tendon to be used on an evolutionary analysis of the breakage process. The model is validated comparing the degradation curves measured in an experimental test previously carried out in the literature, in which accelerated corrosion was induced on a real posttensioning tendon. This work has been developed in an attempt to stablish realistic Performance Indicators (PIs) that could serve as an effective alarm for predicting the tendon breakage. The steel has been modelled as a non-linear elastoplastic material.

1 INTRODUCTION

Recently, several failures have been detected in external post-tensioning tendons due to brittle breakage in stress corrosion cracking situations (interaction of corrosion and mechanical stress) (Texas Transportation Institute 2009). Two examples of bridge collapses are: Viaducto O Castro A-6 (Lugo), 2022 and Morandi bridge, Genova (Italy), 2018. In the case of bonded tendons (strands are protected directly by cement grout), when breakage occurs the grout prevents the strands from sliding inside due to the self-anchoring, so there is a transference of the stressing force from the broken strand to the healthy strands. Therefore, global stressing force in the tendon does not decrease proportionally to the steel section lose despite the breakage of a strand, this complicates the detection of damage, especially through the use of modal properties. The self-anchoring phenomena affects the sensibility of global performance indicators (PIs) and should be taken into account in the design of structural health monitoring (SHM) systems.

The use of non-destructive testing (NDT) techniques to detect potential tendon deterioration is essential to plan the tendon maintenance and anticipate damage. A vibration-based NDT technique can be used in intermittent and continuous monitoring for damage detection. This NDT technique relies on the sensitivity of some structural PIs to damage, such as: the natural frequencies and the ratios between them, the modal shape and even the damping ratios. Structural damage can be represented by deviations of these indicator's normal values during the monitoring process.

The main objective is to propose a modelling strategy of taut short external post-tensioning tendons and validate it using experimental results previously published. Thus, this strategy can be adopted for: i) creating a digital twin to be used within model based SHM systems, ii) assessing performance indicator sensitivity to the grade of degradation, and iii) setting effective alarms when implementing SHM systems.

In the Section 2, a finite element (FE) model-based numerically modelling strategy of taut bonded tendons is presented and contrasted (in Section 3) with experimental results carried out by Lee and Kang (2019).

DOI: 10.1201/9781003483755-215

2 FE MODEL

A detailed FE model of a seven-strand tendon is developed. The experiment carried out by Lee & Kang (2019) is used as reference in order to compare their experimental results and the numerical results obtained in this investigation. The purpose is to determine de sensitivity of de PIs studied and to reproduce as accurately as possible the degradation curves obtained by Lee & Kang.

2.1 *FE model description*

The Lee & Kang experiment consists of stressing a 10 m tendon in two independent cases: at 40% and 70% of the minimum ultimate load of a prestressing strand. Then, five strands are broken successively by accelerated corrosion in 24 hours. To carry out the breakage of the strands, the grout is retired in the 30 cm central section, leaving the strands exposed (Figure 1).

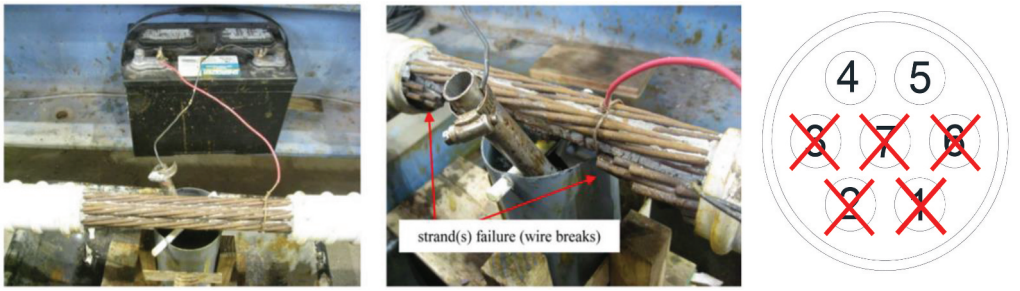

Figure 1. Strand breakage procedure. Lee & Kang (2019).

Therefore, the FE model represents a 10 m tendon of seven steel strands surrounded by grout. The 30 cm central section is modelled without grout to reproduce de Lee & Kang experiment. The strands are designed with a split element in their central section to simulate strand breakages by deactivating the contact between the two sides of the strand (strand-strand contact), which initially are modelled with a bonded contact to guarantee its continuity before breakage. 3D Solid elements are used for the strands and grout in this model. Sweep meshing method has been used so that the positions of the nodes match with those of the grout in each section. Both ends of the seven strands are modelled with fixed support, that is rotation and translation are restrained at both supports.

The stress state reached by the stressing of the strands are modelled by a thermal load. The two stressing states reached by Lee & Kang are considered: 40% and 70% of the minimum ultimate load of a prestressing strand, so the forces considered are 775 kN and 1241 kN, respectively.

A lineal elastic surface-to-surface contact model between the grout and the strands is assumed. Considering the severe self-anchoring observed experimentally and the 30 cm transfer length (Russell & Burns 1993), the contact stiffness adopted is $k = 1 \cdot 10^{15}$ N/m/m^2.

Plasticity of steel strands is considered. The elastoplastic model used presents the following characteristics: i) Bilinear isotropic hardening law (Figure 2), ii) Von Mises yield criterion, iii) Associated flow rule.

2.2 *FE analysis description*

A non-linear analysis by load steps is then performed. A sparse direct solver and the Newton-Raphson algorithm with convergence in forces and displacements are used. The non-linearity is caused by the activation and deactivation of contacts, which is solved by the "Pure Penalty" methodology, in which the contact stiffness is updated during each iteration to ensure minimum penetration between the contact surfaces. Additionally, the influence of plasticity on the

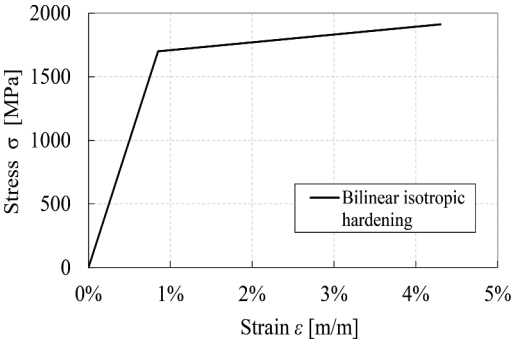

Figure 2. Bilinear isotropic stress-strain behaviour for the strands.

FE model is studied by carrying out two analyses, one where the materials are kept elastic and another where the plasticity of the steel strands is considered (Figure 2).

The FE analysis follows these steps: i) Stressing of strands by applying a thermal load, ii) Activation of strand-grout contacts to simulate the grout injection, and iii) Successive breakage of strands by deactivating the strand-strand contacts (Figure 3).

A modal analysis is carried out following each strand breakage step to evaluate the progressive degradation of the tendon natural frequencies (as PI). The characteristic stress state of the load step in which this modal analysis is carried out has been considered by means of a preload state. To include this preload prior to the modal analysis, the program performs a linear perturbation analysis on the structure, where the tangent matrix $[K_i^T]$ is used to obtain the effect of the preload.

$$[K_i^T] = [K_i^M] + [S_i] \tag{1}$$

where $[K_i^T]$ = global tangent matrix; $[K_i^M]$ = part of the tangent stiffness contributed from the material property; and $[S_i]$ = stress stiffening matrix introduced by non-zero stresses from the structure.

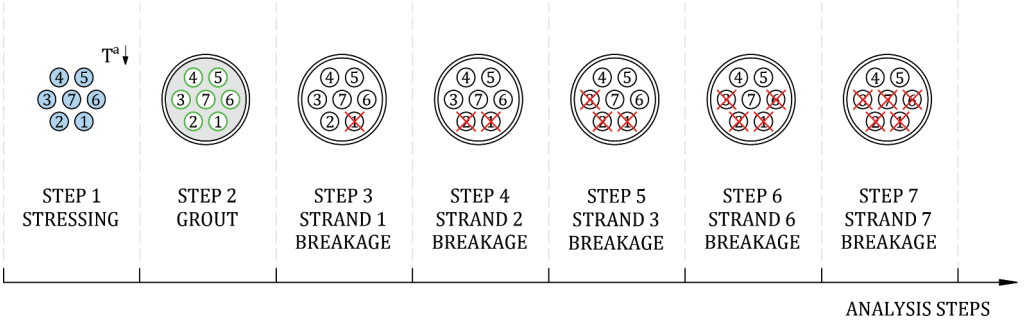

Figure 3. FE analysis steps (crosses indicate the broken strands).

2.3 *Model validation*

The model can be validated by comparing the stressing force in the anchorage obtained with the FE model considering plasticity and the experimental results obtained by Lee & Kang (Figure 4). It can be observed that the results trend is very similar although slight differences arise between both results, probably due to the plasticity model used or to the high stiffness contact between the grout and the strands considered. However, the comparison of results is satisfactory, and the model is validated.

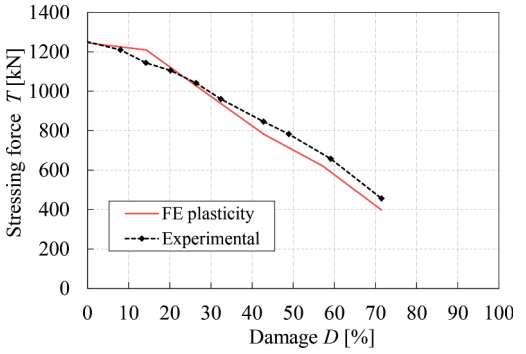

Figure 4. Model validation by stressing force in anchorage comparison.

3 RESULTS DISCUSSION

3.1 *Normal stresses along strand*

The normal stresses along the strands with successive strand breakages are obtained. Three different cases are studied to observe the stress state achieved in each type of strand: i) an outer strand that breaks, ii) an inner strand that does not break and iii) the central strand that breaks. Plasticity has not been initially considered. Subsequently, the normal stresses along the central strand without plasticity will be compared with the case where plasticity is considered.

The sequence of strand breaks is shown in Figure 3: strand 1, strand 2, strand 3, strand 6 and finally, the central strand 7. Strands 4 and 5 are not broken in the analysis. Damage (D) is defined as the ratio of the number of broken strands (N_B) to the total number of strands (N_T):

$$D = \frac{N_B}{N_T} \tag{2}$$

3.1.1 *No plasticity*

Strand 2 is an outer strand that breaks at some point in the analysis. The results show that stresses of a strand increases when a neighbour strand breaks. When breakage occurs, the broken strand normal stress is only lost in the surroundings of the broken section because of

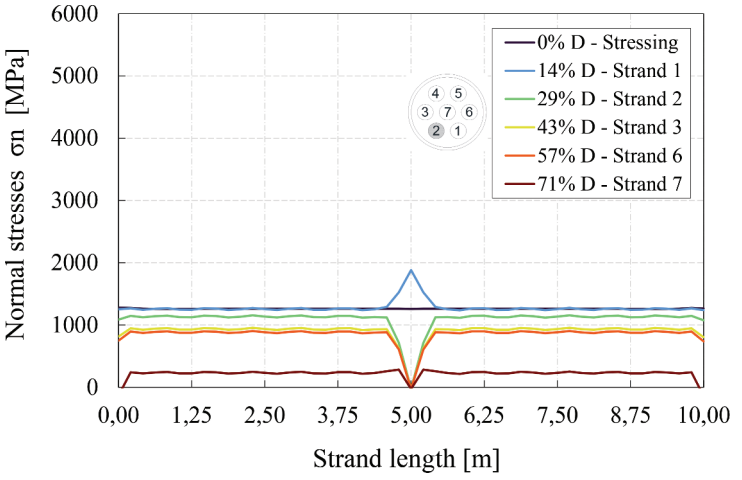

Figure 5. Normal stresses along strand 2 length, no plasticity considered, for different level of damage.

the self-anchorage phenomena. Due to the high stiffness of the elastic grout-strand contact assumed, the relative sliding only takes place in the transfer length, the remaining length approximately keeps its stresses (Figure 5).

Strand 4 is an outer strand that does not break in the analysis (Figure 6). As with strand 2, when strands close to strand 4 break, there is an increase in the stresses. This strand does not break during the analysis; however, a decrease of stresses can be observed in the central section due to the eccentric breakage. This implies the appearance of bending stresses in the tendon, which cause traction of the strands near the broken one and compression of the strands opposite the broken one (Figure 7).

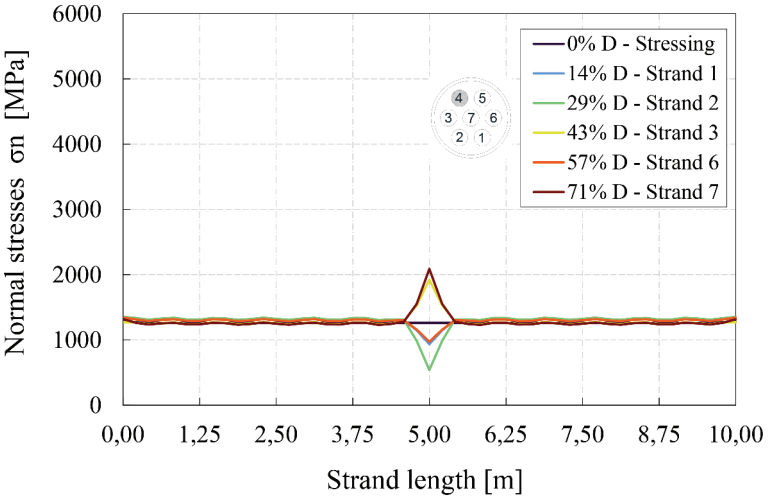

Figure 6. Normal stresses along strand 4 length, no plasticity considered, for different level of damage.

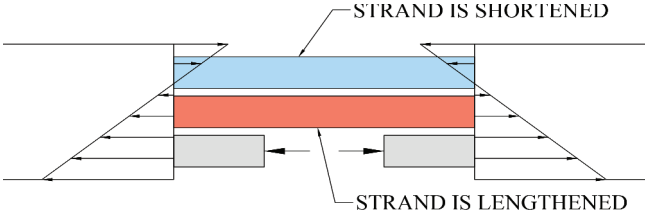

Figure 7. Conceptual illustration of the eccentric breakage in the tendon.

Strand 7 presents a particular situation as it is the central strand (Figure 8). It supports most of the stresses during each successive break because it is located next to all the strands that break. It reaches an excessively high stress in its central section, it should be noted that these values could not be supported in reality by the steel, but in this case a purely elastic behaviour of the steel has been assumed.

3.1.2 *Plasticity*

In Figure 9, the normal stresses along strand 7 considering plasticity are shown. The evolution of stress transference due to successive strand breakage is conceptually similar in the two cases: with and without plasticity. However, the maximum stresses reached are very different. The stresses obtained with plasticity are much lower (and actually, more realistic), demonstrating that the consideration of plasticity is crucial for modelling correctly the breakage strand phenomenon.

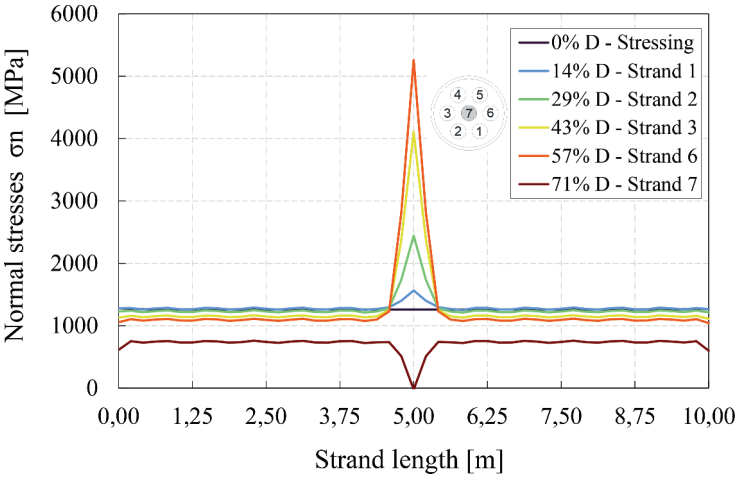

Figure 8. Normal stresses along strand 7 length, no plasticity considered, for different level of damage.

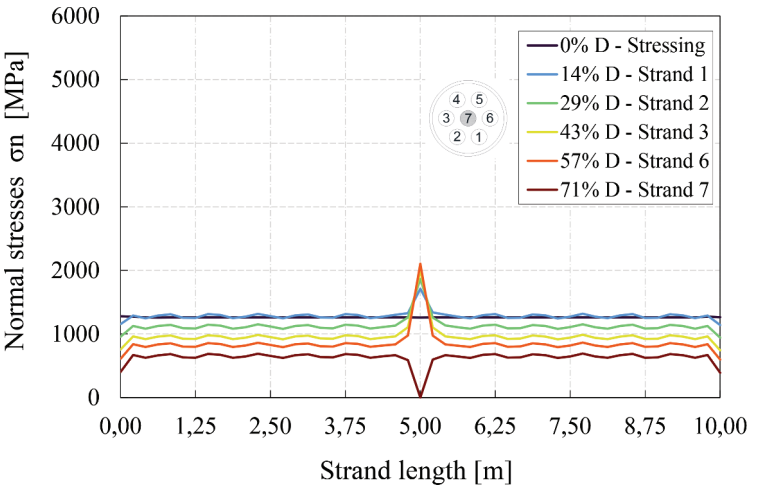

Figure 9. Normal stresses along strand 7, plasticity considered, for different level of damage.

3.2 *Frequencies*

The frequencies are compared with the experimental results obtained by Lee & Kang (2019) (Figure 10). The influence of the plasticity is also studied by comparing the numerical results obtained considering and not considering plasticity.

The experimental and numerical results not considering plasticity follow similar trends; however, differences arise mainly due to the high stiffness contact and the purely elastic materials assumed. When plasticity is considered, the experimental and numerical results are much more similar, this highlights the influence of plasticity on the results.

The results show that a tendon anomaly can be detected, as the frequencies are lower as the damage increases. Generally, tendon damage may be considered noticeable enough when the frequencies register values of 95% of the frequency obtained for healthy tendons (D=0% (Saluwu 1997)). Taking this into account, Lee & Kang's experimental results show that from approximately 20% damage the frequencies can be considered a sufficiently sensitive indicator. Also, the degradation curve is more pronounced for higher frequencies, therefore this indicator is more sensitive as the modal order increases.

Anyway, temperature dependency of the frequencies should be also analysed to confirm that this frequency variation is not marked by temperature variation (Chillitupa et al. 2023).

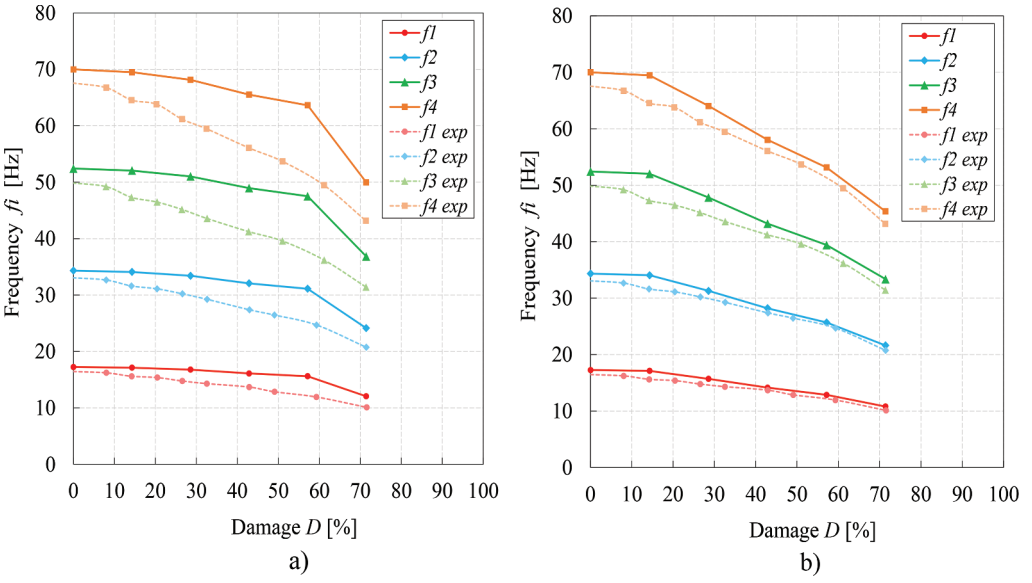

Figure 10. Evolution of the frequencies with the level of damage. a) No plasticity considered b) Plasticity considered.

3.3 *Stressing force in anchorage*

Stressing effective force in anchorage is the resultant of the stresses in the boundaries. Numerical results are also compared with the experimental results obtained by Lee & Kang (2019), as well as the numerical results with and without considering plasticity (Figure 11).

The same situation occurs with the stressing force as with the frequencies, the experimental and numerical results follow similar trends. The main differences are obtained when plasticity is not considered. Its great influence is again proved when it comes to detailed modelling in order to match realistic results. Figure 11 also show the degradation curve of the stressing force in the case where no self-anchorage is present, the curve is lineal. This is the case of non-adherent (unbounded) external post-tensioning tendons, where grout is replaced by a grease and the strands slide inside when the breakage occurs with minimum friction. The self-anchoring explains why the increase in damage is not proportional to the loss of steel cross-section.

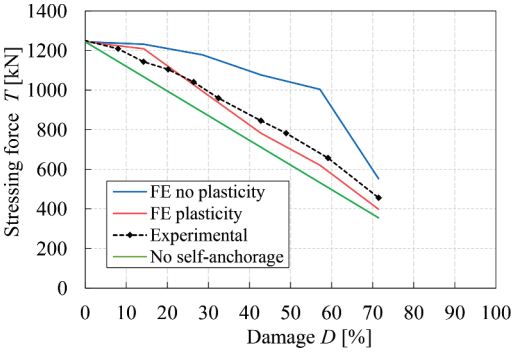

Figure 11. Stressing force in anchorage.

4 CONCLUSIONS

The proposed FE modelling approach reproduces quite well the mechanical behaviour of a prestressed bounded tendon under successive breakages. In this case, self-anchoring of strands in the grout is fundamental to understanding why stressing forces do not decrease proportionally with the area of steel lost in the strand, the FE model is able to successfully reproduce this phenomenon. Additionally, plasticity of strands plays an important role on the modelling accuracy.

The non-consideration of plasticity causes the stress redistribution when a strand breaks to be non-uniform, which seems to conclude that the stress redistribution in the strand is governed by the plastic nature of the steel. The consideration of this factor allows a more uniform distribution of the stresses in the healthy strands in the vicinity of the breakage and a greater deformation of this zone. Both elements are key to achieve a better adjustment of the model with the experimental results.

The high stiffness contact might not be the most suitable, leading to some small discrepancies of the results compared to reality. Once it has been demonstrated that plasticity is essential to obtain a more accurate FE model, as a subsequent modelling enhancement, it is necessary to refine a more realistic contact model to remove the remaining slight differences between numerical and experimental results.

As for the structural PI, the frequencies have been found to be the most sensitive indicator of damage detection, especially in the case of the higher frequencies.

Digital twin, BIM and asset management systems implementation

E. Spallarossa
Archimede srl

A. Bonicelli
Sina Spa

ABSTRACT: This paper describes a specific Inventory and Inspection System development with BIM (Building Information Modeling) applications for visual inspection data management and BMS (Bridge Management System) strategies development within a Bridge and Asset Management System implementation process. The specific Inventory and Inspection System is SINA ASTM company inspection system and its integration is developed within a collaboration with Archimede srl company, performing BIM and digital transformation. The paper focuses on a methodology for the dynamic management of infrastructures, ordinary maintenance and predictive maintenance, with a view to Asset Management development. Bim implementation, with the specific BIM use identification, other than design and construction, focused on inventory and inspection data organization, management, and capitalization. Typical Asset management KPIs are defined and business intelligence dashboards are implemented, also connected to BIM models. Asset Management System processes are developed developing scenarios and maintenance optimization processes towards network safety assurance.

1 INTRODUCTION

BIM (Building Information Modeling) is widely recognized for its application as a new design methodology. However, one of its significant added values lies in its application for infrastructure asset management, a concept reinforced by the recently published ISO 19650 standard, which focuses on managing information related to built assets throughout their entire lifecycle.

The adoption of BIM processes and procedures involves the utilization of intelligent parametric multi-dimensional modeling, essentially creating a virtual model of assets, to record and share information. This encompasses design data, information management, and maintenance asset information. With this approach, BIM transforms into a valuable and strategic digitalization tool that facilitates information sharing and management, especially in the context of asset preservation programming. In this scenario, the core of a systematic preservation approach revolves around the recording of inventory and inspection data. [14]

From this perspective, modern digital technologies can be employed not only to visually represent attributes such as position, geometry, and element types (e.g., masonry, concrete, steel structures) and record condition states but also to establish a standardized mechanism for cyclic data recording. These condition states can be aggregated at various application levels, including individual elements, structures (assets), and the entire network. The overarching concept is to transition from "National Bridge Elements" to

DOI: 10.1201/9781003483755-216

"BIM National Bridge Elements," complete with coded information and parameters. Additionally, this data can be translated into 3D models, capitalizing on emerging technologies and the adoption of the "Digital Twin" concept.

BIM delivers value by underpinning the creation, federation and exchange of shared models and corresponding structured data. While BIM development and its application to date has largely focused on the design and construction phases of assets, the most important BIM application is across the entire life cycle of assets as a key enabler of improved asset management within the recognized ISO55000[1].

The Business Value of BIM for Infrastructure' [6] highlights BIM's benefits:

- Conflict reduction through better interoperability.
- Enhanced project quality.
- Reduced rework.
- Improved productivity

BIM centers on an asset's needs, minimizing information loss during management changes. Evolving from CAD and 2D/3D drawings, BIM tools create detailed data files, forming an integrated system for managing construction and asset lifecycle, thus boosting efficiencies and the value of the asset and of the network.

This paper shows different steps of a BMS and BIM implementation towards and asset management system implementation. [10], [11], [12], [13].

2 BRIDGE ASSET MANAGEMENT AND BIM

BIM (Building Information Modeling) [4], [5] and asset/bridge management share a mutually supportive relationship. Both are technologies that empower owners, agencies, public administrations, and the entire supply chain to develop and implement processes, tools, and collaborative practices. These technologies optimize the costs, performance, and safety of infrastructure assets throughout their entire lifecycle. Having accurate and reliable information about assets is crucial for effective asset/bridge management as it underpins decision-making, planning, and the execution of activities. BIM provides a structured framework for the creation, collation, and exchange of asset information, thereby supporting effective asset management. BIM Management Systems (BMS) and BIM can support managers, technicians, and administrations with data recording processes, efficient information retrieval and organization procedures optimization. The ability to record conditions and the extent of deterioration at an infrastructural level (e.g., bridges, networks, etc.) can be accelerated and automated with new technologies and sensors. However, the initial step for consistent data is the organization of a structured data model [6]. A fundamental concept in the implementation of BIM and BMS should be the use of a standard for representing bridge information in a digital format. This standard should be easily adopted by software tools, minimize ambiguity, allow for diverse model applications, and ensure numerous advantages. BIM must provide the right information at the right time and with the correct Level of Information Need, particularly crucial for developing BIM models for inspection and bridge management systems support. Fine-tuning the Level of development needs is essential for maximizing the benefits of BIM, bridge, and asset management integration. This requires technicians and experts to share knowledge, experience, and information. In recognition of this, new standards like ISO 19650 parts 1, 2, and 3 are being developed to extend BIM to cover every phase of asset management. Consequently, new inspection and management approaches are leaning towards BIM technology, giving rise to several innovative techniques, already in use in various SINA and Archimede projects, such as:

1. Asset management — Overview, principles and terminology.

- Automated defect scanning and identification, leading to computer-aided inspection systems.
- Use of 3D digital bridge models, employing laser scanning surveys and 3D point clouds.
- Object-oriented bridge model development, using Building Information Modeling techniques for the design of new structures and the inspection, maintenance, rehabilitation, and repair of existing structures.
- Streamlined procedures for creating BIM Models of bridges and tunnels, aiding visual inspection recordings and management as decision-making tools in asset management."

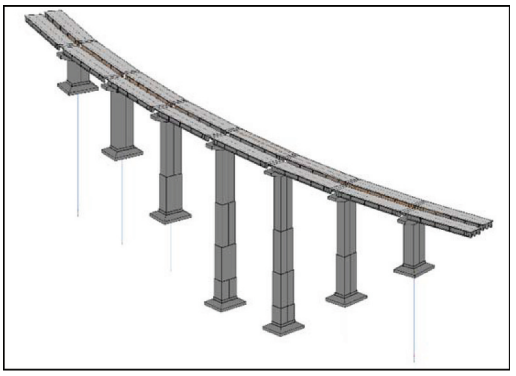

Figure 1. An example of a bridge BIM model to support visual inspection recording and management and business intelligence tools within a pilot project.

BIM and BMS development has been based on:

- Defining reference guidelines comprising definition of BIM modeling Level of information Needs;
- Defining structured data that make up the inventory and inspection databases;
- Optimizing the resources available for maintenance, based on forecasting and/or statistical models;
- Identification and use of the most suitable IT tool for the application area.

3 THE PILOT PROJECT SCOPE AND ITS IMPORTANCE

The pilot project showcased two applications of the Sina methodology Digital Twin, integrating BIM models with business intelligence dashboards:

- Inspection and Technical Approach: This method visualizes digitized deterioration of viaduct components, aiding in identifying deterioration locations, supporting maintenance, and optimizing sensor placement.
- Bridge Management Approach: This focuses on visualizing element condition states within a decision support system for the entire asset.

Asset management dashboards, as digital twins, enable dynamic, real-time navigation, allowing users to interact based on selected elements or deterioration types. Key to this is managing geolocated information, tested through a specialized dashboard that geolocates work and links to data sheets connected to the bridge's digital twin.

Figure 2. Business intelligence dashboard from the pilot project of bridge digital twin. On the geometrical reconstruction of the viaduct, is visible the different structural elements conditions.

The simpler integration systems for models, data, and maps, was tested, exploring alternatives to existing Sina solutions to meet the needs of technical users and operators. The goal was to expand the user base, targeting technicians and decision-makers. Archimede's solution integrates Business Intelligence tools with Sina's structure. This multi-application approach allows dynamic interaction with the BIM model using the Work Breakdown Structure (WBS). Users can view BIM model parameters for essential data, both geometric and inspection-related, graphically and descriptively. Inspection data specifically identifies anomalies and condition states of each structural element. The Business Intelligence tool, essential for creating Dashboards, allows for swift and dynamic information access, catering to different user roles. For instance:

- Inspection teams focus on the condition of structural elements.
- Teams assessing structural health look at service status distribution.

This integration, reflecting the anomaly digitization process, constitutes the 'Digital Twin' for inspection. It involves:

- Displaying elements by service status for targeted model searches and anomaly documentation.
- A comprehensive digitization strategy for anomalies, updating and browsing in real-time based on selected elements or anomalies.

Users can access shared information via a web portal without specific applications. For database and inventory management, we created a sheet that geolocates structures and provides links to technical sheets, all connected to the 3D model.

4 MAINTENANCE SCHEDULE BASED ON BRIDGE MANAGEMENT SYSTEM (BMS) PROGRAMMING

The FHWA's 'Bridge Preservation Guide' underscores the global challenge of cost-effectively maintaining bridges with limited funds. A balanced approach in bridge management, steering clear of the inefficient 'worst-first' strategy, is crucial. This can be achieved through Bridge Management Systems (BMS), which offer decision support across all bridge lifecycle phases and enhance management efficiency by using deterioration models and forecasting tools.

SINA's Inspection and Operational System (SIOS) is progressing towards a BMS, incorporating features such as:

- Inventory and Inspection data records.
- Bridge elements catalogue and condition ratings.
- Defined common actions based on bridge element condition states, including costs and impacts.

The goal is to develop a preservation policy to prolong service life and minimize maintenance costs, with BIM models and dashboards integrated into SIOS.The primary goal of developing SIOS as a BMS is to establish a preservation policy. This policy aims to slow the deterioration of bridge elements and extend their service life. A longer service life implies lower annual costs for rehabilitation and replacement. The integration of BIM models and dashboards within the evolving SIOS will be discussed in the subsequent chapters.

4.1 *Sios BMS home page*

The SIOS BMS homepage efficiently guides users through selecting bridges for analysis. It features bar graphs for a quick overview of the Health Index and Service States of viaduct elements, including a map view and a detailed table of attributes at the bottom for more specific analysis.

Figure 3. SIOS BMS homepage.

The first bar graph gives an immediate overview of the Health Index [1] [2] of the selected viaducts while the graph below shows the deterioration distribution of the last year (or the selected year) visual inspection data. A combined observation of the two graphs allows the user of the software to have an immediate information on the condition of the infrastructure. The table in the lower part of the page summarizes some significant attributes of the selected viaducts, for example the vulnerability class (according to MIMS Guidelines [9]), as well as the possibility of inserting further filters applied to the attributes of the viaducts.

4.2 *SIOS BMS dashboards*

Starting from SIOS BMS homepage it is possible to access dashboards both for in-depth analysis of the conditions of the structural elements [3], [7], [8],of each viaduct and for planning maintenance interventions. The detailed structural condition is presented explaining the state of service of the various constituent elements of the structure according to the last inspection results with particular attention to the analysis of the evolution of the condition during time. For this reason, in this method, it is of great value to have an inventory system of inspection results over time.

Figure 4. SIOS BMS dashboard of the detailed characteristic of a selected viaduct according with visual inspection results.

In the 'maintenance' section, users can plan interventions using a catalogue that outlines the costs and benefits of each action.

5 SIOS DATA FLOW FOR MAINTENANCE PROGRAMMING

This flowchart graphically illustrates the new process, showcasing how manual maintenance planning by the user and automatic planning by the optimizer are developed.

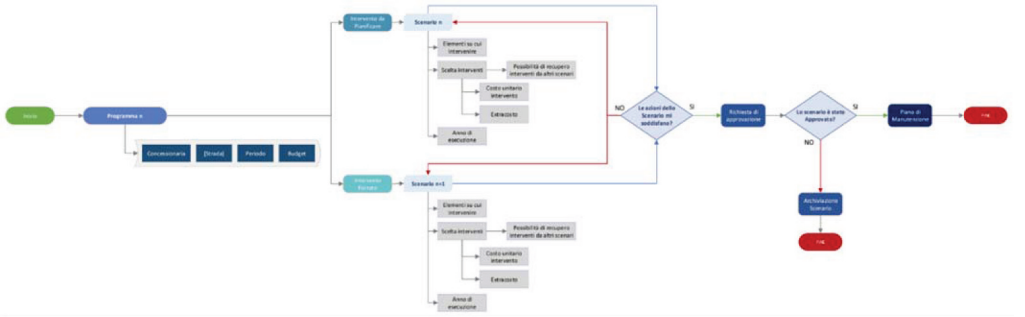

Figure 5. SIOS BMS maintenance programming data flow.

The process unfolds as follows:

- Creation of a Program: This step involves assigning an identifying name to the program and specifying the main properties that will be common to all the different Scenarios developed within it.
- Development of Different Scenarios: Within the program, various scenarios are created, each outlining the proposed maintenance interventions for the examined viaduct.
- Optimization: Within these scenarios, different kind of optimization cycles can be employed to recommend the most appropriate interventions for the viaducts

- Approval of Interventions: The proposed interventions within each scenario are then subject to review and approval.
- Finalization as a 'Maintenance Plan': Once the interventions are approved, the scenario is formalized into an official 'Maintenance Plan'.

6 TUNNELS DIGITAL TWINS PILOT PROJECT DEVELOPMENT

Parallel to the initiatives for bridges, a pilot project is also underway for tunnels. The objective of this project is to streamline the process of creating digital twins for tunnels and to establish the necessary data framework to support the integration of the SINA Inspection and Operational System (SIOS). This integration aims to facilitate comprehensive recording and management of inventory, inspection results, BIM models, and relevant data within an asset management system. During this pilot project, specific BIM models for tunnels have been developed, and SIOS has been adapted to effectively manage tunnel data, contributing to an efficient tunnel management system.

7 TEAM AND TECHNIICAL SKILL

The project was executed by a joint venture team comprising technical staff from both Sina and Archimede. The team involved different technical skills, such as: Project Managers, Bim Managers, Bim Coordinators, CDE specialists, Bim experts, stuctural engineers, Geothecnical Engineers, software developers, technical directors.

8 FUTURE DEVELOPMENT

Building upon the success of geolocating bridges, developing databases, and creating "digital twins" using 3D BIM software suites, SINA's research program aims to enhance asset inspection activities by incorporating virtual reality (VR) and augmented reality (AR). Specific applications of these technologies include: a) Training Inspectors: Using BIM technologies and VR simulations to create an instructional environment. b) Enhanced Inspection Surveys: SINA plans to test an immersive reality tool and software environment, providing real-time technical information to inspectors. This includes superimposing the "digital twin" with inspection data over the actual bridge. c) Remote Inspection Services: SINA is exploring two objectives: i) supporting field inspections with specialized back-office engineering expertise, and ii) pioneering advanced remote inspection services using devices such as drones, scanners, autonomous vehicles, and remote video surveillance. The anticipated benefits of these technologies include increased training effectiveness and efficiency with reduced costs, enhanced safety for trainee inspectors, reduced on-site costs (including indirect costs for infrastructure users), minimized post-processing activities, and improved quality of observations.

The next steps in the project involve:

- Fine-tuning bridge and asset management decision criteria and maintenance work costs.
- Setting up and refining the appropriate Level of Information Need (LOIN) for the BIM Models.
- Utilizing a calibrated photo dataset or high-resolution laser scanner survey to accurately replicate real deterioration in the BIM Model.
- Creating a simulated environment and developing a VR app for instructional use with the "digital twin."
- Analyzing the current database to prepare the necessary information for AR applications.
- Developing asset management software and tools for database updates
- Creating tools to compare, in real-time, the "3D digital twin" with the actual bridge, aiming to contrast the current situation with a previous one, such as deterioration maps from earlier inspections.

- Developing software tools to facilitate remote inspections, allowing on-site inspectors to share observations and exchange information with back-office engineers. Innovating new technologies and specialized sensors for use with AR software, enhancing human capabilities. The ultimate goal is to develop remote technologies capable of replacing the physical presence of inspectors.

Establishing data-driven life cycle benefits of bridge maintenance

B. Bektaş
Minnesota State University, Mankato, USA

ABSTRACT: Bridge maintenance and preservation activities are widely accepted to slow bridge deterioration rates and extend service life. In order to reflect the quantitative impact of bridge maintenance and preservation on bridge performance, State Departments of Transportation (DOTs) typically have utilized deterioration models or service life extension values that are based on expert elicitation in the United States. Research on quantifying the benefits of bridge preservation and maintenance, based on actual bridge data has been limited, if any. Consistently, the variables used for quantifying the impact of preservation in past research studies have either been assigned by expert elicitation, or the service life of treatments, as provided for specific bridge preservation products. Also, performance of bridge preservation treatments and their impact on bridge condition is highly dependent on bridge characteristics and external factors (e.g. traffic volume, climate, bridge condition). Therefore, there is imminent research need to quantify the impact of bridge preservation based on actual data sets for state DOTs. This paper presents preliminary research findings from an ongoing project in Minnesota. To date, the maintenance history data gathered by the Minnesota Department of Transportation (MnDOT) has undergone comprehensive review and evaluation. This data has been integrated with pertinent historical bridge condition information, and a preliminary modeling process has been conducted to forecast the extension of service life for deck components. Minnesota bridge decks were partitioned into four clusters using K-Means clustering analysis technique. Markov transition times for deck component ratings were computed separately for these clusters. Decks with recorded repair and maintenance had significantly higher transition times for ratings 7, 6, and 5 which correspond to good and fair conditions. The findings indicate that deck repair and maintenance extend the service life of bridge decks and significantly delay expensive bridge replacements. Future research steps include computation of Markov transition times for select bridge components and elements, bridge-, component- and element-level life cycle cost analysis and development of decision trees.

1 INTRODUCTION

1.1 *Research scope*

The proposal for this ongoing project outlined the imminent need for transportation agencies to quantify the impact of bridge maintenance and preservation activities. In this project, maintenance and preservation activities refer to bridge treatments that may be cyclical, proactive, or reactive, which may not necessarily improve condition but are aimed to slow bridge deterioration rates and extend service life. Existence of and confidence in data-driven deterioration and treatment efficiency models have been an obstacle in properly quantifying the life cycle cost impacts of bridge maintenance and preservation activities and consequently an obstacle to guiding decisions and resource allocation for these activities.

The expected research benefits from this research are interrelated and twofold. The first expected benefit is improved lifecycle costs for Minnesota bridges through development of models and decision trees that will feed into agency decision making framework and allow selection of appropriate bridge maintenance activities to extend/maintain bridge life in a cost-

DOI: 10.1201/9781003483755-217

efficient manner. The second expected research benefit is operations and maintenance fund savings by increasing the efficient use of funding for bridge maintenance based on the information developed from the research.

1.2 *Progress*

The research premise involves the utilization of agency data, which includes bridge inventory information such as design characteristics, material type, traffic volume carried, age, and environmental factors, along with construction history data regarding timing and cost, as well as historic condition data. The primary objective of this research is to identify the actual treatments applied to the bridge network and model their impacts on bridge condition. Initially, the research will focus on studying both bridge component and element condition data to assess the effects of past treatments on the time it takes for component condition ratings to change or element condition states to transition.

Previous tasks investigated the bridge inventory data with the goal of identifying bridge clusters within the Minnesota network that exhibit different historical behavior or deterioration patterns or have distinct decision-making dynamics, necessitating the development of separate decision trees. Past research in this field has often failed to provide customized research outcomes that offer specific parameters and model values for an agency, rather than just presenting variations in models. The project database is a relational database that includes following data on Minnesota bridges:

- Bridge design and material type
- Construction history, including cost
- Maintenance history
- Condition history of the various bridge components and elements
- Traffic
- Other relevant bridge inventory items

Recent work focused on preliminary Markov transition models for bridge component (deck, superstructure, and substructure) and element conditions. This paper presents and discusses initial models for bridge deck components.

2 DATA

The National Bridge Inspection Standards (NBIS), implemented by the Federal Highway Administration (FHWA) in 1968 (Lichtenstein, 1993), form the basis of bridge inspection and bridge management in the United States today. Typically, all bridges located on public roads with lengths more than 20 feet are inspected at least once every two years. Data on 116 NBI (National Bridge Inventory) items are reported annually to FHWA by the state transportation agencies. The data are compiled into the NBI by the FHWA, and Condition and Performance Reports based on the NBI data are prepared and submitted to Congress (FHWA, 2009). NBI items 58 through 66 in FHWA's Recording and Coding Guide (FHWA, 1995) constitute the NBI condition ratings. Three of them are especially important since they constitute the federal condition performance measures for National Highway System (NHS) bridges. Assigned to the three major parts in a bridge structure, these NBI condition ratings are deck, superstructure, and substructure condition ratings (items 58, 59, and 60 respectively) and are collected on a 9-0 scale (Table 1).

Initial efforts to define and collect bridge element data in the United States started in the late 1990s, with the development and implementation of bridge management systems (BMSs). Commonly Recognized (CoRe) Structural Elements Guide (AASHTO, 1997) was published by the American Association of State Highway and Transportation Officials (AASHTO) to define and standardize bridge element data inspection and collection. In 2011, the AASHTO Subcommittee on Bridges and Structures approved a new element-level bridge inspection manual (AASHTO, 2011), which was later updated in 2013 (AASHTO, 2013).

Table 1. NBI General Condition Rating (GCR) descriptions.

Number	Description
9	EXCELLENT CONDITION
8	VERY GOOD CONDITION
7	GOOD CONDITION
6	SATISFACTORY CONDITION
5	FAIR CONDITION
4	POOR CONDITION
3	SERIOUS CONDITION
2	CRITICAL CONDITION
1	"IMMINENT" FAILURE CONDITION
0	FAILED CONDITION

The new AASHTO Manual for Bridge Element Inspection (MBEI) replaced the Commonly Recognized Structural Elements. The new element inspection methodology incorporated the experience of inspecting elements by the state DOTs over twenty years and improved the guidelines. The bridge elements in the new manual are classified into three categories as National Bridge Elements (NBEs), Bridge Management Elements (BMEs) and Agency Developed Elements (ADEs). The number of condition states (CSs) are standardized as four, whereas CoRe elements had three, four or five CSs. Also, the new manual introduces a new, defect-based inspection methodology and separates wearing surfaces and protection systems from structural elements.

MnDOT has consistently collected both NBI GCR and element condition data over the years and stores both within their Structures Inspection Management System (SIMS). In 2023 NBI data, Minnesota had a total of 13,502 bridges, and 3,682 of these bridges were state-owned. The priority for this research is state-owned structures. Data on maintenance activities have also been consistently collected and stored in SIMS since 2008. The maintenance activity data used in this study covers 2008-2022 duration. In addition to the records in SIMS, MnDOT StateWide Integrated Financial Tools (SWIFT) also archives cost data on maintenance activities. The MnDOT Bridge Office has supplied the research team with two datasets containing maintenance activities: the Structure Information Management System (SIMS) data and the SIMS + SWIFT Bridge Cost Records (BCR) Data. The latter dataset also includes additional financial information, significantly expanding the available maintenance records beyond what is found in the SIMS data alone. Analysis of the datasets showed that SIMS records combined with SWIFT records (SIMS+SWIFT) contain more than five times the number of distinct bridge and year records compared to SIMS data. Figure 1 gives a visual summary of the maintenance acitivity data, categories under different resources. Local agencies (District 8 and counties) also have separate records that will be explored in later stages of the research. One challenge encountered with the SIMS+SWIFT data is the absence of element number associations for certain activities. Nevertheless, the timing of acitivities alongwith the work descriptions and work codes were utilized to create suitable associations to use SWIFT data.

The initial analysis of the dataset primarily centered around establishing connections between bridge components and elements with the recorded maintenance activities. This effort aimed to pinpoint the maintenance activities that had been consistently and comprehensively documented within the network. It's important to note that not all maintenance activities stored in the system held relevance for preservation or service life extension; for instance, activities like graffiti removal or tree maintenance had no impact. MnDOT engineers subsequently reviewed a suggested list of the most prevalent maintenance activities, based on their frequency in the dataset and their potential significance for preservation purposes.

It is important to emphasize that the determination of whether the observed data for a maintenance activity is adequate for the creation of statistically significant models will depend on several factors. These include the generation of inspection pairs involving subsequent element and General Condition Rating (GCR) inspections for calculating Markovian transition probabilities, along with the subsequent model estimation process.

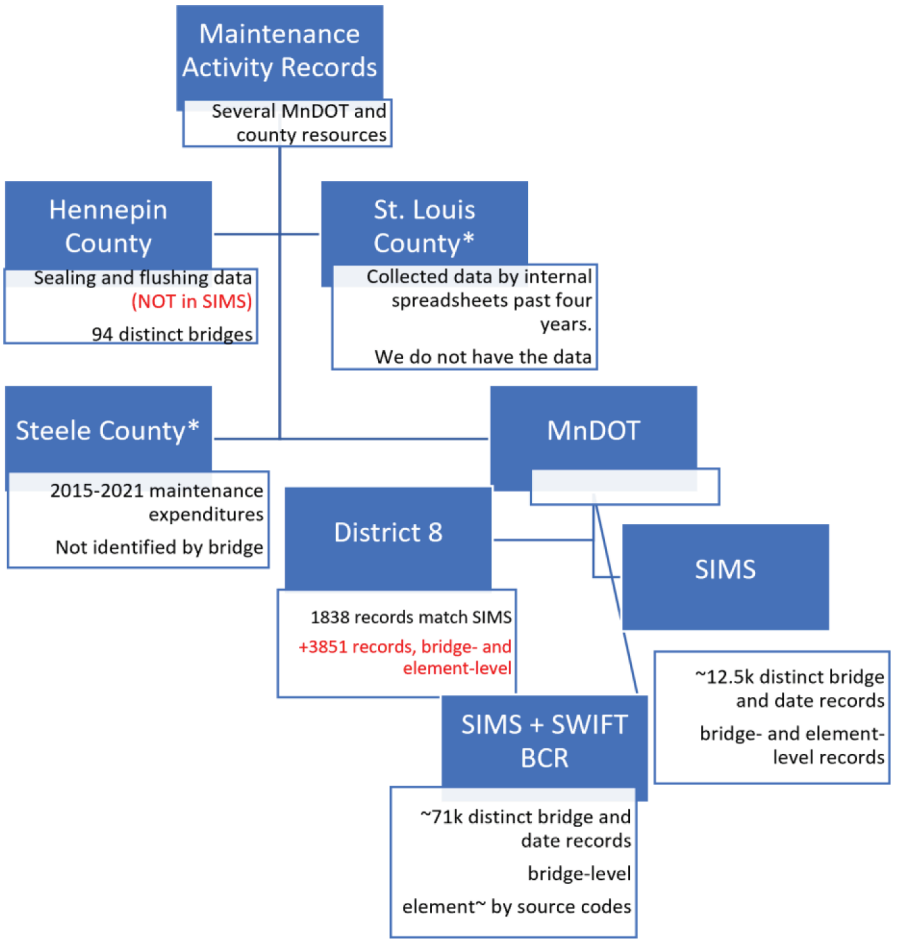

Figure 1. Maintenance data sources.

The list we have provided reflects an optimistic and comprehensive approach taken by our research team. Our intention was to ensure inclusivity and avoid excluding any potential models that could be valuable. Activities with more than fifty observations in the SIMS data were deliberately incorporated into this list. We anticipate that additional instances may be discovered when we leverage the SIMS+SWIFT dataset. The current threshold is informed by our previous experiences and has been set deliberately low to maintain inclusivity at this stage of our analysis.

3 ANALYSIS

3.1 *Approach*

In the initial modeling phase, we calculated Markov transition probabilities for the state-owned bridge decks in Minnesota. These bridge decks were categorized into four distinct groups, determined by the extent of available maintenance activity data spanning from 2011 to 2021. Out of a total of 3,682 state-owned bridges, 3,079 exhibited some level of bridge deck maintenance or repair activity. Descriptions of the bridge deck maintenance activities can be found in Table 3, and Table 4 provides a breakdown of the maintenance records' frequency for each activity across different years.

Table 2. Potential models by work description.

Work Description	Potential Element Models	Potential NBI GCR Models
Bridge poured/ relief joint seal	Poured Seal Joint 301, Approach Relief Joint 816	
Bridge approach panel	Concrete Approach Slab 321	
Bridge bearing assemblies	Elastomeric Bearing 310, Expansion Bearing 311	Superstructure
Bridge conc barrier/rail seal	Concrete Bridge Railing 331	
Bridge culvert maintenance	Concrete Culvert 241	Culvert
Bridge deck	Reinforced Concrete Deck 12, Wearing Surface 510	Deck
Bridge deck crack sealing	Concrete Wearing Surface - Cracking and Sealing 810 & RC Deck 12, 510, 521	Deck
Bridge deck sealing fixed	Concrete Deck Cracking Element 810, & RC Deck 12, 510	Deck
Bridge expansion, relief joints	Strip Seal Joint 300, Approach Relief Joint 816	Super/Sub
Bridge flushing	One to two bridge flushing records. 762 structures that were not flushed. Decks, Joints, Bearings (under joints).	Deck, Superstructure, Substructure
Bridge prep & painting	Steel Protective Coatings 515, steel elements (frequent superstructure elements)	Superstructure
Bridge slope protection	Scour 885, Slopes & Slope Protection 892, Deck & Approach Drainage 894	Substructure
Bridge substructure	Most frequent substructure elements (Concrete Column 205, Reinforced Concrete Abutment 215)	Substructure
Bridge superstructure	Most frequent superstructure elements (Prestressed Concrete Girder or Beam 109) Steel Girder	Superstructure
Joint reestablishment	Strip Seal Expansion Joint 300, Poured Seal Joint 301, Approach Relief Joint 816 underlying super/sub? Deck?	
Protection straps/curb plates	Plow Fingers 815, Strip Seal Expansion Joint 300	
Waterway maintenance	Deck & Approach Drainage 894 might fit better with element 899, 885, or 892. In a lot of cases, this is removing debris from the channel for flow or rip rap placement.	Channel
Maintenance Activity by Bridge	GCR Models for bridges that have low, medium, high levels of maintenance. The levels will be defined in the next task.	Deck, Superstructure, Substructure

The NBI GCR condition data span from 1992 to 2022, encompassing a more extensive timeframe than the available maintenance data. The assumption is that the available maintenance data is representative of the typical levels of maintenance for individual structures and the maintenance clusters sufficiently categorized maintenance levels for the deck sample.

Table 3. MnDOT bridge deck maintenance activities.

Activity Code	Activity Name	Description
2820	Bridge Deck Repair	Bridge deck repair, overlays, replacements, and underside deck delamination.
2836	Bridge Deck Sealing	Flood sealing bridge decks, approaches, and sidewalks.
2837	Bridge Flushing	Flushing bearings, superstructure elements, joints, railings, and decks.
2838	Bridge Deck Crack Sealing	Crack sealing decks, approaches, and sidewalks.

Table 4. Frequency of bridge deck maintenance activities by year.

Years	Repair 2820	Flood Sealing 2836	Crack Sealing 2838	Flushing 2837	Grand Total
2011	176	181	52	16	425
2012	258	265	32	1058	1613
2013	226	247	50	1011	1534
2014	227	250	62	1127	1666
2015	246	239	60	1171	1716
2016	256	191	63	1094	1604
2017	289	210	71	1258	1828
2018	239	208	83	1403	1933
2019	245	298	79	1041	1663
2020	347	302	130	1298	2077
2021	256	333	146	1255	1990

3.2 *K-Means clustering for deck maintenance*

Clustering involves grouping similar data objects into distinct clusters while ensuring differences between data in different clusters. Clustering techniques are widely utilized across various domains such as artificial intelligence, biology, customer relationship management, data compression, data mining, information retrieval, image processing, machine learning, marketing, medicine, pattern recognition, psychology, and statistics due to the increasing need for organizing and extracting valuable insights from vast amounts of data (Na et al., 2010).

K-Means is a straightforward unsupervised learning algorithm used for solving clustering problems. It classifies a dataset into a predetermined number of clusters (k clusters) in a simple manner. The key idea is to define k centroids, one for each cluster, strategically positioned to yield optimal results. These centroids should be as far apart as possible to minimize ambiguity (Kodinariya and Makwana, 2013). The algorithm then associates each data point with its nearest centroid, completing one iteration or group. Subsequently, new centroids are calculated as the centers of the clusters formed in the previous step. This process is repeated, with data points reassigned to the nearest new centroid, creating a loop. Through this loop, it becomes evident that the k centroids gradually change their positions until they no longer shift, signifying convergence. In other words, the centroids reach a stable position, and the clustering process is complete.

To conduct the clustering analysis, we compiled a dataset that documented the record count for each activity listed in Table 3, specifically covering the period from 2011 to 2021. This dataset was organized on a per-bridge basis, with each bridge identified by its unique bridge number. The frequencies of the four maintenance activities were selected as the parameters for the clustering analysis. We experimented with cluster numbers ranging from two to six, ultimately determining that four clusters yielded the most meaningful and coherent groupings. Table 5 summarizes the cluster means (by number of activity) and indicates the number of observations in each cluster. Figure 2 is a visual representation of the cluster means. The groupings are summarized as follows:

- Cluster 1 - “Minimal Repairs with Flushing”: This cluster has low deck repair and flood seal values but relatively high flushing and crack seal values.
- Cluster 2 - “Moderate Repairs with Balanced Maintenance”: Cluster 2 appears to have a balance between deck repairs, flood seal, flushing, and crack seal values.
- Cluster 3 - “Low Repairs with High Maintenance”: Cluster 3 has low deck repair values but relatively high flood seal, flushing, and crack seal values.
- Cluster 4 - “Low Repairs with High Maintenance and Flood Seal”: Cluster 4 has low deck repair values, high flood seal, flushing, and crack seal values, similar to Cluster 3 but with a higher focus on flood sealing.

Table 5. K-Means cluster means.

Cluster	Deck Repair	Flood Seal	Flushing	Crack Seal	Number of observations
1	0.47	0.08	2.80	0.31	1807
2	4.13	0.16	4.34	1.01	306
3	0.67	0.37	5.41	1.95	807
4	0.74	2.14	6.13	1.81	159

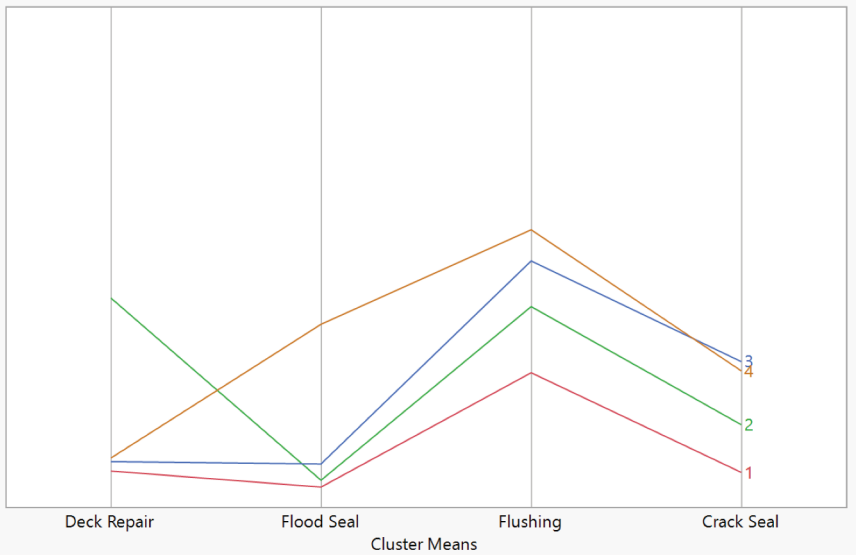

Figure 2. Parallel coordinate plot of cluster means.

3.3 *Markov transition probabilities*

To calculate the Markov transition probabilities, we adopted the methodology outlined in the recent collaborative deterioration model study for Midwest state DOTs conducted by Boadi et al. (Boadi et al., 2022). A specialized Minnesota database was prepared, and the data was updated to incorporate the most recent condition data. Subsequently, deck GCR models were computed for the previously identified bridge maintenance clusters. For conciseness, we have omitted the intricate modeling specifics, which can be found in the report titled "TPF-5(432): Bridge Element Deterioration for Midwest States" (Boadi et al., 2022).

In Table 6, we present computed Markov transition times for 3,711 Minnesota decks for NBI GCRs 9 through 5 for varying levels of maintenance activity. Cluster 0 bridges represent the group of structures with minimal amount of maintenance. Empty cells in the table present the GCRs for which the population size was too small to perform the algebraic computations and obtain a valid transition time. The same situation was valid for GCRs that were smaller than 5. However, GCRs values of 4 and below present poor conditions and bridges that are candidates for replacements and are therefore not of interest for this effort.

For high GCRs of 9 and 8, with the exception of Cluster 4 (Low Repairs with High Maintenance and Flood Seal) the transition times are higher for Cluster 0 (minimal maintenance). However, for GCRs of 7, 6 and 5, the transition times with valid computations for decks with maintenance and repair are consistently and considerably higher. These GCRs are also the GCR levels where most of the deck life cycle is realized. While further refinement and element-level analysis are crucial for the latter stages of the research, the findings quantify the life cycle extension for Minnesota bridge decks, presenting a strong case for data-driven value of bridge maintenance.

Table 6. Markov transition times by deck GCR rating and by maintenance clusters.

Deck GCR	9	8	7	6	5	Number of Observations
Cluster 0	3.29	6.46	9.67	7.83	11.32	2823
Cluster 1	1.07	2.49	16.85	31.33	18.36	487
Cluster 2		3.00	8.33	33.68		112
Cluster 3	1.78	3.40	16.47	44.29		243
Cluster 4	0.92	8.92	20.72			46

4 CONCLUSION

In this paper, we introduce a straightforward framework designed to classify maintenance levels for bridges and quantify the associated extension of their service life. Our research findings, based on consistent record-keeping by MnDOT, demonstrate that the effect of maintenance on extending bridge service life can be effectively measured. We share initial results from an ongoing study in Minnesota, aiming to predict the service life extension of deck components. Through K-Means clustering analysis, Minnesota bridge decks were categorized into four distinct groups. We calculated Markov transition times for deck component ratings within each cluster. It was observed that decks undergoing regular repair and maintenance exhibited notably higher transition times in ratings 7, 6, and 5, representing good to fair conditions. This suggests that timely deck repair and maintenance not only prolong the service life of bridge decks but also significantly postpone the need for costly bridge replacements. Data-driven estimates for bridge service life extension, derived from our findings, can be applied in various aspects of bridge management systems. This includes use in deterioration models, benefit calculations, or performance metric assessments. By relying on data-driven estimates rather than solely on expert elicitations, transportation agencies can gain greater confidence in their Bridge Management Systems (BMS) and the underlying modeling frameworks, reducing ambiguity and enhancing decision-making processes.

Sensitivity analysis of bridge structural vulnerability class based on Italian Guidelines

S. Bianchi
Research Fellow, Department of Architecture, Building & Construction, Politecnico di Milano, Milano, Italy

L. Capacci
Assistant Professor, Department of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

ABSTRACT: Optimal management of existing bridges over their service life is critical for infrastructure owners and practitioners who are called to guarantee adequate structural and functional performance of the transportation network they administrate. Documental analysis and visual inspections are valuable data supporting the decision-making process. A valuable support in the Italian context is provided by the "Guidelines for risk classification and management, safety assessment and monitoring of existing bridges" introduced in 2020. The guidelines promote a multi-hazard approach based on Attention Classes (ACs) defined from the combination of risk indicators regarding operating conditions from different perspectives, such as structural, seismic, hydraulic, and geological. This paper is aimed at providing a sensitivity analysis regarding the Structural Vulnerability Class (VC) defined by the Guidelines, with the aim of investigating the impact of epistemic uncertainties inherently biasing the bridge assessment, such as expert judgement subjectivity and missing historical data and as-built documentation.

1 INTRODUCTION

The urgent need to prioritize maintenance and repair for many bridges approaching the end of their service life is a common challenge faced by most developed countries worldwide (ASCE 2021, Biondini & Frangopol 2019). The adoption of expert-based methodologies and soft-computing tools (Bianchi & Biondini 2022a, b) can help bridge owners and public administrations to identify priorities. Furthermore, optimal allocation of limited resources for maintenance and repair interventions is essential across the entire transportation network considering risk-based bridge prioritization procedures (Yang & Frangopol 2018) and resilience-based management strategies (Capacci and Biondini 2020, Capacci et al. 2020, 2022). To support various road managers in implementing a standardized procedure for creating a uniform classification system of bridges, the Italian Government has adopted the "Guidelines for risk classification and management, safety assessment and monitoring of existing bridges" (Ministry of Infrastructure and Transportation 2022, Buratti et al. 2022), proposing a multi-hazard approach to prioritize maintenance and rehabilitation of the bridges in the Italian transportation network. The methodology defines rules for the evaluation an overall "Attention Class" (AC) for each bridge. The final AC is a comprehensive risk indicator combining four risk-specific AC: (I) Structural and Foundational, (II) Seismic, (III) Hydraulic, (IV) Geological.

This paper focuses on the assessment of the Structural Vulnerability Class (VC) as defined by Italian Guidelines. The procedure involves data collected through document research and

DOI: 10.1201/9781003483755-218

visual inspection. The steps in the approach rely on the engineering judgment of experts in charge of visual inspection process, introducing epistemic uncertainties based on their expertise. Other relevant sources of uncertainty can be related to the lack of design and as-built documentation. Case studies are proposed in this paper to investigate the influence of such epistemic uncertainties on the reliability of Structural VC estimates.

2 STRUCTURAL AND FOUNDATIONAL VULNERABILITY CLASS

According to Italian Guidelines, structural and foundational VC can assume the following values: LOW, MEDIUM-LOW, MEDIUM, MEDIUM-HIGH, HIGH. Four assessment steps are identified based on the logic workflow presented in Figure 1:

1. Identification of the level of Damage (*d*)
2. Evaluation of the effect of "Year of Construction" (VC_1).
3. Evaluation of the effect of "Design Standard" informing design loads (VC_2)
4. Combination of VC_2 with the initial bridge vulnerability VC_0 to obtain final VC.

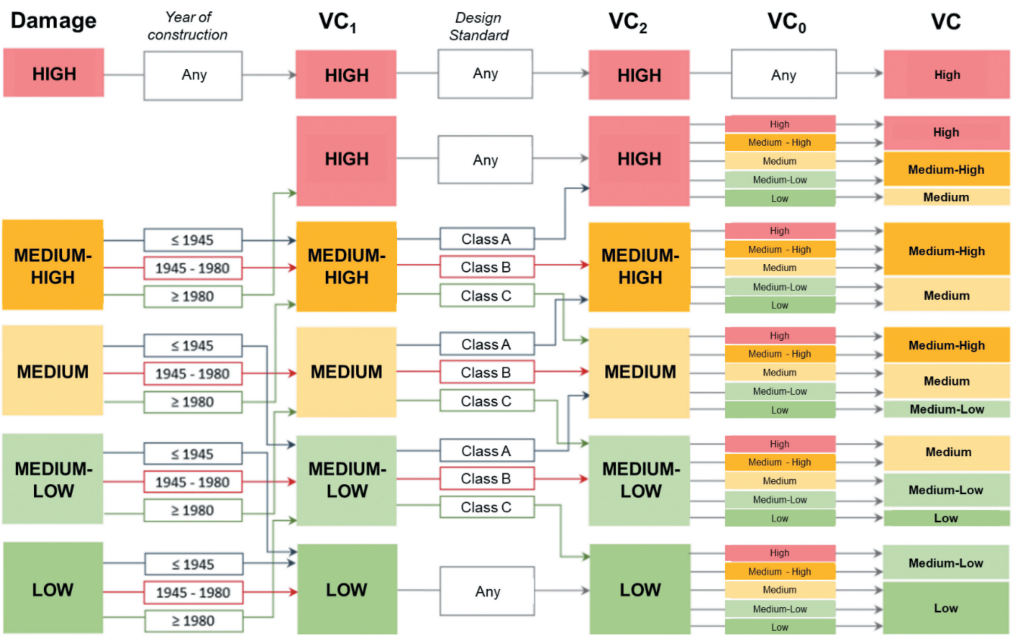

Figure 1. Logic workflow of structural and foundational VC (adapted from Ministry of Infrastructure and Transportation 2022).

2.1 *Step 1: Identification of the Level of Damage (d)*

The determination of damage level *d* relies on bridge visual inspections based on standardized forms filled by technicians during on site activities. These forms list various structural deficiencies categorized based on construction materials and structural members. Each deficiency is associated to a severity level and technicians can grade by predefined indices reflecting its extent and intensity. Value of indices is decided by expert inspectors on the base of engineering judgment. Finally, the damage level *d* is estimated by processing the collected data according to Table 1 based on damage severity and intensity as well as damage relevance in structural members eventually compromising the bridge safety.

2.2 *Step 2: Evaluation of the effect of "Year of Construction" (VC_1)*

Structural and foundational vulnerability can be also related to the year of construction. It represents the time required for the structure to reach the current Damage Level d. The damage level can be adjusted to obtain the Vulnerability Classification VC_1 according to the rules represented in Figure 1 which also depend on the construction periods identified by the Italian Guidelines: ≤1945, 1945–1980, ≥1980. Bridge exposure to chlorides effect, due to the aggressive action of marine wind currents de-icing salts, may result in more rapid evolution of degradation. In this case, value of VC_1 is increased.

Table 1. Damage level (*d*) for the evaluation of structural and foundational VC (adapted from Ministry of Infrastructure and Transportation 2022).

d_1	LOW	Small number of Medium and Low severity; any intensity; any element.
d_2	MEDIUM-LOW	(1) High number of Medium-High severity; Medium-Low intensity; any element. (2) Medium and Low severity; any intensity; any element.
d_3	MEDIUM	(1) High/Medium-High severity; High intensity; non-critical elements. (2) High severity; Medium-Low intensity; any element.
d_4	MEDIUM-HIGH	High or Medium-High severity; High intensity. Damage do not compromise structural safety
d_5	HIGH	High or Medium-High severity; any intensity; critical elements (e.g., Gerber joints, bearing, prestressing cables. . .) or identification of critical condition state (extensive cracks frameworks, foundation scour. . .)

2.3 *Step 3: Evaluation of the effect of "Design Standard" (VC_2)*

The understanding of the assumptions underlying their construction is essential in assessing the vulnerability classification of structures. A pivotal aspect among these considerations is the loading conditions considered during the design phases. The evolution of the historical Italian regulatory landscape has resulted in several updates to the definition of traffic loads (Buratti et al., 2019). Five design time intervals can be identified for bridge classification, along with the previously identified three construction time intervals associated to damage evolution rate informing VC_1. The intersection between such intervals leads to seven reference times t_i with i=1,..7 graphically represented in the timeline in Figure 2.

In this context, it is important to distinguish between bridges designed for both civil and military loads (1st category) and those designed for civil loads (2nd category). The impact of traffic loads also depends on their arrangement on the deck, i.e. on the total bridge span (L). Based on these characteristics, Italian Guidelines identifies three design classes as shown in Table 2. VC_1 is adjusted to obtain VC_2 according to rules represented in Figure 1.

Table 2. Identification of the design class.

	1st Category		2nd Category	
	L≤10 m	L>10m	L≤10 m	L>10m
Prior to 1933	Class A	Class A	Class A	Class A
Normale N.8 1933	Class A	Class A	Class A	Class A
Circ. 6018/1945	Class A	Class A	Class A	Class A
Circ. 772/1946	Class A	Class A	Class A	Class A
Circ. 820/1952	Class B	Class B	Class A	Class A
Circ. 384/1962	Class B	Class B	Class A	Class A
D.M. 1980	Class B	Class B	Class A	Class A
D.M. 1990	Class B	Class B	Class B	Class B
NTC 2005	Class C	Class B	Class C	Class B
NTC 2008	Class C	Class C	Class C	Class C
NTC 2018	Class C	Class C	Class C	Class C

It is worth noting that, the combination of the year of construction and design class can have either a beneficial, neutral, or detrimental effect on the computation of VC_2 (Figure 1), depending on the values they assume within each identified time interval. Table 3 lists the combination of these parameters for total length L<10m and design category I, while also pointing out their overall impact on VC_2 with respect to the level of damage (d). Similar table can be provided for the remaining combinations of total length and category.

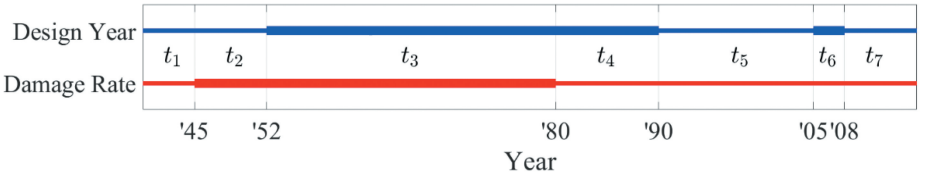

Figure 2. Timeline representing classification regarding damage evolution rate and design category.

Table 3. Year of construction and design class combinations for L<10m and design category I over time with the indication of the overall effect of the combination with respect to level of damage.

Time interval	Year of construction	Design class	Effect				
			d=1	d=2	d=3	d=4	d=5
t_1	≤1945	Class A	=	↑	=	↓	=
t_2	1945–1980	Class A	=	↓	↓	↓	=
t_3	1945–1980	Class B	=	=	=	=	=
t_4	≥1980	Class B	↓	↓	↓	↓	=
t_5	≥1980	Class B	↓	↓	↓	↓	=
t_6	≥1980	Class C	=	=	=	↓	=
t_7	≥1980	Class C	=	=	=	↓	=

Legend: (↑) Improvement; (=) No effect; (↓) Worsening with respect to the level of damage.

2.4 *Step 4: Evaluation of the effect of initial bridge vulnerability (VC)*

The vulnerability of bridges is also associated to their characteristics, including structural typology, maximum span length, number of spans and construction material. Based on combinations of these parameters, the Guidelines identify values of initial vulnerability classification (VC_0). The actual vulnerability class VC is identified based on the combination of classes VC_0 and VC_2 by means of the combination matrix resumed in Table 4.

Table 4. Combination matrix to obtain final VC.

		VC_0				
		LOW	**MEDIUM-LOW**	**MEDIUM**	**MEDIUM-HIGH**	**HIGH**
VC_2	**LOW**	LOW	LOW	LOW	MEDIUM-LOW	MEDIUM-LOW
	MEDIUM-LOW	LOW	MEDIUM-LOW	MEDIUM-LOW	MEDIUM	MEDIUM
	MEDIUM	MEDIUM-LOW	MEDIUM	MEDIUM	MEDIUM-HIGH	MEDIUM-HIGH
	MEDIUM-HIGH	MEDIUM	MEDIUM	MEDIUM-HIGH	MEDIUM-HIGH	MEDIUM-HIGH
	HIGH	MEDIUM	MEDIUM-HIGH	MEDIUM-HIGH	HIGH	HIGH

3 CASE STUDY ON PROBABILISTIC ASSESSMENT OF VULNERABILITY CLASS

3.1 *Epistemic uncertainties regarding engineering judgment*

The reliability of the expert judgment in correctly identifying the damage level d depends on the expertise of technical inspectors, who could overestimate (i.e., false positive) or underestimate (i.e., false negative) the actual bridge conditions. To account for realistic inspector's experiences, three expertise indices e_i are defined:

1. Complete lack of knowledge e_1. This scenario is representative of situations where bridge managers are prevented from conducting a detailed visual inspection to evaluate the extent and intensity of damage and identify specific vulnerability parameters.
2. Low inspector expertise e_2. Damage assessment is carried out via hasty visual inspections or by inadequately trained professionals leading to relevant potential biases.
3. High inspector expertise e_3. Damage assessment is thoroughly carried out highly trained professionals, reducing inaccuracies that may arise in scenario e_2.

The bias matrices in Tables 5–7 represent the epistemic uncertainties in the expert-based judgment. Each numerical value refers to the column-to-row conditional probability that the bridge is in the actual damage level (i.e., along the reference column) given the expert-based judgment of such damage level (i.e., along the reference row).

Table 5. Bias matrix for each expertise scenario e_1.

Actual Judgment	Low	Medium-Low	Medium	Medium-High	High
Low	0.20	0.20	0.20	0.20	0.20
Medium-Low	0.20	0.20	0.20	0.20	0.20
Medium	0.20	0.20	0.20	0.20	0.20
Medium-High	0.20	0.20	0.20	0.20	0.20
High	0.20	0.20	0.20	0.20	0.20

Table 6. Bias matrix for each expertise scenario e_2

Actual Judgment	Low	Medium-Low	Medium	Medium-High	High
Low	0.45	0.25	0.15	0.10	0.05
Medium-Low	0.20	0.40	0.20	0.12	0.08
Medium	0.10	0.20	0.40	0.20	0.10
Medium-High	0.08	0.12	0.20	0.40	0.20
High	0.05	0.10	0.15	0.25	0.45

Table 7. Bias matrix for each expertise scenario e_3

Actual Judgment	Low	Medium-Low	Medium	Medium-High	High
Low	0.80	0.12	0.06	0.02	0.00
Medium-Low	0.10	0.70	0.10	0.08	0.02
Medium	0.05	0.10	0.70	0.10	0.05
Medium-High	0.02	0.08	0.10	0.70	0.10
High	0.00	0.02	0.06	0.12	0.80

3.2 *Structural typologies*

The methodology for the evaluation of structural and foundational VC is applied to five bridges associated to five levels of VC_0. A brief description of structural typologies is provided in Table 8 aligned with the reference cases collected in Figure 3.

Table 8. Structural typologies identified by VC_0.

Bridge	Description	VC_0
Structural Typology 1 Figure 2a	Single span RC arch bridge with length lower than or equal to 5 m	0-LOW
Structural Typology 2 Figure 2b	Single RC arch bridge with length ranging 5 to 15 m	1-MEDIUM-LOW
Structural Typology 3 Figure 2c	Multi-span PC simply supported bridge with a maximum span length ranging 5 to 15 m	2-MEDIUM
Structural Typology 4 Figure 2d	Multi-span PC simply supported bridge with a maximum span length ranging 15 to 25 m	3-MEDIUM-HIGH
Structural Typology 5 Figure 2e	Multi-span PC simply supported bridge with Gerber joints with a maximum span length greater than 15 m	4-HIGH

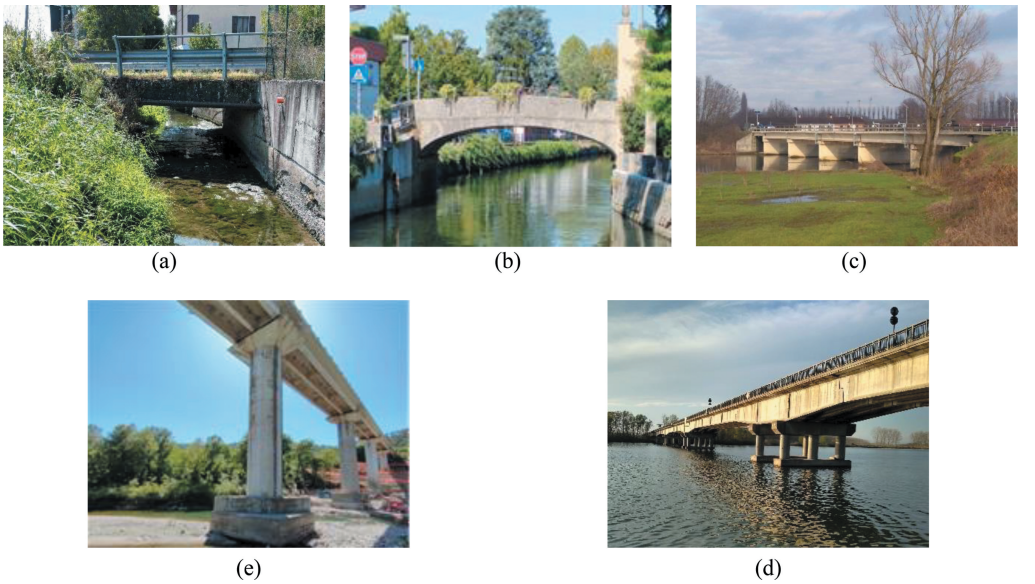

Figure 3. Examples of reference bridges: (a) Typology 1, (b) Typology 2, (c) Typology 3, (d) Typology 4 and (e) Typology 5.

3.3 *Impact of expertise in probabilistic vulnerability class VC*

The bridge is assumed to be designed in 1970 with total length L<10m, design category I, and not exposed to chlorides. The results can be extended to other combinations of input data. Each stacked bar chart collected in Figure 4 shows the statistical representation of the discrete random variable associated to the structural and foundational VC. Each bar represents the marginal probability for all five classes identified by the colors of each stacked bin consistently with the color palette shown in Figure 1. Then, each stack represents the results for a given scenario e_i related to the inspector's expertise. Finally, the results for a selected structural typology and damage level assigned by the inspector are collected over rows and columns, respectively.

The epistemic uncertainties related to different expertise scenarios result in an increase of the dispersion of the results about the central value. It is also worth highlighting that damage level of any investigated structural typology tend to exacerbate the expected value of the random variable VC. Consistently with the process, VC is not dependent on structural

typology for the highest level of damage. Therefore, if VC_0 is greater than or equal to 4, VC is not affected by the structural typology. Furthermore, graphs associated to VC_0 lower than 2 and damage level equal to 5 highlight the importance of the technicians' expertise in correctly assessing the level of damage. In these cases, a slight underestimation of the damage level (i.e. d=4) leads to a significant underestimation of VC, finally resulting as MEDIUM.

3.4 *Impact of bridge age in probabilistic vulnerability class VC*

Figure 5 Represents the time-variant probabilistic VC consistently with the seven intervals for design class and damage evolution identified in the timeline in Figure 2. For damage level 5, VC is not dependent either on design class or damage evolution, consistently with the workflow presented in Figure 1. For all other damage levels, graphs exhibit a pattern of alternating improvements and deteriorations of VC over time. This phenomenon can be primarily attributed to the combined effect of construction year and design class: Table 8 provides an overview of the overall effect for different combinations in this case study. Pairs of temporal intervals t_4–t_5, as well as t_6–t_7 share the same parameter combinations. This consistency is illustrated in Figure 5, where bars associated to these pairs of temporal periods are identical. It is worth noting that charts corresponding to d=2 deserves attention, as they reveal a negative difference of two VC between time instants t_1 and t_2 for VC_0 greater than 2. This is due to the fact that for d=2, there is an overall improvement effect at t_1 followed by a worsening effect at t_2.

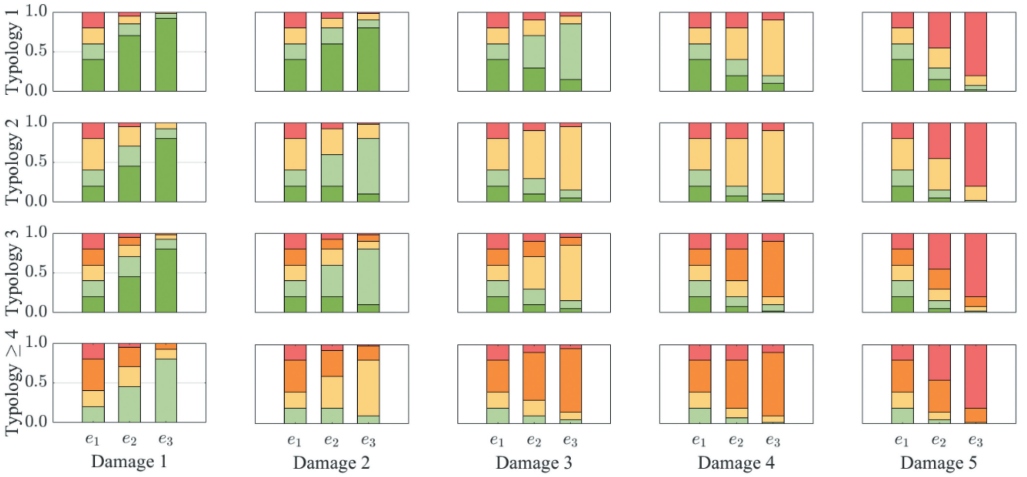

Figure 4. Probabilistic structural and foundational VC for all bridge typologies and observed damage levels considering total length L<10m, design category I, no exposure to chlorides, and design year 1970.

4 CONCLUSION

The prioritization of investments for maintenance and retrofit interventions over large bridge stocks is a crucial task for public administrations. The optimization of bridge management is aided by automated procedures implemented in BMSs exploiting logical workflows and numerical indicators computed on documental information and expert evaluations. This paper focuses on the assessment of the Structural Vulnerability Class (VC) as defined by Italian Guidelines and introduces a probabilistic perspective, introducing epistemic uncertainties related to bridge data collection process.

The results highlight the impact of the expert evaluations for the damage level on the final VC and point out the need of improving the quality of the data through an appropriate training of technicians. Expanding the proposed approach to other risk components such as the

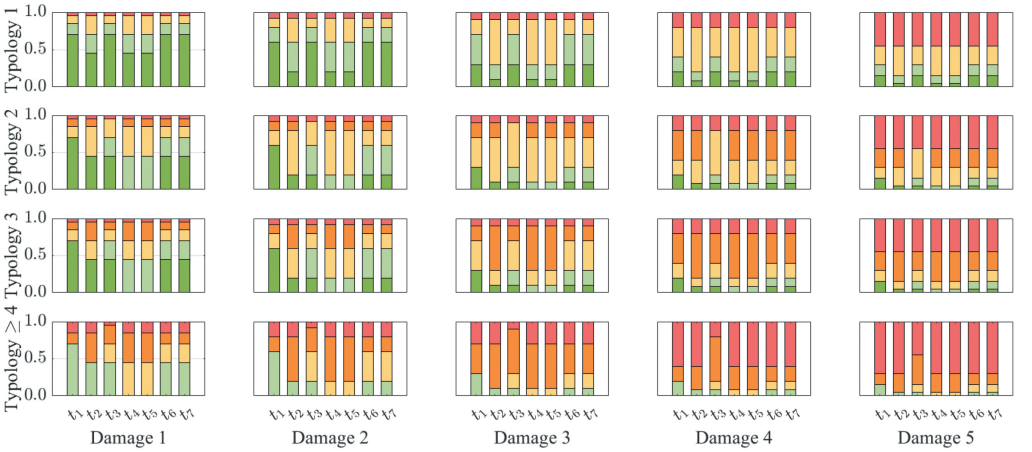

Figure 5. Probabilistic structural and foundational VC for all bridge typologies and observed damage levels considering total length L<10m, design category I, no exposure to chlorides, and expertise e_2.

seismic vulnerability (Capacci and Bianchi 2024) would allow to scale the impact of epistemic uncertainties up to the bridge Attention Class with a fully risk-based probabilistic approach.

ABSTRACT: The application of BIM in infrastructure asset management is intended to facilitate current management practices. For this purpose, existing bridges must be digitalised, which is challenging due to the related workload. Recent advancements in 3D surveying and artificial intelligence offer new possibilities for digitalisation. This paper presents a novel, modular framework for an automated construction of BIM models from bridge point clouds. The framework is based on a fusion of artificial intelligence and heuristic algorithms. Machine learning and geometric processing systems are utilised to segment bridge elements in point clouds and transform them into solid models. The final result is an as-is BIM model of a bridge, enriched with semantic information from databases, in the standardised IFC file format. The proposed framework could become a part of an expert system for interactive, machine-assisted construction of BIM models that will enable large-scale bridge asset digitalisation campaigns.

1 INTRODUCTION

The use of building information modelling (BIM) models (Sacks et al., 2018) in new construction projects is already included in the German implementation strategy (BMDV, 2021). These digital asset models can be then also used for more efficient asset management in operation and maintenance lifecycle phases. The benefit of the digitalisation in the later lifecycle phases will be fully exploited only when BIM models are available for most of the existing infrastructure assets. Depending on the quality of the information in the available 2D plans and infrastructure databases, the manual digitalisation of 2D plans could be labour-intensive or infeasible. BIM models derived in this manner may also represent the as-planned and not the wanted as-is state of an asset. Recent advancements in 3D surveying and artificial intelligence have unlocked new possibilities for an automated generation of BIM models from point cloud scans.

The objective of this work is to establish a BIM model generation procedure that is well-suited for bridge asset management. A novel, modular framework is presented, designed for the automated provision of as-is bridge BIM models from 3D point clouds (a process also known as Scan2BIM) for existing road bridges. This work can serve as the starting point for a comprehensive digitalisation campaign of the whole bridge inventory. The potential of artificial intelligence (AI) methods for the segmentation of bridge elements in point clouds is tested. Segmented point clusters of bridge elements are then algorithmically transformed into 3D solid models. Finally, a methodology for enriching geometric representations of bridge elements data from structure databases and geographical information systems (GIS) is developed.

DOI: 10.1201/9781003483755-219

2 BACKGROUND

The reconstruction of geometric data and associated semantics based on 3D survey is a key aspect of the digital representation of the built environment. The Scan2BIM process for bridge infrastructure assets typically consists of a collection of procedures that start with captured, raw point clouds and result in semantically enriched point clouds with clusters that correspond to bridge elements. The use of bridge element properties and parameters as well as geometry reconstruction methods are necessary to construct solid geometries and save them, e.g., in standardised Industry Foundation Classes (IFC) format. Most authors in the research field of bridge Scan2BIM process are showing efforts to obtain semantically meaningful bridge models in an automated way (Lu et al., 2019, Qin et al., 2019). They recursively decompose the bridge into parallel equidistant slices and then describe the bridge elements by analysing their 2D cross-section parameters and extrusion paths. Acquired bridge BIM models can then be linked with structure databases, GIS systems and bridge management systems (BMS). BMS (Lauridsen et al., 1998, Ryall, 2009) are used to manage the bridge assets more efficiently, e.g., with inventory organisation, maintenance planning and bridge inspection with condition assessment.

3 METHODOLOGY AND RESULTS

The methodology and results shown in this paper stem from the research project (Hajdin et al., in prep.), where a typical Scan2BIM process was enhanced by several significant features. These features are summarised in the following, as procedures that are split into two main parts.

3.1 *The learning part*

The learning part consists of the preparation of bridge data set, neural network training, design of procedures for point processing and transformation into solid models, as shown in Figure 1.

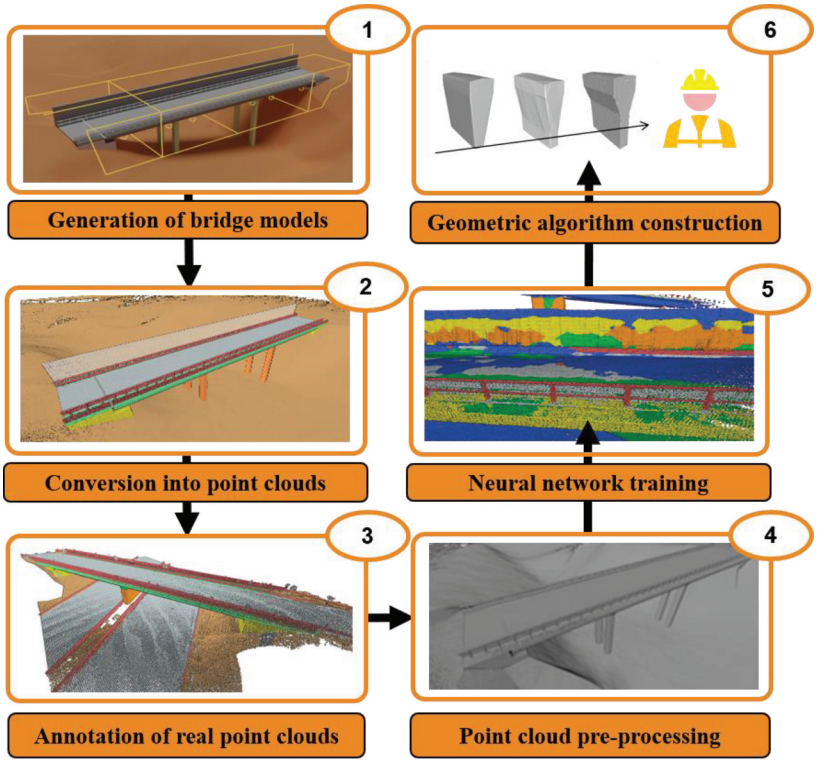

Figure 1. The learning part and its procedures.

3.1.1 *Procedure 1: Generation of bridge models as training data set*
Since the manual preparation of training data by 3D surveying is work intensive, another approach was chosen. 3D bridge models with semantics for each bridge element were generated in software and used to construct a training data set. The bridge models were generated by combining typical bridge elements from the specially developed bridge element database. The construction of this training data set was not a single step, but rather an iterative procedure, where the results of AI-based segmentation and processing were repeatedly evaluated, and new bridge and element models were added to the data set to mitigate the observed deficiencies.

3.1.2 *Procedure 2: Conversion into annotated point clouds*
Training data that are fed to the neural networks must resemble as far as possible the real-world scan data. The generated bridge models are therefore virtually scanned in software and converted into annotated bridge point clouds, as visualised in Figure 2. Both scans along virtual flight routes (mimicking drone scans) and scans on predefined static points (alike terrestrial scans) are simulated in this procedure, designed to mimic real scans and obtained point clouds.

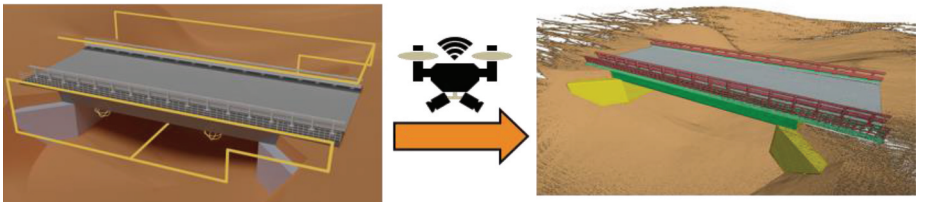

Figure 2. Bridge models and virtual scanning paths to obtain annotated bridge point clouds.

3.1.3 *Procedure 3: Annotation of real-world point clouds*
The training data set must also contain at least several real-world bridge point clouds, which ensures that all specific structural features are included. The training data was generated by annotating real-world bridge point clouds manually in software so that each point possesses in the end the semantics of the corresponding bridge element. This procedure is depicted in Figure 3.

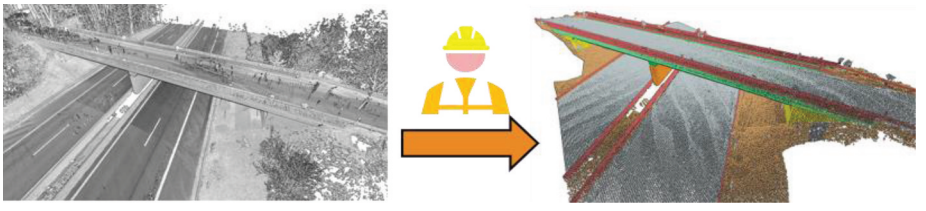

Figure 3. Manual annotation of real-world bridge point clouds for training data.

3.1.4 *Procedure 4: Point cloud pre-processing*
Point clouds are large data that can vary in point resolution and accuracy. Therefore, filtering procedures are required to bring point clouds in an adequate form for further processing. The data quality is improved by removing unwanted points and objects, as can be seen in Figure 4.

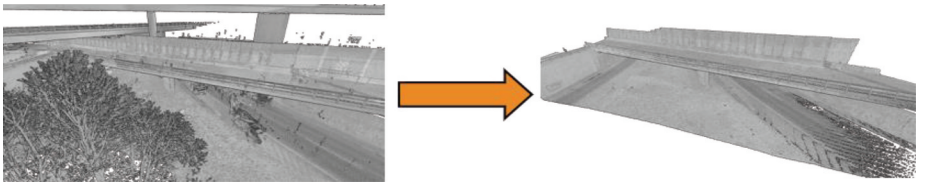

Figure 4. Point cloud pre-processing to improve the data quality for further procedures.

3.1.5 *Procedure 5: Neural network training*

Neural networks are trained with the training data consisting of generated and real-world annotated point clouds, as seen in the previous procedures. Trained neural networks can assign a bridge element class to every point of the point cloud with good accuracy, as shown in Figure 5.

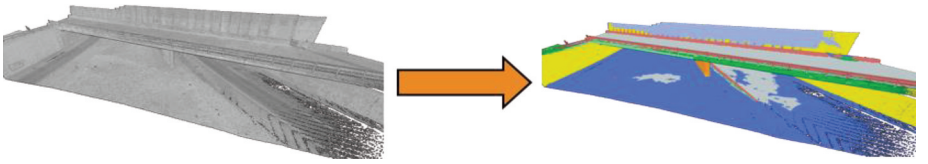

Figure 5. Neural networks add semantics to bridge point cloud points.

3.1.6 *Procedure 6: Geometric algorithm construction*

Geometric rule-based algorithms are developed to transform point clouds in higher-order geometric representations, surface and solid models, which are better suited for bridge representation in BIM. This is done by analysing different bridge element types and describing cross-sections and extrusion parameters, based on the established bridge property knowledge base.

3.2 *The application part*

The application part involves the processing of raw real-world bridge point clouds and the automated construction of BIM models from them, using trained neural networks and established geometric algorithms from the learning part. These procedures are overviewed in Figure 6.

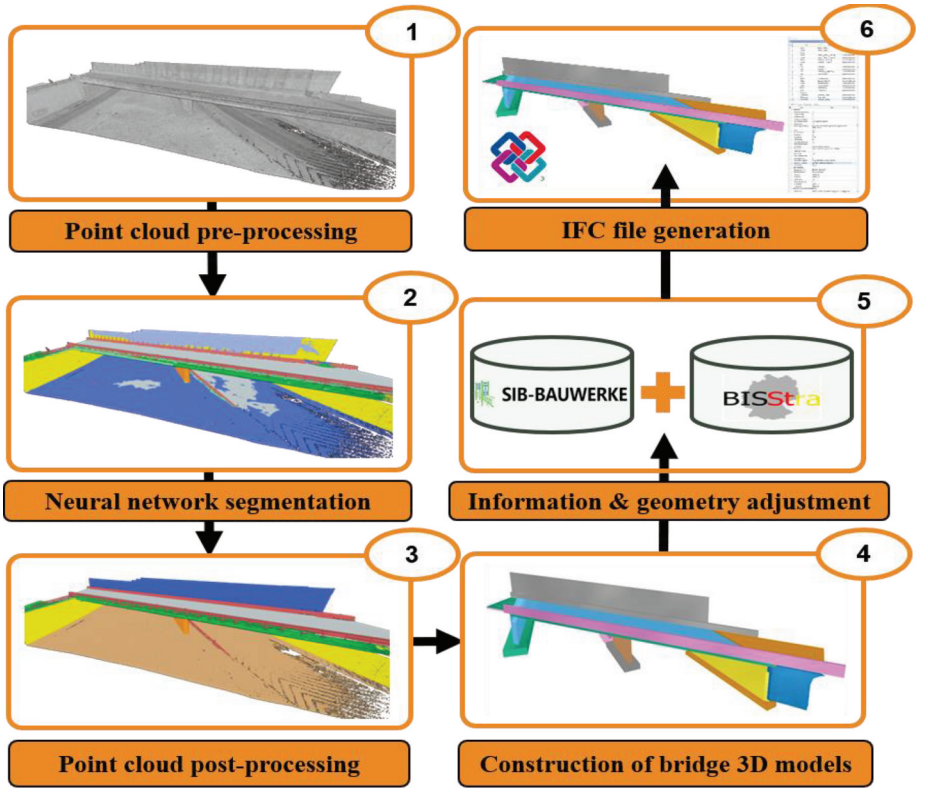

Figure 6. The application part and its procedures.

3.2.1 *Procedure 1: Point cloud pre-processing*
The pre-processing techniques already explained in the learning part are applied to raw real-world bridge point cloud scans to bring them in a suitable form for the upcoming procedures.

3.2.2 *Procedure 2: Neural network segmentation*
The trained neural network analyses points of the point cloud, where each point and its neighbours are processed and the most likely bridge element class is assigned to them. As a result, the bridge point cloud is segmented into point clusters belonging to different bridge element classes, based on what the neural network learned in the learning part. This segmentation is not perfect and post-processing steps are applied next to improve the bridge element assignment accuracy.

3.2.3 *Procedure 3: Point cloud post-processing*
Post-processing of segmented point clouds is necessary because AI-based segmentation can incorrectly classify individual points, especially on bridge elements' boundaries. By applying different analysis methods (e.g., region growing, clustering, majority voting), points are checked for their plausibility for the classes assigned by the AI-based segmentation and corrected as necessary. The resulting segmented point cloud of a real-world bridge is then given in Figure 7.

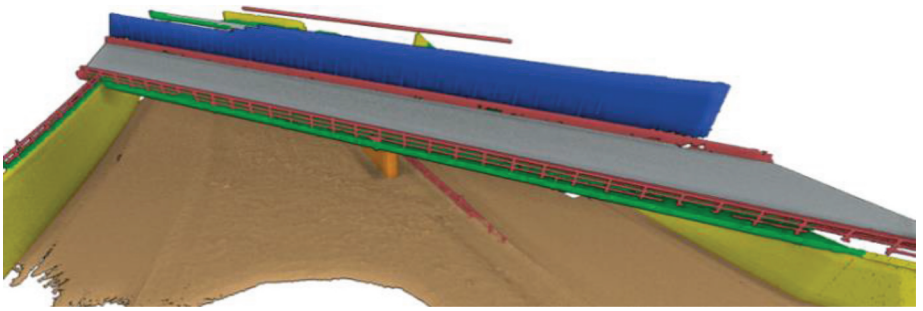

Figure 7. The result of AI-based segmented bridge point cloud showing different bridge elements.

3.2.4 *Procedure 4: Construction of bridge 3D models*
Methods for the cross-section recognition and extrusion direction of bridge elements have been implemented to generate 3D bridge element solid geometries. There are different cross-section characteristics and possibilities for parameterisation: predefined template, bounding box, convex envelope etc. The most suitable cross-section parametrisation and extrusion direction variants are chosen for each bridge element, generating solid bridge element geometries in Figure 8.

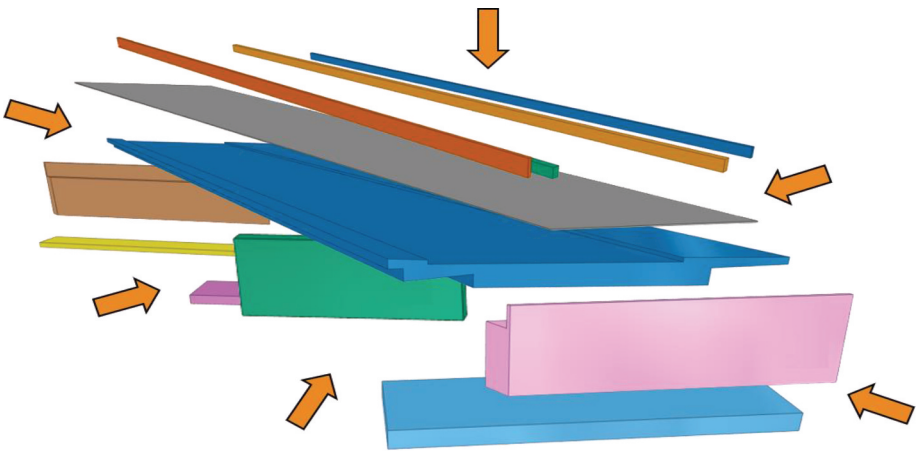

Figure 8. Bridge 3D model reconstruction with solid geometries for each element.

3.2.5 *Procedure 5: Information enrichment and geometry adjustment*
Bridge elements are enumerated based on the algorithmically determined bridge axis using the alignment data from the German Federal Road Information System (BISStra, 2024). Data from structure database of the German Building Database from the Federal and State Governments (SIB-Bauwerke, 2024) can be afterwards linked to the corresponding bridge elements and occluded bridge elements in scans, such as pavement layers, footings, expansion joints, bearings, abutment parts can be added and improved. Typical bridge properties and default values from the established knowledge base are used to generate realistic geometries where the information in point clouds or databases is lacking. The result of this step are improved and informationally enriched bridge elements and their merging into a single bridge model, shown in Figure 9.

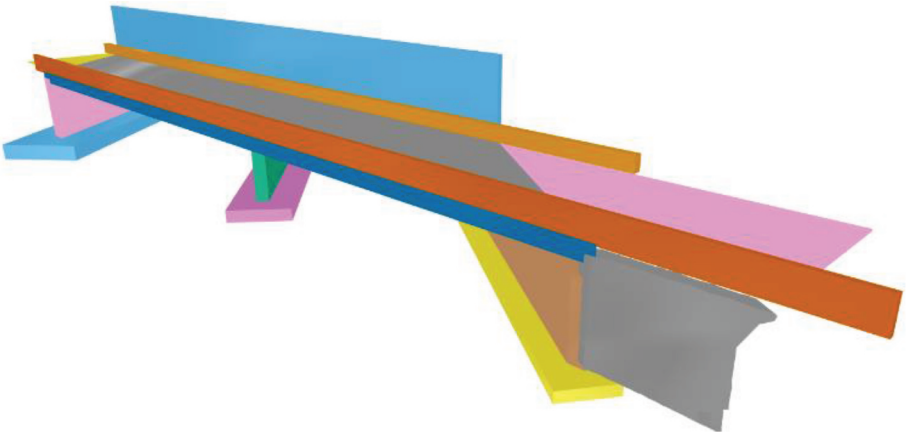

Figure 9. Resulting complete bridge model with reconstructed geometries of bridge elements.

3.2.6 *Procedure 6: IFC file generation*
The IFC format is an open file exchange format, intended to improve the data flow and file exchange between different disciplines. It captures the geometric, spatial, and semantic relationships between the individual elements of a structure (Liebich, 2009). The developed procedure in this work contains the conversion of the geometric representation and linked information from databases from the previous procedure into one IFC file, where a dedicated programming script has been implemented to automate this procedure. The IFC hierarchy corresponding to bridges with individual IFC entities for different bridge elements is established (e.g., IFC entities for beams, bearings, railings, slabs, columns) and additional information from structure databases and GIS systems (in the form of IFC property sets) is linked to these IFC entities.

3.3 *Results*

The final result of a processing procedure is a BIM model representing the as-is state of an existing bridge. Bridge elements are represented with solid geometries, enriched with information from structure and road databases in the standardised, open IFC file exchange format. The entire procedural chain from raw point cloud scan data to the final BIM model was implemented and tested on real bridges to demonstrate that the automated derivation of BIM models from point clouds is attainable. The used data formats ranging from point clouds to 3D solid models are all standardised. Different framework procedures are implemented modularly so that a further enhancement of the individual procedures is easily achievable. An example of the generated BIM model starting from the raw point cloud of a real bridge of the German Federal Highway Network is given. The raw, input point cloud to the framework is shown on the left, and the framework output, an IFC model with bridge geometry, is on the right in Figure 10.

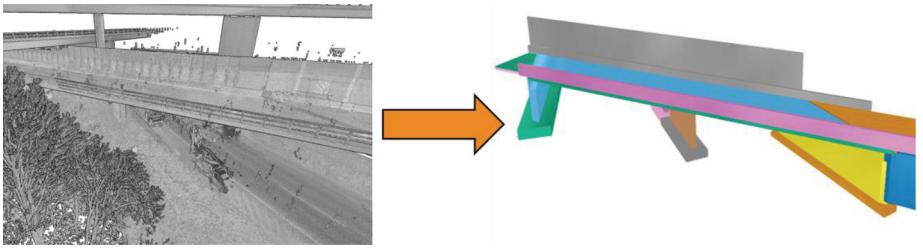

Figure 10. Transformation of raw bridge point cloud into IFC model with complete bridge geometry.

4 CONCLUSION

The developed procedure uses a blend of artificial intelligence and heuristic algorithms to process bridge point clouds into BIM models. By automating a rather strenuous Scan2BIM process, this work addresses the needs of bridge owners to have updated bridge asset data in their inventories. The developed methods exhibit robustness and prove the practical applicability that is needed for further development and a large-scale asset digitalisation campaign. Technological challenges such as large data volumes, varying acquisition data properties and distinct, complex geometry and bridge elements could be addressed and solved. The results and findings may accelerate digital transformation in the bridge infrastructure sector and improve asset management processes. The applicability of the developed procedures was tested on several existing road concrete bridges of the German Federal Highway Network System.

A significant potential lies in the complete digitalisation of structural inspection and maintenance planning. All findings, structural inspections and changes can be traced in the BIM model and processed over the entire lifecycle of a structure. This helps not only in decision-making on the individual structure, but also in providing valuable information strategically for the management of the entire structure inventory. Digital bridge models could also be embedded into 3D terrain models, which would enable a simulation of negative environmental impacts and the calculation of community resilience. It is evident in summary that these models are well-suited for use in asset management.

Obtained 3D element geometries can be also manually refined in modelling software to achieve a higher level of detail, add elements that are missing in scans, or record structural changes incurred during maintenance interventions. This means that the BIM model would stay up-to-date through the whole structure lifecycle, and such a model is also referred to as the digital twin (DT). The model may be even used for structural reassessment with some further post-processing steps, bringing it in a form suitable for finite element modelling (FEM) and structural analysis.

Lines of future work would include the construction of a more comprehensive 3D bridge element database. Neural networks trained on that exhaustive data collection and further geometric algorithms capturing more bridge properties would increase automation levels and the quality of results. An extended knowledge base of bridge properties will further aid in generating more detailed bridge geometric representations and better model proxies for bridge elements not visible to scanning devices and not properly recorded in the available databases.

ACKNOWLEDGEMENT

The presented work was funded by the Federal Highway Research Institute (BASt), Germany, through a research project Nr. FE 02.0436/2020/ARB “Development of procedures for the semi-automated construction of BIM models for existing road bridges”. The presented work was also partially funded by the Federal Ministry of Education and Research, Germany, through grant 01IS22062 “AI research group FFS-AI”.

Leveraging digital twin tools for the Minnesota DOT Robert Street Bridge inspection

S. Becher
Bentley Systems, Neptune Beach, Florida, USA

B. Lovelace
Collins Engineers, St. Paul, Minnesota, USA

ABSTRACT: Many organizations who are responsible for inspecting, monitoring, and maintaining bridge infrastructure are faced with the challenges of workforce shortages and an increasing backlog of aging bridges. Addressing these challenges requires a multi-faceted solution from the owner/operators, the engineering consultants they rely on as well as the entire infrastructure industry. Leveraging the latest technology to improve the current workflows should be a significant component of the comprehensive solution. The collection of reality data with a UAS and creation of a digital twin has proven to be a valuable tool in augmenting traditional inspections by utilizing remote visualization. As the technology matures, there continues to be advances in the tools that can be used along with the digital twin to assist inspectors. This paper will highlight how Collins Engineers used these tools to augment their existing workflows as a consultant to the Minnesota Department of Transportation in a detailed inspection and rehabilitation plan for the Robert Street Bridge. This includes the use of photo navigation alongside the 3D model, inspection forms with georeferenced issues, and mobile tools used in the field. The technology and associated workflow utilized by Collins saved over 30% in inspection hours and the improved quality of the data collection will generate a 20% savings in construction costs.

In addition to highlighting the tools used in the case study, the paper will cover other tools that can be used within a digital twin including artificial intelligence crack and spall detection, augmented reality model visualization and internet of things (IoT) sensors for structural health monitoring. Other AI detectors that are currently under development will be discussed and how these innovations will continue to transform traditional workflows. The transformation from traditional inspection workflows has the potential to enhance safety, reduce costs and improve the accuracy of inspection results.

1 INTRODUCTION

Many organizations who are responsible for inspecting, monitoring, and maintaining bridge infrastructure are faced with the challenges of workforce shortages and an increasing backlog of aging bridges. Addressing these challenges requires a multi-faceted solution from the owner/operators, the engineering consultants they rely on as well as the entire infrastructure industry. Leveraging the latest technology to improve the current workflows should be a significant component of the comprehensive solution. The collection of reality data with a UAS and creation of a digital twin has proven to be a valuable tool in augmenting traditional inspections by utilizing remote visualization. As technology matures, there continues to be advances in the tools that can be used along with the digital twin to assist inspectors. These tools include georeferenced annotations of a 3D reality model, AI/ML assisted defect detection, AR/VR visualization, and IoT assisted structural health monitoring.

DOI: 10.1201/9781003483755-220

An effective way to demonstrate the benefits of the technology is to highlight a project where the tools were used to augment existing workflows. Collins Engineers worked closely with Bentley to implement the software to provide a completed inspection to Minnesota Department of Transportation on the Robert Street Bridge Rehabilitation project.

Figure 1. Robert Street Bridge.

2 PROJECT OVERVIEW

The Robert Street Bridge is an eight-span reinforced concrete arch bridge with the main span consisting of massive rainbow arch ribs that define its modern architectural style. The bridge is located in downtown St. Paul, MN and was constructed in 1926. The Robert Street Bridge is on the National Register of Historic Places and is an important vehicular and pedestrian connection crossing the Mississippi River. The bridge is owned by the Minnesota Department of Transportation and in addition to crossing the river it also crosses two railways and a local roadway for a total length of 1429 feet (436 meters).

The bridge was rehabilitated in 1989 but significant deterioration has occurred since then and the project includes a detailed inspection to support a bridge management plan to facilitate another rehabilitation project in the future.

Collins Engineers Inc. teamed with Michael Baker on this important project and our role included creating a digital twin of the structure, performing the detailed inspection and documenting, and communicating the condition of the bridge.

A key objective of this project includes collecting detailed information on the condition of the bridge through inspection and testing. Another objective is to calculate a load rating of the bridge based on the condition information to determine the current load carrying capacity

of the bridge. The last objectives include a bridge management plan and service life analysis that will inform the rehabilitation efforts.

The main challenge of this project is the difficulty in efficiently and accurately collecting detailed inspection information for such a large structure with so many defects and deficiencies. Using traditional inspection data collection methods would be very tedious and expensive so the team had to find innovative ways to not only be more efficient but also to provide a higher quality deliverable for the Minnesota Department of Transportation.

Workforce shortages are another challenge we needed to address. With traditional inspection methods highly trained and educated engineers spent much of their time doing mundane tasks such as measuring and sketching defects. The project team proposed using these new technologies and workflows to make data collection easier and ensure engineers were spending their time making decisions versus collecting data.

Figure 2. Field inspection.

3 PROJECT PLAN

In order to meet the challenges of this project, Collins' team proposed using UAS to collect data in order to create a detailed digital twin of the bridge. It was imperative to use a digital twin visualization tool that could be shared across the team, and would become the central repository for the inspection, inventory, and testing information. The team proposed collecting all the inspection information in the field using internet connected tablet computers using a custom form built by the project team to address the key observations relevant to the structure. Using this form would ensure consistent data and the ability to quickly input inspection information. The scope of work for the project included the following:

- Collected data using drones equipped with artificial intelligence to autonomously collect all images.
- Post process the images and ground control points to build digital twins of each span. Both automatic ground control points and semi-permanent QR codes were used to aid in the processing. The high-resolution images, georeferencing aids and software tool produced high quality models that were used to pre-inspect the bridge in the office.
- The models were uploaded into an online digital twin sharing service. The entire bridge could be viewed at one time or by individual span.
- The engineers on the team performed a pre-inspection in the office using the digital twin visualization tool along with the custom forms. Additionally, the team used artificial intelligence defect detection to automatically find and document concrete cracks and spalls.
- The fieldwork was performed, and all previously input inspection results were verified. Additional inspection information was input in the field using internet connected tablet computers.
- The digital twin with annotated inspection information was shared with the entire team and all team members had the ability to review and add information to the models.

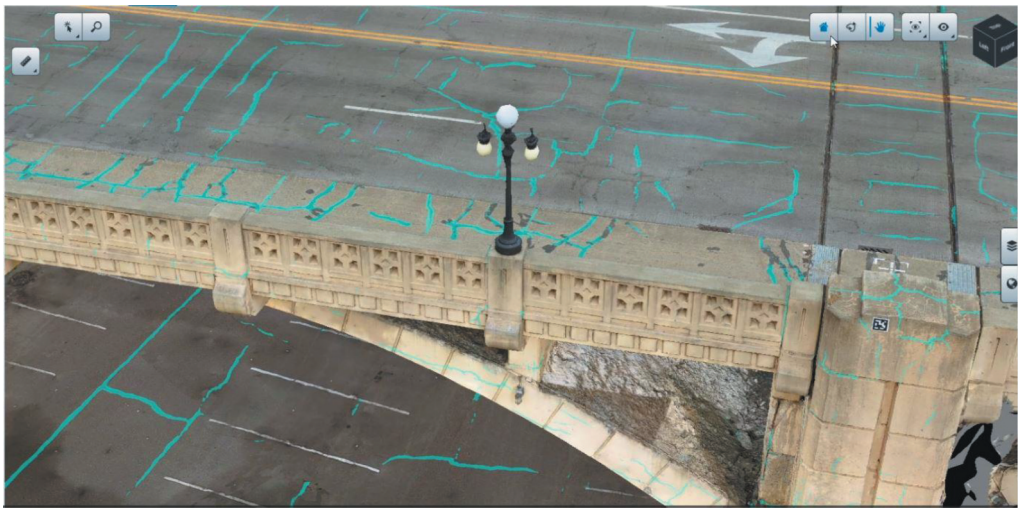

Figure 3. AI/ML crack detection.

One of the largest breakthroughs of our team approach included the ability to pre-inspect the bridge by using the digital twin in the office prior to starting field work. This method allows engineers to validate defects instead of recording detailed information in the field. Another significant breakthrough was the ability to use artificial intelligence to automatically find, quantify and communicate concrete crack information. This workflow using the tools is revolutionary and is a large leap forward in the bridge inspection industry. With our workforce shortages, applying these technologies will provide the industry with a way to deliver improved inspection results.

Another significant breakthrough is the ability to perform quality control based around the digital twin and photo navigation feature in the digital twin visualization tool. Previously, if an inspector missed a defect, the only way to verify was by performing an independent inspection. Using the digital twin, another inspector can easily and remotely check the field inspectors work for accuracy.

4 RESULTS

By using digital twins for the inspection our team saved over 30% on inspection hours and fees with a very significant improvement in the quantity and quality of the deliverables.

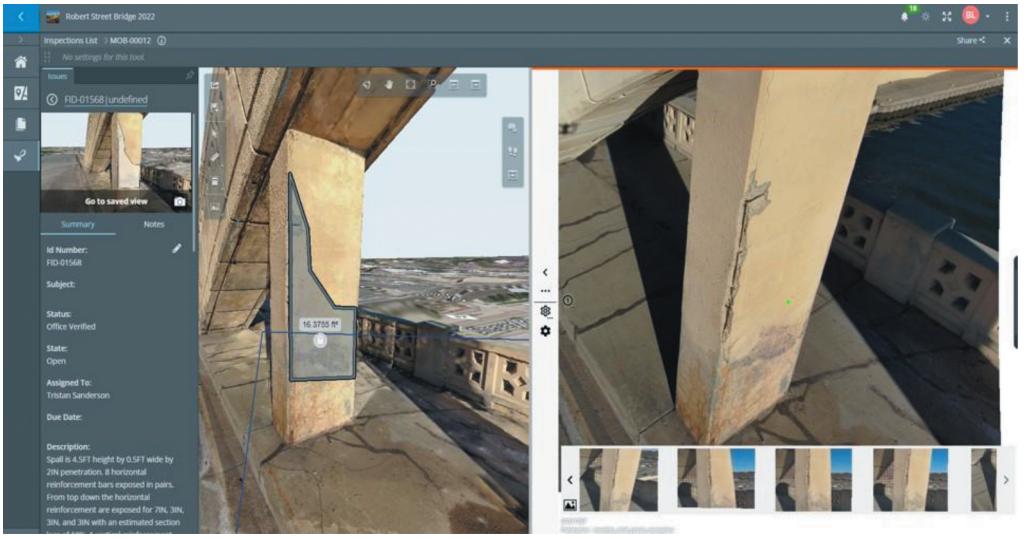

Figure 4. Office pre-inspection using digital twin.

As our team works through bridge rehabilitation process, we expect to see a minimum of 20% construction savings stemming from the improvements in the quality of inspection data since better decisions can be made with more complete information.

Our innovative workflow is impacting the local community by reducing the amount of time our teams need to spend in the field, which in turn reduces traffic control and lane closures. This not only reduces traffic impacts that the public is affected by but also reduces safety risks associated with lane closures and traffic control.

Implementing these tools into the workflows not only reduces safety risks for the public and inspectors, but it also reduces risk for the project team and MnDOT. Better data leads to better decisions, thereby reducing the risk of design errors or applying the wrong repair and rehabilitation solutions. The digital twin visualization tool provided a means to ensure that everyone on the project team had easy access to all the relevant information regarding the bridge. Team members also had the ability to contribute data to the model to further enhance collaboration from all stakeholders and used across disciplines. Due to the technology implemented, The Robert Street Bridge Rehabilitation Project has more quality data accessible to all team members than any other similar bridge inspection project.

Quantitative Summary of Results:

- 30% Reduction in inspection hours which is over $90,000 USD in savings.
- 20% Estimated future construction savings which could translate to up to $15M in savings.
- 20% fuel reduction.
- 10% reduction in material production during future construction.
- 1000x increase in the amount of quantifiable data available to decision makers.

5 FUTURE OUTLOOK

The Robert Street Bridge Project utilized tools to augment a workflow that generated significant benefits, despite being one of the first projects where the Collins team had used these tools. Future projects will undoubtedly use these tools faster and more easily to further improve the benefits. Additionally, the reliability and power of the tools will continue to be enhanced.

The Collins team effectively used the AI/ML concrete crack detector to streamline a tedious task of identifying a specific defect, however bridge inspections required identification of other defects such as spalling, corrosion, and delamination. AI/ML defect detection is still in early stages and the quality and types of the detectors will continuously be improved as the amount of data is inputted into the models.

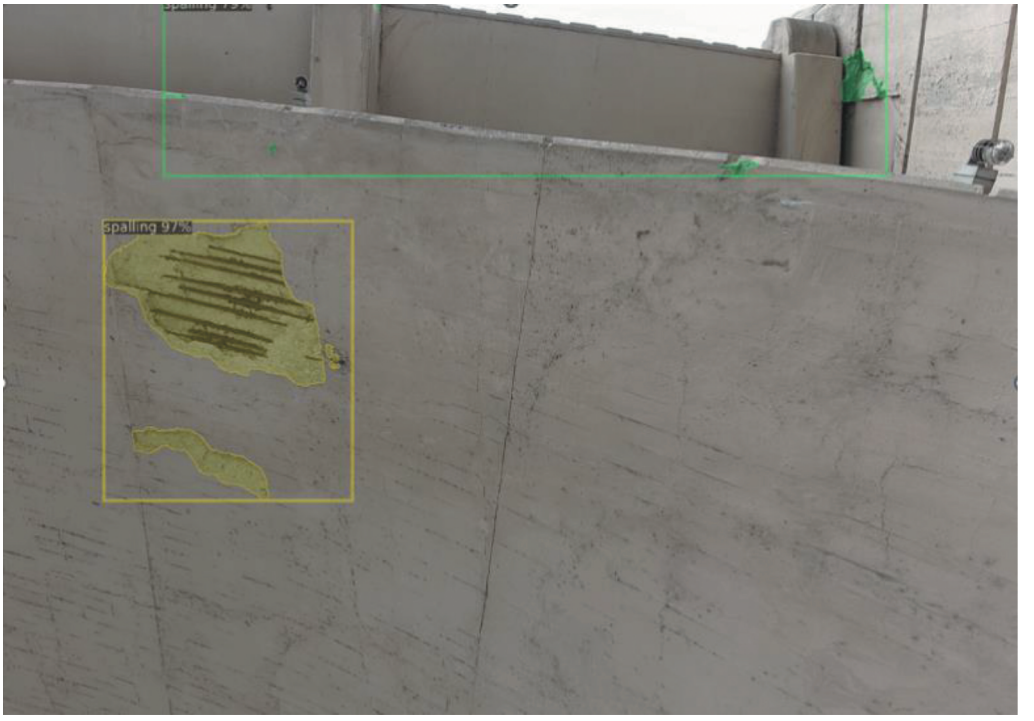

Figure 5. AI/ML spalling detection.

The visualization of 3D models also presents an opportunity for further enhancement of bridge inspection workflows. Extended reality (XR) offers many potential benefits including remote worker collaboration and bridge inspector training programs. The ability to easily navigate an accurate reality model at 1:1 scale, make annotations and have access to all relevant information at the touch of a hand, will further transform bridge inspection workflows. Essentially, workers will have the benefits of being onsite, with the convenience of a computer for documentation and reduce many of the inherent risk factors associated with bridge inspection.

Although IoT sensors were not used in the Robert Street Bridge, the integration of sensors into a monitoring program has the potential to further supplement the technology discussed earlier. While IoT sensors are not necessarily new, the data feeds they provide can be visualized in the same model created for remote inspections, giving owner/operators a more complete picture of the health and performance of the bridge in one environment.

The digital twins created, and the inspection data collected were targeted for our specific rehabilitation project, however it is expected that it will be used to manage this important bridge for many years to come. While the Robert Street Bridge is a large, multi-faceted project, this workflow can be adapted and streamlined for almost any kind of structure including smaller bridges, retaining walls and sign structures, among others. This type of technology will only continue to grow within the inspection and construction field. Collins and Bentley anticipate this new workflow will be adopted for many projects of this type in the next few years since the benefits are so compelling.

6 CONCLUSION

The Robert Street Bridge project serves as a compelling case study, showcasing the effectiveness of digital twins in augmenting traditional inspections through remote visualization. The challenges posed by workforce shortages and the complexity of inspecting aging structures were met with an innovative approach, resulting in substantial benefits, and paving the way for future advancements in the industry. The collaboration between Collins Engineers and Bentley Systems has demonstrated the transformative impact of leveraging the latest technology to streamline workflows and enhance the quality of inspection data. The project's success is evident in the significant reduction in inspection hours. The innovative workflow not only improved efficiency, but also had a positive impact on the local community by reducing the time spent in the field, minimizing traffic disruptions, and enhancing safety for both the public and inspectors. The outlook is promising, with continuous enhancements anticipated in AI/ML defect detection, extended reality (XR) applications, and the integration of IoT sensors.

While the digital twins and inspection data collected were tailored for the specific rehabilitation project of the Robert Street Bridge, the adaptability of this workflow for various structures, from smaller bridges to retaining walls, signifies a broader industry transformation. In essence, the Robert Street Bridge project marks a significant leap forward in the bridge inspection and maintenance field, setting a precedent for the industry to embrace and integrate advanced technologies that not only address current challenges but also pave the way for a more efficient, data-driven, and future-ready approach to infrastructure management.

ABSTRACT: The bridges monitored within one cluster is characterized by multiple device nodes, wide coverage, and dispersed locations. In order to improve the efficiency of system data transmission, this study proposes a monitoring method for wireless chain networking using device nodes. It not only reduces system construction costs, but also fully utilizes the characteristics of the monitoring system. Firstly, device nodes obtain information about neighboring nodes through channel detection and signal strength detection. Secondly, with the help of wireless data transmission methods, device nodes construct a data transmission protocol and extract a list of device nodes. Finally, a calculation method for optimal path of nodes is proposed to calculate the chain network path that includes all device nodes. This method effectively expands the data transmission distance of the monitoring system, improves data transmission efficiency and reduces the number of system device nodes used. This method fully meets the current and future needs for safety monitoring of bridge cluster structures.

1 INTRODUCTION

With the rapid and mature evolution of wireless technology, wireless sensing technology has attained a significant level of advancement. Presently, numerous monitoring solutions leverage wireless technology for communication. Wireless sensing technology offers distinct advantages over traditional wired sensing approaches. Firstly, Wireless sensors are flexible to use and easy to deploy, obviating the necessity for wired connections and mitigating safety hazards associated with intricate wiring. Secondly, the construction of wireless sensors is characterized by simplicity, as the collection and transmission modules are integrated on a single mainboard, leading to heightened hardware integration and obviating the requirement for expensive collection devices, consequently reducing overall system costs. Additionally, the wireless communication method facilitates the seamless addition and replacement of nodes within the network.

2 WIRELESS NETWORKING TECHNOLOGY OVERVIEW

The deployment of wireless sensors is contingent upon wireless networking technologies, with prevalent options encompassing mesh networks, clustered tree networks, and star topology networks such as Mesh networks, ZigBee networks, and LoRa networks. Mesh networks and clustered tree networks prove efficacious for extensive coverage of wireless sensing points. Nevertheless, when applied to structures like bridge clusters with elongated configurations, these network structures become unduly intricate, posing challenges in capitalizing on their advantages

DOI: 10.1201/9781003483755-221

and escalating network configuration expenses. The star topology network distinguishes itself through its uncomplicated structure, enabling direct communication between each terminal sensor device and a gateway device in a one-to-one fashion, thereby facilitating straightforward command transmission and reception. However, its limitation lies in the constrained transmission distance, necessitating terminal sensor devices and gateway devices to be confined within a fixed area for effective communication. In scenarios involving a high number of terminal sensor devices or an expansive coverage area, the requirement for multiple gateway devices often arises for zone-based management, resulting in a substantial escalation of system costs.

2.1 *Mesh wireless networks*

Mesh[1] wireless networks adopt a mesh pattern wherein nodes establish network connections. Depending on the method of connection between nodes, Mesh networks can be categorized as fully connected or partially connected. In a fully connected Mesh network, illustrated in Figure 1, direct communication is facilitated between any two terminal nodes. The connections between nodes constitute fixed routes, minimizing the occurrence of "multihop".

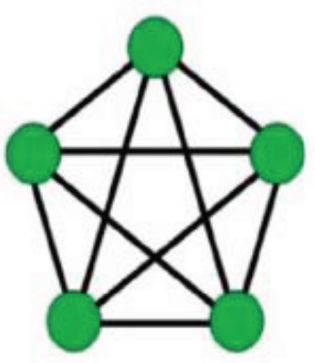

Figure 1. Fully connected Mesh network.

Fully connected networks [2] are typically only viable when the network scale is very small, as the complexity of such networks escalates with the increasing number of nodes. In the case of wired Mesh networks, the substantial and intricate number of cables interconnecting nodes renders fully connected Mesh networks nearly impractical in real-world scenarios. In contrast, partially connected Mesh networks feature nodes with routing capabilities, while others exclusively serve as terminals without routing abilities. Consequently, in practical engineering applications, partially connected Mesh networks are more commonly employed.

2.2 *ZigBee networks*

ZigBee networks[3] utilize a clustered tree routing structure comprising a coordinator, routers, and terminals. While each cluster includes only one coordinator, there can be multiple routers along with their corresponding terminals, as depicted in Figure 2. The cluster head node (router) in each cluster primarily manages routing discovery and maintenance. Communication between terminal nodes necessitates routing through routers and cannot occur directly, thereby reducing routing maintenance overhead but concurrently increasing the demand for routers in the network. Routing between routers is facilitated by the AODV[4] algorithm.

Within the ZigBee network architecture, low power consumption is achieved by allocating networking responsibilities exclusively to non-terminal nodes. Furthermore, the adoption of a clustered tree structure significantly diminishes the number of routing paths between nodes, thereby enhancing routing efficiency.

Notwithstanding these advantages, ZigBee networks exhibit certain drawbacks. Firstly, routers and coordinators within the network are unable to enter a sleep mode, resulting in network

Figure 2. Clustered tree network.

paralysis during the discovery or maintenance of new routes. Secondly, the efficiency of routing links between nodes is suboptimal, leading to diminished network throughput, especially in scenarios with substantial data volumes where message collisions may occur, potentially resulting in data loss. Lastly, there exists a notable dependency on coordinators. Given that the entire network relies on the coordinator for initiation and management, any malfunction of the coordinator can impede the addition of new nodes or even result in network paralysis.

2.3 *LoRa networks*

LoRa networks[5] embrace a star topology network architecture predominantly employed for low-power, multi-node communication, comprising terminal nodes, gateways, and servers, as depicted in Figure 3.

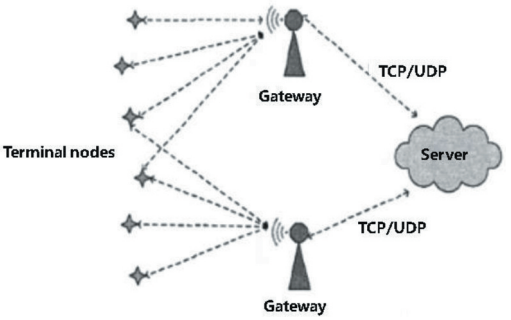

Figure 3. LoRa network.

1. Terminal Nodes: These nodes are responsible for data collection utilizing various sensors based on specific application requirements. In the uplink, terminal nodes transmit collected data to gateways through LoRa radio frequency signals. In the downlink, terminal nodes can receive messages from the gateways.
2. Gateways (Base Stations): Gateways handle the modulation and demodulation of LoRa signals. In the uplink, they encapsulate received data packets and establish connections to the server through standard IP. In the downlink, gateways receive data packets from the server and, based on the packet, determine transmission power, frequency, data rate, and specific transmission time.
3. Server: The server controls and processes messages. Network servers perform multiple functions, including extracting, storing, and analyzing payload data from terminal data packets according to the LoRa protocol. They manage terminal node registration and adjust physical layer parameters for terminal nodes in the network, such as transmission power, transmission rate, and encoding rate.

To mitigate concurrent conflicts in LoRa networks, it is crucial to ensure that only one node can send data at a given time. Traditional star network communication management employs a master node polling and slave nodes responding approach for data communication.

However, this method has drawbacks: if a node continuously sends data, other nodes may be unable to communicate with the master; slave nodes cannot actively send data and must wait for the master's query, jeopardizing real-time functionality; as the number of nodes in the network increases, the time used for each polling cycle and network latency also increase.

3 WIRELESS CHAIN NETWORK CONSTRUCTION METHOD

3.1 *Construction principle*

For the safety monitoring system of a bridge cluster structure, traditional network structures face limitations in fully harnessing the network's capabilities, leading to increased system costs and network configuration challenges. In response to the shortcomings of existing wireless networking technologies, this paper introduces a wireless chain networking method.

The wireless chain sensing network comprises a master device and multiple slave devices, with each node serving as both a terminal sensing device and a data forwarding router. Slave devices are equipped with functions for sensing data collection and data forwarding. The master device consolidates and summarizes data collected by each slave device, transmitting it to a designated server through cellular mobile networks or wired networks. This method optimally exploits the system's inherent characteristics, effectively extending the transmission distance, reducing the number of digital collection devices in use, and significantly lowering system costs and configuration complexities. The wireless chain network structure is illustrated in Figure 4.

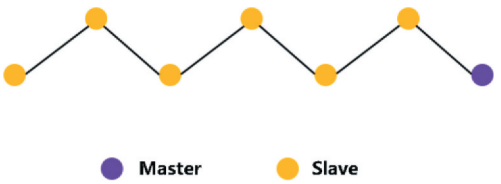

Figure 4. Wireless chain network structure diagram.

The construction principle of wireless chain network is as follows:

1. Sensor Node Deployment:
   Sensor nodes are strategically deployed in accordance with specific guidelines, considering factors such as geographical location, coverage range, and communication distance. The distance and arrangement of nodes play a crucial role in influencing network performance and coverage.
2. Network Detection and Connection:
   Following node deployment, sensor nodes initiate the establishment of communication links with neighboring nodes. The primary device broadcasts a network detection command, which includes its wireless address. Unconnected slave devices respond to this command, incorporating their wireless addresses. The primary device selects the closest slave device based on signal strength as the initial contact node.
3. Network Confirmation and State Transition:
   The primary device dispatches a network confirmation command to the chosen slave device, transitioning it to a connected state, signifying successful network formation. The slave device responds with a confirmation, and the primary device records the wireless address of the slave device, establishing a predecessor/successor relationship.
4. Chain Expansion:
   The first slave device temporarily assumes the role of the primary device, autonomously transmitting network detection commands. Devices not yet part of the network can respond to this command, including their wireless addresses. Through signal strength detection and the exchange of network confirmation commands, the first and second slave devices establish contact, recording each other's wireless addresses in their predecessor/successor tables.

5. Completion of Network Formation:
   This process continues until a slave device sends a network detection command but receives no reply, indicating that all devices have formed a chain network. At this juncture, each device, excluding the main and last slave devices, possesses both a predecessor and a successor. Adjacent nodes can freely communicate using wireless address identifiers. The wireless chain network offers an extended transmission distance, with each device functioning not only as a terminal but also as a relay. This network maximizes system and network characteristics, achieving long-distance data transmission.

In a chain sensor network, nodes typically transmit data along the chain's direction. The source node generates or collects data and transmits it to the next node. This sequential process continues until the data reaches the target node. To ensure reliable transmission, chain networks often implement data transfer protocols such as packet retransmission, error detection, and correction mechanisms. These measures address issues like signal interference, packet loss, and transmission errors that may occur in wireless environments.

3.2 *Time synchronization solution in wireless chain network*

In a sensor network, maintaining time synchronization is paramount as it ensures a consistent time reference for data collection across various sensors within the network[6]. This synchronization coordinates their actions and promotes data accuracy. The absence of time synchronization may result in disparate data, posing challenges in effectively coordinating information among sensors. For instance, in applications like structural safety monitoring for a cluster of bridges, if the timestamps of sensor data are not synchronized, accurate analysis of the sequence and duration of events becomes challenging. Moreover, time synchronization contributes to energy conservation. Through collaborative operation at specific time points and subsequent entry into sleep mode [7], sensors can collectively enhance overall efficiency. Consequently, achieving precise time synchronization stands as an indispensable step in constructing a resilient and efficient sensor network. The method to address time synchronization in wireless chain network is outlined as follows:

The master device first connects to the network and calibrates its own time. Once calibrated successfully, the clock synchronization program retrieves the current time t of the device, encapsulates it into a time synchronization signal frame, searches its successor table, identifies the master device's successor node, and sends the clock synchronization signal frame point-to-point to its successor node.

After the successor node receives the clock synchronization signal frame, it updates its own time to t based on the time information in the data frame. Assuming the transmission delay between the two devices is Δt_{11}, the time taken to encapsulate the frame, send data, receive data, and parse the data frame is Δt_{12}. Therefore, the total delay during the signal frame transmission process is given by:

$$\Delta t_1 = \Delta t_{11} + \Delta t_{12} \tag{1}$$

At this point, the time at the master device is $t + \Delta t_1$, and the time at the first subordinate device is t. After the first subordinate device receives the data, updates its own time to t, and continues to look up its successor table to find the successor node, it forwards the data frame to its successor node. The successor node, upon receiving the clock synchronization data frame, updates its time to t based on the time information in the signal frame and continues forwarding until it reaches the final node.

Assuming this wireless chain network has one main node and n subordinate nodes, when the data frame is transmitted to the j-th node ($1 \leq j \leq n$), the time at the j-th node is updated to t. At this moment, the time at the master device remains:

$$T_0 = t + \sum_{i=1}^{j} \Delta t_i \tag{2}$$

For the k-th node($1 \leq k \leq j$), its time is updated to

$$T_k = t + \sum_{i=k+1}^{n} \Delta t_i \tag{3}$$

When the data frame is transmitted to the last device, the time of the main device is

$$T_0 = t + \sum_{i=1}^{n} \Delta t_i \tag{4}$$

For the k-th node($1 \leq k \leq n$), its time is updated to

$$T_k = t + \sum_{i=k+1}^{n} \Delta t_i \tag{5}$$

When the last node in a wireless chain network receives the clock synchronization frame from the preceding node and adjusts its own time to t, it first checks its successor table. If no successor nodes are found, it indicates that the signal frame has reached the last node in the chained network. At this point, the node device searches the pseudorandom table, introduces a random delay timet_r, and inserts its current time $t + t_r$, into the time synchronization response frame. It then looks up the predecessor table, identifies its own predecessor node, and sends the clock synchronization signal response frame to its predecessor node.

Upon receiving the data, the predecessor node subtracts its own time $t + t_r + 2\Delta t_n$. from the time in the signal frame $t + t_r$. The average of this difference is taken as the offset for the time $t + t_r$ in the signal frame. The predecessor node updates its own time to $t + t_r + \Delta t_n$ and continues forwarding the data frame to its own predecessor node. This process continues until the final data frame is transmitted back to the main device.

During the process of the time synchronization response frame returning, when the data frame is transmitted back to the k-th node, the time at the k-th node is:

$$T_k = t + 2 \times \sum_{i=k+1}^{n} \Delta t_i + t_r \tag{6}$$

Taking the difference between the encapsulated time in the signal frame and the actual time, averaging this difference to obtain the time offset, and adding it to the time $t + t_r$, update the current device's time to:

$$T = t + \sum_{i=k+1}^{n} \Delta t_i + t_r \tag{7}$$

At this point, the time for the j-th device to the n-th device is:

$$T_k = t + \sum_{i=k+1}^{n} \Delta t_i + t_r \tag{8}$$

The time synchronization response frame is sent back to the main device node, and at this point, the time for all subordinate devices has been synchronized. However, there still exists a time difference with the baseline time of the main device, and the size of the time difference is:

$$\Delta T = \sum_{i=1}^{n} \Delta t_i \tag{9}$$

The time difference is equal to the current time at the main device minus the encapsulated time in the signal frame $t + t_r$, and the average of this difference is calculated. This time

difference is then used as the time offset, and it is placed in a clock offset frame, which is sent to each subordinate device. Upon receiving the offset frame, each subordinate device adds the time offset to its own time and forwards the offset frame to its successor node. This process continues until the last node completes the offset synchronization. At this point, the clock synchronization in the wireless chain network is completed, and the times of master and all subordinate devices are synchronized and aligned with the current standard time.

4 CONCLUSION

This paper addresses prevailing challenges in wireless networking technology by proposing a wireless chain networking method specifically tailored for the safety monitoring system of bridge cluster structures. The method offers several advantages:

1. The construction of a wireless chain sensor network ensures that each node serves dual functions as a terminal sensing device and a data forwarding router, thereby fully maximizing the node's performance.
2. Investigation into clock synchronization methods within the wireless chain sensor network guarantees uniform time benchmarks for data collection across all sensors. This synchronization coordinates their actions, ensuring precision in data accuracy.
3. In the context of safety monitoring systems for elongated structures such as bridge clusters, this method capitalizes on the inherent characteristics of the network structure. It effectively extends transmission distances, enhances data transmission efficiency, reduces the number of digital acquisition devices, and substantially diminishes system costs and configuration complexities.
4. In the future, through the integration of machine learning and intelligent algorithms[8], the wireless chain sensor network can autonomously adjust configurations, optimize resource allocation, and dynamically adapt its operating mode based on environmental changes. This integration enhances overall performance and adaptability. Through intelligent decision-making and collaboration within the network, higher levels of self-organization and coordination can be achieved, thereby augmenting overall performance and robustness.

ABSTRACT: Damage monitoring is an essential step to ensure the safety of concrete structures. Smart aggregate technique has been proven for its advantage to detect early-stage internal cracks in concrete. In this study, a 1-D CNN-based method is developed for autonomously classifying the damage feature in a concrete anchorage zone using the raw impedance signatures of the embedded SA sensor. An overview of the developed method is presented. A 1-D CNN classification model using the impedance signals is constructed. The experiment on the SA-embedded concrete anchorage zone is carried out, and the impedance signals of the SA sensor are recorded under different applied force levels. The feasibility of the developed 1-D CNN model is examined to classify concrete damage features via noise-contaminated signals. The results show that the developed method can accurately classify the damaged features in the concrete anchorage zone.

1 INTRODUCTION

In demand for real-time SHM monitoring, the electromechanical impedance (EMI) technique has attracted significant attention from researchers due to its advantages, such as sensing and driving functionalities, fast response speed, stable performance, and low price (Na et al. 2018). The technique utilizes the coupling interaction between a PZT (lead zirconated titanate) transducer and the monitored structure to provide information about the local structural characteristics of the examined region (Liang et al. 1994). The technique has been extensively implemented for monitoring stress in concrete structures (Ai et al. 2019, Pham et al. 2021). Many studies propose using PZT sensors placed on the surface of concrete structures to detect changes in impedance response induced by local damage near the surface (Ai et al. 2019, Pham et al. 2021). However, those surface-mounted PZT sensors are found to be less sensitive to changes in internal concrete stress. The so-called smart aggregate (SA) sensor (Gu et al. 2006), which was embedded into a monitored concrete structure, has recently emerged as an alternative internal stress monitoring method. The change in internal concrete stresses and the occurrence of damage events can directly reflect on the impedance response (Wu et al. 2022).

In recent years, convolutional neural network (CNN)-based deep learning algorithms have emerged as efficient approaches for assessing structural conditions of civil infrastructures (Sony et al. 2021). While the traditional damage detection method consists of two main steps: (i) feature extraction and (2) dam-age identification (Yuan et al. 2020), a CNN-based method combines them in a single procedure (Abdeljaber et al. 2018). The network can directly process raw signals and autonomously learn optimal features for a damage identification task, considerably reducing the initial processing workload. Several studies explored the combination of the CNN and the impedance-based technique for damage assessment. Nguyen et al.

DOI: 10.1201/9781003483755-222

(2021) proposed a 1-D CNN model that learned impedance signatures for classifying different health conditions of a smart PZT interface. Recently, Nguyen et al. (2022) explored the ability of the 1-D CNN for autonomous features extraction for impedance-based prestress force prediction. Ai et al. (2022) proposed a 2-D CNN model to classify compressive stress and damage in concrete samples based on the admittance responses obtained from the PZT sensors surface-mounted on a concrete block. The above studies have demonstrated the applicability of CNN as an innovative algorithm for impedance-based damage detections with minimal signal preprocessing.

Despite the previous research attempts (Nguyen et al. 2021, Nguyen et al. 2022, Ai et al. 2022), the 1D CNN algorithm with the SA technique has not been investigated for damage classification of concrete anchorage zone. In this study, a 1-D CNN-based method is developed for autonomously classifying the damage feature in a concrete anchorage zone using the raw impedance signatures of the embedded SA sensor. Firstly, an overview of the developed method is presented. A 1-D CNN classification model using the impedance signals is constructed. Secondly, the experiment on the SA-embedded concrete anchorage zone is carried out, and the impedance signals of the SA sensors are recorded under different applied force levels. Finally, the feasibility of the developed 1-D CNN model is examined for classifying concrete damage features with noise-contaminated signals.

2 OVERVIEW OF METHOD

The overview of a method for automated concrete damage classification is illustrated in Figure 1. The key idea is to combine the smart aggregate-based impedance monitoring technique and the 1-D CNN-based damage classification model to classify concrete damage features induced by compression forces automatically. The proposed method combines feature extraction and damage classification tasks into a single architecture, enabling direct processing and automatic learning of optimal features from the raw impedance signals. This approach allows for streamlined and efficient analysis of the signal. As shown in Figure 1, the schematic of the proposed method includes two main stages: impedance measurement (stage 1) and damage features classification (stage 2).

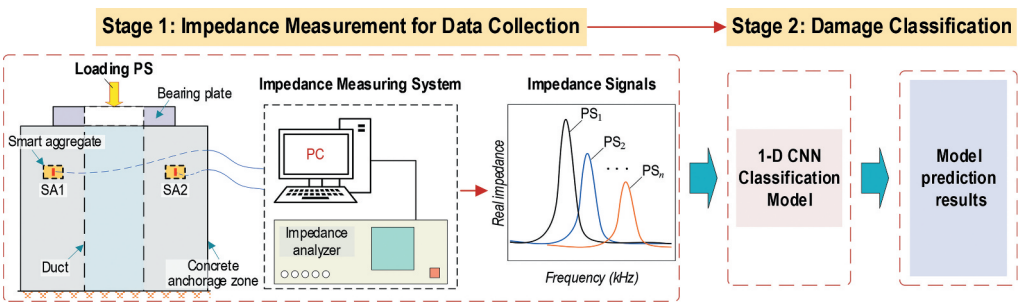

Figure 1. Schematic of methodology.

Figure 2 shows the architecture of the 1-D CNN classification model using SA's raw impedance signals. The model started with one Input layer, four Conv (Convolutional) layers, four ReLU (Rectified Linear Unit) layers, four Maxpool layers, three Fc (Fully Connected) layers, and finally, a Classification layer. The 1-D CNN model takes the 1×251 series raw impedance signal as the input, then returns the output, which can be used for classifying damage features in the anchorage zone.

The Conv layer comprises a set of trainable filters or kernels that slide over each element of the input data. The filters multiply the corresponding entries of the filters and data and then add them up. Each filter generates a frame of the feature map in the next subsampling layer,

and the depth of the convolution layer equals the number of frames. The ReLU layer replaces negative values from the output of the preceding layer with zero while keeping all positive values. The Maxpool layer slides filters over the output of the preceding layer and ex-tracts the element with the highest value. The purpose of the Maxpool layer is to reduce the computational cost by decreasing the size of the convolved feature. The Fc layers establish all possible connections between layers, meaning every input from the preceding layer influences every element of the output layer. The Fc layers combine and transform learned features into lower-dimensional representations suitable for the Classification layer.

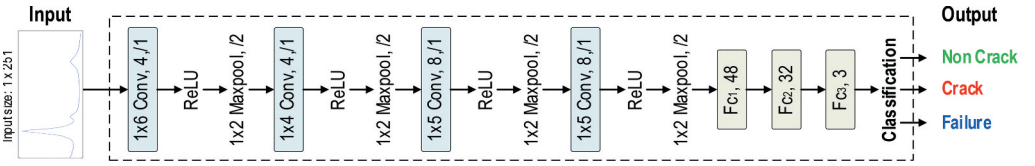

Figure 2. The architecture of the 1-D CNN classification model using SA's raw impedance signals.

3 EXPERIMENT

3.1 *Impedance monitoring of anchorage zone under compression*

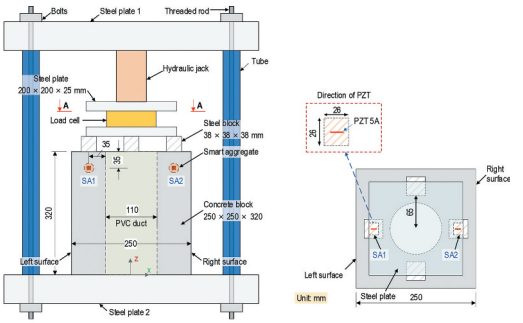

Figure 3 shows the schematic of an experiment on a lab-scale concrete anchorage zone embedded with smart aggregates under compression. The experiment was performed to obtain impedance responses of smart aggregates under the loading process. These impedance signals will be employed for data generation and fed to the 1-D CNN classification model. For impedance monitoring, two smart aggregate sensors SA1 and SA2 were installed in the concrete anchorage zone (see Figure 3a,b). The distance between the centers of these SA sensors to the concrete surface was set at about 35 mm. Note that SA1 was embedded in the left side of the anchorage zone, and SA2 was embedded in the right one. For the compression test, the anchorage zone was put on a supporting steel frame, which included two thick steel plates connected using four steel tubes and bolt connections (see Figure 3a). The steel frame was designed to resist tension induced by the anchorage zone. The compression force was generated via a hydraulic jack, and a combination of a load cell and indicator was utilized to monitor the actual compressive forces.

The impedance signals of the smart aggregates were measured using a wired impedance analyzer, specifically the HIOKI 3532. The analyzer excited a harmonic voltage of 1 V and recorded the impedance signals of the smart aggregates within a frequency range of 100-600 kHz (251 points). For each loading case, impedance signals were obtained four times or four ensembles. The laboratory temperature was kept constant at approximately 22°C to minimize the influence of temperature changes on the impedance responses. Eleven loading cases were assigned for impedance measurement in the anchorage zone. The compressive force P1 was set as the baseline at 100 kN, and the forces were gradually increased for the first six loading cases (P1-P6) from 100 to 200 kN with an increment of 20 kN. The applied forces were then raised from 200 to 230 kN for the next three loading scenarios (P7-P9) with an interval of 10 kN. Following that, during the P10 loading case, the compression force was increased to 235 kN, resulting in a partial collapse of the concrete. Finally, the applied force decreased to P11, set at 102 kN.

3.2 *Impedance signal of smart aggregates*

Figure 4 shows the impedance signals of SA1 under loading cases P1-P11, which were used to feed to the 1-D CNN classification model. It can be noted that the impedance signals are more sensitive to the applied forces at the highest peaks around 210 kHz. The impedance signatures of SA1 were slightly changed under forces P1-P6. Then a sudden change occurred

under force P7, thus showing a transformation of the concrete domain surrounding SA1 (e.g., inner concrete damage (Kocherla et al. 2020)). The signals were constantly varied under force P8, and another abrupt variation appeared under loading case P9 (the pristine crack close to SA1). The impedance signatures changed under force P10 (crack propagation), and the most variation in signals of SA1 occurred under force P11 (concrete failure). The impedance signatures of SA1 were matched to the crack appearances to make the following observations. First, when cracks occurred, significant changes in impedance signals were observed in SA1. Second, early incipient cracks and concrete damage appeared on the anchorage zone's left side, possibly due to unequally applied force (via four steel blocks) and the concrete structure's inelastic nature.

4 DAMAGE CLASSIFICATION RESULTS

4.1 *Databank generation*

The signals of SA1, which were measured for eleven force levels (i.e., P1-P11), were used to construct the databank for the 1-D CNN model. The noise was injected considering the uncertainty of the measurement situation under the premise that the measured impedance signal data is insufficient for deep learning training, validation, and testing. The noise was injected into the impedance signal using Gaussian noise with several signal-to-noise ratio (SNR) levels. The following formula calculates the SNR level in decibels (dB) (Johnson 2006).

$$SNR = 10\log^{10}\left(\frac{P^{signal}}{P^{noise}}\right) \quad (1)$$

Since 1-D CNN models require data and corresponding annotated labels to train, a process called data labeling is needed. This process is to form a representation of what class of data signals belong to. The SA1 sensor during the experiment's loading of the eleven cases (i.e., P1-P11) is observed. Each observed status is assigned and grouped under the three labels "Non Crack", "Crack", and "Failure". The "Non Crack" label includes force cases ranging from P1 to P5, corresponding with the observed status "No crack". The "Crack" label includes force cases ranging from P6 to P10, which correspond to the observed status "Inner crack", "Inner crack + surface crack + crack propagation", and "Crack propagation". The "Failure" label is used for force case P11 corresponding to the observed status "Failure". Figure 5 shows the impedance signals classified under these assigned labels.

The 1-D CNN model requires a massive dataset for training and validation to achieve a reasonable generalization capability. In the experiment, the impedance signals of SA1 were recorded with four ensembles for each force case. Three groups, "Non Crack" (for P1-P5), "Crack" (for P6-P10), and "Failure" (for P11), have 20, 20, and 4 impedance signals, respectively. Table 1 shows the training and validating data for the 1-D CNN model. With each SNR level, 20, 20, and 18 impedance signals were generated in three groups "Non Crack", "Crack", and "Failure", respectively. Thus, a total of 160 samples were collected from the measured signals and the noise-contaminated generated signals. 80% of the total samples were used for training, and 20% were used for validating the 1-D CNN model.

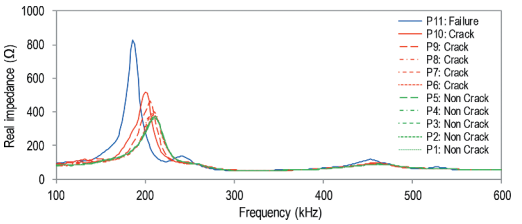

Figure 5. Impedance signals classified under three assigned labels.

With the same measured impedance signals, the larger the SNR, the smaller the noise is added. As a result, the impedance signal changes when adding noise with an SNR of 35 dB are smaller than that of 30 dB. It can be seen that noise with SNRs of 35 dB and 30 dB induces an insignificant effect on the general shape of the measured signals while it can simulate the realistic situations of noise contamination. The measured signals were injected by different SNR levels ranging from 20 to 16 dB with an interval of 2 dB. As shown in Table 2, in each noise level, there were 60, 60, and 40 new signals were generated in three groups "Non Crack", "Crack", and "Failure", respectively. A total of 480 signals were utilized for testing the 1-D CNN model. The noise-contaminated signals in three groups corresponding to SNR of 16 dB are illustrated in Figure 6.

Table 1. Training and validating data.

Assigned label	Current sample	Generated sample via SNR		Total sample	Ratio (Train/Validation)
		35 (dB)	30 (dB)		
Non Crack	20	20	20	60	80/20
Crack	20	20	20	60	
Failure	4	18	18	40	

Table 2. Number of testing data sets for evaluating trained model.

	Generated sample via SNR		
Assigned label	20 (dB)	18 (dB)	16 (dB)
Non Crack	60	60	60
Crack	60	60	60
Failure	40	40	40

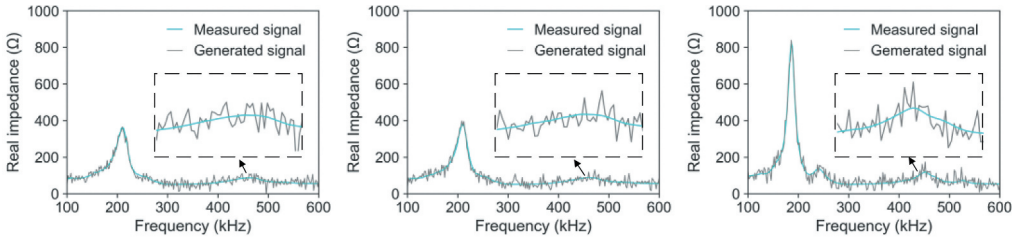

Figure 6. Adding noise to impedance signal with SNR = 16 (dB).

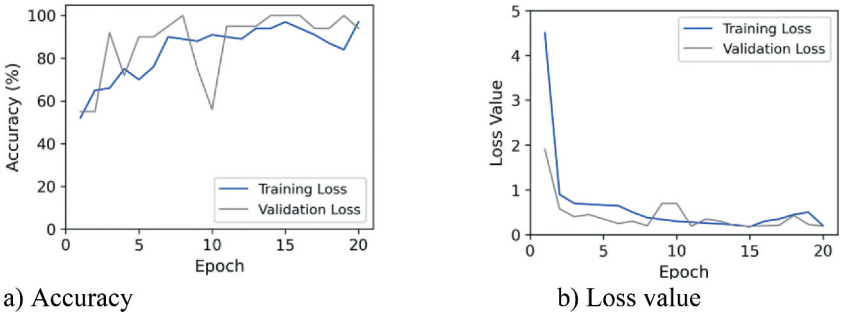
4.2 *Training results*

All experiments were performed on a desktop computer (GPU: GTX 2080 Ti 11G, CPU: Intel i9-9000KF 3.6 GHz, RAM: 64 GB). The 1-D CNN model was programmed using Python programing language (version 3.8). The designed 1-D CNN model was trained using the Adam training algorithm (Kingma and Ba 2014) with a mini-batch size of 1 and a learning rate of 0.001. Figure 7 shows the accuracy and loss value during the training and validation process of the 1-D CNN model. The training and validation accuracy of the 1-D CNN model gradually increased and reached over 95% at the 20th epoch. At the same time, the training and validation losses sharply reduce in a few first epochs and continue to converge at the end of the learning process. At the 20th epoch, the training and validation losses are recorded at approximately 0.1, suggesting the high accuracy of the trained 1-D CNN model.



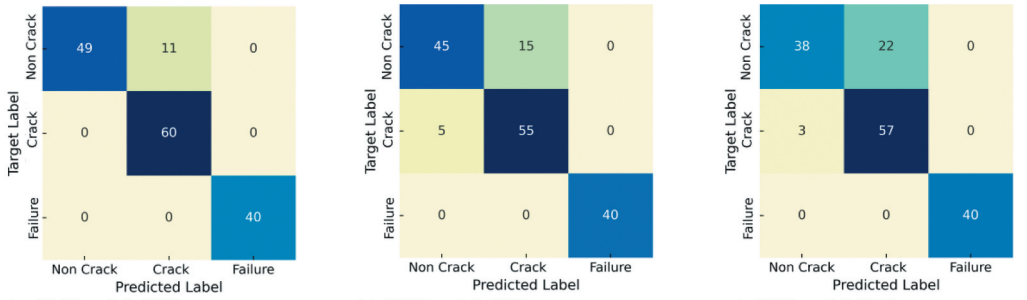


Figure 7. Accuracy and loss value during training and validating.

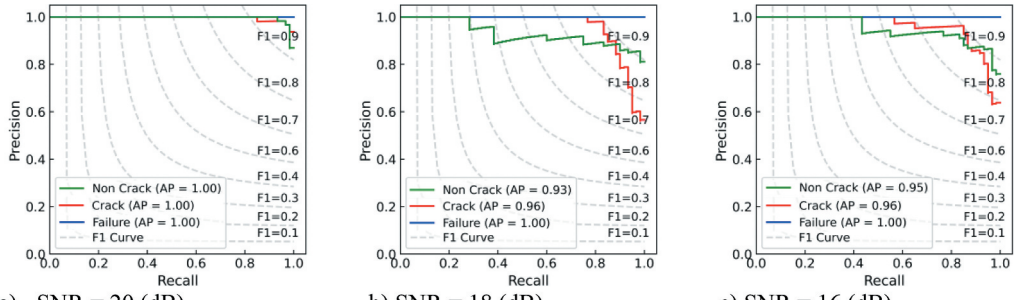
4.3 *Performance under noise levels*

Figure 8 illustrates the results of the damage feature classification of the trained model utilizing confusion matrixes without normalization. The confusion matrixes were plotted to show the number of correctly classified signals reflected in Table 2. Using absolute values in the confusion matrix to highlight correct classifications of investigated sample numbers has been utilized in some previous research studies (Mei et al. 2020, Yang et al. 2022). As shown in this



figure, in each SNR level, a total of 160 data samples in testing datasets are used to evaluate the performance of the model. With the SNR value of 20 dB, there are 11 samples that are misclassified between "Crack" and "Non Crack" conditions. The misclassified samples increased to 20 and 25, corresponding to SNR levels of 18 and 16 dB, respectively. It can be concluded that as the SNR level decreases, the accuracy of prediction labels tends to decrease.

As evaluation indicators, precision, recall, false negative rate, and false positive rate, which are calculated from four basic evaluation factors: true positive, true negative, false positive, and false negative, are applied. Figure 9 illustrates the performance of the trained 1-D CNN classification model, which is evaluated using precision/recall (P-R) and fusion (F1) curves. Higher precision means that the 1-D CNN model returns more relevant results than irrelevant ones, and high recall means that the 1-D CNN model returns most of the relevant results. The integration of the area under the P-R curve is called average precision (AP) and indicates the classification ability of the 1-D CNN model. The F1 curve measured the similarity between the predicted and target labels. In Figure 9, the AP indices reached 1.00, and the F1 score was larger than 0.9 in all three groups, indicating the high accuracy and reliability of the detector at SNR = 20 dB. In Figure 9b-c, when decreasing the SNR, the results show that the 1-D CNN maintained its classification performance as the AP indices are larger than 0.90.

a) SNR = 20 (dB) b) SNR = 18 (dB) c) SNR = 16 (dB)

Figure 8. Confusion matrix.

a) SNR = 20 (dB) b) SNR = 18 (dB) c) SNR = 16 (dB)

Figure 9. P-R curve and F1 curve.

5 CONCLUDING REMARKS

In this study, the 1-D CNN-based method was developed for autonomously classifying the damage feature in the concrete anchorage zone using the raw impedance signatures of the embedded SA sensor. Firstly, the overview of the developed method was presented. The 1-D CNN classification model learned the impedance signals for classifying the damage feature induced by compression was constructed. Secondly, the compression experiment on the SA-embedded concrete anchorage zone was carried out, and the impedance signals of the SA sensors were recorded under different applied

force levels. Finally, the feasibility of the developed 1-D CNN model for classifying concrete damage features with noise-contaminated signals was examined. The results revealed that the developed method could accurately classify the damaged features in the concrete anchorage zone.

Based on the analyzed results, the following remarks could be drawn: (1) the proposed classification model implicitly processes the raw impedance signals obtained from smart aggregates and autonomously outputs the concrete damage features; (2) the accuracy of the 1-D CNN model was significantly influenced by noises in the impedance signal, and the classification accuracy decreased with the increased of noise level; (3) the proposed 1-D CNN model was able to classify damage features even if from impedance signals having contaminated noises larger than noises in impedance signals used to train the model.

ABSTRACT: The connectivity reliability analysis of bridge networks has been the focus of research in this field and is also a difficult problem because of NP-hard problem. In particular, when performing network strategy or optimization, it is very time-consuming as the network connectivity probabilities need to be solved hundreds of times. This study finds that neural network with fewer neurons and layers can quickly and efficiently solve the all-terminal connectivity reliability for large-scale bridge networks. Firstly, for the same network benchmark model, based on real bridge inspection data, the state probability samples of each edge in the network are extracted by data fitting, and Monte Carlo simulation is applied to approximate the all-terminal connectivity reliability of each network model under each sample. Secondly, multiple neural network models containing one, two and three layers with different neurons are proposed and 5-fold cross-validation is applied to obtain the hyperparameters of each model. Finally, in conjunction with appropriate optimizers and hyperparameters, it can be shown that simple single-layer network models can find sufficiently accurate all-terminal connectivity reliability for large-scale bridge network. The accuracy and efficiency of the pro-posed method is verified based on a real bridge network containing 216 directed edges with 63 nodes.

1 INTRODUCTION

Under the influence of combined effects, the service performance of bridges in bridge network will inevitably deteriorate or even fail (Yang & Frangopol, 2019). In recent years, bridge network connectivity reliability (reliability) analysis has gradually become the focus and difficulty of bridge network assessment. It mainly considers the safety of hardware facilities in the assessment, which refers to the probability that the nodes of the network will remain connected due to the degradation or failure of the hardware facilities (bridges), and therefore can also be called "hard connectivity performance" (Estes, 1997; Saydam et al., 2013). At the same time, the connectivity reliability is proved to be an NP-hard problem. At present, based on the number of relevant nodes, connectivity probabilities of bridge networks can be classified into 3 categories: two-terminal, *k*-terminal and all-terminal connectivity probabilities (Reed et al., 2019). Among them, the 2-terminal connectivity reliability calculates the probability of connectivity between 2 specified nodes (origin and destination points) without caring about the other nodes; the *k*-terminal and all-terminal are concerned with whether the selected *k* nodes and all nodes are connected or not, respectively. Currently, most studies have focused on evaluating two-terminal connectivity probabilities for small-scale bridge networks (Bai et al., 2020; Bocchini et al., 2011; Kang et al., 2008; Liu & Frangopol, 2006; Yang & Frangopol, 2020).

There are many well-established and easy-to-implement methods for 2-terminal connectivity reliability for small-scale networks (Yeh et al., 2022). The commonly used methods can be

DOI: 10.1201/9781003483755-223

classified into exact methods and approximate methods (Bai et al., 2016). Exact methods mainly refer to enumeration methods, which can be further classified into state-based enumeration methods and cut/path set-based enumeration methods. Meanwhile, researchers have proposed a variety of methods for approximating network connectivity probabilities, mainly including improved algorithms for exact methods (Wang et al., 2020), simulation algorithms (Claudio & Zio, 2005) and deep learning based methods (Lei et al., 2022). The evaluation of bridge networks based on deep learning algorithms is the result of the combination of artificial intelligence and traditional complex networks in recent years, showing good time-efficiency advantages (Davila-Frias et al., 2023; Nabian & Meidani, 2018). Therefore, this paper proposes a neural network-based all-terminal connectivity reliability analysis method for bridge networks.

Specifically, this paper applies the fully connected neural network (FCNN) to calculate the all-terminal connectivity reliability of the bridge network. Firstly, based on the limited real bridge inspection samples in the directed urban bridge network proposed in our previous work (Wang et al., 2024), the number of samples is expanded by data fitting, so as to fully ensure the amount of data required for neural network computation. Secondly, combining the experience of domestic and foreign research scholars, several FCNN model structures are designed, and 5-fold cross-validation is applied to obtain the computational error of each model. And the model with the highest accuracy is selected as the method for the all-terminal connectivity reliability of bridge network in this paper. The final results show that a simple single-layer fully connected neural network model can be used to derive the all-terminal connectivity reliability of a large bridge network with sufficient accuracy if coupled with appropriate optimizers and hyperparameters.

The rest of the paper is organized as follows: Section 2 briefly introduces the directed urban bridge network. Section 3 describes the data expansion method for finite number of samples. Section 4 presents the processing of FCNN hyperparameter selection based on 5-fold cross-validation. Section 5 concludes this paper.

2 GENERAL INTRODUCTION OF THE DIRECTED URBAN BRIDGE NETWORK

In this paper, a city located in the southern part of the Yangtze River Delta in China is used as an example. Based on the inspection information of 299 actual bridges in the city,

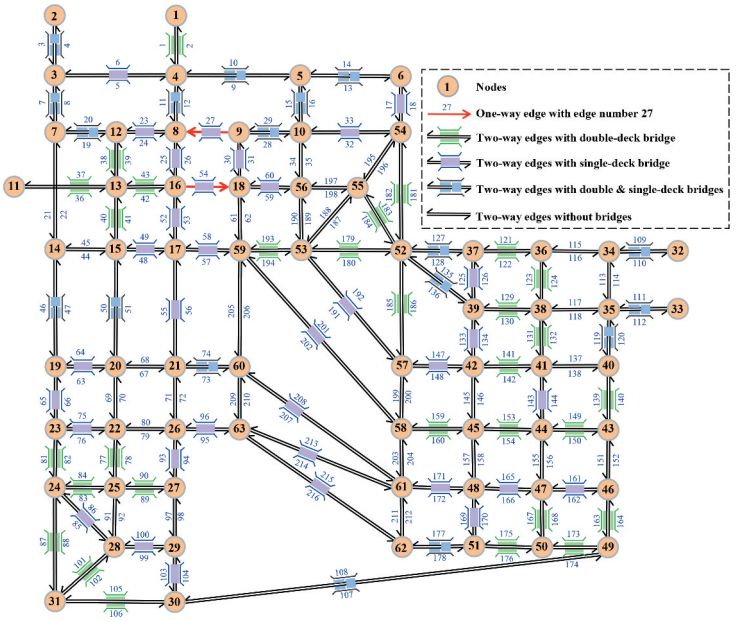

Figure 1. Topological model of the investigated urban bridge network (Wang et al., 2024).

a directed bridge network topology model is built according to the rules described in our previous work (Wang et al., 2024), which is designed to simulate the actual service state of the network to the maximum extent on the basis of the road directions and bridge types between all the nodes in the city, as shown in Figure 1. The topological model contains 63 nodes and 216 directed edges, including 107 two-way edge pairs and 2 one-way edges. Meanwhile, it has derived the failure probabilities of all bridges in the network, as well as the state probabilities of all edges or edge pairs for the period 2014-2018, and our goal of this paper is to efficiently derive the all-terminal connectivity reliability of the network based on neural network.

3 DATA EXPANSION METHOD FOR FINITE NUMBER OF SAMPLES

Before solving the all-terminal connectivity reliability of a bridge network based on neural networks, a sufficient number of data sets need to be prepared for processes such as training of the neural network. When analyzing the connectivity reliability of the directed urban bridge network, the state probabilities of the 216 directed edges in the network need to be used as 1 set of input data, while the connectivity reliability of the network needs to be used as the output of the model. However, only the state probabilities of each edge (pair) for 5 consecutive years from 2014-2018 and the network connectivity probabilities for the 5 years in (Wang et al., 2024) are available as input and output data, respectively, which is far from sufficient for the number of samples to perform the neural network training. Therefore, this section achieves data expansion through data fitting based on only existing real data.

As shown in Figure 2, the probability of being in the connected state (1 or (1, 1)) is high (greater than 0.99) for both the one-way edge containing 2 states and the two-way edge pair containing 4 states. By observation and fitting, it is found that the state probability distribution fits well with the power law distribution ($y = a \times x^b$). where a and b are the coefficients of this power law distribution, and for this research problem, x is the probability that an edge or edge pair is in the connected state (1 or (1, 1)).

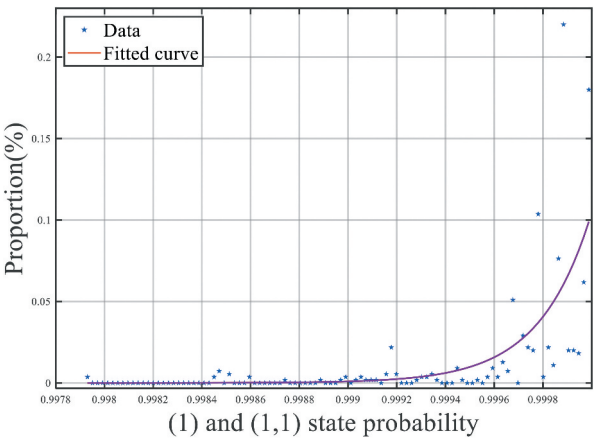

Figure 2. Fitting results of (1) and (1, 1) state probability.

Therefore, as shown in Figure 2, fitting based on the samples of 107 groups of two-way edge pairs and 2 one-way edges in the directed urban bridge network was calculated as a = 0.1046 and b = 4733.7955, and the root mean square error of the fitting result was 0.0234, which indicates that the fitting is good. Therefore, the probability of the connectivity state of each edge or edge pair in the newly extended sample can be generated based on the fitted power law distribution.

For a two-way edge containing 4 states, when the probability of the (1,1) state is known, it is necessary to determine the probabilities of the other three states ((1,0), (0,1), and (0,0)) separately. From a statistical point of view, 2 random numbers can be randomly selected based on the uniform distribution shown in Equation 1, and the third random number can be derived based on the probability of summing to one. Since the probability of the (0, 0) state is minimized. Therefore, the smallest of the 3 random numbers generated is assigned to (0, 0) as its state probability, and the remaining 2 random numbers are assigned as the state probabilities of (0, 1) and (1, 0), respectively.

$$U\left(\frac{1-P\left(\bar{e}_{i\to j},e_{j\to i}\right)}{3}\times(1-0.8),\frac{1-P\left(\bar{e}_{i\to j},e_{j\to i}\right)}{3}\times(1+0.8)\right) \tag{1}$$

Finally, the different state probabilities of each edge in the extended samples will be used as input data for the training, validation and testing process of the neural network, while the Monte Carlo simulation presented in (Wang et al., 2024) is used to compute the network connectivity reliability corresponding to the state probabilities of the edges or edge pairs obtained as the output dataset of the neural network. Eventually, a total of 1000 datasets were extended for subsequent studies.

4 FCNN HYPERPARAMETER SELECTION BASED ON 5-FOLD CROSS-VALIDATION

Fully-connected neural network is a multi-layer perceptual machine structure, which is designed based on the signal propagation process between animal nerves in biology (as shown in Figure 3), i.e., neuron receives the signal and distributes and passes it to each neuron in the next layer, which receives the input signals and calculates to generate the output command signals. And finally, aggregating neurons aggregate information for signal transmission, recognition, judgement, classification and control.

.

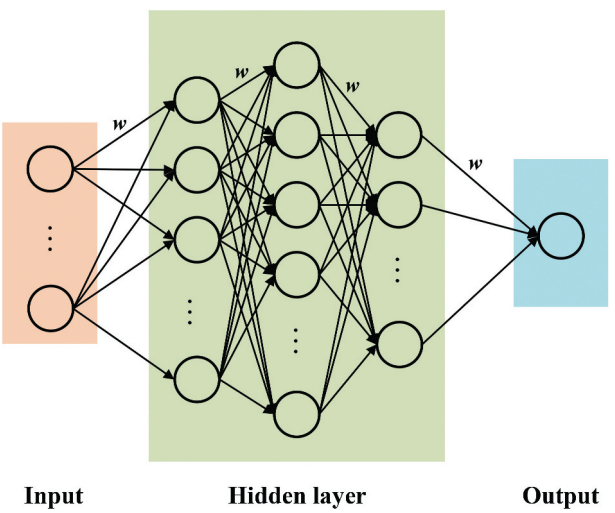

Figure 3. Schematic diagram of a FCNN model.

However, there are multiple neural network models that can be applied to the same problem. Parameters related to the model framework, such as the number of hidden layers, the number of neurons per layer, etc., are "hyperparameters" of the model. In order to determine the specific performance of the selected models on the target problem, a cross-validation

approach can be used for evaluation. Therefore, 5-fold cross-validation is used in this paper, i.e., the training set is divided into 5 parts, 4 groups are selected as the training set each time, and the remaining 1 group is used as the validation set. After completing the training and validation process and calculating the loss function value 5 times, the error of the 5 validation sets is averaged as the performance of the model.

Therefore. In this section, based on the existing research experience, several FCNN models are constructed, and the different parameters involved in the models are the number of hidden layers (NoHL), the number of neurons in the hidden layer (NoN), the value of droupout layer, the adjustment method of learning rate (lr_scheduler). And finally, the mean square error (MSE) of each model is calculated by applying 5-fold cross validation, which is used for evaluating the performance of the models in calculating the probability of all-terminal connectivity of the bridged network, and the final comparison results are shown in Table 1.

Table 1. Comparison of MSE of different models.

NO.	NoHL	NoN	lr_scheduler	Droupout	Min(MSE)
1-8	1	32	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00014270
9-16	1	64	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00015169
17-24	1	128	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00018043
25-32	1	256	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00023664
33-40	2	256×128	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00036135
41-48	2	128×64	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00015240
49-56	2	64×32	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00021468
57-64	3	256×128×64	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00023207
64-72	3	128×64×32	StepLR/CosineAnnealingLR	0/0.3/0.6/0.9	0.00019780

As shown in Table 1, when the number of hidden layers is 1, the number of neurons in the layer is 32, the Droupout value is 0.6, and the cosine annealing is selected for the learning rate decay method, the model has the lowest MSE value, and finally it is also selected as the final FCNN for solving the required connected probability of the directed urban bridge network. Meanwhile, the selected neural network model was validated on the test set and the results are shown in Figure 4 as shown below. The results show that the selected FCNN model is able to complete the problem of solving the connectivity reliability of the directed urban bridge network very well, and also the algorithm is computationally efficient.

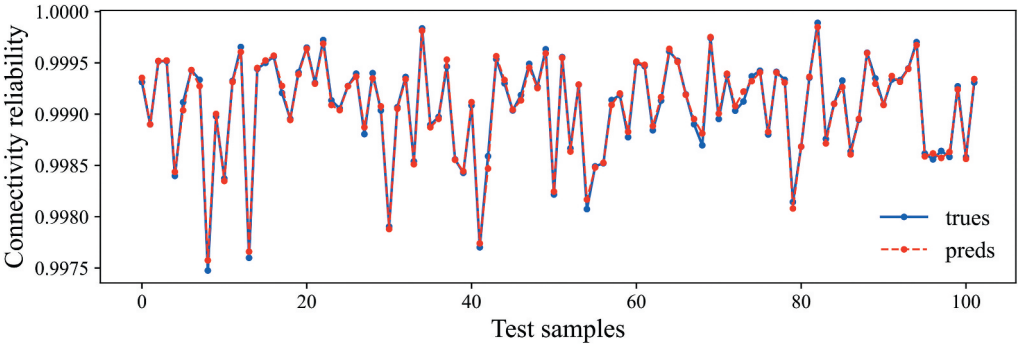

Figure 4. Comparison of computational results of selected FCNNs on the test set.

5 CONCLUSION

This paper implements a fast and efficient solution for the all-terminal connectivity reliability of bridge networks based on the fully connected neural network with fewer neurons and layers. Firstly, for the same network benchmark model, based on real bridge inspection data,

the state probability samples of each edge in the network are extracted and expended by data fitting to fulfill the data volume requirements. Secondly, several FCNN models containing one, two and three layers with different neurons are proposed and compared by the 5-fold cross-validation to obtain the hyperparameters. Finally, it has be proved that simple single-layer network models with 32 neurons can efficiently solved the all-terminal connectivity reliability problem of large-scale bridge network. The method accuracy and efficiency are by the real directed urban bridge network containing 216 directed edges with 63 nodes.

Forward UQ based on Bayes-informed mixture distribution

Y. Zhang, Y. Dong & R.W. Feng
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT: Assessing the reliability of bridge infrastructures under seismic excitations is of great importance for structural design and maintenance, where uncertainties of both structural parameters and loadings should be taken into account. However, evaluating the first-passage failure probability of bridge infrastructures subjected to stochastic seismic excitations efficiently and accurately is still a challenging problem. The first-passage failure probability can be estimated through the extreme value distribution (EVD) of structural responses. To obtain the underlying EVD of interest, three candidate distributions are first selected, i.e., two inverse Gaussian distributions and one Gamma distribution. The mixture of these three distributions is conducted from Bayesian perspective. First, a moment-generating function-guided likelihood function is employed for Bayesian inference, where the benchmark data can be obtained by Latin partially stratified sampling technique and the predicted data can be yielded by the mixture distribution. Then, the transitional Markov chain Monte Carlo can be employed to detect the posterior distributions of unknown parameters of the mixture distribution. Finally, the calibrated mixture distribution can be an explicit representation of the underlying unknown EVD and the failure probability can be easily obtained.

1 INTRODUCTION

Uncertainties are inevitable and widely exist in engineering problems, which significantly affect the structural response of interest. It is of paramount importance to assess the safety of engineering structures under the influence of these uncertainties. Various approaches have been developed for structural reliability analysis in the past few decades. Monte Carlo simulation (MCS) is regarded as a benchmark method for estimating the failure probability (Rubinstein & Kroese, 2016). MCS requires too many calls to the original physical model so many advanced simulation-based methods are further developed such as the importance sampling (Dai et al., 2016, Engelund & Rackwitz, 1993, Melchers, 1989), directional sampling (Ditlevsen et al., 1988) and subset sampling (Au & Beck, 2001). To circumvent substantial number of calls to the physical model, surrogate model or metamodel is widely employed to replace the original time-consuming physical model. Commonly used surrogate models include the polynomial chaos expansion (Blatman & Sudret, 2011, Zhang & Xu, 2021), Kriging model (Echard et al., 2011, Echard et al., 2013), artificial neural networks (Chojaczyk et al., 2015) and so on.

However, these methods may not efficient for the reliability analysis of stochastic dynamic systems. Commonly, a stochastic system, for instance, a random structure subjected to the fully non-stationary stochastic seismic excitation, is a high-dimensional system. The number of involved random variables is usually larger than 1000. The high-dimensional problem is caused by the process of simulating stochastic excitation. For example, the spectral representation method can be adopted to simulate the stochastic seismic excitation (Rice, 1944, Shinozuka, 1971). To ensure the accuracy of the simulation, thousands of random phases are required to simulate the random process, which leads to a high-dimensional forward

DOI: 10.1201/9781003483755-224

uncertainty propagation problem. Since the extreme structural response is of interest, so many researchers focus on the extreme value distribution of the response and the first passage failure probability (Chen & Li, 2007). Various moments-based approaches have been developed to fit the underlying EVD. To address the high-dimensional problem, sampling-based methods are adopted to assess the statistical moments of the structural response. Then, the possible distribution models such as the maximum entropy method and the mixture distribution are employed to reconstruct the unknown EVD by fitting a series estimated statistical moments (Dang et al., 2021, Dang & Xu, 2020).

Nevertheless, it is still hard to determine which kind of distribution model should be adopted and the estimation of the hyper parameters of the distribution model should be further investigated. In this paper, Bayesian inference is employed to infer the unknown hyper parameters of a mixture distribution. Two inverse Gaussian distributions and a Gamma distribution are utilized to fit the unknown EVD. The values of moment generating function related to the unknown EVD are employed for the likelihood function of Bayes' theorem. The transitional Markov chain Monte Carlo is utilized to determine the posterior distribution of hyper parameters of the mixture distribution. To validate the accuracy and efficiency of the proposed method, a continuous concrete highway bridge subjected to the fully non-stationary stochastic seismic excitation is investigated.

2 EXTREME VALUE DISTRIBUTION OF THE STOCHASTIC DYNAMIC SYSTEMS

2.1 *Structures subjected to the seismic excitation*

The governing equation of motion of a dynamic system subjected to the seismic excitation can be given as:

$$\mathbf{M}(\mathbf{X}_S)\ddot{U} + \mathbf{C}(\mathbf{X}_S)\dot{U} + F(U, \mathbf{X}_S) = -\mathbf{M}(\mathbf{X}_S)A(\mathbf{X}_L, t) \tag{1}$$

where **M, C** are mass and damping matrix, respectively. **F** represents the vector of restoring force. U, $\dot{U}$and U represent the displacement, velocity and acceleration, respectively. $\mathbf{X}_S$ and $\mathbf{X}_L$ denote n_1 random structural parameters and n_2 random variables related to the loading, i.e., the stochastic seismic excitation. Denote $\mathbf{X} = (\mathbf{X}_S, \mathbf{X}_L)$ as a n-dimensional random variable and $n = n_1 + n_2$.

The time-series structural response of interest can be denoted as:

$$Z(t) = H(\mathbf{X}, t) \tag{2}$$

where H is a physical operator. Then, the maximum absolute structural response can be given as:

$$Y = \max|Z(t)| = G(\mathbf{X}) \tag{3}$$

where Y is the extreme value of the time-series structural response over a time duration [0, T].

Given a threshold b, the so-called first passage failure probability can be calculated as (Chen & Li, 2007):

$$P_f = \Pr(Y > b) \tag{4}$$

It can be readily obtained from the extreme value distribution of the structural response:

$$P_f = \int_b^{+\infty} f_Y(y)\mathrm{d}y \tag{5}$$

Hence, it is of great importance to obtain the extreme value distribution of a stochastic dynamic system. However, it is usually hard to estimate the extreme value distribution since the stochastic dynamic system is commonly a high-dimensional system (n>1000). Assessing

the statistical moments of responses or estimating the failure probability is tricky for such a high-dimensional dynamic system.

2.2 *Spectral representation method for generating the stochastic seismic excitation*

Spectral representation method is employed to simulating the fully non-stationary stochastic seismic excitation in this paper. The ground acceleration can be expressed by (Shinozuka & Deodatis, 1991):

$$A(t) = \sqrt{2}\sum_{k=0}^{n_2-1}\sqrt{2S_A(w_k,t)\Delta w}[w_k t + \phi_k] \tag{6}$$

where $S_A(w, t)$ is the double-sided evolutionary power spectral density function:

$$S_A(w,t) = |M(w,t)|^2 S(w) \tag{7}$$

in which $M(w, t)$is a modulating function defined by:

$$M(w,t) = \exp\left(-\eta_0 \frac{wt}{w_a t_a}\right)\cdot\left[\frac{t}{c}\exp\left(1-\frac{t}{c}\right)\right]^2 \tag{8}$$

and $S(w)$ is the one-sided power spectral density function given by:

$$S(w) = \frac{w_g^4 + 4\zeta_g^2 w_g^2 w^2}{\left(w^2 - w_g^2\right)^2 + 4\zeta_g^2 w_g^2 w^2}\cdot\frac{w^4}{\left(w^2 - w_f^2\right)^2 + 4\zeta_f^2 w_f^2 w^2} S_0 \tag{9}$$

The relevant parameters can be specified as follows: Δt = 0.02s, T=30s, η_0 = 0.15,w_a = 5π rad/s, t_a = 30s, c=9, $w_g = w_a$, $w_f = 0.1w_g$, $\zeta_g = \zeta_f = 0.60$ and S_0 = 48.9332cm^2/s. To ensure the accuracy of the simulated stochastic seismic excitation, the number of random phases ϕ_k is set to n_2 = 1001 and $w_k = k\Delta w$, k = 0, 1, .., n_2 − 1. Hence, the stochastic dynamic system is a high-dimensional system with more than 1000 random variables.

3 BAYES-INFORMED MIXTURE DISTRIBUTION FOR EVD ESTIMATION

3.1 *Bayesian inference for unknown parameters estimation*

Bayesian inference is a core step for model calibration in Bayesian model updating. Let $\theta = (\theta_1, \theta_2, \ldots, \theta_m)$ be the unknown parameters that characterize a model $\mathcal{M}$. The basic idea of model calibration is to determine the posterior distributions over unknown parameters according to the observed data $\mathcal{D}$ and prior knowledge of θ. The posterior PDF of θ based on the Bayes' theorem gives:

$$p(\theta|\mathcal{D},\mathcal{M}) \propto p(\mathcal{D}|\theta,\mathcal{M})p(\theta|\mathcal{M}) \tag{10}$$

where $p(\mathcal{D}|\theta,\mathcal{M})$ is the likelihood function and $p(\theta|\mathcal{M})$ is the prior distribution of unknown parameters θ. To find the posterior distribution of θ, simulation-based method such as the transitional Markov chain Monte Carlo can be employed.

3.2 *Mixture distribution for constructing the unknown EVD*

The shape of the EVD of the response of a stochastic system is hard to be understood since the involved high-dimensional problem and complex dynamics. Moments-based method provides a possible way to deal with the high-dimensional uncertainty propagation problem, that is, the unknown distribution can be reconstructed by a distribution model via fitting a series

of estimated statistical moments. Herein, we assume a mixture distribution $\bar{\mathcal{M}}$ includes different kinds of candidate distributions:

$$\bar{\mathcal{M}} = \omega_1 C_1 + \omega_2 C_2 + \cdots + \omega_p C_p \tag{11}$$

where ω_i ($0 \le \omega_i \le 1$) is the i-th weight of the i-th candidate distribution C_i. Denote the unknown parameters of these candidate distributions as $\theta = (\theta_1, \theta_2, \ldots, \theta_m)$. According to the Bayes' theorem, the posterior distribution of θ can be expressed as (Zhang et al., 2023):

$$p(\theta, \omega | \mathcal{D}, \bar{\mathcal{M}}) \propto p(\mathcal{D} | \theta, \omega, \bar{\mathcal{M}}) p(\theta, \omega | \bar{\mathcal{M}}) \tag{12}$$

Hence, the distribution parameters and the weights are required to be calibrated through the observed dataset $\mathcal{D}$ and prior knowledge. Once the hyper parameters can be determined, the mixture distribution can be an explicit expression of the underlying EVD.

3.3 *Moment generating function-based likelihood function*

To determine the posterior distribution of hyper parameters of the mixture distribution, the observed data is of great importance. Different from the conventional engineering model calibration, the observed data is usually the structural response of interest. Herein, the hyper parameters of a distribution model are of interest so the probability densities should be the "response" instead. However, it is hard to use the probability densities directly from a limited number of samples. In this paper, the moment generating function is employed to construct the likelihood function since it can be regarded as an alternative specification of the probability density function. The moment generating function can be defined by (Dang et al., 2021):

$$M_Y(\alpha) = E[\exp(\alpha Y)] = \int_0^{+\infty} \exp(\alpha Y) f_Y(y) \mathrm{d}y, \ \alpha \in R \tag{13}$$

Thus, the problem of finding the PDF of Y is equivalent to finding the MGF. Equation (13) can be reformulated as:

$$M_Y(\alpha) = \int_{\Omega_{\mathbf{X}}} \exp(\alpha G(\mathbf{X})) f_{\mathbf{X}}(\mathbf{x}) \mathrm{d}\mathbf{x} \tag{14}$$

Nevertheless, it is hard to calculate the integral shown in Equation (14) directly. Simulation-based methods can be employed to estimate the integral. Herein, a so-called Latinized partially stratified sampling (LPSS) technique is adopted, which can be expressed by:

$$d^{(i)} = \frac{1}{N} \sum_{j=1}^{N} \exp\left(\alpha_i G\left(\mathbf{x}^{(j)}\right)\right), \ i = 1, 2, \ldots, N_d \tag{15}$$

where d is the value of moment generating function and N is the number of LPSS samples used for calculating d and N_d is the number of observed data used for Bayesian inference. These N_d samples can be seen as the "true" value of the moment generating function of Y, and the predicted one can be calculated by the mixture distribution:

$$\hat{d}^{(i)} = \omega_1 F_1(\alpha_i) + \omega_2 F_2(\alpha_i) + \cdots + \omega_p F_p(\alpha_i) \tag{16}$$

where F_i, $i = 1, 2, \ldots, p$ denotes the moment generating function of i-th candidate distribution.

Once we get the "true" and "predicted" data of the moment generating function, the MGF-based likelihood function can be taken as a Gaussian distribution with zero mean and equal variance σ^2 (Zhang et al., 2023):

$$p(\mathcal{D} | \theta, \omega, \bar{\mathcal{M}}) = \frac{1}{(2\pi\sigma^2)^{\frac{N_d}{2}}} \exp\left[-\frac{1}{2\sigma^2} \sum_{i=1}^{N_d} \left(d^{(i)} - \hat{d}^{(i)} \right) \right] \tag{17}$$

3.4 *Candidate distributions for the mixture distribution*

We can hardly know the shape of the extreme value distribution of the structural response so we select several candidate distributions to fit the underlying EVD. Two inverse Gaussian distributions and one Gamma distribution serve as the candidate distributions.

The first one is the inverse Gaussian (IG) distribution, which is a two-parameter distribution with support on (0, + ∞):

$$f(x;\theta_1,\theta_2)=\sqrt{\frac{\theta_2}{2\pi x^3}}\exp\left(-\frac{\theta_2(x-\theta_1)^2}{2\theta_1^2 x}\right) \tag{18}$$

and the MGF of inverse Gaussian distribution gives:

$$M_x(\alpha,\theta_1,\theta_2)=\exp\left[\frac{\theta_2}{\theta_1}\left(1-\sqrt{1-\frac{2\theta_1^2\alpha}{\theta_2}}\right)\right] \tag{19}$$

The first-four central moments of IG are listed as follows:

$$\mu_{\mathrm{IG}}=\theta_1,\sigma_{\mathrm{IG}}=\sqrt{\frac{\theta_1^3}{\theta_2}},\gamma_{\mathrm{IG}}=3\sqrt{\frac{\theta_1}{\theta_2}},\kappa_{\mathrm{IG}}=15\frac{\theta_1}{\theta_2} \tag{20}$$

Note that the second distribution is also an IG distribution characterized by parameters θ_3 and θ_4.

The third one is a Gamma distribution, which is also a two-parameter distribution on (0, + ∞). Its PDF is given by:

$$f(x;\theta_5,\theta_6)=\frac{1}{\Gamma(\theta_5)\theta_6^{\theta_5}}x^{\theta_5-1}\exp\left(-\frac{x}{\theta_6}\right) \tag{21}$$

The MGF of Gamma distribution gives:

$$M_x(\alpha,\theta_5,\theta_6)=(1-\theta_6\alpha)^{-\theta_5} \tag{22}$$

and the first-four central moments are:

$$\mu_{\mathrm{Gamma}}=\theta_5\theta_6,\sigma_{\mathrm{Gamma}}=\sqrt{\theta_5\theta_6^2},\gamma_{\mathrm{Gamma}}=\frac{2}{\sqrt{\theta_5}},\kappa_{\mathrm{Gamma}}=\frac{6}{\theta_5} \tag{23}$$

Based on Equation (16), the MGF of the mixture distribution can be calculated by:

$$\begin{aligned}\hat{d}^{(i)}&=\omega_1 M_x(\alpha_i,\varphi_1,\varphi_2)+\omega_2 M_x(\alpha_i,\varphi_3,\varphi_4)+\omega_3 M_x(\alpha_i,\varphi_5,\varphi_6)\\&=\omega_1\exp\left[\frac{\theta_2}{\theta_1}\left(1-\sqrt{1-\frac{2\theta_1^2\alpha}{\theta_2}}\right)\right]+\omega_2\exp\left[\frac{\theta_4}{\theta_3}\left(1-\sqrt{1-\frac{2\theta_3^2\alpha_i}{\theta_4}}\right)\right]+\omega_3(1-\theta_6\alpha_i)^{-\theta_5}\end{aligned} \tag{24}$$

To implement the TMCMC, the prior distributions of all hyper parameters follow uniform distributions, the parameters of uniform distributions are given by (Zhang et al., 2023):

$$\Omega_\theta=[0.9\theta_0,\ 1.1\theta_0],\ \Omega_\omega=[0,\ 1]^p \tag{25}$$

Herein p=3 and θ_0 can be calculated by the following:

$$\theta_1^0=\mu_{\mathrm{IG}},\ \theta_2^0=\frac{\mu_{\mathrm{IG}}^3}{\sigma_{\mathrm{IG}}^2},\theta_3^0=\mu_{\mathrm{IG}},\ \theta_4^0=\frac{\mu_{\mathrm{IG}}^3}{\sigma_{\mathrm{IG}}^2},\theta_5^0=\frac{\mu_{\mathrm{Gamma}}^2}{\sigma_{\mathrm{Gamma}}^2},\ \theta_6^0=\frac{\sigma_{\mathrm{Gamma}}^2}{\mu_{\mathrm{Gamma}}} \tag{26}$$

and α_i, i = 1, 2, .., $N_d$are $N_d$uniformly distributed discrete points over the interval [− 2, 0]. In this paper, N_d = 100 is adopted.

Once the posterior distribution over hyper parameters θ is determined, then the mixture distribution for representing the unknown EVD can be calculated through the mean values of θ:

$$\hat{f}_Y(y) = \omega_1 \sqrt{\frac{\theta_2}{2\pi y^3}} \exp\left(-\frac{\theta_2 (y-\theta_1)^2}{2\theta_1^2 y}\right) + \omega_2 \sqrt{\frac{\varphi_4}{2\pi y^3}} \exp\left(-\frac{\varphi_4 (y-\varphi_3)^2}{2\varphi_3^2 y}\right) + \omega_3 \frac{1}{\Gamma(\varphi_5)\varphi_6^{\varphi_5}} y^{\varphi_5 - 1} \exp\left(-\frac{y}{\varphi_6}\right) \tag{27}$$

4 NUMERICAL EXAMPLE

In this section, a practical continuous concrete highway bridge is investigated and the detail of the finite element model and involved random variables can refer to references (Wang et al., 2022, Zhang et al., 2023). The maximum pier drift ratio is of interest:

$$y = \max_{1 \le i \le 7} \left(\Delta_i^{\text{Pier top}} / h \right) \tag{28}$$

where $\Delta_i^{\text{Pier top}}$ denotes the top displacement of the i-th pier and h represents the height of the pier. There are 8 random structural parameters and 1001 random phases for simulating the stochastic seismic excitation are involved so it is a 1009-dimensional dynamic system.

To estimate the underlying EVD of the pier drift ratio, 900 samples generated by LPSS are employed to calculate the reference data of the moment generating function and 100 reference points are obtained by Equation (15). The predicted data is calculated by Equation (24). Once we get the reference and predicted data, the likelihood function expressed by Equation (17) can be constructed and then the posterior distribution of hyper parameters θ can be found by TMCMC. Table 1 shows the mean value and the coefficient of variation (CoV) of the hyper parameters. It can be seen that the CoV of all hyper parameters are very small, which indicates the margin posterior distributions of hyper parameters are highly peaked. Therefore, we can use the mean value of these hyper parameters to estimate the EVD.

Table 1. Mean and CoV of the hyper parameters.

Hyper parameter	ω_1	ω_2	ω_3	θ_1	θ_2	θ_3	θ_4	θ_5	θ_6
Mean	0.182	0.483	0.336	1.024	12.073	1.035	11.816	13.531	0.078
CoV	0.013	0.013	0.015	0.001	0.002	0.0003	0.003	0.003	0.004

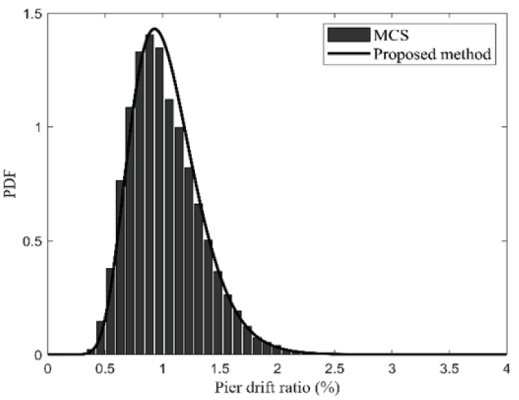

Figure 1. PDF of the maximum pier drift ratio.

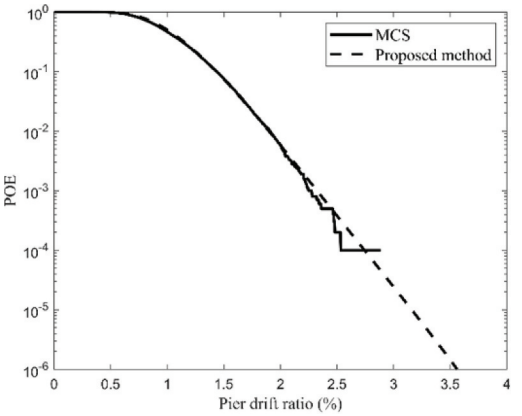

Figure 2. POE of the maximum pier drift ratio.

The PDF of the maximum pier drift ratio is depicted in Figure 1. The reference result is provided by 10^4 MCS and it can be found that the PDF by the proposed method is in accordance with the benchmark one. Note that the proposed method only consumes 900 calls to the finite element model. The probability of exceedance (POE) is of interest and POE in logarithmic scale is shown in Figure 2. The reliability analysis focuses more on the tail distribution. It can be found that the proposed method can also achieve fairly good accuracy in the tail of the distribution.

5 CONCLUSION

In this paper, a Bayes-informed mixture distribution is developed for fitting the extreme distribution of a high-dimensional stochastic system. The mixture distribution is composed of two inverse Gaussian distributions and a Gamma distribution. The unknown hyper parameters of the mixture distribution are calibrated by the Bayesian inference with the transitional Markov chain Monte Carlo. The reference data for likelihood function is the values of moment generating function, which can be calculated by a sampling method called LPSS. The predicted data can be easily calculated by the mixed moment generating function. Therefore, the hyper parameters can be easily found by Bayesian inference and the calibrated mixture distribution can be an explicit representation of the unknown EVD. A continuous concrete highway bridge subjected to the stochastic seismic excitation is investigated in this paper and the results show that the proposed method can ensure the efficiency and accuracy of the EVD estimation for a high-dimensional stochastic dynamic system.

ABSTRACT: Currently, a comprehensive management system for transportation networks incorporating bridges and pavements is still missing. In this study, both bridges and asphalt pavements are considered critical components in the connection among all nodes in the network. A framework for estimating the probabilistic life-cycle connectivity of transportation networks is proposed. Specifically, flexural and shear failure modes are considered for bridges. Four failure modes, including international roughness index, rut depth, alligator cracking, and transverse cracking, are considered for asphalt pavement using a neural network-based deep learning (DL) model trained by the Long-Term Pavement Performance (LTPP) database. In the case study of an existing transportation network located in Chester, Pennsylvania, the matrix-based system reliability method is applied to investigate the life-cycle connectivity and component importance based on the obtained reliability associated with individual bridges and asphalt pavement segments. The results show that both bridges and asphalt pavements make a significant contribution to the probability of network connectivity.

1 INTRODUCTION

A transportation network comprises several components such as roads, bridges, tunnels, and roadside features. Traditionally, bridges have been emphasized as critical components, often considered bottlenecks (Akgül & Frangopol 2003; Shinozuka et al. 2006). However, it is essential to recognize that pavements are equally significant components which are integral to a transportation network, by providing mobility and access to a diverse range of users. Illustratively, the United States has over 617,000 bridges, of which approximately 46,154 (i.e., 7.5%) are classified as structurally deficient, and more than 6 million kilometers of roadways, of which about 40% of pavements are in poor condition (ASCE, 2021). Therefore, prioritizing strategic investments in enhancing and preserving the conditions of bridges and pavements is imperative to prevent severe traffic disruptions, hindered post-event activities, and negative impacts on the economy, environment, and society (Akiyama et al. 2020; Frangopol 2011; Frangopol & Bocchini 2012).

In the assessment and prediction of the network performance, the associated indicators should take into account network connectivity since transportation networks involve multiple origin-destination pairs and numerous paths (Xin et al. 2023b; Firdaus et al. 2023). Meanwhile, the connectivity of each Origin-Destination (O-D) pair is inherently probabilistic due to uncertainties involved in the modeling of loading and structural resistance, characteristics of

DOI: 10.1201/9781003483755-225

hazards, and variations in operating conditions (Sabatino et al., 2016). To the best knowledge of the authors, however, there is currently no comprehensive probabilistic management system for transportation networks that integrates both bridges and pavements.

This paper introduces a framework for estimating the connectivity probability of transportation networks by incorporating both bridges and asphalt pavements through neural network-based deep learning models. The methodology involves evaluating the time-variant performance of bridges and asphalt pavements, considering the time-variant probability that captures the propagation of uncertainties throughout their life-cycle. The reliability analysis of individual bridges takes into account flexural and shear failure modes, considering corrosion hazards and traffic loads. For asphalt pavements, a bidirectional LSTM neural network (referred to as the BiLSTM model) is trained using data from the Long-Term Pavement Program (LTPP) (LTPP 2023). Subsequently, the pavement reliability is calculated, incorporating uncertainties related to pavement structure and property variables, climatic and traffic conditions, BiLSTM model predictions, and performance indicator measurements.

In a case study utilizing the matrix-based system reliability (MSR) method proposed by (Kang et al., 2008), the time-variant transportation network performance indicator is explored. This includes the probability of disconnection and importance measures for bridges, pavements, and bridge-pavement groups within an existing transportation network comprising seven bridges and five asphalt pavement segments located in Chester County, Pennsylvania.

2 PROCEDURE OF ESTIMATING THE CONNECTIVITY PROBABILITY OF TRANSPORTATION NETWORKS

2.1 *General procedure*

Figure 1 presents the flowchart of connectivity probability estimation of transportation networks containing bridges and asphalt pavements, which consists of three main parts:

(1) Bridge system analysis, including the reliability calculation considering two failure modes of flexural and shear.
(2) Pavement system analysis, including deep learning model training and the associated reliability analysis based on four performance indicators.
(3) Transportation network analysis, including connectivity reliability and importance measure using matrix-based system reliability method.

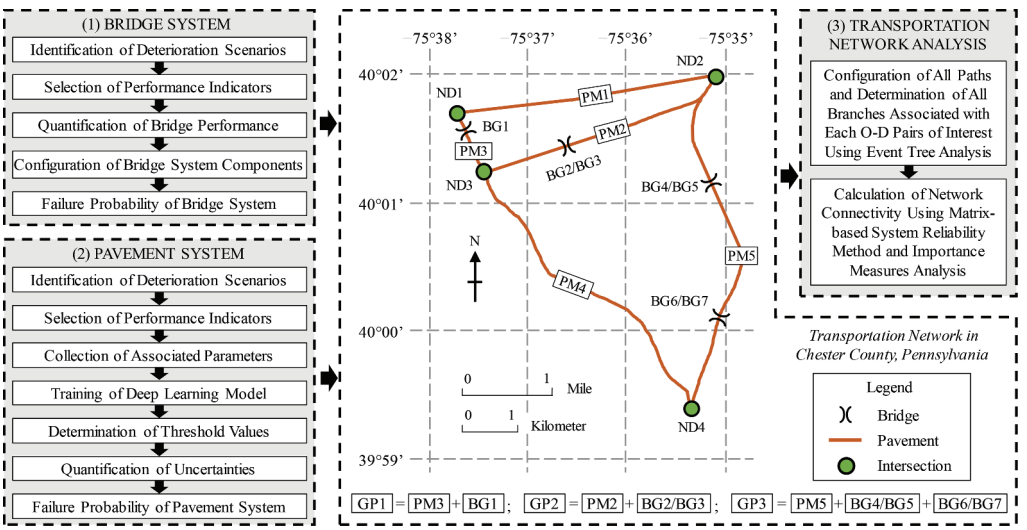

Figure 1. Flowchart of connectivity analysis of transportation network integrating bridges and pavements.

2.2 *Bridge analysis*

The failure analysis of a bridge involves treating it as a series-parallel system, where adjacent girders form parallel subsystems. Correlations between the load effects and resistances among different bridges are considered to assess the system reliability of an individual bridge. The number of girders in each parallel subsystem is related to factors such as the maximum live load effects generated by parallel trucks and the redundancy of the bridge superstructure (Han & Frangopol 2022). The equivalent component method, introduced by Gollwitzer & Rackwitz (1983), is employed to transform the series-parallel system model into a series system model. Then, the reliability of this series system is computed using the sequential compounding method, as detailed by Gong & Zhou (2017). More detailed information and reliability results are provided by Xin et al. (2023b).

2.3 *Pavement analysis*

Deep learning excels at handling large datasets by automatically and efficiently learning the complex relationship between inputs and outputs (Chollet 2021). In this study, a deep learning model comprising BiLSTM neural networks (Greff et al. 2016) was developed and trained to predict the performance indicators of asphalt pavement based on relevant operating conditions, including climate, traffic, and pavement property and structure (Xin et al. 2021a, b, 2022). The data used for model training are obtained from the LTPP database (Standard Data Release 37) published in August 2023 (FHWA 2017; LTPP 2023). The asphalt pavement is conceptualized as a series system encompassing four failure modes associated with indicators of (a) International Roughness Index (*IRI*), (b) rut depth (D_{rut}), (c) alligator cracking (C_{gator}), and (d) transverse cracking (C_{trans}) (AASHTO 2020; Ang and Tang 2007). The system failure probability is then calculated through the Monte Carlo simulation method. Additional details and reliability results are available in Xin et al. (2023a, 2023b).

2.4 *Transportation network analysis*

In this study, the matrix-based system reliability (MSR) method, introduced by Kang et al. (2008), is employed. This method is selected for its capability to efficiently estimate the probabilities of complex system events through simple matrix calculations. The network failure probability can be calculated as:

$$P(E_{DIS}) = \sum_{c:e_c \subseteq E_{DIS}} p_c = \mathbf{c}^{\mathrm{T}}\mathbf{p}, c = 1,\ 2,\ \ldots,\ Nev \tag{1}$$

where E_{DIS} = disconnection of the network; e_c (c = 1, …, *Nev*) = basic mutually exclusive and collectively exhaustive events with the total number of *Nev*; p_c = probability of e_c; $\mathbf{c}$ = event vector that represents the network event whose cth element is 1 if e_c belongs to the network event and 0 otherwise; and $\mathbf{p}$ = probability vector that contains p_c's. Details associated with the construction of event $\mathbf{c}$ and probability $\mathbf{p}$ vectors are provided by Kang et al. (2008).

Importance measures (IM) are helpful when identifying the bridges or pavements whose preservation and maintenance would most efficiently enhance the network connectivity (Song & Der Kiureghian 2005). Based on the Equation (1), the $\mathrm{IM_c}$ associated with component c can be calculated as:

$$\mathrm{IM}_c = P(E_c E_{sys} = E'_{sys})/P(E_{sys}) = (\mathbf{c}'^{\mathrm{T}}\mathbf{p})/(\mathbf{c}^{\mathrm{T}}\mathbf{p}) \tag{2}$$

$$\mathrm{NIM}_c = \mathrm{IM}_c / \sum_{c=1}^{Nc} \mathrm{IM}_c \tag{3}$$

where E_c = c component event; $\mathbf{c}'$ = event vector of E'_{sys}; NIM_c = normalized IM_c; and *Nc* = number of components in the network.

3 CASE STUDY

3.1 *Network connectivity*

The transportation network selected in the case study is shown in Figure 1, which contains seven bridges (i.e., BG1, BG2, BG3, BG4, BG5, BG6, and BG7), five pavement segments (i.e., PM1, PM2, PM3, PM4, and PM5) and four nodes (i.e., ND1, ND2, ND3, and ND4). Note that BG1 and PM 3 in series are lumped as group GP1; BG2, BG3, and PM2 in series are lumped as group GP2; BG4, BG5, BG6, BG7, and PM5 in series are lumped as GP3. Based on the reliability results obtained in sections 2.2 and 2.3, the network connectivity results considering at least 3 and 5 O-D pairs disconnected are shown in Figure 2 using Equations (1). Specifically, Figure 2(a) shows that the probability of disconnection associated with at least 3 and 5 O-D pairs increases with time. Figure 2(b) shows the comparison of the probability of disconnection associated with at least 3 O-D pairs using a base-10 logarithmic scale among three cases: C, C1, and C2. C is the base case in which both bridges and pavements are considered. PM1 and PM4 are assumed to never fail in the case of C1, and C2 only considers the bridges as vulnerable elements. It can be seen that the probability of disconnection is underestimated if the pavements are not taken into account in the connectivity analysis of a transportation network.

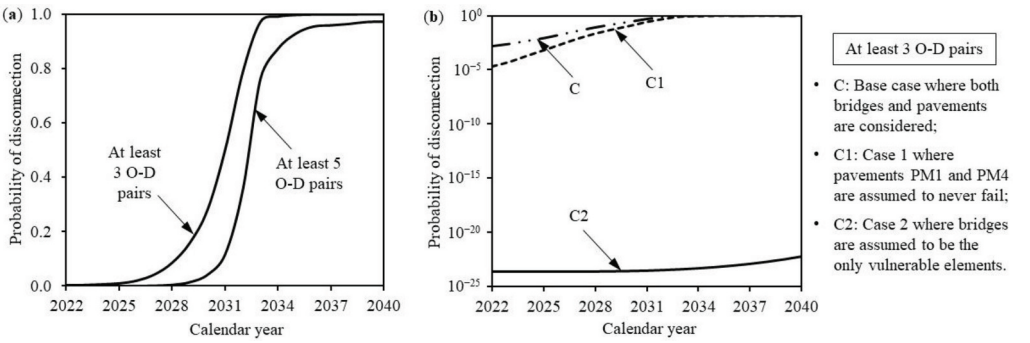

Figure 2. Probability of disconnection associated with (a) at least 3 and 5 O-D pairs and (b) a base-10 logarithmic scale for at least three O-D pairs that are disconnected under cases of C, C1, and C2.

3.2 *Importance measures of components*

Figure 3 shows the normalized importance measures of five components (i.e., PM1, PM4, GP1, GP2, and GP3) in the transportation network associated with the disconnection of at least 3 and 5 O-D pairs using Equations (2) and (3). For example, the importance associated with GP2 increases significantly from 2022 to 2031 for the case of at least 3 O-D pairs disconnected. Therefore, GP2 is expected to effectively reduce the network failure probability if retrofitted during this period.

4 CONCLUSIONS

A probabilistic framework for connectivity analysis of transportation networks incorporating bridges and asphalt pavements is proposed in this paper. The network connectivity and component importance measures associated with different O-D pairs are calculated using the matrix-based system reliability method.

Both bridges and asphalt pavements significantly influence the connectivity of the transportation network. Consequently, a traditional bridge network analysis that neglects pavement performance leads to an overestimation of network connectivity.

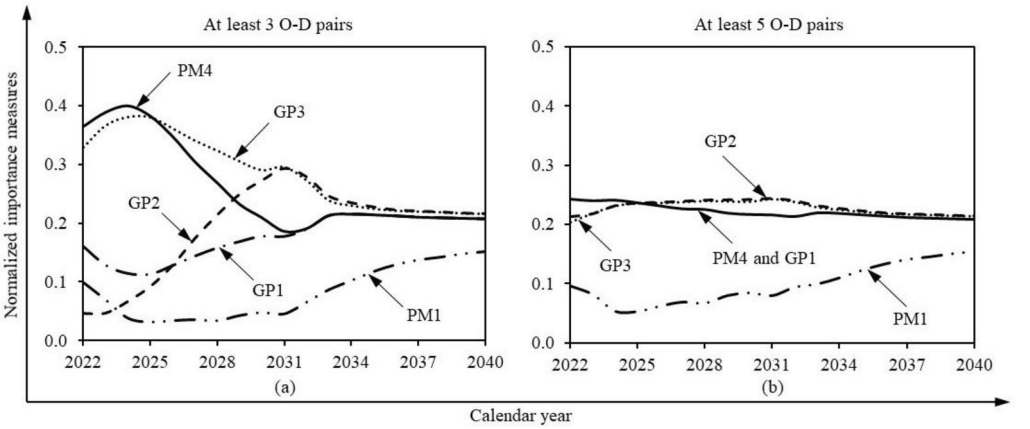

Figure 3. Normalized importance measures of bridge, pavements, and bridge-pavement groups associated with the disconnection of (a) at least 3 O-D pairs and (b) at least 5 O-D pairs.

Asphalt pavement generally offers a shorter service life of 15 to 25 years compared to bridges. Therefore, it is crucial to extend the service life of asphalt pavement to maintain network connectivity and to cope with postevent interventions.

U-Net model-based XCT images segmentation for steel corrosion in concrete

M. Zhang & W. Wang
College of Civil and Transportation Engineering, Shenzhen University, Shenzhen, China

ABSTRACT: The corrosion of reinforcing bar in concrete has been regarded as one of the most predominant factors for the degradation of reinforced concrete (RC) bridges. The accurate predictions of corrosion damages are the basis for the safety assessment of in-service bridges and the enhancement of new bridge designs. X-ray computed tomography (XCT) has been widely utilized to understand the corrosion process inside the concrete, offering three-dimensional (3D) visualization of steel corrosion. This study uses U-net model to detect various phases of steel corrosion evolution in concrete. The developed U-net model has shown superior segmentation performance on XCT images relating to steel corrosion in concrete. This significant advancement has automated the process of visualizing and 3D reconstructing the steel corrosion process inside the concrete. It enables the quantification of the volumetric expansion ratio of corrosion products.

1 INTRODUCTION

Steel corrosion in concrete is a major durability and maintenance issue for reinforced concrete (RC) bridges, particularly those in marine environments where chloride ion penetration often triggers steel corrosion. The depassivation of rebar occurs directly when a threshold concentration of chloride ions is reached in the concrete near the rebar surface, which finally results in the initiation of the rebar corrosion (de Vera et al. 2017, Alonso et al. 2000). The corrosion products occupy more volume than the original steel, causing volumetric expansion that induces tensile stresses in the surrounding concrete, resulting in cracks and eventually spalling of the concrete cover. This exposes the rebar to aggressive agents, further accelerating corrosion. Proper maintenance planning is crucial for ensuring the safety of aging RC bridges, especially under seismic loads (Akiyama et al. 2017, 2020, Zucca et al. 2023). Accurate corrosion damage prediction is fundamental for the safety assessment of in-service RC bridges and for improving designs of new bridges. In modeling corrosion-induced concrete cracking, the volumetric expansion coefficient is vital. Commonly, it is assumed constant, however, this approach overlooks the complexity of the corrosion process and can lead to imprecise predictions, as the actual boundaries of corrosion products do not always align with those estimated using a constant expansion coefficient (Du et al. 2014, Chen & Leung 2015).

X-ray computed tomography (XCT) offers a non-destructive method to acquire data for prediction models of corrosion damage. XCT has proven effective in providing detailed insights into steel corrosion in concrete, aiding in the durability assessment of RC structures (Jiang et al. 2023, Robuschi et al. 2021, Sun et al. 2021). XCT enables the capture of interior concrete images, showing the progression of reinforcement corrosion and allowing for the creation of three-dimensional images. However, processing XCT images for accurate analysis and reliable results is labor-intensive, often referred to as image segmentation. Multi Otsu's method, a popular segmentation approach, uses thresholding to segment phases in XCT images based on varying gray values (Bernachy-Barbe et al. 2020). However, this method

DOI: 10.1201/9781003483755-226

faces challenges in distinguishing features like cracks and pores in steel corrosion cases, and it struggles with image quality issues, impacting accuracy and performance. Moreover, its applicability is limited to specific specimen parameters.

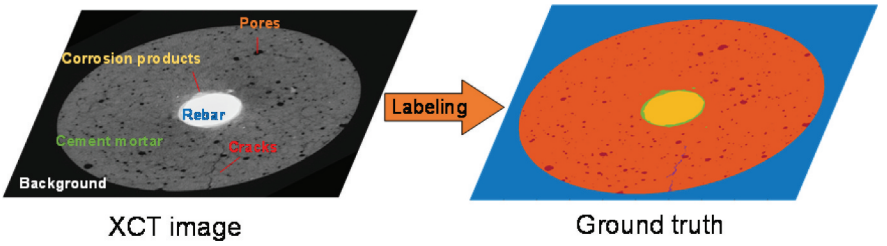

Figure 1. XCT image for steel corrosion in concrete and image labeling.

To address these limitations, deep learning (DL) algorithms should be proposed for automating the analysis of steel corrosion in concrete.

This study evaluates the effectiveness of a DL model (i.e., U-Net model) in processing XCT images of steel corrosion in concrete. The model, trained on XCT images showing rebar corrosion, is used to quantify the evolution of corrosion products, enhancing understanding of the corrosion process.

2 U-NET MODEL

2.1 *X-ray computed tomography and image labeling*

The obtained XCT images (image resolution: 2048 × 2048) for the specimen display a multi-phase system that includes cement mortar, pores, steel, corrosion products, and corrosion-induced cracking, as illustrated in Figure 1. To automatically distinguish the different phases in the XCT images, initial labeling is essential. This process is to establish the training dataset for the U-Net model. For the labeling process, it is necessary to associate each pixel in the XCT image with its respective phase. Before labeling, the XCT image has a pixel value ranging from 0 to 255. Once labeled, these values are transformed to a scale of 0 to 5, representing the different phases: cement mortar, pores, steel, corrosion products, and corrosion-induced cracking. It is worth noting that distinguishing between the pores and cracks is a challenging task, requiring increased manual effort. Considering the computational load and the learning ability of the U-Net model, the XCT images with 256 × 256 image resolution are obtained by automatic clipping, serving as the final inputting image.

2.2 *U-Net model structure*

Figure 2 displays the structure of the U-Net model, where its encoder path includes four contraction blocks. Each block typically contains two 3×3 convolutional layers, followed by a rectified linear unit (ReLU) activation function. The convolutional layers extract features from an image, beginning with padding to maintain consistent matrix size. A 3×3 sliding window moves across the image, using a stride of one, with convolutional operations applied via a kernel matrix to produce a numerical output. The output of this process is a feature map, a new matrix that serves as a condensed representation of the original image's specific features. Additionally, the ReLU activation function is used due to its efficiency in model training and reducing computational demands compared to other activation functions.

In the U-Net model, each convolutional block is followed by a 2×2 max-pooling layer, reducing the image's spatial dimensions by half and increasing its depth. With each

max-pooling layer, the number of feature channels typically doubles, allowing for the capture of more complex features. A 2×2 filter with a stride of 2 extracts the maximum value from each region of a 4×4 input sample, reducing the dimensions of a 256×256 matrix to 128×128.

The deepest layer serves as a bridge between contracting and expanding paths, consisting of two 3×3 convolutions with ReLU activations. The expansion path then employs up-convolution layers, doubling the image size at each step while halving the depth. Each up-convolution output is combined with a corresponding feature map from the contracting path, integrating high-resolution features. This process involves two 3×3 convolutions with ReLU activations after each up-sampling, culminating in an image size of 256×256×64. The final layer, a 1×1 convolution, maps feature vectors to the desired number of classes, producing a segmentation map with the same spatial dimensions as the original input.

2.3 *Model training*

A total of 2032 images were used during the training process of the U-Net model. These images are obtained from different positions of the specimens. The network was trained by using Adam optimizer with a learning rate of 1e-3 and batch size of 32. The training process was implemented in MATLAB on a system with 64GB RAM, a 13th gen Intel Core i9-13900KF CPU, and an NVIDIA GeForce RTX 4070Ti GPU. The training comprised a total of 1770 iterations. The entire training duration was about 1 hour. Figure 3(a) shows the loss function for both training and validation sets. The U-Net model's loss function stabilized after approximately 500 iterations. Figure 3(b) displays a rise in accuracy for both training and validation, which eventually plateau.

2.4 *Model evaluation*

Segmentation tasks aim to distinguish and label different objects, effectively classifying separate entities. Evaluating the effectiveness of a trained segmentation model necessitates testing its performance on a designated dataset. Key metrics for semantic segmentation models include precision, recall, F1 score, and intersection over union (IoU).

The precision metric quantifies the accuracy of positive predictions, calculated as the ratio of true positives (TP, correctly identified object pixels) to the sum of true and false positives (FP, incorrectly identified object pixels). It is defined as:

$$\text{Precision} = \text{TP}/(\text{TP} + \text{FP}) \tag{1}$$

Recall measures the proportion of actual positives that are correctly identified. It is defined as:

$$\text{Recall} = \text{TP}/(\text{TP} + \text{FN}) \tag{2}$$

where FN is false negatives (i.e. pixels of the object of interest that the model failed to identify).

The F1 score offers a balanced mean between precision and recall, accounting for both false positives and false negatives. It is the harmonic mean of precision and recall:

$$\text{F1 score} = (2 \times \text{Recall} \times \text{Precision})/(\text{Recall} + \text{Precision}) \tag{3}$$

IoU assesses the overlap between the model's predicted segmentation and the actual ground truth. It is the ratio of the intersecting area to the union area of the predicted and true segments, with scores ranging from 0 (no overlap) to 1 (perfect overlap):

$$\text{IoU} = \text{TP}/(\text{TP} + \text{FP} + \text{FN}) \tag{4}$$

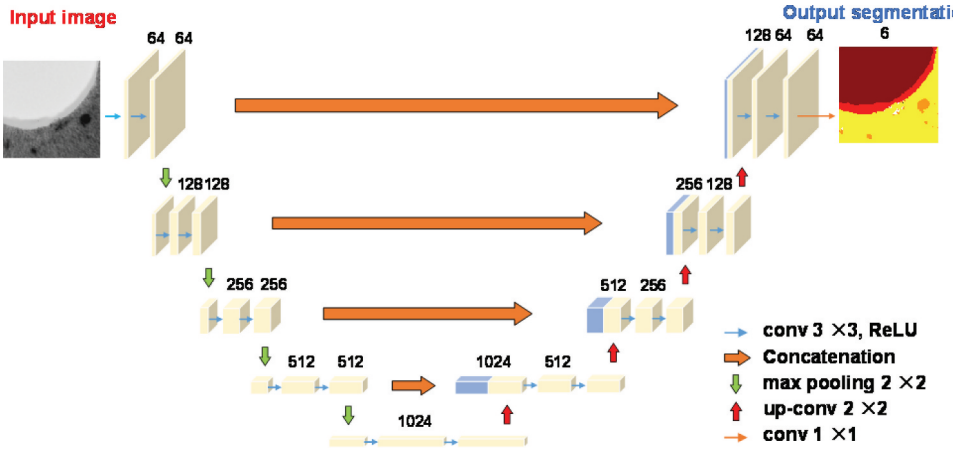

Figure 2. U-Net model structures.

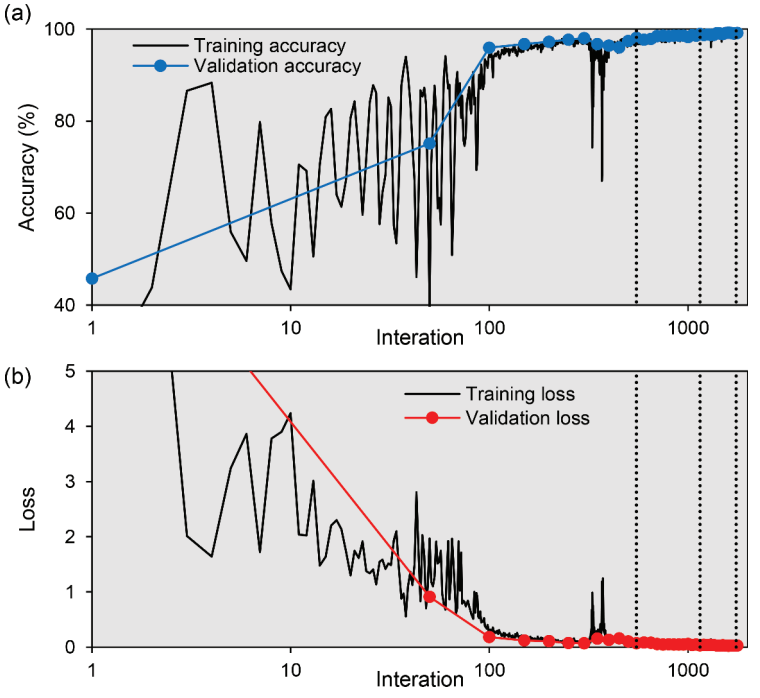

Figure 3. The accuracy and loss curves for U-Net model.

3 RESULTS AND DISCUSSIONS

3.1 *Performance on testing data*

Table 1 provides the results of the U-Net model's segmentation efficacy across various phases, showing its exceptional proficiency in categorizing both steel and cement mortar, as evidenced by F1 scores and IoU metrics. Table 1 also presents a comparative assessment with another deep learning model, specifically the Fully Convolutional Network (FCN) (Long et al. 2015), both trained on the same dataset. In contrast, the FCN model fails in accurately segmenting

cracks. Meanwhile, FCN demonstrates low results in F1 score (0.502) and IoU (0.339) for recognizing the corrosion products. These are lower than the results of the U-Net model. The U-Net model exhibits its lowest performance in crack segmentation, achieving an F1 score of 0.733 and an IoU of 0.603, possibly due to the structural similarity and segmentation complexities inherent in XCT images. Specifically, thin and irregular characteristics of the cracks, often merging with pores, pose significant segmentation challenges. Meanwhile, manual labeling of cracks in XCT images further complicates this task. Nevertheless, an IoU of 0.603 for crack segmentation is considered effective. Overall, the U-Net model demonstrates a robust mean IoU of 0.821 and an average F1 score of 0.891 on the test dataset, outperforming the FCN model in segmenting steel corrosion in concrete XCT images into different categories.

Table 1. Averages of the evaluation indicators for DL models.

Deep learning model	U-Net model		FCN model	
Category	F1 score	IoU	F1 score	IoU
Steel	0.995	0.990	0.960	0.924
Corrosion products	0.869	0.753	0.502	0.339
Pore	0.872	0.785	0.728	0.599
Cement mortar	0.986	0.976	0.979	0.962
Cracks	0.733	0.603	-	-

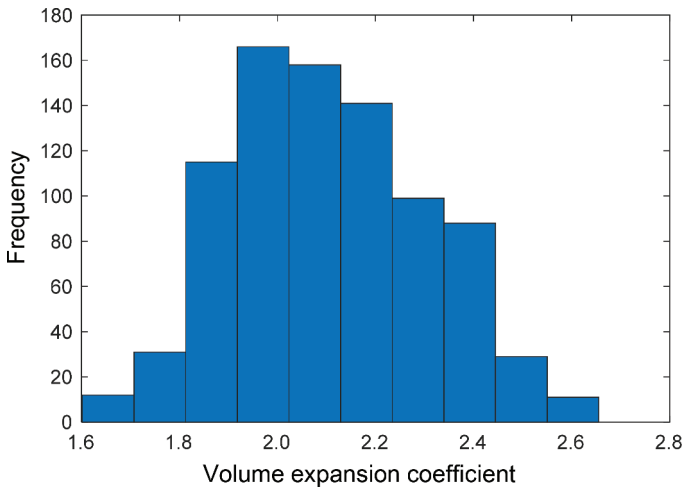

Figure 4. Histogram of volume expansion coefficient.

3.2 *Volume expansion coefficient of corrosion products*

The volume of corrosion products significantly impacts concrete damage, directly influencing structural performance modeling and service life prediction. Corrosion product accumulation causes volumetric expansions in steel, which is a critical factor in concrete cracking models, especially for predicting the time of surface cracking due to rebar corrosion. Previous research (Zhao et al. 2011) indicates a range of 2–4 for the expansion coefficient of corrosion products, with many models adopting a value of 3 (Zhang et al. 2021, Fang et al. 2023). However, there is a lack of consensus on the exact value, and most studies assume this coefficient to be constant, ignoring its variability and uncertainty.

Based on the acquired XCT images for the corroded RC specimens, the volume expansion coefficient can be derived for each cross-section by using U-Net model to recognize the

volumes of corrosion products and corroded rebar. As illustrated in Figure 4, the histogram of the volume expansion coefficient is obtained by a specimen corroded by the galvanostatic method. The average steel weight loss is 6.43%. The expansion ratio ranges from 1.60 to 2.66, with a mean of 2.11 and a standard deviation of 0.2. The result suggests that the expansion coefficient varies spatially. For more accurate modeling of corrosion-induced concrete cover cracking, it is recommended to consider the expansion coefficient as a probabilistic variable, accounting for its inherent uncertainty. The current practice of using a constant value oversimplifies the issue by not accounting for its spatial variations. Therefore, adopting mathematical frameworks that incorporate uncertainties, including the representation of ignorance, is crucial for more realistic and comprehensive modeling.

4 CONCLUSIONS

Over the last decade, XCT technology has significantly progressed in the field of durability analysis of RC bridges. Despite this, there has not been an introduction of a semantic segmentation model specifically for distinguishing different phases in XCT images associated with steel corrosion in concrete. This study presents a deep learning-based image segmentation model designed to automatically detect various phases of steel corrosion in concrete. The results show the efficacy and efficiency of the proposed U-Net model.

The volume expansion coefficient for corrosion products demonstrates spatial variability and uncertainty. Considering this coefficient as a constant in calculations might result in imprecise predictions. Due to the complexity of the corrosion process, it is crucial to treat this parameter as a random variable in a probabilistic approach to analyze concrete damage caused by corrosion. To accurately characterize this random variable, its statistical properties, including probability distribution, mean, and standard deviation, need to be established through additional experimental research.

Fragility interval predictions in non-seismically designed bridges

H. Neduri & J. Ghosh
Indian Institute of Technology Bombay, Mumbai, Maharashtra, India

ABSTRACT: Seismic fragility analysis of highway bridges remains a widely used technique to assess the structural damage and subsequent disruption to transportation networks during a seismic event. While modern bridge seismic design codes prescribe enhanced seismic detailing of bridges located in moderate to high seismic zones, a significant percentage of bridges are still non-seismically designed in these regions. Moreover, in addition to ground motion characteristics, a multitude of potentially uncertain parameters affect the seismic fragility of bridges leading to considerable variations in fragility predictions. In such cases, although a statistical screening may help in pruning down a large set of initial variables, the uncertainty in the significant parameters needs to be propagated through low-discrepancy sampling techniques to effectively cover the sample space. The samples can then be utilized for nonlinear fine element simulations of bridge models to determine the confidence intervals of seismic fragility predictions.

1 INTRODUCTION

In regions characterized by moderate seismicity, earthquakes, albeit infrequent, can have devastating consequences. The misconception of the risk associated with infrequent seismic events resulted in the delayed onset of seismic detailing requirements in these regions. The Central and Southeastern United States (CSUS), which is taken as the test bed for this study, is regarded as a typical moderate seismic zone. It is only after 1990, highway bridge design is shifted from conventional non-seismic design to seismic design practices in this region (Chen & Duan, 2014; Ramanathan et al., 2012). This delayed adoption of seismic design practices resulted in significant percentage of bridges being non-seismic till date (Nielson, 2005).

Although, considerable amount of literature exists on the seismic vulnerability assessment of these non-seismically designed highway bridges in CSUS (Choi et al., 2004; Nielson & DesRoches, 2007; Padgett et al., 2007), little research prevails on the seismic vulnerability assessment through parameterized fragility functions that may also aid in visualizing the fragility confidence intervals. Unlike "classical" fragility curves, these parameterized fragility functions are conditioned not only on the ground motion intensity measure (IM) but also on other critical bridge modelling parameters (Ghosh et al., 2013; Rokneddin et al., 2015). This helps in reassessing the bridge condition using instrumentation data (obtained from structural health monitoring techniques) without running time-intensive nonlinear time history analysis.

This study adopts a novel gradient-based ensemble learning metamodel for approximating the relationships between critical bridge modelling parameters (obtained from sensitivity analysis) and bridge component responses. Unlike traditional regression techniques, this method employs multiple weak learners (regression models) and follows the *wisdom of the crowd* principle, i.e. the collective opinion of the group is considered more accurate than any of the individual weak learner. Seismic vulnerability assessment of the bridge is realized by using the metamodel predictions of different bridge components and the parameterized fragility functions. This study takes it a step further and uses these parameterized fragility functions for uncertainty quantification of critical bridge modelling parameters using statistical linearization technique.

DOI: 10.1201/9781003483755-227

The paper begins by providing a brief overview of the ensemble-learning based metamodel framework adopted for seismic fragility assessment. The following sections elaborate the methodology involved in the development of parameterized fragility functions and the input parameter uncertainty quantification. Next, the application of the proposed framework is demonstrated using a case study example of Multi-Span Simply Supported (MSSS) steel girder bridge, describing each step of the framework in great detail. Finally, the paper concludes by highlighting the key insights from ensemble learning framework and parameterized fragility functions.

2 METAMODEL FRAMEWORK

This study adopts gradient-based least square boosting (GLS Boost) regression technique to fit the data. The data consists of predictor variables $\{IM, x_1,\ldots,x_n\}$, where IM is the intensity measure of ground motion and $x_1,\ldots,x_n$ are other bridge modelling parameters, and the predicted seismic response (y) of the selected bridge components.

GLS Boost is an ensemble learning technique that involves sequentially combining weak learners, like decision trees, into a strong predictive learner while minimizing a least square loss function. This works in a stage-wise approach by adding a new weak learner to correct the residuals (errors) made by the preceding learners. The ensemble technique also scales each weak learner appropriately to minimize overfitting and determine a generalized strong learner with low variance (Friedman, 2002; Hastie et al., 2009).

The goal of the GLS Boost algorithm is to find a function $F^*(IM, \mathbf{x})$ which maps $(IM, \mathbf{x})$ to y, such that the expected value of some specified loss function $\Psi[y, F(IM, \mathbf{x})]=0.5[y-F(IM, \mathbf{x})]^2$ is minimized.

$$F^*(IM,\mathbf{x}) = \underset{F(IM,\mathbf{x})}{\arg\min}\, E_{y,(IM,\mathbf{x})}\Psi(y, F(IM,\mathbf{x})) \tag{1}$$

Boosting approximates $F^*(IM, \mathbf{x})$ by an additive expansion of each weak learner as

$$F(IM,\mathbf{x}) = \sum_{m=0}^{M} \gamma_m h[(IM,\mathbf{x});\alpha_m] \tag{2}$$

where, $h[(IM, \mathbf{x});\alpha_m]$ is the base learner (typically a decision tree) with $\boldsymbol{\alpha}=\{\alpha_1,\alpha_2,\ldots,\alpha_M\}$as parameters and $\boldsymbol{\gamma}=\{\gamma_1,\gamma_2,\ldots,\gamma_M\}$as expansion coefficients. These coefficients are determined using gradient boosting algorithm (Friedman, 1999) to fit the training data in a forward stage-wise manner, that is coefficients for m^{th} weak learner $\{\alpha_m,\gamma_m\}$ are obtained only after $\{\alpha_i,\gamma_i\}$ $(i=0,1,\ldots,m-1)$ are trained. Furthermore, each successive weak learner tries to correct the residuals from all the previous learners thus promoting better fit to the data.

$$F_m(IM,\mathbf{x}) = F_{m-1}(IM,\mathbf{x}) + \nu\cdot\gamma_m h[(IM,\mathbf{x});\alpha_m] \tag{3}$$

Each successive weak learner is added to the existing prediction $F_{m-1}(IM, \mathbf{x})$ with a shrinkage parameter $0<\nu\leq 1$ as shown in Equation (3), that controls the learning rate of the algorithm. Small values of learning rate (<0.1) have been found to prevent overfitting and improve the generalization of the model (Friedman, 1999).

3 PARAMETERIZED FRAGILITY FUNCTIONS

Traditional fragility curves are conditioned only on the uncertainty of ground motion intensity measure (IM), even though it is well understood that a single parameter cannot adequately determine seismic response of a structure. To consider any number of uncertainty parameters in predicting the probability of structural damage, a popular statistical learning technique called logistic regression is proposed (Koutsourelakis, 2010). This technique is widely used where predictions of binary outcomes such as success or failure are sought. In bridge fragility, the binary outcomes imply whether or not a particular limits state is exceeded.

The logistic regression model is based on the logistic function, also known as the sigmoid function, which transforms the linear equation into a probability between 0 and 1. The logistic regression model estimates the coefficients of the predictor variables that maximize the likelihood of the observed data. LOGistic unIT is the natural log of the odds of binary (Bernoulli) function. It maps the probability values to real number range (0, ∞).

If d is the output binary variable (1 for failure and 0 for success) and $\boldsymbol{x_i}$ are the predictor variables then the probability p that $d=1$ for given $\boldsymbol{x_i}$ is represented by the logistic regression as:

$$logit(p) = \ln\left(\frac{p}{1-p}\right) = \sum_i \theta_i x_i \tag{4}$$

where θ_i are the regression coefficients for predictor variables $\boldsymbol{x_i}$ and the above equation can be manipulated to get the probability p as:

$$p = P[d = 1|x, \theta] = \frac{e^{\sum_i \theta_i x_i}}{1 + e^{\sum_i \theta_i x_i}} \tag{5}$$

The implementation of logistic regression to generate parameterized fragility functions is discussed in the subsequent sections.

4 STATISTICAL LINEARISATION

To quantify the modelling parameter uncertainty at the fragility level, a popular technique called statistical linearization is proposed (Lei & Schilling, 1994). This technique works by fitting a multi-linear regression model between the input parameters and the output response by minimizing the mean square error and then the variance of output is quantified using the obtained regression coefficients and intrinsic input parameter variances.

Consider n-independent input parameters ($U_1, U_2, U_3, \ldots, U_n$) with their respective means and variances as ($\mu_1, \mu_2, \mu_3, \ldots, \mu_n$) and ($\sigma_1^2, \sigma_2^2, \ldots, \sigma_n^2$) and V is the model output with mean μ_V. Model output and input parameters can be related using statistical linearization as follows:

$$V \approx \mu_V + \omega_1(U_1 - \mu_1) + \ldots + \omega_n(U_n - \mu_n) \tag{6}$$

The coefficients ω_i's and μ_V are obtained from multi-linear regression analysis. The variance of model output can be obtained from variance of input parameters as follows:

$$\sigma_Y^2 = \sum_{i=1}^{n} \omega_i^2 \sigma_i^2 \tag{7}$$

The variance in the output can be quantified from each input parameter separately by varying only single input variable and keeping others at their means using Equation (7).

Statistical linearization is well suited for seismic fragility development since input parameters in fragility are largely uncorrelated and relation between output response and input parameters is mostly linear (in the log-transformed space). However, it may not be well suited if the system is significantly nonlinear in nature. In those cases, nonlinear regression techniques should be considered (Lei & Schilling, 1994).

5 CASE STUDY EXAMPLE

Even with the advent of seismic design provisions emphasizing on the seismic design of bridges in moderate seismic zones like CSUS, significant number of bridges that stand till date are non-seismically designed. Among these non-seismically designed bridges, multi-span simply supported (MSSS) and multi-span continuous (MSC) type bridges of concrete and steel

girders are most prevalent. This study considers non-seismically designed MSSS steel girder bridge as a case study. A brief description of the selected bridge is given below.

The 3-D finite-element models for the case study bridge are developed using OpenSees (McKenna et al., 2000). The bridge superstructure consists of a set of steel girders with thin concrete deck on top. The super structure is modelled as elastic beam-column elements since it is expected to remain elastic during seismic loading. Since the superstructure is simply supported, gaps are present between adjacent decks as well as between abutment walls and decks, which significantly impacts the severity of pounding during a seismic event. Fixed and expansion type steel bearings are prevalently used for this bridge type. Past studies show that these types of bearings are a vulnerable component of this bridge type (Choi, 2002). The columns and bent beams (pier caps) are modelled using nonlinear displacement-based beam-column elements with fiber-defined cross-sections. This helps to model outer cover concrete, core concrete and steel reinforcement discretely with their appropriate stress-strain curves. One potential difference between column and bent beams models is the type of cross section, while the columns have circular cross section, the bent beams involve rectangular sections. The behavior of the bearings and abutments is modelled using nonlinear springs in both longitudinal and transverse directions. The pile foundations are modelled using simplified linear translational and rotational springs at the bases of the columns. Impact elements are modelled between the abutments and deck as well as between adjacent decks to capture the pounding effect during earthquake shaking using a contact element as proposed by (Muthukumar, 2003).

The bridge modelling discussed above is essential for performing nonlinear time history analysis with given ground motion data to predict seismic responses which can further be used for fragility predictions. While ground motion is a critical factor influencing these responses, other bridge parameters can also introduce significant uncertainties.

Table 1. Modelling parameters considered for preliminary screening (Nielson, 2005).

Sl. No.	Parameter name	Variable (units)	Lower bound (−)	Upper bound (+)
1	Concrete strength	f_{ck} (MPa)	26.70	40.80
2	Steel strength	f_y (MPa)	403.50	524.30
3	Steel fixed bearing coefficient of friction (multiplicative factor)	COF_fxd	0.5	1.5
4	Steel expansion bearing coefficient of friction (multiplicative factor)	COF_exp	0.5	1.5
5	Abutment passive stiffness	K_{abp} (kN/mm/m)	12.36	27.94
6	Abutment active stiffness	K_{aba} (kN/mm/pile)	3.85	10.15
7	Foundation translational stiffness	K_{ft} (kN/mm)	30.80	81.20
8	Foundation rotational stiffness	K_{fr} (kN/mm)	96.42	253.92
9	Mass	M (%)	91.00	109.00
10	Damping ratio	ζ	0.025	0.066
11	Initial stiffness of steel fixed bearing (multiplicative factor)	$mult_{brg}$	0.85	1.20
12	Adjacent decks gap (hinge gap)	h_{gap} (mm)	18	33
13	Abutment—deck gap	a_{gap} (cm)	3.09	4.52
14	Earthquake direction	Dir (deg)	0	360

Preliminary screening can be carried out on these bridge parameters to identify significant parameters that impact the bridge responses under seismic loading. Nielson (2005) considered these modelling parameters as shown in Table 1, for preliminary screening and performed an analysis of variance (ANOVA) to screen the important parameters. These parameters are shown in Table 2 and subsequently adopted for uncertainty propagation in this study.

Table 2. Significant parameters after preliminary screening (Nielson, 2005).

Significant parameters	
Initial stiffness of steel fixed bearing (multiplicative factor)	Steel fixed bearing coefficient of friction (multiplicative factor)
Abutment passive stiffness	Abutment active stiffness
Foundation translational stiffness	Foundation rotational stiffness
Mass	Damping ratio
Steel strength	Adjacent decks gap (hinge gap)
Abutment—deck gap	Earthquake direction

5.1 *Metamodel fitting*

For metamodel fitting, the above parameters have to be sampled randomly to have uniform representation of the whole sample space, in order to achieve this Sobol sequence (Hellekalek et al., 1998), one of the low-discrepancy quasi-random sequences, is adopted. As a general thumb rule, number of design runs (a design run is a nonlinear time history analysis of a particular bridge model in *OpenSees*) have to be $10\times n$ or higher for a good model fit, where n is the number of input parameters. In this study, 5 replicates of 96 available ground motions are made and are randomly paired with 480 random samples of all critical bridge parameters through Sobol sampling. This results in 480 design runs which far exceeds the general thumb rule by a considerable margin. The ground motion data used in this study is obtained from (Wen & Wu, 2001), (Rix & Fernandez, 2004) who developed synthetic ground motion based on the site-specific characteristics relevant to moderate seismic zone of CSUS.

As discussed earlier, this study adopts GLS Boost metamodel to fit analysis results, with significant parameters and peak ground acceleration (PGA) as predictor variables and the bridge component responses as outputs. While gradient boosting algorithms are generally better than other ensemble learning techniques like random forests (Caruana & Niculescu-Mizil, 2006),(Caruana et al., 2008) it should be tuned appropriately to the available data using several hyperparameters like number of trees, minimum leaf size (number of observations per each node) and learning rate. Along with tuning these hyperparameters, a 10-fold cross-validation is adopted to minimize the chance of overfitting. GLS Boost has been fitted to the 480 design runs and the goodness of fit is assessed across all the component responses using different measures like Root Mean Squared Error (RMSE) and Adjusted Rsquared (Adj. R^2). The adjusted R^2 for all the component responses is above 0.75 along with very low RMSE values, implying that GLS Boost fits the data adequately, as shown in Figure 1.

5.2 *Seismic fragility assessment*

The capacity limit states for MSSS steel bridge are adopted from (Nielson & DesRoches, 2007). By making use of the earlier discussed logistic regression technique, parameterized fragility curves can be developed for each bridge component (Ghosh et al., 2013) and the failure surface can be represented as Equation (8).

$$PF_{k|PGA,x_1.....x_n} = \frac{e^{\theta_{k,0}+\theta_{k,PGA}\ln(PGA)+\sum\theta_{k,i}x_i}}{1+e^{\theta_{k,0}+\theta_{k,PGA}\ln(PGA)+\sum\theta_{k,i}x_i}} \tag{8}$$

where $\theta_{k,0}$, $\theta_{k,PGA}$ and $\theta_{k,i}$ are the logistic regression coefficients for kth bridge component. The component level logistic regression can be upgraded to a system level logistic regression resulting in the development of parameterized fragility for the whole bridge. The logistic regression coefficients of the bridge system level at all damage states are shown in Table 3. It is important to note that although some parameter coefficients are very small compared to others, the values of each parameter coefficients are relative to the units of each parameter, hence parameters with typically large values may have small coefficients but still significantly affect the fragility function.

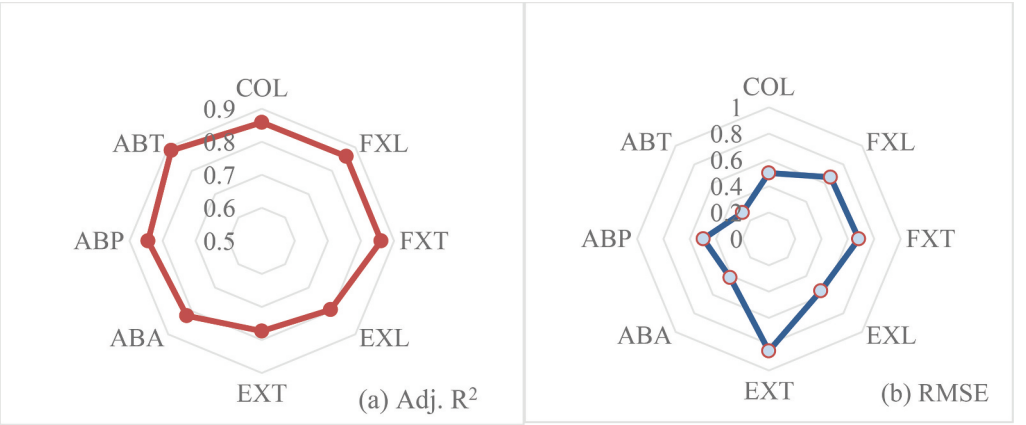

Figure 1. Radial charts showing adjusted R2 and RMSE estimates for column (COL), fixed bearing (FXL, FXT), expansion bearing (EXL, EXT) and abutment responses (ABA, ABP, ABT) for GLS Boost algorithm.

Table 3. Logistic regression coefficients at the bridge system level for all damage states.

Parameter	Slight	Moderate	Extensive	Complete
constant	7.775	5.682	2.945	1.155
$ln(PGA)$	3.799	4.327	4.051	3.752

Dir	0.000	-0.001	0.000	0.000

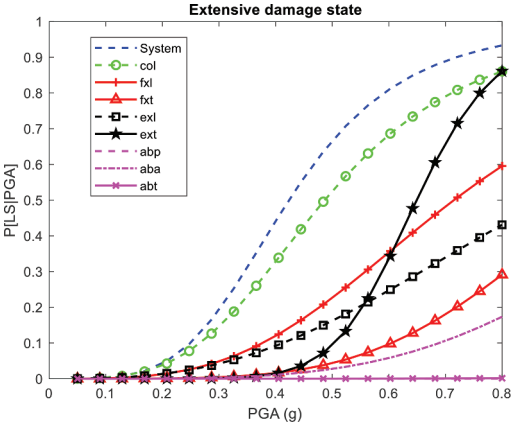

Figure 2. "Classical" component and system level fragility curves obtained after reducing the parameterized fragility functions for extensive limit state.

From these parameterized functions, "classical" fragility curve conditioned only on intensity measure (IM) can also be obtained by keeping all the other modelling parameters at their median values as shown in Figure 2. These multi-dimensional fragility curves are superior to the "classical" fragility curves, primarily in their capacity for uncertainty quantification of modelling parameters.

5.3 *Parameter uncertainty quantification*

Although parameter uncertainty propagation is very well integrated in seismic fragility assessment of bridges, quantification of that uncertainty at the system fragility level remains underexplored. This uncertainty quantification can be achieved by integrating parameterized fragility functions with statistical linearization technique. Statistical linearization can be applied to Equation (4), leveraging logistic regression coefficients previously evaluated using the survival-failure binary vector of the bridge at the system level. Through the utilization of the intrinsic variance of each modelling parameter's uncertainty, in conjunction with Equation (7), the variance in failure probability of the bridge can be computed. This makes it feasible to develop 95% confidence bounds around the mean fragility curve as illustrated in

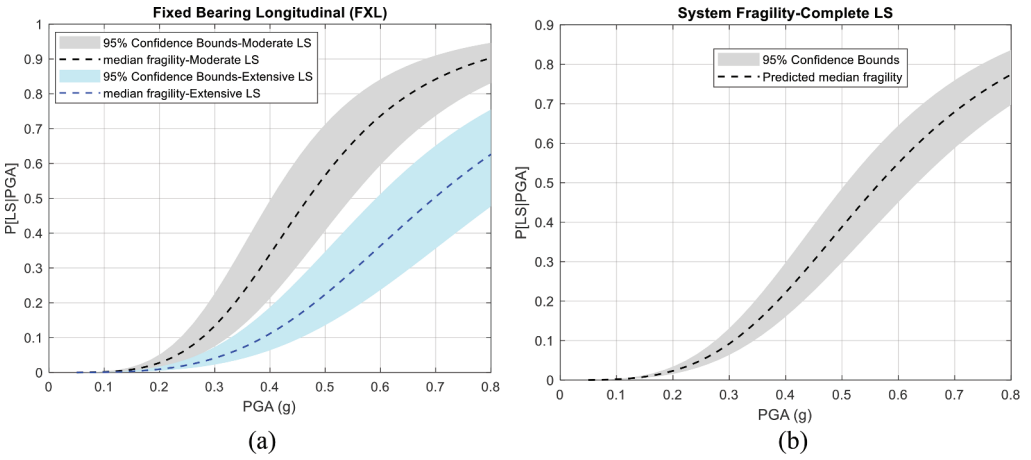

Figure 3. Predicted median fragility with 95% confidence bounds due to parameter uncertainty for: (a) fixed bearings in longitudinal direction (FXL) at moderate and extensive limit states; and (b) overall bridge system at complete limit state.

6 CONCLUSIONS

This study proposes a framework for parameter uncertainty quantification at the system fragility level which is little explored in the past literature. The framework involves a three-fold approach, using a novel ensemble learning-based metamodel for capturing the relationship between modelling parameters and component demand responses. Next, the development of parameterized fragility functions using logistic regression and the trained metamodel which are conditioned on all the critical bridge modelling parameters along with ground motion intensity measure (IM). Finally, statistical linearization technique is adopted for parameter uncertainty quantification and the 95% confidence bounds are developed to visualize this quantification using "classical" fragility curve at all damage states. This study recommends quantification of critical parameter uncertainty for reliable seismic fragility predictions of all bridge types both seismically and non-seismically designed variants.

ABSTRACT: An axial loading test was conducted on a steel column specimen with a box-shaped cross section, for improving structural health monitoring and non-destructive evaluation using machine learning. In the loading test, 8 acceleration sensors were placed on the surface of the column to obtain vibration characteristics at each loading step. A standard autoencoder was trained on intact frequency responses obtained before the loading test. From the results, anomaly scores calculated from the autoencoder were high around the local buckling regions. Furthermore, another autoencoder model trained on data measured from another specimen using applied transfer learning agreed with the results from the standard autoencoder. The effectiveness of coupling an autoencoder-based anomaly detection method and transfer learning when there is a lack of training data was shown.

1 INTRODUCTION

Many civil structures are aging in Japan. In addition, some structures have serious damage from accidental loads, such as large earthquakes, tsunamis, floods, landslides, and avalanches). To maintain safety performance and functions of the existing structures, it is needed to evaluate the conditions and structural performance of the structures. Non-destructive evaluation and structural health monitoring are useful for the reasonable maintenance of civil structures. The population of construction workers is decreasing, particularly in Japan, resulting in a serious shortage of human resources for the inspection and maintenance of civil structures. To address this issue, innovative technologies (e.g. inspection robots, sensing, monitoring, machine learning) have been investigated around the world.

In the previous study (Fujisaku et al., 2023), an axial loading test was conducted on a steel column specimen (Specimen No.0) with a box-shaped cross section. Moreover, an autoencoder-based anomaly detection method was built for damage evaluation of the column. Results had indicated the possibility of damage detection, though, it was only possible to compare data before and after loading with a single column specimen No.0. Deep learning should be available to detect damages for individual structures, using pre-trained models by capturing

DOI: 10.1201/9781003483755-228

similar data features. The use of machine learning is thought to be effective for improving inspection and evaluation of various civil structures.

In this study, an additional column specimen (Specimen No.1) was installed for improving the autoencoder-based damage detection method for individual structures. An axial loading test was conducted on the additional column specimen No.1. In the loading test, 8 acceleration sensors were placed on the surface of the column, to obtain vibration characteristics at each loading step. Moreover, unsupervised learning and transfer learning were examined to detect damage to the column. In particular, a trained model on the previous specimen No.0 was applied to the damage evaluation of the additional specimen No.1, through transfer learning.

2 AXIAL LOADING TEST ON A STEEL COLUMN

A steel column specimen (No.1) was installed. The details and material properties are shown in Figure 1 and Table 1. The column had a length of 900 mm and a box-shaped cross section with a sectional height of 450 mm and a sectional width of 450 mm. The column consisted of four-sided panels (2 flanges and 2 webs) and eight longitudinal ribs (stiffeners). Four ribs were welded on the outside of the flanges. Other ribs were welded on the inside of the webs. The design tensile strengths of the panels and ribs were 400 MPa and 700 MPa, respectively.

The test setup is shown in Figure 2. The column specimen had upper and lower loading plates on both sides. The panels were welded to the loading plates and subjected to the axial load. Whereas the ribs were not welded to the loading plates and not subjected to the axial load directly. Loading speed was set at 0.005 mm/s.

Figure 3 shows the load and displacement relationship in the loading test, where the displacement was obtained from averaging displacements using gauges at four corners. Figure 4 shows a buckling deformation diagram, where the buckling deformation was measured using mold gauges after the loading test. The flanges and webs buckled toward the outside and inside of the cross section, respectively. The buckling deformation increased in the post peak region in Figure 3, however, the load decreased slightly.

3 VIBRATION TEST ON THE COLUMN

Forced vibration testing with a portable electric-magnetic vibrator was conducted. Figures 3 and 4 show the measurement steps of vibration testing and deformation of the column. The excitation and measurement locations with acceleration sensors are shown in Figure 5. The

sensors were placed on the panels and ribs at the top (CH 5), middle (CHs 1-4), and bottom (CHs 6-8) of the column. The locations were the same as those of Specimen No.0 (Fujisaku et al., 2023).

The vibrator had a mass of 1.8 kg, a diameter of 95 mm, a height of 62 mm, the maximum excitation force of 50 N, and a frequency range of 100 to 20,000 Hz. Using the vibrator, white noise force was applied to the bottom of the column, as shown in Figures 2 and 5. The excitation force was controlled at a power spectral density (PSD) of 0.5 $(m/s^2)^2$/Hz over a frequency range of 1000 to 20,000 Hz. The root mean square of acceleration amplitude (RMS) was 97.6 m/s^2.

Frequency response functions were obtained from acceleration records using a fast Fourier transform. The frequency responses had a range of 1000 to 20,000 Hz with a resolution of 97.7 Hz. The amplitude was normalized by the maximum amplitude for each frequency response. Deep learning used 256 parameters of one-dimensional data as features, as described in a later section.

4 DAMAGE DETECTION

4.1 *Standard autoencoder*

4.1.1 *Model and evaluation method*

A conventional standard autoencoder based on a neural network (standard AE) was used for damage detection. The structure of the standard AE is shown in Figure 6. The model was built and trained with Tensorflow2 (tf.keras) in Python. The input data f_i (i = 1 to 256) was given from the frequency responses. The input data was compressed through three hidden layers, and decoding was applied to the compressed data in the same process. Rectified Linear Unit (ReLU) was used as activation functions of the hidden layers. Sigmoid function was used in the output

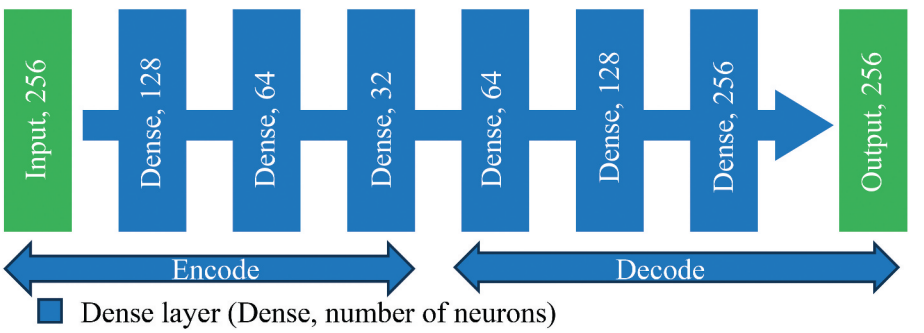

Figure 6. The structure of the autoencoder.

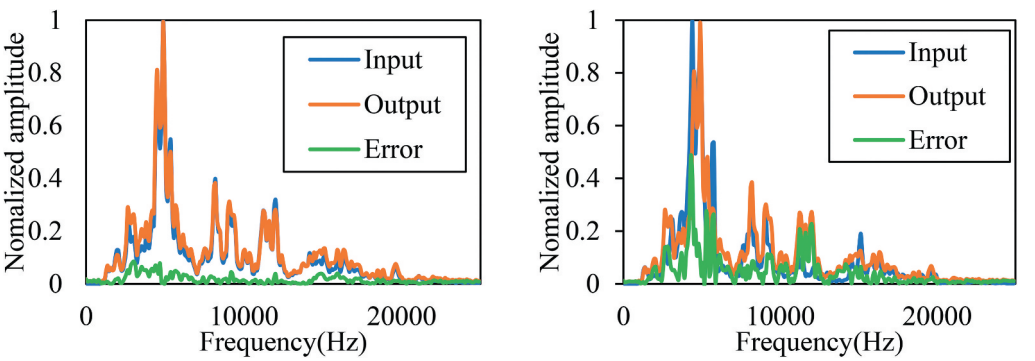

Figure 7. Comparisons between input and output (CH5, left: intact, right: damaged region).

layer. Adam optimization was used in the training process, with a batch size of 16 and a learning ratio of 0.001. Early stopping was applied during the training process to prevent over fitting.

The standard AE was trained on frequency responses obtained from the intact column before loading. The standard AE can reconstruct data of frequency responses well when they are similar to the training data. Whereas data from the damaged column cannot reconstruct, as the data is different from the intact training data. Damages could be evaluated with anomaly scores calculated from the reconstruction errors. In calculating the anomaly scores, two processes were conducted. First, averages of the input f_i (i = 1 to 256) and the output g_i (i = 1 to 256) with a width of 10 parameters were taken. Second, the error of $f_i - g_i$ (i = 1 to 256) was set to zero when the error was below 0.2, to reduce the influence of noise. The anomaly score was defined as,

$$e = \frac{\sum_{i=1}^{256} |f_i - g_i|}{\sum_{i=1}^{256} f_i} \tag{1}$$

4.1.2 *Anomaly scores from the standard autoencoder*

The standard AE was trained on approximately 250 frequency response functions for each sensor location, where the training data was measured before the loading test. Moreover, five test data of frequency responses were obtained at each measurement step and sensor location. Anomaly scores were evaluated for the test data using the trained standard AE.

As an example, Figure 7 shows frequency responses of CH5 obtained before loading and at measurement step 13. The trained model was able to successfully reconstruct the data

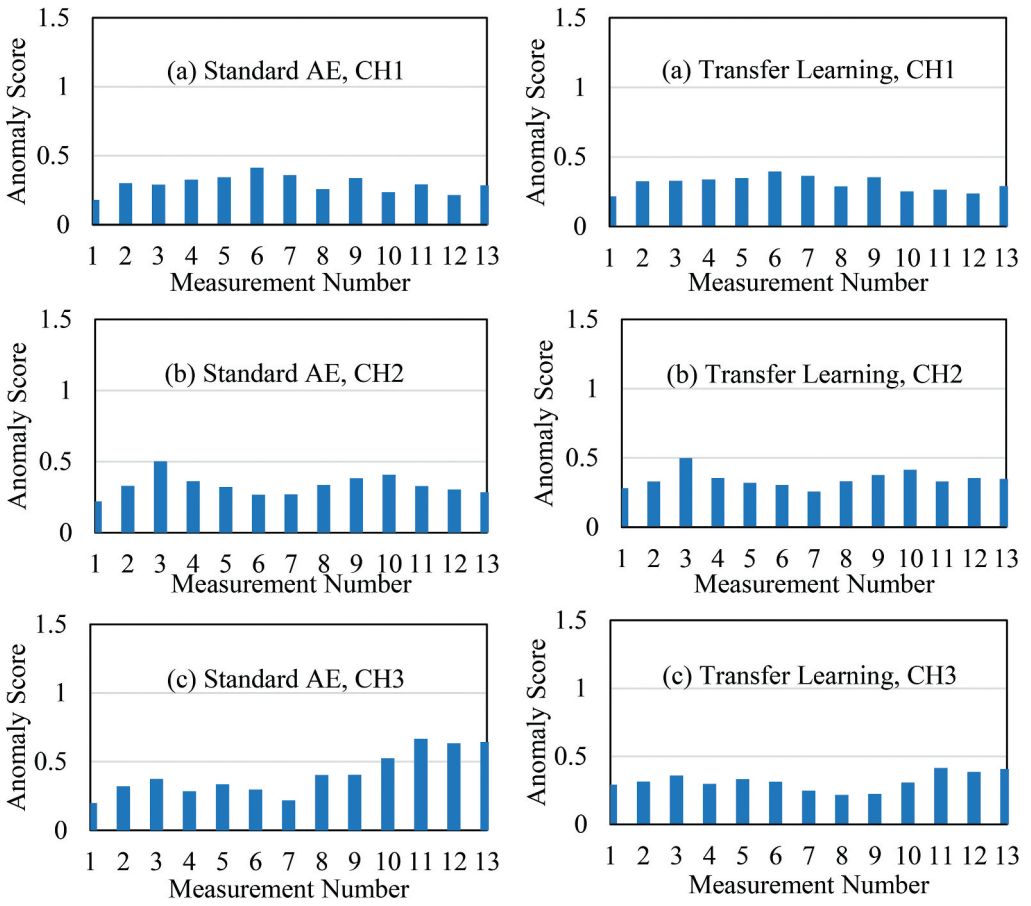

Figure 8. Anomaly scores using the standard AE and transfer learning (CHs 1-3).

obtained before loading, whereas the frequency response obtained from the damaged column did not reconstruct. The reconstruction error is used to evaluate anomaly scores in Eq. (1).

The left column in Figures 8 and 9 show the relationships between anomaly scores and measurement steps. Where, the mean of anomaly scores of the intact data was 0.186. As shown in Figure 9 (b), the anomaly score of CH5 increased as the measurement step increased. It is thought that the anomaly score of CH5 indicated the global damage level of the column, since the location of sensor CH5 was placed far from the excitation location, as shown in Figure 5.

In Figure 9, CHs 6-8 at the bottom of the column had high anomaly scores in the loading test. In particular, the score of CH6 placed on the rib was higher. In addition, the anomaly score of CH4 was similar to that of CH6, where CHs 4 and 6 were placed on the same rib. It is thought that local buckling deformation of the rib affects the anomaly score sensitively, compared to the panels. It is recommended to place sensors on ribs for health monitoring of steel columns.

In Figure 8, CHs 1-4 placed at the middle of the column had lower anomaly scores. This indicates that the boundary condition at the bottom affected the anomaly scores strongly.

As described above, the results show that: i) a sensor placed far from an excitation source is useful to evaluate the global damage level of columns, ii) it is recommended to place a sensor on a rib around the bottom for monitoring local buckling of steel columns. These results i) and ii) were also observed in the previous study with Specimen No.0 (Fujisaku et al., 2023), even though the buckling modes of Specimens Nos. 0 and 1 were quite different.

4.2 *Transfer learning on the autoencoder*

4.2.1 *Model and evaluation method*

In Section 4.1, the standard AE was trained on the intact data of Specimen No.1. In this section, a model was trained on data from Specimen No.0, that was installed in the previous study (Fujisaku et al. 2023). The differences between Nos. 0 and 1 were the rib width (No.0: 94 mm, No.1: 76 mm), the rib thickness (No.0: 8.3 mm, No.1: 6.3 mm), and the welding condition to the loading plates (No.0: welded, No.1: no weld).

Model-0 was trained on the intact data obtained before the loading test of Specimen No.0, through the autoencoder. Figure 10 shows the anomaly scores of CH5 in Specimen No.1, using Model-0. The anomaly scores did not change, since the training and test data were given from Specimens No.0 and No.1, respectively. This indicates that the standard AE is useful for monitoring structures with known initial conditions. However, the method has difficulty in detecting damage when there is a lack of the initial data, such as for aged structures.

In this section, transfer learning was examined for detecting damage of Specimen No.1 using Model-0. Transfer learning retains most of the weights of feature parameters in a model, for applying to another model through retraining with a few data. Figure 11 shows the structure of the transfer learning.

For retraining during transfer leaning, 9 frequency responses were taken randomly from each sensor location from the 250 intact data of No.1. The output and one hidden layer were retrained on the 9 frequency responses, where the weights of feature parameters in other layers were not changed. The retraining conditions were the same as described in Section 4.1.

4.2.2 *Anomaly scores from the transfer learning*

The right column in Figures 8 and 9 show the anomaly scores using the transfer learning. The scores agreed with those of the standard AE, except for CH6. Transfer learning improved damage evaluation using Model-0 and 9 retraining data. Results indicated the effectiveness of coupling unsupervised learning (autoencoder) and transfer learning. The proposed method is useful for non-destructive evaluation and structural health monitoring when initial inspection/monitoring data of structures are unavailable.

The reason for the differences in scores of CH6 was not clear. The sensor CH6 was placed on the rib at the bottom of No.1. It was sensitive to the deformation of the column with increases in loading step. It is thought that the amount of retraining data (9 frequency responses) was too small for the transfer learning of CH6.

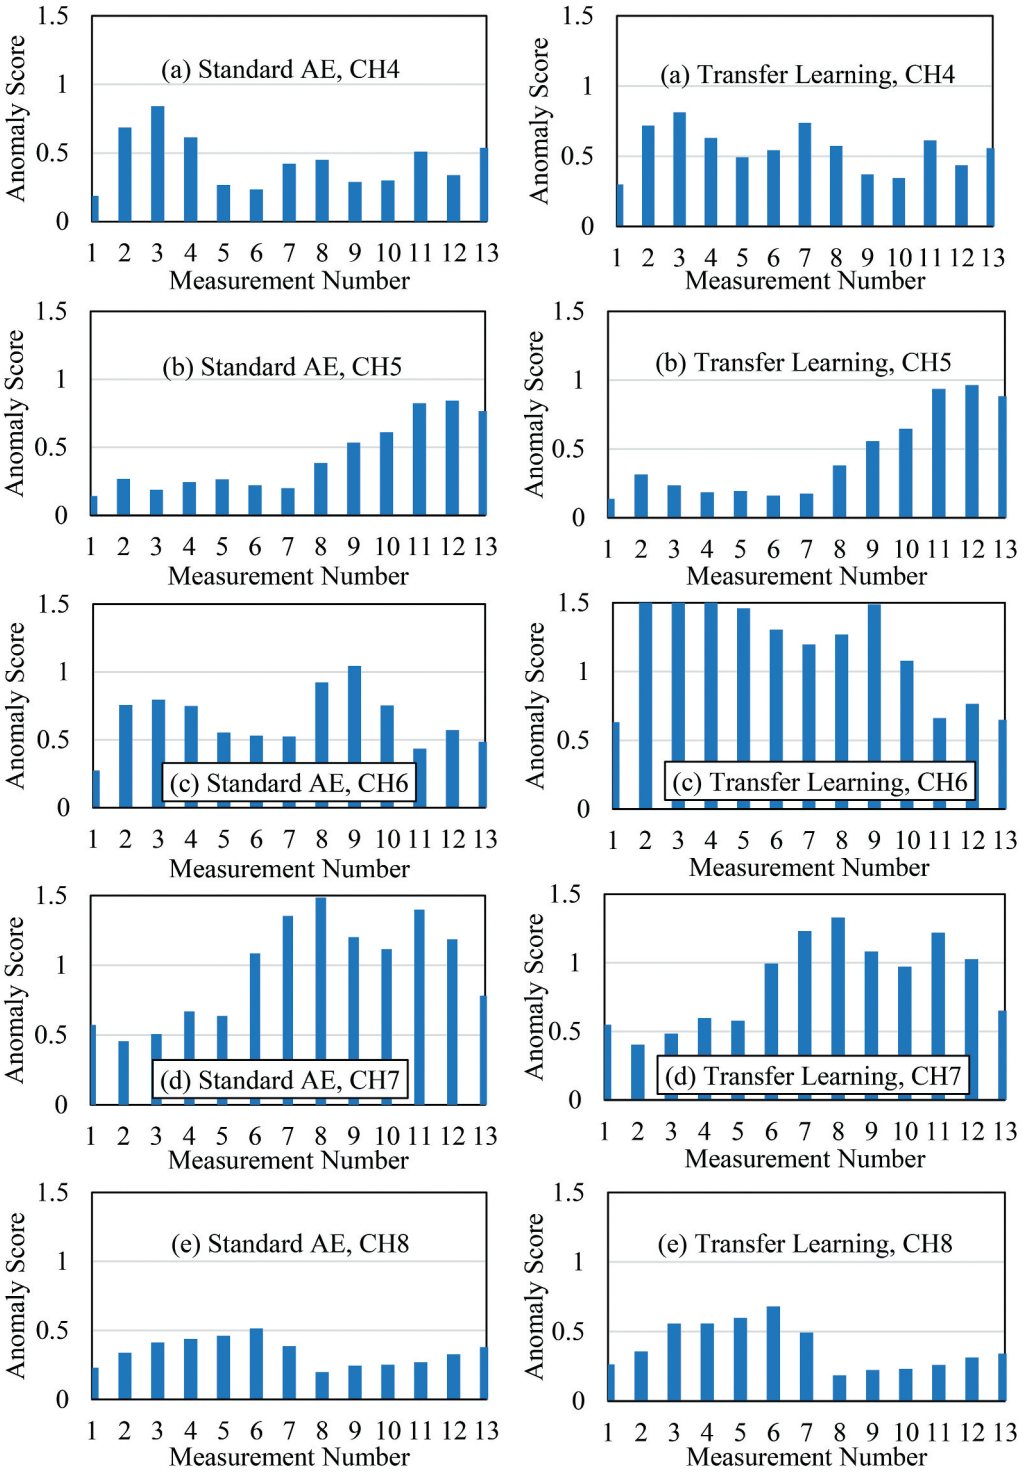

Figure 9. Anomaly scores using the standard AE and transfer learning (CHs 4-8).

5 CONCLUSIONS

In this study, an axial loading test was conducted on a steel column with a box-shaped cross section, for examining damage detection using machine learning and vibration characteristics. In particular, the effectiveness of coupling unsupervised learning and transfer learning was examined. From the experimental results, the following findings were observed:

1) A standard autoencoder model was trained on 250 intact frequency responses measured before the loading test. The effectiveness of anomaly detection using an autoencoder was shown through the damage evaluation of a column containing local buckling of panels and ribs. In particular, the results indicated that: i) a sensor placed far from an excitation source is useful to evaluate the global damage level of columns, ii) it is recommended to place a sensor on a rib around the bottom for monitoring local buckling in steel columns.
2) An autoencoder model was trained on data measured from another column specimen. The trained model was retrained on 9 frequency responses through transfer learning. Anomaly scores from the transfer learning agreed well with those from the standard autoencoder trained on 250 intact data.

Coupling unsupervised learning (autoencoder) and transfer learning was effective for improving non-destructive evaluation and health monitoring of structures, even when initial inspection/monitoring data is lacking. However, these findings were obtained from a column specimen. Further experimentation and calculations are needed before applying the proposed method to actual civil structures.

ACKNOWLEDGEMENTS

A part of this research was conducted by the support of Steel Structure Research and Education Assistance Project, The Japan Iron and Steel Federation, JST FOREST Program (Grant

Number JPMJFR2150, Japan), and Japan Society for the Promotion of Science (Grant Number 22H01568). In addition, we thank students of Waseda University, Ryosuke Yamazaki, Rintaro Taguchi, and Haruhisa Kobayashi, for their help in the loading test on the column.

Probabilistic modeling of bridge deterioration due to earthquakes

Leandro Iannacone
University College London, London, UK

Paolo Gardoni
University of Illinois at Urbana-Champaign, Champaign IL, USA

ABSTRACT: The physical state of a structure can be modeled as a function of its state variables (e.g., material and geometric properties). Deterioration processes cause changes in the state variables that in turn modify its ability to sustain given demands over time. Typically, deterioration processes are divided into gradual processes, where the deterioration evolves continuously over time, and shock processes, where the deterioration is modeled as discrete jumps. The damage accumulation within shock events is usually disregarded in simplified procedures that only model the total effect of the shock and use aggregated measures to quantify the shock intensity. However, this simplification can produce inaccurate estimates of the structure's reliability. As a result, it is important to account for the specific evolution of the damage also in such processes. This paper models shock deterioration as a rapidly evolving but still gradual process. We use the formulation based on Stochastic Differential Equations proposed by Iannacone & Gardoni (2023) to model the effect of the time history of ground motion sequences on the deterioration of a bridge. This formulation allows obtaining the state variables together with their associated uncertainties during the shock, which in turn can be used to obtain the time-varying reliability of the system. The models are calibrated based on the results of advanced Finite-Element Models which record the state of the system in real time. We combine the proposed formulation with available methods for generating spectrum-compatible seismic excitations for a site of interest to predict the deterioration over time and the time-varying reliability of the bridge during the occurrence of the shock.

1 INTRODUCTION

The long-lasting effect of ground motions on the condition of existing bridges has been of interest over the past few decades (e.g., Cui et al. 2019, Torti et al. 2022). Apart from exerting direct stress, for which assessing the probability of failure is crucial, these events also serve as one among various ongoing processes that deteriorate the system. In other words, even if a bridge is able to withstand an initial shock, its deteriorated conditions will affect its ability to sustain subsequent events (in particular, aftershocks). In fact, most bridges go through multiple earthquakes during their lifecycle, and aftershocks become problematic mainly due to the weakened state of the structure after the main shock, rather than the intensity of the aftershocks themselves (Li & Ellingwood 2007, Kumar & Gardoni 2014, and Iervolino et al. 2020). Multiple authors have addressed the estimation of the state of a bridge following the occurrence of a seismic event (e.g. Jeon et al. 2015, Raghunandan et al. 2015), with most recent works addressing the interactions between multiple processes (Jia et al. 2017). Building on the state-dependent framework proposed by Jia & Gardoni (2018), Iannacone & Gardoni (2019, 2023) proposed the use of Stochastic Differential Equations (SDEs) to model the time-varying evolution of the state variables of the system, i.e., a set of important properties (e.g., geometric properties, material properties) that determine its conditions. In Iannacone & Gardoni (2019,

DOI: 10.1201/9781003483755-229

2023), shocks are incorporated into the formulation using SDEs driven by a semimartingale driving noise (Grigoriu 2013). The discontinuous part of the semimartingales creates jumps in the evolution of the state variables which can be interpreted as the effects of shocks. An alternative approach to shock deterioration modeling is proposed by Iannacone & Gardoni (2021), also using SDEs as the basis. In this interpretation, the shocks are interpreted as short-time, continuous gradual deterioration processes. Ordinary Brownian motions (Grigoriu 2013) are used as the driving noise (as there is no need to have discontinuities in the processes), streamlining the calibration of the SDEs based on available data. In addition, this interpretation allows us to account for the specific ground motion characteristics (time-histories) for prediction purposes, rather than aggregated measures such as Peak Ground Acceleration and spectral acceleration. It also allows us to make full use of recent tools developed for the simulation of synthetic ground motions, both for mainshocks (Rezaeian & Der Kiureghian 2008) and mainshock-after shock sequences (Hu et al. 2018).

Iannacone & Gardoni (2021) observed that using the entire set of available ground motions (unrelated and coming from different locations around the world) to perform the calibration of a single deterioration process did not produce satisfactory results in terms of accuracy with the Finite Element Models (FEMs). As such, the results presented in Iannacone & Gardoni (2021) are based on calibrations performed on individual ground motions. While the results show high similarities with the FEM results, calibration performed on individual ground motions may limit the prediction capability of the models, as the synthetic ground motions used for future events may not share the same characteristics as the one used for calibration.

In this paper, we perform the calibration based on a set of spectrum-compatible ground motions (Choi & Lee 2003). We investigate the degree of accuracy of the calibrated model compared with the results from the Finite Element Models (FEMs) and compare it with similar results obtained by calibrating the models based on a set of unrelated ground motions. The deterioration models produced in this paper can be used for prediction purposes at the location of interest, as future earthquake events are realistically going to share the spectrum characteristics as the ones used for calibration.

The paper will be organized as follows: in Section 2 we will provide a brief overview of the SDE formulation introduced by Iannacone & Gardoni (2019, 2023) and of how it can be used to interpret shock occurrences as short-time gradual deterioration processes (Iannacone & Gardoni 2021); in Section 3 we will show the limitations of the calibration methods proposed in the aforementioned works when dealing with seismic excitations that are not spectrum-compatible; in Section 4 we will show how using spectrum-compatible excitations greatly improves the accuracy of the model and makes it suitable for prediction purposes; finally, in Section 5 we will present the conclusions of the work.

2 FORMULATION

Following the formulation by Jia & Gardoni (2018), we can define the vector of external conditions, $\mathbf{Z}(t)$, as a collection of the variables affecting the time-varying performance of the system, that are not related to the system itself. Subsets of this vector are the environmental conditions $\mathbf{E}(t)$, typically affecting gradual deterioration processes (e.g. atmospheric pressure, relative humidity and temperature), and the shock measures $\mathbf{IM}(t)$, typically affecting the shock deterioration processes. The vector $\mathbf{Z}(t)$ can hence be expressed as

$$\mathbf{Z}(t) = [\mathbf{E}(t), \mathbf{IM}(t)] \tag{1}$$

Jia & Gardoni (2018) proposed to investigate the evolution of a system subject to deterioration by looking at a set of state variables $\mathbf{X}(t) = [X_i(t), \ldots, X_n(t)]$, defined as the variables of the system that might be subject to change over time (e.g. material and geometric properties). In other words, the value of the state variables at any time t can be expressed as

$$\mathbf{X}(t) = \mathbf{X}[t, \mathbf{X}_0, \{\mathbf{Z}(t)\}; \Theta_{\mathbf{X}}] \tag{2}$$

where $\mathbf{X}_0$ is the value of the state variables at time $t = 0$, $\{\mathbf{Z}(t)\}$ is the sequence of external conditions up to time t, and $\boldsymbol{\Theta}_{\mathbf{X}}$ is a set of unknown parameters. Different forms have been proposed in the literature for the model in Eq. (2). In particular, Iannacone & Gardoni (2019, 2023), proposed to describe the evolution of the state variables using a set of Stochastic Differential Equations (SDEs). According to this formulation, the infinitesimal change in the state variables at time t, $\mathrm{d}\mathbf{X}(t)$, can be defined with the following formula:

$$\mathrm{d}\mathbf{X}(t;\boldsymbol{\Theta}_{\mathbf{X}}) = \boldsymbol{\mu}\left[t, \mathbf{X}(t), \{\mathbf{Z}(t)\}; \boldsymbol{\Theta}_{\boldsymbol{\mu}}\right]\mathrm{d}t + \boldsymbol{\sigma}[t, \mathbf{X}(t), \{\mathbf{Z}(t)\}; \boldsymbol{\Theta}_{\sigma}]\mathrm{d}\mathbf{S}(t;\boldsymbol{\Theta}_{\mathbf{S}}) \tag{3}$$

where $\boldsymbol{\mu}[\cdot]$ is a vector of drift coefficients, quantifying the deterministic change in $\mathbf{X}(t)$ over time, $\boldsymbol{\sigma}[\cdot]$ is a vector of diffusion coefficients, quantifying the uncertainties in the change of $\mathbf{X}(t)$ over time, and $\mathrm{d}\mathbf{S}(\cdot)$ is a driving noise term that defines the shape and behavior of the process (Grigoriu 2013). These terms are characterized by vectors of unknown parameters $\boldsymbol{\Theta}_{\boldsymbol{\mu}}$, $\boldsymbol{\Theta}_{\sigma}$ and $\boldsymbol{\Theta}_{\mathbf{S}}$, respectively. As highlighted by Iannacone & Gardoni (2019, 2023), the choice of the driving noise term $\mathrm{d}\mathbf{S}(\cdot)$ is key in determining the behavior of the stochastic process that is solution to the SDE in Eq. (3). Semimartingales have proven to be a suitable option, as they are able to incorporate both continuous changes in time (via a Brownian motion component) and discrete jumps at selected times (via a compensated Poisson process component). However, semimartingales, while extremely flexible, can come with limitations related to their mathematical tractability (Itô 1973). The interpretation for shock processes proposed in Iannacone & Gardoni (2021) allows us to select a continuous driving noise for Eq. (3) (such as a standard Brownian motion/Wiener process), which might facilitate the use of this framework in practice. In addition, an SDE-based formulation allows us to use of semi-closed form solutions that are available in the literature (Itô 1973, Grigoriu 2013).

The vector of shock measures $\mathbf{IM}(t)$ typically depends on the problem under analysis. In the case of earthquakes, it is generally composed of aggregated measures for the intensity of the shocks (e.g., Peak Ground Acceleration). To capture the effect of the time history of the shock, Iannacone & Gardoni (2021) defined the vector of shock measures as a set of functions of the instantaneous acceleration $a(t)$ of the earthquake, $\mathbf{h}[a(t)]$.

$$\mathbf{Z}(t) = \{\mathbf{E}(t), \mathbf{h}[a(t)]\} \tag{4}$$

where $\mathbf{h}[a(t)] = \{h_1[a(t)], \ldots, h_n[a(t)]\}$ is a set of n explanatory functions that relate the evolution of $\mathbf{X}(t)$ to the instantaneous ground acceleration $a(t)$. If this relationship is assumed to be linear, drift and diffusion terms in Eq. (3) can be rewritten as ($\cdot$ denotes the scalar product)

$$\boldsymbol{\mu}[\cdot] = \boldsymbol{\theta}_{\boldsymbol{\mu}\boldsymbol{h}} \cdot \mathbf{h}[a(t)] + f\left[t, \mathbf{X}(t), \mathbf{E}(t); \boldsymbol{\theta}_{\boldsymbol{\mu}\mathbf{x}}\right] \tag{5}$$

$$\boldsymbol{\sigma}[\cdot] = \boldsymbol{\theta}_{\boldsymbol{\sigma}\mathbf{h}} \cdot \mathbf{h}[a(t)] + f[t, \mathbf{X}(t), \mathbf{E}(t); \boldsymbol{\theta}_{\boldsymbol{\sigma}\mathbf{x}}] \tag{6}$$

where $\boldsymbol{\theta}_{\boldsymbol{\mu}h}$ and $\boldsymbol{\theta}_{\boldsymbol{\sigma}\mathbf{h}}$ are the sets of parameters that relate $\mathbf{X}(t)$ to $h[a(t)]$, and are subsets of $\boldsymbol{\Theta}_{\mu}$ and $\boldsymbol{\Theta}_{\sigma}$, respectively. $\boldsymbol{\theta}_{\boldsymbol{\mu}\mathbf{x}}$ and $\boldsymbol{\theta}_{\boldsymbol{\sigma}\mathbf{x}}$ can be defined as $\boldsymbol{\Theta}_{\mu} \backslash \boldsymbol{\theta}_{\boldsymbol{\mu}\boldsymbol{h}}$ and $\boldsymbol{\Theta}_{\sigma} \backslash \boldsymbol{\theta}_{\boldsymbol{\sigma}\mathbf{h}}$, respectively, and represent the subsets of unknown parameters that relate $\mathbf{X}(t)$ to aspects not directly related to the seismic excitation. The set of explanatory functions $h[a(t)]$ depends on the problem under consideration and can be selected based on engineering judgement and/or variable selection methods available in the literature, such as Lasso (Tibshirani 1996), or the stepwise deletion method proposed by Gardoni et al. (2002). The set of unknown parameters $\boldsymbol{\Theta}_{\mathbf{X}}$ in Eq. (3) can be calibrated based on available observations of the state variables, either coming from field observations or Finite Element Models (FEMs). When the semimartingale driving noise $\mathrm{d}\mathbf{S}(t;\boldsymbol{\Theta}_{\mathbf{S}})$ is replaced by an ordinary Brownian motion $\mathrm{d}\mathbf{B}$, the classical Euler-Maruyama approach for SDEs calibration can be used. The method is not reported here, but we refer the reader to Iannacone & Gardoni (2021) for a detailed explanation of the method and how it can be applied to models for the real-time deterioration of bridges during earthquakes.

3 CALIBRATION OF DETERIORATION MODELS BASED ON UNRELATED EARTHQUAKE EVENTS

This section analyzes the effect of a set of unrelated ground motions on a bridge using a FEM, and we calibrate a deterioration model in the form of Eq. (3) using the FEM results. The analyzed bridge is the two-span reinforced concrete bridge reported in Figure 1. We also report the value of important quantities (such as geometric and material properties) in Table 1.

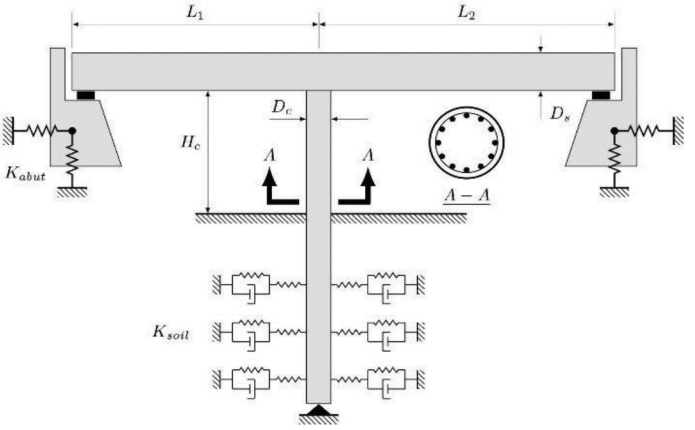

Figure 1. Layout for the bridge under analysis (adapted from Jia et al., 2017).

Table 1. Important quantities of the bridge under analysis.

Parameter	Symbol	Value
Shorter span length	L_1	25 m
Column Height	H	8.5 m
Column Diameter	D_c	1.54 m
Reinforcement Nominal Yield Strength	f_y	475 MPa
Concrete Nominal Strength	f_c'	40.55 MPa
FRP Composite Nominal Strength	f_{FRP}	1302 MPa
Tensile Modulus of FRP Composite	E_{FRP}	12400 MPa
Longitudinal Reinforcement Ratio	ρ_l	0.022
FRP Composite Volumetric Ratio	ρ_{FRP}	0.0334
Additional Bridge Dead Load	w_t	0.7
Long-to-Short Span Ratio	L_2/L_1	1.4
Lap Splice Length	L_S	0.86 m
Soil Type		C
Abutment Type		Roller

The analyses are performed using the software OpenSees (McKenna et al. 2006). The ground motions used for calibration present similar aggregated measures but wildly different time-histories. Namely, we use time-histories coming from the following earthquakes: Loma Prieta (California 1989), Tabas (Iran 1978), L'Aquila (Italy 2009), and Kobe (Japan 1995). Contrary to the analyses performed by Iannacone & Gardoni (2021), we calibrate a single deterioration model using the entire set of ground motions, and we show the limitations of the calibration in terms of accuracy for prediction purposes.

We use the FEM to record the variation of the first natural period of the structure T_n, which is expected to increase over time due to the reduction in stiffness caused by the incremental damage on the bridge. A stochastic model for the evolution of T_n (in the form of Eq. 3) is then calibrated based on the FEM results. Namely, the drift term in Eq. (3) is assumed to have the following form:

$$\boldsymbol{\mu}[\cdot] = \boldsymbol{\Theta}_{\boldsymbol{\mu}} \cdot \mathbf{h}[a(t)] = \sum_{i=1}^{7} \theta_i h_i[a(t)] \tag{7}$$

while the diffusion term is assumed to be a constant of value $\theta_\sigma = \theta_8$. The set of explanatory functions that are selected for the problem is shown in Table 2.

Table 2. Explanatory functions for the drift coefficient.

Explanatory function	Value
$h_1(t)$	$a(t)$
$h_2(t)$	$[a(t)]^2$
$h_3(t)$	$[a(t)]^3$
$h_4(t)$	$[a(t)]^4$
$h_5(t)$	$T_n[a(t)]^2$
$h_6(t)$	$\max_{(t-1)<\tau<t} [a(\tau)]^2$
$h_7(t)$	$\max_{(t-10)<\tau<t} [a(\tau)]^2$

The explanatory functions $h_1(t)$, $h_2(t)$, $h_3(t)$ and $h_4(t)$ investigate the direct effect of the instantaneous spectral acceleration $a(t)$ on the evolution of the first natural period of the structure. The explanatory function $h_5(t)$ investigates the effects of the possible interaction between the instantaneous spectral acceleration $a(t)$ and the value of the first natural period T_n itself, hence making the formulation state dependent. The explanatory functions $h_6(t)$ and $h_7(t)$ are included to capture the effects of the inertia of the system during the seismic excitation. In particular, $h_6(t)$ accounts for the presence of peaks in the seismic excitation in the last second before t, while $h_7(t)$ accounts for the presence of peaks in last 10 seconds before t.

Table 3. Estimates for the unknown parameters (unrelated ground motion records).

Unknown parameter	Mean	Standard Deviation
θ_1	0.0269	0.0613
θ_2	1.3609	0.8013
θ_3	−0.1473	0.4432
θ_4	0.4187	1.0876
θ_5	−0.8030	0.4456
θ_6	0.3630	0.1009
θ_7	−0.0130	0.0258
θ_8	0.0500	0.0014

Table 3 reports the statistics for the calibrated values for the set of parameters $\boldsymbol{\Theta}_{\boldsymbol{\mu}}$.

Figure 2 shows a comparison between the results from the FEM and the expected prediction from the SDE model.

To quantify the discrepancy between the two models, we provide in the figure the Root Mean Square Error for the ground motion *gm* (RMSE_{gm}), computed as follows:

$$\mathrm{RMSE}_{gm} = \frac{1}{N_{data,gm}} \sum_{i=1}^{N_{data,gm}} \left(x_{FEM,gm,i} - x_{SDE,gm,i}\right)^2 \tag{8}$$

where $x_{FEM,gm,i}$ is the data from the FEM model and $x_{SDE,gm,i}$ is the data from the SDE model. The RMSE is computed across the $N_{data,gm}$ datapoints included between the beginning of the ground motion (defined for this paper as the point where $h_2(t)$ exceeds 0.001 cm^2/s^4 for the first time) and the end of the ground motion (defined for this paper as the point where $h_6(t)$ falls below 0.001 cm^2/s^4 for the first time). The thresholds were selected based on engineering judgment to capture the start and the end of the portion of the ground motion record

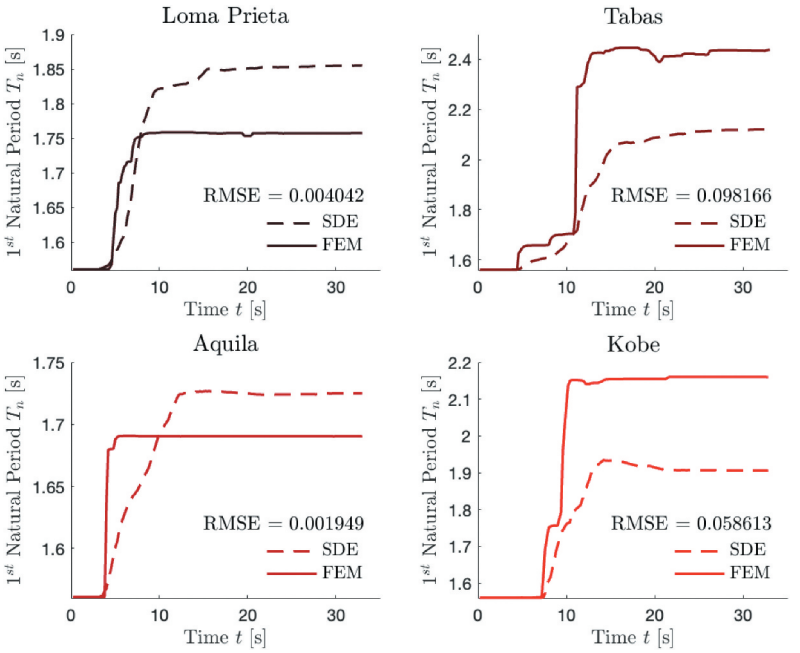

Figure 2. Predictions using the model calibrated based on unrelated ground motion records.

that effectively causes changes to the value of T_n. The average RMSE across the prediction for the four ground motions used for this example is 0.0407 s^2.

4 CALIBRATION OF DETERIORATION MODELS BASED ON SPECTRUM-COMPATIBLE EARTHQUAKE EVENTS

The same bridge as in Section 3 is now subject to a set of 6 spectrum-compatible ground motions. Time histories are spectrum-compatible when they exhibit similar characteristics in the frequency domain. In design practices, several codes require the selection of ground motion records that have response spectra similar to a pre-specified design spectrum (e.g., CEN 2004). Using spectrum-compatible ground motions also reduces the dispersion of the structural response of the structure. For this paper, we selected 6 spectrum-compatible ground motions using the software REXEL (Smerzini et al. 2014) and REXELweb (Sgobba et al. 2021). Figure 3 shows the target spectrum used for the selection along with the spectra of the selected records. The average spectrum of the selected records closely resembles the target spectrum.

The selected ground motions belong to the following earthquake sequences that occurred in Italy over the past few decades: Friuli (1976), Umbria-Marche (1997), Emilia (2012), and Central Italy (2016). A model in the same form as Section 3 is calibrated based on the results from the spectrum-compatible ground motions. Table 4 reports the statistics for the calibrated values of the unknown parameters.

Finally, Figure 4 shows the results of the prediction using the new model, for each of the 6 ground motions used for the calibration. The RMSE is also reported for each of the ground motions, computed as in Section 3. The predictions display a much higher level of accuracy compared with the case with unrelated ground motions. The average RMSE in this case is 0.0016 s^2, which is 96% lower than in Section 3 (even though the model now must adapt to 6 different ground motions compared to the 4 ground motions in the previous case).

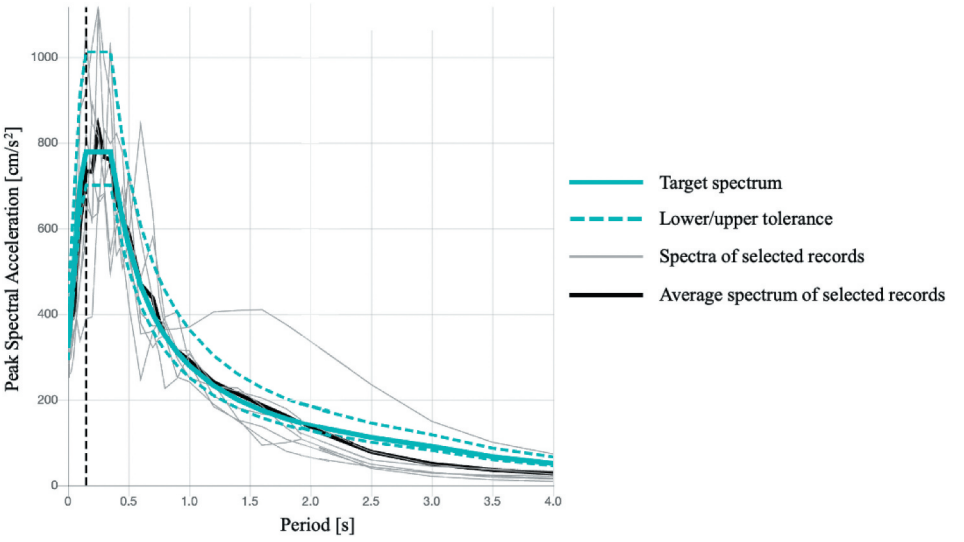

Figure 3. Target spectrum and spectra of the ground motion records selected for this example.

Table 4. Estimates for the unknown parameters (spectrum-compatible ground motion records).

Unknown parameter	Mean	Standard Deviation
θ_1	0.0353	0.0167
θ_2	7.3573	2.8564
θ_3	−2.2709	0.6207
θ_4	−24.2917	2.6009
θ_5	−3.3049	1.7516
θ_6	0.1564	0.0309
θ_7	−0.0191	0.0115
θ_8	0.0053	0.0001

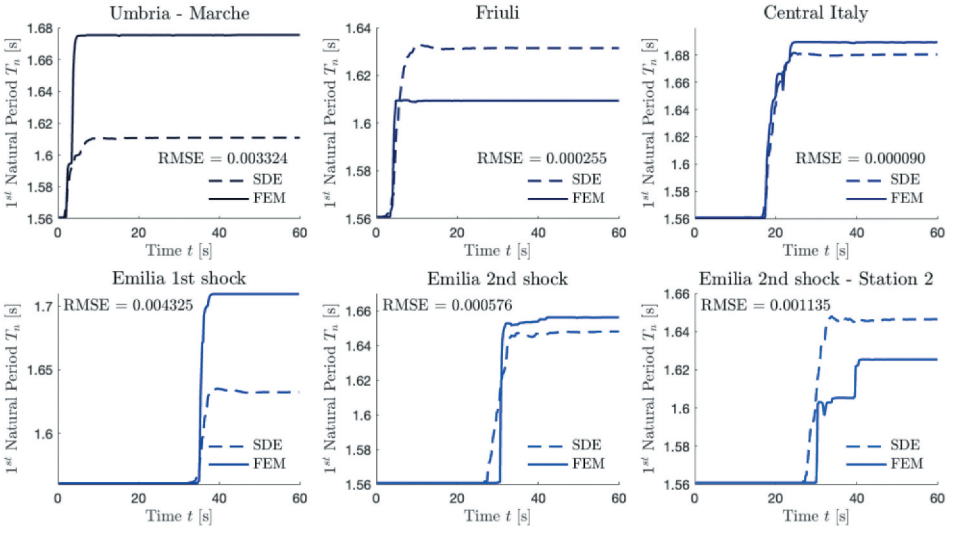

Figure 4. Predictions using the model calibrated based on spectrum-compatible ground motions.

5 CONCLUSIONS

In this paper, we calibrated Stochastic Differential Equation (SDE) models for the real-time deterioration of bridges during earthquake events. The data used for the model calibration was obtained by simulating the response of the bridge to multiple ground motion records through the Finite Element software OpenSees. Namely, we investigated the evolution of the first natural period of the structure as a direct effect of the ground motion. The selected SDE models allow to capture the effects of the instantaneous ground acceleration on the natural period, whereas typically used methods use aggregated measures of the shock (such as Peak Ground Acceleration or Spectral Acceleration) to predict the response of the structure and its deteriorated state at the end of the shock. In particular, the paper investigated how the selection of spectrum-compatible ground motion records can help reduce the scatter in the system response and can facilitate the calibration of a single SDE model for the deterioration of the structure. The results show that calibrating a single model on unrelated ground motion records can produce highly uncertain results that only reflect the original data in an average sense. When the calibration is based on spectrum-compatible records, the uncertainty is reduced, and a single calibrated model can capture the evolution of the system subject to multiple ground motions more accurately. The calibrated model can then be used to predict the response of the bridge to the occurrence of future earthquake events at the location of interest. While the models calibrated in this paper were tailored to the evolution of the first natural period of the structure, the same procedure can be used to calibrate models for the evolution of any of the state variables that are relevant to the system's capacity and demand. In particular, the calibrated SDEs can be incorporated into the recently proposed frameworks for computing the time-varying reliability of complex engineering systems, which use state-dependent models of the state variables (such as the proposed SDEs). Future works include the investigation of possible additional quantities to be included as regressors (and explanatory functions) in the proposed stochastic formulation, to improve the prediction capabilities of the models.

ABSTRACT: Bridges are critical transportation infrastructure components, serving as vital links for mobility and evacuation during and after hazard occurrences. Ensuring their reliability and safety is of paramount importance. Traditional reliability assessment methods for bridge networks rely on complex mathematical models, often resulting in time-consuming processes. This paper leverages the power of data-driven algorithms to streamline and enhance the reliability and resilience evaluation of this infrastructure. A novel data-driven method of approach is developed to quantify the resilience of a transportation network within a community to facilitate proactive maintenance and decision-making processes. An ensemble of machine learning algorithms is used to train the predictive model and test its prediction accuracy to mitigate the risk of overfitting. Feature engineering techniques are employed to extract relevant information from the dataset, further enhancing the model's performance. Subsequently, the estimated reliability indices of bridges are used to perform network analysis and quantify the resilience of the network and its components by accounting for dependency between network components and the degree of centrality of each component for the mobility of the network. The proposed method is illustrated using real-world data for bridges and transportation infrastructure from a US community. The results show that the proposed approach possesses several features. Firstly, its capability to identify vulnerabilities in the transportation network helps inform decisions about prioritizing maintenance efforts during the life cycle of bridges (i.e., prior to extreme hazards) and prioritizing recovery following damaging events. Secondly, its flexibility to adapt to changing environmental conditions and evolving structural characteristics underscores its potential to be integrated into existing bridge management systems, providing a valuable tool for infrastructure stakeholders to make data-driven decisions and allocate resources efficiently.

1 INTRODUCTION

The seismic resilience of transportation networks, particularly bridges, is a critical factor in maintaining their integrity and safety. These structures are integral to the transportation of individuals and commodities, especially during seismic catastrophes. Investigations in this domain enable a thorough assessment of the susceptibilities within these networks, pinpoint areas of potential frailty, and devise methodologies to bolster their robustness. Comprehending the possible damages that might transpire during seismic incidents empowers engineers and policymakers to judiciously allocate resources for retrofitting, maintenance, and disaster preparedness initiatives (Farahani et al., 2023).

DOI: 10.1201/9781003483755-230

Network connectivity must be considered for evaluating network reliability and resilience, as a transportation network consists of multiple origin-destination pairs and paths. Over the past few decades, significant research has been undertaken on simulation-based metrics for transportation networks. Chang & Nojima (1998) suggested measures based on topology for evaluating the seismic performance of entire highway networks. Ng & Efstathiou (2006) defined network disconnectedness based on the number of unreachable node pairs and the maximum possible number of links. Liu & Frangopol (2006) expanded this disconnectedness concept to include uncertainties in network performance evaluation. Bocchini & Frangopol (2011) introduced the probabilistic full connected ratio, which is the ratio of the number of samples where all nodes are reachable to the total number of samples.

Transportation networks can face disruptions due to various factors that impact bridges, including their strength and the likelihood and severity of hazards (Sabatino et al., 2016). Different stakeholders have different concerns regarding the impacts of bridge failures. Therefore, it is crucial to consider all uncertainties related to the probability of bridge failures and their consequences when evaluating and making decisions about the performance of transportation networks. In recent years, researchers have studied how bridge networks respond to extreme events such as earthquakes (Capacci & Biondini, 2020), scour caused by floods (Liu et al., 2020), corrosion risk (Han & Frangopol, 2022), and the life-cycle performance of bridge parts and systems, considering the best actions, checks, monitoring, maintenance, and repairs (Dong & Frangopol, 2019).

Resilience assessment assists practitioners in measuring the physical, social and economic effects of transportation infrastructure investments quantitatively (Gardoni & Murphy, 2020). To perform resilience assessment, three steps are required (Bocchini & Frangopol, 2012): i) develop fragility curves for different damage levels to determine the probability of damage and functionality loss of structures, ii) link structural damage to the recovery patterns to determine the recovery functions for different damage levels, and iii) calculate the recovery time and resilience curves using recovery functions and the damage likelihood from fragility curves. The literature on the resilience of transportation networks has been very limited due to the high computational complexity, data limitations, and lack of relevant methodologies. Traditional reliability assessment methods for bridge networks rely on complex mathematical models, often resulting in time-consuming processes.

Recent advancements in Machine Learning (ML) have led to the integration of ML algorithms in the field of structural and earthquake engineering for taking advantage of their quick prediction and classification capabilities, among others. ML algorithms can detect and identify patterns in data, allowing engineers to better understand the behavior of transportation networks. This knowledge can be used to develop more accurate models for predicting network reliability and resiliency. Xie et al. (2020) studied the significance of different ML techniques, such as seismic hazard analysis, system identification and damage detection, seismic fragility assessment, and structural control for earthquake-related simulation. Wang et al. (2022) provided a comprehensive review of ML methods for risk and resilience assessment of bridge networks.

This paper aims to leverage the power of data-driven algorithms to streamline and enhance the reliability and resilience evaluation of transportation infrastructure. A novel data-driven methodology is developed to quantify the resilience of a transportation network within a community to facilitate proactive maintenance and decision-making processes. The proposed methodology is illustrated using real-world data for bridges and transportation infrastructure from a US community.

2 NETWORK RELIABILITY AND RESILIENCE ASSESSMENT

2.1 *Network reliability*

To make optimal decisions on investment for maintaining and updating the transportation network, including bridges, it is required to assess the network-level performance probabilistically (Frangopol, 1985). However, measuring the network performance under different uncertainties is often expensive or impossible because of its complexity, such as the connections, interactions, and dependencies among its parts (Frangopol & Bocchini, 2012a). This study uses the matrix-based

system reliability method suggested by Kang et al. (2008) because it can calculate the probabilities of complex system events efficiently using simple matrix operations. The network failure probability (i.e., $E_{Network}$= probability of disconnection) can be obtained as follows:

$$P(E_{Network}) = \sum_{j:e_j \subseteq E_{Network}} p_j = P(e_j) = c^T p, \quad j = 1, 2, \ldots, m \tag{1}$$

where e_j represents basic mutually exclusive and collectively exhaustive events with m total events, in which m is the number of distinct states for the ith bridge in the network, the probability of e_j is demonstrated by p_j. The network event vector is demonstrated by c, which for the jth element is 1 if e_j belongs to the network event and 0 otherwise.

2.2 *Resilience assessment*

Resilience is the capacity to reduce the impact of hazards and restore functionality after an event (Bruneau et al., 2003). The resilience of each bridge can be measured by the post-event functionality Q(t) of the bridge over a certain time period, as shown by the shaded area in Figure 1. The formula for resilience R is given by Frangopol & Bocchini (2012b):

$$\mathrm{R} = \frac{1}{\mathrm{t_h} - \mathrm{t_0}} \int_{\mathrm{t_0}}^{\mathrm{t_h}} \mathrm{Q(t)dt} \tag{2}$$

The hazard happened at time $\mathrm{t_0}$, and the recovery process was checked at time $\mathrm{t_h}$. The network resilience can be obtained as follows:

$$R_{Network} = c^T r \tag{3}$$

where c is the event vector, and r represents the component resilience index vector.

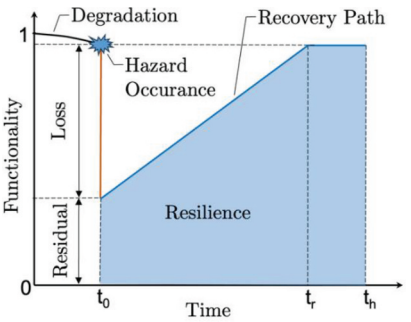

Figure 1. Schematic representation of the resilience of a system. The plot shows the functionality evolution before, during, and following the occurrence of a hazard.

3 PROPOSED METHODOLOGY FOR DATA-DRIVEN NETWORK RELIABILITY AND RESILIENCE PREDICTION

This section presents a proposed data-driven methodology to predict the reliability and resilience of a transportation network within a community. Figure 2 provides an overview of the methodology, which begins with characterizing the transportation infrastructure network. The next step involves implementing seismic reliability and resilience modeling of the networked infrastructure. This is done by i) developing a network connectivity/disconnectivity model and ii) implementing a fragility-based network resilience model using the IN-CORE platform (van de Lindt et al., 2023). The model can quantify the probability of exceeding different damage states for each component under different seismic events. Afterward, the IN-CORE model is used to generate an ensemble of earthquake scenarios by varying the magnitude and epicenter of the earthquakes. Seismic resilience modeling is performed for individual components within the network, and the connectivity/disconnectivity model is used to quantify network reliability and resilience indices.

The outputs of this analysis are then used as input to train reliability and resilience predictive models using an ensemble of ML algorithms that take earthquake event characteristics (such as earthquake magnitude and latitude and longitude of the epicenter) as input and predict reliability and resilience indices. The labeled data is divided into a training set and a testing set, with a ratio of 80% and 20%, respectively. The performance of different ML models is evaluated using two metrics: i) Pearson's r correlation coefficient and ii) coefficient of determination (R2). Pearson's r coefficient is a measure of the statistical relationship between two continuous variables. Its value ranges between -1 and 1, with higher value nearing 1 signifying a perfect linear correlation between the two variables. The R2 quantifies model goodness-of-fit based on the sum of squares method, where values closer to 1 indicate better performance. Conversely, values below zero signify performance that is worse than fitting the values to their median. The scores for each configuration are normalized in ascending or descending order. Models with strong predictive capabilities are evaluated based on a high goodness-of-fit, as indicated by Pearson's r and R2 values. The ML algorithms used in this study are K-nearest neighbors' regression (KNN), Decision trees (DT), Random forest (RF), Artificial Neural Network (ANN), Adaptive boosting (AdaBoost), and Support vector regression (SVR). The prediction accuracy is tested to mitigate the risk of overfitting. To enhance the model's performance, feature engineering techniques are employed to extract relevant information from the dataset.

As shown on the left side of Figure 2, the trained predictive model can ultimately be used by users (e.g., planners and decision-makers) to simulate the effects of an earthquake scenario before it occurs. This can aid in planning and mitigation efforts. Furthermore, the predictive simulation can also be utilized by emergency managers for post-earthquake planning and running scenarios to quantify the impacts.

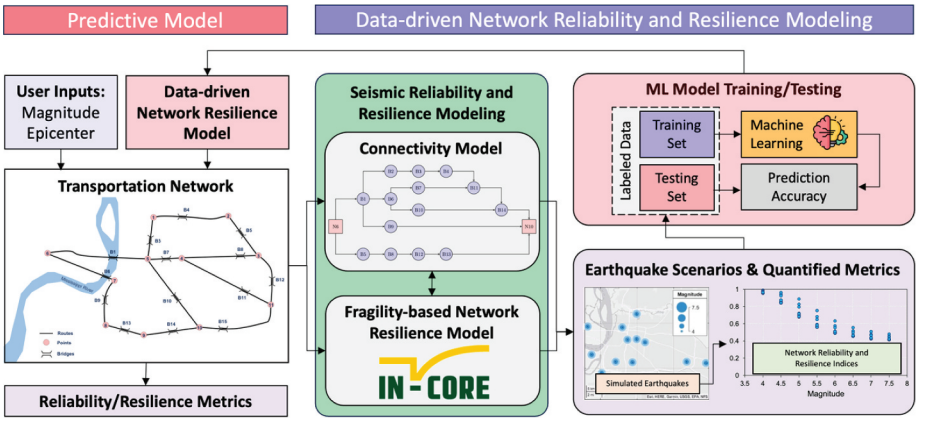

Figure 2. Data-driven framework of quantifying reliability and resilience of transportation network.

4 CASE STUDY

4.1 *Shelby county, memphis, TN, transportation network*

In this study, a simplified transportation network of Shelby County, Memphis, TN, has been employed to demonstrate the proposed approach. For this purpose, routes with bridges are considered and close nodes are merged to each other to show the access point to important centers. As shown in Figure 3, this network includes 11 important access points known as Nodes (1, 2, …, 11) in terms of access to temporary accommodation points, city evacuation, hospitals, and an airport; each route includes a bridge, and a total of 14 bridges are studied in this network. These bridges, which connect critical access points within the city of Memphis, have been selected from the city's bridge network. The bridges are categorized into five different types based on their structural systems, as shown in in Table 1. The geographic location of these bridges is shown in Figure 3 labeled as (B1, B2, …, B14). To calculate the damage probabilities of mentioned bridge types for different

damage states, 104 seismic events were simulated, with magnitudes from 4 to 7.5 on the Richter scale at different network locations, as shown in Figure 3. Various events with different magnitudes occurred at the same location, sharing the same epicenter. The larger earthquakes are represented with bigger circles, while the smaller earthquakes are shown with smaller circles.

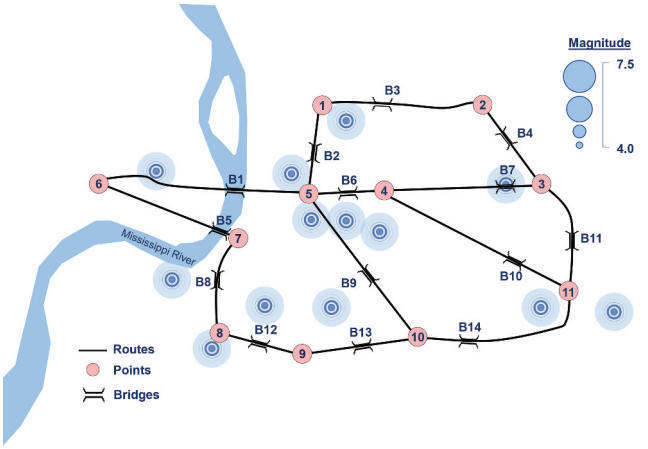

Figure 3. Bridge network representation for the Memphis area and seismic events location.

Table 1. Bridge information in the network.

ID	Classification	Definition	Material
B1, B10, B12, B14, B15	MSSS	Multiple Span, Simply Supported	Concrete
B3, B8, B9	MSC	Multiple Span, Continues	Concrete
B4, B7, B11	MSSS	Multiple Span, Simply Supported	Steel
B5	SS	Single Span	Concrete
B6, B13	MSC	Multiple Span, Continues	Steel

4.2 *Network connectivity/disconnectivity*

The matrix-based system reliability method (Kang et al., 2008) is used to find the network connectivity/disconnectivity between nodes. As an example, Figure 4 shows all the different paths between N10 and N6 that are used to find network reliability and resiliency. To represent any system event, an event vector c can be used, where the jth element is 1 if e_j is part of the system event and 0 if not. Based on the probability rules, the event vector is calculated as follows:

$$c[1] = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \; c[i] = \begin{bmatrix} c[i-1] & \mathbf{1} \\ c[i-1] & \mathbf{0} \end{bmatrix}, \; for \; i = 2, 3, \ldots, n \tag{4}$$

Let $\mathbf{0}$ and $\mathbf{1}$ be the column vectors of 2^{i-1} zeros and ones, respectively. Then, the event vector $c[n]$ has n columns, where the ith column is the event vector of the ith component event E_i, for $i = 1, \ldots, n$. For this example, the event vector can be calculated as follows:

$$C^{N10\to6} = C^{N10\to5\to6} .* C^{N10\to9\to8\to7\to6} .* C^{N10\to11\to4\to5\to6} .* C^{N10\to11\to4\to3\to2\to1\to5\to6} .* C^{N10\to11\to3\to4\to5\to6} .* C^{N10\to11\to3\to2\to1\to5\to6} \tag{5}$$

For example, the event vector for $N10 \to 5 \to 6$ path is calculated as follows:

$$C^{N10\to5\to6} = 1 - \left(1 - C^{E_{B10}}\right) .* \left(1 - C^{E_{B1}}\right) \tag{6}$$

Also, the probability vector is calculated as follows:

$$p[i+1] = \begin{bmatrix} p[i].p_{i+1} \\ p[i].\bar{p}_{i+1} \end{bmatrix} \tag{7}$$

in which $\bar{p} = 1 - p$.

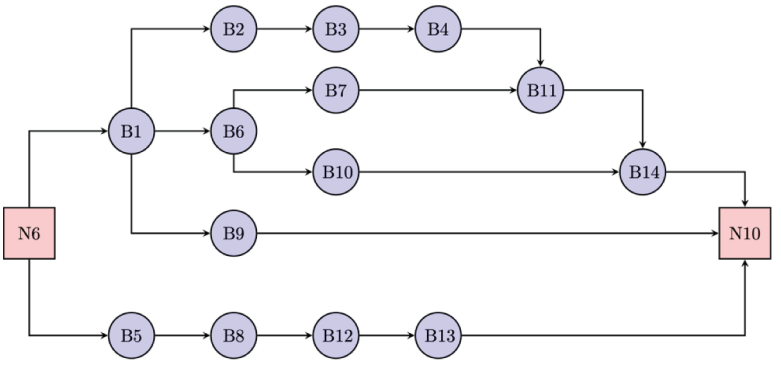

Figure 4. Network connectivity/disconnectivity block for paths from node 10 to node 6.

5 RESULTS AND DISCUSSION

The ML regression methods were applied to the input dataset for the regression of network system reliability and resilience indices. The magnitude, latitude, and longitude of 104 simulated seismic scenarios, as shown in Figure 3, are used as input parameters. Figure 5 represents the calculated actual values of (a) network reliability and (b) network resilience indices based on different seismic scenarios. As the magnitude of the simulated earthquake increases, the network reliability and resilience indices decrease. Furthermore, plot (a) shows a relatively broad range of network reliability index values for each magnitude, implying that an earthquake's location significantly affects network reliability, highlighting the importance of geographic factors in network design. In plot (b), the data points appear to cluster more tightly, particularly at higher magnitudes. This suggests that the network's resilience might be more consistent across different locations when subjected to larger earthquakes. However, there is still some variability, indicating that geographic location affects resilience, but to a lesser extent than it affects reliability. For example, at a Magnitude of 6.0, the reliability and resilience indices vary between 0.18-0.29 and 0.51-0.63 according to the location of earthquake occurrences, respectively. An illustrative example of how the network's resilience can be affected by epicenter is a seismic event that takes place near two routes that converge at a single access point. In this situation, the network's resilience would be compromised for accessing the point that is dependent on these two routes. A hypothetical example of a situation that impacts the network's resilience is a seismic event that happens near B1 and B5, which jeopardizes the movement and escape to access point 6 (N6). This can have consequences for the network's reliability and resilience.

Figure 6 demonstrates the result of ML models using radar plots. The Pearson's r and R2 values for each ML algorithm are calculated. The R2 values are represented by a dashed blue line with circle markers, while the Pearson's r coefficients are represented by a dashed green line with triangular markers. Each ML model on the radar plot is normalized a number between 0 and 1, where a value closer to 1 indicates a more accurate model. The results show that the SVR model is more accurate than other models for predicting the network reliability and resilience indices. Both R2 and Pearson's r values are 1 for SVR algorithm, which indicate it has the best performance in terms of explaining the variance and the strength of the linear relationship with the actual values. Moreover, the ANN algorithm has the subsequent best set of R2 and Pearson's r value after the SVR model. DT, on the other hand, is ranked lowest because it got the lowest reference index, especially in Pearson's r value in both system network (a) reliability and (b) resilience, as shown in

Figure 6. Overall, it is evident that SVR and ANN models achieve some of the highest performance among ML models for predicting the actual values of network system reliability and resilience. For example, for the network system reliability, SVR and ANN achieve maximum R2 scores of 1 and 0.97, and Pearson's r scores of 1 and 0.85, respectively. Moreover, in terms of network system resilience, SVR and ANN achieve maximum R2 scores of 1 and 0.94, and Pearson's r scores of 1 and 0.77, respectively. In contrast, DT algorithm has the poorest performance among ML models for predicting the network system reliability and resilience according to Pearson's r reference index. For the network system reliability and resilience, DT achieves a low Pearson's r score of 0.36 and 0.39, respectively, which indicate that the model has a weak linear relationship with the actual values. These low reference indices suggest that the DT model cannot fit the data well and has a high prediction error. Therefore, DT is not a suitable model for estimating the network system reliability and resilience.

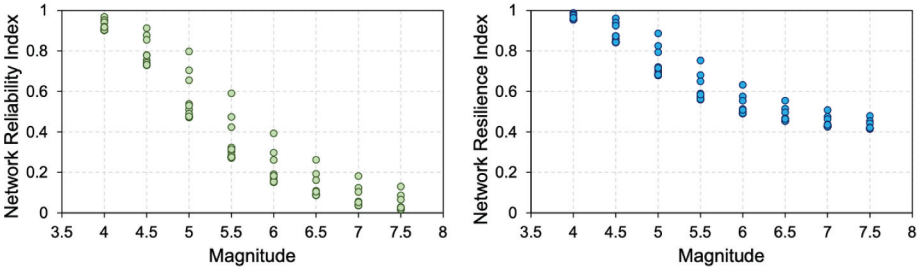

Figure 5. Actual values of network (left) reliability and (right) resilience index for different magnitudes.

The best-tuned model results are presented in Figure 7, where the x-axis represents the actual value of system network (a) reliability and (b) resilience, while the y-axis represents the predicted values by different ML models. The vertical distance of a point from the reference line (1:1 red line) is the error of the specific prediction made by the proposed model's predictions. Various ML models are shown with different colors and markers. Linear regression lines are fitted for a set of actual values to predict the value for network system (a) reliability and (b) resilience across different ML models. The color of each regression line matches the color of the corresponding ML model. As the SVR has the best model performance, its regression line coincides with the reference line, represented by the 1:1 red line. The ideal ML model is the model that the predictive value is exactly equal to actual values, where SVR model nearly demonstrates this case for network system (a) reliability and (b) resilience. The mean square error for the system network reliability and resiliency in the best model (SVR) is 2% and 1%, respectively. Conversely, the DT model, which has the lowest R2 and Pearson's r score, presents a mean square error of 7% for reliability and 4% for resiliency. For both the network system reliability and resilience, SVR regression shows nearly similar slopes to the reference line. Based on this, the predictions made by the proposed models for the network system reliability and resilience are expected to perform well. The data range for the network system reliability is between 0 and 1, while the network system resilience range is from 0.4 to 1. This could be why machine learning (ML) models predict the system network resilience slightly better. However, the predictions for system network reliability seem to follow the same trend as the system network resilience, as indicated by various ML models. Therefore, the proposed models are expected to make adequate predictions for both the network system reliability and network system resilience.

6 CONCLUSIONS

This paper presents a data-driven methodology for predicting the reliability and resilience of a transportation network using seismic reliability/resilience modeling and machine learning (ML) algorithms. The methodology involves characterizing the network, implementing seismic

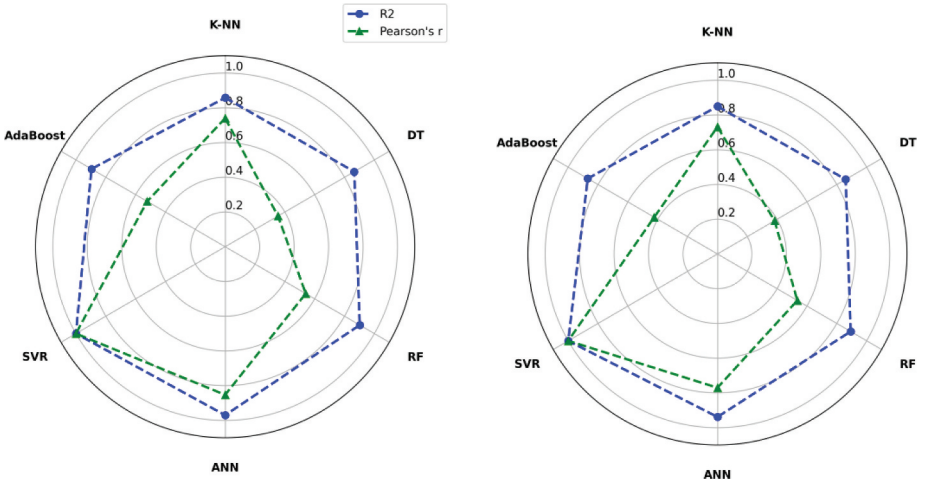

Figure 6. Reference index of network system (left) reliability and (right) resilience for various ML models.

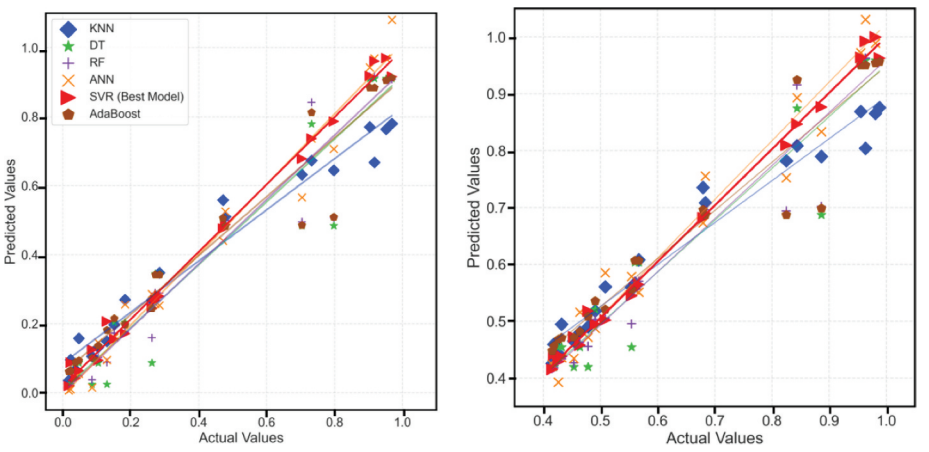

Figure 7. Testing results of proposed ML-based network system (left) reliability and (right) resilience models.

modeling, generating earthquake scenarios, and training predictive models using ML algorithms. The performance of the models is evaluated using Pearson's r coefficient and coefficient of determination (R2). The ML algorithms used include K-nearest neighbors' regression, Decision trees, Random forest, Artificial Neural Network, Adaptive boosting, and Support vector regression. Feature engineering techniques are employed to enhance the model's performance. The models demonstrated the significant impact of an earthquake's magnitude and epicenter location on the network's reliability and resilience. This prediction aids in the recovery of community services by establishing a theoretical calculation of the reliability and resilience of a bridge network.

The proposed framework has been illustrated using a simplified bridge network of Shelby County, TN. The results show that as earthquake magnitude increases, the network system reliability and resilience decrease, with variations attributed to earthquake location. The SVR and ANN models exhibit high performance in predicting the actual values of the network system reliability and resilience, as indicated by their high R2 and Pearson's r scores. The models' predictions for the network system reliability and resilience indices are reliable, as they align closely with the reference line. The mean of the residuals being close to zero suggests an even distribution and absence of systematic bias.

Forecasting the condition of British railway bridges via a hindcast

M.J. Hamer & G.S. Calvert
Network Rail, Milton Keynes, UK

ABSTRACT: Bridges are critical assets for the safe, reliable, and functional operation of transportation networks. Estimating future safety and reliability measures through predicting changes to asset condition, forecasting required interventions, and developing equitable resource allocations from limited budgets is a challenging task. Network Rail (NR) is the infrastructure manager for the railway in Great Britain and is responsible for the management of over 26,000 bridges. NR uses a strategic model (Bridges Forecasting Model) to forecast the work volumes, expenditure, and condition outputs for its bridge portfolio in different funding scenarios. In this paper a 'hindcast' exercise is presented. A hindcast has been employed to refine model parameters by calibrating the modelled bridge condition against the portfolio's observed condition profile between 2010 and 2023. This has enabled key decision makers (Government, regulators, central and regional asset engineers in NR) to have greater confidence in the outputs of the forecasting model.

1 INTRODUCTION

Operational railways are complex systems that are reliant on the dependable performance of a large quantity of different assets across several asset disciplines including track, signalling and civil infrastructure. For the civil infrastructure, bridge management and maintenance command a sizeable demand on resources to ensure the continued provision of safe service, with the Structures portfolio at Network Rail having £2.305 billion (~75% for bridges) allocated for renewal activities in Control Period 7 (CP7) (April 2024 – March 2029) (Office of Rail and Road, 2023).

The structural assessment and reliability analysis of bridges is well documented in the literature (Frangopol, Dong, & Sabatino, 2017). As part of the asset management strategy for bridges, decision support tools known as Bridge Management Systems (BMS) have been developed to support infrastructure managers in their decision making (Mirzaei, Adey, Klatter, & Thompson, 2014).

Network Rail (NR) has the Bridges Forecasting Model (Hamer, Calvert, & Neves, 2022), which predicts the condition of the portfolio of bridges in different funding scenarios. The purpose of this paper is to outline a hindcasting exercise, i.e. test the model by comparing its results over a historical period to real observations. The aim of which was to calibrate the model's parameters and hence improve the model's accuracy in terms of its ability to forecast future condition. Section 2 provides contextual information about NR and its Structures portfolio and asset management strategies. Section 3 outlines the Bridges Forecasting Model including its purpose, how it degrades assets and performs interventions. The hindcast itself is set out in Section 4, starting with the set-up, laying out different intervention effectiveness options, a comparison to the observed condition history of the bridges, and the applications of the findings.

DOI: 10.1201/9781003483755-231

2 BACKGROUND INFORMATION

2.1 *Network rail*

NR owns and operates the railway infrastructure in England, Wales and Scotland on behalf of the nation. That is over 30,000 km of track, over 26,000 bridges, 16,000 km of earthworks and thousands of signals, level crossings and points. It is also responsible for maintenance at 2,500 train stations, fully managing 18 of the largest. The network provides a vital service for passengers and freight users. It is of great strategic importance, both in terms of economic stimulation and within the low carbon agenda, it is a green mode of transport, but secondary it also reduces road usage. Hence, the importance for the railway service to be safe, reliable, and good value for money.

NR is financed by the UK government and paying customers (passengers and freight services). The infrastructure is managed in a devolved structure with decisions on which assets to renew/maintain made at region and route level. Here are regions (bold) and routes: (**Eastern**: Anglia, East Midlands, North East, and East Coast. **North West & Central**: North West, Central and West Coast. **Scotland**. **Southern**: Kent, Sussex and Wessex. **Wales & Western**: Wales and Western). Every five years, NR must apply for funds to maintain the asset portfolio. As part of that submission, NR must demonstrate that it understands the expected changes in portfolio asset condition over a 35-year horizon for different funding scenarios, hence a model is required.

2.2 *Structures portfolio*

The structures portfolio at NR is responsible for underline bridges (rail-over-road), overline bridges (road-over-rail), footbridges, tunnels, retaining walls, culverts, and coastal, estuarine and river defences. There are over 26,000 underline and overline bridges (60,000 decks) and they dominate the repair investment, and consequently the modelling focuses on those assets. The UK has some of the oldest rail bridges in the world; the majority of the NR portfolio was built in the 19th century. There are a wide variety of materials employed, typically classified into concrete, masonry, metallic, and timber, with many bridges composed of mixed materials. However, there are significant differences within each of those broad material types, for instance, the metallic category ranges from cast iron to modern steel. Some bridges are in benign rural environments, others are close to the coast (high salinity) or within highly corrosive urban environments. Whilst underline bridges receive greater loading than overline bridges, there are great differences between train traffic on different lines. Perhaps most problematic is that it is very difficult to even guess the usage, loading and maintenance history of a bridge that has been in service for well over 100 years. All this uncertainty and variability makes it a huge challenge to model the future condition and performance of these assets.

2.3 *Condition measurements*

Bridges are subject to three types of examination. There are yearly visual examinations that are brief and are principally to check if there have been any significant changes from the previous year. Detailed examinations produce a full report that summarises the condition of all the minor elements on the bridge, however, these occur with less frequency. The scheduling of detailed examinations are risk-based and range from an interval of one year for bridges in very poor condition to every eighteen years for good bridges; on average, bridges are examined every seven years. Digital records began at around the year 2000, typically bridges have 2-3 detailed examinations at present. Finally, capability examinations assess the strength of the bridge against its loading requirements, these are far less frequent and as a result typically each bridge has only had one performed. They are undertaken to quantify the relevance in changes in condition to understand the asset's capability for the existing or future loading requirements.

During a detailed examination, the two most significant defects on each minor element receive a score based on the severity and extent. The scores are alpha-numeric with severity (alpha component) defined by the seriousness of the defect and extent (numeric component) determined by how wide-spread the defect is on the element. For the bridges model, the scoring system is simplified onto a one-dimensional scale (0 (bad) – 100 (perfect)). The quasi-linear conversion between the alpha-numeric scale and the one-dimensional scale is derived from engineering judgement, the conversion is also irreversible because it is a many-to-one mapping. See (Hamer, Calvert, & Neves, 2022) for full details.

Using the detailed examination's minor element scores, a weighted average calculation can be performed to find the BCMI (Bridge Condition Marking Index) of an individual deck or an entire bridge. This is scored on the same 0-100 scale with 100 being perfect condition. Some minor elements are more important than others, the structurally important elements are denoted as Principal Load Bearing Elements (PLBEs), e.g., main girders. Finally, the definition of poor condition is important because that is typically the trigger to intervene with repair work, for masonry and concrete minor elements that is defined as elements with a BCMI less than or equal to 50, whereas for metallic and timber elements the poor threshold is 40. At portfolio level, two measures are typically calculated and monitored: BCMI which is a measure of the average condition, and the fraction of PLBEs in poor averaged per deck which relates to risk and is a measure of the size of the tail of the distribution.

2.4 *Interventions*

There are numerous ways that bridges are worked on, with vast differences in their scale, cost, and impact. At NR, there is a Cost and Volume handbook, which defines how to categorise and report the cost, scale and type of works. There is a large variance in the size of bridges, Work Volumes are reported in terms of the area (m^2) worked on. In CapEx Renewals, bridge interventions are reported within:

- Replacement
- Strengthening
- Repair
- Preventative
- Waterproofing

There is still a large degree of variance within those categories, and it is not uncommon for multiple work types to be performed on the same deck. Replacement and Strengthening interventions are usually to combat insufficient capability. Replacement is typically installing a new bridge deck but not all of the original bridge will necessarily be replaced, the supports for example could remain. Strengthening activities insert additional support to the structures (e.g. metallic beams) or modify the existing elements. Repair work is usually fixing defects relating to the condition of the elements. Preventative work refers to improving the surface protection, for example, the paintwork for metallic elements. Waterproofing is activity related to protecting the bridge from water ingress and would not be expected to vastly improve condition. Bridges also receive Minor and Reactive repair works; these are typically cheap activities but are still highly variable and it is difficult to assess the benefit to BCMI condition.

3 FORECASTING MODEL METHODOLOGY

3.1 *Modelling purpose*

Forecasting the impact of projected spend on asset condition is a management and regulatory necessity. The regional businesses themselves decide how much maintenance to perform and

to which assets, the modelling provides 'guidance' and 'assurance'. Typically, there are three broad questions that a forecasting model needs to address:

- How much work volume/spend is required to maintain a long-term steady state condition distribution for an asset portfolio?
- What is the long-term impact on condition for different scenarios of work volumes/ funding?
- How should funding be split at regional and route levels?

To attempt to answer those questions, mathematical models have been employed. For bridges, the methodology is 'bottom-up' and models each of its 26,000 bridges individually using a probabilistic simulation with all events (asset degradation, intervention selection and effectiveness, prioritisation) simulated stochastically.

This paper is largely concentrated on modelling large asset portfolios. NR has historically used modelling for different purposes as well. Previously, the focus of activity was more on asset level modelling. This modelling was applied to find answers to the following questions for a typical asset, for example, a generic metallic bridge: How often to inspect? What condition thresholds should be applied to trigger interventions? What type of interventions should be performed in different circumstances? These results have helped to define Asset Policy, which is a set of engineering rules regarding what interventions to perform in different conditions and those are the basis of the model's rules, even at the portfolio level.

The Bridges Forecasting Model is hosted on an Asset Investment Planning platform developed by Copperleaf Technologies alongside other NR asset models (e.g. Track and Signalling). However, the model is bespoke and the intellectual property is developed and owned by NR.

3.2 *Asset degradation*

In order to understand how bridge condition degrades with time in the future, it is crucial to look at the records of the past. NR has about 20 years of examination data, however that is still only a small fraction of most bridge's lifetime. On average, each bridge has received two or three detailed examinations on record.

The model degrades condition at minor element level because this is the most detailed level at which examinations record condition. To model one minor element's future condition, historical behaviour is the best source of understanding, however rather than using just information from its past, it is more useful to amalgamate the records of all similar elements together to produce greater intelligence. The model uses condition states, defined by the one-dimensional scores described in Section 2.3. It operates in yearly timesteps and hence each minor element has a probability of moving from each condition state to all possible output condition states.

The calculation of these probability matrices used a frequency approach and required several assumptions. The frequency approach requires that the interval between examinations is fixed and at NR the interval between examinations is variable, thus a normalisation procedure was performed to calculate probabilities for a five-year interval.

Additional assumptions were required on which records to exclude. Records were excluded from analysis because an element's condition improved, i.e. suspected maintenance work performed. Alternatively, records could be excluded because of extreme deterioration, which potentially could be due to an external factor, such as vehicle incursion.

Environmental factors such as being close to the coast (high salinity) or in an area of high corrosivity can significantly affect the degradation of bridge elements, particularly metallic elements (Calvert, Hamer, Neves, & Andrews, 2023). The model adjusts the probabilities in the degradation matrix to either accelerate or decelerate the expected degradation profile.

Correlated degradation of bridge elements is little understood and requires significant research. However, the model does implement a crude form of correlated degradation if two

minor elements of the same type and material are in similar condition then there is a probability that they degrade in a correlated manner.

Finally, capability information is held at deck level and is a large driver of work both in the model and reality. The current methodology is crude and degrades capability with time, dependent on the condition of the deck's minor elements. A greater understanding of capability degradation is a clear requirement to improve the model.

3.3 *Interventions – candidate selection and prioritisation*

To ensure the model replicates reality as much as possible and since examinations are infrequent. First the model must perform its own examinations and hence store two condition values: 'Actual' and 'Revealed', the former updates every year, while the latter only updates after a modelled examination. Then intervention decisions can only be made using the 'Revealed' condition information.

The logical framework for how invention candidates are suggested in the model was detailed in (Hamer, Calvert, & Neves, 2022). In summary, it is based on Asset Policy, with the model responding to either poor capability or condition with appropriate activities on an appropriate timescale. Replacements and Strengthening work address poor capability. Repair and Preventative schemes are driven by poor condition. Large works can either be performed to a group of minor elements on a deck (CapEx Renewals) or smaller works target single minor elements (Minor or Reactive Works). There are also opportunities to do Secondary or Tertiary works to elements of a different material or adjacent supports on the back of a large Primary works.

A critical function of the Bridges Forecasting Model is its ability to constrain and prioritise the suggested candidate interventions, this is how different funding scenarios can be assessed. The model has the functionality to constrain on cost and work volume with each model year potentially having a different constraint. These constraints are typically applied to portfolios at either national, regional, or route level.

To fit within constraints, the model must prioritise its assets to decide which receives work first. The model prioritises at deck level with a flexible formulation that includes asset condition, capability, and criticality (some bridges are on busier lines and are therefore more critical than others). However, if the model was to apply this prioritisation rigorously, then only the very worst decks would receive work and huge benefits to asset condition would be witnessed. In reality, engineers consider a multitude of sources of information before judging which intervention activities to prioritise and the information the model holds is only a small part of the picture. Hence the model has the ability to apply random 'noise' to the priority score, calibrating that functionality is challenging.

3.4 *Intervention effectiveness*

In practice, bridges interventions vary significantly, even within the broad categories of Replacement, Strengthening, Repair, Preventative, Waterproofing, and Minor Works. Hence, the resultant condition post-intervention varies too. The works might only be able to fix certain types of defects or cover a small area of the deck and miss other less severe defects. Therefore, it is crucial the model has the functionality to vary the effectiveness, i.e. amount of benefit to asset condition, of interventions. Replacement works are expected to deliver a new deck and hence perfect condition. Strengthening works and Repair interventions provide some condition benefit but vary hugely and therefore are difficult to quantify. Minor works might only benefit one element and so have minimal effect on the whole deck. Preventative and Waterproofing are expected to have minimal direct condition benefit, but they could slow future degradation.

These post-intervention condition distributions can be defined by intervention type and the material targeted. However, defining intervention effectiveness is challenging, a mixture of data analysis and engineering judgement is required.

4 HINDCASTING THE BRIDGES PORTFOLIO

Hindcasting is testing a mathematical model by comparing its results over a historical period to real observations. The intention of performing a hindcast on the Bridges Forecasting Model is to improve its accuracy by calibrating the model parameters so starting from some historical point in time, the model accurately matches present day condition. The steps required to execute the hindcast are:

- Identify a set of bridges with at least two examinations between some historical point and present day.
- Estimate the amount of CapEx renewals and Minor and Reactive work that has been performed to those bridges.
- Execute the Bridges Forecasting Model with that sample of bridges and compare modelled output condition to observed condition measures.
- Adjust the intervention effectiveness parameters (both in terms of asset selection and condition benefit) with the aim being to match observed condition. (At present the degradation behaviour in the model is fixed)

4.1 *Setting up the sample portfolio*

Due to NR's 5-year Control Periods (CP) and reporting mechanisms, the earliest reliable estimates of CapEx Renewals work performed are from 2010 onwards, so that is a logical point to begin the hindcast. In CP5 (2015-2019) reported work volumes in our Annual Return includes work type detail, but in CP4 (2010-2014) the work volumes are total only, hence the work type mix must be inferred from engineering judgement.

For an asset to be useful in a hindcast it must have had at least two examinations. Given that examinations are risk-based, and some bridges are on long intervals, the number of bridges with at least two examinations from 2010 onwards is about 60% of the portfolio. However, that 60% is a biased sample because on average these bridges are in a worse condition than the full portfolio. Moreover, the material distribution is skewed towards metallic because they are typically on shorter examination intervals. Hence the sample of bridges was modified by removing bridges at random, such that the average condition (BCMI) and the distribution and condition of the different material types aligned to the full portfolio. As a result, roughly 50% of the portfolio was utilised within the hindcast, which was deemed a sufficient sample.

4.2 *Intervention effectiveness options*

The effectiveness or the quantity of condition benefit from interventions is probably the largest source of uncertainty within the Bridges Forecasting Model. The effectiveness of interventions is difficult to accurately quantify because as discussed in Section 2.4 interventions are highly variable. Also records of completed works are sparse; applicable records were only available for 5 years (2015-2019) from roughly 50% of regions. The whole sample was less than 1000 work descriptions. Additionally, records are labelled at bridge level which, for multi-deck bridges, it then becomes difficult to judge which decks received work. The final problem is that, for the intervention record to be useful, ideally there would be an examination immediately before the works and another immediately afterwards. In practice however, examinations tend to be many years before the works and also many years after the works or even not performed yet, hence any impact of degradation needs to be assumed and accounted for.

To understand the effectiveness of interventions, two aspects need to be considered. The first is how well targeted the intervention was, hence analysing the asset's BCMI score before the works, in order to help calibrate the efficiency of the prioritisation in the model. The second is the improvement in BCMI score produced by the works. There are many ways to analyse the work history data, Table 1 sets out three options for estimating intervention

effectiveness depending on how the work records are filtered and analysed. Note that that the impact of degradation has been assumed within these results.

- The **'Lower'** option includes all activities that improve a single minor element score by 5 or more, this allows the whole deck to get worse. This filter is likely to be too lenient because Minor and Reactive Works to decks adjacent to workbank decks are potentially included.
- The **'Middle'** option focuses on the most improved deck on each bridge listed, with the idea being to inhibit the multi-deck reporting problem. Hence, this set neglects multi-deck schemes and with no minimum improvement criteria, data errors where no actual work takes place are also included.
- The final **'Upper'** option includes all works where the whole deck improves by more than 2.5 BCMI points. This option does neglect any works with minimal benefit to condition.

Based on reported Work Items and engineering judgement, Minor and Reactive works have been modelled by performing a set number of Single Element Works in each of the three effectiveness options. In terms of the number of Single Element Works for the full portfolio, the Upper, Middle and Lower scenarios are given 3,300, 1,700 and 1,100 respectively per year. Summarising in simple terms, so that only one Single Element Works can apply per deck then those activities equate to 5.6%, 2.9% and 1.9% of the decks for each scenario.

Table 1. Intervention effectiveness quantification options.

Scenario Options (Sample Size)	Criteria	Average BCMI before Works	Average BCMI Improvement	Comments
Lower (966)	All decks, any element improvement by >= 5	46.9	14.3	Likely includes Minor and Reactive Works
Middle (517)	Most improved deck on each bridge	43.9	18.0	Neglects multi-deck schemes
Upper (690)	All decks, deck Improvement by > 2.5	42.9	23.5	Neglects any work with minimal BCMI improvement

4.3 *Comparison to the observed history of bridge condition*

The hindcast model runs begin with each bridge in the condition from their first examination from 2010 onwards, that is declared Year 0. The model run includes all bridge decks in the sample and proceeds for 13 years (the maximum gap between first and last examinations for a single deck). Asset degradation is applied each year as well as appropriate levels of CapEx Renewals and Minor and Reactive work activities. The model outputs that are relevant for comparison to the real history are the condition outputs at the year of each deck's last examination, after that the condition is irrelevant because the real history is unknown. Hence, each deck is considered 'active' within the hindcast up until the year of its last examination and this ranges from 1 to 13 years. 6 years is the most populous interval and the average time spent in the model is 7.1 years.

Figure 1 displays the condition outputs (average BCMI and PLBEs in Poor) of the hindcast modelling for the underline bridge decks with a 6-year examination interval. Selecting different interval slices (e.g. 12-year) show similar results as well as grouping all decks together. Alternatively, investigating the Mean Squared Error (MSE) of the model runs against the real history also produces similar results. Both in terms of average values and MSE the 'Upper' intervention effectiveness option fits well for BCMI but the 'Middle' option works better for PLBEs in poor.

In order to produce a better fit with the real history, the model's intervention effectiveness settings were modified. The prioritisation efficiency was lowered, and the intervention effectiveness distributions were modified such that the BCMI improvement was similar to the

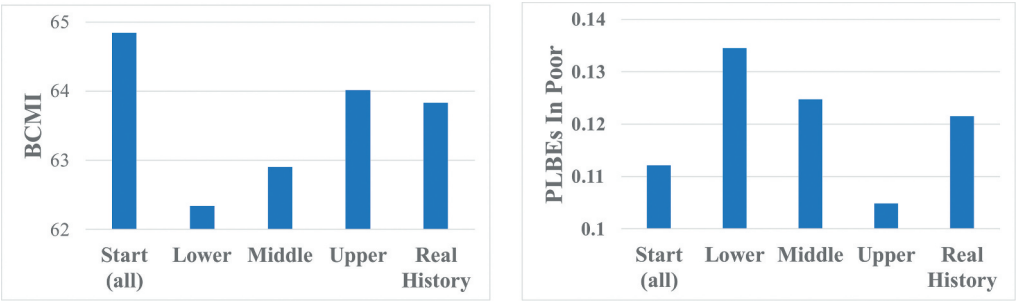

Figure 1. Average condition (BCMI and fraction of PLBEs in Poor) of Underline bridge decks on a 6-year examination interval at the start (first examination), then after 6 years in the model with the three intervention effectiveness options (Upper, Middle, and Lower) as well as the real history (last examination).

'Upper' option, but the distributions were stretched so that more elements remain in poor condition after works as per the 'Middle' option. Compared to the model parameters used in previous planning rounds this change weakened the effectiveness of modelled interventions. Effectively making the Steady State (hold portfolio condition static) scenario more expensive as a greater amount of work is required for the same condition benefit.

4.4 *Application of hindcast findings*

NR's internal and external stakeholders require confidence in the Bridges Forecasting Model's methodology and assumptions but ultimately it needs to be accurate, as the model influences decisions made around the levels of investment provisioned for bridges. This study demonstrates how the forecasted outputs from the model are likely to be more accurate as they have been calibrated on real world portfolio behaviour. Specifically, for planning the next five years (CP7), hindcasting has provided the justification for weakening the intervention effectiveness and hence increasing the required work volumes/funding for the same desired condition outputs in comparison to previous planning rounds. The model and its outputs have become critical evidence in the business planning process supporting the basis for greater funding if the bridges portfolio is going to be held at current condition.

5 CONCLUSIONS

This paper has presented a hindcasting methodology that has been utilised to calibrate NR's Bridge Forecasting Model. The method takes a sample of bridges and models, using degradation and interventions, forward in time from a set of examinations in the recent past with the aim of meeting present day condition. The model has many uncertainties, but the motivation behind hindcasting is that the inaccuracies in asset degradation and intervention selection and effectiveness would somewhat cancel out.

The limitations of the available data and model methodology are explained in greater detail in Hamer, Calvert and Neves (2022); however, it is worth restating the key sources of uncertainty. Bridge examinations are sparse and prone to the subjectivity of examiners. Currently the defects are not tracked and consequently assumptions are required to relate condition across successive examinations. Additionally, there is no engineering context with the condition data, i.e. a low BCMI score does not necessarily mean a repair is required. For hindcasting, accurate and extensive intervention records are crucial, without which it is difficult to know which decks have received work from bridge-level records. Minor and Reactive work records are very crude, especially quantifying condition improvements, so there is a large uncertainty in the quantity of those types of work. The model also has documented weaknesses, implementing asset degradation via a maximum likelihood approach with defect

dependencies would be a vast improvement (Calvert, Neves, Andrews, & Hamer, 2021). Further work would also be beneficial in the areas of environmental factors, correlated degradation of neighbouring elements and capability degradation.

As the existing funding environment is constrained, regions and routes must compete harder for government investment against other NR assets, within the transport sector and with other public spending obligations. It becomes imperative that spending plans are fully justified. Hence it is now even more critical that the Bridges Forecasting Model has been through a comprehensive validation process so that all stakeholders can have high confidence in the model outputs and the likely performance of the Bridges portfolio. This was the first attempt at hindcast analysis for bridges modelling at NR. It will no doubt be an iterative process which will need to be built upon year-on-year as more information is produced.

ACKNOWLEDGEMENTS

Matthew Hamer is a Principal Mathematical Modeller (matthew.hamer@networkrail.co.uk) and Gareth Calvert is a Whole Lifecycle Costing Manager (gareth.calvert@networkrail.co.uk), at Network Rail. Comment and collaboration opportunities from infrastructure asset managers involved with bridge management and modelling are welcome.

Vulnerability of network infrastructure due to potential extreme weather in PEI, Canada

D.J. Evans*
Prince Edward Island Department of Transportation and Infrastructure Charlottetown, Prince Edward Island, Canada

R.M. Ellis*
Stantec Consulting Ltd. Edmonton, Alberta, Canada

ABSTRACT: The Prince Edward Island Department of Transportation and Infrastructure (DTI) is responsible for the densest network of roadway and bridges per capita of any of the Canadian Provinces. DTI own and manage a variety of structures, with about 99.5% of which cross some sort of waterway (a creek, stream or river). Of the water crossing structures, approximately 11% of these are coastal in nature.

Over the last 16 years, DTI has adopted bridge management processes including implementing an advanced bridge management system (BMS). This has enabled the department to make significant improvements in the management of inventory and inspection data, the inspection process, tracking and reporting condition through a standard condition index, performing asset valuation, and in handling of inspection photos, videos, plans and other documents.

Recently, as a result of increased extreme weather events, there have been growing concerns related to the risks to our infrastructure and infrastructure resiliency. Rising sea levels are affecting the PEI coastline with estimated erosion of 30 cm per year and potentially affecting tidal flow in coastal rivers. Storm intensities are increasing; PEI was battered by Post Tropical Storm Fiona in September of 2022, which, among other destruction, downed several hundred hectares of woods in our province which still lays there today. In Spring 2023, wildfires occurred in many provinces across Canada, including several thousands of hectares in neighboring Nova Scotia.

DTI, in conjunction with Stantec, are implementing appraisal indices to include the effects of extreme events on flooding, scour, wildfires and other vulnerabilities and providing useful risk analysis and a measure of resiliency. This paper will highlight how the province is adapting our BMS to account for potential extreme weather-related events, such as flooding, scour, and wildfires. The paper will be of interest to other jurisdictions who manage bridges and culverts.

1 INTRODUCTION

1.1 *Prince Edward Island, Canada*

The Province of Prince Edward Island (PEI) is situated on the east coast of Canada and is the smallest of all the Canadian Provinces. The province has 5660 km of natural waterways throughout its land mass and is crossed at various locations by 5600 km of roadway network with over 1400 structures. It sits anywhere between a low elevation 0.00 m to a peak elevation of 142 m. Its geology is founded on weak to moderate sandstone bedrock overlaid with variations of glacial till, marine sediment deposit, silty sands and silty clays.

The primary industries, agriculture, and aquaculture, rely heavily on the surrounding environment and also rely heavily on the transportation network to get their products to market.

*Corresponding author: djevans@gov.pe.ca, Reed.Ellis@stantec.com

DOI: 10.1201/9781003483755-232

The department has spent the last 16 years developing and maintaining a Bridge Management System (BMS) for the provincial network of structures. Of the 1400 structures, only 289 are inspected on a biennial basis (i.e. once every two years). As of the end of 2023, the department completed its ninth full round of biennial inspections. The remaining structures (buried culverts) are being inspected and input into the system; however, reports on the first full cycle of these structure inspections will not be complete until 2024.

Recently, due to increased extreme weather events, there have been growing concerns related to the risks to our infrastructure and infrastructure resiliency. Rising sea levels are affecting the PEI coastline with estimated erosion of 30 cm per year and potentially affecting tidal flow in coastal rivers.

This paper will highlight how the province is adapting our BMS to account for potential extreme weather-related events, such as flood, scour, and wildfires. The paper will be of interest to other jurisdictions who manage bridges and culverts.

2 BRIDGE INSPECTION

2.1 *Inventory*

Like most jurisdictions across Canada, PEI's bridge inventory is a product of the construction boom from the late 50's to the early 90's. A good portion of the department's inventory is at or very near its intended design life and many structures are nearing the end of service life.

Like many other jurisdictions, the department continues to struggle with the condition of the inventory and the available capital dollars which are available to address these issues.

More information regarding the evolution of bridge inspections and bridge management in Prince Edward Island can be found in Evans et.al, 2014 and Evans, et.al, 2012.

3 BRIDGE MANAGEMENT SYSTEM

3.1 *Evolution of BMS on PEI*

DTI have historically relied on hard paper copies of our safety inspections with a rudimentary spreadsheet for asset management data. This housed such information as structure ID, structure type, material, span length, age (if known), location, route number, and other basic information.

After a literature review, the department decided on the best fit BMS for our inspection program, which was Ontario Bridge Management System (OBMS) (Thompson et.al, 2003). The BMS was compatible with the adopted inspection methodology of the Ontario Structure Inspection Manual (OSIM) (MTO 2000). This methodology is adopted by the majority of provinces in Canada and is based on element level, condition state inspection which is the most common inspection methodology used in bridge management systems today (Mirzaei et al. 2014). There are four (4) condition states Excellent, Good, Fair, and Poor and the inspection manual provides detailed descriptions of the defects for common bridge materials and how to rate the severity and extent of defects.

The department's consultant had been working on significant improvements to the OBMS and in 2010 the department licensed and implemented the new Stantec BMS platform as the new PEI BMS (Evans et.al, 2010).

3.2 *Stantec BMS*

The PEI BMS is compatible with inspection data in the OSIM format and calculates the Bridge Condition Index (BCI) (MTO 2009). There are many built-in reports that support the department in better managing bridge and culvert assets. The BMS meets or exceeds all the requirements of documents such as the AASHTO Guide to Bridge Management (AASHTO, 1994) and Bridge Management in Europe (BRIME 2002).

STANTEC BMS offers the following capabilities that were of interest to the department:

1. Improved photo, video, document management including search capabilities,
2. Automated project scoping and treatment selection using engineering models and benefit-cost analysis,
3. Element, project and network level risk analysis,
4. Network-level priority programming and budgeting,
5. Network and individual bridge target performance analysis,
6. Risk-based decision making,
7. Risk-based setting of inspection frequencies.
8. Bridge asset valuation
9. Tracking Critical Findings
10. Automated reporting of key performance indicators (KPI)

For further information regarding the capabilities of STANTEC BMS and other features, please refer to Evans et.al, 2014, Evans et.al, 2012, Ellis et.al, 2012 and Dalziel et.al, 2012.

4 VULNERABILITIES AND CONSEQUENCES

Being a province with highly erodible soil and being very close (or at) sea level poses some challenges with respect to flooding and scour.

Since 2002, the province has been subjected to increased storm frequency and intensities, which are described in Table 1.

Table 1. Significant weather events by year.

Year	Event	DTI Repair costs ($CDN)
2000	Storm surge event	$ 500 k
2003	Post Tropical Storm Juan	$ 2.8 M
2008	Post Tropical Storm Hanna	$ 1.8 M
2010	Rainfall/Wind event	$ 850 k
2014	Rainfall Event	$ 7.9 M
2019	Post Tropical Storm Dorian	$ 1.5 M
2022	Post Tropical Storm Fiona	$ 4.1 M

These events caused a variety of damage to our infrastructure, including that to roadways, culverts and bridge structures alike; however, there has historically been no method to account for the increased likelihood of a weather event impacting our infrastructure nor the consequences associated with these events.

4.1 *Flooding and scour*

As noted, the province is highly susceptible to flood and scour, be it by overland flooding due to significant rainfall events or by coastal flooding due to storm surges and wave run-up. These events have impacted how our transportation network functions and have been the cause of serious delays and loss of property.

Several locations have been damaged due to the storm events listed in Table 1. As expected, repairs and enhancements to these structures were a reactionary response to an environmental issue; however, this is not always the case.

In 2010, we replaced a structure in Darnley PEI. The former structure was a sixteen span, timber piled bridge structure with a vertical clearance of 4.06 m from HHWMT to the underside of the structure, with the top of the structure at 4.66 m above HHWMT. The new structure has a vertical clearance of 4.66 m above HHWMT with the top of the bridge deck being 6.865 m above HHWMT. The minimum bearing seat elevation on the north end of the

Photo 1. Scour due to overland flooding.

Photo 2. Erosion due to coastal effects.

structure is given at 3.044 m PEI Geodetic, NAD 83 (Hatch Mott MacDonald), which converts to Elev. 2.673 m CGVD2013.

In 2022, Hurricane Fiona introduced a tide elevation of 3.12 m CGVD2013 at the Darnley Tide Gauge, with a peak wind speed of 127.4 km/hr (Jardine, 2023). While this severely impacted the causeway approaches, it did not affect the structure in any measurable means. Had DTI not replaced the structure in 2010 and proactively raised the roadway profile, it would have undoubtedly resulted in a catastrophic loss of the structure. See photos 3 and 4.

Photo 3. Darnley Bridge During Fiona.

Photo 4. Darnley Bridge Post Fiona.

It's interesting to note that the average erosion rate for PEI prior to Fiona was in the 30 cm/ year range. The erosion loss due to Fiona was between 10.0 m in several locations and up to 25 metres in one location, roughly 30 to 80 years-worth of erosion in a single event. See photos 5 and 6.

4.2 *Wildfires*

While significant wildfires in the province of PEI are rare, they do occur. Between 1958 and 2012 (inclusive) there have been 107 wildfires recorded, with the most significant wildfire in 1960, destroying 6880 acres (2800 Ha) of wooded areas and countless properties. There are no records of any damage to any transportation structures.

However, 2023 has set a record in Canada, with over 18 million hectares lost to wildfires this year alone. In May of 2023, there was a wildfire in Crowbush PEI, which was fueled by downed trees due to Fiona and unusually dry conditions. It ravaged trough 7 acres (3 Ha) of woodland and was dangerously close to a propane fuel storage tank before it was brought under control by local fire departments.

Photo 5. Satellite Imagery of PEI before Fiona.

Photo 6. Satellite Imagery of PEI post Fiona.

Our neighboring province, Nova Scotia, also experienced devastating wildfires in 2023, loosing over 25,000 hectares and 200 homes; however, no reports of any transportation network losses.

While the risk of wildfires affecting our transportation network appears low, it doesn't suggest that DTI needs to be complacent about the issue.

5 IDENTIFYING APPRAISAL AND RISK INDICES

As indicated above, the province (for the most part) has taken a reactionary approach to the replacement and enhancement of our transportation structure network post events. Continuing research using BMS tools can enhance DTI's decision-making process with respect to identifying our vulnerabilities and consequences and the applying these to determine a risk profile for climate change and wildfires. For further information regarding these parameters and the science behind them, please refer to Ellis, 2023.

5.1 *Identifying vulnerabilities related to flood and scour*

The department has populated several of our coastal network structures in terms of structure, foundation type, AADT, detour lengths, streambed elevation, mean and high-water elevation

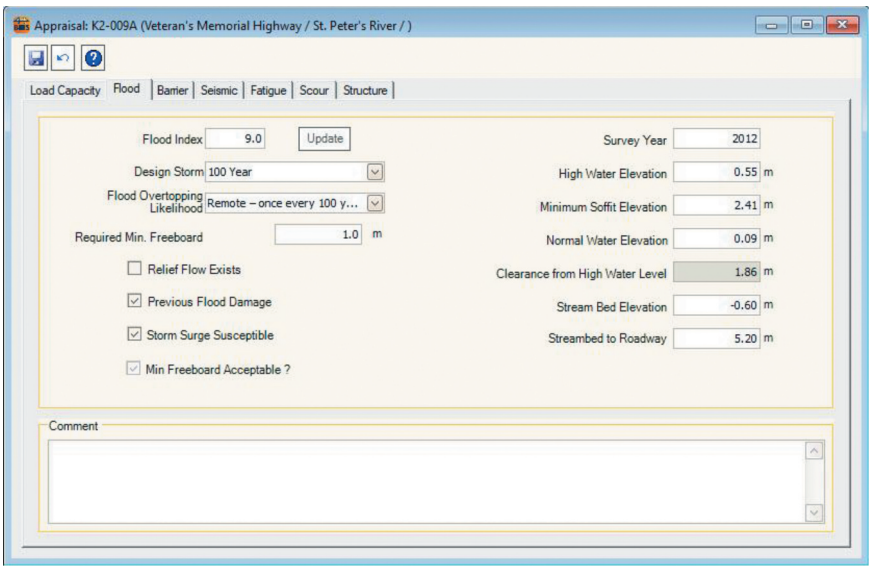

Figure 1. Survey information.

and underside of soffit elevation. There are also fields to include historic flooding or overtopping, the likelihood of overtopping, whether-or-not the structure has an acceptable minimum freeboard available and any relief flow that may be available and traffic delay consequences. See Figures 1, 2 and 3.

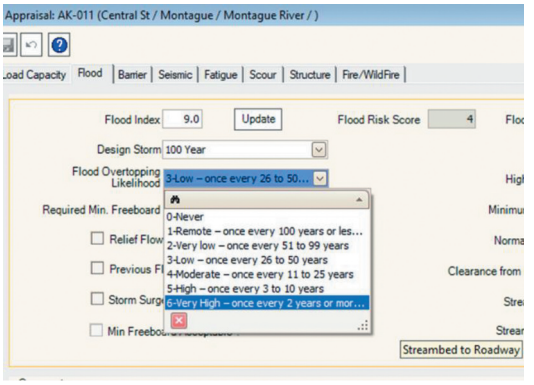

Figure 2. Flood overtopping likelihood.

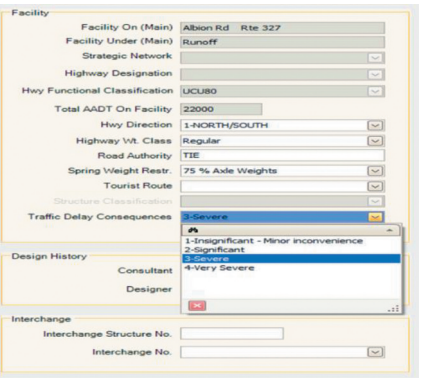

Figure 3. Traffic consequences.

As can be seen, the user will provide input for the pertinent fields and are given a weight with respect to their overall vulnerability and consequence. These are used to produce a risk matrix based on weather related events and can give the province some valuable information regarding their capital programming in any given cycle. See Figure 4 below.

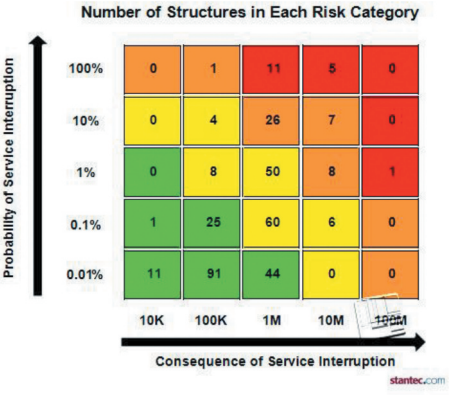

Figure 4. Example risk profile.

5.2 *Wildfires*

In a similar manner, the Department is looking to include the vulnerabilities and consequences associated with wildfire risks. The State of Florida in the U.S. has done some works in relation to structure type and proximity to fuel as it relates to wildfires (Sobanjo & Thompson, 2013).

The province of British Columbia makes provisions for the design of wildfire resistant structures, which includes vegetation management, as well as evaluation of existing structures subsequent to wildfires (BC Ministry of Forestry, 2023).

The province of Alberta, while no official documentation exists, relies on a vegetation management plan, which limits the amount of potential fuel that encroaches their Right-of-Way (ROW). While this is a noble goal to be achieved, it represents a significant cost to the

province of PEI, as land is a valued asset to private owners and vegetation management is an afterthought.

To further compound the issue, there are several structures that are on our highway network which are vulnerable not only due to their proximity of potential fuel, but as well due to their composition (timber superstructures). Of the 1488 structures, over one-third are timber. See Photos 7 and 8.

Photo 7. Upstream vegetation.

Photo 8. Up chainage vegetation.

Based on this, the department has chosen to begin applying pertinent vulnerability values based on main structure material type and proximity to vegetation. This will provide another risk profile for the network which will provide further information to the decision makers with respect to the risk for potential wildfires. More information on these risk profiles can be found in Ellis, 2023.

6 CONCLUSIONS AND RECOMMENDATIONS

The province uses the BMS forecasting models to report to senior management on the possible outcomes of the condition based on different possible budget scenarios (Evans et.al 2018). Considering various environmental factors, the focus is shifting towards a risk-based approach and managing those risks in a calculated manner.

These updated vulnerability and consequence factors will enhance our already robust bridge management system by providing additional information which will guide our policies and decision making.

The department plans to field test these new indices against actual weather-related events in the future, as it's not a matter of if an event will occur, it's when and with what intensity and duration. The department, in conjunction with the software developer, plans to continue to test these indices further to determine the threshold bounds for structure type, composition, and boundary conditions as they relate to weather events.

Considerations for vulnerability and risk assessment of bridges and culverts including extreme weather events

Reed M. Ellis & Zahra Kamranian
Stantec Consulting Ltd., Edmonton, Canada

ABSTRACT: As a result of increased extreme weather events in many parts of the world, there have been growing concerns related to the risks to transportation infrastructure and infrastructure resiliency. Recently, a national survey was completed which included, amongst other topics, how provincial and municipal bridge departments across Canada are responding to these challenges. In conjunction with several transportation agencies, Stantec has been developing appraisal indices to include the effects of extreme events on flooding, scour, wildfires and other vulnerabilities such as fatigue, seismic, and load carrying capacity. The appraisal ratings are being implemented in a Bridge Management System to provide input into risk analysis and resiliency assessment and assist agencies in decision making regarding these challenges. This paper will highlight how agencies can consider in a practical way the effects of potential extreme weather related events, such as flooding, scour, and wildfires. The results of this research as well as the findings of the recent national survey will be shared. Parameters that can be used as input into each appraisal are discussed e.g. for flooding, factors such as flood frequency, risk of overtopping, freeboard, traffic delay consequences can be considered. The paper will be of interest to other jurisdictions who manage bridges and culverts who may be developing responses to these challenges.

1 INTRODUCTION

Canada's bridges are aging and deteriorating due to exposure to aggressive environments, heavier traffic loads, inadequate maintenance and rehabilitation, and limited funding. Nearly 40% of Canada's bridges are in fair, poor, or very poor condition, thus requiring maintenance and rehabilitation, according to the 2019 Canadian Infrastructure Report Card (CIRC-Blue Plan 2019). Values of Canada's infrastructure deficit or gap have been estimated to range from $50 billion to $570 billion (INFC 2018). The situation is similar in many other countries.

The changing climate and increase in average temperature across Canada, as well as the increase in precipitation and wind in some Canadian regions (Cannon et al. 2020) will induce higher loads on bridges and can lead to accelerated aging and deterioration. In addition, extreme weather events, such as flooding, scour, thawing permafrost, etc., can lead to the deterioration, damage and failure of bridges. It has been estimated that climate change could cost Canada $21-$43 billion per year by 2050 (NRTEE 2011). Hence, highway bridges in Canada are at a higher risk if actions are not taken related to climate change adaptation. The consequences of the failure of highway bridges can be quite catastrophic, including fatalities, injuries, and traffic disruptions that impact personal mobility and the transport of goods, which in turn can have serious impacts on society, the economy, and the environment.

In a recent survey and study commissioned by the National Research Council of Canada (NRC), Stantec determined that most of the advanced bridge owner agencies are aware of the challenges surrounding climate change and extreme weather (NRC, 2023). All Provincial government agencies responded that the effects of climate change and extreme weather events are being considered in the design of new structures. Most are using guidance from hydraulic

DOI: 10.1201/9781003483755-233

studies, Environment Canada and other climatic data, and new Intensity-Duration-Frequency (IDF) curves to determine design flows and flood events, increases in scour potential, temperature range etc. In response to these challenges most have internal policies related to design requirements for increased freeboard, deck drainage, more stringent permafrost considerations, erosion and sediment control, river protection works, etc.

The situation is different for the assessment of existing structures when considering the impacts of climate change and extreme weather. These structures are generally designed to older standards. Most indicated that they consider increased design storm events or temperature ranges obtained using updated climatic data. This generally translates into remediation such as increased freeboard, river protection or training works, improved deck drainage etc.. Sometimes, hydraulic capacity can also be increased including constructing relief flow culverts beside existing structures. Beyond the design parameters, the main challenge for agencies is to determine which structures should be prioritised due to which vulnerability.

Agencies identified that guidance would be useful in concepts such as:

(a) what are the vulnerabilities to consider? (e.g., types of extreme weather events, flooding, scour, seismic, wildfire)
(b) what analytical tools are needed to help determine and plan for resiliency?

Vulnerabilities and risks need to be identified and the need for remediation should be considered and prioritised over the transportation network, corridor, etc.. It was concluded that with respect to the impacts of climate change and extreme weather, agencies would benefit from guidance in applying bridge management practices such as lifecycle cost analysis, benefit-cost analysis, risk analysis, determining and reporting of performance measures.

In the following, results of a research and development study into rating systems for structure flooding, scour, fatigue/fracture, load carrying capacity, and wildfire are described. We will specifically consider Flood Appraisal and Wildfire Appraisal as examples where appraisal tools have been developed and implemented in a bridge management system to help bridge owners deal with these challenges.

Application of these appraisal and risk analysis tools is covered in a companion paper by Evans, Darrell J. and Ellis, Reed M. (2023).

2 BRIDGE APPRAISALS, VULNERABILITIES, AND RISK

2.1 *Bridge Condition vs. Appraisal*

Similar to many other countries, in Canada the most common type of bridge inspection is element-level, condition state, severity and extent inspection wherein the structure is inspected by element (e.g. girder, bearing, deck wearing surface etc.) and specific defects are recorded for each element (Ontario Structures Inspection Manual (OSIM), Ministry of Transportation of Ontario, 2018). The resulting element condition state is descriptive of the element condition and the defects can be conveniently tracked over subsequent inspections. Advantages of this type of inspection method include ease of training, consistent and repeatable results, is it lends itself nicely to probabilistic deterioration model development. In addition, a condition index can be readily developed from this type of inspection method. The Bridge Condition Index (BCI) represents the condition of a structure on a 0 to 100 scale where 100 is best (like new) (MTO 2009). The condition index reflects the condition state of each element of the structure, weighted according to the value or replacement cost of the element (i.e. some measure of importance). Not only do these indices reflect condition of the structure, but they also provide a proxy for the current value of the structure wherein 100 represents full economic value of the structure but a deteriorated (lower) value represents a loss of economic value (valuation). Provided that the weighting of the elements that comprise the structure is determined with some consideration of replacement cost of each element, then the index can be taken to represent a measure of valuation (Ellis and Thompson, 2007.) For reference, the AASTHO element

level inspection used in USA (AASHTO 2019) is similar to the OSIM methodology and the BCI is similar to Bridge Health Index (Shepard & Johnson, 2001).

While condition is the most important consideration in determining need for maintenance and repair, strengthening, reporting performance measures, forecasting deterioration etc, it does not by itself reflect to what extent the structure meets level of service and other standards when compared to a structure built to current standards. Bridge Appraisals can be developed to rate many different types of standards such as Load Carrying Capacity, Waterway Adequacy (flooding), Deck Geometry, Roadway Alignment, and others (FHWA 1995). In general, ratings range from 9 to 1 having values such as 'Superior to', 'Equal to', or 'Below present desirable criteria'. Having such a rating system is useful in determining structures that do not meet standards and can therefore compete for funds for improvement. Functional adequacy or inadequacy is a determining factor in the reasons for bridge replacement at the end of service life. These factors are used in bridge management systems to help make decisions on recommended work and priorities.

2.2 *Appraisal, Vulnerability, and Risk*

In this paper, the following generally accepted definitions are being followed as applied to managing transportation structures:

a) Appraisal: an assessment and rating of the degree to which the structure meets current standards or level of service.
b) Vulnerability: the degree to which a system is susceptible to, or unable to cope with, a particular hazard
c) Risk: the potential for damage or loss as defined by probability times consequences.

To assist bridge managers in evaluating common levels of service, appraisals were previously developed and are available in the bridge management system (BMS) and are used to calculate an overall Sufficiency Index (Ellis, Reed M., Evans, Darrell J, 2019). The following appraisals contribute to the Sufficiency Index (SI):

- Load Carrying Capacity
- **Flooding** (most susceptible to climate change and extreme weather)
- **Scour** (most susceptible to climate change and extreme weather)
- Seismic
- Fatigue/Fracture
- Barriers
- Deck/Approach Geometrics

The concept of SI is similar to the Sufficiency Rating (SR) (FHWA 1995) except that for condition it uses the bridge condition index (BCI) instead of the more subjective component (9-1) ratings, it includes a few additional appraisals, and it includes the criticality and urgency of maintenance and repair actions (Ellis, Reed M., Hong, Kang, 2012)

The NRC research and survey indicated in particular agencies would benefit by being able to assess and make decisions regarding the vulnerabilities affected by climate change and extreme weather. In the list above, the two underlined, **Flood Appraisal** and **Scour Appraisal** are the most susceptible and potentially affected by climate change and extreme weather. It was desired that the appraisals be expanded to readily accept input based on updated (changing) climatic data and standards/levels of service. It was also desired to calculate vulnerabilities so that decision makers could more proactively respond in the form of remediation, designate alternate routes, or make other preparations. In addition, to assess probabilities and consequences and further aid in decision-making, a risk analysis and risk profile matrix was desired.

An additional goal was added following increased wildfire activity in several Canadian provinces in recent years. According to the Government of Canada, 2023 was the most destructive wildfire season in Canada on record (Government of Canada, Natural Resources 2023). See Figure 1. This was due to a combination of record high temperatures and

widespread drought across the country. Natural Resources reported that by September 5, more than 6,132 fires had torched a staggering 16.5 million hectares of land. This is more than double the 1989 record and significantly larger than the average of 2.5 million hectares of land that are consumed in Canada every year. For reference the combined area of Denmark and Germany is approximately 16.2 million hectares.

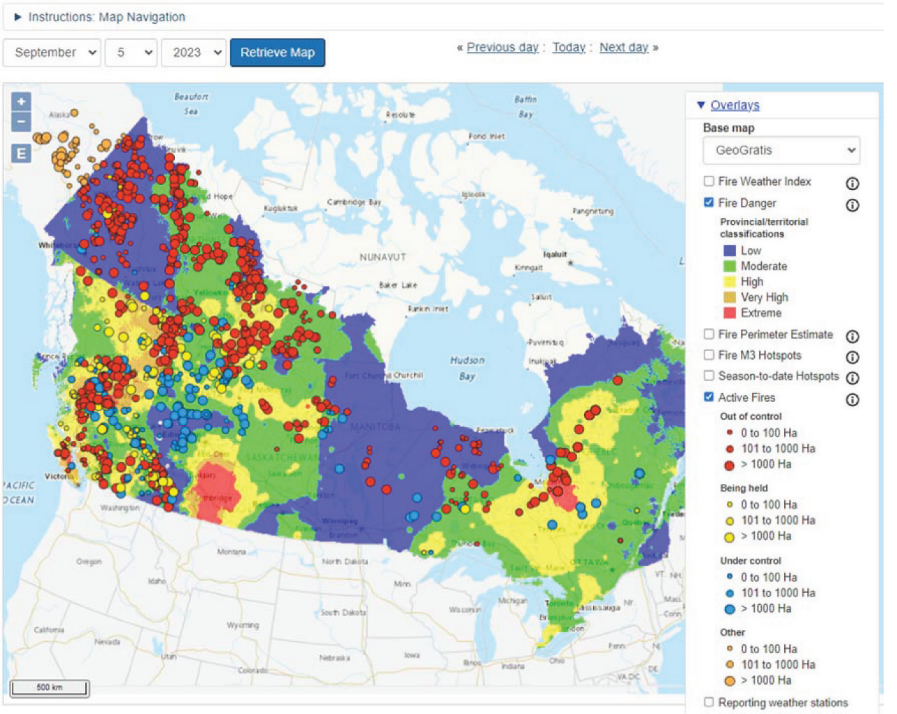

Figure 1. Active Wildfires as of September 5, 2023 (National Resources Canada).

It was therefore decided to research the relevant parameters and develop an appraisal for wildfire and bridge interaction and apply this to a provincial inventory to assess effectiveness of the algorithm. This is described further in Section 2.4.

2.3 *Flood Appraisal, Vulnerability, and Risk*

For bridges crossing watercourses and for culverts, the hydraulic capacity of the opening is an important design consideration. If the hydraulic capacity is inadequate, flooding will occur which can cause negative effects such as traffic delay, washout, or collapse.

Not surprisingly, flood appraisal is one of the more common appraisals and various approaches are used. Based on the results from the NRC report (NRC (2023)), our own design experience, literature review, and technical discussions with various agencies the most common factors considered for appraising flood are:

a) Expected flood level or design flood event
b) Freeboard (available clearance between high water and structure)
c) Desired Freeboard
d) Evidence of previous flood damage
e) Traffic delay consequences (e.g. AADT, highway functional class)
f) Flood overtopping likelihood (frequency)

With these parameters, bridge managers can determine an appraisal, as well as calculate flood vulnerability and risk.

2.3.1 *Flood appraisal*

The approach adopted in the bridge management system is described as follows:

$$Flood\ Appraisal = f(desired\ vs.\ actual\ freeboard,\ previous\ flood\ damage,\ overtopping\ likelihood) \quad (1)$$

where Flood Appraisal varies 10 (best) to 1.

In this case the desired freeboard and the desired level of overtopping likelihood are set as standards. For example, we can set desired freeboard of 1.5m for particular flood event and specify overtopping likelihood of 1/ 50 years and the user can experiment to see the results of these inputs. This allows the bridge owner to identify structures that do not meet current standards but also explore which structures would not meet future higher standards for example due to extreme weather.

The values for flood overtopping likelihood different levels were considered such as those defined by FHWA (FHWA 1995), (FHWA 2022) and others. We elected to use the following as most appropriate for our purposes and to be consistent with FHWA 2022:

Table 1. Likelihood of flood overtopping.

Remote	once every 100 years or less frequently
Very low	once every 51 to 99 years
Low	once every 26 to 50 years
Moderate	once every 11 to 25 years
High	once every 3 to 10 years
Very High	once every 2 years or more frequently

Table 2. Traffic delay consequences.

Insignificant - Minor inconvenience
Significant
Severe
Very Severe

2.3.2 *Flood vulnerability*

For vulnerability, the same inputs used for appraisal are used with the addition of traffic delays as a measure of the inability to cope with the hazard. Since the expected flood level and frequency are variables, vulnerability and risk can be determined for different levels of expected flood level and likelihood. This is ideal for evaluating different extreme weather assumptions. A vulnerability score can be calculated based on the following factors:

$$Flood\ Vulnerability = f\ (desired\ vs.\ actual\ freeboard,\ previous\ flood\ damage,\ overtopping\ likelihood, traffic\ delays\ linked\ to\ flood\ event) \quad (2)$$

where traffic delay consequences are described in Table 2.

2.3.3 *Flood risk and risk profile matrix*

A risk analysis consists of estimating probability and consequences of a particular event and defines risk as the product of probability and consequences. In the case of bridge and culvert flooding, overtopping likelihood is taken as the probability and for consequences we consider traffic delays together with a measure of economic loss of the structure as given by structure replacement cost.

$$\begin{aligned} Flood\ Risk &= Overtopping\ likelihood\ x\ Consequences \\ &= Overtopping\ likelihood\ x\ (traffic\ delay\ consequences + replacement\ cost) \end{aligned} \quad (3)$$

If the risk calculation is performed for the network of structures or highway corridor, the values can be displayed in the classic risk profile matrix as shown in Figure 2. If we define levels of risk as High, Medium-High, Medium, and Low, we can display the number of structures in the highest risk category corresponding to the top right 5 boxes, the next highest risk (medium-high) are shown in the middle band of 7 boxes, followed by Medium 7 boxes, and Low 6 boxes in the lower left.

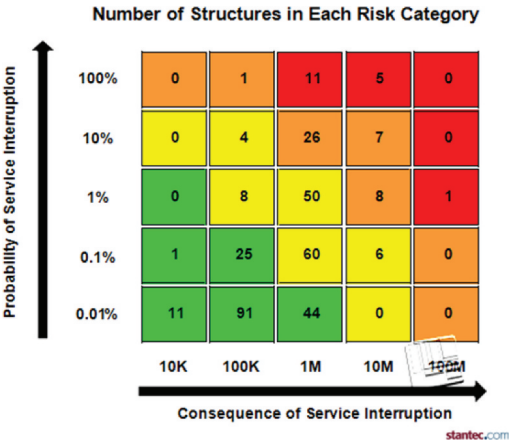

Figure 2. Flood risk profile matrix.

This approach is commonly applied in managing transportation infrastructure and is well suited to application in BMS. In the BMS used by PEI DTI, it was first developed for condition risk as described by Ellis et al 2012.

2.3.4 *Evaluation of the approach*

To evaluate the efficacy of the flood appraisal, vulnerability and risk analysis, a sample inventory was assessed with assistance from the Prince Edward Island Department of Transportation and Infrastructure (DTI). More details are provided in Evans & Ellis, 2023. Based on inputs of desired and available freeboard, previous flood damage, and flood overtopping likelihood (frequency) appraisals were calculated based on Eqn. 1. Vulnerabilities were calculated based on these inputs together with the potential traffic delays linked to the specified flood likelihood as described in Eqn. 2. A risk analysis was performed using the approach described in Eqn. 3. The resulting values provided a list of several structures that were the highest vulnerabilities which were consistent with the opinion of DTI and thus enabled decisions to be made regarding remediation. The priorities for remediation were arrived at using the results of the risk analysis.

In this way DTI could avoid chasing structures with the lowest flood appraisal or the highest vulnerability, even though this information is very useful. Instead, it is possible to focus on the highest risk first. The lowest appraisal or highest vulnerability structures may not represent the highest risk to the Department.

2.4 *Wildfire Appraisal, Vulnerability, and Risk*

For many parts of Canada and indeed many other countries around the world, bridges can be exposed to potential wildfires. As described earlier in this paper, it was desired to develop an appraisal for wildfire and bridge interaction and extend this to wildfire vulnerability and risk profiles. Although most agencies surveyed in the NRC study were keenly aware of wildfire risks, there was no available means to assess. A literature review revealed that very little work has been done. Florida DOT included wildfire as one of the risk models developed for use in

their bridge management system (Sobanjo & Thompson, 2013). The researchers assumed that damage to the structure is dependent on the structure material type and that road closures constitute the largest threat to roadways and bridges rather than physical member damage. Risk models were developed based on historical wildfire data. A risk index was calculated, and the 20 highest risk structures were identified.

The Government of British Columbia, Ministry of Forests, Lands, Natural Resource Operations and Rural Development (FLNRORD) commissioned a study in 2020 to identify information gaps in bridge protection with respect to wildfire events. The study reported that there has been very limited research done on bridge protection against wildfire events. Several knowledge gaps were identified with the main ones being that there is a lack of codes and standards related to fire protection of bridges and the limited number of empirical tests that have been performed to understand the performance of bridges exposed to wildfire. It was proposed that testing be carried out on bridge protection products such as intumescent paints and meshes, fire protective blankets, and insulation boards. Fire protection blankets and insulation boards can be deployed when high fire risk is identified for a given structure(s). Intumescent paints are a type of reactive paint which swells up or 'intumesces' to many times its original thickness when exposed to high temperatures, such as in the event of a fire. In addition, vegetative fuels and water management options should be considered as a hazard reduction practice around bridges.

For bridges in a potential wildfire environment, the following factors are proposed as inputs to the proposed wildfire appraisal:

a) Structure material (e.g. timber, steel, concrete)
b) Wildfire exposure factor (structure setback/clearances, forest fuel ratio, extent of protection provided)
c) Traffic delay consequences (e.g. AADT, highway functional class)
d) Wildfire likelihood (frequency)

With these parameters, bridge managers can determine wildfire appraisal, as well as calculate wildfire vulnerability and risk.

2.4.1 *Wildfire Appraisal*

The approach proposed for a new appraisal for wildfire is described as follows:

$$\begin{aligned} \textit{Wildfire Appraisal} &= f(\textit{structure material},\ \textit{wildfire likelihood},\ \textit{exposure factor}) \\ &= \textit{varies } 10\ (\textit{best})\ \textit{to } 1 \end{aligned} \tag{4}$$

Table 3. Wildfire Likelihood.

Remote
Very low
Low
Moderate
High
Very High

2.4.2 *Wildfire Vulnerability*

For wildfire vulnerability, the same inputs used for appraisal are used with the addition of traffic delays as a measure of the inability to cope with the hazard. Since wildfire likelihood and wildfire expose are variables, vulnerability and risk can be determined for different levels of assumptions. This is ideal for evaluating the future effects of climate change in increased temperature and drought. A vulnerability score can be calculated based on the following factors:

$$Wildfire\ Vulnerability = f\,(structure\ material,\ wildfire\ exposure\ factor\ wildfire\ likelihood,\ traffic\ delays\ linked\ to\ wildfire\ event) \quad (5)$$

where traffic delay consequences are described in Table 2 and wildfire likelihood is given in Table 3.

2.4.3 *Wildfire Risk and Risk Profile Matrix*
In the case of bridge exposure to wildfire, wildfire likelihood is taken as the probability and for consequences we consider traffic delays together with a measure of economic loss of the structure as given by structure replacement cost.

$$\begin{aligned} Wildfire\ Risk &= Wildfire\ likelihood\ x\ Consequences \\ &= Wildfire\ likelihood\ x\ (traffic\ delay\ consequences + replacement\ cost) \end{aligned} \quad (6)$$

A risk profile can be prepared similar to Figure 2.

2.4.4 *Evaluation of the Approach*
To evaluate the efficacy of the new wildfire appraisal, vulnerability and risk analysis, a sample inventory was assessed with assistance from the Prince Edward Island Department of Transportation and Infrastructure (DTI). More details are provided in Evans & Ellis, 2023. A sampling of structures in forested areas were selected having different material types, wildfire likelihood, wildfire exposure factors and traffic delay consequences. Wildfire appraisals were calculated based on Eqn. 4. Vulnerabilities were calculated based on Eqn. 5. A risk analysis was performed using the approach described in Eqn. 6. The resulting values provided a list of several structures that had higher vulnerabilities and thus enabled decisions to make plans for wildfire remediation such as site clearing, setback. Based on the risk analysis none of the structures were found to be high risk but some in medium risk category were identified.

3 FUTURE WORK

As the algorithms used in these appraisal, vulnerability, and risk calculations are new, a level of calibration is being carried out. The wildfire appraisal is entirely new, and it would also be beneficial to test on a larger inventory of wildfire hazard bridges. Nonetheless, the results are promising and already proving useful.

The next stage of work includes completing the similar appraisal, vulnerability and risk calculations for the other appraisals referred to in Section 2.2. Once this is done, it will be possible to create an overall vulnerability score comprising all of the appraisal hazards. Together with the already implemented condition risk profile, bridge managers will have a complete picture for the most common bridge vulnerabilities.

4 CONCLUSIONS

As a result of increased extreme weather events in many parts of the world, there have been growing concerns related to the risks to transportation infrastructure and infrastructure resiliency. Recently, a national survey was completed which included how provincial and municipal bridge departments across Canada are responding to these challenges. In conjunction with several transportation agencies, Stantec has been developing appraisal indices to include the effects of extreme events on flooding, scour, wildfires and other vulnerabilities such as fatigue, seismic, and load carrying capacity. The appraisal ratings are being implemented in a Bridge Management System to provide input into risk analysis to assist agencies in decision making regarding these challenges.

This paper has described how agencies can consider in a practical way the effects of potential extreme weather related events, such as flooding and wildfires. Parameters that can be used as

input into these appraisals were described. For flooding this includes actual vs desired freeboard, previous flood damage, likelihood of overtopping, and traffic delay consequences. A new appraisal was described for wildfires which is based on structure material, wildfire exposure factor, wildfire likelihood, and traffic delays linked to wildfire event. A methodology for risk profiles was described for the flood and wildfire appraisal examples. For a preliminary assessment, the methodologies were applied to the PEI DTI bridge inventory and the results were used to make decisions regarding flood remediation and wildfire preparedness.

ACKNOWLEDGMENTS

The authors would like to acknowledge the assistance of the Prince Edward Island Department of Transportation and Infrastructure (DTI), in particular Mr. Darrell Evans, A/Director for supporting and supplying the test inventory. The support of the National Research Council as part of the national survey and report on bridge management practices across Canada is also gratefully acknowledged.

Province of New Brunswick Bridge Management System

Zahra Kamranian M.Eng, P.Eng. & Reed M. Ellis Ph.D., P.Eng.
Stantec Consulting Ltd., Edmonton, Canada

ABSTRACT: The New Brunswick Department of Transportation and Infrastructure (NBDTI) has recently completed the implementation of their bridge management system (BMS). The system is an advanced customized-off-the-shelf (COTS) BMS that is designed to manage the assets thoroughly, including inventory, inspection, modelling, forecasting, prioritizing, and budgeting. The BMS will be used to manage over 6,100 structures consisting of bridges, bridge-sized culverts, retaining walls, wharfs, sea walls, sign structures, and minor culverts. A massive amount of legacy data had to be loaded, and several existing Department processes were added as links in the new BMS. Province-specific customization was required for deterioration, treatment, and cost models appropriate for local conditions, structure elements, materials, environment, and repair practices. This paper should be of interest to agencies considering implementing a bridge management system.

1 INTRODUCTION

The New Brunswick Department of Transportation and Infrastructure (NBDTI) is responsible for constructing and maintaining approximately 6,100 bridges, bridge-sized culverts, retaining walls, wharves, sea walls, sign structures and minor culverts. This comprehensive and diverse inventory is one of the largest provincial inventories in Canada.

NBDTI aims to make well-informed decisions that can be effectively presented to other departments, elected officials, and the public. It is crucial that NBDTI maintain their capital programs for structures on a firm and justified financial footing that allows a sustainable level of service over the long term and quickly demonstrates how changes to budgets can influence the condition of the network.

In NBDTI's legacy Bridge Management System (BMS), the structures modeling for bridges and large culverts had not been sufficient to assist in developing the capital program. It lacked the functionality to assess how the deterioration of one element may influence the deterioration of one or more other elements in the same structure. This legacy BMS was also not integrated with the inspection report database, forcing NBDTI staff to manually extract the data into a format the model could read. Moreover, it did not consider criteria such as the average annual daily traffic (AADT) and weight restrictions. The system was also approaching end of life due to a number of legacy tools that could become incompatible and inoperative as time progressed.

Therefore, NBDTI sought a mature commercial off-the-shelf (COTS) software system that could be customized to suit department requirements. COTS systems also have the advantage of providing known solutions in minimal time and much lower cost than new development. NBDTI had sophisticated requirements for analysis capabilities, including deterioration and cost modelling, lifecycle cost analysis, and benefit-cost analysis. Risk analysis and risk-based decision-making capabilities were also required for bridges and structures.

In line with NBDTI's vision for a more disciplined, integrated, and structured approach to managing its transportation infrastructure, NBDTI selected Stantec BMS as their COTS system

DOI: 10.1201/9781003483755-234

to implement. Stantec's bridge management system application was implemented between 2020 and 2022 to maximize the benefits of available transportation structures' funding, as well as build support for increased funding levels. The new BMS is an advanced engineering bridge management system designed to manage the assets' entire life cycle, including inventory, inspection data, modelling, forecasting, prioritizing, budgeting, and program development. The BMS fully meets the requirements for BMS as described by AASHTO (AASHTO, 1992) or ISO 55000 Standards for Asset Management (ISO 55000, 2014). The system is reported extensively by other Agencies in Canada in the IABMAS Report on Bridge Management Systems (Mirzaei et al, 2012.)

This paper focuses on NBDTI's first steps in implementing this robust transportation asset management system, how existing data/systems were leveraged, and how NBDTI's practices/ experience were combined with sound engineering models and comprehensive analysis tools to produce a complete management system.

2 OVERVIEW AND BENEFITS OF ASSET MANAGEMENT SYSTEMS

Structures typically represents one of the larger and significant investments transportation agencies manage. To efficiently manage asset information in an easy-to-use, accessible platform, and carry out asset management using industry-standard practices, transportation agencies need to be able to answer the following questions efficiently:

1. What assets do I own?
2. What is the current condition of these assets?
3. What are the current replacement costs and valuation of these assets?
4. What maintenance, repair, and rehabilitation actions are needed for these assets?
5. When do we need to do these actions?
6. How much budget is needed over the budgeting cycle?

Other questions are often raised, such as the tradeoff between budget and condition, what happens if the required budget needs cannot be met, and what risks and vulnerabilities may be present.

Thus, the bridge management system must enable the users to effectively manage the whole structure program, including inspection and data collection, needs identification, and decision-making. The asset management systems must also include the ability to calculate and report Key Performance Indicators (KPI) and performance measures and forecast these for different budget levels.

To achieve the above, it is desirable to follow a bottom-up approach, wherein the systems are data-driven from accepted field inspection and data collection processes. COTS systems tend to model the bottom-up approach, provided that they can be customized to suit an agency's specific practices. 'Enterprise' asset management system tends to work from the top-down and often force agency's to simplify their analysis to be consistent with other assets.
