Trees falling into the river because of their proximity to the riverbank and high winds or soil erosion is a common phenomenon observed in flood events (Hughes et al., 2023; Panici & De Almeida, 2020). Large volumes of accumulated wooden debris may result in debris-damming on the upstream side of the bridge pier or its superstructure, increasing the horizontal demand on the bridge. This causes additional overturning moments at the base. The loads exerted by the debris accumulation can be calculated using Equation 1 with C_D estimated for debris and by considering A as the projected area of debris accumulation (AASHTO, 2021; Elliot et al., 2012; Hughes et al., 2023). Present study assumes wedge-like shape of the debris accumulation and its critical dimensions (maximum size of the accumulated debris for the given flow condition) are calculated from the regression equations proposed by Panici & De Almeida, (2018).

3 FLOOD FRAGILITY ANALYSIS OF WATER-CROSSING BRIDGE STRUCTURE

The previous section enumerated various primary and secondary effects of riverine flood flow. The demands imposed on bridge components due to flood flow can result from both laterally and vertically applied forces. As such, two bridge failure modes are considered in this study: (a) deck unseating, and (b) excessive pier movement. These two failure modes broadly cover the bridge failure patterns observed during past flood events (Padgett et al., 2008; Xiong et al., 2023). This section presents the modeling of flood loads for bridge analysis and the development of fragility functions for different failure modes of the bridge. Given the vulnerability of multi-span simply supported (MSSS) concrete girder bridges against flood hazards, this study considers different configurations of this bridge class to develop the fragility models for the identified failure modes.

3.1 *Finite element modeling of the bridge*

OpenSees (McKenna et al., 2000) is adopted to perform the bridge response and flood load analyses of different bridge configurations, as it has been widely used for analyzing parameterized bridges models subjected to various hazards (Nielson, 2005; Pregnolato et al., 2022). Figure 1 shows the representative sketch of the two-dimensional (2D) bridge model. This

model was derived from a previously validated three-dimensional (3D) bridge model that has been used for seismic excitation as well as for hydraulic wave analysis (Balomenos et al., 2020; Nielson, 2005). The representative 2D model consists of a cross-sectional bridge deck and girders, representative bearings, bridge columns, and a foundation system. The deck-girder along the 2D cross-section is modeled using *elasticBeamColumn* elements connecting each girder-end node. For simply supported spans, the masses are lumped at the girder-end nodes and are assigned based on the specified span length and girder properties (girder weight, cross-sectional area, deck weight) for each analysis. The girders rest on a series of elastomeric bearing pads with steel dowels, modeled using a combination of bilinear *Steel01* material and *Hysteretic* material in *OpenSees*. The columns of the bridge are modeled using displacement-based beam-column elements (*dispBeamColumn*) with fiber-defined cross-section to model confined core concrete (*Concrete04*), steel reinforcement (*Steel02*), and unconfined cover concrete (*Concrete04*). The pile foundation considered in this study is of "drilled-shaft" type which is also modeled using displacement-based beam-column elements (*dispBeamColumn*). The soil resistance is modeled using appropriate *P-y* springs in the horizontal direction, *T-z* springs along the vertical axis, and *Q-z* springs at the tip of each pile, following the modeling strategy of Kameshwar & Padgett (2018). Depending upon the specified soil erosion level, these soil springs are removed from the eroded soil region to account for the scour in the analysis. For simplicity, this study uses uniform scour around each pier. A nonlinear static analysis considering maximum flow conditions of the flood event time-history is performed in this study using *algorithm Newton* as the solution algorithm which is based on the Newton-Raphson method.

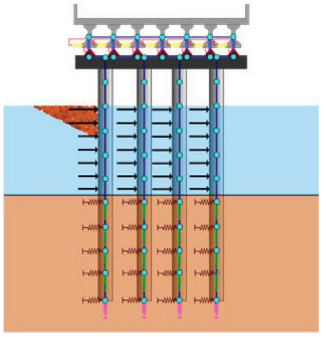

Figure 1. Schematic diagram of case study concrete-girder bridge.

3.2 *Experimental design and bridge parameters*

In order to cover a wide range of bridge, flood and geotechnical parameter combinations, the Latin Hypercube Sampling design was implemented to ensure that the parameter space covers the entire range of the parameter bounds. Table 1 shows the different parameters and their bounds considered in this study. These bounds are collected based on the existing water-crossing bridge inventory from the Houston-Galveston near-coast region. The uncertainty bounds for different drag coefficients are considered based on the results from past studies (Almasri & Moqbel, 2017; Nasim et al., 2019).

This study develops separate fragility functions for the two failure modes considered: (a) excessive pier movement, and (b) deck unseating. The soil type is broadly classified into two categories: cohesive soil and cohesionless soil; and their respective range of soil parameters are propagated into the analysis cases. Two different sets of 20,000 experimental samples are generated for cohesive and cohesionless soil. For each generated sample, the *OpenSees* bridge model is run and the results are extracted to develop parameterized fragility functions. Further, since the flood flow height is required to reach beyond the substructure level for imposing demands on the superstructure, additional 20,000 samples are generated specifically to

Table 1. Ranges of different parameters used to generate Latin Hypercube design samples.

Parameter	L †	U ‡	Parameter	L	U
Column diameter, D_{col} (m)	0.4	1.50	Scour depth, d_{scour} (m)	0	$0.9h_{pile}$
Deck slab thickness, t_{deck} (m)	0.1	0.25	Drag coefficient for pier, $C_{D,\ pier}$	0.7	1.2
No. of girders, n_{gd}	3	9	Drag coefficient for deck, $C_{D,\ deck}$	1.2	2.0
No. of piers per bent, b_n	2	8	Drag coefficient for pier in presence of wooden debris, $C_{D,\ debris}$	1.0	2.5
Deck width, w_{deck} (m)	5.0	24.0	Flood water density, ρ_w (kg/m^3)	900	1100
Span length, l_{span} (m)	6.1	39.6	Flow depth, y (m)	1.0	h_{bridge}
Column height, h_{col} (m)	1.5	17.3	Flow velocity, v (m/s)	1.5	15
Depth of bent, h_{bent} (m)	0.6	1.5	Debris log length, L (m)	0.5	18
Length of drilled pile, h_{pile} (m)	1.5	22.4	Angle of internal friction for soil particles, Φ (degree)	22.8	40
Unit weight of soil, γ (kN/m^3)	12.7	22.5	Cohesion between soil particles, C (kPa)	10	192
Girder type: AASHTO I, II, IV, Type C					

*$h_{bridge} = h_{col} + h_{bent} + h_{girder} + t_{deck}$; †L: lower bound; ‡U: upper bound

examine the deck unseating failure of the bridge considering flood flow depth to vary from the bottom of the girder to the top of the deck level, using the limit states defined in Equation 3.

3.3 *Fragility modeling*

To represent the response of the bridge component of interest, appropriate engineering demand parameters (*EDP*s) are selected for each failure mode. Similar to previous literature for seismic hazard, curvature ductility is chosen as the *EDP* to capture the pier movement (Nielson, 2005). The lognormally distributed capacity limit state of the column is adopted from Nielson (2005). *EDP* for the deck unseating failure mode is selected as its displacement in the horizontal or vertical direction, in accordance with their defined limit states in Equation 3.

EDPs from each analytical simulation are compared with the capacity estimates for each failure mode for the respective component, and the outcome is recorded as a binary variable with 1 representing the case in which demand exceeds the capacity (failure) and 0 represents the case in which demand does not exceed the capacity (no failure). In this study, parameterized fragility functions are developed using logistic regression, which is selected due to its easily transferable closed-form expression. The general form of the logistic-regression model can be expressed as:

$$P[\text{failure}|\mathbf{X}] = \frac{1}{1 + \exp[-l(\mathbf{X})]} \tag{4}$$

where $\mathbf{X}$ is the vector representing polynomial terms of model parameters along with its coefficients. Out of the different parameters used for the analysis, a subset of parameters can be chosen that provides the expected performance of the model. This study utilizes 10-fold cross-validation on the training samples for more robust estimates of the model parameters and to avoid overfitting of the model. The logistic regression model is trained using 70% of the data from the total dataset and tested on the remaining 30% of the data. The parameters considered for each model and the model coefficients are presented in the following sub-sections.

3.4 *Excessive pier movement*

The lateral resistance of the bridge is predominantly characterized by the soil type of the foundation. Since the majority of resistance to pier movement comes from the soil, separate fragility models are developed for bridge foundations in cohesive soil and cohesionless soil. The model estimated coefficients of the polynomial functions $l(\mathbf{X})$ along with their goodness-of-fit estimates evaluated on the test dataset are:

Cohesionless soil (Accuracy: 0.88, Precision: 0.88, F1-score: 0.88):

$$l(\mathbf{X}) = -3.38 - 5.47D - 0.21h_{\text{pile}} + 0.57d_{\text{scour}} + 0.39y + 0.69v + 0.0041V_{\text{debris}} + 1.35I_{\text{debris}} \tag{5}$$

Cohesive soil (Accuracy: 0.84, Precision: 0.85, F1-score: 0.84):

$$l(\mathbf{X}) = -3.67 - 3.61D - 0.13h_{\text{pile}} + 0.41d_{\text{scour}} + 0.32y + 0.52v + 0.0035V_{\text{debris}} + 1.08I_{\text{debris}} \tag{6}$$

The effect of debris accumulation is included by considering the debris volume parameter V_{debris} in the model. For training purposes, the set of the results from experimental design samples without considering debris loads (V_{debris} = 0) are merged with the same set of sample results considering the debris accumulation loads so that the single model is able to predict excessive pier movement failure probability for the two different scenarios. One additional binary categorical feature is introduced (I_{debris}) while training the model which should be taken as 0 when debris effects are neglected and 1 when debris accumulation is considered.

3.5 *Deck unseating analysis*

The estimated coefficients of polynomial function $l(\mathbf{X})$ to develop fragility model for the deck unseating failure mode are:

$$l(\mathbf{X}) = -14.25 + 7.75Z_{\text{c}} + 0.88v + 0.12l_{\text{span}} - 0.05w_{\text{deck}} \tag{7}$$

While selecting these parameters, the accessibility factor was considered so that it could be used for real-time bridge condition assessment. Parameter Z_c represents the height of flood water above the base of the superstructure. The velocity of the flow can be found from the preinstalled current meter readings. The goodness-of-fit estimates of the model on the test dataset are as follows: Accuracy: 0.89, Precision: 0.89, F1-score: 0.89.

4 DISCUSSION

To illustrate parameter sensitivity, a representative MSSS concrete girder water-crossing bridge is selected as a case study. The case study structure is a three-span bridge with a span length of approximately 20 m, a deck width of 12 m, and concrete girders of the AASHTO-IV class. The substructure consists of 4 equal-height circular columns 6.1 m in length and 0.51 m in diameter. The foundation of the bridge is of a drilled shaft type (pier extends and goes through the soil) with a length of 7.6 m and the soil type is cohesionless soil. Assuming no effects of scour formation or debris accumulation, fragility curves of this bridge are generated conditioned on the depth of flow parameter, for excessive pier movement (flow velocity of 7 m/s) and deck unseating (flow velocity of 4 m/s) failure modes (Figure 2). Considering this as a reference case, different parameters in the model are varied to assess the sensitivity of each parameter.

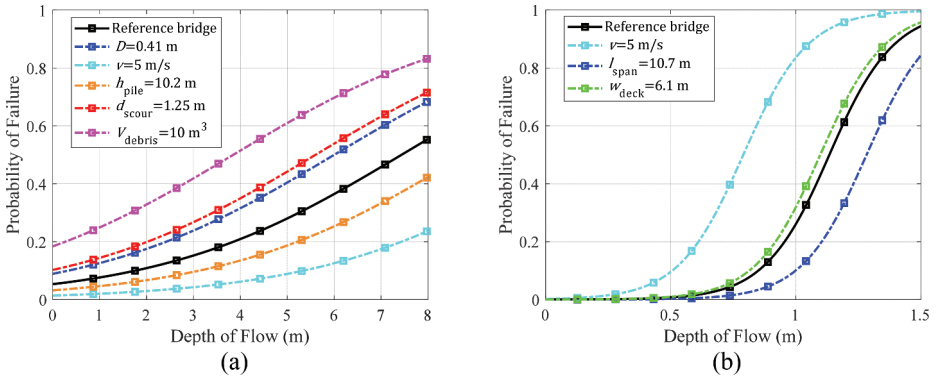

Figure 2. Parameter sensitivity of the proposed flood fragility models developed for (a) excessive pier movement, and (b) deck unseating failure mode.

When the bridge pier diameter is decreased from 0.51 to 0.41 m, significant variation is observed in the flood fragility curve as shown in Figure 2(a). Since the lateral bending capacity of the pier is directly proportional to the moment of inertia of its cross-section, minor change in the pier diameter significantly affects the lateral resisting capacity of the pier, resulting in higher movement of a pier with a smaller diameter when subjected to horizontal forces. Figure 2(a) also represents the fragility curves developed by considering different pile lengths. In the case of lateral loading, the resistance is provided from the soil pressure in the lateral direction. Hence, increasing the pile length provides higher lateral resistance, resulting in lower bridge fragility. It can also be observed that the fragilities change significantly when the flow velocity is changed or the effect of debris accumulation is considered, as evident from Figure 2(a). The formation of the scour at the bottom of the pier crucially affects the structure's lateral and vertical resistance capacity, which can be observed in Figure 2(a) where an increment in the scour depth significantly increases the fragility of the pier damage.

As shown in Figure 2(b), increasing the flow velocity from 4 to 5 m/s dramatically increases the fragility for deck unseating failure mode. On the other hand, decreasing the span length leads to reduction in the fragility. The lateral forces acting on the simply supported superstructure increases with its length for the given flow depth, whereas, the frictional resistance is only provided from its supports. Thus, when bridge decks with higher span length are exposed to the lateral and uplift forces from the floodwater, it attracts higher demands that results in more fragile cases compared to the bridges with shorter spans. Finally, reduction in the deck width leads to lesser self-weight of the superstructure for the given span length, resulting in increasing fragility.

5 CONCLUSION AND FUTURE SCOPE

This study develops parameterized flood fragility functions for a multi-span simply supported (MSSS) concrete girder bridge class to evaluate its failure probability when subjected to a flooding event. Along with the primary stressors caused by the flood flow in terms of the horizontal water-pressure and uplift forces, the study also considers the secondary effects stemming from the flood hazard in the form of scour at the bridge foundation and wooden debris accumulation at the location of bridge columns. Given the type of loading a bridge experiences during flooding conditions, the bridge failure modes are broadly classified into two categories: deck unseating and excessive pier movement. The proposed parameterized flood fragility functions for each failure mode are developed herein using logistic regression. Considering the uncertainties associated with bridge parameters, foundation parameters, and flood-hazard parameters in the statistical sampling, finite-element simulations of the analytical bridge model are performed to generate training dataset for fitting the logistic regression model. The developed fragility functions indicated a high level of accuracy on the test dataset. These models provide useful insights into the contribution of different

parameters on the likelihood of bridge failure when subjected to different flooding scenarios. Application of the proposed models is demonstrated using a representative case study bridge and model parameter sensitivity analysis is performed. Results suggest that the coupled effects from high-velocity flow and the formation of scour at the pier bottom significantly reduce the lateral resistance of the foundation system and increase the failure threat for water-crossing bridge structures. Bridges with slender piers are more likely to experience damage, whereas, narrow bridges (because of lesser superstructure weight) are prone to unseat from their support during extreme flooding events. The proposed fragility models can also help identify bridges vulnerable to flood hazard, and accordingly, suggest prospective interventions based on the insights gained from a parameter study. Moreover, the proposed fragility models can be easily implemented for regional flood-risk and resilience studies given its closed-from formulation. Real-time bridge safety can also be assessed by coupling the proposed fragility models with a situational awareness framework for safer vehicular routing during a flood event. Additionally, while the flood fragility models proposed in this study are developed for a specific bridge class, the presented methodology can be adopted for the development of fragility models for other types of bridge classes. Future work related to this topic may additionally explore the effects of abutment scour or non-uniform scour formation which may result in uneven bridge settlement.

Combining condition deterioration and seismic risks for bridge asset management

A. Ghavidel

A. Du
Assistant Professor, The University of Texas at San Antonio

S. Kameshwar
Assistant Professor, Louisiana State University

ABSTRACT: Traditionally, bridge asset management has been primarily focusing on chronic aging-related deterioration, overlooking the impact of earthquake hazards. Despite extensive research on bridge deterioration and seismic risks, there's a gap in combining both factors in life-cycle cost analysis (LCCA). This study introduces a framework integrating bridge condition deterioration and seismic risks in LCCA, thereby enhancing decision-making of highway bridges. Markovian deterioration process and probabilistic seismic damage analysis are integrated for time-dependent condition rating and seismic damage estimation. The proposed framework can quantify life cycle costs for different maintenance and retrofit strategies. In addition, the framework accommodates different risk perceptions with proposed weighting factors. A sensitivity analysis on a case-study bridge explores the influence of factors and local seismicity on LCCA, making this framework a valuable tool for risk-informed, long-term bridge asset management.

1 INTRODUCTION

Bridge asset management is crucial to ensuring the functionality and operation of regional transportation networks. Traditionally, bridge asset management mainly deals with chronic deterioration resulting from natural aging processes (Assaad & El-adaway, 2020; de Dieu et al., 2020; Sabellano et al., n.d.). Yunovich et al. (2003) demonstrated this by conducting cost analysis throughout the lifespan of reinforced concrete bridge decks, using a corrosion-related deterioration. Kong & Frangopol (2003) introduced a framework to evaluate the life-cycle analysis of structures as they deteriorate. They specifically pointed out challenges arising from uncertainties in changing loads over time, resistance factors, and maintenance interventions.

On the other hand, many studies have focused on bridge damages caused by earthquakes and the overall costs throughout the life cycle (Omidian et al., n.d.; Torti et al., 2022). Kumar et al. (2009) used a probabilistic approach to calculate the life-cycle cost of reinforced concrete bridges that are prone to corrosion in earthquake-prone areas. Padgett et al. (2010) proposed a method to assess the best retrofits for bridges. This approach is based on considering seismic life-cycle costs and conducting a cost–benefit analysis. This method combines probabilistic seismic hazard models, the vulnerability of bridges in their original and retrofitted states for different levels of damage, and the related costs of both damage and retrofitting.

Despite considerable research efforts in quantifying the probabilistic deterioration and evaluating seismic fragility and risks in highway bridges, there is a noticeable gap in the literature regarding the integration of these two crucial stressors into a cohesive LCCA framework. This study aims to address this gap by introducing a new framework that incorporates both the deterioration of bridge conditions and seismic risks into the LCCA of highway bridges. This approach provides

DOI: 10.1201/9781003483755-321

a more comprehensive understanding of the relative contributions of these external threats. By considering the effects of aging-induced deterioration and the potential for sudden and catastrophic seismic damages simultaneously, this framework becomes a valuable tool for making informed decisions in long-term bridge asset management. Moreover, in traditional LCCA, decisions are typically based on predetermined rules and schedules. The proposed LCCA framework can further enable dynamic and adaptive AI-based (e.g., reinforcement learning) decision-making processes by offering episodic random simulations over a planning horizon.

In the following sections, we will offer a comprehensive explanation of the methodology and application of this LCCA framework. We will use a case-study highway bridge to demonstrate its practicality. Moreover, a sensitivity analysis will be carried out to examine the influence of changing weighting factors and local seismicity on the LCCA results. This analysis aims to highlight how different perceptions of risk can impact decision-making in bridge asset management.

2 INTEGRATED CONDITION DETERIORATION AND SEISMIC DAMAGE MODELING

2.1 *Markovian bridge condition deterioration*

The bridge component condition deterioration is modeled via Markov processes. Markov state transition probability matrices under chronical aging deterioration (i.e., do-nothing) are obtained for three bridge components (deck, super structure, and substructure) based on the national bridge inventory (NBI) data (FHWA, 2022):

$$P_{DECK} = \begin{bmatrix} 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.0114 & 0.9886 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.0174 & 0.9826 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.0227 & 0.9773 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0268 & 0.9732 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0714 & 0.9286 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0452 & 0.1011 & 0.8537 \end{bmatrix} \quad (1)$$

$$P_{Super} = \begin{bmatrix} 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.0282 & 0.9718 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.0107 & 0.9893 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.0147 & 0.9853 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.0194 & 0.9806 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.0246 & 0.9754 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0276 & 0.9724 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0532 & 0.9468 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0282 & 0.0995 & 0.8723 \end{bmatrix} \quad (2)$$

$$P_{Sub} = \begin{bmatrix} 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 1.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.0142 & 0.9858 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.0208 & 0.9792 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.0302 & 0.9698 & 0.00 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.0282 & 0.9718 & 0.00 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0207 & 0.9793 & 0.00 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0654 & 0.9346 & 0.00 \\ 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.00 & 0.0349 & 0.0925 & 0.8726 \end{bmatrix} \quad (3)$$

The effect of maintenance actions should also be incorporated into the modeling framework, as these intervention actions may improve and restore the bridge component conditions. Since this research adopts a component-based approach, three generic component-level maintenance actions are considered including: 1-minor maintenance, 2-major maintenance, and 3-replacement. The resulting Markov transition matrices are shown in Eq. 4-6. It is assumed that the three generic bridge components share the same transition probability matrices for under maintenance actions.

$$P_{minor} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.9 & 0.1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.8 & 0.2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0.7 & 0.3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.6 & 0.4 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{4}$$

$$P_{major} = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0.3 & 0.4 & 0.3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0.1 & 0.3 & 0.6 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0.1 & 0.2 & 0.7 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0.05 & 0.1 & 0.85 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0.05 & 0.05 & 0.9 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0.02 & 0.98 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{5}$$

$$P_{replacement} = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{6}$$

2.2 *Seismic damage and risk modeling*

In this section, system-level bridge seismic fragility models will be used to provide probabilistic seismic damage estimates. The general functional form of the system-level seismic fragility model is shown in Eq. 7, which follows a lognormal distribution:

$$P(DS|PGA) = \Phi\left(\frac{ln\ (PGA) - ln\left(med_{sys}\right)}{\xi_{sys}}\right) \tag{7}$$

where med_{sys} is the mean value of the system fragility, and ξ_{sys} is the dispersion, or logarithmic standard deviation, of the system fragility. $\Phi(.)$ is the standard normal cumulative distribution function. Peak ground acceleration (PGA) is used as the intensity measure. The as-built state fragility models for the four damage states (slight, moderate, extensive and complete) and modification factors that reflects the effect of retrofit on the bridge system fragility of Multi-Span Simply Supported (MSSS) concrete bridge are adopted from Padgett et al. (2010). Then the annual rate of exceeding a certain damage state can be calculated as follows:

$$\lambda_{annual}(DS) = \int_{IM} P(DS|IM) \left| \frac{d\lambda(IM)}{dIM} \right| dIM \tag{8}$$

where λ(IM) denotes the annual rate of exceeding a certain IM, which is available from site-specific seismic hazard curve (e.g., from the USGS Unified Hazard Tool). Under the homogenous Poisson earthquake occurrence assumption, the annual probability of exceeding certain damage state can be finally calculated as follows:

$$P_{annual}(DS) = 1 - e^{-\lambda_{annual}(DS)} \tag{9}$$

It is assumed that all seismic damages will be repaired right after the earthquake impact. For slight and moderate damage state, it is assumed that the repair actions won't have any effect on the bridge condition ratings, but for extensive and complete damages, it is assumed that the repairs will restore the bridge conditions to the best condition.

3 COST QUANTIFICATION

3.1 *Annual direct cost*

The annual direct costs related to the intervention actions carried out in each year are quantified. The direct costs of the intervention actions are represented as percentages of the total construction cost for the bridge components or the entire bridge. Three maintenance actions and various seismic retrofit actions are considered, and their associated costs are obtained from the references (Du & Ghavidel, 2022; FHWA, 2021; Heath et al., 2004; Huang et al., 2014; Padgett et al., 2010). Seismic repair and cost estimates for various damage states are adapted from Padgett et al. (2010).

3.2 *Annual indirect cost*

In addition to the direct costs associated with intervention actions in bridge asset management, it is crucial to consider the indirect costs, which encompass the socioeconomic consequences arising from the disruption to the traffic-carrying capacity of bridges. These indirect costs comprise three components: (1) vehicle operation costs; (2) time costs incurred by passengers and trucks; and (3) safety costs, calculated based on empirical equations in the literature (Du & Ghavidel, 2022; Mackie & Stojadinović, 2005).

3.3 *Total life-cycle cost*

The above direct and indirect costs are then aggregated into the total annual cost. For the cost aggregation, weighting factors are introduced for the indirect costs as they are typically much higher than the direct costs. Moreover, different weighting factors are considered for the indirect costs induced by bridge condition deterioration/maintenance actions and by seismic repairs to reflect different risk perceptions.

$$C_{total} = (C_{D0} + C_{D1} + C_{D2}) + w_1 C_{I1} + w_2 C_{I2} \tag{10}$$

where C_{D0}, C_{D1}, and C_{D2} respectively denote the direct cost due to seismic retrofit, maintenance, and seismic repair. C_{I1} and C_{I2} denote the indirect costs due to bridge condition deterioration/maintenance and due to seismic damages/repair. w_1 and w_2 denote the indirect cost weighting factors for condition deterioration/maintenance and due to seismic damages/repair, respectively.

The estimates for both direct and indirect costs are computed for a specific year and should ultimately be aggregated to determine the life-cycle cumulative costs. This enables a straightforward comparison of various intervention actions, while explicitly incorporating different sources of uncertainties. The time-cumulative cost C_T over a T-year period is calculated as follows:

$$C_T = \sum_{t=1}^{T} \gamma^t C(t) \tag{11}$$

where $C(t)$ denotes the annual cost estimate at year t, $\gamma \in (0,1)$ is a discount factor to account for the effect of inflation and delayed reward, where in this study a discount factor of 0.96 is considered (USDOT, 2018).

4 CASE STUDY AND EVALUATION

4.1 *Case study setup*

In this section, a comprehensive analysis of a case-study bridge (as shown in Table 1), selected from the NBI database (FHWA, 2022), is conducted. The objective is to evaluate the effectiveness of the developed framework for bridge life cycle cost analysis considering a 75-year life cycle, considering 10,000 random life-cycle episodes to incorporate the different sources of uncertainties. This assessment is performed by considering the bridge located in two distinct cities (San Francisco and Memphis) with different seismic hazard.

Table 1. Case study bridge specifications.

Bridge parameter	Deck area (m^2)	Detour length (km)	Average Daily Traffic (Vehicle/day)	Truck ratio (r_{truck})
Value	809.25	19	14740	0.02

To assess the impact of various maintenance strategies on the life-cycle cost of the bridge, several prescribed maintenance scenarios are considered as follows, each offering unique insights into the interplay of maintenance actions and life cycle dynamics.

- Scenario #1: Do nothing
- Scenario #2: Minor maintenance every 10 years
- Scenario #3: Major maintenance every 25 years
- Scenario #4: Replacement of all components at the 35^{th} year
- Scenario #5: A condition-based policy:

  If components in good condition: Do nothing
  If components in fair condition: Minor maintenance
  If components in poor condition: Replacement

Furthermore, several practical assumptions have been incorporated into the framework, including:

- The replacement of the substructure will lead to reconstruction of the entire bridge.
- The replacement of the girder is assumed to lead to the replacement of the deck.
- Initial component conditions are randomly sampled from the categories of good and fair conditions (CR = 9 - 5). This stochastic approach reflects the bridge condition rating uncertainty.

Additionally, several seismic retrofit strategies, namely steel jacketing (SJ), seat extender (SE), shear key (SK), and their combinations are introduced in conjunction with maintenance scenarios.

4.2 *Cost-benefit analysis of different seismic retrofit strategies*

This section presents a detailed cost-benefit analysis to evaluate the effectiveness of various seismic retrofit strategies. This sensitivity analysis is focusing exclusively on seismic hazard-related costs to assess the effectiveness of retrofit strategies in mitigating earthquake-induced expenses. To this aim, the bridge condition ratings are assumed to be at the best conditions all the time to isolate the contributions solely from seismic hazard and retrofitting. Table 2 summarizes the results, providing a comprehensive overview of cost-benefit ratios (i.e., the reduced indirect cost compared to the no retrofit scenario respect to the increased direct cost compared to the no retrofit scenario) for diverse retrofit strategies.

Table 2. Cost benefit ratio of different seismic retrofit strategies.

Retrofit Strategies		No Retrofit	SJ	SE	SK	SE+SK	SJ+SE	SJ+SE+SK
Memphis	CI*	683484	508194	588998	666805	595245	485322	517671
	CD†	8670	173989	48789	50143	90562	215457	257606
	CBR‡	N/A	1.06	2.36	0.40	1.08	0.96	0.67
San Francisco	CI*	2297066	1828645	2207142	2399218	2196767	1763731	1716294
	CD†	29723	191646	68371	72564	109678	232368	273312
	CBR‡	N/A	2.89	2.33	-2.38	1.25	2.63	2.38

* CI: Indirect cost
† CD: Direct cost
‡ Cost benefit ratio (CBR) = $(CI_{No\ Retrofit} - CI_{Retrofit})/(CD_{Retrofit} - CD_{No\ Retrofit})$

As indicated in Table 2, the cost-benefit ratios vary across different retrofitting scenarios and geographical locations with different local seismicity. Between the two cities, it is observed that it is more cost-effective to implement seismic retrofit for the San Francisco case, which may experience more frequent earthquake events compared to Memphis.

4.3 *Life cycle cost analysis of different maintenance strategies*

In this section, a life cycle cost analysis is carried out. Figure 1 shows the direct, indirect, and total costs (direct cost + 0.05 × indirect cost) of different maintenance strategies for San Francisco, with each curve corresponding to a specific maintenance strategy outlined in Section 4.1. Analyzing the figure reveals higher direct costs for "Replacement at 35th year" scenario and condition-based policy, while "Do nothing" scenario and "Minor maintenance every 10 years" scenario lead to lowest cumulative direct costs. Based on Figure 1 (B), condition-based policy demonstrates the lowest cumulative indirect costs, suggesting a balanced approach. Figure 1 (C) presents the total cost across various strategies for bridge, with a similar trend to the indirect cost curves. The above results can effectively reveal how the cumulative direct and indirect costs vary for different maintenance strategies.

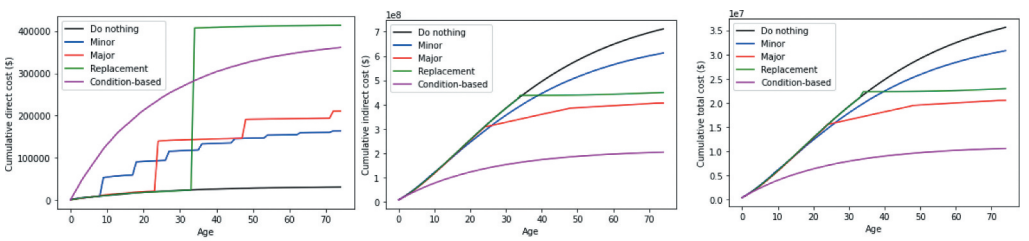

Figure 1. Cost curves for case study bridge: (A) Direct cost, (B) Indirect cost, and (C) Total cost.

For demonstration purposes, Figure 2 shows the influence of weighting factors on earthquake-induced indirect costs for the condition-based policy incorporated with a multi-retrofit scenario (SJ+SE+SK). The analysis of three weight configurations consistently shows that: as earthquake hazard weights (w_2) increases, indirect costs also rise proportionally, with a more significant impact in San Francisco. According to Figure 2, increasing earthquake-induced indirect costs from 5% to 100% results in a 30% increase for San Francisco and a 10% increase for Memphis in terms of cumulative indirect costs. This visualization can assist decision-makers, by highlighting the significance of weight selection in seismic risk assessments.

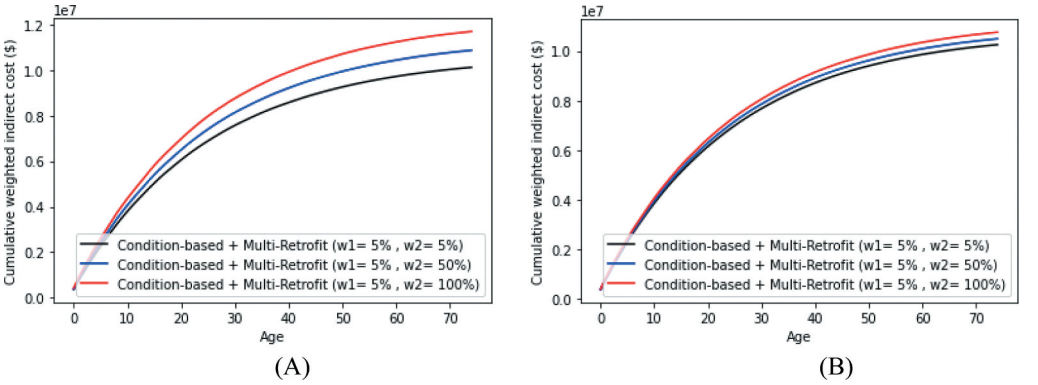

Figure 2. Different weighted indirect cost for case study bridge: A) San Francisco, B) Memphis.

5 CONCLUSION

This study introduces a simulation framework that enables episodic random simulations over a planning horizon for life-cycle cost analysis (LCCA) of highway bridges. This framework for the first time integrates the effects of bridge condition deterioration and seismic risks, by leveraging Markovian deterioration modeling and probabilistic seismic risk analysis. This framework can flexibly consider different maintenance and seismic retrofit strategies, and compare their efficacy in terms of life-cycle costs. Furthermore, by introducing different weighting factors, this approach enables the aggregation of indirect costs from different sources, facilitating cost assessment aligned with the stakeholders' risk attitude.

Ultimately, this research aims to empower decision-makers, engineers, and stakeholders involved in bridge asset management with a powerful tool that fosters more informed, risk-aware, and long-term-focused strategies for safeguarding bridge infrastructure in seismic-prone regions. The integration of bridge condition deterioration and seismic risks in the LCCA framework presented herein marks a significant step toward enhancing the resilience and longevity of our transportation networks. This framework can be further integrated with artificial intelligence to offer AI-informed sequential decision support for more proactive long-term bridge asset management.

ABSTRACT: A short-term hyperlocal meteorological forecast is an important tool for mitigating bridge risks as it empowers bridge operators and maintenance teams with timely and accurate weather predictions. Accurate predictions enable proactive responses to adverse conditions. Bridges are particularly vulnerable to extreme weather events, which can compromise their structural integrity and pose significant hazards. For instance, heavy rain can lead to flooding and erosion around bridge foundations, high winds can impose dynamic loads that strain the bridge's superstructure, freezing temperatures can cause ice accumulation and expansion within concrete or steel components, and fog can severely limit visibility for drivers, increasing the likelihood of accidents. This study presents a short-term hyperlocal meteorological forecast framework designed to assist in the real-time decision-making processes on the bridge. The proposed framework leverages cutting-edge machine learning algorithms, integrating a blend of local and global sensor systems to continuously collect real-time data. The data also forms a comprehensive dataset for the training process. The capacity of the framework to provide real-time weather insights for one geographic location is evaluated. In this context, this study critically examines one potential application of the proposed framework in predicting wind gusts, scrutinizing its versatility and efficacy in addressing diverse weather-related challenges faced by bridge management. Furthermore, the potential of the framework to enhance the resilience of transportation networks by minimizing disruptions and structural damage caused by adverse weather events is discussed and quantified.

1 INTRODUCTION

Bridges, as critical components of transportation infrastructure, are highly susceptible to adverse weather conditions (Markolf *et al.*, 2019). The integrity and safety of these structures can be significantly compromised by extreme weather events, necessitating proactive and effective management strategies. The importance of hyperlocal meteorological forecasts in mitigating bridge risks is becoming increasingly evident.

Recent studies highlight the growing role of machine learning and artificial intelligence in improving real-time decision-making for high-impact weather events, which are known to disrupt infrastructure (McGovern *et al.*, 2017). Machine learning algorithms have shown significant potential in enhancing weather data modeling, a computationally intensive task, by learning from data and producing relevant predictions (Trieu *et al.*, 2021).

The advancement in the application of machine learning for predicting extreme weather conditions has been remarkable. Lee and Chen (2021) developed a hybrid machine learning method that effectively predicts long-range precipitation under extreme weather conditions,

DOI: 10.1201/9781003483755-322

demonstrating the capability of machine learning to handle statistical variations caused by such conditions. Lucente *et al.* (2019) employed machine learning to predict high impact climate events like El Niño, highlighting the significance of machine learning in climatology. Mdegela *et al.* (2023) applied machine learning to classify extreme rainfall events, a key factor in predicting rainfall-induced floods. Lastly, Fang *et al.* (2021) surveyed the use of deep learning in predicting extreme weather, underscoring the role of advanced neural networks in meteorology.

This paper focuses on a short-term hyperlocal meteorological forecast framework, leveraging advanced machine learning algorithms. Following this introduction, the outline of this paper is as follows: Section 2 delves into the foundational concepts, methodologies, and theoretical underpinnings of the study, providing a detailed overview of the technological and algorithmic infrastructure utilized. In Section 3, the focus shifts to the specific tool developed for meteorological forecasting, discussing its design, functionality, and operational mechanisms, particularly its efficacy in short-term and localized weather predictions. Section 4 illustrates the practical implementation of this tool through various case studies or real-world scenarios, highlighting its effectiveness and practical utility. Section 5 expands on the versatility of the tool by exploring a wider range of possible scenarios and fields where the tool could be significantly beneficial. The paper concludes with Section 6, which synthesizes the key findings and insights from the research, discusses its limitations, and suggests directions for future research, emphasizing the broader impact and potential of the study in meteorological forecasting and related areas.

2 FRAMEWORK

The proposed framework for a short-term hyperlocal meteorological forecast tool for mitigating bridge risks is depicted in Figure 1. The proposed framework has versatile applicability across a range of scenarios; however, the forthcoming sections will specifically illustrate its application in the context of preventing truck overturning incidents caused by extreme lateral wind gusts. It signifies a step for risk mitigation for bridge operations, particularly in areas prone to severe weather events that could endanger vehicles crossing the structure.

The local weather station plays a pivotal role in the architecture, as it supplies real-time, site-specific atmospheric data, such as wind speed, wind direction, wind gusts, temperature, humidity, etc. which are critical for predicting the likelihood of high wind gusts that could compromise vehicular stability on bridges. This data is analyzed alongside information from one or more global weather stations that provides a broader context of weather patterns and predictions, thereby enhancing the system's ability to forecast local weather conditions (e.g., thunderstorms, etc.) imminent in the area of the the weather station.

Central to the operational efficacy of this system is the ML forecast algorithm. The predictive model within this system offers flexible operational modes: it can be executed locally, given that the computational demands are not substantial for edge computing. This local execution allows for rapid response times and reduces the need for constant cloud connectivity, which can be crucial in time-sensitive situations. Alternatively, the model can operate in cloud mode, harnessing greater computational power and resources. By potentially omitting data from the global weather stations, the framework can be streamlined to run entirely locally. This configuration, while less computationally intensive, still provides the capacity for accurate short-term forecasts, sufficient for initiating the early warning systems necessary to mitigate the risks of high wind events on bridge infrastructure.

The integration of hyperlocal real-time data with historical weather patterns to inform ML algorithms represents a significant advancement in location-specific weather forecasting. This methodology is corroborated by studies indicating that ML can substantially enhance the precision of weather-related risk assessments (Hall *et al.*, 2019; McGovern *et al.*, 2017). The framework's ability to rapidly process and analyze complex datasets exemplifies the tangible benefits of integrating AI with traditional meteorological techniques, enabling a more proactive approach to infrastructure safety management.

In the following, this paper seeks to present the technical design and operational testing results of the ML-based forecast tool, providing a detailed examination of its effectiveness in reducing the risk of truck overturning incidents on bridges. Through this exploration, the paper contributes

valuable insights to the domains of meteorology, civil engineering, and traffic safety, offering a replicable model for similar applications in other high-risk infrastructure scenarios.

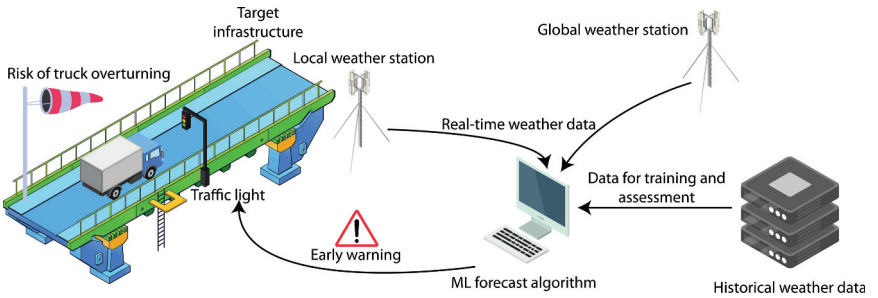

Figure 1. Proposed framework: example of application of the case of truck overturning under extreme lateral wind gusts.

3 SHORT-TERM HYPERLOCAL METEOROLOGICAL FORECAST TOOL

The short-term hyperlocal meteorological forecast tool is designed as a practical solution for accurate weather forecasting, particularly useful for bridge safety and transportation infrastructure.

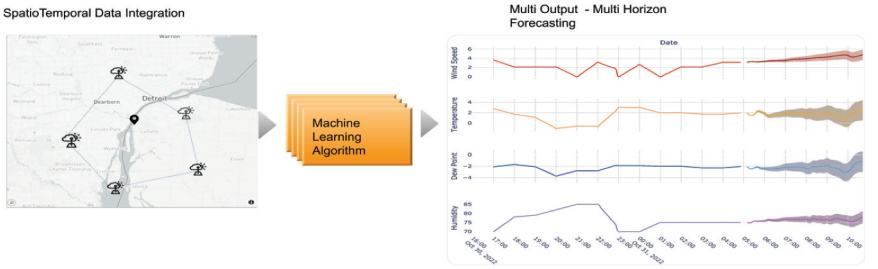

Figure 2. Short-term hyperlocal meteorological forecast tool: example of inputs and outputs.

The tool utilizes deep neural networks for its forecasting capabilities, chosen for their efficiency in processing complex weather data (see Figure 2). The core machine learning algorithm leverages Long-Short-Term-Memory (LSTM) and Convolutional (CNN) layers and has the following characteristics:

- **Multivariate and Multi-Output Forecasting**: The tool can handle multiple weather variables simultaneously and produce forecasts for several weather parameters. This feature allows for a comprehensive understanding of potential weather conditions.
- **Spatiotemporal Data Integration**: The framework combines data from local and global weather stations to train the machine learning algorithm. This ensures that the forecasts consider both local weather nuances and broader meteorological trends.
- **Customizable Inputs**: The tool's architecture permits customization through parametrized inputs, allowing it to be tailored to specific environmental conditions and user needs.
- **Scalability**: Designed to handle increasing amounts of data, the tool is scalable, ensuring its continued effectiveness as forecasting needs evolve.

The tool takes an input of past short sequences and forecasts a multi-horizon forecast of the desired time steps.

4 APPLICATION

High winds and wind gusts pose a significant hazard on highways and bridges, notably increasing the risk of vehicle accidents and particularly the overturning of high-profile vehicles

like trucks, buses, and trailers. This risk is heightened on highways where the combination of higher speeds and wind-induced forces can result in dangerous vehicular movements. Accurate short-term forecasting of wind gusts enables timely alerting of drivers and transportation authorities, who can then implement crucial safety measures, including speed restrictions, rerouting, and temporary road closures.

4.1 *Database*

The area chosen for this analysis is Cheyenne, Wyoming, USA, which is characterized by its high average wind speeds. Cheyenne's geographic and climatic conditions contribute to frequent and intense wind events, making it an ideal location for examining the impacts of wind on road safety. The significance of this choice is underscored by previous research and data indicating a notable correlation between the area's high wind speeds and the occurrence of wind-related vehicle accidents (Neupane *et al.*, 2022). By focusing on this area, the analysis aims to understand better the dynamics between high wind conditions and road safety.

The dataset is historical weather data from the stations nearest to the analysis point. The data starts from 2005-03-14 up to 2023-11-01 and comprised from 5 min interval of weather measurements. The data is split into three sets: training, validation and test set. The local station is ASOS station CHY and global station is chosen as the LAR station.

4.2 *Results*

The datasets are further split in sequences of 180 min interval (36 timesteps), the model is set to forecast 90 min interval (18 timesteps). The results and the performance of the proposed framework will be evaluated both in relation to forecasting the exact values but also in terms of distinguishing exceedance of thresholds relevant to the application. The model is forecasting the wind gust magnitude (Figure 3) and the vertical and horizontal components of the wind.

The forecast performances are assessed by using the following metrics: Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE). Table 1 illustrates the regression model's capability in forecasting wind-related parameters, with a particular focus on wind gusts and wind direction. Notably, the model demonstrates higher accuracy in predicting specific components of wind gusts (U and V) compared to general gust measurements, as indicated by lower MAE and RMSE values.

The model is evaluated in relation to the detection of values above a particular threshold. Specifically, for the assessment of truck overturning risks, the critical threshold is set at 20 m/sec (Baker et al., 2022). Figure 4 presents a confusion matrix, offering a detailed visual representation of the model's performance in this context. In this analysis, there are 331 instances where

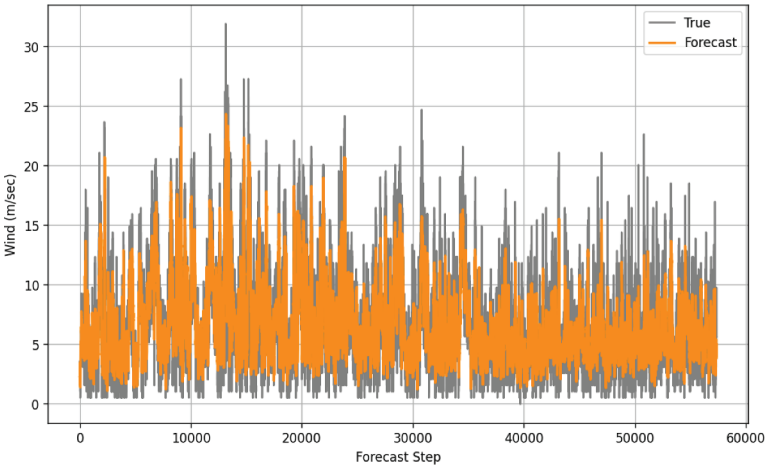

Figure 3. The complete test set true and forecasted wind gust values; each step is a 5-min interval step.

Table 1. Regression forecast performances.

	MAE	RMSE	Units
Wind Gust	1.61	2.21	m/sec
Wind Gust-U	1.24	1.72	m/sec
Wind Gust-V	1.36	1.94	m/sec
Wind Direction	23.81	-	degrees

TARGET / OUTPUT	Below 20m/s	Above 20m/s	SUM
Below 20m/s	56834 99.07%	201 0.35%	57035 99.65% 0.35%
Above 20m/s	159 0.28%	172 0.30%	331 51.96% 48.04%
SUM	56993 99.72% 0.28%	373 46.11% 53.89%	57006 / 57366 99.37% 0.63%

Figure 4. Confusion matrix for each 5 min observation of test set converted to binary above or below the 20m/sec threshold.

the wind gust surpasses the established threshold. The model demonstrates a high level of precision in identifying these occurrences, achieving an impressive accuracy rate of 99.3%. Additionally, its performance is further underscored by a robust Receiver Operating Characteristic (ROC) Area Under the Curve (AUC) score of 0.97, indicating excellent predictive capability.

Referring to Table 2, the model incorrectly forecasts 201-time steps where wind gusts exceed 20 m/sec. Upon closer analysis of these false positives, it is observed that 70% of these instances feature wind gusts above 15 m/sec. Despite being below the critical threshold, such wind speeds can still represent a significant risk for various types of vehicles.

Table 2. Statistics of false positives.

Samples	201	-
Mean Wind Gust (m/sec)	16.3	m/sec
Standard Dev (m/sec)	3.18	m/sec
30% percentile (m/sec)	15.43	m/sec

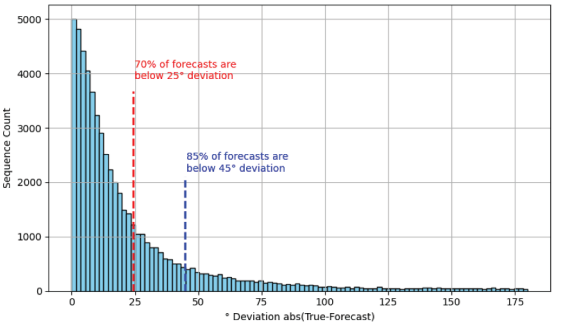

Figure 5. Distribution of absolute angle difference between true and forecasted wind vectors for each step.

The error in wind direction forecasting is quantified by the absolute difference between the true wind vector's angle and that predicted by the forecast model. As illustrated in Figure 5, the histogram of forecast deviation shows that 70% of forecasts have an error within 25°, and 85% fall within a 45° deviation. This distribution indicates a generally reliable directional forecast, with a significant majority of predictions deviating less than half a right angle from the actual wind direction.

5 VARIOUS POTENTIAL APPLICATIONS

The proposed short-term hyperlocal meteorological forecast tool can be used as an approach to bridge safety and operational efficiency. Its capacity to anticipate and react to various weather-related risks is pivotal in mitigating potential hazards (Figure 6).

Here, we explore five key applications of this innovative tool:

- **Icing Prevention:** Bridges are particularly susceptible to icing, which poses a significant risk to vehicular stability and safety. The forecast tool can predict temperature fluctuations and humidity levels that lead to ice formation, enabling preemptive deployment of deicing measures. By doing so, it ensures the maintenance of safe passage during cold spells and winter storms, thereby reducing the incidence of accidents related to slippery surfaces (Wu and Peng, 2011).
- **Truck Overturning Alerts:** High winds can lead to the overturning of high-profile vehicles like trucks, especially on exposed bridges. The tool's capability to provide real-time wind speed and direction forecasts allows for the issuance of timely alerts. These alerts can inform traffic management systems and drivers, prompting necessary precautions such as vehicular speed restrictions or temporary traffic halts, thus averting potential overturning incidents (Lim, Kim, and Kim, 2020).
- **Flood Prediction and Management:** Flash floods represent a formidable threat to bridge integrity and road user safety. The forecast tool's integration of high-resolution rainfall estimates offers a proactive flood management approach. This approach not only fortifies flood preparedness but also facilitates the execution of emergency plans such as road closures and traffic redirection, thereby safeguarding both infrastructure and commuters (Naulin, Payrastre, and Gaume, 2013).

Figure 6. Key applications of the short-term hyperlocal meteorological forecast tool.

- **Visibility and Fog Detection:** Reduced visibility from fog is a frequent challenge in bridge environments. The forecast tool's ability to predict low-visibility events enables the activation of safety protocols, such as fog lighting and signage, and the implementation of speed reduction measures. This not only prevents accidents due to poor visibility but also enhances the overall safety of the driving experience during adverse weather conditions (Chun-Hua, 2008).
- **Structural Health Monitoring:** Extreme weather events exert considerable stress on bridge structures, which can lead to wear and eventual failure. The forecast tool's detailed weather predictions allow for timely structural assessments and maintenance scheduling. Such predictive maintenance ensures the longevity of the bridge and uninterrupted service, reducing the likelihood of catastrophic structural failures (Lin, Peng, and Wu, 2010).

The Short-Term Hyperlocal Meteorological Forecast Tool is pivotal not only for immediate safety measures but also for the long-term maintenance of bridge structures. In addition to its various applications, an essential function is its capacity to predict environmental conditions leading to structural corrosion and degradation:

- **Corrosion and Degradation Prediction:** The tool's precise weather data assists in forecasting conditions like high humidity and salinity, particularly detrimental to bridges. This ability to anticipate corrosive weather conditions allows for preemptive maintenance actions, such as applying corrosion-resistant treatments or scheduling detailed inspections. This proactive approach in combating corrosion and degradation is vital for the longevity and safety of bridge structures, helping to avert costly repairs and ensuring structural integrity over time (Wu and Peng, 2011).

6 CONCLUSIONS

In conclusion, the proposed framework of the short-term hyperlocal meteorological forecast tool, as outlined in this study, demonstrates a significant potential in enhancing bridge safety and operational efficiency. Its versatile applicability across various scenarios, particularly in preventing truck overturning incidents caused by extreme lateral wind gusts, highlights its utility in addressing specific and critical weather-related challenges.

The tool's advanced predictive capabilities, powered by machine learning algorithms, allow for accurate forecasting of high-risk weather conditions, such as strong lateral winds that pose a significant risk to high-profile vehicles on bridges. By providing timely alerts and actionable insights, the framework enables proactive measures to be taken, thereby mitigating the risk of accidents and enhancing the overall safety of bridge infrastructure.

Moreover, the framework's adaptability to different scenarios underscores its potential as a valuable asset not only for specific weather events but also for broader applications in infrastructure management and safety. The detailed exploration of its application in truck overturning prevention serves as a compelling example of how hyperlocal weather forecasting can be effectively utilized in practical, high-stakes environments.

The short-term hyperlocal meteorological forecast tool showcases diverse applications, crucial for both immediate safety and long-term bridge maintenance. Its key strengths lie in accurately predicting and addressing various risks including icing, truck overturning due to high winds, flash floods, fog-induced visibility issues, and structural damage caused by environmental factors.

Additionally, the tool's capabilities extend to long-term structural health monitoring. By predicting weather conditions that could lead to corrosion, it aids in preventive maintenance, thereby reducing the risk of long-term structural damage and extending the lifespan of bridge infrastructure. Overall, this study presents a robust and innovative approach to leveraging meteorological data for enhancing infrastructure safety. The short-term hyperlocal meteorological forecast tool stands as a testament to the advancements in technology and data analytics, offering a promising solution for mitigating bridge risks in various challenging scenarios.

Remaining fatigue service life of the Hillsborough River Bridge in PEI, Canada

C. MacAulay, G. MacDonald, A. MacDonald & R. Keefe
Harbourside Engineering Consultants, Stratford, Prince Edward Island, Canada

D. Evans
Prince Edward Island Transportation and Infrastructure, Charlottetown, Prince Edward Island, Canada

ABSTRACT: The Hillsborough Bridge is Prince Edward Island Department of Transportation and Infrastructures (DTI's) signature structure, which connects the capital city of Charlottetown with the bordering community of Stratford and southern portion of Kings County. It is the busiest section of highway in the province with a peak average annual daily traffic (AADT) of about 40,000 vehicles per day (vpd). Any service interruption at this location would necessitate a 57 km detour, causing significant user costs and delays. Originally a ferry crossing, it was replaced by a railway bridge in the early 1900, supported on 11 masonry piers with a turnstile (or swing) span to allow navigation of the Hillsborough River. This was replaced in 1962 with a truss structure, which carried two-lanes of automobile traffic. The deck truss still exists today.

Several modifications to the truss structure have since been completed including: widening of the structure to four lanes by used of a variable depth trapezoidal box structure, as well as strengthening some transverse members and truss joints to aide in the installation of municipal services and an Active Transportation Corridor.

Harbourside Engineering Consultants Ltd. (HEC), with the support of DTI, are conducting a Remaining Fatigue Life analysis of the deck-truss structure (the scope does not include the box girders). Due to the unique nature of the structural system in place, the analysis requires detailed modelling of the elements and connections, including the newer trapezoidal box details and connection to the deck truss.

This paper details the approach, including the use of a model calibrated using structural response data from controlled loadings, in determining the remaining fatigue life for the truss portion of the Hillsborough River Bridge per CSA S6:19 (Canadian Highway Bridge Design Code).

1 INTRODUCTION

The Hillsborough River Bridge in Charlottetown, PEI, Canada is an aging piece of infrastructure that is critical to the local traffic network. Originally constructed in 1959, the bridge superstructure is a 3-span (78 m – 91 m – 78 m) steel box truss and in 1996 was widened on each side by variable depth steel box girders. The following is a report on the fatigue life analysis for the truss members of the Hillsborough River Bridge, located between Charlottetown and Stratford, PEI, Canada.

In 2021, an arm's length inspection of the structure, performed by Harbourside, identified several fatigue prone details on the truss and a subsequent investigation, using non-destructive testing, revealed the presence of cracks at some of these details. These cracks were drilled as part of repairs to attempt to arrest their growth (Harbourside, 2023).

The analysis was conducted to determine the theoretical residual fatigue life is for each detail. Concerns identified in the analysis could potentially be addressed prior to or during the upcoming coating project.

DOI: 10.1201/9781003483755-323

To provide additional context for the report, a brief history of known major upgrades and evaluations of the structure is provided as follows:

- Originally constructed in 1959, the bridge superstructure is a 3-span (78 m – 91 m – 78 m) steel box truss and in 1996 was widened on each side by variable depth steel box girders. During the widening project, the box truss underwent a significant reinforcing program which stiffened many of the members of the truss due to the anticipated increase in load effects (CBCL, 2018), including the addition of post-tensioning bars for some bottom chord members.
- In 2015, Bridge Diagnostics Inc. (BDI) was hired by Prince Edward Island Transportation and Infrastructure (PEITI) to complete load tests and field verified modelling on the structure to better quantify the structure's behaviour. BDI worked alongside Stantec during this process. CBCL also had a role as they had performed an analysis on the structure in 2014. CBCL used the results of BDI's testing to update their own model and provided dead load effects and member capacities to BDI (BDI, 2016).
- In 2017, additional member strengthening was completed in anticipation of future works.
- In 2019, two sewage pipes were added to the structure supported by W-sections spanning between lower floorbeams. IFT drawings for the pipes (Stantec, 2019) do not reflect the as-built condition, but the as-built condition was used in this analysis.
- In 2021, an active transportation (AT) trail was installed on the west side of the structure, which had the effect of narrowing the traffic lanes and shifting them to the east.
- In 2021, Harbourside, with the assistance of a Tacten Rope Access Team, completed a detailed arm's length inspection on the truss members and connections to develop tender documents for repairs and recoating.
- In 2022, Harbourside with the assistance of a Tacten Rope Access Team, completed NDT testing on select welded details, as well as repairs on three locations that were found to have cracks.

2 ASSUMPTIONS

A list of all major assumptions made during the analysis is provided below:

- A loss of sectional area due to corrosion of 5% was assumed to be present on all members. Due to severe corrosion noted on elements within group BC1.1, the loss of area due to corrosion was assumed to be 20% for these elements. This is consistent with CBCL's assumptions (BDI, 2016). No allowance was made for future corrosion.
- Evaluation of the structure was completed as per Section 14 of CSA Group (2019). The traffic lanes marked on the structure were assumed to be the design lanes.
- The passage of a CL-625 design vehicle causes one stress cycle for each member as per Table 10.5 in the Canadian Highway Bridge Design Code.
- The fatigue analysis considered the full life of the structure since construction in 1959. The poor (Detail Category E and E1) fatigue details were added in 1996. Prior to 1996, the truss members would have been Detail Category D (due to riveted connections). Analysis demonstrated the Category E and E1 details for the stress range and number of cycles post 1996 governs over the Category D detail for the full life of the structure. Fatigue damage from the Category D and E details have not been summed together as the defect(s) introduced by the welding of the cover plates is remote from the original rivets when considering the cross sections of the elements.
- The Dywidag post-tensioning (PT) rods were post tensioned to 20 kN as per CBCL (2018). The primary members of the bottom chords are back-to-back C-channels and the ends of the post tensioning rods connect to the bottom chord by bearing on horizontal shear plates welded onto the back side of each channel. The post tensioning rods are also supported vertically at regular intervals via saddles (vertical plates with holes for the rod, welded to transverse angles which are in turn welded to top flanges of the bottom chord channels).
- The concrete deck was assumed to be uncracked over the piers. BDI (2016), indicated that at the load levels they tested the deck appeared to be acting in an uncracked manner over the pier and their test loads were similar to the weight of the fatigue truck.

– The concrete deck was assumed to be fully composite with top chord as per the results of BDI (2016).
– The concrete deck stiffness was based on a compressive strength of 55 MPa as per the results of BDI (2016).
– The total weight of the paint and bolts/rivets was assumed to be 4% of the truss self weight.
– The density of sewage within the pipes was assumed to be 1200 kg/m^3.
– All tack welds noted in the 2021 inspection are assumed to be removed.

3 MODEL GENERATION

Harbourside received CAD files for BDI's model geometry and a text file containing information from BDI's model, such as member section properties and material properties. The CAD files were converted to a S-Frame 3D finite element model and the section and material properties from the text file were imported into the model. Harbourside performed geometry checks throughout the model to verify it was representative. Harbourside also checked the section properties for a random selection of 10% of the members to verify BDI's values.

To confirm that Harbourside's model agreed with BDI's model, Harbourside prepared four test load cases and requested BDI perform the same four test load cases. By comparing the results of the two models, Harbourside determined:

– The original model considered the truss members with fixed end member releases, not pins.
– The original model did not model the real support conditions. Instead, the original model only considered vertical supports, with a couple of transverse and longitudinal supports added for model stability. In addition, each of the box girder bearings were modelled as a pair of closely spaced rigid vertical supports.
– The original model did not include any post tensioning force in the PT rods.
– The original model had the PT hangers shear connected to the PT rods (i.e., the rods/chords could transfer axial load between each other at each hanger).
– The results from the original model were produced using a linear static analysis.
– In the original model the TC5 and TC6 top chords had the incorrect section properties. The section properties of TC5 and TC6 had been reversed. These are the top chord members above and adjacent to the piers.
– The box girder-to-truss members at the abutments and piers were not considered in the original model (only the top beams between the box and the truss at the piers).
– Harbourside's S-Frame model matched the stiffness of the original model to within ±6%. In other words, a comparison of the vertical deflection values at various locations throughout the bridge were within ±6% between the two models.
– Total vertical reactions to a pier/abutment were within 0.4%.

After reviewing the results of the BDI to Harbourside model comparison (in particular, the stiffness and reactions) Harbourside determined that the two models were behaving similarly and therefore Harbourside's model could be considered calibrated to BDI's model. There were, however, some concerns in BDI's model that needed to be addressed. It is worth noting that it is possible some of the issues may have been generated during the model translation process, or BDI accounted for them in some other way that was not indicated in their report or subsequent communications. To address these concerns, prior to performing the analysis, the following adjustments were made to the Harbourside model:

– The support conditions were adjusted to better reflect the true conditions. The pair of closely spaced rigid supports under each box girder were replaced with a single vertical support per bearing, and the longitudinal and lateral supports were modelled with stiff springs and placed at the locations indicated in the drawings.
– The PT rods were post tensioned to 20 kN.
– The intermediate PT rod hangers were deleted from the model. They were acting as shear connectors and axial load from the PT rods was being transferred into the bottom chord at

each hanger location. In reality, aside from a small amount of friction, the rods are free to slide inside the hangers and can only transfer axial force into the bottom chord at the ends of each rod.
- Harbourside used a non-linear static analysis to generate results. The non-linear analysis allows for the PT rods to be modelled as tension only members. In BDI's model, it is possible for the rods to take compression which results in a decrease in the bottom chord compressive force.
- Harbourside corrected the TC5 and TC6 section properties. These members are in the bays directly above and adjacent to the piers (U9 to U15 and U23-U29) and they have a significant local effect on the stiffness of the truss frames when considering the truss members to have fixed end connections (as BDI did). Using the correct section properties reduces moments in the bottom chord members by approximately 25%. The effects are not as significant in the truss model using pinned connected members.
- Harbourside added the box girder-to-truss members at the abutments and piers that were missing.
- Harbourside adjusted the area of the longitudinal deck stringers to be near zero as it was noted that they were taking axial load due to global bending action. It is unclear if this was happening in the original model but upon review of the drawings and photos from site, it is clear the stringer connections would not be capable of transmitting significant axial forces. Loads were added to the dead load case to compensate for the loss of stringer area.

4 ANALYSIS

Every member was assigned a fatigue category following guidance in CSA Group (2019). The details on Dwg. No 25 of the Hillsborough Bridge Improvement drawings (CBCL, 2018) and S02 of the Truss Strengthening Drawings (CBCL, 2017) show the fatigue prone details. The fatigue categories assigned range from Class D to Class E1. There were no details prone to distortion induced fatigue noted on the truss. Photo 1 and Photo 2 show typical as-built post tensioning details on the truss bottom chord.

Photo 1. Example of post tensioning end connection, category E fatigue detail (Harbourside, 2023).

PEITI provided historical AADT values for 1990-2021, as well as the estimated precent trucks and growth rate. From this information Harbourside was able to determine the annual daily truck traffic (ADTT) and the total number of truck cycles from 1996-2021 at (23.76 million), as well as make predictions for the additional number of cycles for each year after 2021 using an annual growth rate of 1.38% (calculated from the data provided). From 1959 to 1996, traffic was assumed to grow at a rate of 1.38% and consisted of 5% trucks.

To complete the detailed analysis, Harbourside first determined the stress in each truss member due to the dead load of the structure. Although fatigue calculations are only based on

Photo 2. Example of post tensioning hanger connection, category E1 fatigue detail (Harbourside, 2023).

the range of stress caused by the passage of a single CL-625, load-induced fatigue was disregarded when the compressive stress was at least twice the maximum tensile live load stress in locations where the stresses resulting from the permanent loads are compressive as per CSA Group (2019).

Based on the phasing sequence (see Figure 1) provided in the Hillsborough Bridge Improvement drawings (CBCL, 2018) there is a condition where the boxes have been installed and the deck above them is composite while the concrete deck over the truss is still wet (non-composite) and separated from the box girder deck by a gap. During this stage the load effects in the truss members from the self-weight of the steel and concrete, and the load effects from the post-tensioning would have been locked in. The load effects from the asphalt, barriers, and sidewalks on the composite section were superimposed to get the total dead load effects prior to the addition of the AT Trail. The change in dead load due to the addition of the AT Trail was also captured and added. The maximum tensile live load stress caused by the passage of a CL-625 was then compared to the combined dead load effects for each member, to determine if load-induced fatigue could be disregarded.

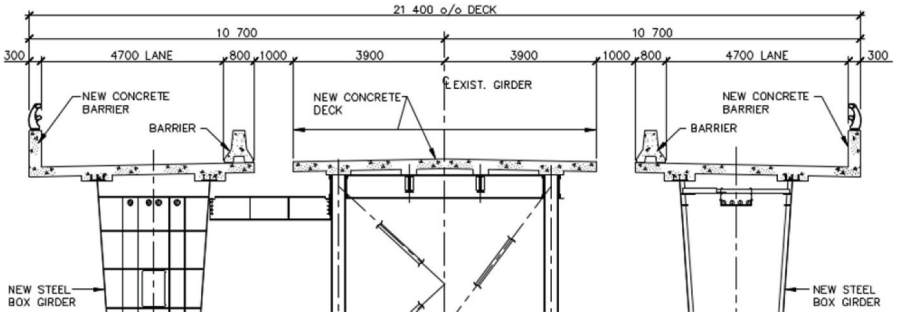

Figure 1. Phase 3 of Bridge Expansion (CBCL, 2018).

From CSA Group (2019), for load induced fatigue, except as otherwise specified, bridge components shall satisfy Equation 1, below:

$$0.52 C_L f_{sr} < F_{sr} \tag{1}$$

where C_L = 1.0 when the weight of the design vehicle ≤ 625 kN; f_{sr} = calculated stress range due to the passage of a single CL-625; and F_{sr} = fatigue stress range resistance of a member or detail.

Furthermore, to determine the fatigue stress range resistance CSA Group (2019), indicates:

$$F_{sr} = \left(\frac{\gamma}{N_c}\right)^{\frac{1}{3}} \tag{2}$$

$$\text{If } F_{sr} = \left(\frac{\gamma}{N_c}\right)^{\frac{1}{3}} < F_{srt},\ F_{sr} = \left(\frac{\gamma'}{N_c}\right)^{\frac{1}{5}} \frac{F_{srt}}{2} \tag{3}$$

where γ = fatigue life constants pertaining to the fatigue detail category; N_c = specified number of design cycles; and F_{srt} = constant amplitude threshold stress range.

The stress range in each truss member caused by the passage of a single CL-625 truck was calculated for each of the travel lanes, with the bridge in the pre-AT trail condition. The stress range for each member was compared to the stress curve for the member's respective fatigue category, and the maximum number of cycles before failure was determined. There are three zones on the fatigue detail stress curve, as shown in Equations 2 and 3, and when the stress range is low enough that it does not exceed half of the constant amplitude threshold stress range the number of cycles is deemed to be infinite for that member i.e. infinite fatigue life. Based on the stress ranges calculated, many of the truss members were determined to fall into this zone; and therefore, have an infinite fatigue life. Equation 1 and Equation 3 can be combined and rearranged as shown below in Equations 4 to 6, to describe the process above.

$$\text{If } 0.52 f_{sr} < \frac{F_{srt}}{2}, N_c = \infty \tag{4}$$

$$\text{Else if } 0.52 f_{sr} < F_{srt}, N_c = \left(\frac{\gamma'}{F_{sr}{}^5}\right) \tag{5}$$

$$\text{Else } N_c = \left(\frac{\gamma}{F_{sr}{}^3}\right) \tag{6}$$

The maximum number of cycles was compared to the number of truck cycles prior to 2021 (pre-AT Trail) and the percent usage was determined. The results from the passage of a single CL-625 truck under the new lane configuration (post-2021 and the addition of the AT Trail) were analysed. For every member, following the same process as described above, working with the fatigue curves and the calculated stress range, the maximum number of truck cycles before failure was determined. Then, following Equation 7, the already used fatigue life was subtracted (i.e., if a member had used 10% of its fatigue life prior to 2021, the post 2021 maximum number of cycles was reduced by 10% as well).

$$\left(1 - \frac{N_{pre\ 2021}}{N_{c,\ pre\ 2021}}\right) \times N_{c,\ post\ 2021} = N_{remaining} \tag{7}$$

where $N_{pre\ 2021}$ = number of design cycles seen by the bridge between 1996-2021; $N_{c,pre\ 2021}$ = maximum specified number of design cycles (from Equations 4 to 6) for stress range pre-2021; $N_{c,post\ 2021}$ = maximum specified number of design cycles (from Equations 4 to 6) for stress range post 2021; and $N_{remaining}$ = remaining number of design cycles. As noted in the assumptions, fatigue damage from the Category D and E stresses have not been summed together as the defect-(s) introduced by the welding of the cover plates is remote from the original rivets when considering the cross sections of the elements.

The ADTT values calculated from the PEITI data were then projected forward using the provided growth rate to determine how long each member can safely remain in service. For

simplicity, if the remaining fatigue life was determined to be more than 50 years (from 2023) the forward projections stopped, and the member's lifespan was labelled as "50+".

5 RESULTS

The members were grouped into three categories (based on percent fatigue life used from 1996) and a graphical representation of this is shown in Figure 2. Only half of the truss members are shown because the results are symmetrical about the centreline of the truss (U19-L19). Elements in green have used 0% of their fatigue life, elements in yellow have used between 0% to 10% of their fatigue life and elements in red have used between 10% to 31% of their fatigue life.

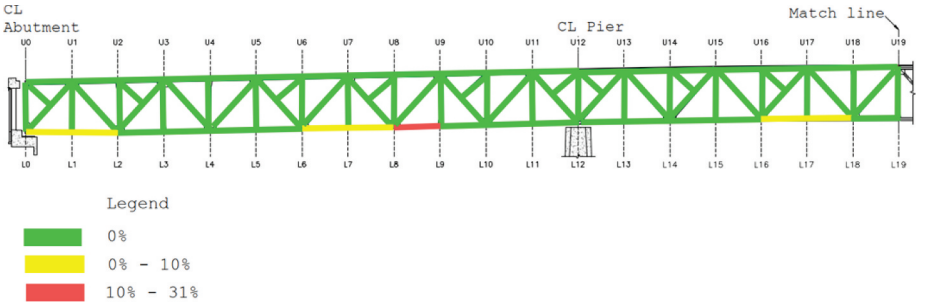

Figure 2. Percentage of fatigue life used.

L8-L9 and L29-L30 on both the North and South trusses were determined to have used 31% of their fatigue life (as of 2021) and have the least remaining fatigue life at 33 years (from 2023). The governing detail on all the yellow and red members is the post tensioning hanger as it is a category E1 Fatigue Detail. If this detail is removed, then all the members except L16-L17 and L22-L23 move to category E (because of the cover plates). L16-L17 and L22-L23 move to category D, as they don't have cover plates but are riveted. The resulting effect is that all members would have 50+ years of remaining fatigue life.

During the 2022 inspection of the welds completed by Harbourside, cracks were noted in three locations (Harbourside, 2022):

- East truss, on L10-U11 near U11 (see Photo 5)
- East truss, on L10-U11 near L10
- East, truss, on U27-L28 near L27

Photo 3. Example of cracked weld (Harbourside, 2023).

While all the cracks are located on members with poor fatigue details (category E cover plates), none of the cracks were located on members noted above that are suspected of having a reduced fatigue life. As discussed in Fisher, Kulak & Smith (1998), there are several reasons why cracks may occur in steel members including, large number of cycles, a large stress range, out-of-plane distortion, corrosion, inappropriate fabrication procedures, poor welding procedures, and large defects. The results of this analysis suggest the cracks were not caused by a large number of cycles or large stress range. Large defects, out-of-plane distortion and significant corrosion were also not observed. This leads Harbourside to believe that the cracks seen on the structure are likely the result of poor welding procedures or inappropriate fabrication procedures.

6 CONCLUSION

Harbourside has completed a theoretical remaining fatigue life analysis for the truss portion of the Hillsborough River Bridge. The analysis was performed after several poor (category E and E1) fatigue details were noted on the truss and subsequent non-destructive testing revealed the presence of cracks in some locations. Due to the complex, indeterminate nature of the structure a detailed model was required. This model used was calibrated using structural response data from controlled loadings. The results of the analysis indicate that theoretically, the structure has approximately 33 years of remaining service life based on the governing elements and with small repairs the remaining service life could be extended to greater than 50 years.

The results of the analysis do not point to load induced fatigue damage alone being the direct cause of cracks observed in some members and further investigation is required to understand the cause of these cracks and the risk associated with them.

7 RECOMMENDATIONS

Harbourside recommends that that metallurgical testing be performed on the L10-U11 and U27-L28 members as well as select other members to be determined. Specifically, Harbourside is recommending Charpy impact tests, yield strength tests, and chemical analyses of both the cover plates and original truss steel. The chemical analysis will provide insight into the weldability of the steel, while the Charpy impact test will help determine how brittle the steel is. As noted in Fisher, Kulak & Smith (1998), brittle fracture is an undesirable situation and low fracture toughness bridge steels can result in brittle fracture under normal service loads when cracks develop. Understanding the fracture toughness of the steel will help Harbourside understand the likelihood of a brittle fracture. The yield strength tests will be useful in other phases of the project and can be completed for minimal additional cost. This information will help narrow down the possible causes for the observed cracks.

Harbourside recommends that the PT rod hangers on all members are removed and replaced with a bolted detail (details for this were provided in Harbourside's Coating and Repairs Package previously submitted to PEITI). During the removal process care needs to be taken to ensure that main chord members aren't damaged and that the welds are ground smooth in the direction of the applied stress. By completing these repairs, the remaining fatigue life of the truss can be considered to be greater than 50 years (post 2023).

Assuming the above noted repairs are completed, a regular monitoring plan for all members (beyond the standard biennial inspections) is not recommended at this time; however, the locations that were noted to be cracked should be re-examined prior to recoating and on a regular basis thereafter, to assess whether the drilled holes have been effective in arresting the crack growth. Particular attention should also be given to the severity of member corrosion during each biennial inspection. Corrosion of the truss members can have a negative impact on the fatigue life of the structure because corrosion reduces the member cross sectional area, increasing stresses. Severe corrosion can also induce discontinuities which cause stress concentrations.

During the 2021 inspection of the structure by Harbourside and Tacten, tack welds were noted on the gusset plates (Harbourside 2023). Harbourside has not considered these tack welds in the fatigue analysis, and experience has shown that these types of tack welds can induce cracks in members and gussets. It is Harbourside's understanding that these tack welds will be removed during the planned recoating project. This is an extremely important assumption in this assessment.

Climate change challenges: A study on bridge accessories and structural performance

D. Greco, A. Moscatelli & D. Briccola
University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Mendrisio, Switzerland

ABSTRACT: Structural bearings and bridge expansion joints are accessories requiring an accurate design, inspection, and maintenance, as their malfunctioning can cause a bridge to depart from its expected behavior and their replacement is a costly activity due to passenger and freight traffic interruption. Because of their exposure to water, deicing agents, and silt, they experience a high level of wearing that limits their serviceability far beneath the warranty period ensured by manufacturers. Climate change exacerbates this trend: storms and hail increase the volume of bridge deck water runoff and cause clogging of expansion joints due to the accumulation of grit and gravel and severe damage to bearings, leading to restrained movements. That causes the onset of distress in structural elements and triggers further damage. A study on the impact of restrained movements at increased temperatures according to Tessin climate change scenarios in 2085 for RCP8.5 has been carried out.

1 INTRODUCTION

The impact of climate change on the frequency and magnitude of natural hazard-related events is evident worldwide (ITF, 2016). By contrast, the potentially highly damaging impact on the built environment, specifically on viaducts and bridges, needs further effort from the scientific and professional community to develop effective adaptation strategies. More in detail, the consequences of increased temperatures and precipitation, especially when considering worst-case emission scenarios, directly affect (i) the design of new bridges in terms of detailing reinforcement for cracking control and design of bearing devices and expansion joints and (ii) the maintenance of existing infrastructures to uncover the relationship between climatic indicators and degradation processes. The paper tackles the impact of climate change on bridge design through a simplified approach, leaving the rigorous uncertainty treatment to further studies on the topic. First, a review of the most common damages on bridge accessories are presented; then, the study focuses on evaluating the impact of temperature variations on bridge superstructure actions in presence of bridge accessories malfunctioning. In Tessin, about 42% of bridges are multi-span box girder bridges in reinforced and prestressed concrete: for this reason, the numerical application focuses on a three-span prestressed concrete box girder bridge.

2 CLIMATE CHANGE RELATED IMPACTS ON BRIDGES

Currently, 52% of expansion joints and 22% of bearing devices in Tessin undergo a pronounced degradation, opening questions on their actual service duration compared with that declared by manufacturers and the bridge one. As stated in Lima et al., 2010 damage to these elements results in average maintenance costs of 20% of the total maintenance cost and their replacement leads to subsequent traffic disruptions and indirect economic losses. Therefore, their condition assessment to timely detect defects that could affect their behavior and compromising their functionality is a crucial activity in bridge management. In fact, as shown

DOI: 10.1201/9781003483755-324

in Figure 1, malfunctioning of expansion joints, and bearing devices can jeopardize the condition of both the super- and sub-structure leading to cracking phenomena on the deck, efflorescence and spalling at half-joint sections, and pouring along the piers together with a diffused degradation of material properties.

For instance, the main cantonal road-network in Tessin comprises 138 bridges with bearing devices and expansions joints 52% on average of which have already undergone multiple localized repair work during their lifespan. Here, bearing devices and expansion joints attain level 3 on a five-levels scale for condition assessment spanning from good to bad conditions, as shown in Figure 2 and Figure 3. Expansion joints are always more damaged than bearing devices because of their direct exposure to deicing salts, abrasion due to traffic loads and thermal degradation.

Their clogging due to the accumulation of sand can lead to premature cracking of the pavement and increased corrosion risk for the deck (Palu et al., 2019). Additionally, there appears to be a correlation between the condition assessment of bearings and expansion joints: for almost all sampled bridges, a level 3 condition assessment of bearing devices corresponds to a level 3-4 condition assessment of expansion joints. Moreover, since degradation phenomena considerably affect the structural capacity, particular attention must be given to head sections in case of prestressed systems where very corrosion-sensitive anchor heads are usually placed. A further difference exists between bridges located in the northern or southern regions of Tessin. Despite the reduced traffic, bridges in the north are more damaged than those in the south: this evidence can be easily understood if one considers the prolonged use of deicing salts in cold regions rather than in hotter ones. Conversely, in the south damage to expansion joints concentrates close to the Italian border, where are daily detected high traffic volume.

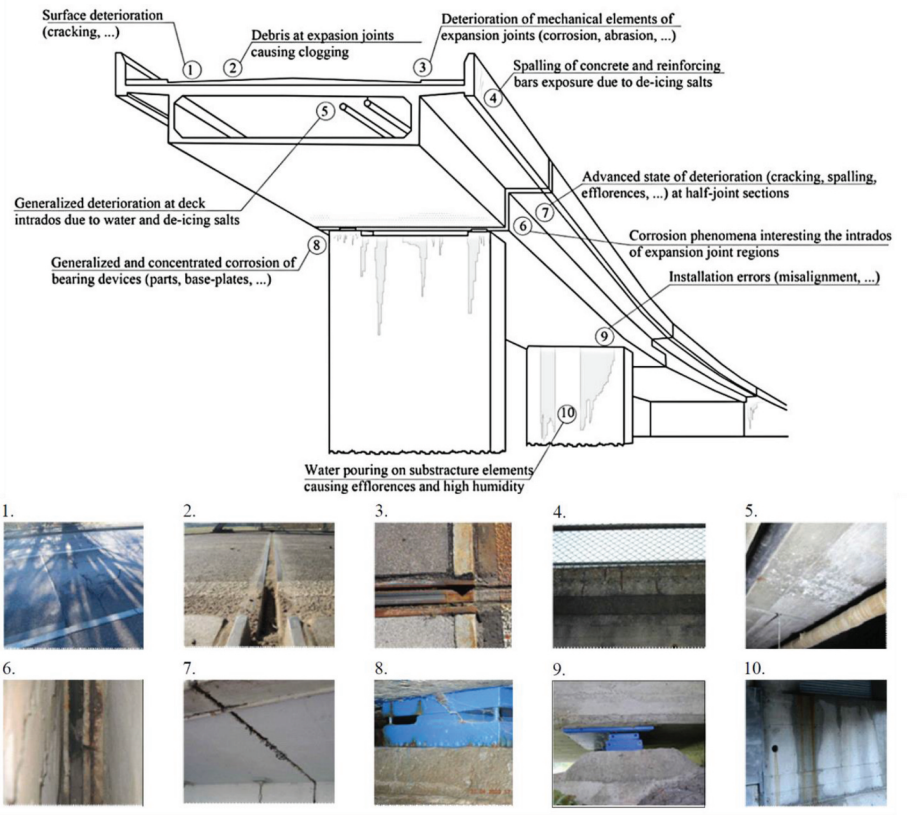

Figure 1. Damages detected on reinforced and prestressed bridges: localization and common appearance.

Figure 2. Common damages on structural bearings (circle) and expansion joints (square) classified according to the corresponding chromatic scale: level 1- good (dark green); 2 - acceptable (light green); 3 - damaged (yellow); level 4: poor (orange); 5: bad (red).

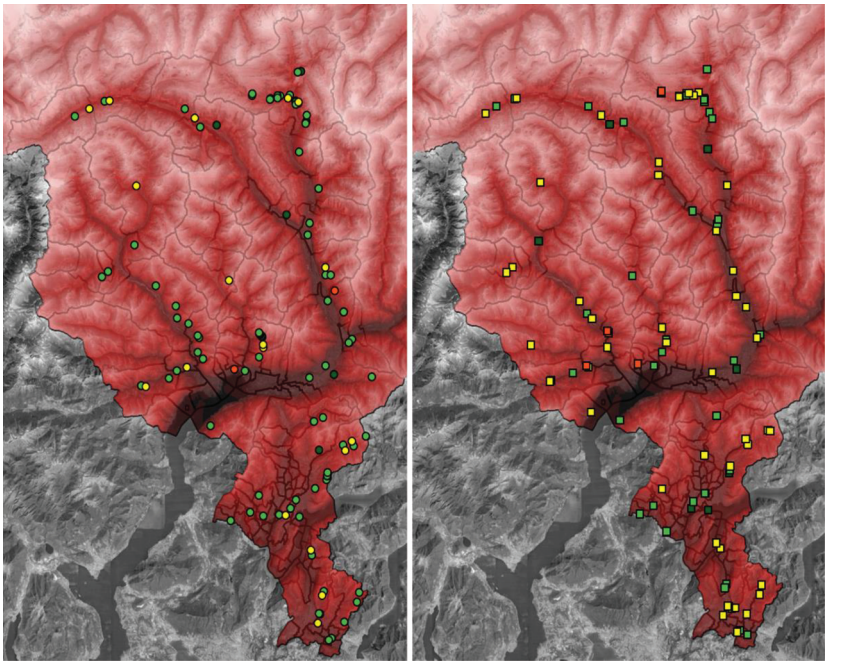

Figure 3. Condition assessment of bearings (left) and expansion joints (right) overlapped with yearly average temperature map RCP 8.5 in 2085. According to the following chromatic scale level 1- (dark green); 2 - acceptable (light green); 3 damaged (yellow); 4: poor (orange); 5 bad (red).

In short, the issues related to bridge accessories are manifold (Ramberger et al., 2003), with many being prompted and exacerbated by climate change, a global phenomenon whose impacts are local, due to either different object's exposure to hazard or specific climate-structure interaction. The impact of climate change on bridges and viaducts can be summarized as in Figure 4. In general, increasing temperatures amplify the magnitude of axial forces (in hyperstatic systems) and bending moments. The increased intensity of rainfall results in significant water runoff volume and subsequent pouring and augmented risk of corrosion. This risk is further intensified by deicing salts, a byproduct of the number of frost days, especially in northern areas of Tessin. Additionally, extended dry summers, leading to the accumulation of dust, sand, and silt on the road platform, in combination with extreme autumn and winter rainfalls, make material to accumulate at expansion joints and bearing devices impeding their proper operation, giving rise to undesirable stresses in the superstructure as reported in Kromanis et al., 2016. The phenomena described above can be aggravated by the presence of pre-existing kinematic and degradation co-factors. All this results in rapidly deteriorating structural problems and in the worst case to failure. If nowadays the impact of climate change on existing structures is a well-recognized field of studies, the same cannot be said as it concerns new structures. Only recently

the quantification of the effects of climate change on load magnitude has been started to be scrutinized as demonstrated in Croce et al., 2018 and Ghosn et al., 2022.

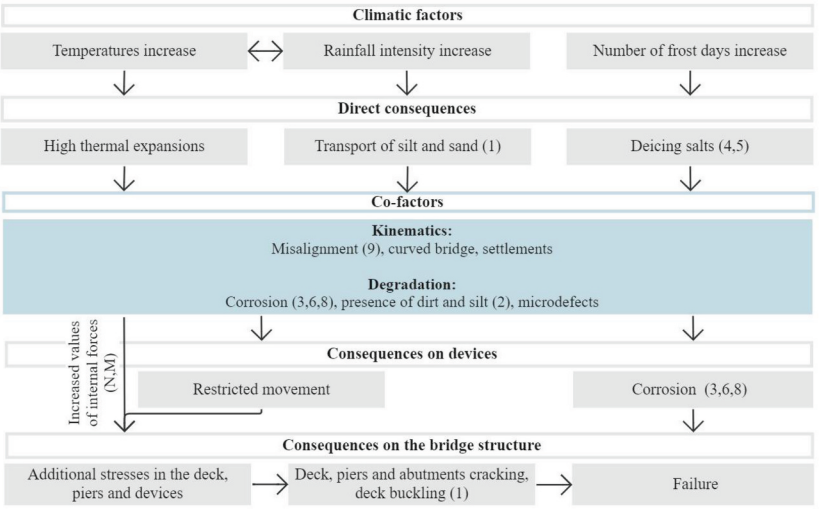

Figure 4. Impact of climate change on existing bridges. Numbers refer to code introduced in Figure 1.

3 CLIMATE CHANGE RELATED DISPLACEMENT DEMAND AND INTERNAL ACTIONS: A CASE STUDY

Structural analysis focused on quantifying the impact of temperature variations due to climate change on bridge bearings movements and superstructure internal actions (mainly axial force and bending moment see Figure 4) considering the RCP8.5 emission scenario in 2085. Simultaneously, prevented movements due to malfunctioning or damages of support devices and expansion joints, exacerbated by clogging due to stormwaters, were considered. Despite the high degree of level of epistemic uncertainty characterizing climate change and related impact on materials and structures would require a sophisticated uncertainty quantification framework, a deterministic approach has been preferred to quantify, in short, the effect of neglecting actual forecast temperature values in designing new bridges.

3.1 *Bridge description and model assumptions*

A three-span box girder bridge ideally located in the north region of Tessin was studied. The geometry and material characteristics are illustrated in Figure 5. As for the prestressing action, five parabolic tendons are placed on each side of the deck: three of them extend over the central and lateral spans, two only over the central span. Figure 6 (right) shows the original bridge bearing layout and those corresponding to restrained movements; expansion joints are placed at the bridge abutments. The structure was modelled by means of beam-type finite elements and actual loads were calculated for comparison according to current design codes. A linear-elastic analysis was carried out to assess the bridge longitudinal behavior.

3.2 *Analysis*

As indicated in several studies (Jaccoud et al., 1982 and Tayşi et al., 2015, Li et al., 2004) the temperature on a box girder section is influenced by many factors among which the material thermal coefficient, the deck height, as well as the pavement characteristics, just to cite few. The thermal loads (see Figure 6(left)) prescribed by the Swiss technical standard SIA 261:2003

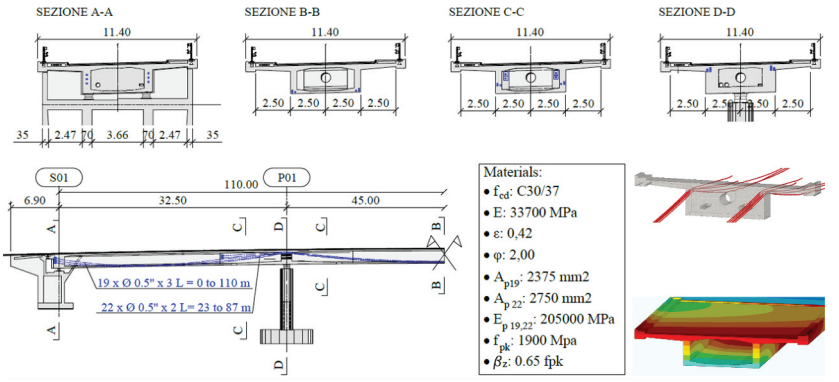

Figure 5. Bridge geometry, material characteristics and FE model views.

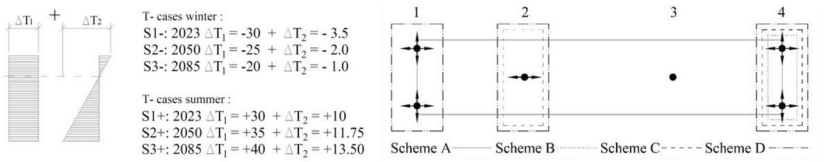

Figure 6. Temperature gradients related to climate scenarios (left) and progressively clogging bridge bearing layout indicated graphically with dotted and dash-dotted lines indication (right). No allowed displacement at: bearing 3 (Scheme A); bearing 3,4 (Scheme B), bearing 2,3,4 (Scheme C), bearing 1,2,3,4 (Scheme D).

provide practitioner engineers with appropriate esteems about temperature variations DT1 (uniform temperature distribution), DT2 (linear distribution relative to the centroid) and DT3 (non-linear distribution) with respect to the average temperature. For reinforced and prestressed concrete structures, DT1 assumes a value of ±20°C to be increased by 50% for joint and bearings movements requirements calculation. Moreover, considering a 2m-depth deck DT2 must be considered equal to 10°C for warm top surface (in summer) and equal to -3.5°C for cold bottom surface (in winter). The representativeness of these values may be jeopardized by climate change particularly under 2085 RCP 8.5 scenario. To roughly estimate the increase in DT1 and DT2 components, annual and seasonal average temperatures, as well as maximum and minimum daily temperatures, made available by the Swiss National Centre for Climate Services NCCS, were analyzed. All temperature loading scenarios used in the analyses are calculated from available data (2085 RCP8.5 scenario). In particular three scenarios were considered: the current reference scenario S1, the 2050 scenario S2 and the 2085 scenario S3. For each of them, the temperatures DT1 and DT2 were determined for both winter (-) and summer (+). For the sake of brevity, these calculations are not shown explicitly; the values taken into account are shown in Figure 6 (left).

In the analysis, various bridge bearing layouts were examined, taking into account their progressive clogging caused by material (sand, silt, dust) debris; these are illustrated in Figure 6 (right).

4 RESULTS DISCUSSION

The results of the analysis carried out to quantify the impact of climate change on superstructure internal actions and bridge accessories movement requirements follow.

Figure 7b illustrates the axial force increase resulting from impeded displacement at supports and expansion joints according to scheme A, B, C, and D (see Figure 6). These

eigenstresses manifest as compression for $DT_1 > 0$ (summer) and tension for $DT_1 < 0$ (winter), respectively diminishing or increasing the prestressing action, shown in Figure 7a. It is important to note that the condition of fully restrained movements at bearings may occur gradually. Therefore, the corresponding axial force values represent an upper limit with a low probability of occurrence. Nevertheless, even with a considerable reduction in axial stress values, corresponding to partial restrained movements at supports, the consequences on structural behavior are not negligible.

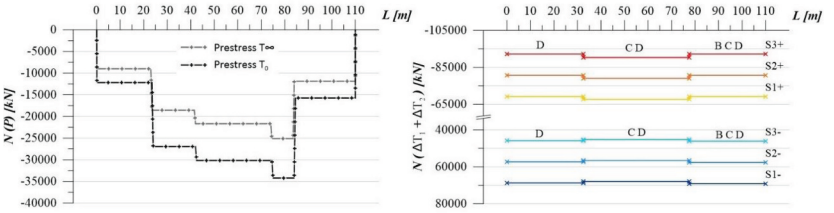

Figure 7. Axial force diagrams due to prestressing (on the left) and restrained bridge accessories movements caused by malfunctioning (on the right). Negative values represent compression, while positive tension.

The displacement requirement at the left of fix support (scheme A, B, Figure6) due to actual temperature gradients (S1, 2023) is equal to 22.5 mm of extension if DT > 0, or 10 mm of shortening if DT < 0 (Figure 8b). Compared to these values, for the S3 scenario (2085), there is a 37% increase in summer extension and a 50% reduction in winter shortening. Similar comments hold for schemes C, D under different climate-change scenarios.

These additional displacements may pose relevant challenges to well-preserved expansion joints and bearing devices during their service duration. Additionally, these values must be combined with shortening values due to prestressing after discounting losses due to shrinkage and creep shown in Figure 8a. These values (shortening) limit the displacement requirement at bearings in summer (S+ scenarios), but represent an unfavorable contribution in winter (S- scenarios), when, combining both effects (temperature gradients and actual prestressing) could lead to a total shortening displacement of 32 mm.

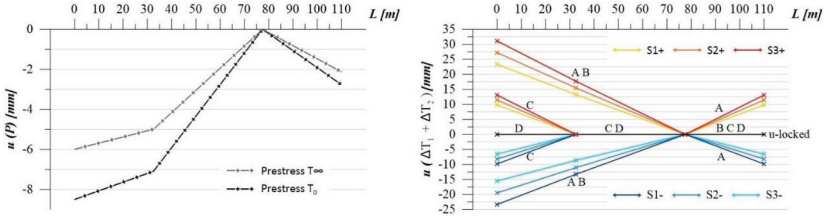

Figure 8. Horizontal displacement due to prestressing, shrinkage, and creep (on the left) and climate change related temperature-gradient scenarios (on the right). Negative values represent shortening, while positive extension.

The additional bending forces due to ΔT2 component (Figure 9b) result in a greater magnitude of positive bending moments along the spans and lower magnitude of negative bending moments at the supports for T>0 (summer) and, conversely, in a lower bending moment along the span and a grater at the support for T<0 (Figure 9a). With respect to scenario S1, these values undergo a 50% magnitude increase for S3+ scenario (extrados 5.81° - intrados 7.60°C) and a 70% reduction for S3- scenario (extrados -0.43°C and intrados 0.57°C).

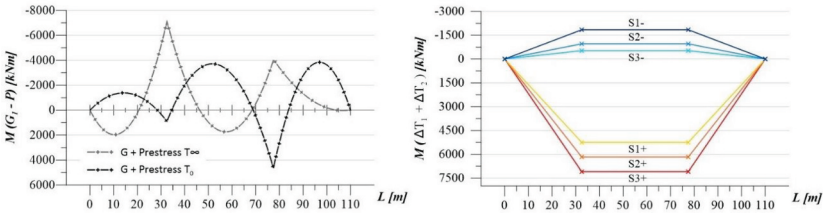

Figure 9. Bending moment diagrams due to permanent loads and prestressing (on the left) and climate change related temperature-gradient scenarios (on the right). Negative values represent stretched top fibers, while positive stretched bottom fibers.

Figure 10 shows the bending moment distribution under service condition compared with the value of the bending moment at first cracking for scenarios S - (winter) under partially restrained movements at bearings. An axial force N = 22500 kN, corresponding to roughly half of the extreme values in case of fully restrained movements due to accessories malfunctioning, was accounted for in the analysis. The tensile force reduces the prestressing action lowering the resistance to first cracking. As a result, the portion of the deck across the supports cracks: this can seriously compromise the bridge service duration favoring chlorides penetration into concrete cover (see deicing salts) and threatening the effectiveness of hogging prestressed tendons in case of defects in ducts and surrounding grout.

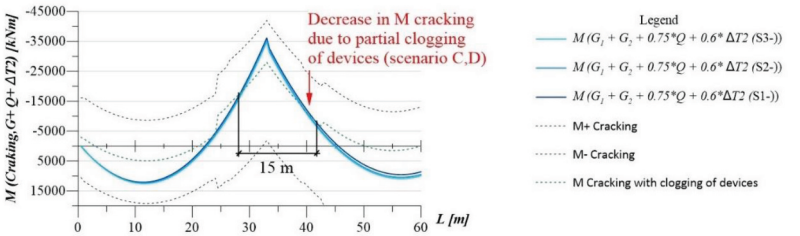

Figure 10. Cracking moment at support according to scheme C and D under service condition and winter temperature-gradient scenarios.

5 CONCLUDING REMARKS

In conclusion, the study allows to reflect on the challenges brought about by climate change on new structures by discussing the results of a deterministic analysis on a prestressed concrete three-span box girder bridge ideally located in the north of Tessin for the 2085 RCP 8.5 scenario.

Despite the epistemic uncertainty character of the phenomenon would require a proper uncertainty quantification framework (the current forecast values are being revised at a national level), the simplification adopted, motivated by reasons of synthesis, enables the identification of possible climate change impact on common structural scheme in case of small to medium-span bridges.

The analysis carried out highlights that increasing temperatures amplify the magnitude of bending moments and axial forces (in case of restrained movements).

The initial analysis on bridge accessories condition encourages further considerations on the interplay between climate stressors and material degradation. Bearings and expansion joints, due to their exposure to multiple factors (water, dirt, wear, and tear), are vulnerable to degradation, harshened by climate change fast kinetics.

In fact, the transport of silt and sand from the road platform to the joints caused by heavy autumn rains coupled with the severe corrosion caused by deicing salts are scenarios with an increasing probability of occurrence especially in the northern region of Tessin. Prevented bearing movements combined with temperature increase can lead to extended and severe

cracked zones along bridges and viaducts. The effects are amplified in case of structures with a high degree of flexural indeterminacy.

Finally, the study highlights the need for the technical community and policy makers to address the issues of climate change to properly:

- design, inspect and maintain expansion joints and bearings, exploiting the potential of structural monitoring on existing viaducts.
- organize a measurement campaign on a territorial scale involving different types of structures (steel, concrete, etc.) to establish a relationship between environmental and structural temperature gradients.
- adopt a rigorous uncertainty quantification framework to deal both with aleatory and epistemic uncertainty (Monte-Carlo and Bayesian methods, etc.) and correctly assess the structural reliability.
- reflect on the opportunity to update design code prescription to evaluate environmental actions and assess the impact of climate change by using deterministic analysis or, alternatively, encourage the adoption of a reliability framework for risk management of climate change and related impacts.

Fatigue life assessment of steel wires with multiple corrosion pits based on peridynamics

Y. Yang, Q.W. Zhang, J.F. Liu, Y.F. Ji & Y.C. Ni
Tongji University, Shanghai, China

ABSTRACT: Pitting corrosion, which results in crack initiation of steel wires, is a critical degradation form shortening the cable's fatigue life. The simulation of crack growth has been a challenging issue in the community of classical continuum mechanics as the assumption of displacement continuity is no longer valid at the crack. In this study, we attempt to employ the Peridynamic (PD) theory to evaluate the fatigue life of steel wires with multiple corrosion pits. The PD theory allows for the spontaneous initiation, propagation, and interaction of cracks, making it particularly suitable for analyzing multiple crack problems. Firstly, a numerical meshfree model of steel wires is established. Utilizing a novel crack tip detection algorithm proposed in this study, the propagation, interaction and merging process of multiple corrosion pits are investigated based on the PD fatigue model. The numerical model is validated and calibrated through comparison with the linear elastic fracture mechanics for the case of a single corrosion pit. Furthermore, fatigue simulations for steel wires with multiple corrosion pits are conducted to obtain the relationship between the remaining area rate and fatigue cycles. The effect of relative circumferential position of pits on the cross-section is investigated. Additionally, a comparative analysis is carried out between the fatigue life of steel wires containing two pits and that of a single pit with an equivalent damaged area. The results indicate that the residual fatigue life of steel wires with multiple pits will be affected by the circumferential position of pits. Converting two pits into a single pit based on an equivalent damaged area will lead to an overestimation of the fatigue life. The pd theory provides a promising new approach for assessing the fatigue life of steel wires with multiple corrosion pits.

1 INTRODUCTION

Due to long-term exposure to natural environments and sustained high-stress states, bridge cables are vulnerable to sheath breakage, resulting in corrosion and mechanical deterioration of steel wires. Pitting corrosion, which is the dominant factor decreasing the fatigue life of corroded steel wires, has been extensively investigated. Despite the intricate and random nature of the pitting morphology, both experimental and numerical results validate that crack initiation takes place at the bottom of the pit(Zheng et al., 2020). The semi-elliptical model is widely utilized and probability distribution models for the depth and radius of the pits are established(Guo et al., 2022, Li et al., 2021). For the residual fatigue life of steel wires with single corrosion pit, Jie et al., 2020, Ma et al., 2019 utilized the Theory of Critical Distances (TCD) (Taylor, 2008) method to predict fatigue life. Cui et al., 2020, Wang et al., 2020 established a damage evolution model for corroded steel wires based on Continuum Damage Mechanics (CDM). Wang et al., 2022, Zheng et al., 2019 calibrated the crack growth rate and predicted fatigue life using the Paris law based on Linear Elastic Fracture Mechanics (LEFM).

While the occurrence of multiple pits is commonly observed, the fatigue life of steel wires with multiple pits remains highly uncertain. Probabilistic methods are predominantly employed to predict the fatigue life of steel wires with multiple pits. The mass loss rate was

DOI: 10.1201/9781003483755-325

introduced to modify the S-N curve considering corrosion(Jiang et al., 2018, Zheng et al., 2017).Ye et al., 2021 introduced the initial crack size to correct the S-N curve. Lan et al., 2018 proposed a three-parameter Weibull model considering the influence of corrosion and stress amplitude, and estimated the model parameters based on experimental data(Ma et al., 2022). Probabilistic methods demand a significant amount of fatigue test, which is both time-consuming and costly. An urgent need for numerical simulation methods exists, while Classical Continuum Mechanics (CCM) based methods encounter significant obstacles as the assumption of displacement continuity is no longer applicable at the crack, posing challenges in dealing with multiple cracks. Among CCM based methods, TCD methods(Chen et al., 2021), LFEM methods(Ye et al., 2020) have been utilized to address multiple cracks, but with limited applicability.

Peridynamic theory, a novel nonlocal theory(Silling et al., 2007), enables the spontaneous initiation, propagation, and final rupture of cracks(Ha et al., 2011, Silling et al., 2010, Yaghoobi et al., 2017), making it particularly suitable for handling multiple cracks. The PD fatigue model was initially proposed by (Silling et al., 2014) and validated by (Zhang et al., 2016). Recently, the PD fatigue model have been employed to address various problems(Bang et al., 2021, Hong et al., 2021, Ma et al., 2020), demonstrating its applicability and accuracy in fatigue-related issues.

In this study, we attempt to employ the PD theory to investigate the residual fatigue life of steel wires with multiple corrosion pits. A novel crack detection algorithm was proposed to track the crack tip during the fatigue simulation process. Subsequently, numerical results obtained from PD simulations of steel wires with a single corrosion pit were compared with results from LFEM. Finally, the residual fatigue life of steel wires with multiple corrosion pits was investigated. Parameter analysis on the relative position and initial damage area was conducted.

2 PERIDYNAMICS THEORY

2.1 *Bond-Based Peridynamics(BBPD)*

In the framework of PD theory, a material body is discretized into a set of discrete material points, as shown in Figure1. Each point **x** only interacts with points within a specified distance δ, called horizon. The interaction between two points is called a bond. Points falling inside horizon are called neighbors of point **x**, and all neighbors consist the family of **x**, denoted by H_x. The PD equation of motion is defined by Eq.(1):

$$\rho\ddot{\mathbf{u}}(\mathbf{x},t)=\int_{H_x}\mathbf{f}(\mathbf{u}(\mathbf{x}',t)-\mathbf{u}(\mathbf{x},t),\mathbf{x}'-\mathbf{x})dV\mathbf{x}'+\mathbf{b}(\mathbf{x},t) \tag{1}$$

where ρ denotes material density, $\ddot{\mathbf{u}}(\mathbf{x},t)$ is the acceleration of point **x** at time t, **b**(**x**,t) is the body force of point **x**, **f**(**u**(**x'**, t) – **u**(**x**, t), **x'**–**x**) is the pairwise bond force function that point **x'** exerts on point **x**. In BBPD, the bond force function is defined by Eq.(2):

$$\mathbf{f}(\mathbf{u}(\mathbf{x}',t)-\mathbf{u}(\mathbf{x},t),\mathbf{x}'-\mathbf{x})=\mathbf{f}(\boldsymbol{\eta},\boldsymbol{\xi})=\mathbf{cs}\mu\frac{\boldsymbol{\xi}+\boldsymbol{\eta}}{|\boldsymbol{\xi}+\boldsymbol{\eta}|} \tag{2}$$

where c denotes the microelastic modulus, which characterizes the stiffness of a bond. For 3D problems, $c = 12E/\pi\delta^4$. $\boldsymbol{\xi}=\mathbf{x}'-\mathbf{x}$ denotes the relative position vector of **x** and **x'** before deformation, $\boldsymbol{\eta}=\mathbf{u}'-\mathbf{u}$ denotes the relative displacement vector of **x** and **x'**, $_s$ denotes the bond stretch which is $(|\boldsymbol{\xi}+\boldsymbol{\eta}|-|\boldsymbol{\xi}|)/|\boldsymbol{\xi}|$. μ is a scalar function to introduce fracture into PD theory. Once the bond stretch exceeds the critical stretch s_c, μ is equal to 0. Otherwise μ is equal to 1. The critical stretch s_c is related to the critical energy release rate G_c and the material fracture toughness K_c. Once the bond is broken, it is irreversible. And the damage of material point **x** can be defined by Eq.(3) as the ratio of broken bonds to total number of bonds connected to point **x**.

$$\varphi(\mathbf{x}) = 1 - \frac{\int_{x' \in H_x} \mu(\mathbf{x}, \boldsymbol{\xi}) dV_{x'}}{\int_{x' \in H_x} dV_{x'}} \tag{3}$$

One critical limitation of traditional PD theory is that the horizon δ must be constant, which results in a significant increase in computational costs as the computational domain expands. To address this issue, the dual-horizon peridynamics(Ren et al., 2017), which allows for non-uniform discretization with varying horizons, is utilized in this study.

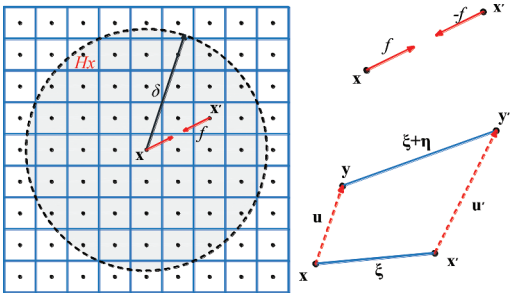

Figure 1. The horizon, family, pairwise bond force function of BBPD.

2.2 *Peridynamic model for fatigue cracking*

In peridynamic fatigue model, a new parameter λ called bond remaining life is introduced to describe the failure process of a bond under fatigue load. λ is initially 1, and gradually decreases to 0 during the fatigue loading process. Once $\lambda \leq 0$, the bond is irreversibly broken, resulting in fatigue damage in corresponding material point. Drawing from the Paris law, the relationship between λ and fatigue cycles N is defined by Eq.(4):

$$\frac{d\lambda}{dN}(N) = -A\varepsilon^m \tag{4}$$

where A and m are material constants, ε the cyclic bond strain under fatigue load which equals to $|(1-R)s_{\max}|$, where $s_{\max}$ is the stretch of the bond under the maximum load and R denotes the stress ratio.

In crack nucleation phase, A_1 and m_1 can be calibrated with the $\varepsilon - N$ curve. In crack growth phase, the crack propagation speed can be derived from Eq.(4) and denoted as:

$$\frac{da}{dN}(N) = \beta A_2 \varepsilon_{core}^{m_2} \tag{5}$$

where ε_{core} is the cyclic strain range of the core bond, which is the bond with the maximum strain range near the crack tip. β is a shape influence factor representing the geometric influence on the strain distribution. A_2 and m_2 can be calibrated with the Paris law(Eq.(6)):

$$\frac{da}{dN}(N) = c\Delta K^M \tag{6}$$

By comparing Eq.(5) with Eq.(6), m_2 is set to be equal to M as the stress intensify factor is proportional to strain. While there is no explicit expression for β, A_2 cannot be directly obtained. To determine A_2, a calibration process must be performed. Firstly, a fatigue calculation process needs to be conducted with an arbitrary value A_a to obtain the crack growth rate $(da/dN)_a$. Because the crack growth rate (da/dN) depends linearly on A_2, A_2 can be calibrated by Eq.(7):

$$A_2 = A_a \frac{da/dN}{(da/dN)_a} \tag{7}$$

where *da*/*dN* can be obtained from the Paris law or experiment data.

3 NUMERICAL SIMULATIONS

3.1 *Model discretization, boundary conditions and static solution*

A numerical model for steel wires with a length of 50mm and a diameter of 7mm is firstly established, as shown in Figure 2. The crack region is set at the middle of the wire, and a mesh density $\Delta x_1 = 0.2\ mm$ is applied, while the remaining region is meshed with a lower mesh density $\Delta x_2 = 0.5\ mm$. In PD theory, virtual boundary region and load region must be specially assigned. The displacement in all directions is fixed for the material points in the boundary region. An external load will be applied on material points in the load region. Horizons δ_1 and δ_2 are set to be $3.015\Delta x_1$ and $3.015\Delta x_2$ respectively, and the boundary region and the load region are set to be $3\Delta x_1$ and Δx_2 respectively in length(Bobaru et al., 2016). A surface without thickness is defined as a pre-existing crack. Bonds through the crack surface are initially set to be broken to introduce the initial crack.

The adaptive dynamic relaxation method(Kilic et al., 2010) is used to accelerate the static solution. The construction of the family list is facilitated through the utilization of the k-dimensional tree algorithm, while parallel computing is applied to compute the peridynamic force.

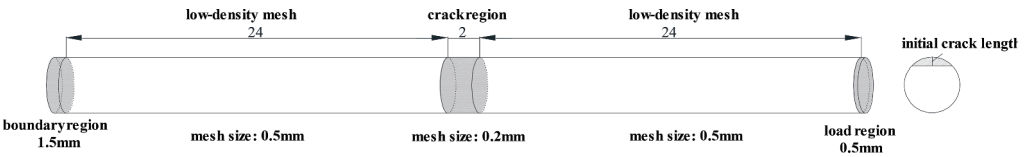

Figure 2. Model discretization of steel wires (unit: mm).

3.2 *A novel crack tip detection algorithm for PD fatigue analysis*

As a pre-crack exists, the crack nucleation phase is ignored and material points within horizon of the crack tip will directly switch to the crack growth phase. Therefore, it is essential to detect the crack tip at every step during the fatigue simulation process, while few crack tip detection algorithms are available in literature. Zhang et al., 2016 converted the PD damage map to black and white images to detect the crack tip. Ma et al., 2023 identified all particles with a local damage coefficient greater than 0.39 as the crack tip. Zhu et al., 2021 utilized the status of bonds which connect a material point with its neighbouring material points only to locate the crack tip. However, these crack tip detection algorithms are only suitable for 2D problems. In 3D problems, the crack tip forms a curve instead of a point, making it more challenging to detect the crack tip.

Therefore, a novel crack tip detection algorithm is proposed in this study. Once the damage index φ_i is calculated for all material points, the normalized damage index $\varphi_{i,\ n} = \varphi_i/\varphi_{max}$ is introduced. $\varphi_{\max}$ is the max damage index of points near crack tip, which is approximately 0.393 for 2D problems and 0.385 for 3D problems(Freimanis et al., 2018). Then points with $\varphi_{i,\ n}$ between 0.48 and 0.52 is identified as the crack tip. Note that due to the limited mesh size, there are typically insufficient points to constitute a continuous curve. Consequently, additional points are generated through an interpolation algorithm. An inverse distance interpolation algorithm is applied in this study.

The remaining life of bonds within horizon of the crack tip is calculated by Eq.(4), and the minimum cycle ΔN needed to break a bond is obtained. Once a bond is broken, a new static

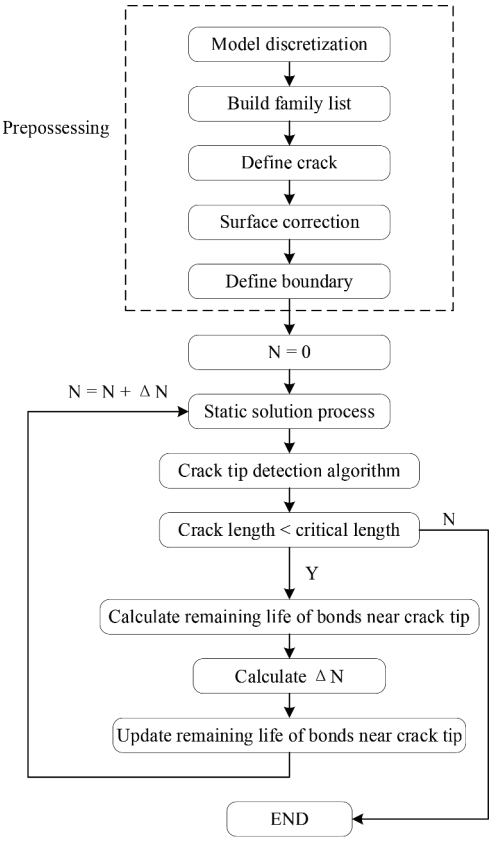

Figure 3. Flowchart of fatigue analysis.

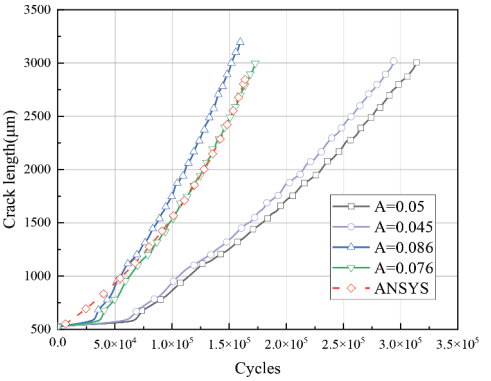

Figure 4. Calibration process of A_2.

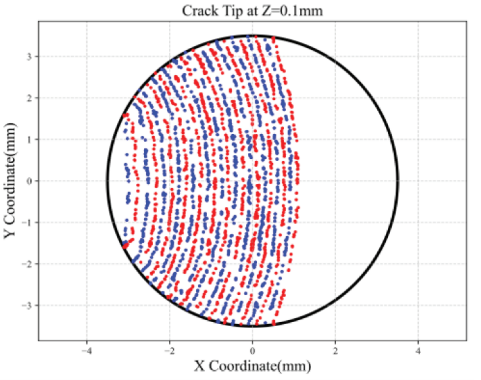

Figure 5. Crack growth path.

solution needs to be run to update the cyclic strain of each bond, which is computationally inefficient. Time mapping(Silling et al., 2014), critical damage factors(Zhang et al., 2016) and the number of cyclic broken bonds are introduced to improve computational efficiency. The broken bonds ratio r, defined as the proportion of broken bonds to the total number of bonds near the crack tip, is proposed in this study. ΔN can be determined as the minimum number of cycles needed to break a certain percentage of bonds. r is set to be 2% combining computational efficiency and accuracy. The fatigue analysis procedure is illustrated in Figure 3.

4 NUMERICAL RESULTS

4.1 *Model calibration and validation*

A fatigue load, with a stress amplitude σ_a = 150MPa and a stress ratio R = 0.1, is applied to the numerical model shown in Figure 2. The PD fatigue parameters A_2 and m_2 are determined according to section 2.2. The values of c and m are set to 3.98e-9 and 1.26 respectively when R = 0.1 (Wang et al., 2022), therefore m, is set to be equal to 1.26. A_2 is calibrated as 0.076 through a series of trial calculations, as shown in Figure 4. The ANSYS Workbench with SMART crack growth is employed here to provide a standard solution of LEFM. The obtained crack growth path is illustrated in Figure 5, which is consistent with theoretical and experimental results.

To further validate the PD fatigue model, the fatigue life of steel wires with a single corrosion pit is analyzed. Various initial crack lengths, specifically 0.3 mm, 0.5 mm, and 0.7 mm,

are applied to investigate the influence of the initial crack length. The relationship between crack length and the number of cycles (a-N curves) obtained from ANSYS, FRANC3D and PD are compared, as shown in Figure 6. The fatigue life decreases with an increase in the initial crack length, and the simulation results from the PD fatigue model exhibit consistent with the FEM results.

4.2 *Fatigue life of steel wires with multiple corrosion pits*

A distinctive advantage of PD theory is its ability to solve problems related to multiple crack propagation and interaction without additional defined criteria. In this section, the fatigue life of steel wires with multiple corrosion pits is investigated. Circumferential double pits on the cross-section are taken into consideration, and the relative angle θ of the two cracks is used to indicate their relative position as shown in Figure 7(a). Firstly, the crack propagation behavior of two cracks with $\theta = \pi/3$ and an initial crack length of 0.3mm is analyzed. The two cracks initially propagate independently, subsequently interact, and ultimately merge into a single crack, as illustrated in Figure 7(a).

Parameter analysis on θ is then conducted. As multiple cracks exist, the remaining area rate is selected to indicate the crack growth speed, which is also the direct result of nondestructive test in field testing(Ni et al., 2021). Figure 7(b) and (c) illustrate the relationship between the remaining area rate and fatigue cycles for different θ. As shown in Figure 7 (b), the rate of remaining area reduction is insensitive to θ when the fatigue cycles is relatively low, while certain diversity appears for different θ when the fatigue cycles increase. The most unfavorable situation occurs when $\theta = \pi/2$, while $\theta = \pi$ leads to the lowest remaining area reduction rate, with the relative difference about 12% when the remaining area rate comes to 50%. This phenomenon can be explained by the stress intensity factor in LFEM as shown in Figure 8. The stress intensity factor along the crack tip when $\theta = \pi/2$ is generally higher than that when $\theta = \pi$, resulting in an accelerated rate of crack growth. The same conclusion can be drawn from Figure 7 (c) where the initial crack length is 0.3mm. Note that the fatigue cracking develops at the slowest pace when $\theta = \pi/6$. This is more likely due to that the two cracks merges into a single crack at an earlier stage, therefore the remaining area reduction rate is more convergent to that of a single crack.

Furthermore, the fatigue life of steel wires with two pits is compared to that of a single pit with an equivalent damaged area as shown in Figure 9. Two cracks each with a size of 0.5mm are considered equivalent in damaged area to a single crack with a size of 0.8mm. Relative to the most conservative result of two-crack situation, the fatigue life of steel wires with a single crack exceeds that of two-crack situation. The same conclusion can be drawn when the initial crack length is set at 0.3mm as shown in Figure 9. These results indicates that the presence of two cracks produces a higher risk compared to a single crack with the same damaged area, and, in application, simply converting multiple cracks into a single crack will overestimate the fatigue life of steel wires.

5 CONCLUSIONS

In this study, the PD fatigue model was employed to conduct a fatigue analysis on steel wires with multiple corrosion pits. A novel crack tip detection algorithm was proposed to track the crack tip during the fatigue simulation process. The PD fatigue model was validated and calibrated through a comparative analysis with the numerical results obtained from LFEM. The effect of relative circumferential position of pits was investigated, and the fatigue life of steel wires containing two pits and that of a single pit with an equivalent damaged area was compared. The following conclusions can be drawn based on numerical results:

(1) The PD fatigue model is capable of capturing the propagation, interaction and merging process of multiple cracks on steel wires. The proposed crack tip detection algorithm can accurately track the crack tip.
(2) The relative circumferential position of two cracks has certain effect on the residual fatigue life, especially for the greater fatigue cycles. It is more unfavorable when $\theta = \pi/2$, while the two cracks merge into a single crack at an earlier stage, hence leads to a longer fatigue life.
(3) The existence of multiple cracks poses a greater risk than that of a single crack, when the damaged area is the same. Simply converting multiple cracks into a single crack would result in an overestimation of the fatigue life of steel wires.

The conclusions in this study are primarily drawn from numerical results, and corresponding experiments will be conducted to further validate these conclusions. The approach of translating the damage area into the size and quantity of the pits requires further investigation, which enables engineers to directly utilize the outcomes of non-destructive testing for assessing the residual fatigue life of corroded steel wires.

Fatigue life estimation for long span suspension bridges due to buffeting

Z.Z. Banday & A. Fenerci

T.M. Lystad & O.A. Øiseth
Norwegian University of Science and Technology, Trondheim, Norway

ABSTRACT: Buffeting-induced vibration of long-span cable-supported bridges is critical for the serviceability and fatigue performance of these structures. Such problems are more prevalent in long-span bridges located in complex terrain and subjected to gusty wind. One of the long-term adverse effects includes the cyclic loading induced by the buffeting which may cause fatigue of the material. As a case study for this work, fatigue life due to buffeting-induced vibrations has been estimated for the longest-span suspension bridge in Norway, the Hardanger Bridge. This bridge is situated in the Norwegian fjords, characterized by consistent and strong winds. The terrain-induced variability in the turbulence field is considered by modelling the field as a joint probabilistic model of turbulence parameters. Utilizing a Finite Element model of the bridge, the modal parameters of the bridge are extracted. Subsequently, the classical multi-modal buffeting analysis is performed to obtain the stress spectra of the hot-spots along the bridge girder. Considering uncertain mean wind velocity and turbulence parameters, fatigue damage is calculated using a Bayesian updating approach, where new simulation points were sequentially added to the training data set. Consequently, the fatigue life of the bridge girder is obtained by numerical integration.

1 INTRODUCTION

Fatigue failure is a critical threat, holding the potential for catastrophic consequences for the structural integrity of bridges. Over the course of decades, bridges bear the brunt of fatigue damage induced by vehicular traffic and wind loads, sometimes manifesting in bridge collapses or costly repairs (Gu, 1999). In the field of contemporary bridge design, the increasing prevalence of longer main spans intensifies the need to address fatigue-related challenges during the structural planning phase as well as the operational phase.

In this work, we study the cyclic loading induced by buffeting forces, impacting the slender girder of the Hardanger Bridge. Nestled in the Norwegian fjords, regions characterized by complex terrain topography and strong wind patterns, this bridge has proven invaluable for understanding the interplay between wind induced forces, and structural resilience. Notably, the Hardanger Bridge has an unusually slender design, as the bridge deck is a mere 18.3 meters wide, with a narrow separation of 14.5 meters between cable planes. A detailed cross section of the bridge girder is shown in (Figure 1). We study the stochastic nature of wind-induced forces, focusing on the buffeting of the bridge girder. Subsequently, we study the cyclic forces induced by buffeting and the accompanying fatigue damage. It must be noted that the Hardanger bridge has been monitored for many years using accelerometers and anemometers (Fenerci, 2021), the anemometry data were used to devise a probabilistic turbulence model that describes the long-term wind characteristics at the site.

DOI: 10.1201/9781003483755-326

We introduce and use a Gaussian process regression (GPR) surrogate model, based on nonparametric regression. Considering the unpredictability of wind forces, we set up surrogate models for the Fatigue Damage Accumulation (FDA) for three points along the girder. These models are sequentially updated, and the result is a computationally cheap and accurate estimate of the fatigue damage.

This study is presented below in the following two sections. Section 2 explains the mathematical tools needed to perform the analysis, namely the buffeting analysis, the probabilistic wind field, and the surrogate modelling using GPR. Section 3 is devoted to the results from the analysis, followed by some discussions and the conclusion.

2 PROCEDURE FOR FATIGUE ANALYSIS

This section will provide the foundation necessary for carrying out the fatigue analysis. We briefly discuss the probabilistic wind spectra and the buffeting theory, introducing the environmental factors. Later, a detailed introduction to Gaussian process regression, kernel functions, surrogate modelling and its sequential updating is presented.

2.1 *Stress spectra from the buffeting response of the bridge*

As opposed to the flutter of the bridges, buffeting of bridges is a stable and random response to the turbulence of the oncoming wind flow. Buffeting seldom leads to catastrophic failures but over large time scales, buffeting can result in fatigue damage accumulation. To begin with, the buffeting response of Hardanger Bridge was calculated in the frequency domain using the classical multimode theory (Scanlan, 1978).

For this purpose, a wind model based on the Kaimal-type spectra, and Davenport's coherence formula for the cross-spectra was used. These are defined as:

$$\begin{aligned} \frac{S_{u,w}f}{\sigma_{u,w}^2} &= \frac{A_{u,w}f_z}{(1+1.5A_{u,w}f_z)^{5/3}}, \quad f_z = \frac{fz}{U} \\ C_{u,w} &= \exp -\left(K_{u,w}\frac{f\Delta x}{U}\right) \end{aligned} \tag{1}$$

where f is the frequency, U is the mean wind velocity, z is the height above the ground, and $A_{u,w}$ are spectral parameters. $\sigma_{u,w}$ are the standard deviations of the turbulence of the wind in the along-wind (u) and vertical (w) directions, while $K_{u,w}$ are the decay coefficients. Δx is the separation along the distance of the bridge. Furthermore, utilizing a Finite Element model of the bridge (Petersen, 2019), we extract the still-air displacement mode and force mode shapes of the bridge deck. The aerodynamic features of the deck, namely the steady-state force coefficients and aerodynamic derivatives, are obtained through forced vibration tests (Siedziako, 2017).

The spectral density matrix G_{FF} of the three components of the sectional forces (SF_1, SM_1, SM_2) at any point along the span of the bridge is obtained by using the cross spectral density matrix of the buffeting load $\tilde{G}_{QQ}$, the frequency response matrix $\tilde{H}(\omega)$, and the section force mode shapes Φ_F, as:

$$G_{FF}(\omega, x) = \Phi_F(x)[\tilde{H}(\omega)\tilde{G}_{QQ}(\omega)\tilde{H}(\omega)^T]{\Phi_F}^T \tag{2}$$

Further, by using a transfer function T, we proceed to calculate the stress spectrum $G_{\sigma\sigma}(\omega, x)$. by using the Euler beam theory:

$$G_{\sigma\sigma}(\omega, x, \kappa) = T(\kappa)\, G_{FF}(\omega, x)\, T^T(\kappa), \quad T(\kappa) = \begin{bmatrix} \frac{1}{A} & \frac{z(\kappa)}{I_y} & \frac{y(\kappa)}{I_z} \end{bmatrix} \tag{3}$$

with κ depending on the position of the point along the cross-section of the bridge girder chosen for the analysis. In this work, three points are chosen for the analysis as shown in

(Figure 1). Each point is assigned its coordinates $(y(\kappa),\ z(\kappa))$, with the shear center of the girder cross-section as the origin. The moments of inertia along the strong and the weak axes are denoted by I_z and I_y, respectively.

2.2 *Probabilistic wind field for the site*

The calculation of the rate of the fatigue damage accumulation, requires a joint probability distribution function of all wind parameters. Wind speeds at the girder of the Hardanger Bridge have been monitored for several years by researchers. Using this this long-term full-scale wind data, a probabilistic model of the wind field was proposed by (Fenerci, 2018). The model fits a Weibull distribution for the mean wind speed, while the remaining six parameters are seen to follow a log normal distribution. In this work, the influence of the turbulence field in the along-wind direction is investigated. The parameters are listed in the table below:

Table 1. The wind and the joint probability distribution parameters at the bridge site for easterly winds.

Wind field parameter	Distribution type	Distribution parameters
U	Weibull	$\lambda = 5.1941, \mathrm{K} = 1.7946$
$\sigma_u \vert U$	lognormal	$\tilde{\mu} = 0.122 + 0.039U,\ \ \tilde{\sigma} = 0.28$

2.3 *Stress time-history simulation and rainflow counting.*

To proceed, we take the stress spectra, $G_{\sigma\sigma}(\omega, x, \kappa)$obtained from the buffeting analysis. We can simulate the time history of the stresses and perform rainflow counting. The SN-curves proposed by NS-EN 1999-1-3 are used. To tackle the scatter of the damage calculated for each set of set of the wind field parameters, 60 Monte Carlo simulations of 600 secs each are realized. The scatter of the damage obtained from the 60 simulations is similar. To this end, the damage used to train the surrogate model is taken as the average of these 60 simulations. Equipped with this understanding, we can commence the establishment of a surrogate model for a comprehensive long-term analysis.

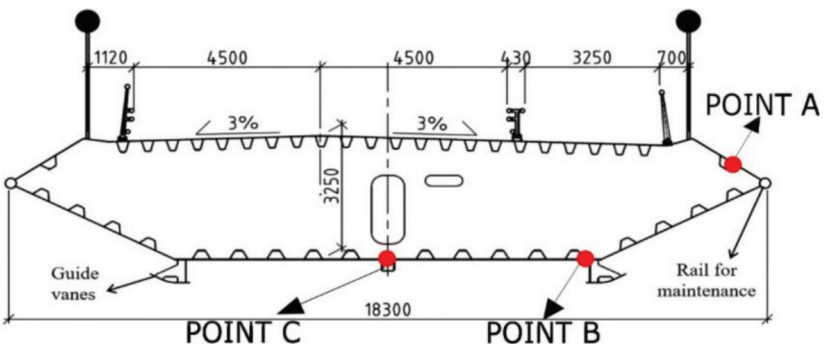

Figure 1. Cross section of the Hardanger bridge along with the three points checked for fatigue damage.

2.4 *Gaussian process regression*

Conversely, complexity of computing the rate of fatigue damage accumulation increases if we consider more wind field parameters to be uncertain. If n is the number of uncertain factors considered, then the computational complexity ~ $O(c^n)$, where c is a constant. To this end, we make use of surrogate modelling and Gaussian process regression to make the operation computationally cheaper.

At its core, Gaussian process regression is a non-parametric regression that uses a prior distribution over functions and uses Bayesian inference to update the distribution based on the observed data (Williams 1995). The result is a posterior distribution that reflects the likely functions fitting the data. Combining this property with the fact that GPR provides uncertainty measurements on the predictions and is valid for multiple dimensions, makes it suitable for our problem.

Mathematically, a Gaussian process is defined by its mean and the covariance function. Assume we have a data stored in $X = [x_1, x_2, \ldots, x_n]$. We proceed by defining the mean and the covariance functions as $m(x) = E[f(x)]$ and $k(x, x') = E[(f(x) - m(x))(f(x') - m(x'))]$, respectively. So, for a Gaussian process with non-zero mean, it is denoted as:

$$f(x) \sim N(m(x)),\ k(x, x) \tag{4}$$

Usually, the observed data is assumed to have some noise, leading to $y \sim \mathcal{N}(m(x)),\ k(x, x) + \sigma_n^2 I$ noise. Now, if we want to make predictions over new points $X^* = [x_1^*, x_2^*, \ldots, x_m^*]$, with $f^* = [f(x_1^*), f(x_2^*), \ldots, f(x_m^*)]$. The conditional distribution over the unknown points remains Gaussian even after the model is updated with more data points. Consequently, we can write:

$$\begin{bmatrix} f \\ f^* \end{bmatrix} \sim ND\left(\begin{bmatrix} M_X \\ M_{X*} \end{bmatrix}, \begin{bmatrix} K(X, X) + {\sigma_n}^2 I & K(X, X^*) \\ K(X^*, X) & K(X^*, X^*) \end{bmatrix} \right) \tag{5}$$

Where M_X and M_{X_*} represent the mean values of the training set and the test set respectively. The term ND denotes a multivariate Gaussian distribution. The values for the new points are predicted using the conditional likelihood and the covariance matrix. These covariance functions are dependent on the Euclidean distance $D(X, X^*)$ between X and X^*. For this work, the squared exponential kernel was used and is defined as:

$$K_{\{RBF\}}(D) = \sigma_{\{f\}}^2 \exp\left(-\frac{1}{2l^2} D^2 \right) \tag{6}$$

Where σ_f and l are the hyperparameters, termed as the scaling factor and the length scale, respectively. A higher value of the length scale and lower value for the scaling factor results in a smoother and more global fit for the data. However, tuning these hyperparameters is essential for making useful predictions.

2.4.1 *Surrogate modelling and updating process:*
A surrogate model is set up for calculating the rate of fatigue damage accumulation (FDA). The model is initiated by calculating the FDA (Lutes, 1984) for a single set of environmental factors. The vector σ_s contains the standard deviations of the surrogate model, while the vector D_{pred} stores the predicted values of the FDA. To this end, we can define a learning function P_{next}, that chooses the next set of environmental factors to be used for updating the model (Lystad, 2023).

$$P_{next} = argmax\left\{ \sigma^{(1-n)} [D_{pred}\, f(\psi_1, \psi_2, \ldots \psi_m]^n \right\} \tag{7}$$

where ψ_i is the i^{th} environmental factor used. $f(\psi_1, \psi_2, \ldots \psi_m)$ is the joint probability distribution function of the m wind parameters. The factor n is used as a weighting factor to prioritize those sets of wind parameters which contribute the most towards the FDA. A value close to zero will result in a quasi linear spacing of the training data points over the entire range of the environmental parameters, which is suboptimal. To avoid this issue, we give precedence to those combinations of the environmental factors that contribute the most to the FDA, setting a value of $n = 0.15$.

The learning function helps our model to quickly converge. Once the convergence is achieved, the damage accumulated for the length of stress signal chosen is calculated as (Gramstad, 2020):

$$FDA = \int_{\psi_1} \int_{\psi_2} \dots \int_{\psi_m} D_{pred}(\psi_1, \psi_2, \dots, \psi_m) f(\psi_1, \psi_2, \dots, \psi_m) d\psi_1 d\psi_2 \dots d\psi_m \tag{8}$$

In the context of the surrogate model, two distinct stopping criteria were selected to determine its convergence. The maximum number of points in the training data or the number of iterations to calculate the learning function, and the relative change in the FDA due to the addition of a new training data set. The limits are chosen based on the number of uncertain environmental factors leveraged for the surrogate model. We now proceed to perform the analysis in the next section and report the results.

3 RESULTS

Initially, the surrogate model is set-up and involves the mean wind velocity, denoted as U, as the singular uncertain parameter. Subsequently, the complexity and precision of the model is enhanced through the incorporation of the standard deviation of along-wind turbulence, denoted as σ_u, as uncertain. It is noteworthy that in the context of these surrogate models, when an environmental factor is not treated as uncertain, the analysis opts for their most probable value derived from the Joint Probability Density Function (PDF).

3.1 *Single uncertain parameter*

Prior to delving into the presentation of results, it is important to provide contextual information about the working of the algorithm. In the context of the squared exponential kernel, the initial configuration involved setting the standard deviation of observation noise and the length scale to unity, while the scale factor was initialized to 5. It is noteworthy that these hyperparameters undergo updates as the model is progressively trained with additional data points. In pursuit of convergence, two termination criteria were also established. The first one regards the maximum number of iterations, which was set to 30 for the case of single environmental factor, namely U. The second one regards the relative change in the FDA over each iteration. For this study, convergence was said to have been achieved when the addition of a new point in the training data set resulted in the relative change of less than 0.1% in the FDA.

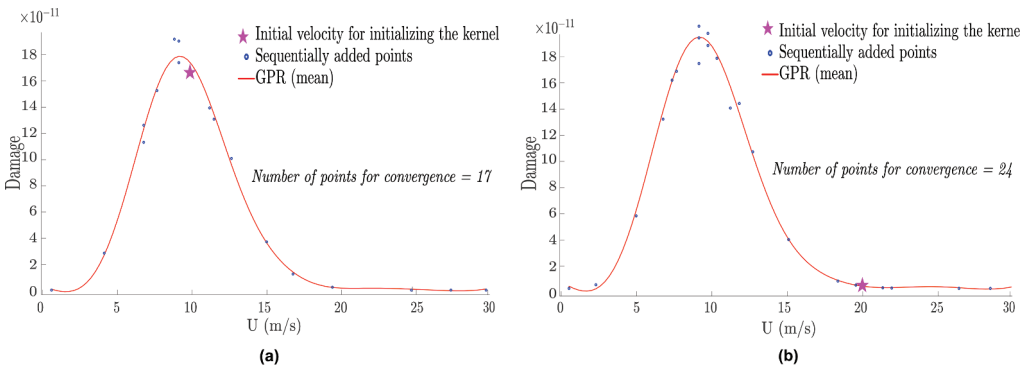

Figure 2. Two surrogate models for FDA at point A for uncertain mean wind velocity, showing two different velocities to initialize the kernel.

The algorithm performs in an optimal way with the value of $n = 0.15$ (Figure 2) shows two surrogate models for the fatigue damage at point A. It is evident from these plots that the mean wind velocities in the range from 5 *m/s* to 15 *m/s* contribute the most to the accumulated damage. This can be attributed to their high probabilities of occurrence. Consequently, to compute the integral in Equation (8), the model needs to have a better fit close to this peak. This implies the necessity of having a greater number of data points within this interval near the peak. Unfortunately, the location of this peak is not a prior knowledge. Nevertheless, (Figure 2a) was initialized with a velocity close to the with $U = 10$ *m/s*, while Figure (2b) was initialized with $U = 20$ *m/s*, and the convergence was achieved in less than 30 iterations for both the cases. The learning function can quickly locate the peak of the damage curve, irrespective of the value of the mean wind velocity used to initialize the kernel.

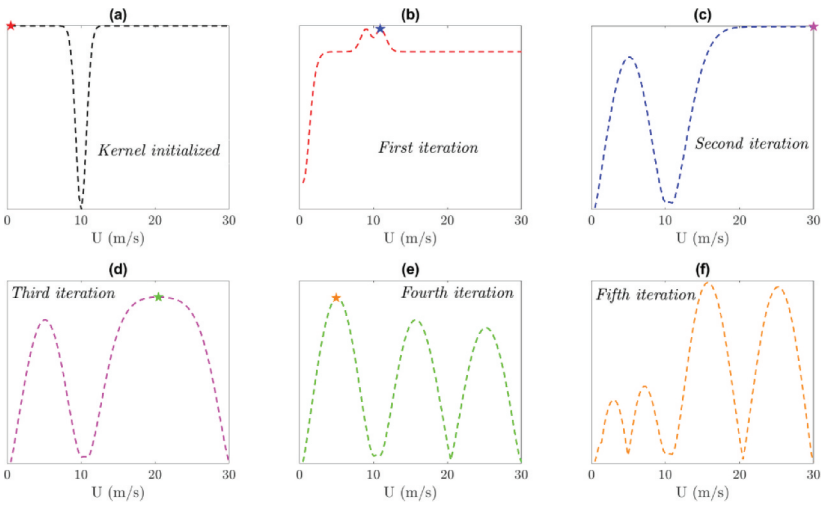

Figure 3. The learning function for the first five iterations, with the marker on each plot denoting the maximum value of the function. The kernel was initialized with a velocity of 10 m/s. The values of the leaning function have been normalized for enhanced clarity.

The learning function is computed at each test velocity as a weighted average of the predicted damage and the standard deviation of the prediction, as shown in Equation (7). This implies that velocities with minimal impact on damage will be given lower priority compared to those near the peak. Consequently, the learning function tends to concentrate most data points in the vicinity of the peak, with fewer points distributed elsewhere, as illustrated in (Figure 2). This process of sequential updating becomes more apparent when we refer to the plots in (Figure 3). The normalized values of the learning function for the first five iterations are plotted. The kernel is initiated with $U = 10$ *m/s*. The training function is plotted in (Figure 3a) and shows a constant value except in the vicinity of this sole training point. The pentagram marks in the plots show the maximum value of the learning function, with the corresponding velocity being chosen as the next point for training. We observe lower values of the learning function corresponding to velocities within the training data, attributed to a decreased standard deviation of the Gaussian Process Regression in the vicinity of the training data points.

Table 2. The fractional fatigue damage accumulated by the three points.

Points	A	B	C
Cumulative damage (100-year period)	0.0066	0.0052	0.003

The FDA calculated at each iteration changes since the mean of the GPR evolves. The addition of the first few points results in a substantial change to the value of the FDA. This is tracked quantitatively using the relative change of the FDA, plotted in Figure (4). We notice that after twelve iterations, the surrogate model is already pretty accurate and converges fully after twenty iterations. Table (2) presents the predicted values of the fraction of the fatigue damage that will be accumulated at the three points in the girder over a 100-year period. The computed values are beneath the expected values, providing evidence of the exceptional aerodynamic characteristics of the cross-section.

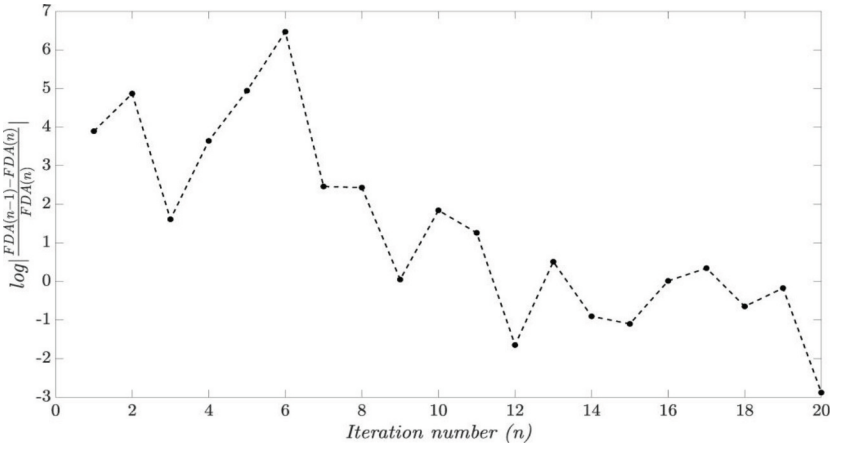

Figure 4. Plot showing the convergence achieved after 20 iterations. The relative change in the FDA has been plotted for each iteration.

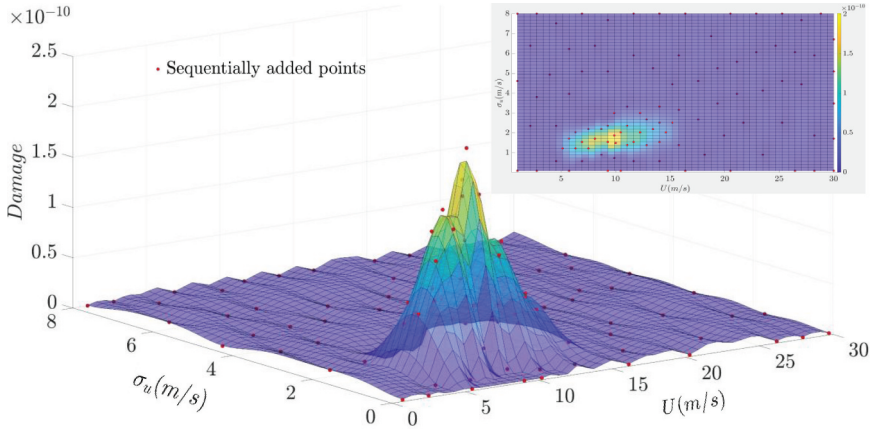

Figure 5. A surrogate model for FDA using two uncertain wind parameters. The insert plot depicts a higher density of points chosen by the algorithm near the peak of the surface.

3.2 *Two uncertain parameters*

In this section, we perform the fatigue analysis considering two uncertain environmental factors. The parameter chosen is the standard deviation of the turbulence intensity in the horizontal direction and orthogonal to the bridge, denoted by σ_u. This choice was motivated by the fact that σ_u has a greater impact on the buffeting response of a bridge, hence the fatigue.

As the number of uncertain parameters increases there is a significant uptick in the number of iterations the algorithm needs to perform to reach convergence. This is where sequential updating has the potential to cut the computational effort.

A 100-point surrogate model is depicted in Figure. (5). The kernel was initialized with $U = 15\ m/s, \sigma_u = 4\ m/s$. The convergence was not achieved after 99 iterations. However, the value of the relative change in FDA was close to the termination criterion and stood at $0.46\% > 0.1\%$. The insert plot in Figure. (5) depicts the points chosen by the learning function, making it evident that the peak is more densely represented. For this case of two uncertain wind parameters, using the algorithm without a learning function is computationally expensive, and the peak of the surface is not well represented. This issue exacerbates when more uncertain parameters are used.

3.3 *Conclusions*

The sequential updating algorithm presented in this work, emerges as a robust and efficient methodology for buffeting-induced fatigue analysis in the presence of uncertain environmental factors. Our study demonstrates the efficacy of a sequential updating algorithm for fatigue analysis in a long-span suspension bridge, in scenarios with uncertain wind-field parameters. The use of a learning function streamlines the selection of training points for the surrogate model of fatigue damage, reducing computational effort, a crucial advantage when dealing with more uncertain parameters. The initial analysis, focusing on a single uncertain parameter, showed rapid convergence, with the surrogate model achieving accuracy after a few iterations.

Expanding to two uncertain parameters, the algorithm's capability to handle increased complexity was demonstrated. Despite increased computational demands, the sequential updating algorithm remains viable for optimizing training point selection, enhancing convergence efficiency. This approach shows promise in applications where accurate fatigue damage prediction is crucial for structural integrity assessments.

Cellular automata damage models incorporating climate change effects for life-cycle assessment of concrete bridges

G.V. Nava, A. D'Iorio & F. Biondini
Politecnico di Milano, Milan, Italy

ABSTRACT: The accuracy of life-cycle assessment of concrete structures exposed to corrosion due to ingress of chlorides and other aggressive agents can depend significantly on the diffusion models adopted. In addition, daily weather fluctuations and long-term changes in climatic conditions can exacerbate the effects of chloride attack, accelerating the onset of corrosion and increasing the rate of damage. This paper presents a novel approach to chloride diffusion simulation and corrosion modeling under climate change using cellular automata. The proposed model is based on the extension of a general formulation established in previous works for life-cycle assessment of concrete structures under corrosion by adapting cellular automata to account for the evolution over time of the environmental parameters that influence the initiation and propagation of corrosion, i.e. temperature and relative humidity, in a changing climate. The methodology is applied to life-cycle structural assessment of a bridge pier under corrosion considering different climate change scenarios. The results allow to quantify the impact of climate change on chloride diffusion, corrosion damage, and structural performance over time.

1 INTRODUCTION

Structures and infrastructure systems suffer over time from the detrimental effects of aging, fatigue, and deterioration processes due to attack by aggressive agents and other damage mechanisms that impair their original structural performance (Ellingwood 2005). These damaging effects may lead to unsatisfactory structural safety and performance, including structural and functional obsolescence. Life-cycle-oriented design, assessment, maintenance and management criteria, methods and procedures are hence necessary to guarantee adequate levels of structural safety and reliability over the entire lifespan of structures (Biondini & Frangopol 2016).

Among various structural degradation phenomena, chloride-induced corrosion in reinforced concrete (RC) structures is particularly damaging, especially for RC bridges whose structural members are frequently exposed to chloride attack. In this context, diffusion and damage models that can accurately reproduce chloride ingress, corrosion initiation and damage propagation are essential for life-cycle structural assessment. Fick's diffusion model is often applied in a simplified one-dimensional form to describe chloride ingress (fib 2006). However, depending on the exposure and shape of structural members, the diffusion process can be better described by two- or three-dimensional concentration gradients (Biondini et al. 2004, Titi & Biondini 2016).

In addition, climate change associated with continued greenhouse gas emissions will lead to increased global warming, which, in turn, leads to exacerbate multiple and concomitant hazards (IPCC 2023), such as the occurrence of extreme events of increased magnitude and frequency and the acceleration of aging and structural deterioration processes. Rising temperature and changes in relative humidity can affect the diffusivity of concrete and the rate of corrosion damage, leading over time to impair the life-cycle structural performance and the residual structural lifetime (Stewart et al. 2011, Nava et al. 2023).

DOI: 10.1201/9781003483755-327

This paper presents a novel approach to chloride diffusion simulation and corrosion modeling under climate change using cellular automata. The proposed approach is based on a general formulation established in previous works for probabilistic life-cycle assessment of concrete structures under corrosion (Biondini et al. 2004, 2006). The main novelty is the extension of cellular automata and evolutionary computation techniques to account for climate change effects by incorporating the variability over time of the environmental parameters that influence the initiation and propagation of corrosion, i.e. temperature and relative humidity. The methodology is applied to life-cycle structural assessment of a RC bridge pier under corrosion considering different climate change scenarios. The effects of uncertainties in the mechanical and environmental damage stressors are also investigated in probabilistic terms. The results allow to quantify the climate change impact and highlight the importance of the proper modelling of degradation processes and environmental conditions over the entire structural lifetime.

2 CLIMATE CHANGE AND FUTURE EMISSION SCENARIOS

Climate change models are based on greenhouse gas emissions which depend on how the future may evolve with respect to a range of different socio-economic variables. Future climate is simulated under different scenarios such as the shared socioeconomic pathways (SSP) combined with the representative concentration pathways (RCP), i.e. SSP-RCP scenarios (IPCC 2023).

SSPs are a set of scenarios developed to describe plausible alternative trends in the evolution of society and ecosystem over a century timescale without considering climate change or climate policies and consist in a narrative storyline describing societal future, and a quantitative description of socio-economic drivers such as population, gross domestic product and urbanization. SSP1 and SSP5 represent scenarios for human development emphasizing education, health, and economic growth. However, SSP5 leans towards an energy-intensive, fossil-based economy, while SSP1 shifts towards sustainability. In contrast, SSP3 and SSP4 envision pessimistic trends with minimal investment in education or health, rapid population growth, and rising inequalities. SSP3 prioritizes regional security, while SSP4 emphasizes large inequalities within and across countries, leading to societies highly vulnerable to climate change. Finally, SSP2 envisions a central pathway where trends continue historically without significant deviations (O'Neill et al. 2016). On the other end, RCPs specify the radiating forces at the end of the century based on different emission trajectories (van Vuuren et al. 2011). A set of five scenarios has been considered in the VI IPCC assessment report (IPCC 2023): SSP1-1.9 and SSP1-2.6 representing a low emission scenario pathway leading to warming below 1.5°C and 2.0°C respectively in 2100; SSP2-4.5 represents a medium emission scenario; SSP3-7.0 and SSP5-8.5 represent a high and a very high emission scenarios, respectively. In the comparative investigation presented in this paper, scenarios SSP2-4.5 and SSP5-8.5 are considered.

3 DIFFUSION AND CORROSION MODELING UNDER CLIMATE CHANGE

3.1 *Cellular automata simulation of diffusion*

The mathematical description of the diffusion process of chemical components within solid media typically involves equations relating the mass diffusion rate to the concentration gradient responsible for the net mass transfer (Glicksman 2000). The simplest model to describe this process is the Fick's second law leading to a linear relationship between the mass flow and the concentration gradient as described by the following differential equation:

$$\nabla[D(\mathbf{x},t)\nabla C(\mathbf{x},t)] = \frac{\partial C(\mathbf{x},t)}{\partial t} \tag{1}$$

where $D=D(\mathbf{x},t)$ and $C=C(\mathbf{x},t)$ are the diffusion coefficient and mass concentration, respectively of the component at point $\mathbf{x}=\mathbf{x}(x, y, z)$ and time t, and $\nabla(\cdot) = \mathbf{grad}\,(\cdot)$.

The closed-form solution of Fick's diffusion equation can be obtained only for simple problems. Cellular automata are used in this study for numerically solving the diffusion equation

(Biondini et al 2004). This technique relies both on temporal (i.e. time step subdivision) and spatial discretization (i.e. regular uniform grid of cells with state variables associated to each cell). In case of diffusion, the state of a cellular automaton at time t is fully defined by the concentration $C_i = C_i(t)$ at each cell i. Evolution occurs at discrete time steps according to parallel state transitions determined by local rules. At time t_{k+1}, the variables C_i^{k+1} are synchronously updated based on the concentration values ${C_{i,n}}^k$ in the neighborhood n of cell i at the preceding time instant t_k, where the neighborhood typically includes the cell itself and adjacent cells within a specified radius r. The diffusion process described by the Fick's model in d-dimensions ($d = 1,\ 2,\ 3$) can be reproduced by adopting $r = 1$ and the following local evolutionary rule (Biondini 2011):

$$C_i^{k+1} = \Phi_0 C_i^k + \sum\nolimits_{j=1}^{d} \left(\Phi_j^- C_{i-1,j}^k + \Phi_j^+ C_{i+1,j}^k \right) \tag{2}$$

where $C_i^k = C(\mathbf{x}_i,\ t_k)$ is the concentration at cell i and time instant k, Φ_0, Φ_j^-, and Φ_j^+ $(j = 1, \ldots, d)$ are evolutionary coefficients. According to mass conservation law, the evolutionary coefficients must fulfil the following normality rule:

$$\Phi_0 + \sum\nolimits_{j=1}^{d} \left(\Phi_j^- + \Phi_j^+ \right) = 1 \tag{3}$$

For isotropic medium, the symmetry condition $\Phi_j^- = \Phi_j^+ = \Phi_1 (j = 1, \ldots, d)$ should be imposed to avoid directionality effects, i.e. $\Phi_0 = (1 - 2d\Phi_1)$. In this way, the evolutionary rule can be rewritten as follows:

$$C_i^{k+1} = \Phi_0 C_i^k + \frac{1 - \Phi_0}{2d} \sum\nolimits_{j=1}^{d} \left(C_{i-1,j}^k + C_{i+1,j}^k \right) \tag{4}$$

Based on the diffusivity D, a proper discretization in space Δx and time Δt has to be chosen:

$$D = \frac{1 - \Phi_0}{2d} \frac{\Delta x^2}{\Delta t} = \Phi_1 \frac{\Delta x^2}{\Delta t} \tag{5}$$

Standard value of central evolutionary coefficient for constant diffusivity is Φ_0=1/2.

3.2 *Cellular automata with time-variant diffusivity*

Concrete diffusion results to be affected by material aging and changes in environmental conditions. Experimental studies have shown an increase in the concrete diffusivity along with the increase in temperature and relative humidity. To account for aging and nonstationary climate conditions, the diffusion coefficient can be expressed as follows (Chirdeep et al 2023):

$$D(t) = k_e\ k_c\ k_t\ D_{ref}\ f_T(t) f_{RH}(t) f_a(t) \tag{6}$$

where D_{ref} is the reference diffusion coefficient for T=20 °C and RH=75%, k_e, k_c, and k_t are environment, curing, and test method factors, respectively, and $f_T(t)$, $f_{RH}(t)$, and $f_a(t)$ are functions which account for temperature and relative humidity variation and aging process, respectively.

The functions $f_T(t)$ and $f_{RH}(t)$ are computed as follows (Martín-Pérez et al. 2001):

$$f_T(t) = e^{\frac{E}{R}\left(\frac{1}{293.15} - \frac{1}{273.15 + T(t)}\right)} \tag{7}$$

$$f_{RH}(t) = e^{\left[1 + \frac{(1 - RH(t))^4}{(1 - 0.75)^4}\right]^{-1}} \tag{8}$$

where E is the activation energy of the chloride's diffusion process (40 kJ/mol), R is the gas constant (8.314×10^{-3} kJ/mol), T is the temperature in Celsius degrees, and RH is the relative humidity. The aging function can be evaluated as a function of the aging factor a, as follows:

$$f_a(t) = \left(\frac{0.0767}{t}\right)^a \tag{9}$$

The variability in time of diffusivity can be incorporated in the cellular automata formulation by updating over time (a) the time step Δt, (b) the evolutionary coefficients Φ_0 and Φ_1, or (c) both the time step Δt and coefficients Φ_0 and Φ_1. Updating the time step only may be not practical for implementation purposes and it is also not feasible for inhomogeneous conditions, such as when diffusivity is modified locally by cracking (Biondini et al. 2004). In fact, chloride ingress may change significantly with the increase of crack width (Bazant et al. 1987, Kwon et al. 2009). Updating evolutionary coefficients only is a more convenient approach that also allows for local variations in diffusivity over time. However, when such variations become important, as it may occur under climate change effects, evolutionary coefficients may deviate significantly from initial values. In this case, simultaneous updating of the time step and evolutionary coefficients is useful to maintain the evolutionary coefficients within appropriate values.

3.3 *Corrosion damage modeling*

For a steel bar located at point $\mathbf{x}_b$, corrosion initiates at time t_{cr} when chloride concentration attains a critical threshold C_{cr}, or $t_{cr} = \min\{t \mid C(\mathbf{x}_b, t) \geq C_{cr}\}$. Corrosion propagation, expressed in terms of corrosion penetration rate p_s (mm), is described based on Faraday's law as follows:

$$\frac{\partial p_s}{dt} = 0.0116\ R_f\ i_{corr} \tag{10}$$

where i_{corr} is the corrosion electric current density ($\mu A/cm^2$), and R_f is the pitting factor, i.e. the ratio between the maximum depth measured at pit and the average penetration calculated indirectly from the weight loss of the steel bar (Stewart & Al-Harthy 2008).

Corrosion propagation is affected by the variation of environmental parameters, such as temperature and relative humidity, as well as chloride concentration and formation of corrosion products. To account for these effects, the corrosion rate is expressed as follows (Nava et al 2023):

$$i_{corr}(t) = i_{corr,ref}\varphi_{RP}(t)\varphi_T(t)\varphi_{RH}(t)\varphi_C(t) \tag{11}$$

where $i_{corr,ref}$ is the reference corrosion rate for T=20 °C and RH=75%, and the functions $\varphi_{RP}(t)$, $\varphi_T(t)$, $\varphi_{RH}(t)$, and $\varphi_C(t)$ account for the formation of rust products and variation of temperature, relative humidity, and chloride concentration, respectively. The following functions are adopted (Liu & Weyers 1998, Vu & Stewart 2000, Stewart et al. 2011, Guo et al. 2015):

$$\varphi_{RP}(t) = 0.85t_p^{-0.29} \tag{12}$$

$$\varphi_T(t) = [1 + K_T(T(t) - 20)] \tag{13}$$

$$\varphi_{RH}(t) = e^{-6000(RH(t)-0.75)^6} \tag{14}$$

$$\varphi_C(t) = \frac{C(t) + C_{cr}}{2\ C_{cr}} \tag{15}$$

where t_p is the time since corrosion initiate, and K_T=0.025 or K_T=0.073 for temperature $T \leq 20°C$ and $T > 20°C$, respectively.

Corrosion damage is modeled based on corrosion penetration in terms of a damage index δ_s representing the percentage of loss of cross-sectional area of the steel bar. The reduction of steel bar ductility and the damaging longitudinal splitting cracks in the concrete surrounding the corroded bars due to the formation of oxidation products are taken into account as reported in Biondini and Vergani (2015), i.e. based on a reduction of both steel ultimate strain capacity ε_{su} and concrete compression strength f_c, eventually leading to spalling of concrete cover.

4 APPLICATION

4.1 *Case study: RC bridge pier*

The two-column RC bridge pier shown in Figure 1a is considered. Each column bent has a two-cellular cross-section with the geometry and reinforcement layout shown in Figure 1b. The concrete cover is 4 cm. Figure 1b shows also the fiber structural model developed in OpenSees (Mazzoni et al. 2006). Material constitutive laws are based on a parabola-rectangle model for concrete (concrete 01) and elastic-plastic model with strain hardening for steel (steel 01).

The life-cycle structural performance of the bridge pier is investigated at cross-sectional level under axial force N=7.1 MN by assuming the bridge pier exposed to chloride attack over the inner and outer surfaces with uniform concentration C_s. Diffusion and damage modeling are based on cellular automata with grid cell size Δx = 1 cm and time step Δt = 0.09 years (Figure 1c). Random variables, probability distributions, descriptors, and bounds are listed in Table 1.

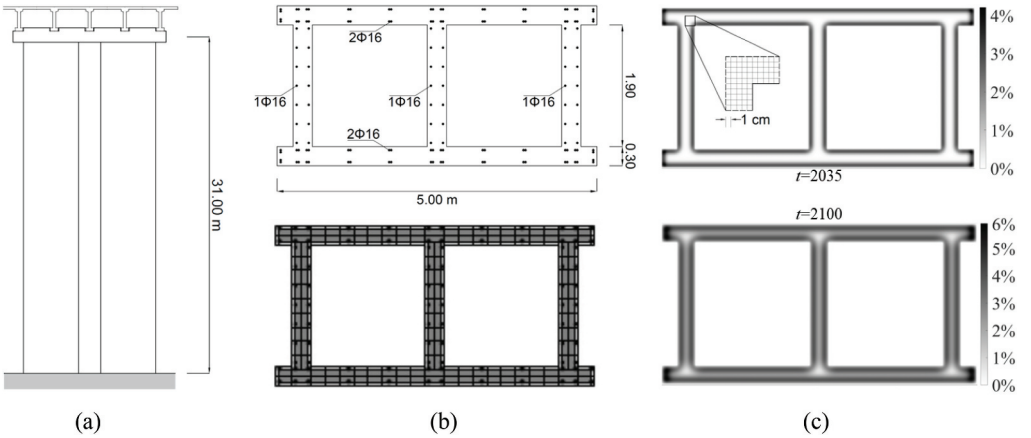

Figure 1. (a) RC bridge pier; (b) Geometry, reinforcement layout, and structural model of the cross-section; (c) Detail of the grid of cellular automata and contour maps of the concentration ratio $\Delta C=(C_{SPP5\text{-}8.5}-C_{HIST})/C_s$ quantifying the difference of chloride concentration predicted with climate change, i.e. $C_{SPP5\text{-}8.5}$, and without climate change, i.e. C_{HIST}, normalized to surface concentration C_s, at years 2035 (top) and 2100 (bottom).

Table 1. Random variables, probabilistic distributions, descriptors, and bounds (Stewart & Al-Harthy 2008, Titi & Biondini 2016, Nasr et al 2022).

Random Variable	Distribution Type	Mean	C.o.V.	Bounds
Surface chloride concentration C_s [%wt./c]	Truncated Normal	3.0	0.30	$C_s \geq 0$
Critical chloride concentrations C_{cr} [%wt./c]	Beta	0.60	0.25	$0.2 \leq C_{cr} \leq 2$

Climate projections are based on the EC-Earth3-Veg-LR climate model (Döscher et al. 2022). Figure 2 shows the projection of mean annual temperature (Figure 2a) and relative humidity

(Figure 2b) with resolution of 250 km in Lombardy Region, Italy, including historical data from 1970 to 2014 (light gray line) and two climate scenarios from 2015 to 2100: medium emission scenario SSP2-4.5 (dark gray line) and very high emission scenario SSP5-8.5 (black line).

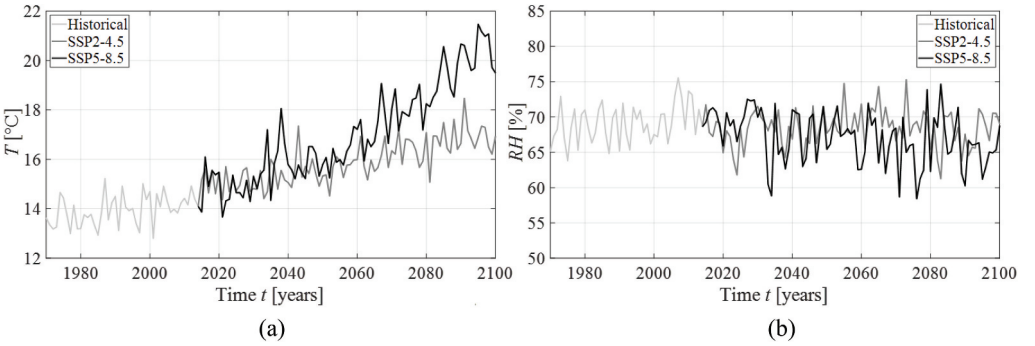

Figure 2. Historical and future climate projections: (a) Mean annual temperature; (b) Relative humidity.

4.2 *Life-cycle structural assessment under climate change*

The influence of climate change is investigated with reference to chloride diffusion, steel bar corrosion, and cross-sectional bending capacity. A deterministic life-cycle analysis is firstly carried out by assuming the mean values listed in Table 1 as nominal values. The contour maps shown in Figure 1c provide the concentration ratio $\Delta C=(C_{\text{SPP5-8.5}}-C_{\text{HIST}})/C_s$ to quantify the difference between chloride concentration predicted for the climate change scenario SPP5-8.5, i.e. $C_{\text{SPP5-8.5}}$, and based on historical climate, i.e. C_{HIST}, with respect to surface concentration C_s, at years 2035 (top) and 2100 (bottom). A difference of about 5% on the outer layers of the box cells holds over the entire lifetime, leading to reduce the corrosion initiation time and increase the corrosion rate of the reinforcing steel bars. This is shown in Figure 3a by means of the evolution over time of the damage index δ_s of the steel bars #1 and #2 located at midspan and end of the bottom flange, respectively, for historical vs SSP5-8.5 climate scenarios. The impact of corrosion damage is reflected at cross-sectional level on the evolution over time of the bending moment vs curvature capacity curves, as shown in Figure 3b, with markers indicating cracking, yielding and ultimate conditions. It is worth noting that climate change effects involve a reduction of both bending strength and curvature ductility with respect to the prediction based on historical climate. Figures 3c and 3d allow to quantify this reduction over the investigated timeframe for the capacity ratio of both ultimate bending moment M_u (Figure 3c) and curvature ductility $\mu=\chi_u/\chi_y$ (Figure 3d), where χ_y and χ_u are the values of bending curvature at yielding and ultimate, respectively. These diagrams provide an effective quantitative measure of the impact of a changing climate also in terms of time lag between the two investigated scenarios, historical vs SSP5-8.5, associated with the attainment of target values of ultimate bending moment and curvature ductility capacity ratios, i.e. $M_u(t)/M_u(t_0)$ and $\mu(t)/\mu(t_0)$.

The probabilistic life-cycle analysis is performed by Monte Carlo simulation (Table 1). The impact of climate change compared to the prediction based on historical climate is confirmed also in probabilistic terms, as shown by the histograms of the probability density functions reported in Figure 4 for corrosion initiation time t_{cr} of bar #1 (Figure 4a) and bar #2 (Figure 4b) for scenario SSP5-8.5, and ultimate bending moment M_u at year 2100 for scenario SSP2-4.5 (Figure 4c) and scenario SSP5-8.5 (Figure 4d). It is worth noting that for several realizations the severity of the corrosion scenario leads over the investigated lifetime to an almost complete corrosion of the steel reinforcement ($\delta_s \rightarrow 1$). The number of realizations associated with this critical condition increases when the effects of climate change are considered (Figures 4c and 4d).

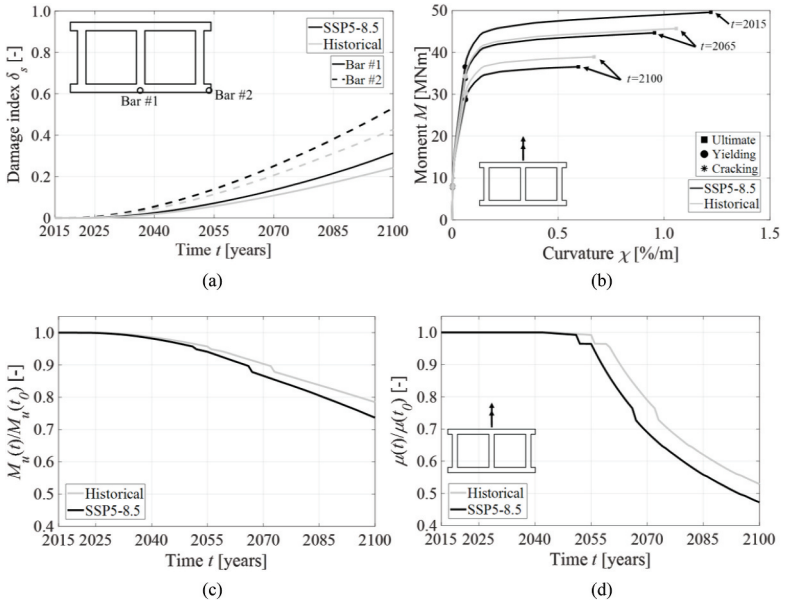

Figure 3. Deterministic life-cycle structural analysis (nominal structure) under historical vs SSP5-8.5 climate scenarios: (a) Evolution of damage index δ_s of bars #1 and #2, and (b) bending moment M vs curvature χ capacity curves at different time instants; Time-variant capacity ratio of (c) ultimate bending moment, $M_u(t)/M_u(t_0)$, and (d) bending curvature ductility, $\mu(t)/\mu(t_0)$.

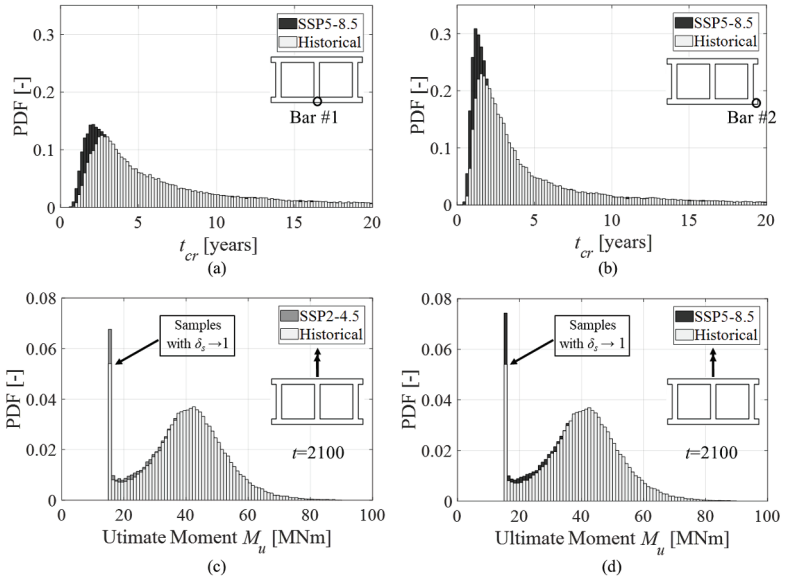

Figure 4. Probabilistic life-cycle analysis considering historical, SSP2-4.5, and SSP5-8.5 climate scenarios: histograms of the probability density functions of corrosion initiation time t_{cr} of (a) bar #1 and (b) bar #2 under historical vs SSP5-8.5, and ultimate bending moment M_u at year 2100 under historical vs (c) SSP2-4.5 and (d) SSP5-8.5.

5 CONCLUSIONS

An approach to chloride diffusion simulation and damage corrosion modeling under climate change using cellular automata has been presented. The proposed cellular automata model, which is an extension of a general formulation proposed in previous works, incorporates the evolution in time of the environmental parameters which affects corrosion initiation and propagation, i.e. temperature and relative humidity. The results obtained by applying the proposed model to life-cycle assessment of a RC bridge pier under different climate scenarios allow to quantify the impact of climate change on chloride diffusion, corrosion damage, and structural performance over time. These results confirm the importance of incorporating the effects of climate change in diffusion and damage models for life-cycle design, assessment, maintenance and management of RC bridges exposed to corrosion. Further research is ongoing along the lines established in Biondini et al. (2004) to extend the proposed approach to account for concrete cracking and other local damaging effects that may interact with the diffusion process and related corrosion damage.

Robustness evaluation of a twin I-girder bridge

P. Acharya*, R. Hao* & W. Lin*
Department of Civil Engineering, School of Engineering, Aalto University, Espoo, Finland

ABSTRACT: With the increasing popularity of twin I-girder bridges, lack of robustness of this bridge type has always been a major concern. Though the AASHTO (2012) specification considers all twin I-girder bridges as non-redundant and fracture critical structures, the robustness of these structures can be improved through design criteria updates and the addition of auxiliary members. This study aims to evaluate the robustness of simply supported twin I-girder bridges. Experimental testing was conducted on two scaled bridge specimens (intact and damaged) under asymmetric loading conditions, and the structural responses were analyzed. Obtained test data were used to validate the developed finite element model and non-linear analyses were performed for further investigation. In this study, the robustness of twin I-girder bridge is studied with different vertical positions of crossbeam, considering different damage locations. The results obtained indicate an enhanced system robustness when the crossbeams are positioned at the lower end of the girder.

1 INTRODUCTION

According to the Euro-code definition, robustness refers to the capacity of a structure to endure events such as fire, explosions, impact, or human error consequences, without suffering damage that is significantly greater than the original cause (EN 1991-1-7). To achieve structural robustness and minimize the risk of disproportionate collapse, various alternative measures should be incorporated into the structural design. These measures encompass the following: 1) ensuring structural integrity and solidarity, 2) implementing a second line of defense, 3) incorporating multiple load paths or redundancy, 4) employing progressive failure or zipper stopper techniques, and 5) harnessing the advantages of strain hardening (Partov et al., 2017).

Twin I-girder bridges is increasing its popularity among the steel-concrete composite bridges among European and other countries due to its easy constructability and other benefits including low weight to span ratio (Lin et al., 2020). These twin I-girder bridges are considered as a non-redundant structure, according to AASHTO (2012) due to lack of load distribution capacity under local failure. Under the member failure condition, these bridges are more susceptible towards collapse of whole structure. Therefore, these structures are considered as a non-robust structure. However, several investigations (Lin et al., 2013; Park et al., 2012) have indicated that various composition of structural members and boundary conditions such as bracing systems, girder continuity and deck system can provide alternate load transfer paths for redistribution, thus escalating structural redundancy and robustness of the system. In their study, Lam et al. (2014) investigated the redundancy level of models for twin I-girder bridges. Their research revealed that multi-span continuous twin I-girder bridges possess adequate redundancy levels and can be classified as redundant structures. Furthermore, the inclusion of lateral X-type bottom bracing was found to increase the redundancy level. The researcher (Lin et al., 2013) also noted that the efficiency of the bridge was improved by incorporating I-shaped cross beams, which offer an alternative load path. In overall, the

DOI: 10.1201/9781003483755-328

redundancy level and robustness of bridge is a result of combined action of various structural parts of the structural system.

This paper studies the post fracture performance of twin I-girder bridge under damage caused by fatigue and corrosion process. It also extends to the parametric study on twin I-girder bridge due to the effect caused with different crossbeam location across the vertical height of main girder.

2 EXPERIMENTAL PROGRAM

Two twin I girder bridge prototypes, one in an intact form and another with an artificially induced fatigue crack were subjected to the laboratory testing to examine the mechanics and structural performance behavior under asymmetrical loading condition as shown in Figure 1(a). Specimens were designed based on Japanese bridge design specifications. Test specimens were steel concrete composite structures with steel reinforced concrete of 4.4m × 1.2m × 0.12m dimension with double layered steel reinforcement of ϕ10mm and steel I-shaped girders of height 300mm and 150mm flange width spaced 800mm from each other. Each I-shaped girders were connected with reinforced concrete slabs with shear stud connectors designed under compliance with JSCE specification (JSCE, 2009). I-shaped crossbeams connecting two main girders placed every 800mm spacing to provides stability against lateral forces. In addition, vertical stiffeners were placed every 400mm spacing to prevent local buckling. Figure 1 provides design details of the bridge specimens along with details on sensor types and position. One of the bridge specimens was subjected to damage in the form of an artificial crack induced through torch cut of 4.5mm created in lower flange and web of main girder as shown in Figure 1(b). The location of such damage was chosen at mid-span, next to the welded area of vertical stiffener. The intact specimen, hereafter known as Specimen 1, was utilized to investigate the performance of the bridge under normal conditions. On the other hand, Specimen 2, which had a fatigue failure in one of its girders, was employed to gain insights into the behavior of the bridge after experiencing a fracture.

2.1 *Material properties*

The concrete slab was constructed using concrete with mean cylindrical compressive strength of 29.3 MPa. This strength value was determined through a compressive strength test conducted on three cylindrical concrete specimens. For reinforcement, SD345 steel bars with a nominal diameter of D10 were employed. The steel components, including the steel girder, crossbeam, and vertical stiffeners, were made from SM490 structural steel with varying thicknesses. The main girder consisted of a 6 mm thick web plate and a 12 mm thick flange, each possessing distinct yield and ultimate strength values. To connect the steel girder with the concrete slab, stud connectors of SS400 were utilized. Details on material properties of concrete, reinforcement bars, and structural steels of various thickness can be seen in Table 1.

Table 1. Material properties.

Materials	Type	Youngs Modulus (GPa)	Yield Strength (MPa)	Yield Strain (μ)	Ultimate Strength (MPa)
Concrete	C35	29.5	-	-	-
Steel Plate (6mm)	SM490	200	450	2250	577
Steel Plate (8mm)	SM490	200	427	2135	556
Steel Plate (12mm)	SM490	200	389	1945	548
Rebar (D10)	SD345	200	406	2030	544
Stud Connector	SS400	200	235	-	400

2.2 *Instrumentation and loading test procedure*

To measure vertical deflection at strategic points, Linear Variable Differential Transformers (LVDTs) were employed, while various strain gauges were attached to measure strains in girder web and flange, concrete surface, reinforcement bars, and studs. Additionally, LVDTs in stud connectors were utilized to measure two distinct types of strains, namely shear and bending strains.

The bridge specimen being tested was supported by two roller supports. Displacement controlled asymmetrical load was applied just above the main girders (Girder 1) until functionality failure of the bridge specimens. To distribute the concentrated load over the flange width, loading plates measuring 200 mm × 150 mm × 30 mm were employed.

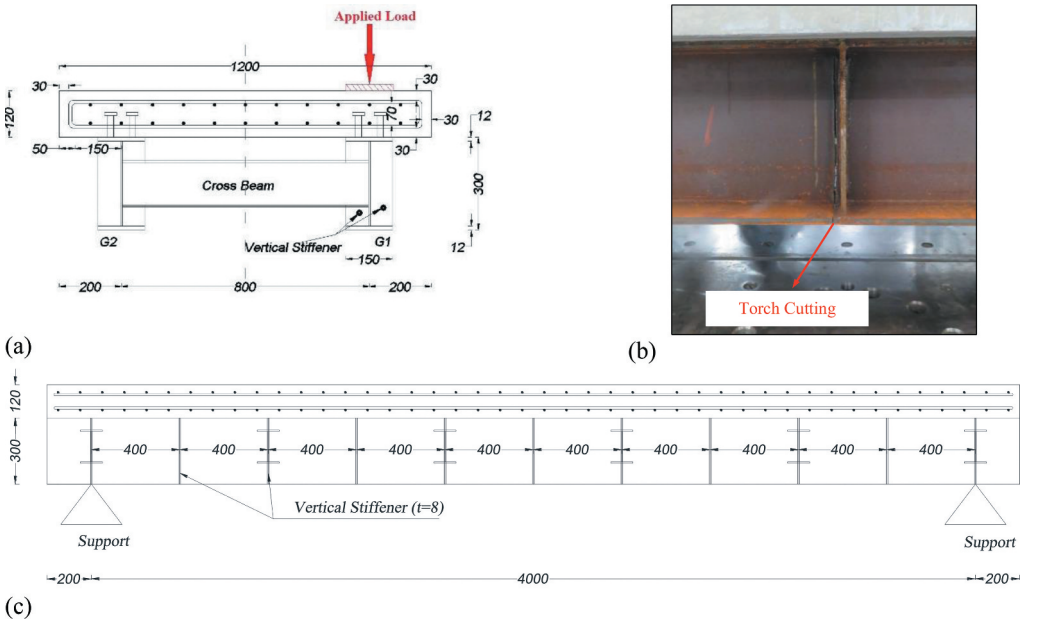

Figure 1. Geometric description of bridge specimen: (a) Transverse section of bridge; (b) Torch cut damage on steel girder; (c) Longitudinal section of bridge.

3 NUMERICAL MODELLING AND VALIDATION

The 3-dimensional finite element model was utilized to conduct numerical modelling and simulation, which was achieved using commercial software ABAQUS. A static non-linear analysis was carried out to simulate the material and geometrical non-linearities. The numerical model of the bridge specimen, featuring various elements and a fatigue crack model, is depicted in Figure 2. For damaged bridge model, fatigue crack is introduced through a geometric cut of 4.5 mm wide created in lower flange and web of main girder.

Three distinct element types were utilized in constructing the numerical model. The concrete model was represented by the solid element C3D8R, while the steel reinforcement and stud connectors were modeled using the beam element B31. The structural steel was represented by the shell element S4R. The reinforcement bars and stud connectors were embedded within the solid concrete element, and a hard contact interaction was established between the concrete surface and the upper flange of the steel girders, with a friction coefficient of 0.5. The simply supported boundary condition was modeled with a pin support at one end and a roller support at the other end. Finally, a displacement-controlled load increment method was enforced for load application at the top of the concrete slab, with a maximum downward displacement of 40mm allowed.

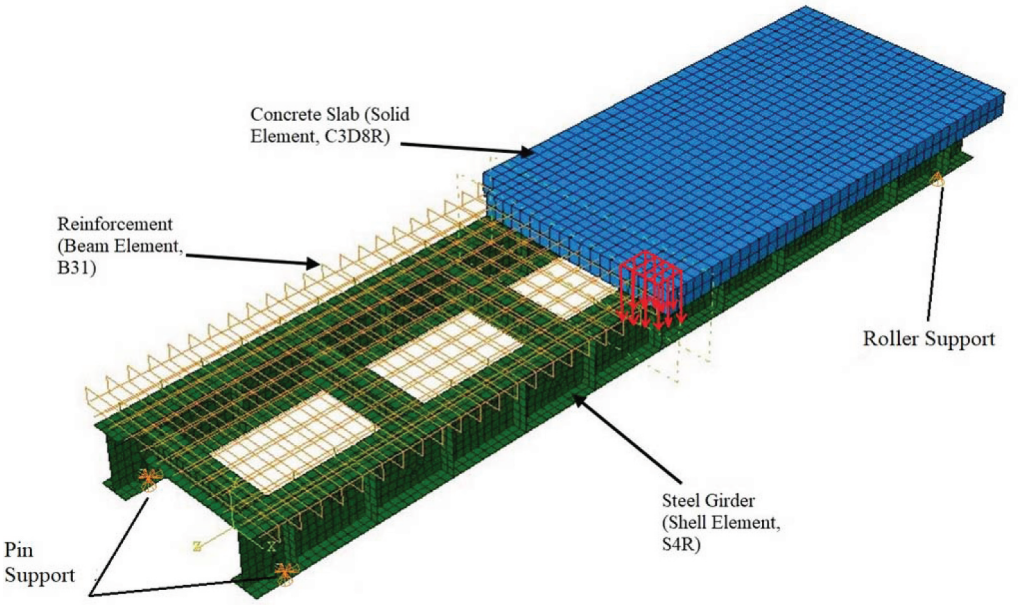

Figure 2. Finite element model with boundary conditions and the corresponding element type for different parts.

3.1 *Material properties modelling*

The concrete properties were modeled in accordance with the JSCE specification for concrete structures, following the stress-strain curve depicted in Figure 3. This allowed for the simulation of both compressive and tensile behavior of the concrete. The model also included the plasticity of the concrete in a damaged state. The compressive behavior of the concrete was determined based on equations (1) and (2), where σ_c, ϵ_c, f_{cd}, f_{ck}, and ϵ_{cu} represent the compressive stress, compressive strain, design compressive strength, characteristic compressive strength, and ultimate compressive strain of the concrete, respectively. On the other hand, equations (3) and (4) define the tensile behavior of the concrete, where σ_t, ϵ_t, f_{tk}, and ϵ_{tk} represent the tensile stress, tensile strain, characteristic tensile strength, and compressive strain corresponding to the characteristic tensile stress of the concrete, respectively.

$$\sigma_c = \begin{cases} k_1 f_{cd} \cdot \frac{\in_c}{0.002} \cdot \left(2 - \frac{\in_c}{0.002}\right); \ \in_c \ \leq 0.002 \\ k_1 f_{cd} \ ; \ \in_c \geq 0.002; \ k_1 = 1 - 0.003\, f_{ck} \end{cases} \tag{1}$$

$$\in_{cu} = \frac{155 - f_{ck}}{30000}; \ 0.0025 \leq \ \in_{cu} \ \leq 0.0035 \tag{2}$$

$$f_{tk} = 0.23\, {f_{ck}}^{2/3} \tag{3}$$

$$\sigma_t = f_{tk} \left(\frac{\in_{tk}}{\in_t}\right)^{0.4} \tag{4}$$

The material properties of reinforcement steel and stud connecters were designed based on the relationship depicted by Figure 4(a) as per JSCE specification. Figure 4(b) represents the stress-strain relationship for structural steel plates adopted from JSCE specification for steel and composite structures. The stress value (σ) for $\epsilon \geq \epsilon_{st}$ is defined by Eq. (5) and (6) for

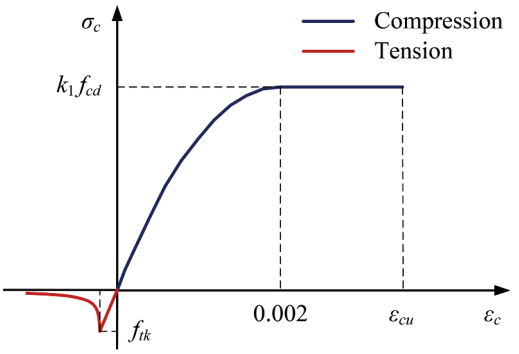

Figure 3. Stress-strain relationship of concrete.

structural steel plates. Table 1 provides a summary of information regarding the elastic modulus, yield stress, yield strain, and ultimate stress capacity of steel reinforcement and structural steel plates with varying types and thicknesses.

$$E = \frac{d\sigma}{d\in} = E_{st}.e^{-\xi\left(\frac{\in}{\in_y}-\frac{\in_{st}}{\in_y}\right)} \tag{5}$$

$$\frac{\sigma}{\sigma_y} = \frac{1}{\xi}\frac{E_{st}}{E}.\left[1 - e^{-\xi\left(\frac{\in}{\in_y}-\frac{\in_{st}}{\in_y}\right)}\right] \tag{6}$$

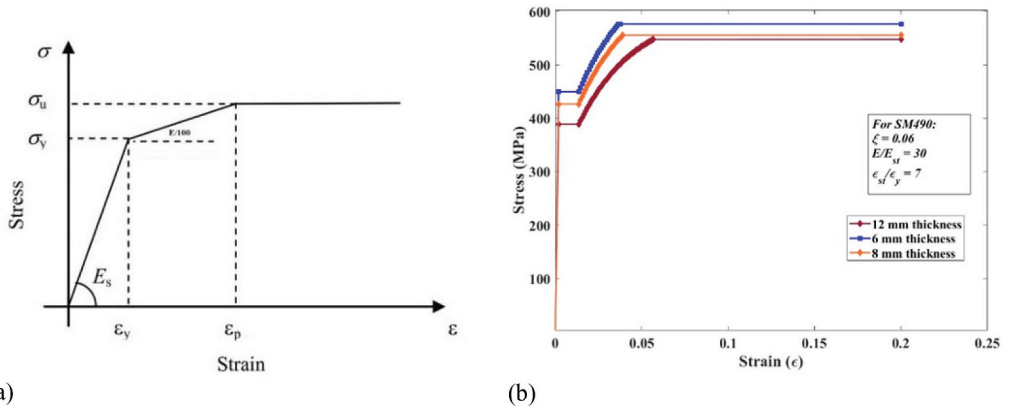

Figure 4. Stress-strain relationship of: (a) steel reinforcement and stud connectors;(b) structural steel plates.

3.2 *Numerical model validation*

The numerical model built in ABAQUS were validated through comparison of analysis results with experimental results. Figure 5 represents the load-displacement curve for both intact and damaged specimen for the load application point at midspan position. Result indicated a close agreement between the results with structural response obtained from numerical analysis with that of experimental results. This provides a validation for the numerical models developed for both intact and damaged specimen.

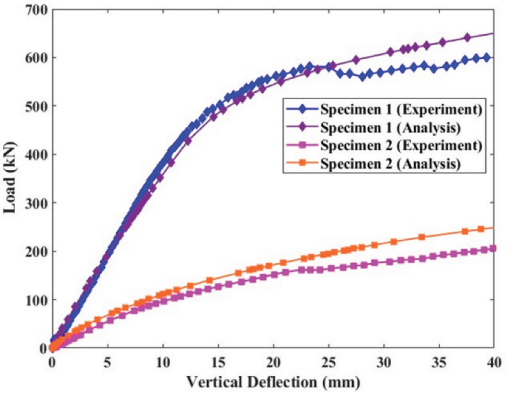

Figure 5. Load-deflection response of bridge specimens with load at mid-span position.

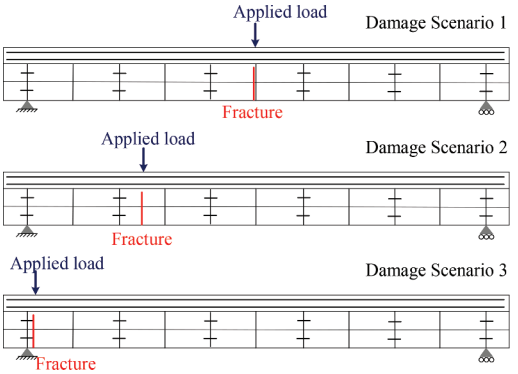
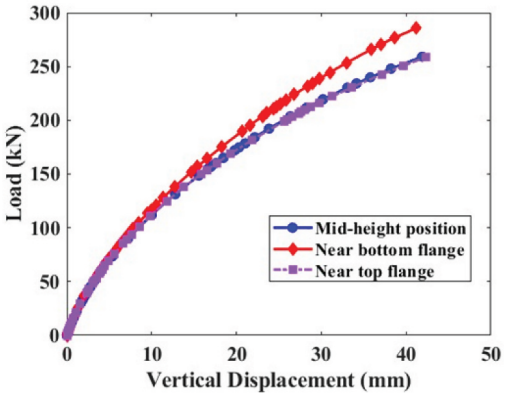
4 PARAMETRIC STUDY

4.1 *Effect of crossbeam position on the robustness of I-girder bridge*

With the shift in position of crossbeam across the vertical depth of main girder changes the transverse geometry of the bridge structure as a system, which in turn changes the performance response of the structure against the applied load. This behavioral change is due to change in mechanics for load transfer. This paper examines the impact of vertical shifts in the crossbeam position along the girder height on the overall performance of a bridge structure. The study analyzes three different positions for the girder - top, middle, and bottom - without making any geometrical changes to the crossbeam. The investigation results are presented in Figure 7 through the load vs. deflection curve and are analyzed for three different damage scenarios where the fatigue crack position and loading position are at the mid-span, quarter-span, and near the end support, as illustrated in Figure 6.





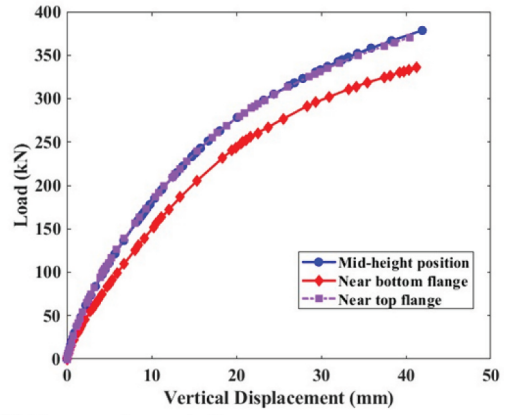


Figure 6. Damage scenarios with different damage location and load application point.

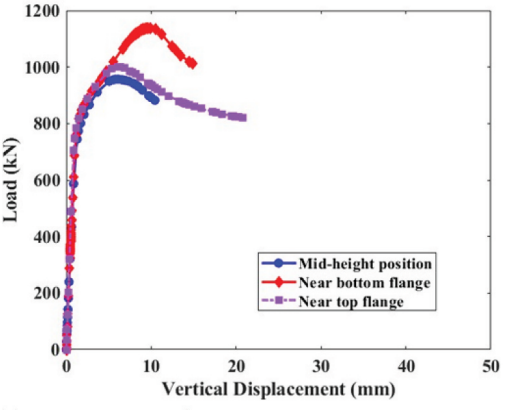

The findings revealed that the positioning of the crossbeam at the top and mid-height of the girder had minimal impact on all three damage scenarios. However, the performance varied when the crossbeam was placed at the bottom position. By incorporating the crossbeam at the bottom position, the structural capacity improved for Damage Scenario 1 and Damage Scenario 3 but decreased for Damage Scenario 2. The proximity of the crossbeam to the lower flange of a twin I-girder bridge can influence the torsional rigidity of the structure

(a) Damage Scenario 1

(b) Damage Scenario 2

(c) Damage Scenario 3

Figure 7. Load-deflection response curve for various damage scenarios with crossbeam location at three different positions along the vertical depth of girder: (a) Damage Scenario 1; (b) Damage Scenario 2; (c) Damage Scenario 3.

(see Figure 7). Under torque application, the twin I-girder bridge's primary beams undergo warping deformation, resulting in deformation in opposite longitudinal directions. By positioning the crossbeam at a lower level on the girder, the bridge's bending and torsional capacity are enhanced. This is achieved by enlarging the closed transverse section, resulting in improved performance for Damage Scenario 1 and Damage Scenario 3. However, the result is opposite for damage scenario 2, where the overall performance of the bridge specimen decreases when crossbeam is located near the lower flange.

5 CONCLUSION

The objective of this study was to analyze the performance of composite I-girder bridges after experiencing fatigue cracks. Both experimental and numerical investigations were carried out on a simply supported composite twin I-girder bridge, considering both intact and damaged systems. The FEM model was built and further verified by experimental results, and then parametric nonlinear analyses were conducted to assess the influence of factors such as crossbeam cross-section, crossbeam position, and damage location on the safety of the bridge models in the post-fracture condition. The findings of this research can be summarized as follows:

Vertical position of the crossbeam along the girder height, has an influence on the overall performance against capacity degradation. The findings revealed that positioning the crossbeam near the bottom flange resulted in better performance for damage scenarios occurring at mid-span and near the support end. However, the performance degraded when damage occurred at the quarter-span position. Similarly, placing the crossbeam near the upper flange had the same effect as positioning it at mid-height.

Fatigue reliability analysis for welding details under traffic flow

Qiaona Zheng, Zichao Pan, Xurui Fang & Rujin Ma
Department of Bridge Engineering, Tongji University, Shanghai, China

Benjin Wang
School of Aerospace Engineering and Applied Mechanics, Tongji University, Shanghai, China

ABSTRACT: Fatigue cracking is the prevalent disease observed in welding details of orthotropic steel decks, especially in deck-rib welded joints. This paper presents a framework for evaluating the fatigue reliability of deck-rib welded joints under the simulated traffic flow based on the S-N curve and linear damage theory. First, we build a combined shell-solid finite element model of the typical area on the panel of a steel arch bridge to obtain the stress influence surface function of the key joint. Then, the traffic flow model is established according to the probability distribution of vehicle parameters. The stress time history curve of the welded joint is further studied. Based on the above analysis, the time-varying fatigue reliability curves of welding details under different traffic flows are investigated. The proposed framework can provide further insight into the management and maintenance of orthotropic steel decks for bridges under construction and existing bridges.

1 INTRODUCTION

The orthotropic steel deck (OSD) has been widely used in modern bridge construction due to its advantages, such as high strength-to-weight ratio, rapid construction, and durability (Deng et al., 2018; Yang et al., 2020). However, the welding detail, especially the deck-rib weld joint, as a critical detail in the OSD structure, is susceptible to fatigue damage under traffic flow loading. Once the accumulation of fatigue damage exceeds the fatigue resistance, the structure will have brittle failure and even lead to the collapse of the bridge (Fisher and Barsom, 2016; Ya et al., 2011). This process involves the random influence of many factors. Therefore, the fatigue reliability assessment of welding details is of paramount importance to ensure the structural integrity and fatigue safety of steel bridges.

In the study of fatigue performance, the initial step involves acquiring the fatigue stress spectrum of critical nodes. This can be accomplished through numerical simulation based on finite element analysis (Sim and Uang, 2012) or through assessment methods based on real bridge inspections (Liu et al., 2010). While the latter method offers greater precision, the former is more universally applicable. Subsequently, fatigue life or reliability is forecasted and assessed using an appropriate fatigue damage model, primarily derived from experimental data. Zhang et al. (2013) investigated the fatigue reliability of steel bridge panels of a large-span cable-stayed bridge under coupled vehicle and wind loads by finite element analysis. Guo et al. (2012) compared vehicle inspection data with evaluation data based on finite element analysis, and demonstrated the consistency of the results of the two analyses. In addition, a large number of scholars (Fang et al., 2020; Ma and Zhang, 2020) have discussed the effects of different conditions such as welding process and foundation scour on the fatigue damage of welded joints in steel bridge decks. Such studies focus more on deterministic analysis.

This paper aims to present a comprehensive analysis of fatigue reliability for welding details under traffic flow loading, with a specific focus on the deck-rib weld joint of the OSD. On the

DOI: 10.1201/9781003483755-329

basis of simulated traffic flow, the fatigue stress history of a steel bridge panel weld detail is analyzed by finite element, and the time-varying fatigue reliability of the structure under the influence of traffic flow parameters is further investigated.

2 FATIGUE DAMAGE AND RELIABILITY MODEL

Fatigue damage in welded structures is a complex phenomenon influenced by various factors such as material properties, stress concentration, and loading conditions. In this context, the fatigue damage function needs to be established first. Moreover, fatigue reliability estimation methods play a crucial role in quantifying the probability of fatigue failure, considering uncertainties in material properties and loading conditions.

2.1 *Fatigue damage function*

There are two commonly used models for the fatigue damage evolution process, one is the fatigue cumulative damage model based on the stress range number (S-N) curve, and the other is the linear elastic fracture mechanics model (LEFM) based on the Pairs crack extension theory. It is generally accepted that the LEFM method is more applicable to structures with initial cracks or defects, whereas the S-N curve method, which uses an abstract fatigue damage model, is widely applicable (Chen et al., 2011).

Definitions of S-N curves are given in different national and regional codes (AASHTO, 1990; European Committee for Standardization, 2005). The OSD with open stiffening ribs, especially the deck-rib details, is characterized by low stress and high number of cycles under vehicle loading. For this type of welding details, the International Institute of Welding (IIW) recommends the use of hot spot stresses in combination with S-N curves to assess fatigue strength (Hobbacher, 2016). The hot spot stresses are obtained by linear derivation of the reference point stresses, as shown in Figure 1. It can be calculated as

$$\sigma_{hs} = 1.67 \cdot \ \sigma_{0.4t} - 0.67 \cdot \ \sigma_{1.0t} \tag{1}$$

where t is the thickness of the base material; $\sigma_{0.4t}$ and $\sigma_{1.0t}$ are the reference point stresses; σ_{hs} is the hot spot stresses. In addition, for variable amplitude loading, the welding detail fatigue S-N curve is expressed as

$$\Delta\sigma_R^3 N_R = K_C = \Delta\sigma_C^3 \times 2 \times 10^6 (\Delta\sigma_R \ \geq \Delta\sigma_D) \tag{2a}$$

$$\Delta\sigma_R^5 N_R = K_D = \Delta\sigma_D^5 \times 1 \times 10^7 (\Delta\sigma_R \ \leq \Delta\sigma_D) \tag{2b}$$

where $\Delta\sigma_R$ is the stress range; N_R is the number of cycles; $\Delta\sigma_C$ is the fatigue detail category, while $\Delta\sigma_D$ is constant amplitude fatigue limit (CAFL); the fatigue strength coefficient is defined as K_C if $\Delta\sigma_R$ is larger than $\Delta\sigma_D$, and K_D if not. In this study, considering the effects of welding improvement process and other factors, combined with the recommendations of IIW, FAT90 is selected as the calculation curve. The parameters are listed in Table 1.

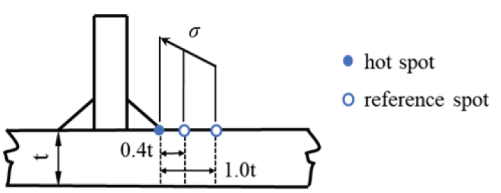

Figure 1. Definition of structural hot spot stress.

Table 1. The parameters of recommended S-N curve.

$\Delta\sigma_C$ (MPa)	$\Delta\sigma_D$ (MPa)	K_C	K_D
90	52.7	1.458×10^{12}	4.046×10^{15}

According to Equation(2a,b) and the Palmgren-Miner rule(Miner, 1945), the fatigue damage under vehicle loading can be obtained as

$$\mathrm{D} = \sum\nolimits_{S_i \geq \Delta\sigma_D} \frac{n_j S_i^3}{K_C} + \sum\nolimits_{S_j \leq \Delta\sigma_D} \frac{n_j S_j^5}{K_D} \tag{3}$$

where n is the number of corresponding stress range S. The stresses under vehicle loading can be converted to equivalent constant amplitude stresses by the equivalence principle, and the equivalent stress range S_{eq} and corresponding number of cycles N is

$$S_{eq} = \left(\frac{\sum_{S_i \geq \Delta\sigma_D} \frac{n_i S_i^3}{K_C} + \sum_{S_j \leq \Delta\sigma_D} \frac{n_j S_j^5}{K_D}}{N/K_D} \right)^{1/5} \tag{4}$$

$$N = \sum\nolimits_{S_i \geq \Delta\sigma_D} n_i + \sum\nolimits_{S_j \leq \Delta\sigma_D} n_j \tag{5}$$

The determination of equivalent stresses lays the foundation for subsequent fatigue performance analysis.

2.2 *Fatigue reliability estimation methods*

Based on the fatigue cumulative damage model, the fatigue limit state equation can be established as (Liu et al., 2016)

$$F(X) = \Delta - D = \Delta - \frac{N S_{eq}^5}{K_D} \tag{6}$$

where Δ is the Fatigue limit of a structure. When $F(X) < 0$, it is considered that fatigue damage has occurred in the structure, then the reliability index can be calculated by the following equation

$$\beta = \varphi^{-1}\left(1 - p_f\right) = \varphi^{-1}\left(1 - p(F(X) < 0)\right) \tag{7}$$

In Equation (7), the uncertainty in Δ and K_D can be quantified by a lognormal distribution. The statistical parameters are shown in Table 2. Then the Monte Carlo method can be used to obtain the time-varying reliability of the target structure under the influence of traffic flow.

Table 2. Statistic information of parameters.

Random Variable	Distribution Type	Mean Value	COV	Source
Δ	Lognormal	1	0.3	(Liu et al., 2016)
K_D	Lognormal	4.046×10^{15}	0.45	(Hobbacher, 2016)

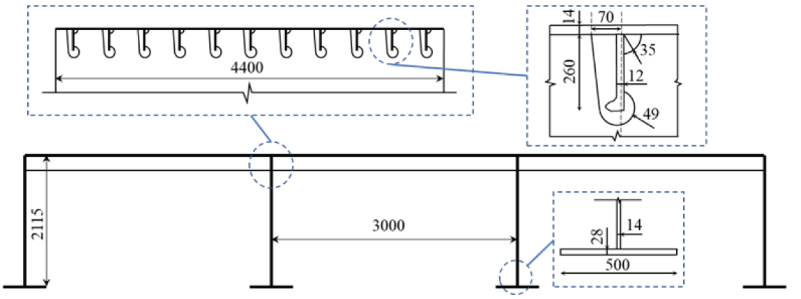
3 FINITE EIEMENT ANALYSIS OF WELDING DETAILS

The numerical simulation in this study consists of two parts. The first part is the analysis of the stress response of welding details under single vehicle loading, which is shown in this section. The second part is the simulation of the traffic flow, which will be shown in the Section 4.

3.1 *Finite element model*

The fatigue problems of the bridge deck under vehicle loads are primarily influenced by the system comprising the bridge deck, transverse beams, and longitudinal ribs. Additionally, due to the short stress influence line of the orthotropic steel bridge deck, the stress calculation results of the local segment model align closely with those of the main beam's overall model. Consequently, this section opts to utilize the local steel bridge deck to establish a full-scale finite element model.

The bridge is a center-bearing steel truss arch bridge featuring orthotropic steel bridge panels consisting of welded open ribs. The numerical model includes four diaphragms and eleven stiffening ribs, with a total length of 9 m and a total width of 4.4 m, as depicted in Figure 2, covering the stress influence range when wheels pass by. The material for the model is Steel Q345, and a UHPC layer is also designed on the bridge deck. The mechanical properties of these two materials are given in Table 3.



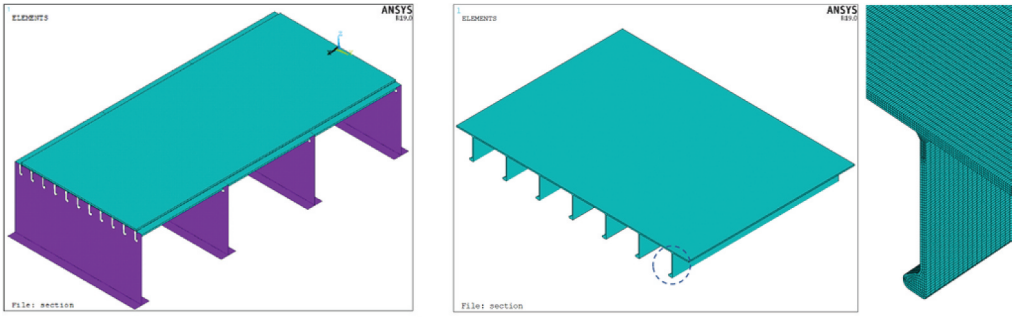


Figure 2. Model component section (unit: millimeters).

Table 3. Mechanical properties of Q345 and UHPC.

Materials	Density(kg/m^3)	Elasticity modulus(N/m2)	Poisson's ratio
Q345	7850	2.1×10^{11}	0.3
UHPC	2700	4.5×10^{10}	0.2

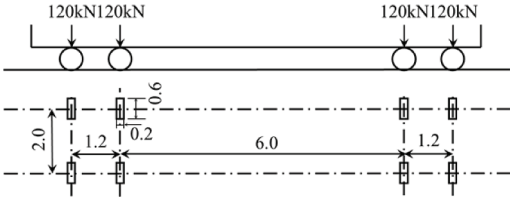
The finite element model is established using SHELL181 cell in ANSYS and the UHPC layer is modeled using SOLID185 cell, and the contact between the two is set to be permanently bound, which is simulated by CONTA174 cell, as shown in Figure 3(a). The lower edge of the modeled transverse bulkhead is fixed and the bridge deck slab displacement is constrained. To study the hot spot stress of the deck-rib welded joint, it is necessary to refine the model of the central position of the rib. A local three-dimensional model is created using SOLID185 elements, with dimensions of 2.0m × 2.8m, and incorporating 7 ribs (Figure 3(b)). The solid model is connected to the shell model using CONTA175 elements to ensure deformation coordination. A fine mesh is required due to the large stress variation near the welding details, and a relatively coarse mesh is used for the rest of the locations to improve computational efficiency.

In the fatigue assessment of bridges, vehicle loads are generally considered in three forms: vehicle load spectra, standard fatigue vehicles, and a heavy vehicle from the standard live load for static strength design(Zhou et al., 2010). Each country's bridge design code provides different models for fatigue vehicle loads. Considering the engineering background of this study, the model adopts the recommended fatigue load calculation model III from the Chinese code for the assessment. Figure 4 illustrates the axle load and contact conditions of this load model. The pavement layer of the bridge has a certain impact on fatigue stress. The thickness of the pavement layer on the bridge is 0.04 m. Assuming that the load spreads at a 45° angle when transmitted downwards, the actual load area acting on the UHPC layer is 0.68m × 0.28m. The coupling effect between adjacent wheels in the fatigue load model is minimal.

(a) (b)

Figure 3. The finite element model: (a) the whole model; and (b) mesh of the solid model.

Therefore, when analyzing local stress, it is sufficient to apply loading using a single wheel to obtain the stress influence function for subsequent fatigue damage analysis.



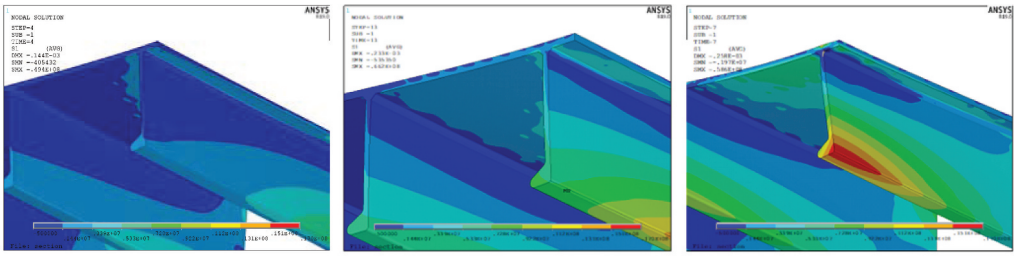


Figure 4. The recommended fatigue load calculation model (unit: meters).

3.2 *Stress response analysis*

The numerical model is loaded and analyzed to obtain the structural response. The results show that the variation of the hot spot stress on both sides of the stiffener section is basically symmetrical in the transverse direction, with differences within 1%. Therefore, the following text only explains the hot spot stress situation on one side of the weld. Figure 5 shows the distribution of the first principal stress near the weld. Stress concentration is prone to occur at the weld position.

(a) (b) (c)

Figure 5. The first principal stress distribution in the simulation (unit: pascals), when the relative position of load center is: (a) 1m; (b) 0.5m; and (c) 0.

Subsequently, the stresses at the reference point under various working conditions are extracted for calculating the hot spot stresses. This allows for the plotting of the stress influence surface under the action of a single wheel, as shown in Figure 6, where the coordinates represent the position of the wheel load center on the bridge deck.

The stress analysis results indicate that as the distance between the wheel load center and the weld decreases, the impact on the weld becomes more significant, leading to a sudden

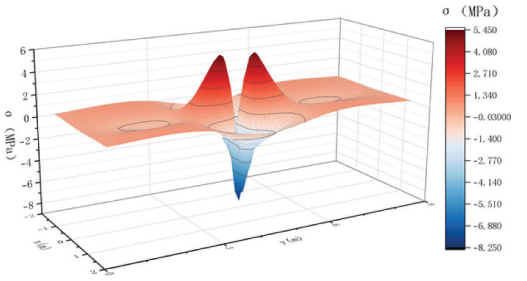

Figure 6. Hot spot stress influence surface.

change in the weld stress. The maximum hot spot stress value is approximately 5.45 MPa, while the minimum value is approximately -8.25 MPa. This finding describes the static response of the structure under the influence of a single wheel. To capture the structural stress history under the standard fatigue vehicle load model (Figure 4), it is essential to account for the dynamic amplification factor, set at 1.3 in this study. The results are depicted in Figure 7, where the horizontal axis denotes the relative position of the center of the first row in the model to the hot spot of the target spot, and the vertical axis represents the hot spot stress.

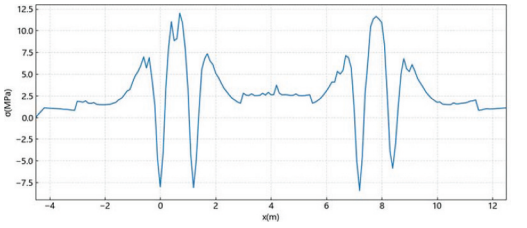

Figure 7. Stress history under the standard fatigue vehicle load model.

4 FATIGUE RELIABILITY EVALUATION

In this section, a comprehensive assessment of the structural reliability is made incorporating the traffic flow model and fatigue damage accumulation.

4.1 *Traffic flow model*

A traffic flow model is essential for capturing the varying load conditions experienced by the bridge structure over its service life. The load model involves various factors such as vehicle type, speed, and spacing. Due to limited operational data, this study references the probability distribution characteristics of vehicle parameters for similar-grade highway bridges in China when establishing the traffic flow load model. After fitting the probability distribution functions, the Monte Carlo method is employed for sampling, and single lane traffic is simulated.

Firstly, contributions of small and medium-sized vehicles to bridge fatigue damage are minimal, with large vehicles being the primary source of damage (Dou et al., 2016; Liu et al., 2017). Therefore, the traffic flow model primarily focuses on standard fatigue vehicles, corresponding to a stress amplification factor of 1.3. Subsequently, based on a highway design speed of 60 km/h, the assumed vehicle operating speed is 15 m/s. Following the recommendations of Eurocode 3, the lateral distribution of the wheels is fitted to a standard normal distribution. The uncertainty of the spacing is stronger and is related to the operational state. Therefore, the daily operation of the bridge is divided into two phases: dense operation (14 hours) and sparse operation (12 hours). In the former, the spacing is based on the safe driving distance at the bridge's design speed, using a Weibull distribution with a shape parameter of 6.5 and a scale parameter of 8; in the latter, the spacing is appropriately increased.

Taking into account the vehicle speed, spacing, and operational state, the equivalent traffic flow can be estimated based on multiple sampling results. Under dense operation, approximately 22 vehicles pass every 10 minutes, while under sparse operation, around 16 vehicles pass every 20 minutes. Therefore, the daily equivalent traffic flow for this single-lane traffic flow model is 2328 vehicles, with an annual equivalent traffic flow of approximately 850,000 vehicles.

4.2 *Results of the fatigue reliability analysis*

Based on the stress influence surface of the weld joint and the traffic flow model, stress time history is computed. Subsequently, the rainflow counting algorithm (Socie, 1992) is employed to analyze the stress time history. Under dense operation, S_{eq} at the hot spot is 20.02 MPa, while under sparse operation, it is 19.63 MPa. Further analysis of the damage situation in conjunction with the S-N curve yields an expected fatigue life of the structure of 699 years.

With the results and statistical information listed in Table 2, the fatigue reliabilities of the deck-rib details can be calculated. Meanwhile, this study quantifies the process of traffic flow growth and stabilization using a simplified three-stage traffic growth model. Three models are defined: Model I does not consider traffic growth; Model II assumes a 1% annual traffic growth rate for the first five years of operation (Stage 1), followed by an accelerated growth rate of 3% for the next 15 years (Stage 2), and then traffic saturation in Stage 3 with no further growth; Model III assumes annual growth rates of 2% and 5% for the first two stages. The resulting time-varying fatigue reliability indices are shown in Figure 8.

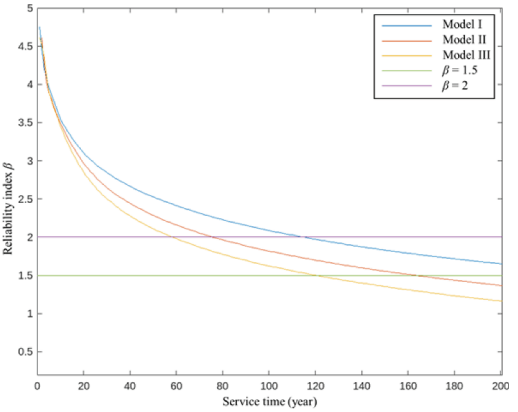

Figure 8. Time-varying fatigue reliability indices.

When the reliability index is 1.5 and 2.0, the structural failure probabilities are 6.68% and 2.28% respectively. The calculation results indicate that the structural reliability index is initially high but decreases over time. Within the 100-year design service life of the bridge, the reliability index remains greater than 1.5. However, contrasting the results of different models, it is evident that traffic growth significantly accelerates the decline in reliability. Under the influence of Model I, the reliability index decreases to 2 after approximately 115 years, while for Model II and Model III, this occurs at 76 years and 59 years respectively. Therefore, it is necessary to monitor changes in bridge traffic flow within the service life, conduct regular inspections, and take timely measures to prevent fatigue failure.

5 CONCLUSIONS

This study investigates the fatigue reliability of deck-rib welded joints in the OSD under simulated traffic flow, utilizing the S-N curve and linear damage theory. The results indicate that

the welding details exhibit quality fatigue performance and maintain satisfactory reliability within the bridge's design service life. However, the study also highlights the significant impact of traffic flow development during the bridge's operational period on the fatigue reliability of the weld, emphasizing the need for monitoring and regular inspections based on actual traffic conditions. Overall, the findings are expected to contribute to the development of robust design guidelines and maintenance strategies for enhancing the fatigue performance and safety of OSDs and steel bridge structures.

ABSTRACT: A welded-bolted hybrid demountable shear connector was proposed for use in steel-concrete composite buildings and bridges. According to Eurocode 4, four standard push-out static tests and four high-cycle fatigue tests were carried out to assess the structural performance of the hybrid connector, respectively. The experimental results show that the initial stiffness, shear resistance, and slip capacity of the proposed connector are higher than those of traditional welded studs. The hybrid connector can be regarded as a ductile connector with a slip capacity higher than 6 mm. Moreover, the primary fatigue failure mode observed was stud fracture at the base. The presence of grout inside the tube significantly increased the WDSC's fatigue life by 5.4 times. The study also analyzed stiffness degradation and relative slip evolution during fatigue cycles. All the findings from present investigation may provide reference for the application of proposed demountable shear connector in sustainable steel-concrete structures.

1 INSTRUCTIONS

The infrastructure construction sector plays an important role to reduce carbon dioxide (CO_2) emissions, waste, and natural resources consumption, thus to achieve the Net-Zero carbon emissions targets (Arsova et al. 2021). Therfore, recent research efforts have been devoted to develop demountable structural systems which can be easily disassembled and reassembled with minimal damage or waste. Also, demountable structural system taking advantage of reusing the structural components, which can maintain their embodied energy content, eliminate the environmental impact of disposal, and save the energy required to produce a new one (Brambilla et al. 2019).

Steel-concrete composite construction is a popular construction method for bridges, buildings, and other infrastructures, due to the advantages of high strength and stiffness, and accelerated construction (He et al 2014). Demountable shear connectors (DSCs) are beneficial to the deconstruction, retrofitting or replacing of damaged slabs and improve the construction efficiency. Therefore, different kinds of DSCs were developed and investigated: Dallam (1968) firstly investigated high strength friction-grip bolts as shear connectors in the 60s by test. Liu et al. (2015) found that high strength friction-grip bolts embedded in geopolymer precast concrete slabs showed high strength and slip capacity. Dai et al. (2015) tested and indicated that the bolted Threaded Nelson shear studs have comparable strength, higher slip capacity, but lower initial stiffness, comparing with welded studs. Feidaki et al. (2019) proposed ductile demountable steel hollow section connectors with high initial stiffness and slip capacity, as well adjustable strength. In order to improve low stiffness at the initial loading stage for demountable bolt connectors,

DOI: 10.1201/9781003483755-330

making full use of good performance of headed studs, and considering the needs of structural disassembly, the authors proposed a welded demountable shear connector (WDSC), consists of a grout-filled steel tube and a partially threaded stud, connecting steel beams to concrete slabs in composite structures. The details including the configuration, construction and deconstruction of WDSC can be referred to Suwaed et al. (2022), as shown in Figure 1.

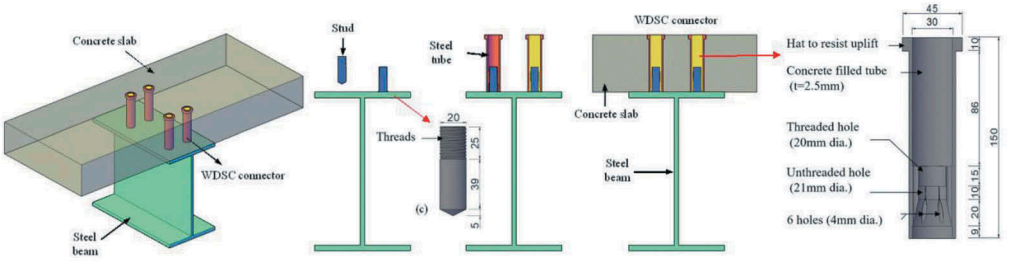

Figure 1. Steel-concrete composite girder with WDSCs.

The static and fatigue behavior of shear connectors is critical in the design of steel-concrete composite structures, particularly in bridges subjected to traffic loads. In present study, a series of standard push-out tests, on the basis of Eurocode 4, were performed to evaluate the static and fatigue performance of the WDSC under monotonic and fatigue loading. The load-slip curves, failure modes, strength and stiffness of WDSC were obtained during static and fatigue loading. Moreover, S-N diagrams were determined through fatigue loading tests, to facilitate their practical application.

2 EXPERIMENTAL INVESTIGATION

2.1 *Test specimens*

Eight standard push-out test specimens were designed and fabricated according to Eurocode 4 (2005). Each specimen is composed of an HEB260 steel section (256 mm in width, 260 mm in height, 10 mm in web thickness and 18 mm in flange thickness), two concrete slabs (650 × 600 ×150 mm), and four WDSCs at each slab, as shown in Figure 2. Two layers of deformed rebars with diameter of 10 mm were placed in each slab to prevent concrete slab cracking.

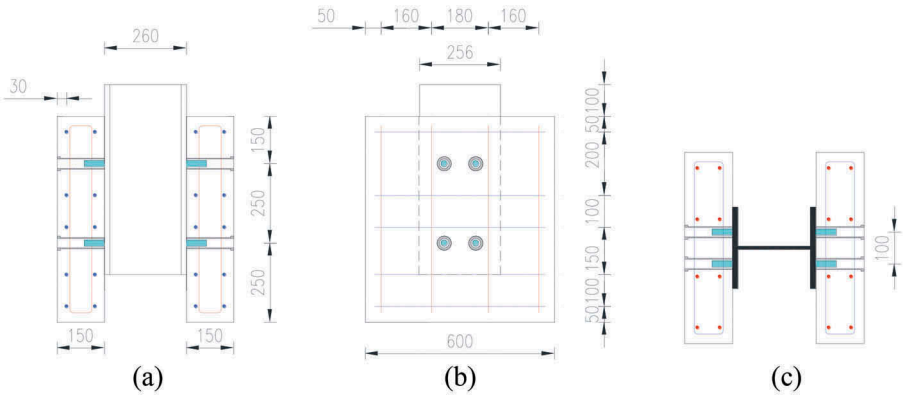

Figure 2. Test specimens (unit: mm): (a) elevation view; (b) side view; (c) plan view.

Eight specimens were prepared and tested, four of them (Group 1) are subjected to static loading, the others (Group 2) are subjected to fatigue loading. Each group has three specimens arranged WDSC filled with flowable grout in steel tube and one without filled grout. In Group 1, the effects of the compressive strength of concrete slab (40 to 54 MPa), loading method (Monotonic-M and Cyclic-C loading) were considered, while in Group 2, constant amplitude fatigue loading is applied for each specimen, but different loading range (Lower limit- Upper limit) was considered, as shown in Table 1.

Then, another four specimens were prepared and subjected to fatigue loading, in which three specimens arranged WDSC filled with flowable grout in steel tube and one without filled grout. Constant amplitude fatigue loading was applied for each specimen, but different loading range (Lower limit- Upper limit) was considered, as shown in Table 1. The upper limit of the loading range were chosen as 700, 600, 500 kN, which account 7/16, 3/8, 5/16 of theoretical ultimate load, considering that the WDSC can be in the elastic and elastic-plastic stages, respective. The stress ratio was chosen as 0.1 for all the specimens.

Table 1. Push-out test specimens.

Specimen group	Specimen name	Grout strength (N/mm^2)	Concrete slab strength (N/mm^2)	Loading procedure		
				Type	Loading method	Loading range
Group 1	S1	47.5	40.7	Static	M	0-F_F
	S2	47.5	48.0		C+M	(5%-40%) $F_{u,e}$ + 0- F_F
	S3	No grout	49.2		C+M	
	S4	47.5	53.7		C+M	
Group 2	F1	48	60.1	Fatigue	C	60-600kN
	F2	No grout	60.1		C	60-600kN
	F3	48	60.1		C	50-500kN
	F4	48	60.1		C	70-700kN

2.2 *Material properties*

Concrete tests were conducted on the in-situ concrete and grout mix of each specimen. The concrete cubes (100×100×100 mm) were casted on the same day as the corresponding specimen using the same concrete mix to perform compressive tests. Table 1 summarizes the average compressive concrete and grout strength of three cubes at test day.

The material properties of the stud and tube were obtained from standard tensile coupon tests (ASTM. 2011). The properties including the modulus of elasticity, the yield stress or 0.2% proof stress, the ultimate stress and the tensile strain corresponding to the ultimate stress for the stud are 193GPa, 454MPa, 658MPa and 0.049, for the tube are 205GPa, 333MPa, 645MPa and 0.185, respectively.

2.3 *Test setup, loading procedure and measurements*

A servo hydraulic testing machine, with load and displacement capacity of 2000 kN and 1200 mm respectively, was used to push the steel section against concrete slab, as shown in Figure 3.

The loading procedure includes two types: static and fatigue loading. As for the static loading, one specimen is subjected to monotonic loading, the other three is subjected to the combined cyclic and monotonic loading in accordance with Eurocode 4, which divided into two steps: Step 1, load was gradually increased up to 40% of the estimated ultimate shear force $F_{u,e}$ and then reduced to 5% of $F_{u,e}$, and this loading cycle was repeated for 25 times; Step 2, monotonic static load was applied using displacement control method with a speed of

0.005 mm/s, and the loading was stopped until the failure of test specimen or the loading capacity of test specimens dropped to 80% of the peak load. As for the fatigue loading, constant amplitude cyclic loading is applied, but different loading range (Lower limit- Upper limit) was considered for each specimen, as shown in Table 1. The fatigue loading was conducted by load control using a continuous sinusoidal waveform with a loading frequency of 0.5 Hz.

Four linear variable differential transformers (LVDTs) were arranged to monitor relative slip between the steel section and the concrete slab, while two LVDTs horizontally placed near the bottom layer of WDSC to measure lateral separation between the slab and the steel section.

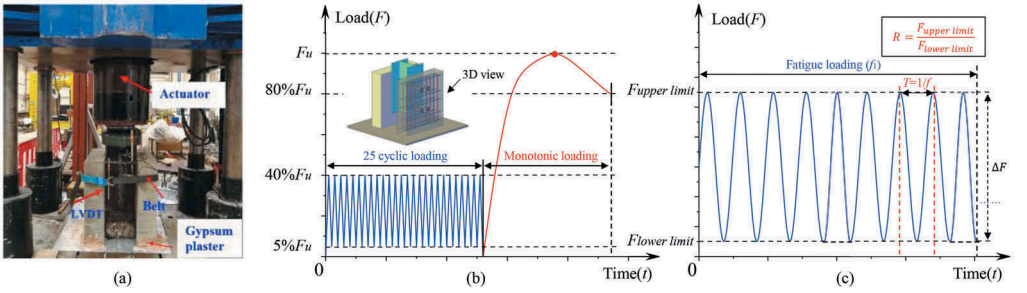

Figure 3. a) Test setup; b) static test loading protocol; (c) fatigue test loading protocol.

3 STATIC TEST RESULTS AND DISCUSSIONS

3.1 *Failure mode*

The typical failure mode of static test specimens was stud shank shear failure, where above the welded collar. Local concrete crushing in front of the tubes was also observed under ultimate load, the damage degree depends on the slab's concrete strength, as shown in Figures 4.

Figure. 4. Failure mode of specimens.

3.2 *Load versus displacement response*

Figure 5a shows the load versus slip responses of all specimens from static loading tests. The load-slip curves can be divided into three phases. The first phase is characterized by linear elastic deformations in the concrete slab and the shear connector, which starts from zero slip to 0.3 - 0.5 mm of slip. In the second phase, the load increases nonlinearly with the slip until the ultimate

load, since the tube and stud bending and bearing against the grout and concrete. In the third phase, the slip develops rapidly, and the load capacity reduces suddenly due to shearing failure of the stud. From Figure 5a, the in-filled grout (47.5MPa) for S2 improved the ultimate strength by 12% and the shear stiffness by 3.4 times in comparison to S3. When the concrete strength of the slab increased from 40.7 MPa to 53.7 MPa for S1 and S4, the shear strength and stiffness increased by 8% and 5%, respectively. Thus, increasing concrete strength of the slab slightly improve the shear strength and stiffness when the specimens failed due to stud's shear off.

Figure 5b shows the load versus separation responses of static test specimens. The separation at ultimate load is 0.57, 0.49, 0.51 and 0.87 mm for S1-4, respectively, which only accounts for 6~13% of the corresponding slip. Thus, the separation between concrete slab and steel flange satisfies the requirement recommended by Eurocode 4 that the slab uplift (i.e., slab separation) should be no more than 50% of the corresponding slip displacement at a shear load equal to 80% of the shear resistance. This proves the effectiveness of the hat at the top of the tube to prevent separation of the slab from the steel section.

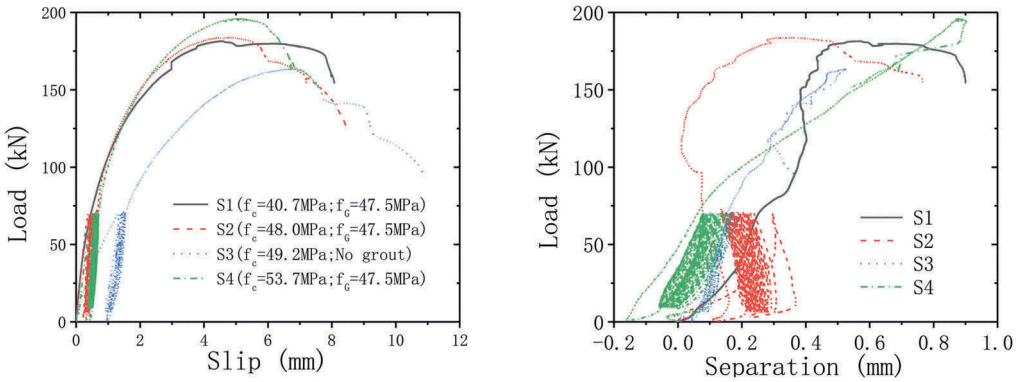

Figure 5. (a) Load versus slip responses for specimens; (b) Load versus separation responses for specimens.

4 FATIGUE TEST RESULTS AND DISCUSSIONS

4.1 *Fatigue failure mode*

The failure process of four fatigue push out specimens was basically the same. The relative slip and separation between steel section and concrete slab gradually increased with the increasing of fatigue cycles. When the fracture of the welded studs occurred at one slab, whose slip and separation is larger than the other one, the concrete slab was separated from the steel section, as shown in Figure 6a.

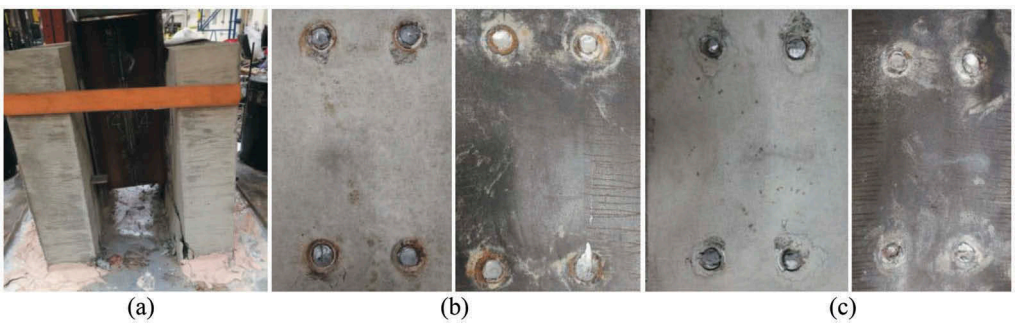

Figure 6. Failure mode of (a) front view; (b) F1 with grout (c) F2 without grout.

Figure 6c-6f describes the fatigue failure characteristic of the WDSC, including the fracture of the welded stud and cracking or crush of the grout and concrete. Smaller cavities were observed vertically below the WDSC subjected to fatigue loading (the area of cavity about quarter of stud section) than that subjected to static loading (the area of cavity about half of stud section) as presented in Xu et al. (2018). The welded stud was greatly deformed for WDSC (F2) without grout filled in the tube. The fracture surface of the failed stud was substantially flush with the surface of the steel plate, dominated by pure shear failure. Ratchet marks caused by multiple crack initiation were found in fatigue failures. The cracks initiated at the weld collar and gradually propagated under continued cyclic loading. Crack progression marks (Beach marks, semi-circular shaped marks) were also observed as shown in Figure 7c. Final fracture zone (Figure 7b) depends on the load magnitude, the severe loading condition result in a large fracture zone.

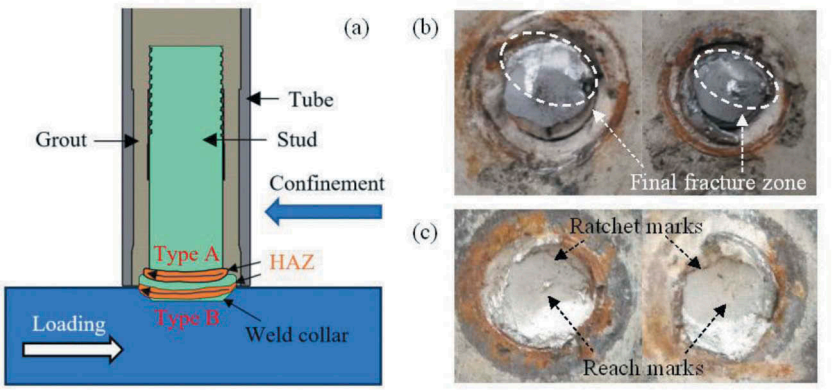

Figure 7. (a) Typical failure mechanism and fatigue fracture zone (b) concrete side; (c) steel side.

4.2 *Fatigue life and S-N curves*

Table 2 lists the loading cycles until failure corresponding to different stress ranges. The fatigue lives of specimens F1 to F4 were 10909, 2016, 41092 and 5326 cycles, respectively. The fatigue life increases significantly as the reducing of stress level. Under the same fatigue stress range, the fatigue life of the specimen F1 is 5.4 times that of the specimen F2. It can be concluded that the fatigue life of the WDSC with grout filled in the tube is much more than that of the WDSC without grout, although their shear strength only changes about 12% in static push out test. The grout improved the shear stiffness of the WDSC, which reduce the relative slip, thus decrease the cumulative damage, resulting in extend fatigue life.

Table 2. Loading cycles until failure corresponding to different stress ranges.

Specimen	Min. Load F_{min} (kN)	Max Load F_{max} (kN)	Min. stress τ_{min} (MPa)	Max. stress τ_{max} (MPa)	Stress range $\Delta\tau$ (MPa)	R	Cycles until failure ($N_{f,test}$)
F1	7.5	75	24	240	216	0.1	10909
F2	7.5	75	24	240	216	0.1	2016
F3	6.25	62.5	20	200	180	0.1	41092
F4	8.75	87.5	28	280	252	0.1	5326

The S-N curve generally depicts the relationship between the fatigue life and stress range. There are three distinct models: "EC model", "BS model" and "Peak Load model" (Johnson 2000). Although the "EC model" does not consider the static shear strength of the stud, it is used in Eurocode 4 (2005) and Specifications for design and construction of highway steel-concrete composite bridge (Ministry of Transport of the People's Republic of China. 2015), as following.

$$\log N + m\log\Delta\tau = C \tag{1}$$

where N is the number of fatigue cycles, m is the slope of the S-N curve, $\Delta\tau$ is the stress range, and C is a constant.

The test data of the WDSC subjected to fatigue loading is plotted in a log–log coordinate system as show in Figure 8. Linear regression analysis of log $\Delta\tau$ on logN was conducted, and the mean regression curve with a 50% survival probability (Hobbacher. 2016) for the WDSC with grout is expressed as Eq. (2):

$$\log N + 7.631\log\Delta\tau = 21.922 \tag{2}$$

A survival probability no less than 95% is recommended for fatigue design. So, the regression curve with a 95% survival probability was also performed, the S-N curves with a 95% survival probability for fatigue design for WDSC with grout is expressed as Eq. (3):

$$\log N + 7.631\log\Delta\tau = 21.618 \tag{3}$$

Eqs. (2, 3) are also plotted in Figure 8. When $N = 2 \times 10^6$, Eq(2) gives the mean shear stress range $\Delta\tau cm = 112$ MPa for WDSC with grout, the characteristic shear stress range $\Delta\tau ck = 100$ MPa for WDSC with grout, respectively.

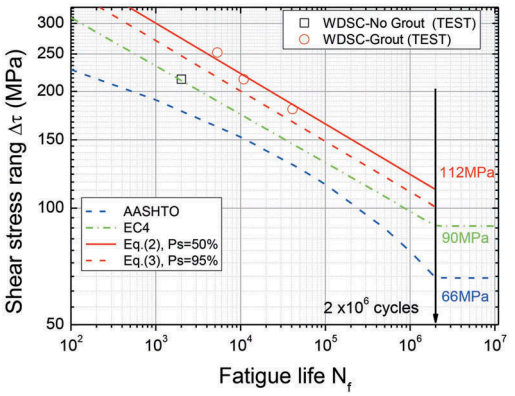

Figure 8. S-N curves for WDSCs.

The test results of fatigue lives for the WDSC were also compared with that for shear studs recommended by specifications—AASHTO (2014) and Eurocode4 (2005). The related S-N curve and the test results with the regression line are shown in Figure 8. It can be seen that both Eurocode 4 (2005) and AASHTO (2014) evaluations have large safety redundancies, especially AASHTO (2014). The slop of fitted S-N curve for WDSC with grout is 7.678, which is smaller than 8 recommend by Eurocode 4. The stress range at 2 million cycles ($\Delta\tau$) for the WDSC was also compared to the specifications. The fatigue strength was taken as 112 MPa for WDSC with grout, estimated from the S-N curves with a 50% survival probability, is larger than fatigue strength for stud connectors which was taken as 90 MPa, recommended by Eurocode 4, also higher than 66 MPa recommended by AASHTO.

5 CONCLUSIONS

- All the specimens including WDSC with or without in-filled grout show ductile shear failure at the base of stud shank and surrounded concrete crush, all specimens achieved a slip capacity higher than that required by Eurocode 4, i.e., higher than 6 mm.
- Slightly smaller shear strength but greater slip capacity is achieved when the tube is not grout-filled. In addition, there is no tolerance or initial slip issue, and the initial stiffness is comparable to that of traditional welded studs.
- Under high-cycle fatigue loading, the WDSC exhibited a consistent shear failure mode at the base of the short stud, no cracking but only minor concrete crushing in the concrete slab was observed. The degree of concrete crushing under fatigue loading was lower than that under static loading.
- The grout significantly improved fatigue life of WDSC, a 5.4-fold increase compared to the WDSC without grout, due to the enhanced stiffness caused by the infill grout.

Optimization of maintenance program for bridge cable in service lifetime

Shijie Liao*, Jianxin Peng, Lei Wang & Jianren Zhang
School of Civil Engineering, Changsha University of Science and Technology, Changsha, Hunan, China

ABSTRACT: The complex service environment and increasing traffic volume make the maintenance of service bridges more and more important, and how to improve the service life of bridge members and reduce bridge operation and maintenance costs by optimizing maintenance strategies is a hot issue today. In this paper, a state transfer matrix is constructed based on NBI bridge inspection data, and an optimization model for state maintenance of bridge cables is proposed by using semi-Markov process theory. Taking a large-span cable-stayed bridge as a case study, where the objective is to maintain the normal service level of the ties for 200 years, the most economical maintenance programs for the cables is proposed based on the whole-life-cycle maintenance cost. This case study can provide an effective reference for bridge maintenance departments.

Keywords: Semi-Markov process, Bridge Cable, Maintenance Strategy

1 INTRODUCTION

The frequency and load of bridges are growing daily due to the ongoing expansion in urban traffic. Over 7.5% of American bridges are currently deficient, and the government is under a lot of pressure due to large maintenance costs. The United States has an infrastructure financing gap of up to 2.59 trillion US dollars, according to figures [1]. The frequent repair or replacement of bridges increases the consumption of energy and materials and also causes damage to the environment. The cable, which is the fundamental part of a cable-stayed bridge, assists the construction of the bridge in carrying weight, distributing the load on the bridge tower, transferring force, etc. Its working performance is directly related to the normal use state of the cable-stayed bridge. Under the requirements of ensuring the safe service state of the cable, the frequency and cost of maintenance and repair are minimized, which is of great significance for the operation and maintenance safety of the bridge structure and social and economic stability.

The cable service process is often subject to wind loads, vehicle loads, and external corrosive environmental erosion, making it prone to corrosion and fatigue damage. Some studies have shown that the probability of the occurrence of these two types of damage accounted for the impact of the cable operating life factors, respectively, at 52% and 35% [2]. Numerous scholars have carried out research on the corrosion and fatigue damage of cable slanting. Nakamura et al. [3] conducted fatigue tests on corroded galvanized steel wires with different corrosion levels, and the results show that the increase in corrosion rate leads to a reduction in the fatigue strength of steel wires. According to Wu et al. [4], on the bridge of the old cable performance indicators for experimental research, test results show that the yield strength, tensile strength, and elongation of the steel wire are not significantly weakened, but the number of fatigue tests is only 308,000 times, far below the standard of 2 million times. Lan et al. [5] established a multi-parameter Weibull model of cable fatigue life, derived a maximum

*Corresponding author: csliaoshijie@163.com

DOI: 10.1201/9781003483755-331

likelihood algorithm for model parameter estimation, and proposed an EM algorithm for model parameter estimation considering truncated data according to conditional probability.

The above studies discussed the correlation between corrosion and fatigue damage of bridge cable ropes and clarified the deterioration mechanism of cable ropes' performance. Some scholars further carried out the research on cable rope repair and replacement strategies in the life cycle, considering structural deterioration and cycle cost. M. ASCE [6] and others studied the cable-stayed cable repair and replacement strategy of a cable-stayed bridge in service and arrived at the most economical solution based on the whole life cycle cost assessment. Wang Libin et al. [7] proposed the cable life function and the series-parallel model of the cable system and combined the life function with the whole life cycle cost to put forward the cable optimization maintenance strategy.

The existing studies focus on the replacement strategy of bridge cable, while there are few studies on the comprehensive consideration of maintenance strategies, such as maintenance cycles, maintenance methods, This paper constructs the state transition matrix and establishes the state degradation model of the stay cable based on the semi-Markov process. At the same time, taking a cable-stayed bridge as an example, based on the whole life design concept, the maintenance strategy of the combination of cable-stayed maintenance and replacement is proposed, which can provide a useful reference for the bridge maintenance department.

2 SEMI-MARKOV PROCESS

Given two events, A and B, and the probability of the occurrence of event A is greater than 0, then:

$$P(B|A) = \frac{P(AB)}{P(A)} \tag{1}$$

In the semi-Markov process, the residence time of each state is T_i, assuming that the random variable T_i follows a certain probability distribution. Let $f_i(t)$, $F_i(t)$ and $S_i(t)$ be the probability density function, probability distribution function, and survival probability distribution function of the residence time of state i respectively. If the structure is in state 1 at time t, the conditional probability of it moving to state 2 at the next time is calculated as follows:

$$P[X(t+dt) = 2|X(t) = 1] = \frac{f_1(t)dt}{S_1(t)} \tag{2}$$

The time for state i to transfer to state j is $T_{i\text{-}j}$, so that $f_{i\text{-}j}$ (t), $F_{i\text{-}j}$ (t), and $S_{i\text{-}j}$ (t) are the probability density function, probability distribution function, and survival probability distribution function of $T_{i\text{-}j}$, respectively. If the structure is in state i at time t, the conditional probability of it moving to state i+1 at the next moment is calculated as follows:

$$P[X(t+dt) = i+1|X(t) = i] = \frac{f_{1-i}(t)dt}{S_{1-i}(t) - S_{1-(i-1)}(t)} \tag{3}$$

3 STATE DEGRADATION MODELLING OF SLOPING CABLES

The service status of the cable is divided into four categories based on NBI's test results: status 1 means excellent; status 2 means good; status 3 means medium; status 4 means qualified. The service level below status 4 means unqualified, the function of the cable has failed.

The life of the corroded cable generally obeys the Weibull distribution. For the general case of the Weibull distribution, you need to solve the β_i and λ_i two parameters. You can choose any two times of NBI data. By solving the algebraic equations to obtain the target parameters, the calculation process is as follows in Equations 4 and 5. The parameters of the first four states are calculated as shown in Table 1.

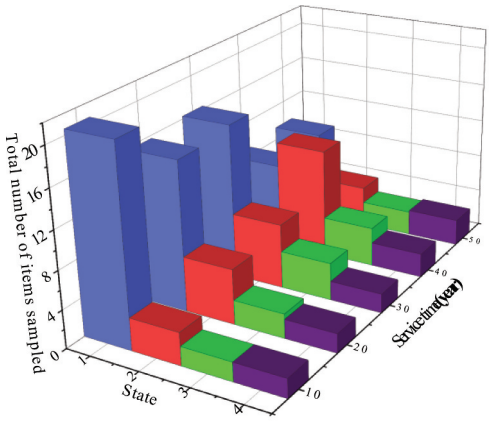

Figure 1. Cable state distribution.

$$\begin{cases} S_i(u) = \exp\left[-(\lambda_i u)^{\beta_i}\right] \\ S_i(v) = \exp\left[-(\lambda_i v)^{\beta_i}\right] \end{cases} \Rightarrow \begin{cases} \ln[S_i(u)] = -(\lambda_i u)^{\beta_i} \\ \ln[S_i(v)] = -(\lambda_i v)^{\beta_i} \end{cases} \Rightarrow \ln\left(\frac{\ln[Si(u)]}{\ln[Si(v)]}\right) = \beta_i \ln\left(\frac{u}{v}\right) \tag{4}$$

$$\beta_i = \frac{\ln(\ln[S_i(u)]) - \ln(\ln[S_i(v)])}{\ln(u) - \ln(v)} \lambda_i = \frac{1}{u}(-\ln[S_i(u)])^{1/\beta_i} \tag{5}$$

Table 1. Value of Weibull distribution parameter.

State i	u	$S_i(u)(\%)$	v	$S_i(v)(\%)$	β_i	λ_i
1	10	46.91	20	16.75	1.23	0.08
2	20	52.20	30	19.64	2.26	0.04
3	30	55.73	40	24.28	6.43	0.03
4	40	93.57	50	6.42	16.67	0.02

The state transfer probability $P^{i,i+1}$ between two different moments, e.g., $P^{2,3}$, is calculated according to equation (3) as follows:

$$P^{2,3} = \begin{bmatrix} 0.9416 & 0.0584 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 1 \end{bmatrix} \tag{6}$$

When the cable is put into use, each part of the cable is in state 1, and no transfer occurs between states. It can be assumed that the initial state vector is $A(0)$. After serving for a period of time, the updated state transition matrix $A(t)$ can be obtained by the following formula:

$$A(t) = A(0) \prod_{k=0}^{t-1} p^{k,k+1} \tag{7}$$

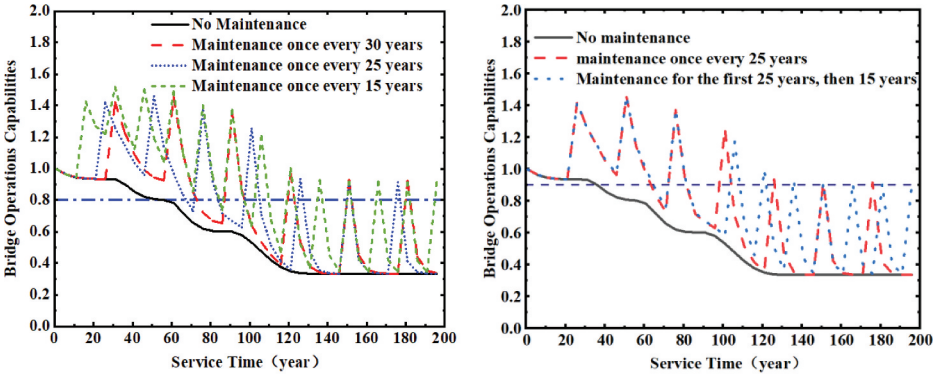
The maintenance effect of the cable is generally determined by the state of the cable before maintenance and the maintenance means used. Define the repair matrix *rep* as shown in equation 8, where $r_{i,1}$ is the probability that state i returns to state 1 after repair.

$$rep = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 \\ r_{2,1} & 1-r_{2,1} & 0 & 0 & 0 \\ r_{3,1} & 0 & 1-r_{3,1} & 0 & 0 \\ r_{4,1} & 0 & 0 & 1-r_{4,1} & 0 \\ r_{5,1} & 0 & 0 & 0 & 1-r_{5,1} \end{bmatrix} \tag{8}$$

When maintenance is performed at year t, the state transition matrix after maintenance is updated as follows:

$$A(t)^{new} = A(t)rep \tag{9}$$

4 CASE ANALYSIS



This paper takes a large-span cable-stayed bridge as a case study, whose cable-stayed cables are parallel steel wire cables, and the steel wire used for the cables is a 7mm zinc-aluminium alloy high-strength, low relaxation steel wire with a tensile strength of 2100 MPa. Combined with the construction background of the bridge, the target service life of the bridge is formulated as 200 years. According to the study of scholars Fu et al. [8], the longest-stay cable has the greatest impact on the strain of the main beam; that is, the outermost cable has the most important function among all cable members. Therefore, the mid-span cable numbered NM40 is selected as the object of the study, and the stress-free length between the anchor points of the cable is 610m, with a total weight of the cable body of 65.6t.

Select maintenance intervals of 15 years, 25 years, and 30 years. In this case, it is assumed that after one repair, all the cable bodies of states 1 and 2 can be restored to state 1, while 90% of state 3 can be returned to state 1, 80% of state 4 can be returned to state 1, and only 50% of the cable bodies that have reached the limit of normal use can be returned to state 1 after repair. If the cable is replaced, the states and their state transition matrix will be restored to the initial stage. Establish the service level matrix Re, Re^T=[1 0.8 0.6 0.4 0.2] as shown in section 3. Considering the degradation of cable status, the service level under different service times is calculated as follows:

$$Q = sum(A(t)[Re]/5) \tag{10}$$

According to the bridge access requirements in the NBI, the normal service level of the cable is set to be maintained above 0.9. Combining equations 8 and 9, the service level of cable can be calculated for different maintenance strategies, and the results are shown in Figure 2(a). Without maintenance, the cables fails at 36 years; at a maintenance interval of 30 years, the cables fails at 70 years; at a maintenance interval of 25 years, the cables fails at 60 years; and at a maintenance interval of 15 years, the cables fails at 70 years. Between 100 and 200 years, the service level under all three maintenance strategies is lower than 1. In order to improve the service level of the cables in the last 100 years, the number of maintenance visits in the last 100 years is taken to be encrypted, and the result is shown in Figure 2(b), which shows that the maintenance effect is not satisfactory.

The above results show that a repair-only strategy cannot ensure that the cable will maintain its normal service level throughout its 200-year service life. In order to keep the bridge structure in service during its design life, a combination of repair and replacement strategies is required, including the replacement of the cable when the service level after repair no longer returns to 0.9. According to Figure 2a, cables that do not undergo maintenance will be replaced in the 35th year of service; for maintenance intervals of 25 years, replacement is in the 60th year of service; for maintenance intervals of 30 years and for maintenance intervals of 15 years, the failure of the cable occurred around 70 years; therefore, it should be replaced in the 70th year of service.

(a) (b)

Figure 2. Service level of cable under different maintenance strategies.

5 MAINTENANCE COST ANALYSIS

In this paper, the present value formula of a one-time payment is used to discount, and the expected cost of each repair or replacement is calculated as follows:

$$E\left[C_{main}^{t}\right] = A(t) * C_{main} * (1+\gamma)^{-t} \tag{11}$$

Where γ is the interest rate, the latest interest rate of 3.65% was chosen for the calculation; C_{main} is the maintenance cost of the diagonal cable.

The maintenance cost of the stay cable in this paper is estimated according to the national industry standard JTG/T5612-2020[9]. As shown in Table 2 below, the calculation shows that the maintenance cost of the NM40 cable is about 260,000 yuan, and the replacement cost is about 1.55 million yuan.

Table 2. Maintenance cost unit price quota.

Maintenance Mode	Unit Price		Maintenance Mode	Unit Price		
Cable Repair	Project Base Price	430yuan/m	Parallel Wire Cable Replacement	Project Base Price	Demolition 3588.9yuan/t	Installation 20000.7yuan/t

According to the maintenance strategy, the statistics of the maintenance items of the cable are shown in Table 3, and the maintenance cost under each maintenance strategy is shown in Figure 3,

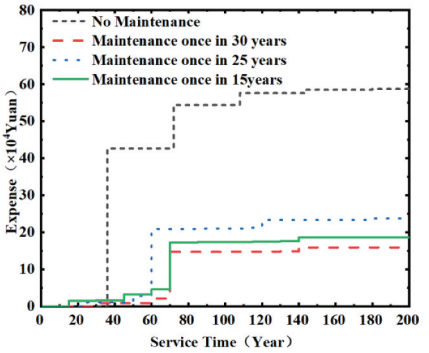


Figure 3. Maintenance costs expectations.

which shows that the maintenance cost expectation is the lowest at a maintenance interval of 30 years, which is only 159,200 yuan. And the cost of maintenance every 15 years is lower compared to the strategy with a maintenance interval of 15 years and a maintenance interval of 25 years, mainly due to the fact that there are fewer cable replacements during the service life of the bridge.

Table 3. 200 years of Nerazo maintenance project statistics.

Maintenance Strategy	No Maintenance	Maintenance once in 30 years	Maintenance once in 25 years	Maintenance once in 15 years
Maintenance (Times)	0	5	6	11
Cable Changes (Times)	5	2	3	2

6 CONCLUSION

This paper establishes a state maintenance optimization model based on a semi-Markov process, selects the inspection data of NBI to calculate the state transfer matrix of the diagonal cable, and combines it with the maintenance optimization model to derive the service level of the cable under different maintenance strategies in 200 years.

Taking a cable-stayed bridge as an example, the maintenance cost of the bridge during its life cycle is calculated. The results show that the service life of a cable-stayed cable-stay is about 60 to 80 years using only maintenance, and furthermore, encrypted maintenance during the latter 100 years is not satisfactory. Considering the full life-cycle maintenance cost of the zip wire within 200 years, the lowest maintenance costs of 159,200 yuan were achieved by using maintenance at 30-year intervals and replacement at 70-year intervals.

ABSTRACT: The durability and reliable operation of bridges play a critical role in society's development and economic growth. Nevertheless, the existing structures' deterioration over time, increasing structural demands, and exposure to extreme events may raise safety concerns and consequently limit the bridges' lifetime. The service life extension and durability of these structures rely on successful maintenance, repair, and rehabilitation activities supported by the rational use of inspection and monitoring information. In general, as the repair decision follows inspection results, a timely and accurate inspection plan can avoid unnecessary early repair and prevent repair being administered only when the degradation is at an advanced stage, resulting in a structurally deficient operating bridge with a high failure risk and complex and costly rehabilitation strategies. At all stages involved in the decision-making process, the presence of uncertainties associated with the onset and spread of damage, the occurrence of extreme events, the accuracy of inspections, and the effect of maintenance actions must be recognized, so that the structure's long-term performance is rationally quantified during the life cycle. Additionally, because of the limitations of visual inspections, non-destructive testing can be employed to enhance the level of inspection reliability and contribute to a better prognosis of structural performance, thereby supporting the decision process. By developing appropriate inspection and repair policies through an optimization framework, safety and cost requirements can be achieved during a structure's life cycle. In this sense, this work aims to demonstrate the application of an optimum inspection planning framework for a deteriorating reinforced concrete railway bridge affected by reinforcement corrosion based on a probabilistic analysis.

1 INTRODUCTION

The service life extension and durability of deteriorating bridges rely on successful maintenance, repair, and rehabilitation activities supported by the rational use of inspection and monitoring information. Such interventions have a crucial impact on the structure's life cycle by mitigating the deleterious effects of deterioration that lead to decommissioning and failure of systems. Concomitantly, they impose an inevitable increase in their life-cycle costs, once the maintenance and use phases frequently figure as the primary sources of environmental and economic impacts during the service life (Navarro et al. 2019, Yang & Frangopol 2019).

In general, as the decision to repair a deteriorating bridge follows inspection results, an optimized inspection plan can avoid unnecessary early repair and prevent the repair from occurring only when the degradation is at an advanced stage, resulting in a structurally deficient operating bridge with a high failure risk and complex and costly rehabilitation strategies (Abdallah et al. 2022). At the same time, owing to the conflicting cost and performance requirements, the utilization of optimization algorithms subsides the finding of appropriate

DOI: 10.1201/9781003483755-332

management techniques throughout the structure's life cycle (Barone & Frangopol 2014; Orcesi et al. 2018). To this end, at all stages involved in the decision-making process, the presence of uncertainties associated with performance prediction models, the onset and spread of damage, the occurrence of extreme events and their effects on the structure, the effect of inspection and maintenance actions, and others, must be recognized (Biondini & Frangopol 2016; Frangopol et al. 2017; Frangopol & Soliman 2016).

In the context of probabilistic decision-making, Barone et al. (2014) formulated a life cycle inspection and condition-based repair optimization framework considering the entire system of deteriorating components, minimizing both the failure rate and the expected costs of inspection and maintenance. A methodology for probabilistic assessment and optimal life cycle management of bridges was proposed by Kim et al. (2013) to obtain the time and types of inspection and condition-based repair events, satisfying the maximization of the expected service life and the minimization of the expected life cycle cost. The inspection and repair schedules, as well as the criteria for performing repair, were obtained by Zou et al. (2019b), considering the minimization of life-cycle costs (inspection, repair, and failure) and, alternatively, the minimization of the probability of failure over the life cycle of a fatigue-prone detail. The optimal schedule for condition-based maintenance with perfect and imperfect inspection information, as well as detection-based maintenance, was investigated. Kim & Frangopol (2018a) proposed a probabilistic inspection planning for fatigue-prone structures based on multi-objective optimization with weighted objectives, where a single solution was obtained to optimize six different objectives. A framework with two multi-objective optimization processes, before and after damage detection, was proposed by Kim et al. (2019), where the information collected in the scheduled inspections was used to update the probabilistic model of fatigue crack propagation and optimize the repair schedule, minimizing the maintenance delay and total maintenance cost. Barone & Frangopol (2013) considered uncertainties in both the detection and the propensity of the repair to be performed. The use of the instantaneous failure rate function was analyzed, and an iterative process to determine the number and instants of inspection and repair was suggested. Gong & Frangopol (2020) aimed to provide a decision-making framework considering managers' risk perceptions. A multi-objective optimization was performed to obtain the optimized inspection interval and load rating threshold for maintenance, in terms of expected repair and failure costs. The utility theory and the cumulative prospect theory were used to evaluate the preference between the solutions obtained. Gomes & Beck (2014) developed an investigation to establish the optimal moment of the first inspection, the interval between subsequent inspections, and the appropriate criterion for performing repair, to minimize the costs involved in inspection, repair, and failure for a renewable system.

This work focuses on the application of a risk-based optimum inspection planning framework for a deteriorating reinforced concrete railway bridge affected by carbonation-induced reinforcement corrosion.

2 RISK-BASED LIFE-CYCLE OPTIMIZATION

The process of bridge inspection and repair planning involves predicting structure deterioration and loading occurrence, interpreting the ability of the inspections to detect the developing damage and the repair outcomes, and formulating a comprehensive optimization problem that can reflect realistic expectations for efficient life-cycle management while considering the uncertainties involved in the life-cycle events (Frangopol 2011).

2.1 *Service life prediction under uncertainty*

In concrete structures, deterioration can occur through efflorescence or leaching, sulfate, carbon dioxide and chloride attack, corrosion, and alkali-aggregate reaction, as well as physical damage mechanisms, like ice/defrost cycles, thermal expansion, abrasion, erosion, shrinkage, and fatigue (Ellingwood 2005). However, depending on the characteristic of the structure utilization, the stochastic nature of the loading events indicates that the failure event may not be governed only by the strength loss due to damage progress and, thus, a combination of both loading and deterioration leads to structural failure in a first-crossing failure problem.

2.1.1 *Corrosion in reinforced concrete structures*

The life cycle of structures subject to corrosion consists, in general, of the period of corrosion initiation, where aggressive agents are transported inside the concrete to the surface of the reinforcements, and the propagation period, where the depassivation of steel allows the beginning of corrosion until the structure reaches the end of its service life. When present in a sufficient amount, aggressive elements such as chlorides and carbon dioxide can destroy the passive layer that initially protects the steel bars against the deterioration process. The duration of the initiation phase depends mainly on the transport rate of the aggressive elements, environmental conditions, and design parameters (Guo et al. 2015). In the case of concrete structures, the degenerative effects of reinforcement corrosion manifest as superficial stains caused by corrosion products, the cracking and spalling of concrete cover, reduction of reinforcement cross-section area, and bond loss (Ribeiro et al. 2020). Based on Faraday's law, the diametrical reduction of a steel bar under corrosion Δd in an instant t_n can be estimated by Equation 1 (Val et al. 1998):

$$\Delta d(t_n) = 0.0232 \int_{t_{oc}}^{t_n} i_{corr}(t)dt \tag{1}$$

where t_{oc} is the corrosion onset time (in years), the corrosion current density $i_{corr}(t)$ is expressed in μA/cm², and d in mm.

2.2 *Probability of damage detection*

The application of non-destructive testing plays an important role in obtaining a better prognosis of structural performance when compared to visual inspections, subsiding the decision process with more reliable information (Soliman et al. 2013). Acoustic emission, ground penetrating radar, electrical resistivity, half-cell potential, impact-echo testing, infrared thermography, and pachometer are examples of non-destructive tests that can be applied to concrete structures (Lee et al. 2014). The advancement of non-destructive testing methods and inspection techniques indicates that comprehensive planning of inspections should consider the type of method to be utilized (Abdallah et al. 2022).

The probability of damage detection, also referred to as the "detectability function", is the conditional probability of detecting damage given the defect size or damage degree, δ, and can be utilized to describe different inspection techniques in terms of their quality (Kim et al. 2011, Soliman et al. 2013, Yang & Frangopol 2018). This relationship can be statistically represented by shifted exponential, logistic curve, and standard normal cumulative distribution functions (Kim & Frangopol 2011). The higher the inspection quality, the lower the mean value of damage detectable by the inspection method, $\delta_{d,i}$. Although more accurate lifetime predictions may result from better inspection quality, the cost of technology and required expertise increases as more refined methods are employed. In this way, the choice of the appropriate moment to perform the inspection balances the level of damage, the inspection cost and quality, and, consequently, the cost of failure. The event for damage detection can be expressed as Equation 2.

$$D = \left[\delta_{d,i} - \delta \leq 0\right] \tag{2}$$

2.3 *Modeling of repair events*

Conventional repair methods for already damaged concrete bridges include the utilization of patches, overlays, sealers and coatings, crack injection, cathodic protection, and chloride extraction (Tabatabai et al. 2004). To represent the effect of protective and recovery measures, simplified assumptions have been utilized in optimization frameworks, including the replacement of components – and resulting reestablishment of initial capacity or initial lifetime, also regarded as "as good as new" repair (Barone et al. 2014, Benítez et al. 2020, Bismut & Straub 2021, de Angelis et al. 2017, Gong & Frangopol 2020, Kim et al. 2019, 2013, 2011, Kim & Frangopol 2018a, 2018b, 2016, Sun et al. 2018, Tolentino & Ruiz 2014, Yang & Frangopol 2018, Zhang et al. 2020, 2019, Zou et al. 2021a, 2021b, 2020, 2019); the suppression of deterioration rate for a period of time, that may be deterministic (Barone et al. 2014, Gong & Frangopol 2020, Vereecken et al.

2020), or random (Kim et al. 2013, Kim & Frangopol 2016); partial recovery of initial structural properties – that is usually modelled as an uncertain variable (Benítez et al. 2020, Zhang et al. 2019, Zou et al. 2021a); and reduction of the deterioration rate (Abdallah et al. 2021).

Usually, the repair events are classified according to the criterion for their application. In a detection-based repair strategy, the repair is performed once the damage is detected, and the event for detection is the same as for repair. A condition-based repair, in turn, occurs if the measured defect exceeds a repair criterion, which is typically defined as a damage level for repair $\delta_{r,i}$. In this case, when the damage is encountered during an inspection, the flaw is measured in an in-depth inspection, and the repair decision is made upon the measurement results. The event for repair differs from the event for inspection and can be expressed as:

$$R = \left[\delta_{r,i} - \delta \leq 0\right] \tag{3}$$

2.4 *Expected life cycle cost*

The total expected life cycle cost can be calculated according to the event tree depicted in Figure 1, where an inspection event at $t_{insp,i}$ can result in the events of damage detection and in-depth inspection resulting in the need for repair type 1 (D&R1), damage detection and in-depth inspection resulting in the need for repair type 2 (D&R2), damage detection and in-depth inspection resulting in no repair (D&$\overline{\text{R}}$), and no detection ($\overline{\text{D}}$). Each one of the intervention events can lead to a survival (S) or failure (F) event in the time gap before the subsequent inspection event.

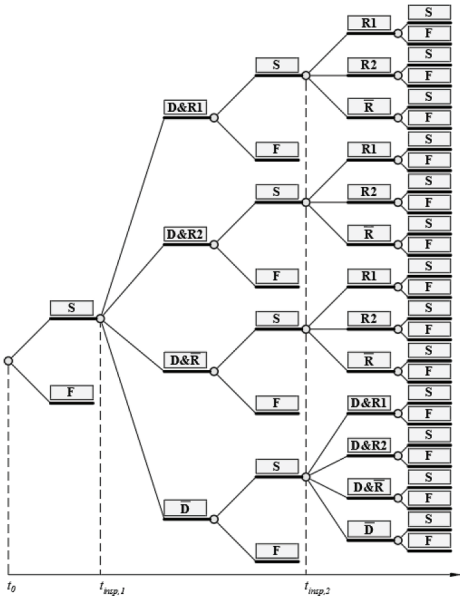

Figure 1. – Event tree for two inspection events and two repair options.

2.5 *Optimization problem formulation*

Based on the information obtained through life-cycle analyses, the optimization problem can be formulated to determine the optimal inspection times $\boldsymbol{t_{insp}}$ and repair thresholds δ_r for the available repair options to minimize the expected total costs consisting of inspection costs C_{insp}, repair costs C_r, and failure costs C_f:

$$\begin{gathered} Find: \boldsymbol{t_{insp}} = \left\{t_{insp,1}, \ldots, t_{insp,n}\right\}, \boldsymbol{\delta_r} = \left\{\delta_{r1},\ \delta_{r2}\right\} \\ That\ minimizes:\ E[C_{tot}] \\ Subject\ to: t_{insp,i} - t_{insp,i-1} \geq 2 \end{gathered} \tag{4}$$

3 CASE STUDY

To demonstrate the application of the optimization of life-cycle interventions, a Brazilian reinforced concrete railway bridge is studied. The structure has three simply supported spans of 18.67m and a broad-gauge ballasted track where the primary rolling stock consists of trains transporting iron ore. To characterize the loading events, wheel-load measurements conducted during instrumentation campaigns were utilized to compute the annual maximum bending moment through a moving-load dynamic analysis.

The degradation of the structure is simulated by the progress of general corrosion and carbonation depassivation of steel as the onset mechanism. To this end, the model proposed by Papadakis & Tsimas (2002) is applied to simulate the carbon dioxide ingress, and the model proposed by Ghods et al. (2008) is used to simulate the corrosion current density with values of concrete resistivity calculated according to Zhang et al. (2021). The damage is represented as a reduction of the main girder steel cross-sectional area, that is utilized as an input to calculate the resistant flexural capacity of the reinforced concrete cross-section yearly. The fraction of the steel cross-sectional area lost due to the corrosion progress is considered as the representation of the damage degree. Furthermore, the effect of concrete cover cracking due to corrosion products is investigated by applying the thick-walled cylinder model (Bažant 1979, Chernin & Val 2011).

To investigate the effect of inspection quality, the degree of damage detectable by the inspection method (δ_d) is varied, assuming values from 1×10^{-4} to 1×10^{-2}, represented by a normal distribution with a coefficient of variation of 0.1. Two repair methods are considered available for decision-making: the utilization of patch repair as a minor repair method; and the reestablishment of the initial resistant capacity as a major repair method applied in cases of more severe damage observation. The effect of patch repair is represented by the stagnation of damage progress for a random period, described by a uniform random variable U(4 years, 10 years) (Tabatabai et al. 2004). The effect of the bending moment occasioned by the passing train is, however, kept unchanged, to address both the failures governed by the degradation of the strength barrier and loading.

The costs of in-depth inspection, patch repair, major repair, and cracking of concrete cover are assumed as 2/3, 2, 10, and 1×10^3, respectively. In contrast, the cost of failure is varied assuming values from 1×10^5 to 5×10^5. The cost of non-destructive testing for damage detection can be associated with its quality by the expression (Mori & Ellingwood 1994):

$$C_{insp,i} = \left(1 - \delta_{d,i}\right)^b \tag{5}$$

where b is assumed as 190. The optimization problem is solved by utilizing the Genetic Algorithm from the Matlab Global Optimization Toolbox.

4 RESULTS

The utilization of the mentioned deterioration models resulted in a mean value of the depassivation time of 62.51 years with a standard deviation of 22.79 years. The mean time of concrete cracking due to corrosion products was 75.29 years with a standard deviation of 48.69 years.

The solution to the optimization problem is presented in Table 1. As seen in Figures 2a and 2b, the optimal repair criteria values for both repair types tend to decrease with higher inspection quality and cost of failure. This is because detecting damage earlier (Figure 3a) allows repairs to be made at lower damage levels, thereby reducing the associated expected life-cycle costs, since to higher failure costs, the relative repair costs decrease compared to the potential expected failure cost reduction. This is further supported by scheduling higher quality inspections earlier in the service life as observed in Figure 2d. However, observing Figure 2c, for higher values of δ_d and failure costs, the number of inspections increases, as the relative costs of inspections decrease compared to failure costs.

Figure 3a Illustrates the expected damage detection delay for the optimized solutions. The schedule with $C_f = 5 \times 10^5$ and $\delta_d = 1 \times 10^{-4}$ exhibited the shortest delay in detecting the developing damage, (20.28 years). However, the highest probability of detecting damage before

failure (Figure 3b) was observed for $\delta_d = 1 \times 10^{-3}$ and $C_f = 4 \times 10^5$, with a probability of 0.41, corresponding to the highest probability of repair (0.12) as well (Figure 3c). Moreover, the expected reduction in the life cycle costs increases with the utilization of more refined inspection methods and assigning higher values to the cost of failure (Figure 3d).

5 CONCLUSIONS

This paper presented an application of probabilistic inspection planning for a reinforced concrete railway bridge subjected to carbonation-induced corrosion. The uncertainties in the deterioration process, loading occurrence, inspection detectability, and repair effectiveness are considered to determine the optimized inspection times and repair criteria. The results showed that improving the probability of damage detection before failure and the probability of repair does not necessarily lead to the maximum expected life cycle cost reduction, as the optimization procedure identifies the best arrangement on the choice of inspection times and damage levels for performing repair for a given inspection quality and cost of failure. In this way, it is possible to reduce the expected total costs by employing the resources of inspection and repair rationally during the life cycle, even for relatively late deterioration initiation and low deterioration rates, thus subsiding the process of decision-making with a risk-based point of view.

Management of earth retaining structures based on condition and criticality

J.L. Amado, M.A. Pratas, B. Monteiro, A. Costa & M. Pinheiro
Infraestruturas de Portugal, S.A., Almada, Portugal

ABSTRACT: This article presents a risk-based framework for managing earth retaining structures (ERS) in the Portuguese National Road and Railway Network, managed by Infraestruturas de Portugal, S.A. With a substantial inventory of over 20,000 ERS in mainland Portugal, the company has developed a specialized management system aligned with industry best practices in asset management.

1 INTRODUCTION

In the pursuit of enhancing operational efficiency and optimizing resource utilization, the application of asset management principles and techniques has been tailored for earth retaining structures, commonly known as retaining walls. The conceptual framework of the management system revolves around a model founded on systematic processes of data collection, analysis, and decision-making.

The data collection phase commences with Inventory campaigns, encompassing the compilation of jurisdictional and technical information. This includes geometric and locational details concerning road or railway infrastructure. The amassed data serves as the foundation for computing a criticality index, a metric that assesses the significance of each asset in aligning with organizational objectives and desired goals.

Central to the structural analysis process are Principal Inspections, utilizing predefined observations as indicators to evaluate component condition and derive an overall rating for each Earth Retaining Structure. This rating is integrated with factors such as seismic risk, precipitation, and load considerations, resulting in a semi-quantitative condition index. By integrating the qualitative condition rating with these factors, the Condition Index furnishes a comprehensive evaluation of the health and safety of each earth retaining structure.

The Condition Index functions as a measure of the probability of failure, while the Criticality Index offers insights into the consequences of failure. Through an integrated approach using a risk matrix, resource allocation can be optimized, facilitating inspection scheduling and intervention prioritization based on risk assessment outcomes. This article delves into the indicators utilized in condition and criticality analysis, elucidating the processes supporting risk-informed decision-making.

2 STRATEGIC MODEL

2.1 *A collaboration process*

The management of earth retaining structures (ERS), hereafter referred to as ERS, is conceptualized as a collaborative process involving specific participants, interlinked activities, both internal and external to the process, and standard outputs, as articulated by Amado et al. (2019). Drawing on best practices outlined in ISO/IEC (2013) and ISO 9000:2015, which defines a process as a set of interrelated activities, the strategic model emphasizes understanding the desired outcome when implementing a management system.

DOI: 10.1201/9781003483755-333

The prioritization of maintenance and investment needs, along with defining inspection frequencies, constitutes the overarching goals of the system. Differentiating these needs is contingent on varying levels of risk, determined through a matrix combining the structure's condition with its criticality. The condition rating reflects the structure's response to designed conditions, obtained through principal inspections, structural health monitoring, and information about the operating environment. Simultaneously, the criticality index hinges on the structure's impact on organizational objectives, integrating physical characteristics and functional location. Inventory and principal inspection activities serve as the cornerstone of the system, complemented by routine inspections for preventive maintenance needs and monitoring when necessary. The strategic model, illustrated in Figure 1, provides a clear representation of activities and their interdependencies without representing exceptions or actors for immediate perceptibility.

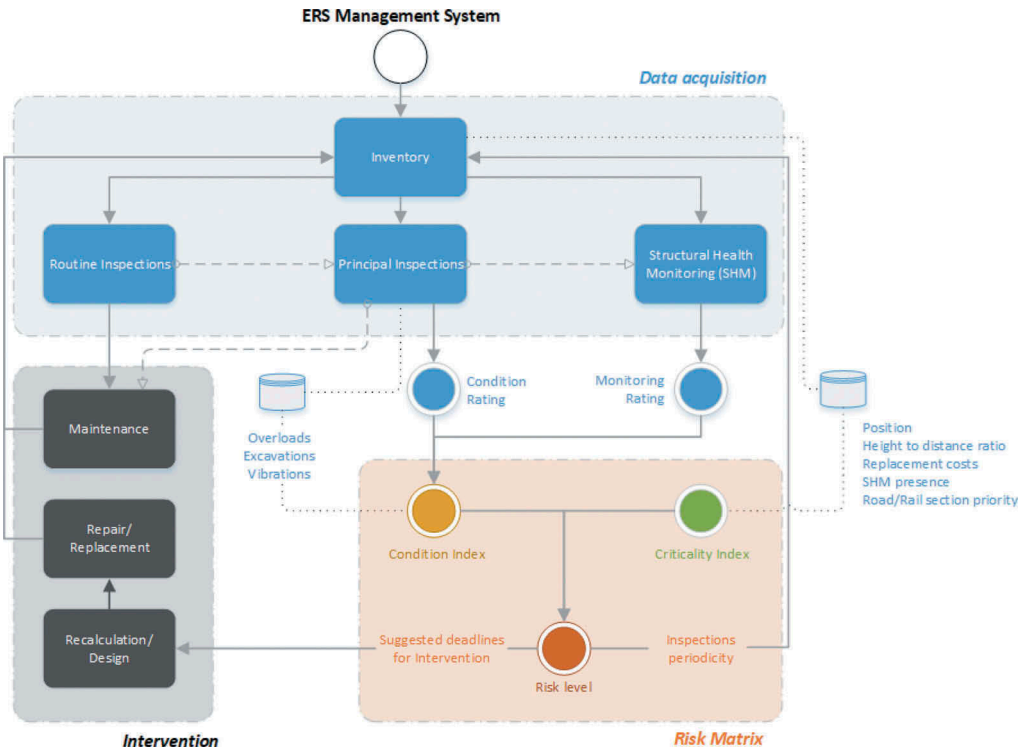

Figure 1. Infraestruturas de Portugal's strategic model for the management of earth retaining structures.

2.2 *Risk informed decision-making*

The risk-based decision model employed by Infraestruturas de Portugal for retaining structures is rooted in the Risk Level, calculated based on a Condition Index and a Criticality Index. These indices encompass intrinsic and external factors, combined through weighted averages, as depicted in Figure 2.

The methodology employed by Infraestruturas de Portugal for calculating the risk level of earth-retaining structures is more comprehensively illustrated in the model presented in Figure 3. This model identifies the factors included in the calculations of each index, along with the relevant parameters considered for each factor, where applicable.

As depicted in Figure 3, the parameters (level 4) used in the calculation of the factors (level 3) are analyzed on a discrete scale from 1 to 5, based on established intervals. Their combination is

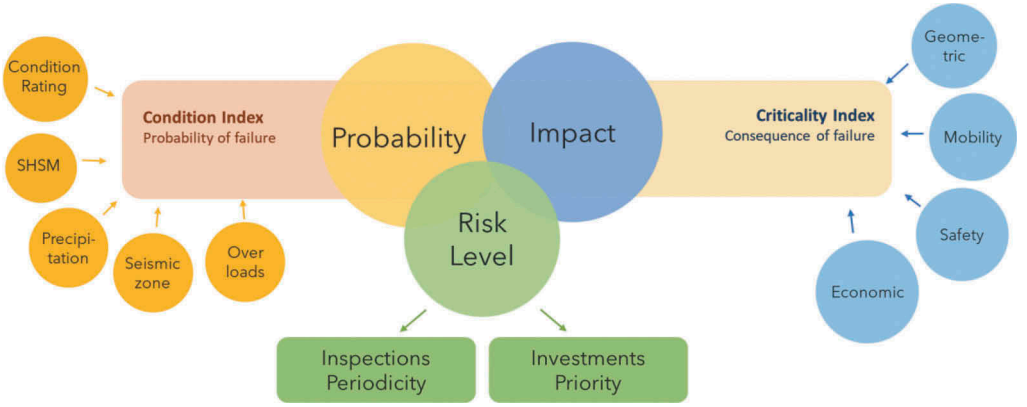

Figure 2. Infraestruturas de Portugal's risk-based decision model.

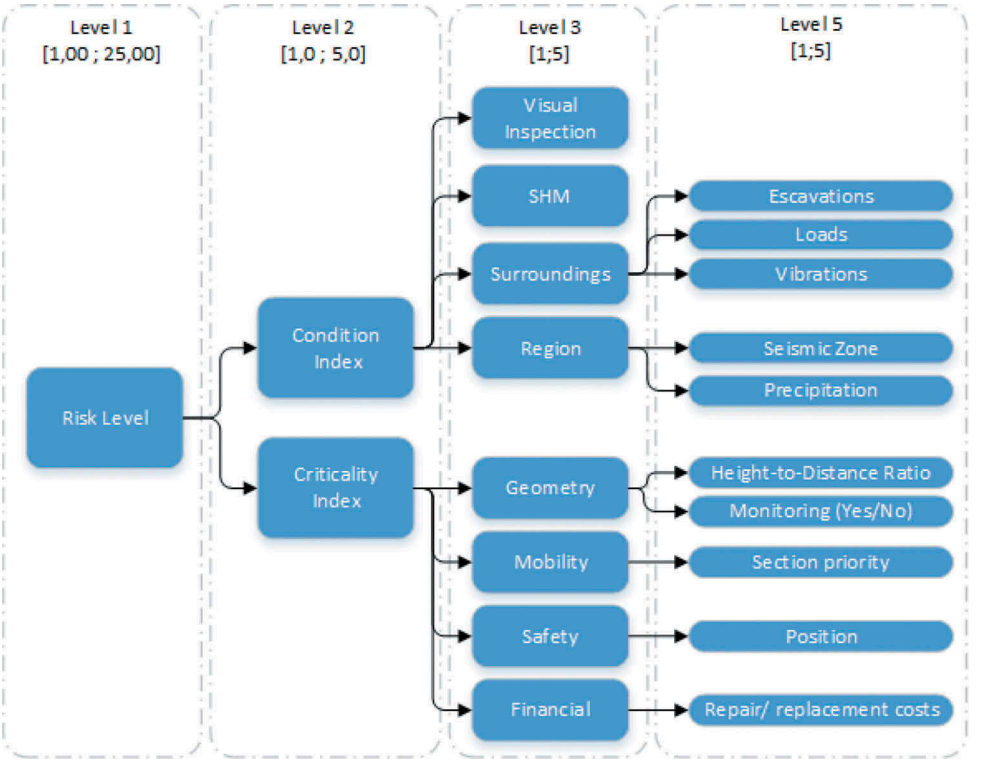

Figure 3. Infraestruturas de Portugal' earth-retaining structures methodology for risk level calculation.

performed through a weighted average. Similarly, the factors (level 3) are also assessed on a discrete scale from 1 to 5, and their combination through a weighted average results in an index (level 2) on a continuous scale from 1 to 5. Finally, the simple multiplication of the two indices (level 2) yields a Risk Level (level 1), falling within a discrete scale from 1 to 25.

As stated, the parameters and factors, analyzed on discrete scales, are combined through weighted averages to generate two indices, Condition and Criticality index.

The Condition Index intends to be a qualitative measure of the observable physical state of the structure under operational conditions and design loads. It serves as an indicator of reliability and acts as a proxy for the probability of failure. This index integrates a qualitative condition

rating derived from visual inspections with factors including monitoring results, environmental conditions, and surroundings, offering a comprehensive assessment of the overall health and safety of the structures. Conversely, the Criticality Index assesses the significance of an asset in accomplishing organizational objectives and fulfilling desired goals, considering its impact on the organization, stakeholders, and the overall system. As depicted in the Figure 3, criticality is determined by geometric factors, positioning in relation to the transportation corridor (for protection or support), segment priority, and estimated costs related with its typology and size.

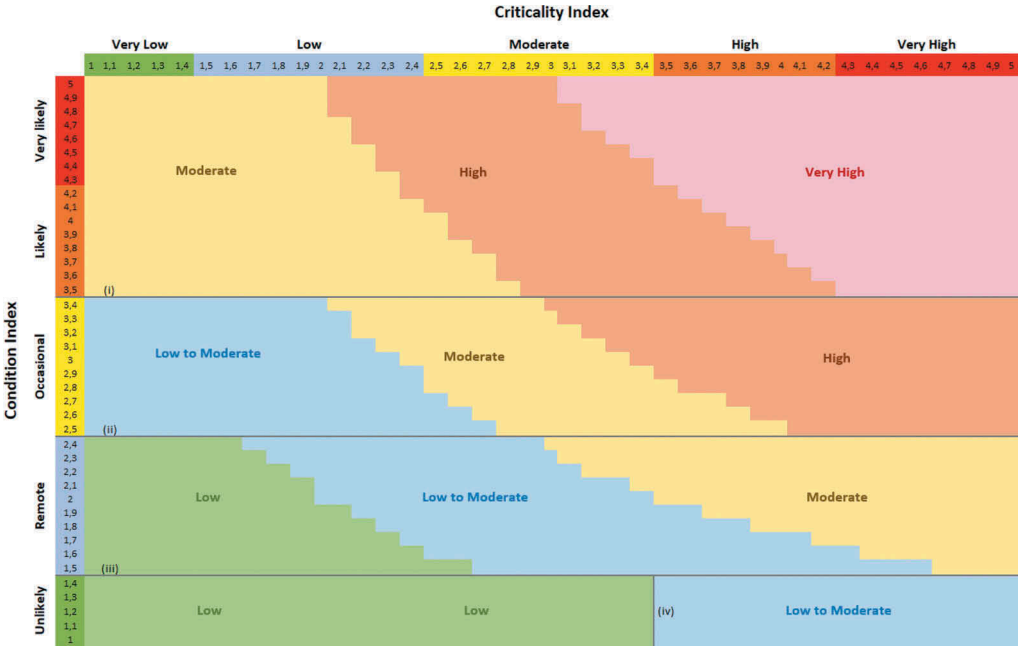

Figure 4. Infraestruturas de Portugal' risk matrix for the management of ERS.

Table 1. Risk levels for earth retaining structures and subsequent actions

Risk Level		Inspection Intervals	Intervention time frame
< 4	Low	Routine inspections up to 2 yrs Principal inspections upon request	No actions beyond annual routine maintenance.
< 7	Low to Moderate	Routine inspections up to 2 to 4 yrs Principal inspections up to 6 years	Actions to be planed under maintenance contracts.
< 10	Moderate	Routine inspections up to 2 to 4 yrs Principal inspections up to 4 yrs	Medium-term intervention needed.
< 15	High	Routine inspections up to 2 yrs Principal inspections up to 2 yrs	Medium-term intervention needed. Risk mitigation measures in the short-term.
≥ 15	Very High	Principal inspections up to 1 yr	Short-term intervention needed. Risk mitigation measures including immediate circulation restrictions.

Building upon the preceding risk matrix, five risk levels were established, each corresponding to specific subsequent actions concerning inspection frequencies and intervention timeframes, as illustrated in Table 1.

3 PERFORMANCE INDICATORS

3.1 *Inspection protocol*

As delineated in Section 2, the Condition Index incorporates data derived from visual observations, particularly those conducted during Principal Inspections. To institute a comprehensive framework for these diagnostic procedures, a protocol for inspections was formulated. This protocol centers on three pivotal components: Wall, Drainage, and Influence Area, encompassing all pertinent elements of the ERS. Throughout the inspection, specialized technicians undertake visual assessments

Table 2. Condition rating assigned in principal inspections.

Condition Rating (CR)	Description
1	No damage
2	Low severity damage
3	Medium severity damage, in a limited to medium extent
4	Medium severity damage, in a medium to high extent
5	Severe damage

Table 3. Elements and observations/indicators for condition assessment of the wall component.

Elements	Observations/ Indicators	Detail
Surface Finishing Materials	Disintegration	
	Blisters or swelling	
	Detachment or peeling	
	Hairline cracking	
Wall body	Failure	
	Deformations	Bulging; Flexure; Settlement; Disarray of wall elements; Abnormal joint opening
	Displacements	Horizontal displacement; Rotation to the extrados; Rotation to the intrados
	Cracks	Horizontal; Vertical; Diagonal
	Loss of material from the backfill	
	Surface degradation	
	Damage to joint mortar	Cracking; Degradation and loss of cohesion; Vegetation growth
	Corrosion/section loss in metal elements	
	Stains, runoff, or efflorescence	
Foundation	Foundation exposure	
	Soil deformation	Bulging; Subsidence
Parapet installed on the wall	Abnormal inclination	
	Deformation	
	Malfunctions	
Safety Barrier installed on the wall	Abnormal inclination	
	Deformation	
	Malfunctions	
Other elements or equipment installed on the wall	Abnormal inclination	
	Deformation	
	Malfunctions	

and allocate ratings within the 1 to 5 range to indicators linked with identified defects. These ratings aim to articulate the severity and scope of the damages, in accordance with the general description delineated in Table 2. Additionally, for each observation, a distinct description has been formulated and is accessible to inspectors in a dedicated manual (Infraestruturas de Portugal, unpubl.). This manual furnishes comprehensive guidance and directives on how to evaluate and assign ratings to each indicator, thereby ensuring uniformity and precision in the inspection process.

The performance indicators for the elements within the Wall component, along with the corresponding assessment details are summarized in Table 3.

For the elements within the Drainage and Influence Area components, Table 4 and Table 5 respectively present the performance indicators and assessment details.

Table 4. Elements and observations/indicators for condition assessment of the drainage component.

Elements	Observations/ Indicators	Detail
Drainage Inlets and Outlets	Blocked	
	Damaged	
Rear Gutters	Blocked	
	Damaged	
Frontal Gutters	Blocked	
	Damaged	
Side Gutters	Blocked	
	Damaged	

Table 5. Elements and observations/indicators for condition assessment of the influence area component.

Elements	Observations/ Indicators	Detail
Backslope or embankment on the rear side	Deformations	Bulging; Subsidence; Abnormal inclination of trees
	Displacements	Falls; Slides; Erosion
	Cracks	Horizontal; Vertical; Diagonal
	Vegetation	
	Presence of water in the backfill	
Buildings or constructions on the rear side	Settlement	
	Cracks	
	Evidence of failure	
Pavement or sidewalk on the rear side	Settlements	
	Bulges	
	Cracks	Transverse/oblique; Longitudinal
Frontal slope or embankment	Deformations	Bulging; Subsidence; Abnormal inclination of trees
	Displacements	Falls; Slides; Erosion
	Cracks	Horizontal; Vertical; Diagonal
	Vegetation	
Buildings or constructions on the frontal slope or embankment	Settlement	
	Cracks	
	Evidence of failure	
Pavement or sidewalk on the frontal slope or embankment	Settlements	
	Bulges	
	Cracks	Transverse/oblique; Longitudinal

After assigning ratings to each observed indicator, a rating is computed for each of the three components of the structure (wall, drainage, and influence area), along with an overall

rating for the entire structure. This comprehensive rating serves as the primary determinant in the calculation of the Condition Index, as discussed in section 2.2. For detailed insights into the inspection protocol, encompassing the algorithm employed for computing the condition rating for each component and the wall as a whole, readers are referred to Amado (2023a).

In summary, this calculation takes into consideration the varying degrees of relevance associated with the made observations, with some deemed critical, following the methodology proposed by Butler (2016) and Rasdorf (2016). This approach prevents the masking of severe situations through the adoption of a simple average. If any component receives a rating exceeding 4, the overall rating assumes that value. In other instances, the rating is calculated using a straightforward average. An additional rule pertains to the Wall component, stipulating that the overall rating cannot be lower than the rating assigned to this component.

Building upon the findings of the COST ACTION TU1406 project (Hajdin 2018, Pakrashi 2019), the inspection protocol of Infraestruturas de Portugal also documents the causes of defects and underlying damage processes. This documentation provides valuable insights for evaluating the structure's condition. Noteworthy causes, including capacity issues, material deterioration, execution problems, natural phenomena, and maintenance deficiencies, are recorded to enhance the assessment process and pave the way for future development of degradation models, thereby facilitating long-term planning.

4 DISCUSSION

This article has presented a simple and comprehensive risk-based framework for managing retaining walls, encompassing a strategic model, criticality and condition assessments, and risk analysis to support decision-making. A set of performance indicators was also proposed based on a general discretization of the structures in components and elements. The integration of these entities forms a robust and feasible management approach, ensuring the resilience and reliability of earth retaining structures. This framework's applicability extends beyond ERS, offering potential benefits for managing diverse asset types. Notably, bridges emerge as a pivotal domain wherein the framework can be adeptly employed, showcasing its potential benefits for strategic asset management. According to Amado (2023c) the company is currently testing the efficacy of this framework in overseeing overhead sign gantries, thereby establishing a precedent for its successful implementation across various asset classes.

ABSTRACT: Building Information Modeling (BIM) enables the creation of digital twins that simulate physical assets like buildings and infrastructure. Achieving an accurate representation of the true structural behavior necessitates calibrating the properties of these virtual models using real on-site measurements. The calibration process holds particular significance for the federated structural model, as on-site damages can potentially compromise crucial mechanical attributes, jeopardizing the asset's safety and integrity. Although Structural System Identification (SSI) methods can derive actual parameters from on-site measurements, integrating these calibrated properties into BIM models poses challenges. Typically, the calibration process involves manual operations, such as modifying predefined structural databases and updating properties for damaged elements. This manual approach introduces complexities and potential inaccuracies. This paper proposes a novel approach using Robot Process Automation (RPA) to automate the calibration of BIM structural models. The proposed RPA tool automates the generation of new sections in the structural database and the assignment of updated mechanical properties to damaged elements. By leveraging RPA, the integration of SSI results into BIM models can be significantly enhanced, improving interoperability between architectural and structural federated models. Furthermore, this automation supports informed decision-making in structural assessment and maintenance. To validate the proposed tool, a case study is presented involving the calibration of mechanical properties in a real steel bridge. Autodesk software, including Revit and Robot Structural Analysis, is utilized in this case study. The findings demonstrate the effectiveness and potential benefits of the proposed RPA tool in streamlining the calibration process and ensuring the accuracy of BIM structural models.

1 INTRODUCTION

In the context of the ongoing fourth industrial revolution, often referred as Industry 4.0, Architecture, Engineering, and Construction (AEC) industry is undergoing a profound shift driven by digitalization. One prominent methodology at the forefront of this transformation is the pivotal role played by Building Information Modeling (BIM). BIM methodology is based on a federated approach that integrates multiple discipline-specific models into a single, cohesive virtual and holistic representation of a construction project. This integration fosters

DOI: 10.1201/9781003483755-334

improved communication, reduces errors, and improves decision-making throughout the construction project's lifecycle. However, as highlighted by Bellido et al. (2019), challenges related to interoperability among disciplines frequently emerge.

To properly reproduce the actual structural response of a structure, BIM models need to be calibrated. This calibration involves aligning the models with the real mechanical properties of the structural elements including the effects of structural pathologies, such as steel corrosion and concrete cracking. The calibration of the structural parameters, such as axial or flexural stiffnesses, is traditionally carried out by Structural System Identification (SSI) techniques from the static or dynamic structural response measured on site. An overview of some of the most common SSI methods, as well as future trends in the field are presented in Lei et al (2018) and Wu and Jahanshahi (2020). Currently, most SSI methods remain disconnected from the BIM methodology, operating independently with their own structural models. The few studies presented in the literature about this topic focus primarily on calibrating the mechanical and material properties of a structural model exported from the BIM model. This is the case of Bouzas et al. (2022), focused on the calibration of corrosion degradation in a steel bridge. In this work, the BIM model of the bridge is first exported to a dedicated structural software, specifically Ansys. Subsequently, an optimization algorithm was used to update the steel plate thicknesses to minimize the discrepancy between the predicted dynamic response and the actual observed behavior on site. A literature review of other works focused on the geometric parameter updating of BIM models was presented in Osadcha et al. (2023).

Robotic Process Automation (RPA) refers to an advanced technology that employs business rules and activity structures to automate tasks traditionally performed by humans, replicating the same user interface interactions as a human operator. The advantages of RPA include a user-friendly interface, faster and more streamlined programming, and direct execution in productive environments. Asatiani and Penttinen (2016) provide a comprehensive examination of RPA's application in various industries, such as banking, healthcare, and manufacturing. Noteworthy examples of RPA in the construction field include the work of Atencio et al. (2022), who proposed automating the management of low-cost sensors for dynamic structure monitoring using RPA tools, and Jiang and Ling (2022), who suggested employing RPA to automate the operation of building equipment in BIM models. In this context, this paper proposes the application of RPA to automate the calibration of the mechanical properties of BIM models.

This conference paper is organized as follows: Section 2 illustrate the identified problems associated with calibrating structural parameters in BIM models. In Section 3, the utilization of RPAs is presented for the automatic calibration of structural damages in BIM models. Section 4 presents the application of the proposed methodology in a case study. Finally, the main conclusions are drawn in Section 5.

2 INTEROPERABILITY PROBLEMS BETWEEN REVIT AND ROBOT

Connecting structural elements across different software platforms may result in the loss of either geometry or structural attributes. To illustrate these challenges, this section examines interoperability problems in two specific information flows: from Revit to Robot and from Robot to Revit. Additionally, this section shows the challenges of the manual calibration of structural parameters.

2.1 *From Revit to Robot*

In the BIM modeling software Revit, structural elements like beams or columns are organized into families. The analytical model attributes of these families are interconnected with predefined structural databases, such as "EuroPro.xml" for steel profiles. Consequently, when a structural element is added to the BIM model, its structural attributes, such as area and inertia, are automatically retrieved from the corresponding database. The EuroPro database is structured as follows: (1) Definition of the name, section, and shape parameters for various steel shape families, (2) Mathematical equations determining the steel profile boundary based on the defined geometry, and (3) Values of the dimensions and mechanical properties for different steel profiles. Figure 1 illustrates the definition of the IPE 220 profile in the "EuroPro.xml" database.

```

IYb="0.0000277184"/>
```

Figure 1. Fragment of the definition of the IPE220 in the "EuroPro.xml" database.

Not all mechanical parameters specified in the databases are readily visible in the corresponding Type Properties in Revit. This discrepancy is particularly evident in the case of flexural inertias (I). This lack of accessibility of the structural parameters prevents its direct customization within Revit.

2.2 *From Robot to Revit*

The mechanical properties of predefined structural elements can be manually adjusted in Robot and incorporated into structural analyses. Nevertheless, the structural attributes of the customized profiles in Robot are not accurately imported into Revit. This interoperability problem arises because the updated mechanical value is not included into the steel profile database (Euro-pro.xml) employed by Revit. Consequently, the customized parameter cannot be properly imported as a BIM object.

2.3 *Manual calibration*

To ensure the interoperability of customized structural sections, it becomes essential to modify the structural databases. However, manually updating the profiles database presents various challenges and limitations. Firstly, the process is time-consuming and labor-intensive, demanding considerable effort to manually adjust and update the model's parameters and attributes. Secondly, manual calibration is susceptible to human error, relying on individual judgment and interpretation, which can introduce inaccuracies and inconsistencies into the model. Additionally, manual calibration lacks a systematic and standardized approach, making it difficult to replicate the calibration process in other projects. Finally, as the model evolves over time, manual calibration becomes cumbersome to maintain and update, potentially resulting in outdated or inaccurate information.

To automate the solution of these three problems, Robotic Process Automation (RPA) protocols are developed in the subsequent section.

3 AUTOMATIC CALIBRATION WITH ROBOTIC PROCESS AUTOMATION

The process for calibrating the BIM models consists of the following steps:

- Step 1: Generation of the analytical model. The BIM model of the structure is initially created in Revit. In this model, the structural elements are assumed to be undamaged, and their properties are extracted from a predefined database. For example, in the case of normalized steel profiles the "EuroPro.xml" database case be used. Subsequently, the analytical model of the structural elements is generated in Revit.
- Step 2: Exporting the analytical model. The analytical model is exported from Revit to Robot Structural Analysis using the integration with Revit Structure dialogue box.
- Step 3: Introduction of the damages in Robot. The effects of the different damages in the mechanical properties and their assignation to the structural elements are defined into a Microsoft Excel sheet. This information is then used to create new damaged sections and assign them to the corresponding elements, thus updating the structural model. This updated model can be used to investigate the effects of damages on structural reliability.
- Step 4: Calibrated structure in Revit. The updated Robot model is imported back into Revit using the integration with the Revit Structure dialogue box.

After manually specifying the necessary information, Steps 3 and 4 can be automated to calibrate the identified structural damages into the analytical model using Robot. This automated procedure is based on the creation of new sections for each damaged element in the structural database, uploading the damaged sections, updating the sections of the damaged elements in Robot, and subsequently updating the model in Revit. This process is automated through an RPA, that is based on the following two protocols: (1) Automatic updating of the structural databases to facilitate the transfer of analytical models between Revit and Robot, and (2) Automatic updating of structural damages in the BIM digital twins. The steps of this RPA are summarized in Figure 2 and elaborated as follows:

- RPA 1: (1) Reading damage information. The RPA opens the Excel sheet input data, reads, and stores the information of the damages, including their name, the values of their mechanical properties, and their allocation to the structural element's identificatory (ID). Then the Excel sheet is closed, and (2) Updating the database with the damaged sections. The RPA opens the .xml database of mechanical properties and creates a new section for each of the damaged properties detailed in the Excel sheet. Then the database is saved and closed.
- RPA 2: (3) Loading the damaged sections in Robot. The RPA opens Robot and loads the damaged sections introduced into the structural database, and (4) Updating the cross-sections of the damaged elements. In this step, the damaged elements are assigned the damaged sections according to the definition of the Excel sheet.

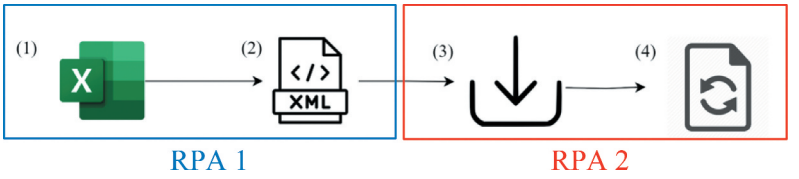

Figure 2. Septs followed by the developed RPAs.

In the following section, the proposed methodology is applied in a case study.

4 CASE STUDY

This section applies the proposed methodology for automating the calibration of structural damages in BIM models to a case study. Firstly, the geometry and the BIM model of the structure are described. Next, the pathologies identified during the on-site inspection of the structure are reviewed. Finally, the application of the RPA protocols to automate the calibration of the structural parameters in the BIM mode is presented.

4.1 *Geometry and BIM model*

The analyzed structure is the Pajareles footbridge, a suspension bridge located in Albacete, Spain, and built in 1935. This bridge includes two steel pylons and a span of 85 meters. The steel deck, measuring 2.35 meters in width, is connected to the main suspension cables through vertical hangers. A picture of this structure is presented in Figure 3. Since no drawings of the structural elements were available, a point cloud was generated on-site using a drone for aerial flights. The resulting point cloud was subsequently processed and cleaned using Autodesk Soft-ware Recap.

The point cloud data was used to create the BIM model presented in Figure 4. The structure depicted in this figure is composed of normalized steel profiles, each family indicated by a different color. The geometry and mechanical properties of the sections in the structure (FL4x30, FL5x60, HEB160, IPN100, CAE30x3, CAE50x5, CAE120x15, ROND10, ROND30, UPN80, UPN140, and UPN 160) were obtained from the "EuroPro.xml" database.

Figure 3. Picture of the Pajareles footbridge.

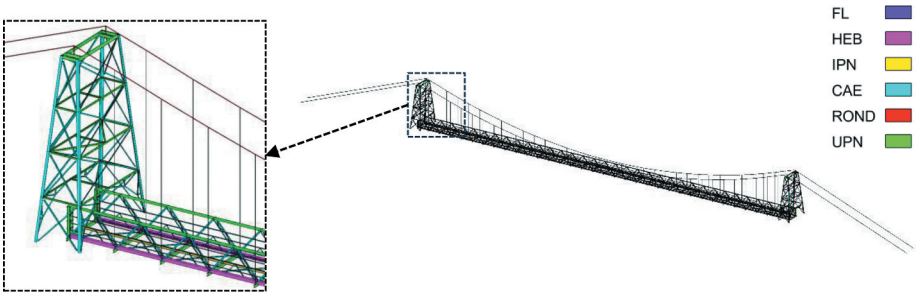

Figure 4. BIM model of the Pajareles footbridge.

The analytical model of the structure was then created in Revit. The obtained model is presented in Figure 5 and it includes 747 analytic bar elements.

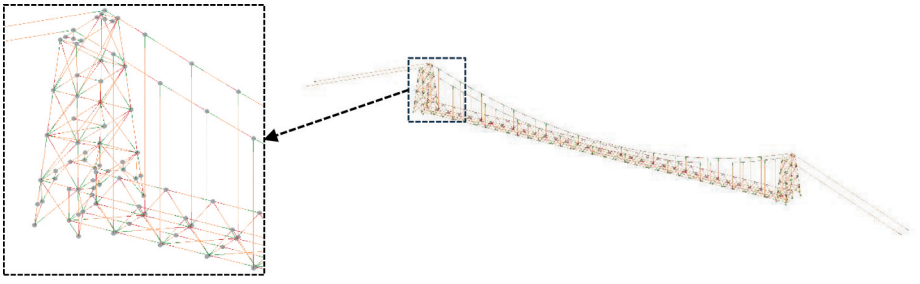

Figure 5. Analytical model of the Pajareles footbridge.

4.2 *Inspection on site*

To assess the condition of the structural elements, an on-site inspection of the Pajareles footbridge was conducted in 2022. This inspection revealed that the majority of steel elements exhibited significant corrosion in most structural elements. In order to study the application of the proposed calibration methodology, a scenario involving damage to all structural members was examined. In this situation, corrosion-related pathologies were presumed to result in significant decreases in mechanical properties, especially concerning areas and inertias, in contrast to the standardized values of the corresponding steel profiles. To simulate the corrosion-induced strength reduction, a random percentage ranging from 0% to 15% was employed as an average value for the entire bar. This percentage was based on previous tests reported in the literature (e.g., Ducuan et al. (2020)).

The perceptual corrosion damages are graphically represented in Figure 6. This illustration incorporates a color-coded filter to categorize the perceptual corrosion damages into three ranges: lower than 5%, between 5% to 10%, and between 10% to 15%.

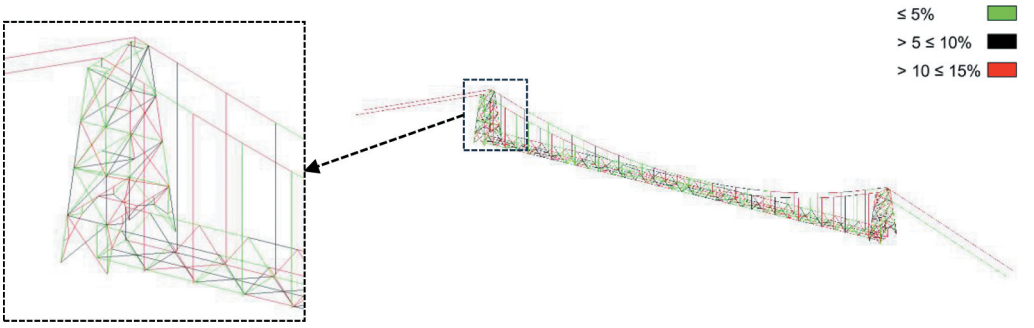

Figure 6. Assumed corrosion damages in the elements of the BIM model.

4.3 *Automatic calibration of the BIM model*

The procedures delineated in Section 3 for automating the calibration of mechanical properties due to corrosion effects were specifically customized for the given case study in the RPA software UiPath.

Following the establishment of the BIM model and the incorporation of damaged information (Step 1), RPA 1 was developed to automate the updating of structural databases, streamlining the transfer of analytical models between the BIM models (Step 2). The input data for this process is sourced from the Excel sheet outlined in Figure 7, and the resulting output encompasses the updated profile database, specifically the Euro-pro.xml database. The actions followed by RPA 1 in can be summarized as follows:

(i) The Euro-pro.xml database is uploaded in .txt format.
(ii) The length of the .txt file is retrieved and stored in a new variable.
(iii) The list of corrosion damages is imported from the Excel sheet.
(iv) The .txt file is copied into a string variable.
(v) The .txt file undergoes a comprehensive editing process, involving an analysis and update of the steel profile family information based on the damaged elements defined in Activity iii.
(vi) The modified .txt file is exported to .xml format to enable compatibility with Revit an Robot software.

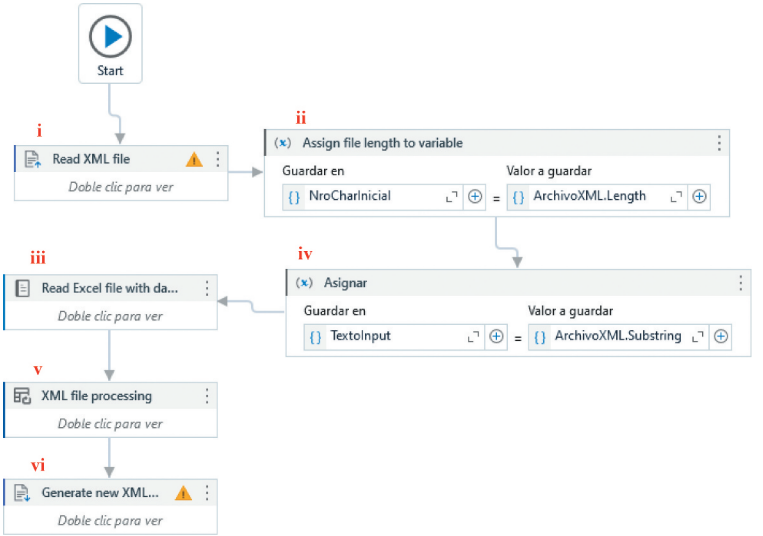

Figure 7. RPA 1 in UiPath highlighting the followed steps.

RPA 2 was customized to facilitate the automated updating of structural damages within the BIM model of the case study. The input data for this process included both the updated profile database and the analytical model in Robot, while the resulting output corresponds to the analytical model updated with the specified corrosion damages. As illustrated in Figure 8, RPA 2 is organized into two distinct modules—one operating within Revit and the other within Robot. The detailed activities carried out by each of these modules are summarized as follows:

(i) Access the BIM model through its Revit .rvt file.
(ii) Export the analytical model of the case study from Revit to Robot using the integration with the Revit Structure dialogue box.
(iii) Import the updated database containing the damaged sections into Robot.
(iv) Extract the list of families for the damaged sections.
(v) Load each damaged family into Robot.
(vi) Import the list of damages from the Excel sheet.
(vii) Attribute the updated properties to the damaged elements. This process involves modifying the section type of the damaged elements from their original designation to the corresponding damaged one in the table of properties of the beam elements within Robot. This task can be automated by pasting the section name specified in the Excel sheet into the section type column for the respective beam elements.

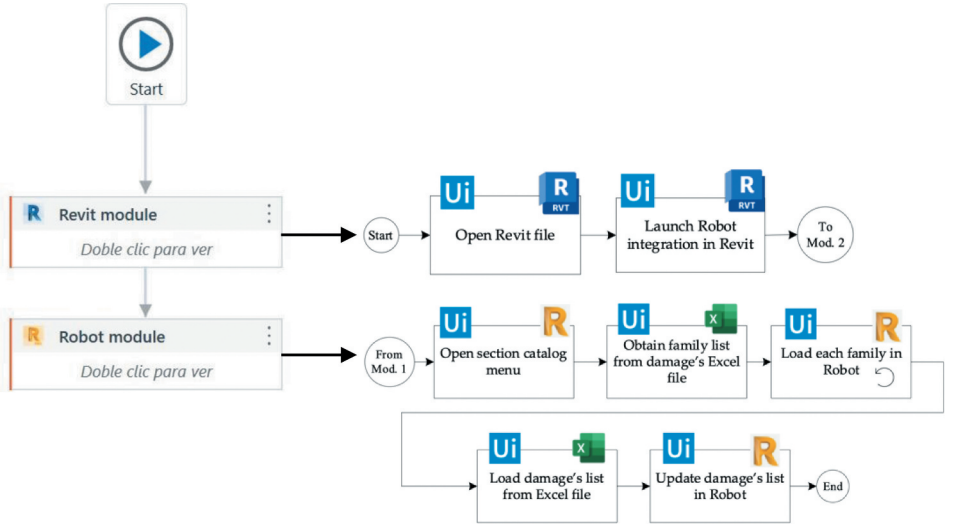

Figure 8. RPA 2 in UiPath highlighting the followed steps.

The calibrated analytical model was transferred from Robot to Revit employing the integration with the Revit Structure dialogue box. The resulting model is presented in Figure 9. It is worth to remark that both the nomenclature and attributes of the elements corresponds with the updated mechanical sections. To exemplify this characteristic, the properties of five damaged sections (UPN_1 160, UPN_2 160, HEB_160, HEB_4 160, and IPN_5 100) are highlighted in the figure.

5 CONCLUSION

This paper proposes a novel tool for automating the calibration of building information modelling (BIM) structural models. This methodology is based on an innovative use of robot process automation (RPA) tools that automates, from a user-friendly and intuitive approach, both the

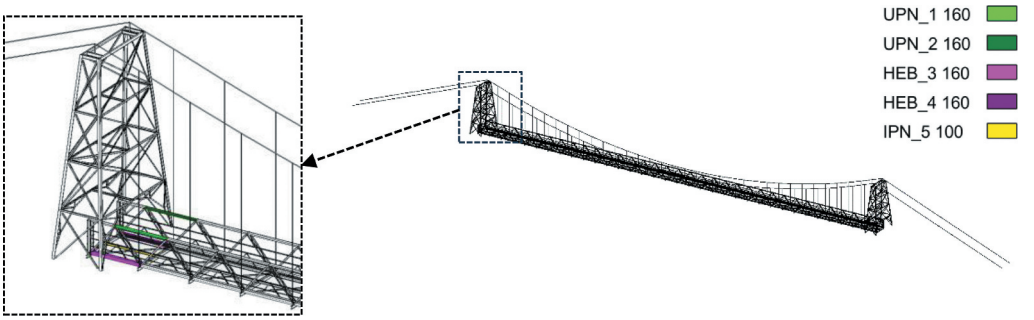

Figure 9. RPA 2 in UiPath highlighting the followed steps.

generation of new sections in the structural database, and the assignment of the updated mechanical properties to damaged elements. State of the art BIM, including Revit and Robot Structural Analysis, and RPA, UiPath, software is used in this study to ensure robust and reliable results. This work contributes to bridging the gap in the automation of BIM models. The effectiveness of the proposed tool is validated in the calibration of the effects of corrosion pathologies in the structural model of a suspension bridge.

Sustainable-centered approach for bridge management: A game-changer paradigm

D. Duzzi & D. Briccola
University of Applied Sciences and Arts of Southern Switzerland (SUPSI), Mendrisio, Switzerland

ABSTRACT: Bridge owners and operators are responsible for delivering users reliable infrastructures within the road network to develop a prosperous economy and a well-functioning society. As bridges are essential components of the transport road network, especially in alpine countries like Switzerland, switching from bridge- to network-based prioritization rankings to ensure a predefined level of sustainable development considering available resources is paramount. That implies the definition of simplified indexes based on specific indicators to establish a bridge's importance at the network level. The traffic volume, the distance of each artifact from cantonal first aid facilities, the bridge condition assessment, a simplified vulnerability-to-degradation measure, and exposure to natural hazards play a role. The proposed approach, developed for Tessin, could be extended to countries with few principal axes and numerous valleys, like Switzerland. The strategy appears as a potential game-changer paradigm for management of stocks of viaducts and bridges considering multi-hazard risks.

1 INTRODUCTION

In an era characterized by rapid evolutions and continuous changes, the built environment increasingly manifests its vulnerability during extreme weather events. Direct and indirect social, environmental, and economic damages are significant and can jeopardize the well-being of entire nations. Therefore, it is evident that climate change seriously threatens the built environment, and there is an emerging need to develop strategies to implement adaptation actions that reduce damage. Asset managers should guarantee sustainability under all circumstances, not only when natural hazards or extreme weather events occur. That is more desired, the greater the value of the assets considered, like with critical infrastructures, among which road and rail transport infrastructure are prominent.

Especially in Alpine and pre-Alpine countries like Switzerland, the recognition of the socio-economic value of bridges within the transport infrastructure is a driving force for asset managers to identify actions to ensure network continuity in time (availability), space (maintainability), and performance commensurate with changing environmental and operating conditions. Operators must guarantee users a reliable system of bridges characterized by operational efficiency, structural safety, and durability. Nowadays, climate change jeopardizes durability: degradation processes tend to accelerate, become more severe, and increase in time and space. In this framework, damages take the role of additional risks for existing bridges and viaducts.

Not least, increasingly around the world and in Europe, the aging of transportation infrastructure (such as bridges), which are the foundations of modern society freeways, is receiving more and more interest in the wake of the "Morandi bridge" and "Caprigliola bridge" collapse. In fact, many artifacts were built in the period after World War II up to the 1960s, years in which many European nations laid the foundations of modern highway systems, for example, in Italy the 760 km of the "Autostrada del Sole" highway system linking Milan to

DOI: 10.1201/9781003483755-335

Rome and Naples was built, in which 853 bridges and viaducts and 38 tunnels were constructed to complete the work. Nowadays, many European artifacts are reaching their nominal design life, especially there is a need to allocate resources for their assessment, repair and upgrading (see e.g. (Calvi, G.M., 2019) and (Scattarreggia, N., 2022)).

To worsen the already complex framework, the interdependence, deferred in time, between the changes that occur at the global level and those at the local level plays a crucial role. Additionally, adaptation strategies to changes, due to the socio-economic and geo-political structure that has come into being, can only be elaborated and implemented at local level and territorial scale because of the economic resources available and the importance of the individual heritage objects within the reference infrastructure networks. Thus, there is a need to develop management strategies capable of implementing the long-sought paradigm shift related to prioritizing systemic interventions based on simple parameters.

Moreover, to deal with the inherent uncertainty of bridge management due to the continuous and sudden change of boundary conditions (environmental factors, traffic, state of preservation), while respecting operational and economic constraints, it is necessary to move toward management processes establishing thresholds of accepted risk without compromising the well-being of communities. For a unified multi-parameter management, it is essential to make a paradigm shift: consider anomalies and defects affecting condition assessment like risks. That is conceptually feasible due to the randomness in space and time that characterizes climate change.

In such a way, related damages, like durability limitation and the potential impairment of safety and structural efficiency, can be treated together with damages induced by natural hazards. Moreover, based on a priori structural reliability assessments, the technical community can establish an acceptability threshold. Indeed, the growing push for sustainability calls for further reflections on the need to consider it, not only as a discriminating parameter between different maintenance options, but as a cue to devise a sustainable bridge and viaduct management strategy on a territorial scale.

For Tessin, some indicators and indexes are proposed. They measure the importance of each artifact within the infrastructure network in terms of sustainable development, at least concerning the two dimensions society and economy, without neglecting the importance of the structural aspect. The importance metric translates automatically into a scale of attention that allows prioritizing in-depth verification and/or intervention activities since the socio-economic impact of any maintenance work is clearly proportional to the importance of the artifact at the network level. After a description of the social, economic, environmental, and structural aspects considered and the indicators selected, the structure of the indexes of economic, social, and structural vulnerability importance is presented. Finally, a sort of sustainability footprint of the entire road network is shown for bridges and viaducts of the main and secondary roads in Canton Ticino.

The section further development outline the main adaptation measures that should be implemented to extend the methodology beyond the target territory (see e.g. (Mitoulis, S.A., 2021); (Stipanovic, I., 2020) and, (Gaowei, X., 2022)).

2 FROM DATA TO INDEXES: SPATIAL AND CLUSTERING CONSIDERATIONS

With the aim of quantifying the systemic importance of each artifact through a cumulative measure, three indexes were introduced namely the Social Significance Index, the Economic Significance Index, and the Structural Vulnerability Index. Defining an Environmental Significance Index would have required either to introduce a metric related to (i) Life Cycle Assessment, or (ii) to natural hazards. In the first case, that would have meant encompassing the requirement of simplicity at the basis of the developed strategy; in the second case, the inherent uncertainty on the occurrence of natural hazards is emphasized by climate change therefore its representativeness appears too weak. As a result, the Environmental dimension of sustainability was not accounted for in this study.

2.1 *Indicators*

Each index is in turn composed by indicators related to the three dimensions of sustainability and the technical dimension related to structural safety and vulnerability.

The indicators used for indexes formulation are given in Table 1.

The indicators are extrapolated from a set of data collected at the territorial level, timely updated by the Cantonal Statistical Office, and aggregated through specific weights to form significance indexes.

Table 1. List of indicators for each dimension of interest.

Dimension	Social	Economic	Environmental	Structural
Indicator	(I) Number of inhabitants (II) Distance of each bridge from the first aid facility	(I) Number of registered cars (II) Average Daily Traffic	(I) Location and level of risk associated with each natural hazard	(I) Structural scheme (II) Bridge length (III) Bridge condition assessment

2.2 *Data elaboration*

Data collected were subjected to geographical and statistical elaboration.

Clustering criteria based on regional considerations helps in determining the importance of a bridge in terms of socio-economic value through the quantification of indicator SI_1, SI_2 and EI.

For instance, the number of inhabitants that lives close to a bridge and use it to commute every day to work can be considered a measure of the economic importance of an artifact. Likewise, the number of inhabitants that lives close to a bridge also represent a measure of the social importance of the artifact that, during leisure time, represent the access to specific recreational sites or, in case of emergence, to reach first aid centers.

Statistical elaboration (descriptive statistics) of indicators and/or other collected data enables the definition of specific weightings, as explained for each significance index.

2.3 *Indexes*

As anticipated, three indexes were defined to measure the importance of a bridge, and therefore the impact of its temporary closure, within the cantonal road network.

Each index can maximum attain the unitary value and indicators are weighted by means of parameters ranging from 0.25 to 1.00.

2.3.1 *The social significance index*

Table 2. The social dimension of sustainability.

Dimension	Indicator	Description	Index
Social	SI_1	Minimum distance (as the crow flies) of each bridge from the nearest First Aid-equipped hospital.	$SSI_k = \gamma^{I,k}{}_{SI} \cdot \frac{SI_1}{max(SI_1)} + \gamma^{II,k}{}_{SI} \cdot \frac{SI_2}{max(SI_2)}$ **
Social	SI_2	Number of inhabitants belonging to the social contributory area of each artifact.	

**Where γ are the weightings, values assigned to the index based on the percentiles obtained through descriptive statistics, $\gamma_{SI}^{I,k}$ is based on the number of inhabitants per bridges.

2.3.2 *The economic significance index*

Table 3. The economic dimension of sustainability.

Dimension	Indicator	Description	Index
Economic	EI	Average Daily Traffic (ADT) value subdivided based on the automated traffic control station-artifact distance rational. For artifacts along international routes, the ADT value is equal to that of the reference station.	$ESI_k = \gamma_{EI}^{I,k} \cdot \gamma_{EI}^{II,k} \frac{EI^k}{max(EI)} \cdot \gamma_{EI}^{III,k}$ *

*Where γ are the weightings values assigned to the index based on the percentiles obtained through the descriptive statistics, $\gamma_{EI}^{I,k}$ is based on the registered cars numbers in the whole region, $\gamma_{EI}^{II,k}$ is based on the ADT and, $\gamma_{EI}^{III,k}$ is the value given to the type of configuration of the asset (series and parallels).

2.3.3 *The structural vulnerability index*

Finally, the large number of artifacts in the area and reasons for operational sustainability led to the definition of a simplified vulnerability index as a function of artifact type and length. The probability of damage occurrence was implicitly assumed proportional to the length of each artifact. In this way, a masonry bridge is less vulnerable than a viaduct responding to the structural scheme of an arch-frame artifact, and for the same structural scheme, an artifact bypassing a larger obstacle is more vulnerable (see e.g. (Sonnenberg, A., 2018) and (Thompson, P.D., 2018)).

Table 4. The structural dimension.

Dimension	Indicator	Description	Index
Structural	VI	Value of the structural vulnerability of an artifact in relation to its static type.	$SVI_k = \gamma_{VI}^k \cdot \frac{VI^k}{max(VI)}$ ***

***Where γ_{VI}^k is a weighting value based on the different static scheme per bridges.

3 BRIDGE SYSTEMIC SIGNIFICANCE AND CRITICALITY

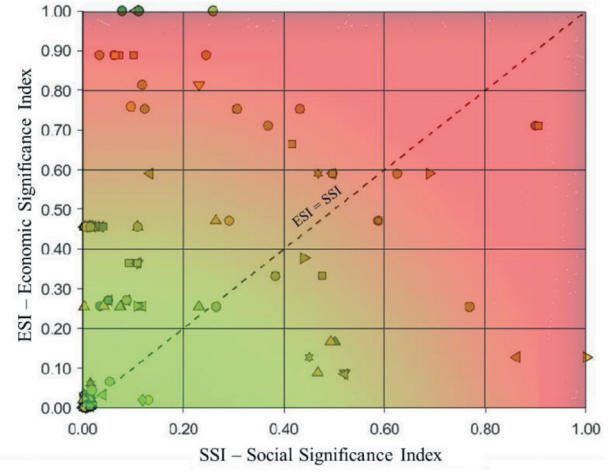
For each bridge, after the definition of the social and economic significance index, its systemic importance at the territorial scale can be defined. This requires normalizing each index against the maximum value attained along each involved dimension.

As a result, each artifact attains a precise position in a two-dimensional plane identified by the Social Significance Index (x-axis) and Economic Significance Index (y-axis). There each bridge can be represented by a point with a specific shape and color to take into account different structural typologies and artifact condition assessment, as explained in Figure 1.

If a bridge is identified by a point lying along the bisector, it means that within the cantonal road network is equally important respect to social and economic metrics. More in detail, by measuring the distance of each point from the axes 'origin, a measure of the bridge significance in the road network can be obtained.

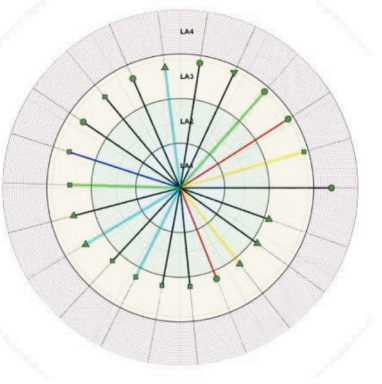
Of course, the greater the importance of a bridge – the point-origin distance –, the greater the impact of its, albeit temporary, unavailability could produce in the road network.

Conversely, in terms of sustainable development, the maximum benefit could be obtained if and only if asset managers move along the bisector first.



The bridge significance can change over time as the number of inhabitants, the traffic volume, etc. do, therefore points can roam in the SSI-ESI plane.

The plane is ideally subdivided in region that contains bridges with limited to great social and/or economic importance following a green-to-red blended chromatic scale.



Additionally, the bridge significance and its structural vulnerability index define the so-called bridge level of attention. This level of attention can be visualized in a 3D space, the so-called sustech (sustainability-technical) management space SSI-ESI-SVI, bounded by the axes of Social Significance Index, Economic Significance Index and Structural Vulnerability Index. Asset managers and decision makers can refer to this aggregate measure to define inspection priorities and diagnostic campaigns.

Given that all indexes can attain at maximum a unitary value within the network, in case of unlimited resources, asset managers will have to deal with bridges represented by points close to unpoint (1,1,1) in the space SSI-ESI-SVI as in Figure 3.

It will then be sufficient to calculate the complementary part to unit of the point(bridge)-origin distance in the SSI-ESI-SVI space to obtain for each bridge a so-called systemic level of criticality. For each bridge condition assessment class, asset managers can plot the level of criticality on a radial basis. The higher the level of criticality, the greater the attention bridge managers have to place on that specific bridge.

4 DISCUSSIONS

The systemic significance and level of criticality measures were conceived with the clear intent of considering technical and contextual aspects in a concise manner.

To validate the representativeness of the measures introduced and their soundness, a sensitivity analysis with respect to each of the indicators and weighting introduced is required.

This extensive analysis is object of a different contribution on the subject (Briccola, D., 2024) and it is not included here just for the sake of brevity.

Due to the high level of heterogeneity in bridge condition assessment, this parameter was intentionally excluded from the definition of systemic measures. However, pursuing a pure clustering approach, for each bridge condition assessment class, asset managers can plot the level of criticality on a radial basis. The higher the level of criticality, the longer the segment in the radial plot and the greater the attention bridge managers have to place on that specific bridge. The information associated with the environmental dimension (natural hazards) and structural typology appear in the radial priority diagrams by means of a chromatic and geometric code, see Figure 1b (see e.g. (Duzzi, D., 2023), (Itoh, Y., 1997) and (Y. Yang, D., 2020)).

Doing that, no information is lost, and asset managers can choose to pay attention to specific aspects from time-to-time, pursuing strategic choices (see e.g. (Frangopol, D.M., 2001)).

Moreover, considering resource constraints and policy, asset managers can fix thresholds to aggregate bridges based on their level of criticality. Once again, these thresholds are dynamic as they can change depending on resource availability subject to political strategies.

5 CONCLUSIONS

The proposed strategy for managing operations on cantonal bridges and viaducts at a territorial scale is based on a comprehensive understanding of the context and the complex variables involved, including bridge number and typology, as well as spatial and operational considerations.

The ultimate objective is to ensure that the infrastructure assets remain resilient and sustainable in the face of continuous change. The strategy considers four basic elements: economy, society, environment, and technical components, to achieve a sustainable development informed by technical aspects.

The article presents indicators and indexes to measure the significance of each artifact within the cantonal transportation network. Although these indicators are specific to the Swiss context – especially Tessin –, they can be easily extended to territories with similar orographic characteristics with valleys and few major commutation axes. The proposed strategy is agile, as it is based on timely data collection and updates, enabling managers to replan decisions to capitalize on emerging opportunities. This potential can be effectively captured by aligning it with pre-existing policies and strategies as well as available resources.

Furthermore, the proposed strategy aligns well with a predictive maintenance approach, rather than a corrective one. By projecting economic, social, environmental, and structural data for a predetermined reference time interval, a picture of the evolving importance of each artifact within the network can be obtained. Based on these results, effective choices can be made to ensure the development of resilient and sustainable infrastructures.

Expediting the bridge management practice: A structural reliability-based method

F. Brighenti, M.F. Bado, F. Poli, F. Romeo & D. Zonta
Department of Civil, Environmental and Mechanical Engineering, University of Trento, Trento (TN), Italy

J.D. Rotilio & A. Ferman
Società Autostrade Alto Adriatico S.P.A., Trieste (TS), Italy

ABSTRACT: A significant percentage of assets within the Italian national bridge stock have exceeded their nominal design service life, leading to an escalating number of structural failures over time. While it is impractical to replace all existing infrastructure, the focus has shifted to maintenance and upkeep, commonly achieved through the implementation of well-planned and prioritized maintenance interventions. To effectively manage their bridge stock, infrastructure managers thus require a prioritization tool capable of rapidly assessing the urgent need for maintenance of a particular unit. The present study introduces a novel and expeditious structural reliability model. Specifically, this model provides a comprehensive framework for evaluating risk factors related to overload and degradation, seismic response, hydraulic and landslides conditions, and a detailed formalization of the most widespread ones i.e., overload and degradation. The latter was developed to be applied to the bridges of the Italian highway operator Autostrade Alto Adriatico to enhance their stock management processes. The simplified reliability model presented in this article represents a departure from the complex and time-consuming methodologies currently employed, as it efficiently provides an informative value of Structural Reliability in a proper and expeditious manner. This expeditious approach allows infrastructure managers to promptly discern bridges in critical condition, enabling the swift detection of rapidly deteriorating structures and ensuring timely interventions to enhance user safety.

1 INTRODUCTION

The global landscape of infrastructure is undergoing a critical phase, as a substantial number of bridges have either surpassed or are on the verge of surpassing their intended design life and consequently exhibit potentially severe defects. This predicament is alarmingly widespread, with 42% of American bridges aged 50 years or more, of which 7.5% are structurally deficient, as reported by the American Society of Civil Engineers (ASCE) in 2021 (ASCE 2021). The repercussions of this aging infrastructure are dire, with approximately 178 million trips occurring daily on structurally deficient bridges, posing a significant risk to public safety. In the 2011-2021 decade, 60 bridge failures occurred worldwide (Bado & Casas 2021). This grim reality has manifested in numerous structural failures, including the tragic collapse of the Morandi Bridge in Genoa, Italy, in 2018, resulting in the loss of 43 lives (Calvi et al. 2019).

Addressing this crisis presents a formidable challenge, primarily due to budgetary constraints and the environmental and logistical complexities associated with widespread demolition and reconstruction efforts which, as observed by Regier & Hoult (2014), makes it not feasible to replace all the structures that have surpassed their intended service lives. Consequently, the most viable strategy involves meticulous assessment and strategic maintenance of the bridges still deemed serviceable (Faber 2002). Hence, the importance of determining their

DOI: 10.1201/9781003483755-336

deterioration level, serviceability performance and public safety through a series of inspections, monitoring and maintenance protocols (Bado et al. 2022).

Effective maintenance protocols are not merely about preserving the structural integrity of bridges; they are about maximizing the utilization of economic resources while safeguarding the lives of those who use these critical infrastructural assets (Chase et al. 2016, Denysiuk et al. 2016). Achieving this delicate balance requires up-to-date knowledge concerning durability, defect evolution, and structural reliability (Deng et al. 2014). This knowledge must be continuously updated through regular inspections and the extraction of key data on the asset conservation state. Timely intervention in deteriorating structures can yield significant benefits with minimal financial outlay. Critically, given the constraints of infrastructure managers' budgets, it is imperative to prioritize maintenance interventions based on a rigorous assessment of structural reliability (Frangopol 2019).

Most of the modern-day approaches to the management of bridge stocks are based on the evaluation of the bridge Condition States (Zonta et al. 2007). This one implicitly assumes that the reliability of the bridge is somehow related to the Condition State. Yet, as highlighted by Das (1996), these evaluations often overlook the direct influence of structural defects on bridge reliability and load-carrying capacity. Despite the expectation that bridges in poor structural health would exhibit lower reliability indexes, a direct correlation between the two variables is not straightforward. For instance, an old bridge can be unsafe, even if impeccably preserved, due to inadequate load-carrying capacity resulting from changes in traffic patterns. Conversely, a deteriorated bridge might still possess sufficient capacity.

In the current landscape, there are sophisticated methodologies available for the comprehensive evaluation of bridge structural reliability. However, many of these methods are time-consuming and intricate, making them less than ideal for swiftly assessing bridges in urgent need of maintenance. Infrastructure managers require rapid assessments to prioritize interventions effectively. To expedite this evaluation process and subsequently prioritize bridge maintenance interventions, this article proposes a simplified structural reliability model. This model thus enables infrastructure managers to swiftly identify bridges undergoing rapid deterioration, ensuring timely intervention and enhancing user safety.

2 STRUCTURAL RELIABILITY: ITS THEORETICAL BACKGROUND IN BRIEF

Structural Reliability, a fundamental aspect of bridge engineering, is a concept rooted in the probabilistic quantification of a bridge's safety coefficient, delineating its capacity to meet specific structural requirements (Luo et al. 2009). Central to this assessment is the Probabilistic Reliability Theory, providing indispensable methodologies for evaluating Structural Reliability and, consequently, the Probability of Failure. A plethora of practical numerical techniques has been developed, including the Monte Carlo simulation (Tonelli et al. 2023), Importance Sampling, Response Surface Approximation (Rajashekhar & Ellingwood 1993), and Moment Methods such as the First-Order reliability method (Hasofer & Lind 1974) and the Second-Order reliability methods (Hohenbichler & Rackwitz 1988, Luo et al. 2009).

It is important to note that although the First-Order method is considered one of the most efficient computational approaches for Probabilistic Structural Reliability (Luo et al. 2009), the Second-Order method is widely employed for reliability calculations and code calibration purposes as well (Melchers & Beck 2018). Typically, a structure's reliability is quantified using a Reliability Index, determined based on probabilistic data, technical models, and additional bridge-related information (Möller & Beer 2004). This Reliability Index serves as a crucial parameter used by infrastructure managers to prioritize maintenance interventions for their inventory (Zonta et al. 2007). Crucially, the Reliability Index inversely correlates with the Probability of Failure P_F, exemplifying that higher β values translate to lower collapse probabilities (Der Kiureghian & Liu 1986).

In structural reliability analysis, dealing with the computational complexities, often involves resorting to a method known as First-Order Second-Moment (Ayyub & Haldar 1984). Essentially, Second-Moment reliability methods, encompassing both First-Order and Second-Order

Methods, simplify the complexities by expressing all uncertainties related to a structure's reliability in terms of expected values (first moments) and covariances (second moments) of the input parameters (Cornell 1969, Ditlevsen 1981). This means estimating the approximate mean and variances of Z (μ_Z and ${\sigma_Z}^2$, respectively) using information derived from the means ($\mu_{x,i}$) and variances (${\sigma_{x,i}}^2$) of the fundamental random variables X_i (Ayyub & Haldar 1984). These Second-Moment methods find extensive application in reliability calculations and are instrumental in code calibration purposes as well (Melchers & Beck 2018).

Certainly, the Limit State Function is commonly conceptualized as the disparity between a system's resistance (R) and the corresponding load effect S (Denysiuk et.al. 2016), thus Z is defined by Equation (1).

$$Z = R - S \tag{1}$$

Given this perspective and assuming the uncorrelation hypothesis of R and S, a Reliability Index β can be defined using the First-Order Second-Moment Method, as outlined in Equation (2):

$$\beta = \frac{\mu_Z}{\sigma_Z} = \frac{\mu_R - \mu_S}{\sqrt{{\sigma_R}^2 + {\sigma_S}^2}} \tag{2}$$

Where the symbols μ_R, μ_S are the mean value of R and S respectively and ${\sigma_R}^2$ and ${\sigma_S}^2$ are the variance of R and S, respectively.

When assuming both R and S follow a lognormal distribution, Equation (2) can be reformulated as Equation (3) in terms of Expected Value $E[\cdot]$ akin to the formulation by Rosenblueth and Esteva (Ditlevsen & Madsen 2007).

$$\beta = \frac{E[\ln R] - E[\ln S]}{\sqrt{Var[\log R] + Var[\log S]}} \cong \frac{\ln E[R] - \ln E[S]}{\sqrt{V_R^2 + V_S^2}} = \frac{\ln \mu_R - \ln \mu_S}{\sqrt{V_R^2 + V_S^2}} = \frac{\ln \mu_R - \ln \mu_S}{V_z} \tag{3}$$

In this context, $V_R = \sigma_R/\mu_R$ signifies the Coefficient of Variation for R, $V_S = \sigma_S/\mu_S$ indicates the Coefficient of Variation for S and $V_z = \sqrt{(V_R^2 + V_S^2)}$ represents the Limit State Coefficient of Variation. Notably, the latter, encapsulates the overall uncertainty of a specific model based on Equation (1) including uncertainties in its parametrical distribution, variance, and load effects calculation methodologies, among others.

3 A NOVEL APPROACH TO THE ASSESSMENT OF STRUCTURAL RELIABILITY OF BRIDGES

In the framework of contemporary engineering practices, the assessment of structural reliability has become increasingly intricate, necessitating advanced methodologies (Luo et al. 2009). However, to streamline the evaluation process and expedite the prioritization of bridge maintenance interventions, there arises a compelling need for a swift and simplified structural reliability model. Addressing this need, this article introduces an innovative approach, streamlining the complexities inherent in the reliability assessment of bridges.

Navigating the complexities of Structural Reliability, this article delves into the intricacies of the Limit State Function, emphasizing the integral role of Reliability Index (β) in this context (Ayyub & Haldar 1984). This index, representing the difference between the resistance (R) and the load effect (S) of a structure, is pivotal in gauging reliability. The formulation of β, often derived using the First-Order Second-Moment Method, encapsulates the mean values and variances of R and S, shedding light on the reliability landscape (Ayyub & Haldar 1984). Despite the inherent challenges, this method offers a pragmatic approach, especially when dealing with lognormal distributions of R and S, enabling a nuanced evaluation of reliability

(Cornell 1969). Armed with these foundational concepts, this article introduces a simplified model for bridge structural reliability assessment, bridging the theoretical underpinnings with practical applications.

To achieve this, our novel model incorporates several simplifications and assumptions:

1. Reference Condition: A designated reference state denoted by the subscript "0."
2. Log-Normal Distributions: Resistance R and Load Effect S follow log-normal distributions: $R \sim L(\mu_R, V_R)$ and $S \sim L(\mu_S, V_S)$ respectively.
3. Resistance Coefficient of Variation: V_R of an undamaged bridge aligns with the reference code's Resistance Coefficient of Variation $V_{R,0}$, making $V_R \equiv V_{R,0}$.
4. Constant Load Effect: S remains constant according to the reference code. In fact, by selecting the most recent available code as the reference, it is implied that the traffic load on all present-day bridges irrespective of their original design code or current state of damage conforms to the specifications outlined in the reference codes., i.e., $S \equiv S_0$ (consequently $L(\mu_S, V_S) = L\left(\mu_{S,0}, V_{S,0}\right)$.
5. Uncorrelated Risk Factors: Risk factors influencing bridge reliability are considered uncorrelated.

When a bridge transitions from its reference state 0 to a generic state ≠0 due to its service life, its structural reliability varies. In this context, the reliability index of the bridge in the generic state is denoted as β, while the index for the same bridge in its just-built state, designed as per the reference code 0, is noted as β_0. Leveraging these assumptions and Assumptions 1-5 along with Equation (3), the relation between these two reliability indices can be calculated Equation (4).

$$\begin{aligned}\beta &= \frac{\ln\left(\frac{\mu_R}{\mu_{s,0}}\right)}{V_z} = \frac{\ln\left(\frac{\mu_R}{\mu_{s,0}}\frac{\mu_{R,0}}{\mu_{R,0}}\right)}{V_z} = \left\{\frac{\ln\left(\frac{\mu_{R,0}}{\mu_{s,0}}\right)}{V_z} + \frac{\ln\left(\frac{\mu_R}{\mu_{R,0}}\right)}{V_z}\right\} \cdot \frac{v_{z,0}}{v_{z,0}} \\ &= \left\{\frac{\ln\left(\frac{\mu_{R,0}}{\mu_{s,0}}\right)}{v_{z,0}} + \frac{\ln\left(\frac{\mu_R}{\mu_{R,0}}\right)}{v_{z,0}}\right\} \cdot \frac{v_{z,0}}{v_z} = \left\{\beta_0 + \frac{\ln\left(\frac{\mu_R}{\mu_{R,0}}\right)}{v_{z,0}}\right\} \cdot \frac{v_{z,0}}{v_z}\end{aligned} \tag{4}$$

The reliability index β can be computed for different risk factors based on the analysis objectives.The risk model proposed in the present article calculates a Reliability Index and the Probability of Failure P_F for the main risk factors associated with civil engineering structures: risk for Overload and Degradation (D), Seismic risk (S), Hydraulic risk (H) and Landslides risk (L). Furthermore, under the Assumption 6, the risk factors can be combined in order to extract a unique value of Total Probability of Failure P_F as in Equation (5).

$$P_F = P_{F,D} + P_{F,S} + P_{F,H} + P_{F,L} = \phi(-\beta_D) + \phi(-\beta_S) + \phi(-\beta_H) + \phi(-\beta_L) \tag{5}$$

In the present article the authors proceed to showing only the calculation-modus-operandi of $P_{F,D}$, commonly the most impactful and widespread risk. The Overload and Degradation Risk encompasses two core components: Overload risk linked to different codes than the reference one, leading to varying Traffic Loads, and Degradation risk, representing capacity reduction due to structural defects. The Overload and Degradation Risk sees the above two risks combined into one, in light of the fact that they both have a direct influence on the Carrying Capacity of a bridge.

Before delving in the extrapolation of $P_{F,D}$, it should be kept in mind that, whenever dealing with any of the above introduced risks, additional uncertainties beyond mathematical modeling $V_{z,0}$ come into play, denoted as ΔV_z. These uncertainties arise from variations in the bridge's state from its reference condition, persistently increasing over time.

Indeed, whenever mathematical modelling uncertainties are the only ones being discussed – as in the previous section – the overall uncertainty V_z coincides with $V_{z,0}$ i.e., $V_z = V_{z,0}$ (which fundamentally is $V_z = \sqrt{V_{z,0}^2}$). Whereas when other uncertainties are present, then the overall

uncertainty V_z can be expressed as $V_z = \sqrt{\left(V_{z,0}^2 + \Delta V_z^2\right)}$. The parameter ΔV_z represents the variation of uncertainty arising whenever a divergence of the state of the bridge from its reference condition. Considering that a variation of the state occurs from the first moment that the bridge is built (environmental factors, constant use, etc.), this one is always positive.

In light of the fact that both degradation and overload are inherently correlate as both impact the Carrying Capacity of a bridge, they are unified into a single Uncertainty Variation ΔV_z and Reliability Index β_D.

4 MATHEMATICAL FORMULATION FOR ASSESSING THE OVERLOAD AND DEGRADATION RELIABILITY OF BRIDGES

The authors will now guide you through the steps to derive the mathematical formulation of β_D. Starting with the undamaged state of a bridge and Equation (4), we'll now express the $\ln \mu_R$ and $\ln \mu_{R,0}$ terms. To achieve this, we employ the fractile or lower/upper percentile of order 5% related to the log-normal probability distribution of the Resistance evaluated against its median value $R_{50\%}$ utilizing Equation (6) (Melchers & Beck 2018).

$$\ln R_k = \ln R_{50\%} - 1.645 * V_R \tag{6}$$

Here, the characteristic value of the Resistance R_k is equal to $R_{d,U} * \gamma_R$, where $R_{d,U}$ denotes the Design Resistance of a bridge in its undamaged condition, and γ_R signifies the Resistance Safety Coefficient. Based on Assumption 3, Equation (6) and the system in Equation (7), we can deduce the mean value of Resistance $\ln \mu_R$, as follows:

$$\begin{cases} \ln R_{50\%} = \ln R_{d,U} + ln\gamma_R + 1.645 * V_R \\ ln\mu_R = lnR_{50\%} + \frac{V_R^2}{2} \end{cases} \rightarrow \ln \mu_R = \ln R_{d,U} + \ln \gamma_R + 1.645 * V_R + \frac{V_R^2}{2} \tag{7}$$

Note that, the same equation can be formulated for the reference condition 0 (in terms of $R_{d,0}$, $\gamma_{R,0}$ and $V_{R,0}$). On the grounds of Equations (4) and (7) and Assumption 6, the difference between the two Reliability Indexes can be evaluated as per Equation (8).

$$\beta_D = \left\{ \beta_{D,0} + \frac{\ln\left(\frac{R_{d,D}}{R_{d,0}}\right)}{V_{z,0}} \right\} \cdot \frac{v_{z,0}}{v_z} = \left\{ \beta_{D,0} + \frac{\ln\left(\frac{R_{d,D}}{R_{d,0}} \cdot \frac{R_{d,U}}{R_{d,U}}\right)}{V_{z,0}} \right\} \cdot \frac{v_{z,0}}{v_z} = \left\{ \beta_{D,0} + \frac{\ln\left(\frac{R_{d,D}}{R_{d,U}} \cdot \frac{R_{d,U}}{R_{d,0}}\right)}{V_{z,0}} \right\} \cdot \frac{v_{z,0}}{v_z} \tag{8}$$

Let's consider the known effects of (1) Permanent Load G, (2) Traffic Load calculated according to the reference code $Q_{d,0}$, and (3) Traffic Load calculated using a specific outdated code $Q_{d,U}$. Based on these factors, the following extrapolations can be made:

- $R_{d,\mathrm{D}} = G + Q_{d,\mathrm{D}}$ representing the Resistance of a bridge in its damaged condition;
- $R_{d,0} = G + Q_{d,0}$ representing the Design Resistance calculated according to the reference code;
- $R_{d,U} = G + Q_{d,U}$ indicating the Design Resistance calculated based on an outdated code and, significantly, in its undamaged state. It's essential to note that this value aligns with the Resistance of the bridge in its newly constructed state, reflecting the construction standards of the past years;
- $I = Q_{d,U}/Q_{d,0}$ denoting the Performance Index. Generally, if we consider the more recent code as the reference, then $I < 1$. This is because modern-day reference traffic loads tend to be more conservative than their outdated counterparts.

Given these considerations, the authors now delve into the $R_{d,U}/R_{d,0}$ ratio presented in Equation (8). This ratio signifies the potential Resistance deficiency of a bridge solely due to

its design with an outdated code compared to the reference one. Referred to as the Capacity Index C, it can be elaborated as per Equation (9).

$$\frac{R_{d,U}}{R_{d,0}} = \frac{1 + \frac{Q_{d,U}}{G} * \frac{Q_{d,0}}{Q_{d,0}}}{1 + \frac{Q_{d,0}}{G}} = \frac{1 + \frac{Q_{d,U}}{Q_{d,0}} * \frac{Q_{d,0}}{G}}{1 + \frac{Q_{d,0}}{G}} = \frac{1 + I * \frac{Q_{d,0}}{G}}{1 + \frac{Q_{d,0}}{G}} = C \tag{9}$$

Now, let's shift our focus to the damaged state of a bridge. In this scenario, Equation (8) not only includes the $R_{d,U}/R_{d,0}$ ratio (representing the undamaged condition) but involves also a new ratio, $R_{d,\mathrm{D}}/R_{d,0}$ (D for damaged condition). This definition therefore encapsulates both the impact of overload and damage on the Carrying Capacity of the bridge. This ratio can be expressed as $R_{d,D}/R_{d,0} * R_{d,U}/R_{d,U} = R_{d,D}/R_{d,U} * R_{d,U}/R_{d,0}$.

Whilst the $R_{d,U}/R_{d,0}$ ratio has already been defined as the Capacity Index C, the $R_{d,D}/R_{d,U}$ ratio represents the Resistance deficiency of a bridge solely due to the presence of damage. This ratio is now referred to as the Damage Index $D \in (0, 1)$. It's important to note that this index can be calculated in various ways, such as through meticulous static calculations or simulations, predefined reduction values linked to different damage levels, visual inspections, instrumental damage diagnosis, and so on.

Considering these factors, Equation (8) can be reformulated as Equation (10). Equation (10) incorporates both D and C, reflecting the bridge's state transition.

$$\beta_D = \beta_{D,0} + \frac{\ln\left(\frac{R_{d,D}}{R_{d,0}}\right)}{V_{z,0}} = \beta_{D,0} + \frac{\ln\left(\frac{R_{d,D}}{R_{d,U}} * \frac{R_{d,U}}{R_{d,0}}\right)}{V_{z,0}} = \beta_{D,0} + \frac{\ln(D * C)}{V_{z,0}} \tag{10}$$

As previously mentioned, the variation of the state of the bridge versus its initial/reference condition 0 (integrated through D and C), inevitably brings along an increase in uncertainty. This needs to be accounted for in terms of reliability. In particular, the output of Equation (10) needs to be decreased of an amount equivalent to the increase in uncertainty i.e., the ratio $V_{z,0}/V_z \in (0, 1)$, as in Equation (11).

$$\beta_D = \left\{\beta_{D,0} + \frac{\ln(D * C)}{V_{z,0}}\right\} \frac{V_{z,0}}{V_z} \tag{11}$$

Finally, incorporating the Overload and Degradation Reliability Index β_D, Equation (12) calculates the Probability of Failure $P_{F,D}$ using the standard normal cumulative distribution function:

$$P_{F,D} = \phi(-\beta_D) = \phi\left(-\left\{\beta_{D,0} + \frac{\ln(D * C)}{V_{z,0}}\right\} \frac{V_{z,0}}{V_z}\right) \tag{12}$$

Note that, being the Reliability Index calculated for both the bending limit state M and the shear one V, the overall Overload and Degradation Reliability Index β_D is assumed as their minimum: $\beta_D = \min(\beta_{D,M},\ \beta_{D,V})$.

Nonetheless, being the reference period of the model 50 years, the degradation over this time should be taken into account as well. The approach can be integrated with a sophisticated degradation model rooted in Markov Chains (Ayyub & Haldar 1984), offering a nuanced depiction of the evolution of the parameters associated with structural defects. In this framework, the pivotal element of the Markov Chain is encapsulated in Transition Matrixes T, delineating the likelihood of maintaining the current state on the diagonal elements and the probabilities of transitioning to subsequent states on the elements external to the diagonal, facilitating a robust foundation for projecting the system's behavior.

The evolution of the defect can therefore be dynamically captured by iteratively modifying the Transition Matrix T through matrix multiplication, leading to the derivation of state

probability vectors which, in turn, crystallizes the likelihood of specific states of degradation after a defined temporal interval (Ayyub & Haldar 1984). Crucially, the methodology accommodates scenarios where the defect is both present and absent during the initial inspection, forming a nuanced narrative of the defect's evolutionary trajectory over time.

Key structural parameters, namely the weighted average value of Damage Index D_i, the coefficient of variation $V_{z,i}$ in consideration of such weighted average value of Damage Index, and Reliability Index for a return period of 1 year $\beta_{D,01}$, can then be extracted from the state probabilities, offering a dynamic portrayal of the structural system's health at any given i-th year. The temporal descent of D_i underscores the structural deterioration over time, while the ascent of $V_{z,i}$ is emblematic of evolving uncertainties in the model projection and defect degradation. Reliability Index $\beta_{D,01}$ is discerned for the undamaged reference state with a 1-year return period through meticulous consideration of Poisson processes (Ayyub & Haldar 1984), laying the groundwork for computing the Probability of Failure $P_{F,D,i}$ at various time horizons, encompassing all conceivable status of defect during the initial inspection. This meticulous procedure culminates in the creation of a robust matrix of projected collapse probabilities, enriching the understanding of the structural system's resilience.

This innovative approach not only simplifies the complex task of structural reliability assessment but also provides a comprehensive framework for evaluating multiple risk factors, paving the way for efficient and informed bridge maintenance strategies.

5 CONCLUSIONS

The global scenario of aging bridges poses an intricate challenge, with many of these structures exhibiting potentially severe defects as they approach or surpass their nominal design life. The impracticality of replacing all these structures underscores the necessity for an alternative approach: preserving the assets still functional through judicious, scheduled maintenance interventions. Achieving this preservation imperative hinges on a nuanced understanding of bridge performance, specifically in terms of structural reliability.

Modern strategies for managing bridge stocks predominantly rely on the evaluation of bridge Condition States, a method that erroneously assumes a direct relationship between these states and structural reliability. This oversimplification obscures the actual impact of structural defects on bridge reliability and load-carrying capacity. For instance, an aging bridge, even if meticulously preserved, can be perilous if its original load-carrying capacity no longer aligns with contemporary traffic demands. Conversely, a deteriorating bridge might possess adequate capacity, complicating the evaluation further.

In response to this complexity, a myriad of intricate methodologies have emerged for comprehensive bridge structural reliability assessments. However, not all of these methodologies are conducive to swift application. Addressing this gap, our article presents a groundbreaking solution: a simplified structural reliability model. This innovative model integrates crucial risk factors such as Overload, Degradation, Seismic, Hydraulic, and Landslides, focusing primarily on Overload and Degradation—the two most widespread risk factors. Crucially, our model incorporates an element of uncertainty inherent in the assumed model and the presence of Overload and Degradation, providing an extensive understanding of structural reliability.

The simplified reliability model represents a departure from the nowadays complex and time-consuming methodologies, as it is able to provide an informative value of Structural Reliability in a proper and expeditious manner. On the grounds of such swift reliability assessment, this model empowers infrastructure managers to swiftly identify bridges undergoing rapid deterioration. This timely identification ensures interventions occur promptly, significantly enhancing user safety and safeguarding critical infrastructure assets.

Development of a bridge rating tool for optimised multi-hazard life-cycle-based maintenance

M. Calò, N. Scattarreggia, G. Mucedero & R. Monteiro
IUSS – School for Advanced Studies, Pavia, Italy
RESISK s.r.l., Pavia, Italy

ABSTRACT: Providing and maintaining a resilient and sustainable transport infrastructure is a main priority nowadays for a solid economic development. While infrastructure plays an important role in the economies of most countries, it also represents a considerable cost. The financial consequences of neglecting maintenance are often only seen in terms of reduced asset life and premature asset replacement expenses. However, more importantly, neglecting maintenance implies increased costs of operating facilities and waste of financial resources when failure/out-of-service occurs. In Italy, recently observed bridge collapses have put pressure on management authorities to set up procedures for prioritisation of asset maintenance, that led to the introduction in 2020 of specific guidelines on risk classification and management, safety assessment and monitoring of existing bridges. However, because of the qualitative description of the risk foreseen by such guidelines, management entities are not able to produce fine-grained prioritisation rankings of bridges within a network. This paper presents the development of a bridge rating application, using C# language, integrating the results of guideline-based rankings with those obtained through available or newly proposed risk-based quantitative methods. The goal is to provide operational support to the relevant bridge management stakeholders, with more refined prioritisation rankings that become particularly helpful when dealing with large bridge stocks.

1 INTRODUCTION

Bridges play a crucial role in infrastructure systems, and their interruption or failure can result in not only loss of life but also significant economic and traffic disruptions. In Italy and many other countries, the backbone of the existing road infrastructure was constructed after World War II, meaning that numerous bridges are now over 50 years old. Recent failures like the collapse of the Morandi bridge in Genoa (Calvi *et al.* 2019) and the multi-span arch bridge between Albiano Magra and Caprigliola (Scattarreggia *et al.* 2022) have raised concerns, prompting the need for assessment and, if necessary, intervention. However, in a resource-constrained world, it is essential to adopt a rational approach to determine which bridges require further analysis.

Detailed safety assessments of bridges can be performed using current code-based methods, potentially revealing the need for structural retrofitting or replacement, but their application is highly demanding for large-scale assessment. This situation has emphasized the need to find rapid techniques to assist in evaluating large portfolios of bridges. Consequently, there have been recent efforts to develop practical risk assessment methods, such as those proposed by (Bertola and Brühwiler 2023; Meoni *et al.* 2023; Zizi *et al.* 2023; Abarca *et al.* 2023), following similar studies conducted in past decades (e.g., Castorani *et al.* 2011). Despite substantial progress in bridge evaluation, particularly in assessing damage and deterioration in many countries, Italy has only recently introduced guidelines (Ministry of Infrastructure and Transportation 2020) for a unified and effective approach to manage existing bridges. However, these guidelines may conflict with the procedures of the main bridge management entities (e.g., ANAS, RFI), which are now required to adopt the national guidelines.

DOI: 10.1201/9781003483755-337

The Italian guidelines use a multi-level, multi-hazard approach for assessing the risk of existing bridges, considering various hazards such as structural, seismic, landslide, and flooding. They take on the challenge of addressing the issues concerning existing bridges by employing a comprehensive approach that involves multiple levels of assessment. Indeed, this method begins with regional-scale risk evaluations, which rely on a qualitative assessment of bridges. It then proceeds to establish rules for conducting more detailed assessment procedures. Importantly, this approach takes into account various types of hazards arising from structural vulnerabilities and the surrounding environment. This leads to the assignment of an overall class of attention (CoA) and results in a qualitative assessment and categorization into five main classes. As a result, the primary drawback of these guidelines is their qualitative nature, making it challenging to rank bridges falling within the same CoA, unlike quantitative methods.

This paper presents the development of a bridge rating application, using C# language, used to store bridge data collected over time, which is employed to evaluate the CoA according to the current Italian guidelines. The web application provides the capability to arrange and verify data, conduct queries, process information, and present the results visually. The post-processing enabled by the tool permit to analyse the outputs from different viewpoints, thus better plan maintenance interventions. Additionally, the tool is integrated with a recently proposed risk-based quantitative indicator proposed by Hamidpour *et al.* 2023 to operationally support relevant bridge management stakeholders, with more refined prioritisation rankings that become particularly helpful when dealing with large bridge stocks to facilitate the decision-making process. This permits to overcome the limitations of the Italian Guidelines, which, relying on five classes of attention, need to be integrated with additional parameters. For instance, the introduction of a defect index related to gravity/traffic loads (the most relevant hazard as per the Italian Guidelines) enables the planning of maintenance interventions to groups of bridges with the same issues, rather than addressing each bridge individually according to their relative importance. An approach based on clusters of bridges sharing similar types of defects, albeit with varying degrees of extent and severity, helps minimizing both economic and social costs.

A case-study stock of thirty real bridges located in northern Italy is analysed using the developed web tool application. Although the primary objective is to provide a description of the platform that permits to organise recorded data and monitor deadlines, it is also used here to derive the multi-hazard risk classification, in a digital format, according to the recently issued Italian Guidelines. Furthermore, the developed tool permits to carry out priority sub-rankings through vulnerability indicators, taking advantage of the required input data (thus readily available) for the Italian Guidelines application.

2 ADOPTED RATING METHODS

2.1 *Italian Guidelines*

The 2020 MIT Guidelines propose a multi-level and multi-component approach that classifies bridges in risk categories through the processing of qualitative metrics, specific to each of the considered hazards: a) structural/foundational; b) seismic; and c) flood/landslide. The framework foreseen by the Italian Guidelines for the derivation of the Class of Attention (CoA) is briefly summarized in the following steps:

- Data Collection: Gather comprehensive data about the bridge, including its design, construction materials, historical records, and past inspection reports;
- Visual Inspection: Perform visual inspections of the bridge to identify any visible defects or damage. This includes assessing the condition of various components, such as piers, girders, abutments, joints, and superstructure. Report of the extent and severity of damage, corrosion levels, and any signs of distress;
- Data Assessment: Evaluate the collected data and analyse it in accordance with predefined criteria and thresholds set by the Italian Guidelines;
- Classification: Based on the assessment results, classify the bridge into one of several predefined classes of attention, namely High (H), Medium-High (M-H), Medium (M), Medium-Low (M-L), and Low (L), indicating the level of attention that must be given to a bridge for a

specific hazard. Finally, using logical models, the final CoA is derived from the CoA for each hazard.

Particularly, the procedure that leads to the identification of the CoA is divided in the three well-known main components of risk: a) hazard; b) exposure; and c) vulnerability, each of which being assigned one of the five possible attention levels. This is done by processing qualitative characteristics of each bridge and road to which it belongs using a specific set of tabular values and according to logic trees. These guidelines have been recently analysed and evaluated by Santarsiero *et al.* (2021), where a thorough summary of the entire classification methodology is presented.

2.2 *Index for quantifying the Vulnerability under Gravity loads (V-G)*

The vulnerability index for Gravity loads (V-G) is herein introduced for a refinement of the prioritization carried out using the Italian Guidelines. It is derived from the risk-based assessment method proposed by Hamidpour *et al.* 2023, which employs a quantitative priority ranking (PR) model that, in a simplified manner, through a weighted average, combines vulnerability (V), exposure (E), and hazard (H) indicators. Consequently, quantitative risk-based scores are derived for each bridge and can be used to identify prioritization schemes. While interested readers are referred to the work by (Hamidpour *et al.* 2023), a brief overview is given for what concerns the main assumptions behind the definition of the vulnerability component of interest for the present study.

The vulnerability (V) is calculated according to Equation (1), which is composed of two primary subcomponents: one representing the "as-built" vulnerability based on the structural characteristics (V_{Str}),and the other representing the vulnerability associated to damages and defects reported in the bridge elements (V_{Def}). The consideration of defects either due to construction errors (see e.g., Pinho *et al.* 2023) or deterioration over time due to ageing (see e.g., Scattarreggia *et al.* 2021) is of high relevance to the quantification of the residual capacity and structural performance of existing bridges. V_{Str} is essentially determined based on the parameters foreseen by the Italian guidelines described in §2.1 (e.g., year of construction, static scheme, number of spans, etc.), while V_{Def} is assessed using the procedure adopted in the Unit Kingdom (UK) for the definition of a Bridge Condition Index (BCI) with some modifications. Particularly, the UK method categorizes bridge defects into two conditions for each bridge: the average defect condition (herein identified as *Avg. Def.*) and the critical defect condition (herein identified as *Crit. Def.*). The assessment based on *Avg. Def.* defines the overall condition of the bridge based on all its damaged and undamaged elements, whereas the one that uses *Crit. Def.* associates the extremely poor condition of a specific element that holds significant importance in the overall structural integrity of the bridge. The latter is the one foreseen in a qualitative manner by the Italian Guidelines. As a result, V_{Def} can be either defined considering *Avg. Def.* or *Crit. Def.* to take into account the condition of the bridge. It is worth mentioning that V_{Def} is defined as the reverse of the BCI and is normalized to the range (0,1).

$$V = \sqrt{\frac{V_{Str}^2 + V_{Def}^2}{2}} \tag{1}$$

This study is focused on the quantification of the damage/defects for planning future interventions and the subsequent overall vulnerability. The BCI is determined by considering the severity and extent of damages observed in the bridge components during visual inspections, as well as the importance of elements. To be able to adopt the UK BCI method using the available information provided by the application of the Italian Guidelines, the equivalences given in Table 1 are adopted with the Italian Guidelines for what concern the score of the damage extent and severity.

Furthermore, the Italian guidelines assign a weight (G) to each type of damage, ranging from 1 to 5, which represents the severity of damage, considering the bridge construction material. This aspect is not covered by the UK-BCI method. For instance, in reinforced concrete elements, reinforcement corrosion (G=5) and broken brackets (G=4) are regarded as more severe damage types than active moisture stains (G=3), detachment of the concrete cover (G=2), or spider web cracks (G=1). Accordingly, Hamidpour *et al.* 2023 proposed to

Table 1. Equivalence adopted for damage extent and severity between Italian Guidelines and UK – BCI method.

ITA-Guidelines (k_1)	UK-BCI	ITA-Guidelines (k_2)	UK-BCI
0.2	C	0.2	2
0.5	D	0.5	3
1.0	E	1.0	4

incorporate this parameter into the UK-BCI damage assessment process by multiplying the damage weight ratio (G/5) by the damage severity score, k_2. This adjustment helps to account for the varying importance of different damage types based on their relative significance. Finally, the UK-BCI method foresees importance factors for elements under gravity loads, which are herein adopted as reported in by Hamidpour *et al*. 2023.

3 BRIDGE RATING WEB TOOL

The main purpose of the web-service application in C# language and developed with Microsoft Visual Studio is to provide an easier interface for an operational support to stakeholders having access to a more refined prioritization ranking. In addition, the tool is capable of collecting and computing future interventions within the portfolio of bridges based on the inspections conducted and the observed level of degradation. This aspect is related to life-cycle–based maintenance of bridges, which is beyond the scope of this study hence is not discussed in this paper.

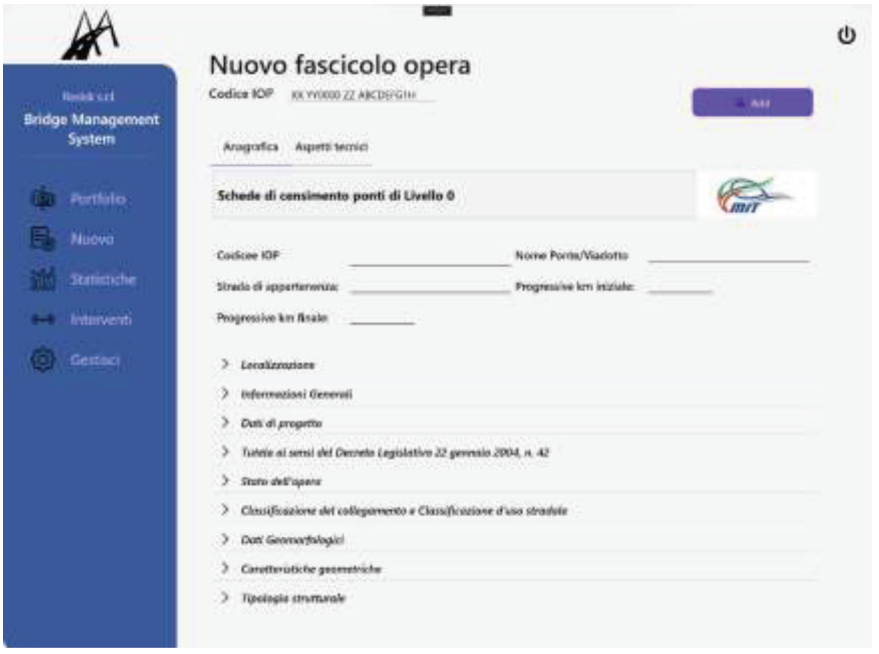

Figure 1. Main interface web-tool interface. Sample of information required for level 0 and 1 of the Italian Guidelines.

The main input data primarily focused on the first three levels of the Italian Guidelines is illustrated in Figure 1, including level 0 (gathers available data for individual bridges from design documents and results of periodic inspections), and level 1 (site inspection outcomes to verify the current state of degradation and the possibility of having structural and non-structural components affected by serious defects).

For what concerns Level 2, for each bridge, the information collected through Levels 0 and 1 will be used to consider risks taking into account hazard, vulnerability and exposure of the related structural vulnerabilities and the surrounding environment, as: (i) structure-foundations, (ii) earthquakes, (iii) flood related, and (iv) landslide related. When the information is combined, a total class of attention (CoA) of the bridge under examination is assigned (Figure 2). Based on such assignment, bridge owners can take appropriate measures spanning from normal periodic inspection to more detailed safety assessment.

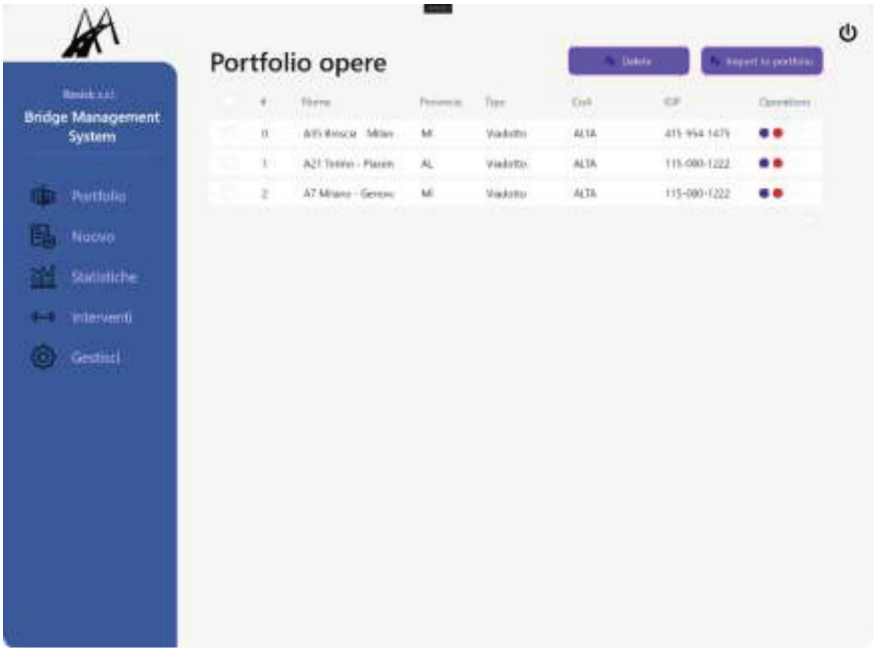

Figure 2. Example of portfolio after the user have completed the input data: the Class of Attention (CoA) is automatically determined for each bridge.

Based on the qualitative approach of the Italian guidelines, several bridge structures may have the same CoA, which makes it difficult to establish a rational decision-making process for determining the priority of bridges for further assessment or intervention. For this reason, the vulnerability indicator introduced above has been considered of interest and implemented in the tool to increase the resolution of priority among bridges belonging to the same CoA, while posing high priority to the health condition under gravity loads as recommended by the current Italian Guidelines.

4 CASE-STUDY BRIDGE STOCK

The risk assessment of thirty highway viaducts and overpasses situated in the northern Italy, described in Hamidpour *et al.* 2023, is used here to illustrate the tool. Figure 3 provides an overview of the key characteristics of these bridges obtained from the analysis of the data collected using the web platform. The data pertaining to the structural and geometric attributes of the bridges, as well as details about defects and damages, was gathered through visual inspections. In addition to this information, data regarding the geotechnical properties and potential hazards at the bridge sites was also collected. Expert teams conducted these assessments in accordance with the aforementioned Italian guidelines.

The collected bridges were predominantly constructed between the 1960s and 1990s, feature a straightforward design with a supported deck system comprising steel girders and a concrete

slab. Many of the bridges have multiple spans with either constant or varying lengths, with the largest span usually of 25 m, with two of them reaching up to 50 m. The total length of the bridges varied from approximately 15 to 125 m. The bridges are positioned alongside major roadways that typically carry an average daily traffic volume exceeding 25,000 vehicles.

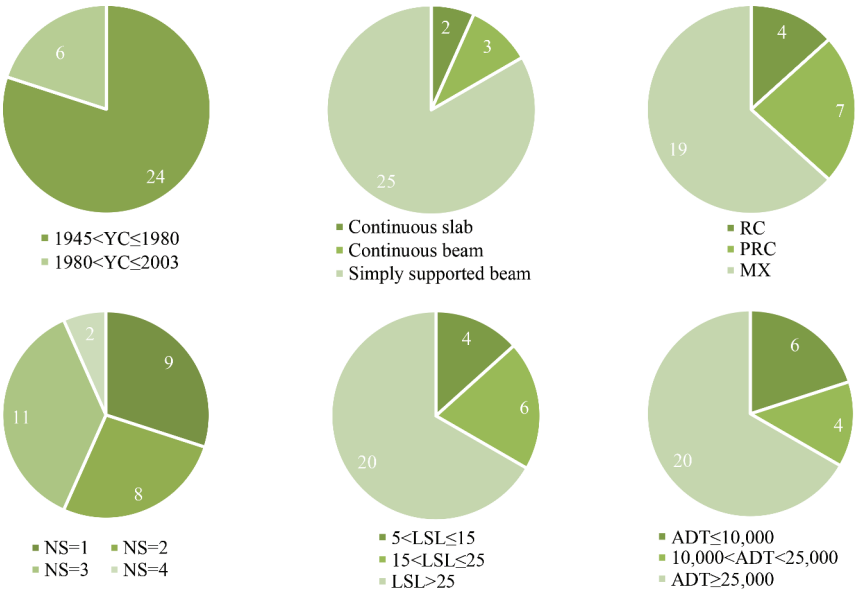

Figure 3. Main features of the analysed case-study bridge stock.

5 PRIORITIZATION RESULTS

5.1 *Application of Italian Guidelines*

The case-study stock was analysed by means of the developed tool and the obtained results, in terms of initial data post-processing, are illustrated in Figure 4. In what follows, the state of conservation of the bridges is analysed distinguishing the typical damages for element groups, as well as the severity. Following the analysis of defects, the total CoA and its disaggregation per hazard is presented. Finally, the derivation of the Vulnerability index for Gravity loads (V-G), described in §2.2, is used to produce sub-priority rankings among bridges that belong to the same CoA.

State of conservation

Figure 4 statistically represents the collected data concerning defects and damages observed in the case-study bridges. The chart displays the frequency of the most severe damages for different bridge components, along with their corresponding weights (G) based on the Italian Guidelines specifications. Among the observed damages, corroded bars were mostly found in piers, reinforced concrete girders, abutments, and slabs. According to the ITA-Guidelines, steel bar corrosion is classified as the most severe type of damage in reinforced concrete elements, with a rating of G=5. On the other hand, steel girders were more frequently affected by corrosion (G=4) and oxidation (G=2), while bearings primarily suffered from oxidation. With the statistical analysis of this data, automatically produced by the tool, bridge operators can have an idea of how the analysed bridges are in terms of state of conservation. The data will also serve as one of the inputs for the derivation of the Classes of Attention for each hazard.

Class of Attention (CoA)

Figure 5 shows the Classes of Attention (CoA): Low, Medium-Low, Medium, Medium–High, and High, obtained from the application of the Italian Guidelines to the analysed bridge stock. As presented in Figure 5-a) the majority of bridges belong to the High CoA. Particularly, the disaggregation of results in terms of hazard shown in Figure 5-b) indicate

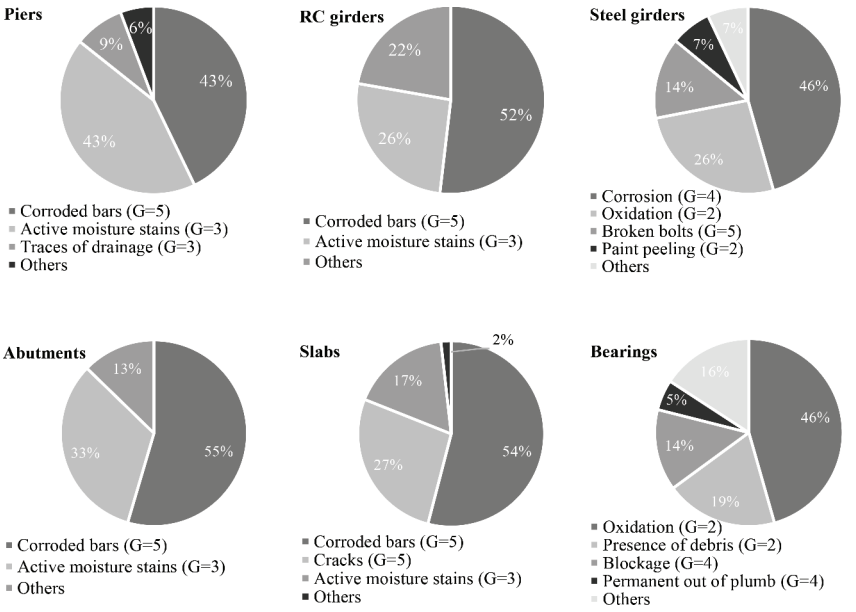

Figure 4. Defects scheduled for main bridge components.

that most of the bridges in the high total CoA are due to the high structural/foundational CoA. Notwithstanding, decision-makers experience difficulties to identify high priority cases due to the grouping of large number of bridges in a single CoA. The problem is likely even more serious when increasing the number of bridges within a stock. The vulnerability indicator previously described is therefore introduced in the following section to derive priority sub-ranking in each CoA to assist decision-makers in planning further actions.

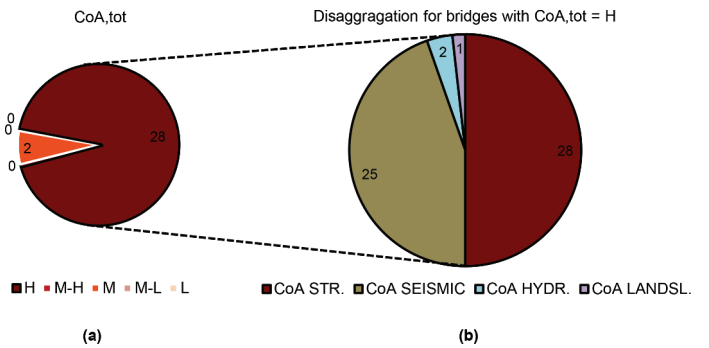

Figure 5. (a) Total Class of Attention ($CoA_{,tot}$) and (b) CoA for each hazard for bridges with HIGH $CoA_{,tot}$.

5.2 *Prioritization refinement using the Vulnerability index for Gravity loads (V-G)*

In a similar fashion to the scheme followed for the application of the Italian Guidelines, the V-G index is defined for each bridge and a priority ranking based on this indicator is derived. Considering the prioritization schemes given by the Italian Guidelines that group bridges in five classes, this indicator is used to obtain sub-ranking for bridges belonging to each CoA. According to Hamidpour *et al.* 2023, the V-G index has been calculated for each bridge by using the two conditions of deterioration for the definition of vulnerability associated to defects, both average and critical. Figure 4 presents the analysis and further post-processing results, which highlight that many bridges among those analysed present similar indicators aside of the defect condition used for the definition of the vulnerability implying a uniform

condition of conservation/deterioration of the bridge. On the other hand, cases where the vulnerability due to the critical defects is much higher than the one associated to the average condition imply that localised defects are responsible for a potentially higher vulnerability. Finally, the ranking of bridges belonging to the High CoA has been produced ordering structures from the most to the less critical according to the vulnerability that accounts for the critical defects condition. Consequently, a comparison between the V-$G_{,crit}$ and V-$G_{,avg}$ clearly shows that, depending on the indicators used to produce the ranking, the priority order may change. Still, considering that the proposed method is applied to bridges that belong to a pre-identified CoA according to the Italian Guidelines, the results do not invalidate the overall conclusion foreseen by the legally binding guidelines.

6 CONCLUSIONS

The developed bridge rating web application utilizing C# language marks a significant step towards enhancing bridge management processes. It can collect data and guide future interventions of the portfolio of bridges based on conducted inspections and the given level of degradation for their optimal management over time. The feature related to the large-scale risk assessment of bridge portfolios by means of simplified methods is given particular attention. To this end, the developed tool combines guideline-based rankings, namely the Italian Guidelines, with a vulnerability indicator incorporating deterioration considerations through a risk-based quantitative method available in current literature. The integration of diverse metrics offers a more comprehensive evaluation of bridge conditions and assists in the refinement of risk assessment of bridges belonging to the same Class of Attention (CoA), ultimately empowering stakeholders involved in bridge management. By analysing the stored data, the tool automatically assesses the CoA and the corresponding vulnerability indicator under gravity loads of each bridge within the considered stock. As result, the inclusion of the vulnerability indictor permits to increase the resolution of priority among bridges belonging to the same CoA highlighting their relative priority, while posing high attention to the vulnerability under gravity loads as recommended by the current Italian Guidelines. Finally, a case-study of thirty real bridges has been analysed to show the potential of the developed tool with its implemented methods of providing operational support to the relevant bridge management stakeholders, with more refined prioritisation rankings that become particularly helpful when dealing with large bridge stocks.

Enhancing bridge monitoring through supervised anomaly classification

I. Bayane, J. Leander & R. Karoumi
Structural Engineering and Bridges, KTH-Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: Bridge monitoring is a useful tool for alerting to changes in behavior and supporting informed bridge management decisions. However, the triggering of alerts is often based on predefined thresholds, which results in incomplete anomaly detection, leading to excessive false positives or negatives. This highlights the need for an efficient anomaly detection approach adapted to bridges. This paper presents a supervised classification framework for detecting and classifying anomalies in bridge monitoring data. The framework involves labelling data from existing datasets and training a classification algorithm to detect similar anomalies in new measurements. The focus is on strain measurements labelled using a predefined time series taxonomy, as illustrated by a case study of a bascule railway bridge. The framework demonstrates high accuracy in detecting and classifying anomalies, making it easy to identify their causes. It triggers alerts only when necessary and provides a reliable method for detecting changes in behavior.

1 INTRODUCTION

Recent technological advances have given rise to data-driven methods for bridge management exploiting the latest innovations in sensors, data processing, high-speed internet, and cloud computing, which makes bridge monitoring increasingly complementing traditional inspection methods. Within this context, new techniques are being developed to process monitoring data and finding patterns that deviate from expected behavior, to help identify potential damage and assess bridge behavior.

The detection of patterns in data that are inconsistent with expected behavior is called anomaly detection, and the inconsistent patterns are called anomalies. Anomaly detection in time series has received considerable attention in various fields including computer science, the stock market domain and medical applications (Mejri et al.). However, in civil engineering, research on anomaly detection and classification in monitoring data remains limited. Current research focuses mainly on the use of numerical modelling (Ghiasi et al.) and laboratory experiments (Li et al.) for this purpose, with limited validation at full scale. Uncertainties in numerical simulations and questions about the transferability of laboratory results to real-world scenarios pose challenges in applying knowledge to full-scale case studies. Bridging this gap requires the exploration of field data, which is challenging in the absence of labelled datasets.

To address this challenge, the study suggests the use of anomaly taxonomy and monitoring data to generate labeled datasets for training and testing. The established anomaly taxonomy for time series, originally designed for evaluating anomaly detection algorithms, provides a broad classification of anomalies across various domains (Choi et al.; Golmohammadi and Zaiane; Lai et al.; Yu et al.). This taxonomy, discussed by Choi et al. (2021), categorizes anomalies into three main types: point, contextual, and collective outliers. An updated taxonomy by Lai et al. (2021) further distinguishes between point outliers (comprising global and contextual outliers), and pattern outliers (including trend, shapelet, and seasonal outliers).

DOI: 10.1201/9781003483755-338

Based on this defined taxonomy, this paper proposes a framework for supervised classification of anomalies in bridge monitoring data, providing guidance for the creation of synthetic datasets for training and testing. This study focuses on strain measurements due to their local and direct sensitivity to damage. Emphasis is placed on monitoring data during loading events, which include train passages and bridge openings.

2 METHODOLOGY

The supervised classification framework is presented in the following sections. Monitoring data used in this study is described, with the extracted features used for anomaly detection and classification. Anomaly types are introduced, derived from observations over years of measuring strain variations in bridges, and informed by a taxonomy that evaluates metrics for outliers in time series. Subsequently, the process of constructing and labeling datasets with the identified anomaly types is then presented. The datasets are separated into testing and training subsets. Classification is then performed using a supervised learning model based on a decision tree classifier. The methodology is shown in Figure 1.

2.1 *Monitoring data*

The presented methodology involves capturing local behavior of bridge structural elements at critical points using strain gauges. Monitoring is performed continuously over long periods with a high frequency to capture the effect of different loading events. The case study focuses on a steel bascule-railway bridge constructed with riveted truss members from 1914 to 1916. Strain variations are continuously measured at critical truss members with a high frequency of 200 Hz, over a 15-month period from December 2021 to March 2023.

2.2 *Data preprocessing*

To facilitate anomaly detection and classification, monitoring data is divided into subsets corresponding to distinct loading events. After extracting features for both anomaly detection and classification and before and after injecting synthetic anomalies, a normalization is performed according to equation 1.

$$x = \frac{X - \min(X)}{\max(X) - \min(X)} \tag{1}$$

where $X(X_1,\ X_2, \ldots, X_n) \in R^n$ is the measured-strain vector during a loading event, and x is the normalized measurement vector.

2.3 *Feature extraction*

The features used for anomaly detection are Minimum, Maximum, Mean, Covariance, Kurtois, RMS, PRMS, RSS, and peak-to-peak. These features are defined in equations 2–8.

$$\text{Mean } (\mu)\ \ \mu = \frac{1}{n}\sum_{i=1}^{n} X_i \tag{2}$$

$$\text{Covariance } (cov)\ \ cov = \frac{1}{n-1}\sum_{i=1}^{n} (X_i - \mu)^2 \tag{3}$$

$$\text{Kurtois } (K)\ \ K = \frac{\frac{1}{n}\sum_{1}^{n} (X_i - \mu)^4}{\left(\frac{1}{n}\sum_{1}^{n} (X_i - \mu)^2\right)^2} \tag{4}$$

$$Root - Mean\ Square\ (RMS)\ \ RMS = \sqrt{\frac{1}{n}\sum_{i=1}^{n} X_i^2} \tag{5}$$

$$\text{Peak to RMS}\ (PRMS)\ \ PRMS = \frac{\max|X|}{\sqrt{\frac{1}{n}\sum_{i=1}^{n} |X_i|^2}} \tag{6}$$

$$\text{Root} - \text{Sum of Squares}\ (RSS)\ \ RSS = \sqrt{\sum_{i=1}^{n} |X_i|^2} \tag{7}$$

$$\text{Peak to Peak (P2P)}\ \ \text{P2P} = \max\ (X)\ - \min\ (X) \tag{8}$$

For the supervised classification process, more features are extracted from strain measurements, and ranked to identify the relevant features for classification. The extracted features include the statistical features defined in Equations 2–8, along with various factors like clearance factor, crest factor, and shape factor. The set of features also includes parameters like those used for acoustic emission(Bayane and Brühwiler, 2020), such as the time of the highest amplitude point, the number of threshold crossings from the first to the highest point, and the count of signal crossings above a threshold. The threshold here is defined as half of the peak-to-peak amplitude. Additional features include properties related to the power spectrum, such as its maximum, as well as the time and frequency of its occurrence.

To select the most relevant features for classification, they are ranked using the minimum-redundancy maximum-relevance algorithm. The algorithm minimizes feature set redundancy while maximizing its relevance to the response variable. The redundancy and relevance are quantified through the mutual information of variables, involving pairwise mutual information among features and the mutual information of a feature with respect to the response(Darbellay and Vajda; Ding and Peng). The top six features are then selected from the initially defined features for the classification process.

2.4 *Anomaly detection*

Anomalies are detected using the isolation forest algorithm that clusters instances in a dataset by building an ensemble of random decision trees. It measures an instance's anomaly score based on the number of splits needed to isolate it. The algorithm is based on the idea that anomalies are easier to isolate and require fewer splits than normal instances. It provides scores between 0 and 1, with higher scores indicating more pronounced anomalies.

2.5 *Anomaly types*

Observed anomalies in strain measurements are occasional, gradual, or permanent shifts, that are in the form of points or patterns. They are due to diverse factors such as electrical or mechanical disturbances (power supply fluctuations, electromagnetic fields, wheel impact), variations in applied load (a loading interruption or changes in loading characteristics), or strain release associated with damage. Five outlier types are defined from these observations as illustrated in Figure 2:

2.5.1 *Global outliers*

Points in the signal that exhibit significant deviation from the rest. These are typically spikes frequently caused by electrical disturbances. They are defined as point shifts exceeding the maximum or falling below the minimum strain levels recorded during loading events.

2.5.2 *Contextual outliers*

Points in the signal that deviate from their contextual surroundings within a specified range of neighboring time points. These deviations are attributed to minor shifts in strain measurements typically caused by inherent electrical noise that persists after sensor calibration, and

mechanical noise due for example to wheels. They are defined as small point shifts within the normal range of variation between the minimum and maximum strain values.

2.5.3 *Trend outliers*
A pronounced shift in strain measurements resulting from a sudden release of strain, often associated with the occurrence of damage. They are defined as a continuous-constant shift of strain during the loading event.

2.5.4 *Shapelet outliers*
Random fluctuations in strain gauge output resulting from electrical or mechanical disturbances, including power supply fluctuations and electromagnetic fields or random variations in strain measurements caused by loading irregularities. They are defined as a change in the shape of the signal.

2.5.5 *Drift outliers*
Gradual shifts in strain gauge output over time, attributed to aging, temperature variations, or humidity, or a slow increase in damage. They are defined as a linear drift of strain over time.

2.6 *Injecting synthetic anomalies*

Synthetic anomalies are introduced into strain variations recorded during loading events, with the associated context determined from observed strain variations during similar events. The assumption is made that each loading event contains one type of anomaly. This assumption is applied to simplify dataset labelling and facilitate anomaly classification, although it's recognized that certain events may involve multiple types of anomalies.

2.6.1 *Global outliers*
This anomaly type is generated by randomly selecting a time step r from the interval $[1, n]$ and replacing x_r with a value that either exceeds the maximum value or falls below the minimum value. This process is shown in Equations 9–10, where λ presents a random number within the range $[0, 1]$.

$$x_r = x_r + \lambda \max(x) \tag{9}$$

$$x_r = x_r - \lambda \min(x) \tag{10}$$

2.6.2 *Contextual outliers*
This anomaly is generated by randomly selecting a time step r from the interval $[1, n]$ and replacing x_r with a value between the maximum and the minimum values. This process is shown in Equation 11–12, where λ presents a random number within the range $[0, 1]$.

$$x_r = \lambda(\max(x) - x_r) \tag{11}$$

$$x_r = \lambda(\min(x) + x_r) \tag{12}$$

2.6.3 *Trend outlier*
This anomaly type is synthesized by changing the trend of the measurement vector leading to a permanent shift. The anomaly is injected within the signal's 10% to 90% range, ensuring a substantial change without affecting the entire signal. This process is shown in Equation 13, where m presents a random integer between $0.1n$ and $0.9n$, and λ presents a non-zero random number within the range $[-1, 1]$.

$$\forall i \in [m, n] \; x_i = x_i + \lambda \tag{13}$$

2.6.4 *Shapelet outlier*

This anomaly type is generated by changing the shape of the signal for a subset of points. To avoid changing the entire signal, this anomaly is injected within the signal's 10% to 90% range, ensuring a change without affecting the entire signal. The initiation point and length of the modified subset are determined by two random variables. The procedure is detailed in Equation 14, where m_1 and m_2 present random integers within the range of $0.1n$ to $0.9n$, with $m_2 > 1.1m_1$. Additionally, f denotes a function, that is adapted based on the context to change the shape of the signal, and it is for the case study, a random constant, or a sinusoidal function based on the nature of the loading event.

$$\begin{gathered} \forall i \in [m_1, m_2]\ x_i = f(\ x_i)[\lambda,\ x_i] \\ \text{such us } f(x_{m_1}) = \ x_{m_1} \\ \text{and } f(\ x_{m_2}) = \ x_{m_2} \end{gathered} \tag{14}$$

2.6.5 *Drift outliers*

This type of anomaly is generated by adding a linear trend to the measurement vector, as it is shown in Equation 15, where λ presents a random number within the range $]0, 1]$.

$$\forall i \in [1, n]\ x_i = \ x_i + \lambda i \tag{15}$$

2.7 *Dataset labelling*

To label monitoring data, synthetic anomalies are introduced into anomaly-free data. The anomaly-free data is identified from measurement vectors by selecting the vectors with the lowest scores obtained from the isolation forest algorithm. The resulting vectors are normalized according to Equation 1. Anomalies are introduced into the normalized vectors with an assigned label, and the vectors are again normalized and subjected to feature extraction.

2.8 *Anomaly classification*

Classification is performed using the binary classification decision tree, which is a supervised machine learning model that operates based on a tree structure for binary classification. The nodes of the tree present decision points based on input features, leading to recursive splits until a final classification is reached at the leaves. Trained on labeled datasets, it learns decision patterns and relationships for categorizing instances into two classes.

The study uses a supervised classification model trained on selected top six features and class labels from synthetic datasets. The training and test sets are split 80%/20%. Model performance is evaluated using a confusion matrix to determine classification accuracy. Classification is performed using the 'fitc-tree' function in MATLAB R2023. The prediction results were obtained using the 'predict' function with default configurations for optional arguments in both the classifier and predictor.

3 CASE STUDY

In this section, the methodology is applied to strain data obtained from a bascule-railway bridge, focusing on various critical components. For detailed information and datasets, refer to Leander et al.(2023). Three loading events are identified: train passage, bridge opening, and bridge closing. The analysis focuses on strain variations from two critical components during train passages and bridge openings, as strain variations during bridge closing are similar to those observed during bridge opening.

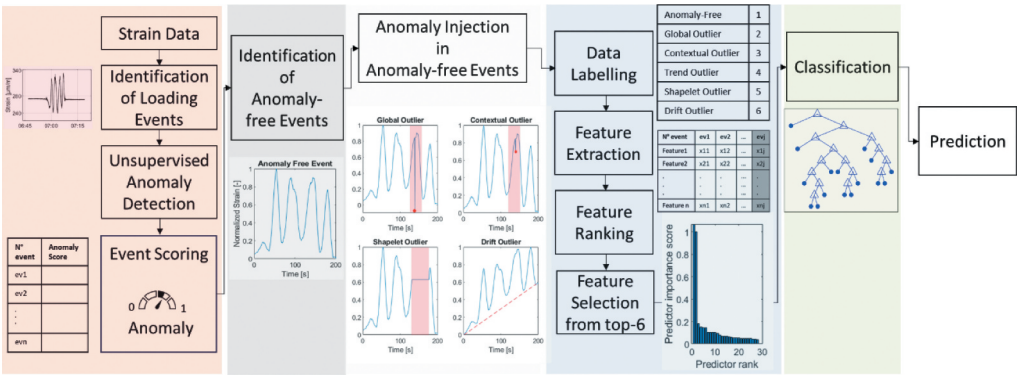

Figure 1. Proposed methodology.

The dataset is separated into loading events labeled "opening" or "train passage." Anomaly scores, ranging from 0 to 1, are assigned using the isolation forest algorithm. The 300 events with the lowest scores, corresponding to one month of continuous monitoring, are selected as anomaly-free events. Synthetic anomalies are introduced into these events, each labeled to indicate the specific anomaly type added (Figure 2).

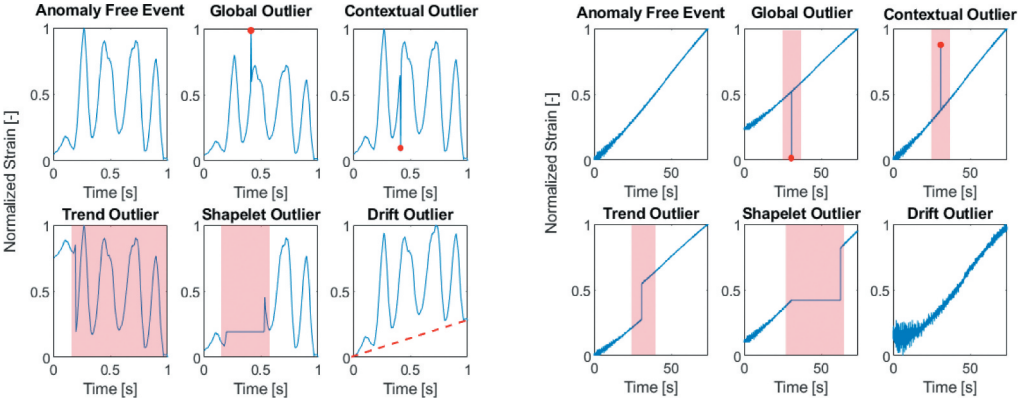

Figure 2. Normalized strain variations during train passage (left), and bridge opening (right) with anomaly-free event compared to the same event containing injected anomalies.

The supervised classification model is trained on 80% of the synthesized datasets (240 events for each class) and validated with the remaining 20% (60 events for each class). A binary classification decision tree is then used to classify unlabeled monitoring data. Figure 3 illustrates the confusion matrix, with known and predicted classes for train passages and bridge opening loading events.

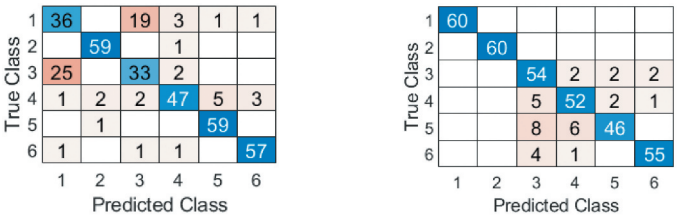

Figure 3. Confusion Matrix for the known and predicted classes, for train passage events (left) and bridge opening events (right).

The supervised classification model demonstrates robust performance during bridge opening achieving a 90% test accuracy. It correctly classifies anomaly-free events and global outliers, identifying 91% of drift outliers, 90% of contextual outliers, 86% of trend outliers, and 76% of shapelet outliers.

For train passage events, the model exhibits an 80% test accuracy. It accurately identifies 98% of global and shapelet outliers, 95% of drift outliers, and 78% of trend outliers. However, challenges arise in accurately classifying contextual outliers, often misclassifying them as anomaly-free events, which is similar with anomaly-free events being misclassified as shapelet outliers.

The observed decrease in model performance for contextual outliers and anomaly-free events during train passages is attributed to electrical and mechanical vibration associated with the train and wheels, contributing to the normal occurrence of contextual outliers. In contrast, bridge-opening events, where such vibration is absent, result in higher precision (90%) in contextual outlier classification.

The trained supervised classification model is used to predict and classify anomalies in new measurements collected over 15 months of continuous monitoring, comprising 5048 train passages including different train types, and 2642 bridge openings. Among train-passage events, 76% are identified as anomaly-free, 20% as contextual anomalies, and 4% as anomalies related to various train types, categorized as shapelet, trend, or drift outliers.

For bridge-opening events, 97% are classified as anomaly-free, while 3% exhibit anomalies, manifesting as signal shifts, loading irregularities (e.g., breaks or sudden stops during bridge opening), and strain releases associated with damage, as illustrated in Figure 4.

It is possible to achieve a high-precision classification within 300 events for training and testing, which corresponds to one month of continuous monitoring. Precision can be further enhanced by increasing the number of events considered for training.

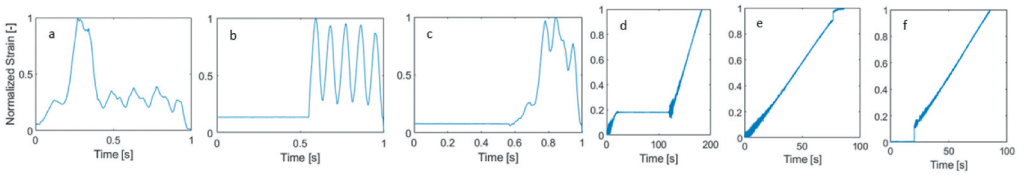

Figure 4. Examples of detected and classified anomalies: a-c) Unrecognized-train configurations during train passage; d) a stop during bridge opening, e) strain release linked to damage during bridge opening; f) signal loss during bridge opening.

4 CONCLUSIONS

In this paper, a context-specific framework is introduced for the supervised classification of anomalies in strain monitoring data. The supervised model exhibits strong performance, demonstrating its reliability in real-world scenarios, by achieving 80% accuracy for train passages and 90% accuracy for bridge opening events over 15 months of monitoring. Three important conclusions are drawn:

- The integration of time series anomaly taxonomy with empirical observations provides a framework for supervised anomaly detection and classification in bridge monitoring.
- The generation of synthetic datasets from monitoring data demonstrates the potential to achieve high-precision classification within one month of monitoring, which offers a practical approach for rapid implementation.
- The application of the framework to real strain data from a bascule bridge validates its efficiency to provide bridge owners with an automated method for detecting anomalies related to damage, irregular loading, and sensor failures.

Future work will explore multivariate monitoring data, combine data from different strain gauges and introduce additional classes of combined anomalies.

Reshaping bridge inspection with AI, 3D tools and BIM: Outcomes from an R&D initiative

T. Mendonça, V. Brito & S. Costa
Betar Consultores Lda, Lisbon, Portugal

J. Matos & S. Fernandes
ISISE, University of Minho, Guimarães, Portugal

ABSTRACT: This paper offers an in-depth review of a European-funded R&D project involving Minho University, the Center for Graphical Computation, and Betar, a Portuguese company specializing in asset management and bridge inspection. The project's goal was to digitally transform Betar's existing BMS system by integrating BIM standards, AI, and 3D technologies. Key developments included a computer vision AI for defect detection in bridges, a BIM-to-3D model conversion tool, a mobile app for efficient inspection using 3D models, a user-friendly tool for generating 3D models in the absence of BIM models, and frameworks for degradation prediction and maintenance optimization. The paper details the project's objectives, developed tools, and main outcomes, providing a practical assessment of these tools, their operational details, and real-world applicability based on pilot tests. It also discusses the challenges faced, key learnings, and future research directions to enhance civil engineering and infrastructure maintenance.

1 INTRODUCTION

1.1 *Context*

Transport infrastructures, such as highways, railways, airports, and ports, play a crucial role in economic development, supporting personal well-being and economic growth. These assets are vital for national and international development, both socially and economically. They contribute indirectly to economic development through various channels, highlighting their importance in wealth generation (International Transport Forum, 2013).

In the late 20th and early 21st centuries, developed countries invested heavily in transport infrastructure. In Portugal, after joining the European Union in 1986, the transport sector, especially highways, saw significant improvements to meet socioeconomic development needs (Diário da República nr. 188/2003, 2003). Traditional infrastructure design focused on minimizing initial investment costs, often leading to high maintenance costs.

The introduction of Life-Cycle Cost analysis marked a shift towards balancing investment and maintenance costs (Hammervold et al., 2013). Despite financial constraints, strategic infrastructure investments have been crucial in Portugal's transport sector. The 2008 financial crisis, however, led to reduced public investments in transport infrastructures.

Currently, the ageing of transport infrastructures in Portugal poses maintenance challenges. The Auditors Court identified urgent maintenance needs, particularly in railways, which are generally older than highways (Simões et al., 2020). Despite these issues, Portugal ranks high in global infrastructure quality but faces problems in railway infrastructure, with a significant portion of railway tracks and bridges below adequate quality levels (Simões et al., 2020).

The decrease in public investments is a common problem worldwide, affecting the quality of transport infrastructure (World Economic Forum, 2019). Modern structures have shorter

DOI: 10.1201/9781003483755-339

lifespans due to economic and time constraints in construction. The Morandi Bridge collapse is a recent example highlighting the consequences of inadequate maintenance (Calvi et al., 2018).

The World Economic Forum recommends re-igniting public and private investment in infrastructure, education, and innovation to boost national economic growth (World Economic Forum, 2019). Environmental sustainability has become a key consideration in infrastructure projects, affecting the feasibility and public support for new constructions.

Implementing a national asset management system for transport infrastructures is essential (Simões et al., 2020). Such a system supports decision-making and helps policymakers collect high-quality data for investment prioritization, crucial under tight budget constraints. The OECD notes the need for a cross-country analytical framework to assess the impact of transport infrastructure on economic development, highlighting challenges in data management across different systems (International Transport Forum, 2013).

A renovation of asset management of such kind should most probably come with the help of digitalization tools and industry 4.0 advances. In fact, bridge inspection is traditionally a labor-intensive task, sometimes involving safety risks to inspectors and demanding great investment in expert training to reduce subjectivity and error. Introducing artificial intelligence (AI) in inspection activities, namely machine learning and computer vision is a clear path forward, by enabling automated, accurate and efficient defect detection. Computer vision has been a very hot topic in a wide variety of applications and industries, and progress moves rapidly with the advancements in algorithmic sophistication and increased computation capabilities in easily accessible hardware. There are several deep learning models available to train, and much of the algorithm efficiency results from the quality of the training dataset.

Any reference to digitalization in the construction sector immediately leads to the topic of Building Information Modelling (BIM). BIM is one of the major topics in the construction industry and is believed to be the most adequate option to support the digital transition in this sector (Santos et al., 2022). Gathering and sharing information about structures has always been a challenge in civil engineering, and there is a transformative potential in BIM that brings a holistic approach to design, construction, and maintenance, encompassing not only the geometric aspects but also the functional characteristics of the bridge, creating a shared knowledge resource. The integration of BIM in BMS systems is still in the early stages, but as BIM use gains traction in design and construction phases, it will inevitably be used in the operation phase where BMS systems are a pivotal tool.

1.2 *Existing bridge management systems*

GOA.BI is a technologically driven project designed to address challenges in the management of highway and railway infrastructures. It aims to establish a smart interface to assist various stakeholders, including owners, transport agencies, and inspectors, in managing the lifecycle of transport infrastructures. These infrastructures involve a diverse array of assets starting with bridges, viaducts, and tunnels, and contemplating other structural assets present in road and rail infrastructure. The project's foundation is an integrated Asset Management System, primarily based on the concept of a Bridge Management System (BMS), which provides a versatile framework adaptable to various infrastructure assets.

The importance of BMS in infrastructure conservation has been recognized by many owners, given the structural complexity and significant investment needed over different lifecycle stages of bridges (Costa et al., 2019). BMS software should support maintenance management by developing maintenance timelines and strategies that balance cost efficiency with performance, considering the societal, economic, and environmental impacts.

Globally, numerous BMS have been developed, including BRIDGIT, Pontis, FinnRABMS, and others (Mirzaei et al., 2014). The evolution of BMS began in the 1960s, driven by the need to address the increasing deterioration of bridges. The United States pioneered this approach following the Silver Bridge collapse, leading to the creation of the National Bridge Inspection Standard (NBIS) in 1968. Initially, bridge management relied on replacement theory and basic mathematical models, which later evolved to incorporate data from

inspections into more sophisticated maintenance planning. By the 1990s, American BMS like BRIDGIT and Pontis were using detailed condition states derived from inspections to guide maintenance decisions (Neves et al., 2003; Santamaria et al., 2019).

In Portugal, the bridge management system GOA® - Gestão de Obras de Arte, developed by Betar, Lda., became a significant tool in the national market. Launched in 1997, GOA filled a market gap and was first implemented by Lisbon's City Council and subsequently by Refer, the Portuguese Railways Company. The 2001 Hintze Ribeiro Bridge collapse, a major tragedy in Portugal, underscored the importance of effective bridge management systems and led to the wider adoption of GOA (Carmo, 2021). Over two decades, GOA has evolved with continuous improvements and has even expanded internationally.

GOA encompasses a comprehensive inventory process for asset characterization, including administrative and technical data, component identification, and material details. The system is structured to continuously receive updated information, primarily from various types of inspections: routine, principal, underwater, and surveys. Routine inspections focus on service quality and traffic safety, recommending preventive maintenance tasks. Principal inspections, conducted every four to six years, are more detailed, assessing structural damages and assigning condition states to components. Also available are modules for planning activities and for maintenance management, allowing for the complete tracking of a defect lifecycle within the structure. Other supporting modules, like extensive reporting features and BI and online map integration constitute a complete tool for managing bridges and similar assets.

2 GOA.BI PROJECT

After twenty years of evolution and wide adoption, GOA has helped bridge owners to guarantee security and better management of over 20.000 bridges. GOA allows for the collection of data and making it available for use under a tested and successful system, which has in recent years been successfully implemented in Mozambique, with various other opportunities arising in countries in Europe and other Portuguese speaking nations.

However, several major challenges are growing in importance, which constituted the reason for this project. There is a growing demand for actionable information by managers that can help the decision-making process, for prioritizing strategies and forecasting while reducing costs. The maturity and effectiveness of asset management systems for bridges has also propelled owners to look to other relevant assets, following an increasing awareness of economical, security, environmental and reputational risks both from owners and broad society. The leading idea behind this project is that the digital transformation of the system can address many of the rising challenges.

Data is organized and readily available, but it is still difficult to extract meaningful information that can help management activities. Also, processes in the field, like inspection, are still largely manual and form based. Asset characterization data is still difficult and expensive to obtain and maintain in ways that bring added value to the user. It involves extended visits to the site, is susceptible to errors and very frequently requires post-processing of the information to extract data required by the manager (for example, estimating the area of a pier for painting may require intermediate processing of height and cross-section data).

Bridge Information Modelling (BrIM) technology facilitates the visualization, characterization and retrieving of geometrical data, used throughout the different activities of asset management. BrIM technology will also facilitate the extension of the system to other structural assets. Traditional static records must be completely changed (changing data models and user interface) when a new asset is characterized. With BrIM models, new assets can be introduced to the system without major disruption to the software.

Inspection is one of the main activities of the system and still requires time-consuming visits by the inspection teams. Inspectors must record all relevant data associated with the bridge or structure in a descriptive fashion, and mobile tools still include major hindrances to effective and fast inspection. Simplified mobile BrIM technology can facilitate work for the teams in the field, simplifying location and characterization of defects. BrIM technology also shows the

potential to enable autonomous drone inspection, easily correlating information between drone sensors and the model.

The extraction of relevant information from the data, namely concerning defect location, defect characterization, the evolution of the defect through time and defect tracking between different inspection records has always been difficult to perform due to analogue methods and traditional data models that struggle to effectively model geometric data. These shortcomings have also hindered reliable implementations of prediction models and other forecasting tools. The use of BrIM technology during the recording of inspection data solves many of the underlying problems and helps implement more reliable tools for forecasting and decision making.

2.1 *Objectives and proposed solutions*

The project's consortium defined as the main objective the development of a new bridge management system designated GOA.BI. This new system should exist and be accessible both in the format of a desktop web-based platform and in the format of an intelligent interface platform. The former is intended for the central management team; thus, it is a full version of the system, including all its modules. The latter is to be used by in-situ inspectors, which will access it employing mobile devices. Hence, this needs to be a lighter version only including a smaller number of features and a reduced number of modules.

Besides the objectives directly related to the development of a new bridge management system, main tools developed included:

- The training and use of a computer vision AI tool for detecting defects in bridges, working alongside the inspector for accurate identification of defects;
- The development of a BIM-to-3D-model conversion mechanism that facilitates seamless BIM model integration with the BMS system;
- A mobile application, supported by the 3D model, for fast and accurate inspection;
- The development of a user-friendly 3D model generation tool specifically designed to address scenarios where BIM models are absent;
- The deployment of degradation prediction models and a maintenance optimization framework;

2.2 *Implementation*

The success of the project depends on good coordination between all intervening co-promoters. In that sense, the activities for each objective were designed to extract the best of each promoter and better pursue the objectives of the project.

A total of eight activities were foreseen, ranging from industrial research to experimental development. The major tools developed are described in the following sections.

2.2.1 *BrIM module*

In the development of the BrIM module for the project, a comprehensive approach was adopted, emphasizing data-driven design methodologies. The module's framework was structured around a detailed data diagram, which meticulously outlined the requirements for information exchange and storage.

A pivotal feature of the module is the integration of Building Information Modelling (BIM) Authoring. This allowed for the application of various modelling protocols, enhancing the module's versatility and effectiveness in creating digital representations of bridge infrastructures. Additionally, the module adopted an object-oriented approach to alignment modelling, which significantly increased the accuracy and adaptability of the digital models.

Technologically, the module leveraged tools such as IfcOpenShell-python, combined with commercial algorithmic tools for 3D digital modelling. This synergy facilitated the effective extraction and processing of Industry Foundation Classes (IFC) model data, focusing on key parameters like element IDs, dimensions, and specific locations. The processing phase utilized four distinct algorithm sets, each dedicated to handling different aspects of the data: input,

location, dimension, and geometry. These algorithms were crucial in developing a parametric bridge model that could dynamically adapt to varying data inputs. The BrIM Module consists of two essential tools: the one described previously, that constitutes an assisted tools for BIM model import to that BMS, and a second tool, that offers simple model construction features. Because existing bridges and structures seldom have an existing BIM model (more so in the case of a maintenance specific model) it was necessary that the new platform enabled the creating of maintenance appropriate 3D models. Overall, the two tools are complementary are guarantee that a 3D model can always be used within the app to use during inspection and for post-inspection activities.

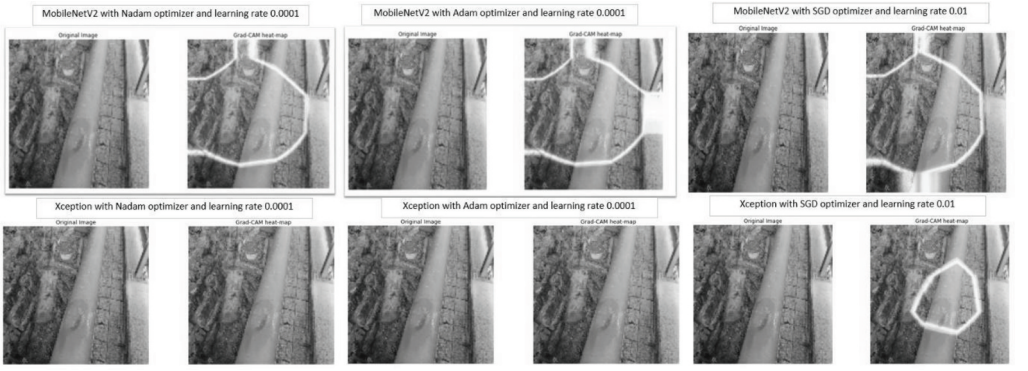

Figure 1. Model performance comparison.

2.2.2 *Defect detection using AI*

This module was designed to allow for the automatic detection of anomalies in bridge structures using advanced deep learning vision algorithms. The initial phase of the development involved constructing a comprehensive image database.

This database was crucial for training the deep learning algorithms and was initially populated with a diverse range of images sourced from Betar. It encompassed six different types of defects commonly found in bridge structures. The meticulous process of manual image processing undertaken was a critical step in ensuring the accuracy and quality of the data. The images were carefully processed, annotated, and categorized to facilitate effective machine learning.

Following this, the dataset was strategically segmented into three parts: training, testing, and validation sets. This segmentation was vital for the proper training of the algorithms and for evaluating their effectiveness and accuracy in real-world scenarios. Additionally, data augmentation techniques were employed to enhance the diversity and robustness of the dataset. These techniques involved modifying the existing images in ways that are likely to occur in real-life scenarios, thereby preparing the algorithms for a wide range of possible defect presentations.

The core of the module was the Intelligent Sensor for Optical Inspection. This component utilized TensorFlow, a powerful open-source software library for machine learning, alongside various Convolutional Neural Network (CNN) architectures. These architectures were specifically chosen and optimized for their ability to classify and identify anomalies in the images effectively.

The testing phase of the module was comprehensive and rigorous. It focused on scrutinizing the performance metrics and classification accuracy of the algorithms, particularly on previously unseen samples. This phase was crucial in determining the practical applicability and reliability of the module in real-world conditions. A notable innovation in the testing phase was the incorporation of Grad-CAM, a sophisticated visual explanation technique. Grad-CAM provided clear visual explanations for the decisions made by the CNN models, highlighting the specific areas in the images that influenced the algorithms' conclusions. This

transparency was instrumental in refining the models and in building trust in their decision-making processes.

The tool was implemented within the GOA.BI platform as a confirmation feature to the inspector's work. Images are uploaded and classified in the field by the inspector. On the server side, the algorithm runs and compares the classification from the inspector to its own result. If they are the same, no action is performed (with the guarantee that the defect identified in the image was double-checked!); if there is a difference, the inspector is prompted, asking about the divergence. The final decision remains in the hand of the inspector and its ultimate decision is used as feedback to the algorithm, guaranteeing increasing accuracy.

In summary, the development of this module was a major milestone in the integration of Vision AI tools and machine learning technologies into a BMS commercial product. It exemplifies the potential of these technologies to revolutionize infrastructure monitoring and maintenance, enhancing safety, efficiency, and reliability. The meticulous development process, from the creation of a comprehensive image database to the rigorous testing and validation of the algorithms, underscores the commitment to quality and precision in applying AI to real-world engineering challenges.

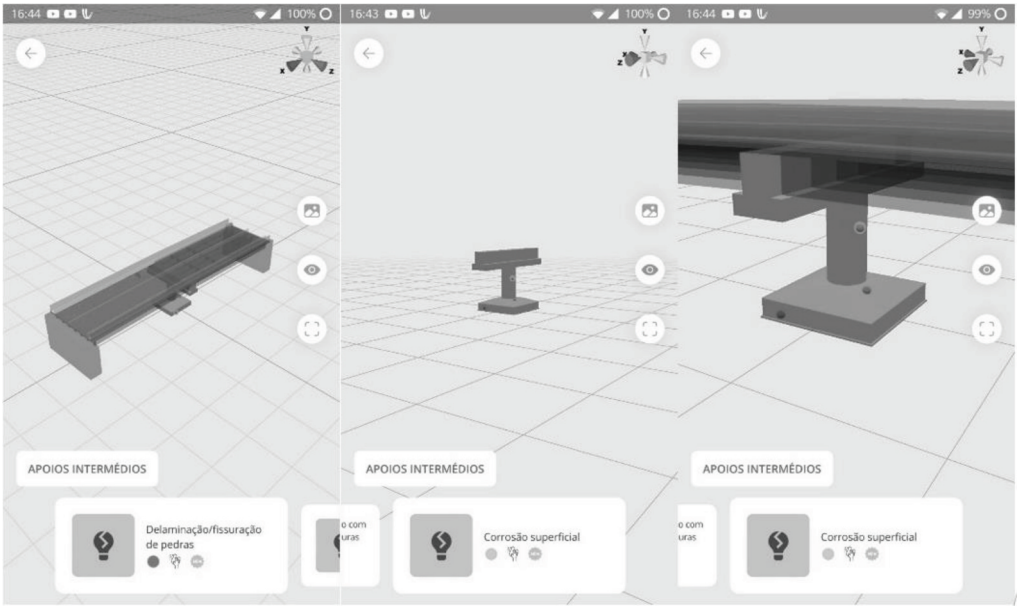

Figure 2. Mobile app views of the 3D model.

2.2.3 *Mobile 3D platform*

The mobile application interface was meticulously tailored for on-field work, focused on creating a user-centric, efficient, and responsive tool for infrastructure management.

The mobile app includes a variety of functionalities: multi-language, inspection campaign details and selection, tracking and management of planned inspections, inspection creation, bridge rating, defects lists and a rich visual user interface. Additionally, the inclusion of auxiliary table data ensures that users have access to all necessary information at their fingertips. The development process also emphasized the integration of 3D models into the mobile platform. This integration not only enhances the visual and interactive experience of the users but is transformative in the quality of the information that is recorded.

By recording precise geometric information of defect location, the app allows for the effective creation of a maintenance *digital twin*, with an enormous field of possible use cases with beneficial impact. Starting in inspection results that are easier to share and interpret, maintenance planning and activities that are less prone to error and a new dimension of data that

allows for a new generation of prediction and optimization algorithms, enriched by defect location data and geometric and physical data from the structure.

The development underscores a commitment to enhancing the efficiency, accuracy, and accessibility of bridge infrastructure management through technological innovation, while maintaining a grounded and practical perspective on its application in the field.

2.2.4 *Mixed reality module*

Unity was used as the development engine to design the prototypes for the mobile, holographic and desktop/web applications. The holographic application was developed for HoloLens, specifically HoloLens 2, and mainly uses the user's hands and fingers as the interface for interacting with and manipulating the holograms.

The 3D models that are created and used throughout the platform are consumed by the mobile and holographic applications. Through the mobile application, the user can visualise the model and record defects detected during the inspection, and with the holographic application it can see and manipulate the complete 3D model of the bridge.

The holographic application was developed in Unity using the MRKT (Mixed Reality Toolkit) augmented reality framework and includes the following features: i) choice of language; ii) Bridge visualisation on a 3D map; iii) Visualisation of bridge information; iv) Viewing photographs; v) Viewing the list of inspections; vi) Viewing and interacting with the 3D model of the bridge superimposed with inspection results.

Figure 3. Mobile app use during pilot testing.

2.3 *Testing and pilot*

In the development of the project a comprehensive testing and validation phase was undertaken. This phase was crucial in refining the application, ensuring its effectiveness and suitability for the intended end-users.

A pivotal aspect of the development process involved integrating the application into real-world field inspections. This practical application provided invaluable insights into the application's performance under actual operating conditions. Inspections of various bridges were conducted, allowing for a thorough evaluation of the application's functionality in diverse scenarios.

The focus was significantly placed on assessing the user experience. It involved gauging the application's usability, understanding how intuitive the interface was for the users, and determining the ease with which users could navigate and utilize the various features. Performance metrics were also meticulously recorded, providing quantitative data on the application's speed, responsiveness, and reliability.

User feedback was a critical component of the testing phase. Feedback from the end-users, who interacted with the application during the bridge inspections, was gathered systematically. This feedback encompassed aspects of user satisfaction, including the application's practicality, efficiency, and overall usability. It served as a direct indicator of the application's alignment with the real needs and preferences of its users.

Another key area of focus was the system's agility – its ability to perform efficiently under various conditions. Observations were made on how the application handled large data sets, its performance in different network conditions, and its adaptability to various user inputs and scenarios. Based on the feedback and performance metrics, several areas for improvement were identified, leading to iterative enhancements of the application.

The development was finalised with the execution of a pilot session executed on two integral days of field work (inspections to bridges), with the app being used by two different inspectors from Betar's team. All phases of the development of the work were gauged, from bridge and model creation to field work. Results from the feedback collected allowed for the validation of the interface, confirming the benefits in speed and accuracy of the data collection when compared with typical workflows.

3 CHALLENGES AND INSIGHTS

In the development of a bridge management system incorporating BIM technology numerous challenges and insights have emerged. The project navigated the fluid landscape of BIM standards, notably IFC, confronting the hurdles posed by their novelty and instability. This situation impeded seamless integration, demanding adaptability and innovative problem-solving to align with the evolving digital framework.

Concurrently, the implementation of AI for defect detection required a substantial investment in image collection and preparation. This foundational stage, while resource-intensive, was crucial for ensuring the model's accuracy and effectiveness. It highlighted the necessity of a robust groundwork for AI applications, especially in domains where precision is paramount.

Field manipulation of 3D models presented a unique set of challenges. The complexity of interacting with intricate models in a real-world context revealed a gap between digital sophistication and practical utility, underscoring the need for user-friendly interfaces and real-world applicability in technological solutions.

The ambition of real-time image processing via AI faced technical constraints, particularly the necessity for high computational power and optimized algorithms. This aspect of the project underscored the importance of computational advancements and algorithmic efficiency in real-time data processing applications.

Balancing the complexity and thoroughness of data collection with the need for operational efficiency in fieldwork was a recurring theme. Developing methods that streamline data capture without compromising data quality emerged as a critical factor in enhancing field operations' efficiency.

In addition to these challenges, the project navigated issues related to data security and privacy, especially pertinent given the sensitivity of infrastructure data. The integration of various technologies also highlighted the need for interoperability between different systems and platforms, requiring a harmonized approach to ensure seamless functionality.

From these challenges, several key insights were gained. The fluidity of BIM standards, though challenging, offered a platform for continuous improvement and adaptation in asset management systems.

The project's experiences emphasized the importance of user-centric design, particularly in field applications. Solutions that prioritize intuitive interfaces and align with real-world fieldwork conditions can effectively bridge the gap between technological innovation and practical usability. Furthermore, the development of strategic data collection methods that balance depth with speed can significantly improve operational efficiency. The project's experiences also highlighted the importance of continuous learning and adaptation in the face of technological advancements and changing industry standards.

In summary, the project offered a rich learning experience, providing key insights into the integration of advanced technologies in infrastructure management. The lessons learned extend beyond the scope of this project, offering valuable guidance for future endeavours in digital asset management and infrastructure inspection.

A quantitative methodology for risk-based priority ranking of deteriorated bridges: Application to a bridge stock

S. Hamidpour, N. Scattarreggia, R. Nascimbene & R. Monteiro
University School for Advanced Studies (IUSS) of Pavia, Italy

ABSTRACT: Bridges play a crucial role in a nation's infrastructure, facilitating connectivity in road networks. Recent global incidents of bridge failures have heightened concerns about the existing bridge structures, prompting the development of more effective bridge management techniques. Italy, among other countries, has addressed this concern by introducing national guidelines for the risk assessment and management of bridge portfolios. While these guidelines offer a detailed multi-level and multi-hazard approach, their qualitative nature limits enhance precision of risk classification for a specific bridge stock. This study addresses this limitation by presenting a quantitative approach to evaluate bridge risk conditions. The method provides quantifiable expressions for vulnerability, exposure, and hazard, considering both the general robustness of the bridge structure and the presence of defects and damages. Leveraging the Italian guidelines' specifications, the priority ranking approach employs a refined scoring system to convert qualitative bridge characteristics into quantitative parameters. The study focuses on prioritizing 130 bridges in northern Italy through both the priority ranking method and the ITA-Guidelines. It thoroughly assesses the ITA-Guidelines' classes of attention for various risk parameters and compares the outcomes with the priority ranking method.

1 INTRODUCTION

Ageing bridge structures have become a significant global concern in recent decades, driven by the increased occurrence of bridge failures worldwide (e.g., the muti-span arch bridge failure in 2020 in Italy,Scattarreggia et al., 2022). These structures are subjected to various forms of deterioration and degradation, which can compromise their structural integrity. Ensuring the safety and reliability of these critical infrastructure elements is essential to prevent unforeseen failures that could lead to severe consequences, including harm to human life, disruption of transportation networks, and economic losses. Implementing prioritization methodologies for assessing the overall condition and risk of bridges is crucial to help managing bodies decide over further assessment, maintenance, rehabilitation or demolition of the bridges to prevent or minimize further socio-economic consequences.

This subject has gained significant interest in recent years with numerous studies exploring various aspects. Meoni et al. (2023) proposed a priority ranking method for bridges that considers both risk assessment and visual inspection costs, aiming to develop a visual inspection plan. Zizi et al. (2023) introduced an empirical risk assessment method based on seismic hazard to establish a priority ranking for bridges, for planning detailed on-site visual inspections. Bertola & Brühwiler (2023) formulated a risk-based approach to assess the condition of bridges by linking the degradation state of the bridge with the consequences of element failure, utilizing visual inspection data. Ivanković et al. (2021) developed an approach for the prioritization of bridges for repair purposes, utilizing data from damage inspections. Kim et al. (2018) developed a method for prioritizing maintenance, considering diverse risk factors optimized through an examination of conventional methods and insights from engineering

DOI: 10.1201/9781003483755-340

consultants. The Federal Highway Administration of the United States (FHWA, 2022) issued instructions for the condition assessment of highway bridges to ensure their safety. As outlined in FHWA (2016) numerous other bridge health indices are currently utilized worldwide, along with recent optimal prioritization methodologies proposed by researchers, such as Abarca et al. (2023) or D'Apuzzo et al. (2022).

Italy has around 120,000 bridges, mainly built between the 1950s and 1970s (Pinto & Franchin, 2010; Santarsiero et al., 2021). Many of these bridges may lack sufficient durability due to outdated construction standards, which precede the introduction of modern design regulations (e.g., NTC 2018); may encounter challenges with current traffic demands; and may alter in their residual capacity due to unknown defects, e.g., the ones correlated to construction errors (e.g., Pinho et al., 2023). Inadequate maintenance coupled with ageing was evident in recent failures like the Annone overpass (di Prisco et al., 2018) and the Morandi bridge (Calvi et al., 2019). To address this, the Italian Higher Council of Public Works introduced the Italian guidelines, to regulate the risk assessment and management of existing bridges (ITA-Guidelines, 2020). These guidelines classify bridges into five Classes of Attention (CoA): High (H), Medium-High (MH), Medium (M), Medium-Low (ML), and Low (L). While each class indicates the level of attention required for a bridge, due to their qualitative definition of risk, these guidelines hinder prioritization within the same CoA.

This study presents a quantitative approach to prioritize bridge importance, addressing the limitations of qualitative methods, such as the ITA-Guidelines (Hamidpour et al., 2024). The approach utilizes closed-form expressions for definition of vulnerability, exposure, and hazard parameters aligning with the ITA-Guidelines and recent methodologies (Zizi et al., 2023). Vulnerability combines structural features as outlined in the ITA-Guidelines and defects using the approach foreseen for the United Kingdom Bridge Condition Index (UK-BCI, 2007). This innovative quantitative integration using two distinct guidelines elevates the comprehensiveness of vulnerability assessment. Exposure assesses the bridge and network-level impacts of a bridge failure. Hazard considers commercial vehicle traffic and expected Peak Ground Acceleration (PGA) of an event with 475-year return period. The priority ranking is determined as a weighted combination of these three parameters showing the relative priority of a bridge within a stock. The study involves the application of the priority ranking method and the ITA-Guidelines to assess 130 bridges located in northern Italy. A thorough evaluation of the ITA-Guidelines' classes of attention for different risk parameters is carried out, and a comparative analysis is conducted between the results obtained from the adopted priority ranking and the ITA-Guidelines.

2 RISK-BASED PRIORITY ASSESSMENT METHOD

The risk-based assessment methodology used in this study is described in Hamidpour et al. (2024), to which interested readers are referred for additional details. It incorporates three primary parameters: vulnerability (V), exposure (E), and hazard (H), each quantified knowing the general and physical characteristics of the bridge and the road to which it belongs through equations outlined in this section. The priority ranking (PR) is then determined as the weighted combination of these three parameters, as per Equation 1. The formulations have been crafted in parallel with the fundamental principles outlined in the ITA-Guidelines as the main reference for the mentioned quantitative methodology. Furthermore, the UK-BCI approach has been used to evaluate the vulnerability of bridges by considering the extent and severity of the existing damages and defects in a quantitative manner.

$$PR = 0.4(V + E) + 0.2H \tag{1}$$

2.1 *Vulnerability*

In vulnerability definition, two primary factors are considered representing vulnerability attributed to structural characteristics ($V_{Str.}$), and vulnerability arising from the condition of damages and defects in the bridge elements ($V_{Def.}$). The two components are combined using the Root Mean Square (RMS) method to obtain the overall vulnerability of bridge as in

Equation 2. While the $V_{Str.}$ is defined using the ITA-Guidelines specifications, the $V_{Def.}$ is determined based on the previously mentioned UK method for bridge condition index (BCI) using the formulations presented in Equation 3 and 4, respectively.

$$V = \sqrt{({V_{Str.}}^2 + {V_{Def.}}^2)/2} \tag{2}$$

Structural vulnerability, denoted as $V_{Str.}$, considers five characteristic parameters: V_{YC}, V_{SS}, V_{LS}, V_{NS}, and V_{DM}, which respectively represent the influence of the year of construction, structural static scheme, largest span length, number of spans, and deck material. The determination of structural vulnerability involves converting the bridge specifications to numerical values, as specified in Table 1. The weights assigned to parameters in Equation 3 and the values in Table 1 are primarily aligned with the ITA-Guidelines, with some modifications based on recent research findings (e.g., Zizi et al., 2023), along with expert judgment.

$$V_{Str.} = 0.25(V_{YC} + V_{SS}) + 0.2V_{LS} + 0.15(V_{NS} + V_{DM}) \tag{3}$$

Table 1. Structural vulnerability parameters ($V_{Str.}$).

Year of construction	V_{YC}	Static scheme	V_{SS}	Largest span length (m)	V_{LS}
YC≤1945	1.00	Simply supported beams/slab (SSB/S)	1.00	LS<5	0.10
1945<YC≤1980	0.75			5≤LS<15	0.30
1980<YC≤2003	0.50	Continuous beams/slab (CB/S)	0.90	15≤LS<25	0.70
2003<YC≤2018	0.25			LS≥25	1.00
YC>2018	0	Arches (A)	0.80		
Number of spans	V_{NS}	Deck material	V_{DM}		
NS=1	0.10	Steel and reinforced concrete (MX)	0.80		
NS=2-4	0.30	Prestressed concrete (PRC)	0.90		
NS=5-7	0.60	Reinforced concrete (RC)	0.95		
NS=8-10	0.90	Masonry (M)	1.00		
NS>10	1.00				

Regarding the other component of bridge vulnerability associated with defects, denoted as $V_{Def.}$, it is assessed using the UK method based on data obtained from visual inspections of the bridge elements damages (Equation 4). This method generates an index (BCI_{UK}) considering the extent and severity of defects observed at the element level and indicates two states of conservation: "Avg-Def." and "Crit-Def.". The "Avg-Def." state provides a comprehensive evaluation of the bridge condition, illustrating the extent of deterioration across all damaged and undamaged bridge elements. In contrast, the "Crit-Def." state signifies the criticality of the structure due to the exceptionally poor condition of a critical element, deemed essential to the overall integrity of the bridge. Further details about the evaluation of the bridge condition indicator can be found in Hamidpour et al. (2024).

$$V_{Def.} = 1 - (BCI_{UK}/100) \tag{4}$$

2.2 *Exposure*

The exposure parameter for a bridge (E) is calculated using Equation 5, where E_{AT}, E_{DL}, E_{MS}, E_{EB}, and E_{RC} represent the average daily traffic on the entire roadway, detour length in the event of bridge closure, mean span length, entity bypassed by the bridge, and road category, respectively, reflecting in the scores given in Table 2.

$$E = 0.3E_{AT} + 0.2(E_{DL} + E_{MS} + E_{EB}) + 0.1E_{RC} \tag{5}$$

Table 2. Exposure parameters (E).

Average daily traffic (vehicle/day)	E_{AT}	Detour length (km)	E_{DL}	Mean span length (m)	E_{MS}
AT≤10k	0.80	DL≤1	0	MS<5	0.10
		1<DL≤10	0.25	5≤MS<15	0.30
10k<AT<25k	0.90	10<DL≤20	0.50	15≤MS<25	0.70
AT≥25k	1.00	20<DL≤40	0.75	MS≥25	1.00
		DL>40	1.00		
Entity bypassed	E_{EB}	Road category	E_{RC}		
"High" social/public effects (railways, main roads, constructed areas)	1.00	Highway or railway (HRW)	1.00		
		Main suburban road (MSR)	0.90		
"Medium" social/public effects (secondary roads, waterways and water bodies)	0.70	Secondary suburban road (SSR)	0.80		
		Urban road (UR)	0.70		
"Low" social/public effects (Natural grounds and areas)	0.20	Local road (LR)	0.60		

2.3 *Hazard*

This study incorporates two potential sources of hazard, specifically traffic load and seismic action. As indicated in Table 3, the determination of the hazard component considers the frequency of commercial vehicles per lane (H_T) and the ratio between the Peak Ground Acceleration (PGA) expected to be exceeded every 475 years at the bridge's location and the highest anticipated PGA in the Italian territory (H_S), as per the seismic hazard maps (i.e., 0.35g).

Table 3. Hazard parameters (H).

Commercial vehicle/day	H_T	PGA ratio	H_S
CT≤300	0.50	Event with 475-year return period/	
300<CT<700	0.75	Highest expected event in Italy	PGA(g)/0.35
CT≥700	1.00		

3 SELECTED CASE-STUDY BRIDGE INVENTORY

The studied inventory encompasses 130 viaducts and overpasses in Lombardy region, northern Italy. Figure 1 provides an overview of the primary characteristics of the bridges and their statistical distribution. The data including geometrical, geotechnical, and structural features, along with potential on-site hazards and structural element damages was made available by the managing operator through visual inspections following the protocol prescribed by the ITA-Guidelines. The predominant design of most bridges includes a simply supported deck system with steel girders and concrete slabs, and they were mainly constructed between years 1960 and 2010. A significant number of bridges have multiple spans (mostly 3 spans) with varying or uniform lengths; typically, the largest span length varies from 6 m to 70 m, with one bridge spanning up to 125 m. These bridges are situated mostly on local roads or highways with an average daily traffic between 10,000 and 32,000 vehicles throughout the entire road, and the daily commercial traffic from 300 to 12,000 vehicles per lane. As the majority of the bridges primarily span over highways, their surrounding area may encompass high social or economic consequences in the event of failure.

4 RISK ASSESSEMENT OF THE CASE-STUDY BRIDGES

4.1 *ITA-Guidelines*

The ITA-Guidelines prescribe a multi-level multi-hazard procedure to evaluate the risk associated with existing bridges. The process initiates with an extensive data collection through visual

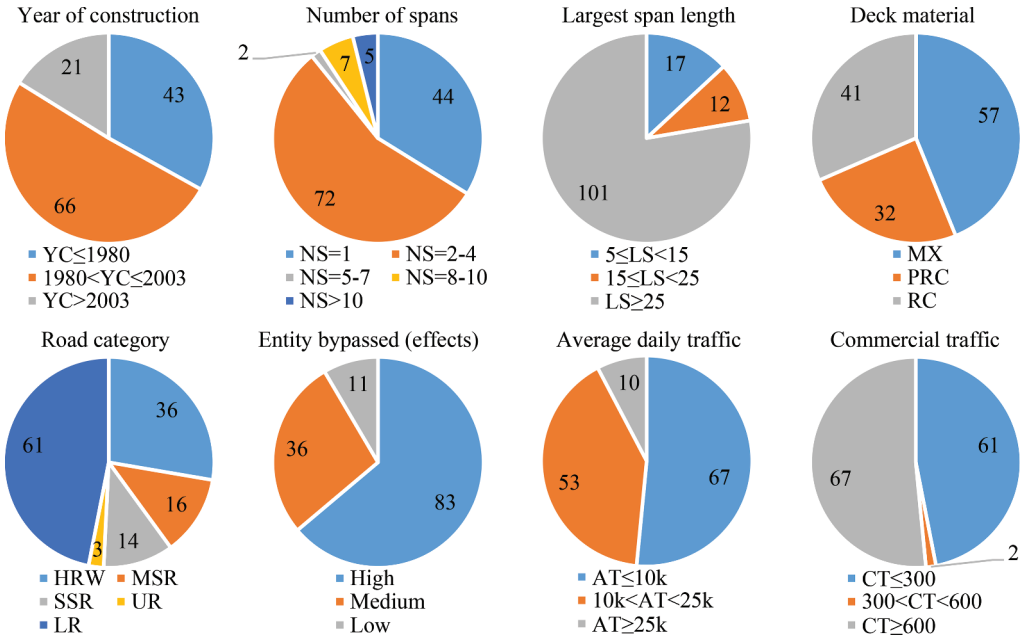

Figure 1. Summary of primary characteristics of bridges and their statistical distribution.

inspections, covering various aspects such as geometrical, structural, and geotechnical characteristics, as well as potential on-site hazards and structural element damages and defects. This data is then used to categorize bridges into different classes of attention based on hierarchical logic models for risk components, which are vulnerability, exposure and hazard. This preliminary classification indicates the required level of attention for each bridge under a specific hazard. By combining the classes of attention associated with all relevant hazards through a hierarchical model, an overall CoA is obtained for bridges. According to ITA-Guidelines, in defining the possible combinations, greater weight is given to the structure-foundation (traffic) CoA as it is linked to the operability of bridges. This means that if it is high, the overall CoA is high, irrespective of the CoAs related to seismic, hydraulic, and landslide hazards.

Figure 2 illustrates the outcomes of such evaluations for the case study inventory introduced in Section 3, displaying the CoA for various risk parameters. The CoA has been assessed separately in two risk categories including structure-foundation and seismic as outlined in the ITA-Guidelines. Since the structure-foundation risk considers commercial traffic as the potential hazard, it is denoted as traffic CoA in this study. The results indicate relatively higher seismic CoA for bridges considering defects, attributed to the presence of high-importance defects including oxidation and corrosion in seismic-critical components of the bridges, such as support devices and piers. On the other hand, vulnerability shows almost similar results for traffic and seismic CoAs, as both incorporate very similar input physical and geometric parameters during the evaluation procedure. Moreover, exposure remains identical for traffic and seismic CoAs, as the studied bridges do not feature strategic nature considering seismic emergency conditions, resulting in the same seismic CoA as traffic. Since the Lombardy region is not an area with a high seismicity, seismic hazard CoA for all bridges results as medium, while due to the intense daily traffic of roadways, the traffic hazard CoA is classified as medium-high and high. The analysis of results revealed that a greater number of bridges are assigned a high CoA in traffic risk category compared to the seismic counterpart (95 and 77 bridges, respectively). The overall CoA, resulting from the combination of traffic and seismic CoAs, yields to 95 bridges identified as requiring a high level of attention. This implies that most of the studied bridges demand further detailed assessments in accordance with current technical standards for construction.

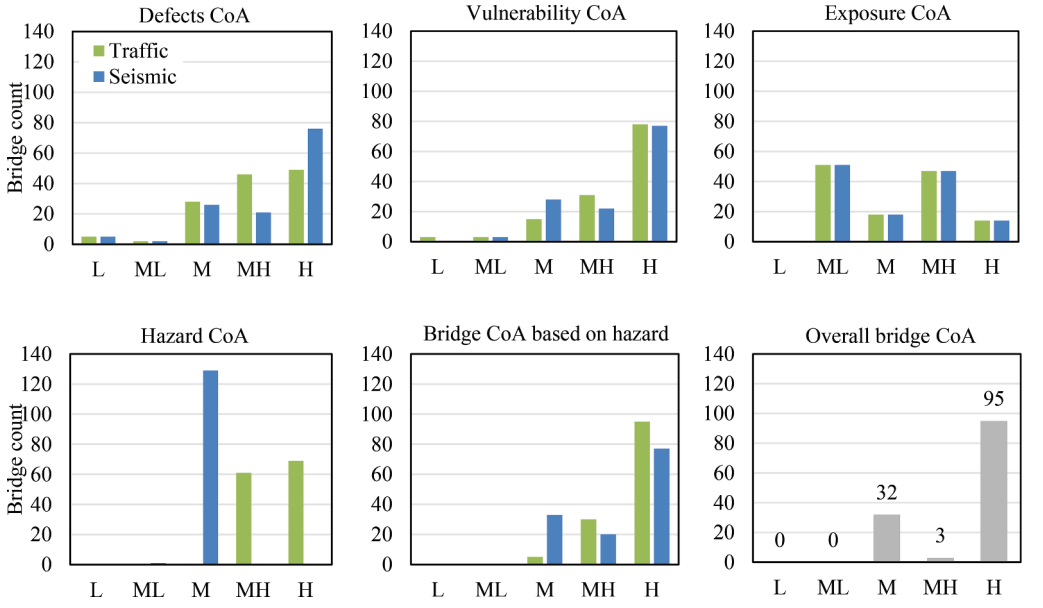

Figure 2. Statistical distribution of bridges based on the ITA-Guidelines CoA considering defects, vulnerability, exposure, hazard, bridges CoA based on hazard, and overall bridge CoA.

4.2 *Quantitative priority ranking*

The priority rankings of the studied bridges, calculated using Equation 1 and considering different approaches to determine the vulnerability parameter as defined in Equations 2 to 4, are depicted in Figure 3. The results indicate that when defects are accounted for, mainly when using the indicator based on the critical one (i.e., Crit-Def.), the total number of bridges with higher priority ranks for both traffic and seismic hazards increases. For instance, Figure 3 shows that none of the bridges fell within the range 0.6-0.8 or higher, and within the range 0.8-1.0 when neglecting the presence of defects (i.e., the case "Str. & wo-Def.") under seismic and traffic hazards, respectively. On the other hand, when defects are accounted for, either in average or critical states, some bridges move to ranges that imply higher priority. In other words, including the contribution of defects to vulnerability confirmed a more severe risk condition for the bridges. Finally, an overall look indicates most bridges are ranked in the ranges of 0.6-0.8 and 0.4-0.6 under traffic and seismic hazards, respectively.

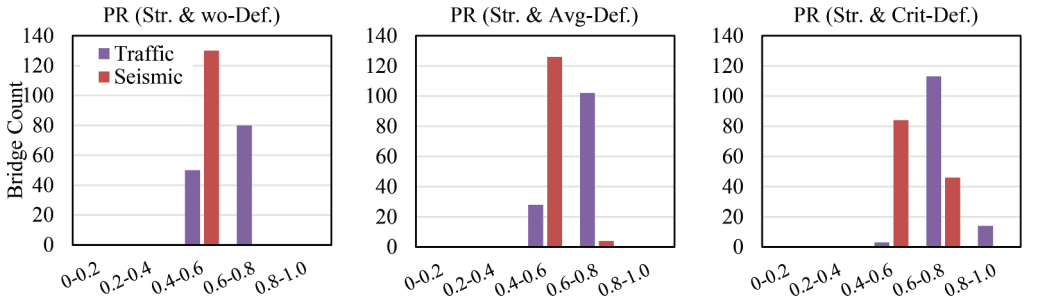

Figure 3. Statistical distribution of bridges based on the priority ranking (PR) for seismic and traffic hazards, under various vulnerability definitions: Str. & wo-Def., Str. & Avg-Def., and Str. & Crit-Def.

4.3 *Comparison of the results*

Since the ITA-Guidelines incorporates defects in the risk classification of bridges, in this section the priority ranking method results are discussed when defects are considered in determination of the vulnerability. To provide consistency between the results of the two methods, the priority ranking subranges of the presented method, defined in intervals of 0.0-0.2, 0.2-0.4, 0.4-0.6, 0.6-0.8, and 0.8-1.0 were viewed as the Low (L), Medium-Low (ML), Medium (M), Medium-High (MH), and High (H) classes of attention of the ITA-Guidelines, respectively. According to Figure 4, for the traffic hazard, the results of the priority ranking method with the vulnerability case of "Str. & Avg-Def." show that many of the bridges are classified within the 0.6-0.8 subrange (equivalent to the medium-high CoA), while most bridges were classified as high CoA according to the ITA-Guidelines. For the seismic hazard, with similar vulnerability, most bridges were classified in the 0.4-0.6 subrange (equivalent to the medium CoA), whereas using the ITA-Guidelines, most bridges are classified in the medium-high and high CoAs. Even when considering the critical defects, resulting in a higher vulnerability and consequently higher priority rankings than the case of the average defects, the ITA-Guidelines approach tends to classify the bridges at higher levels than the proposed method by Hamidpour et al. (2024). The method's ability to generate individual bridge scores provides a notable advantage in determining relative priorities within extensive inventories, especially when multiple bridges share the same CoA.

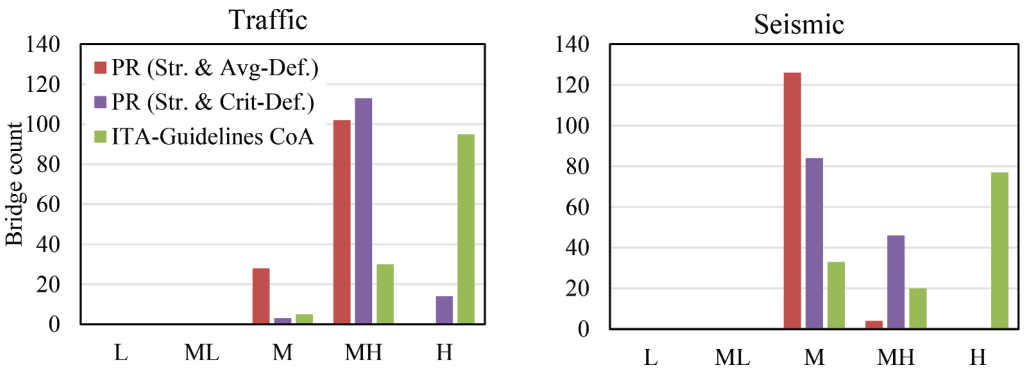

Figure 4. Comparison of the statistical distribution of bridges using the priority ranking (PR) method or the ITA-Guidelines' CoA for traffic and seismic hazards.

5 CONCLUSIONS

This study addresses the risk associated with existing ageing bridge structures, showing an application of a recently proposed risk priority method to a bridge inventory that encompasses 130 bridges in the Lombardy region, in northern Italy. While acknowledging the comprehensive multi-level, multi-hazard approach of the Italian guidelines issued in 2020 for risk assessment and management of existing bridges, this study highlights their limitation in creating a refined risk classification for bridge stocks due to their qualitative description of risk. Such a limitation is overcome by providing quantitative rankings, interpreting the qualitative characteristic of bridges and roads into numerical values, as proposed by the adopted approach (Hamidpour et al., 2024). Both methods were applied to the case-study bridge stock, conducting a thorough evaluation of the Italian guidelines classes of attention (CoA) for various risk parameters and a comparison between the results of the two methods. The primary findings confirm that considering bridge defects and damages amplifies vulnerability, resulting in a higher risk priority ranking. Furthermore, the research highlights variations in a bridge's priority ranking within the stock based on the specific hazard source, with an overall tendency for traffic-related risk to rank higher than the seismic counterpart. The study concludes that the selected

quantitative method offers more refined priority ranks for the 130 bridges, helping their relative priority ranking when they feature the same CoA according to the Italian guidelines. This provides an advantage for bridge operators managing large inventories, allowing for a more refined determination of relative priorities of bridges.

ABSTRACT: Recent bridge collapses have highlighted the urgent need for rapid risk analysis methods to support infrastructure managers in the selection and prioritization of disaster risk mitigation measures. As far as existing road bridges are concerned, their construction was mainly carried out between the 1960s and 1980s, implying that many of those structures have exceeded or are reaching their typical 50-year nominal lifespan. Previous studies have shown that bridges often fail due to a range of natural and human-induced hazards, including floods, vehicle impact, and overloading. Such hazards together with earthquakes should be duly considered into disaster risk assessment of existing bridges. Therefore, the identification of critical structures within a large bridge portfolio should rely upon comprehensive multi-hazard risk assessment approaches. This study presents an index-based methodology for disaster risk assessment of existing bridge portfolios, accounting for a variety of natural and human-made hazards and their potential impact on the roadway network. The proposed risk-based methodology considers various factors that influence structural vulnerability and potential consequences of bridge failure, depending on the specific nature of each hazard. Additionally, the structural condition of the bridges is taken into account when computing single-hazard risk indicators for traffic, seismic, fire, and vehicle impact. These indicators are then integrated into a multi-hazard risk measure using multiple formulations. The final part of the study shows the application of the methodology to a set of road bridges located in northern Italy. The analysis results are compared with those provided by methods available in the literature, discussing the benefits of the proposed methodology.

Keywords: Multi-hazard risk assessment, existing bridges, risk indicators, risk-based ranking, comparative analysis

1 INTRODUCTION

The importance of bridges in road infrastructure cannot be underestimated. Bridges are not merely structural components of a road infrastructure, but an integral part of the socio-economic development and overall well-being of a nation. The significance of bridges in road infrastructure lies in their ability to connect people, promote economic growth, enhance safety, and contribute to the efficient movement of goods and people. Therefore, investing resources on design, construction, and maintenance of bridges is a wise and essential step in ensuring the prosperity of a region or a country as a whole. All around the word, especially in Italy, the backbone of existing road infrastructure dates back to the Second World War, which implies that many of the existing bridges are 50 years old or more. Their natural ageing in combination with the recently observed collapses, e.g., the Morandi bridge in Genoa (Calvi et al. 2019), the multi-span arch bridge

DOI: 10.1201/9781003483755-341

between the municipalities of Albiano Magra and Caprigliola (Scattarreggia et al. 2022), have prompted the need for assessment and, if necessary, intervention. However, in a world where resources are limited, it is needed a rational prioritization approach to support decision-makers allowing the identification of critical structures when dealing with large bridge portfolios. Available approaches for bridge prioritization typically involve the use of indices associated with information on the structural elements (e.g. Bianchi et al. 2022).

A risk-based approach for prioritizing bridges is a systematic method that considers factors such as structural integrity, safety, maintenance needs, and potential consequences of failure for the definition of a priority ranking. Several statistical studies have shown that bridges often suffer failure due to either natural or human-related events (see e.g. Deng et al. 2016). Optimal prioritization approaches should therefore be multi-hazard in addition to having features for an easy application on a large scale. As result, it is important to use quantitative approaches to create a ranking of bridges based on their criticality (Moon et al. 2009), contrary to those based on a qualitative description of risk. Indeed, qualitative approaches do not permit to obtain refined rankings, thus rendering difficult their employment for the management of existing bridges, as the recently issued Italian guidelines foresee (MIT 2020).

In this study, single-hazard risk-based quantitative methods associated with road traffic and seismic ground shaking (Hamidpour et al. 2023b), fire (Kodur et al. 2013), and vehicle impact (Kim et al. 2020) have been selected from those available in the literature. Initially, a brief overview of each of the adopted methods is given. Subsequently, individual risk-based indicators used to derive multi-hazard risk indicators (I_{MH}) according to different well-established combination approaches are described. A group of thirty real bridges located in northern Italy was selected as case-study with the aim of applying the proposed quantitative multi-risk approach for bridge risk prioritization. Single-hazard indicators have been defined for all bridges, and then combined according to the selected approaches for the definition of multi-risk indicators. Obtained results were compared with each other, and the impact on the priority ranking of each multi-hazard combination commented. Finally, a comparison between the proposed quantitative method and the qualitative Italian guidelines is carried out.

2 SINGLE-HAZARD METHODS FOR QUANTITATIVE RISK ASSESSMENT

2.1 *Road traffic and seismic risk*

The weighted multi-factor average model proposed by Hamidpour et al. (2023b) is used for road traffic and seismic hazards to evaluate the priority index of existing bridges. It accounts for hazard (H), vulnerability (V) and exposure (E) components, that are combined according to specific weights as in Eq. (1):

$$PR = 0.2H + 0.4V + 0.4E \tag{1}$$

Multi-parameter formulations are employed to determine each risk component (i.e. H, V, and E), based on the general characteristics of bridges, road category, and their hazards when providing numerical values. In particular, this approach foresees that the overall vulnerability is determined according to Eq. (2), thus, in addition to the structural characteristics, the level of deterioration/defects is also explicitly accounted for.

$$V = \sqrt{\frac{V_s + V_D}{2}} \tag{2}$$

The structural vulnerability (V_s) considers five characteristic parameters including the year of construction, static scheme, largest span length, number of spans and deck material. On the other hand, the vulnerability due to defects (V_D) represents the bridge condition, which accounts for the deterioration effects resulting from the structures ageing and lack of maintenance. This term is defined based on the United Kingdom Bridge Condition Index (UK-BCI) approach (2007). The exposure component of the bridge is estimated using parameters that

account for average daily traffic, detour length, mean span length, entity bypassed and road category. Each of these parameters would represent the expected losses for the bridge itself and the network to which it belongs. Finally, the hazard is evaluated differently depending on whether it is due to traffic load or seismic loading, considering the frequency of commercial vehicles per lane (H_{CT}) and the expected Peak Ground Acceleration (PGA) at the bridge site (H_E), respectively. Further details can be found in Hamidpour et al. (2023b).

2.2 *Fire risk*

The simplified methodology proposed by Kodur and Noser (2013) is employed to identify the most critical bridges regarding the effect of fire, through the determination of an Importance Factor (IF). The method takes into account hazard, vulnerability, and exposure. Specifically, five classes are identified, each of which is composed of parameters that in turn include sub-parameters:

- Class I (ψ_g): Geometrical features, material properties, and design characteristics. The sub-parameters are the number of lanes, age, current standard rating in terms of functionality, and the additional presence of service features.
- Class II (ψ_h): Hazard (fire) likelihood. The sub-parameters are the response time in terms of necessary time before actions, architectural/historical importance, threat perception according to historical fires close to the bridge, and probable fire scenario in terms of consequences.
- Class III (ψ_t): Traffic demand. The sub-parameters are the average daily traffic and location of nearby facilities.
- Class IV (ψ_e): Economic impact. The sub-parameters are the presence of alternative routes, time and cost expected for repair.
- Class V (ψ_f): Expected fire losses. The sub-parameters are life and property losses, and environmental damage.

Each sub-parameter is assigned a weighting factor ($\varphi_{i,x}$) between 1 (best) and 5 (worst). The importance factor (IF) can be estimated indirectly by an overall class coefficient (λ) calculation:

$$\lambda = \sum \Delta_x \psi_x \tag{3}$$

$$\psi_x = \sum \frac{\varphi_x(max)}{\varphi_{total}} \tag{4}$$

The maximum factor ($\varphi_{x(max)}$) corresponds to the highest weight that the sub-parameters can assume for each parameter. Once the λ value has been calculated, the method proposes to assign an arbitrary IF (from 0.2 to 1.5) to qualitatively describe the risk grade from "low" to "critical".

2.3 *Vehicle impact risk*

The risk associated to vehicles impact on bridge piers is evaluated using the method by Kim et al. (2020), who proposes a priority index based on the vulnerability and hazard components. The parameters that need to be taken into account for the hazard evaluation include the type of lower road, the existence of bridge columns within 9 m of the road verge, the distance from industrial sites, and truck accessibility to the road. On the other hand, the vulnerability is characterized taking into account the service years, the current safety level, the number of columns, the minimum diameter of the column(s), the slenderness ratio, and the design load.

The method foresees an initial screening through the so-called "preliminary risk analysis" (PRA) to determine if a bridge is exposed to such kind of hazard. This initial step is conducted by checking for the presence of the following parameters: the existence of a bridge column, the type of bridge column, and the existence of a lower road near a bridge column. As result, bridges without columns, as well as wall-section piers, are not analysed and thus categorized

into the "No Risk" (NR) group, because of the unlikely probability of failure under vehicle impact. Bridges that pass the preliminary risk analysis, are further analysed according to the proposed "simplified risk analysis" (SRA). It is foreseen that both hazard and vulnerability are defined as the sum of weighting factors (from 1 (best) to 3 (worst)) assigned to each parameter, according to the definition of sub-parameters. The standard deviation method (SDI Method) is used to evaluate the scale that defines the attribution of the weighting factor, with reference solely to the quantitative parameters (e.g., number of columns, slenderness ratio, and distances).

Finally, according to SRA, the risk index (I) for each bridge is calculated through the additive combination of hazard (I_H) and vulnerability (I_V) indices according to Eq. (6):

$$I = (I_H + I_V)/2 \tag{6}$$

The two components of the risk index (I_H and I_V) are evaluated individually by normalizing the sum of the weighting factors assigned to each sub-parameter, to the sum of the maximum value that the weighting factor assumes for each of the sub-parameters considered.

3 MULTI-HAZARD RISK ASSESSMENT

3.1 *Qualitative assessment according to the Italian guidelines*

The Italian guidelines method for risk assessment of existing bridges is based on a multi-level and multi-hazard approach that considers the presence of various hazards, i.e. structural/foundational, seismic, landslide, and flood. The guidelines are articulated on six levels (from 0 to 5) of assessments, with increasing complexity and accuracy. Level 2 analysis relates to the Class of Attention (CoA) definition based on the data acquired in Levels 0 and 1 (see MIT 2020) regarding, e.g., location, road use, year of construction, geometrical characteristics, and defects (based on visual inspections), as well as potential risks associated with landslide and flood. The CoA is determined by considering the hazard, vulnerability, and exposure components, with the results being High (H), Medium-High (M-H), Medium (M), Medium-Low (M-L), and Low (L). Logic trees, based on relevant parameters (see MIT 2020), are employed to calculate CoAs associated to a single hazard as well as for their combination. Thus, the derived CoA represents a qualitative description of the risk. Among all analysed hazards, the structural/foundational-related CoA assumes the highest importance and governs over all the others. The method foresees further actions according to the obtained CoA, as, for instance, immediate accurate evaluations for High CoA and preliminary assessments for Medium-High and Medium CoA. The CoA also addresses the decisions on future interventions to be carried out (e.g., monitoring and safety assessment).

3.2 *Proposed quantitative multi-hazard assessment*

The individual risk indicators (I_{Hj}) briefly described above are combined to obtain a total multi-hazard risk indicator (I_{MH}), similarly to what carried out by Scattarreggia et al. (2023). To this end, two combinations are considered: i) a quadratic combination of individual risk indicators, normalized with respect to the number of considered hazards (N_H) (see Eq.7), and ii) a summation of individual risk indicators, but considering the possibility of using weighting factors (C_{Hi}) that can be applied to each risk, e.g., according to the level of knowledge of input required (see Eq.8).

$$I_{MH_i} = \sqrt{\frac{\sum_j {I_{Hj}}^2}{N_H}} \tag{7}$$

$$I_{MH_i} = \frac{\sum_j C_{Hj} I_{Hj}}{\sum_j C_{Hj}} \tag{8}$$

4 APPLICATION TO A BRIDGE STOCK

4.1 *Case-study description*

The multi-hazard methodology has been applied to a group of thirty real bridges, located in primary roads of the Lombardy region in northern Italy (Hamidpour et al. (2023a)). These bridges are viaducts and overpasses, that were mainly built during the second half of the last century (from 1962 to 1967). Most of them (63%) present a deck composed by mixed-steel reinforced concrete and a simply supported beam static scheme (83% of the portfolio). The bridges are located on highways with an average traffic flow of more than 25.000 vehicles per day, indicating a significant amount of daily traffic. The majority of the bridges under study is single or few-span (2 or 3) structures, and most feature decks that are simply supported and have a longest span length of over 25 m. Simple supports are used at the extremities of parallel beams in single or multi-span bridge decks in simply supported beam systems. When they are continuous, they pass continuously over the central piers to span between the abutments. A cast-in-place slab covers every span in continuous slab bridges. Finally, the RC piers on every bridge are either multi-column or single-wall. The statistical distribution of these bridges in terms of year construction (Figure 1 (a)), static scheme (Figure 1(b)), deck material (Figure 1(c)), average commercial daily traffic (Figure 1(d)), largest span length (Figure 1(e)) and number of spans (Figure 1(d)) are shown below.

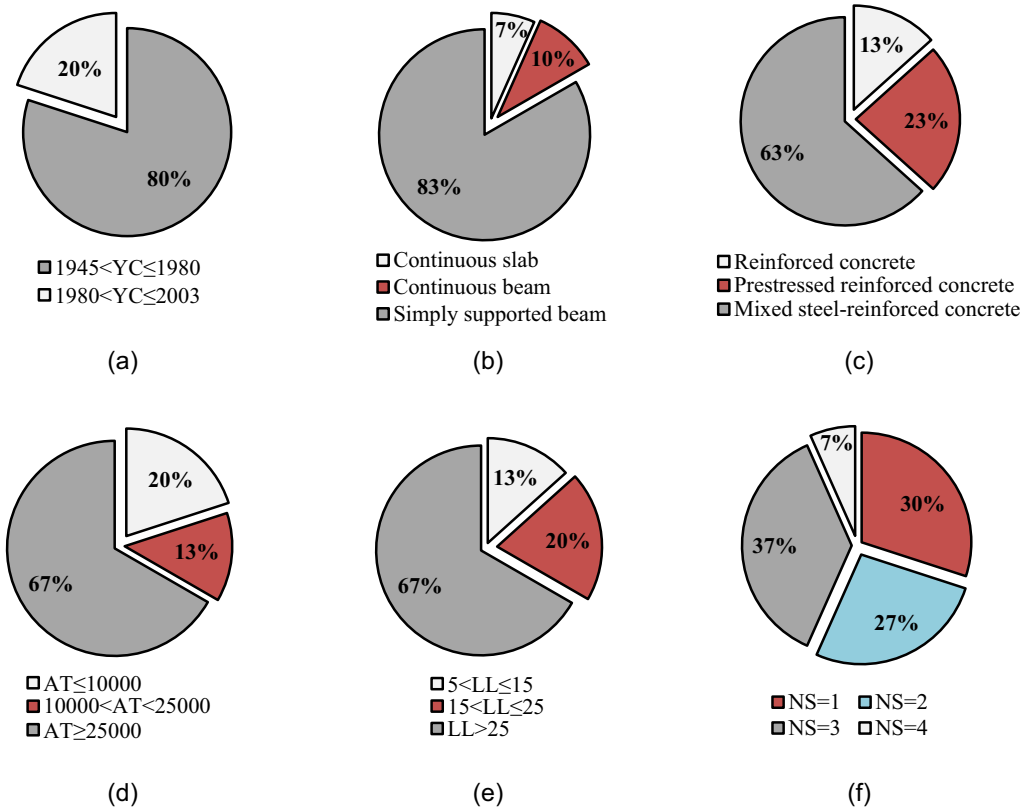

Figure 1. (a) Year of construction, (b) static scheme, (c) deck material, (d) average daily traffic, (e) largest span length and number of spans (f) for the analysed bridges.

4.2 *Quantitative multi-hazard risk assessment*

Although the Italian guidelines propose a multi-level multi-hazard method, their qualitative nature precludes from ranking bridges within the same CoA, as quantitative approaches do. However, instead of the Italian guidelines relying on four hazard classes, namely gravity loads, landslides, floods, and earthquakes, the method provided herein explores the possibility to account for two additional key anthropic hazards, namely vehicle impact (against piers) and fire. Therefore, the quantitative methods introduced in Section 2, are herein applied to evaluate the single-hazard risk indicators that are subsequently used for the assessment of the multi-hazard indicators. Accordingly, the individual risk indicators, i.e., structural/road traffic (I_G), seismic (I_S), fire (I_F), and impact (I_I), were computed, and results are shown in Figure 2. It is herein noted that for the evaluation of index I_I, the exposure component was integrated following the approach of Kodur et al. (2013), in such a way that all the quantitative methods examined, even if simplified manner, account for the three typical components of risk, namely hazard, vulnerability and exposure.

For the evaluation of the seismic indicator two levels of earthquake intensity have been considered: Lower Level (LL) and Upper Level (UL) which correspond to a 10% probability of exceedance in 50 years (which corresponds to a return period of 475 years) and a 5% probability of exceedance in 50 years (with a return period of 975 years), respectively (hence the use of the $I_{S,LL}$ and $I_{S,UL}$ notations in Figure 2). Similarly, for the evaluation of the road traffic hazard indicator two states of damage/defects are considered (according to UK-BCI method): average (Avg.) and critical (Crit.) defects. Particularly, the state named "average" is an overall picture of the bridge condition through a weighted indicator, obtained considering the state of conservation of all elements and considering their importance for the bridge safety. On the other hand, the state identified as "critical" associates the bridge condition to the wors condition among the critical elements for the bridge safety.

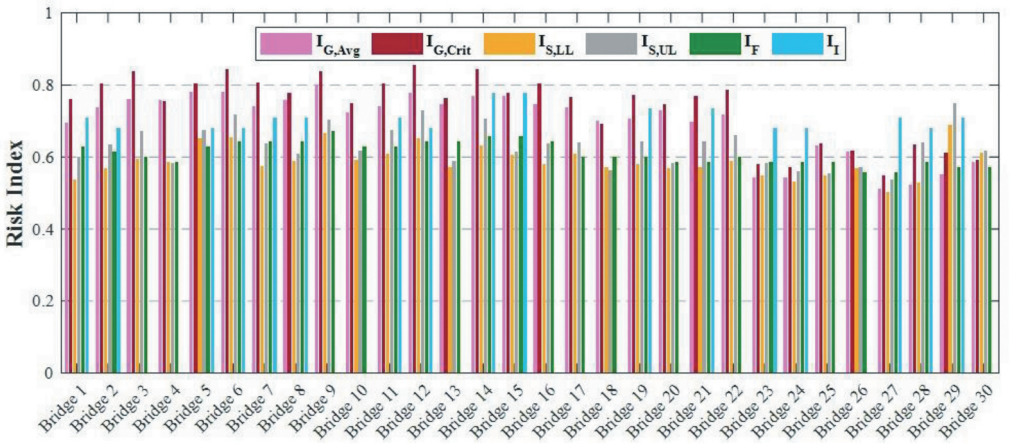

Figure 2. Single-hazard risk indices for the bridges examined.

Once the single-hazard indicators have been evaluated, they can be employed for the multi-hazard assessment. Indeed, assuming $I_{G,Avg}$ as road traffic indicator and considering both the lower $I_{S,LL}$ and the higher $I_{S,UL}$ levels of seismic action, in combination with I_F and I_I, two multi-hazard risk indicators I_{MH1} and I_{MH2} can be calculated using Eq. 7, respectively. Similarly, Eq. 7 can be used to compute another indicator I_{MH3} by combining $I_{G,Crit}$, $I_{S,UL}$, I_F and I_I. Based on the former, Eq. 8 is used to carry out an additional combination using various weighting factors for the different hazards (I_{MH4}). For example, given the comparatively low probability of occurrence (when computable) of fire

and impact hazards, C_F and C_I were set to 0.25. The highest weight was attributed to the road traffic risk indicator C_G=1, due to its larger likelihood in comparison to the other hazards (a logic also followed by the Italian guidelines). C_S=0.5 was used as the seismic-related weight. As a result, Figure 3 shows the total multi-hazard risk indicators (I_{MH}) obtained for the four combinations considered. Results obviously show that thanks to the quantitative nature of indicators a refined ranking can be obtained as opposite to the qualitative grouping of Italian Guidelines. The comparison between I_{MH3} and I_{MH4} highlights the importance of the UK-BCI approach employed for the assessment of the structural condition. On the other hand, the comparison between I_{MH1} and I_{MH3} indicates that the intensity level of the seismic action would not have played a relevant role in the definition of the total risk, reflecting the low hazard of the region where the bridges are located. Finally, I_{MH3} points out bridges that are more vulnerable to structural and seismic actions, given that both fire and impact were weighted minorly.

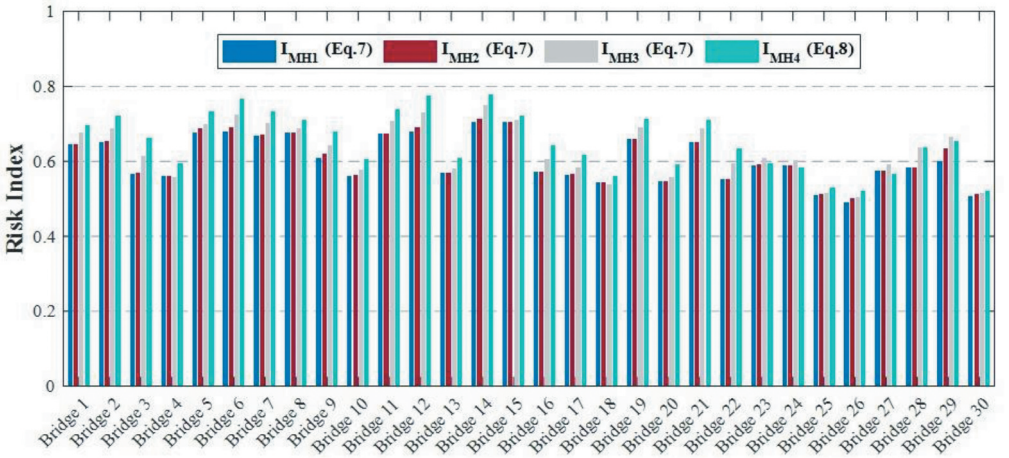

Figure 3. Multi-hazard risk indices proposed for existing bridges examined.

4.3 *Comparison between proposed quantitative approach and Italian guidelines*

According to the Italian guideline's procedure, the analysed bridges fall in the "High" and "Medium" CoA (26 and 4, respectively), considering seismic and road traffic as the only hazards (fire and vehicle impact are not considered by these guidelines). Due to the large number of bridges falling in the same CoA, a managing entity would not be able to prioritize interventions on the selected bridge stock, as opposed to the ranking obtained in Section 4.3 using the proposed multi-hazard quantitative method. Assuming a correspondence between High (H) to Low (L) risk condition ranges of the Italian guidelines with the proposed multi-hazard indicator via the equivalent scale given in Table 1, the proposed method allows grouping bridges as illustrated in Figure 4. Particularly, the comparison is conducted as follows: (i) using Eq. 7 and Eq. 8 considering the single-hazard indicator $I_{G,Crit}$ due to road traffic (i.e. gravity loads) and the seismic indicator $I_{S,UL}$; (ii) using only the single-hazard indicator $I_{G,Crit}$, that has been preferred with respect to $I_{G,Avg}$ considering it match better with the CoA as observedby Hamidpour et al. (2023a).

The comparison in Figure 4 leads to similar observations to Hamidpour et al. (2023a), indeed $I_{G,Crit}$ produces the closest results to the Italian CoA. On the other hand, when both the traffic and seismic indicators are combined according to Eq. 7 and Eq. 8, i.e., I_{MH7*} and I_{MH8*}, respectively, the differences slightly increase.

Table 1. Equivalence adopted between Italian guidelines CoA and multi-hazard indicators (I_{MH}).

ITA CoA	High	Medium-High	Medium	Medium-Low	Low
Proposed I_{MH}	0.60-1.00	0.35-0.60	0.20-0.35	0.10-0.20	0.00-1.00

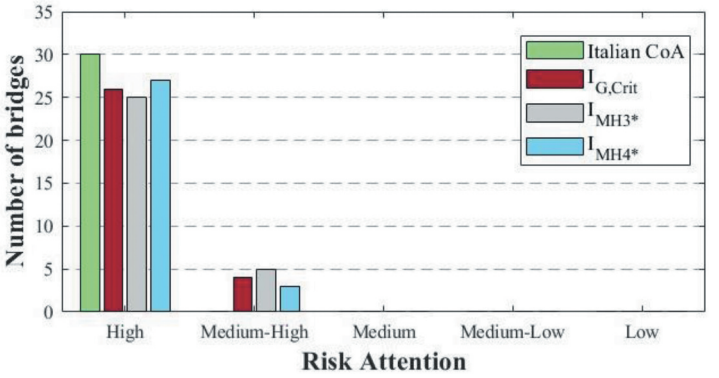

Figure 4. Comparison between Italian CoA and multi-hazard risk indicators range proposed.

5 CONCLUSIONS

This work proposed a preliminary multi-hazard risk analysis method for large bridge portfolios by calculating quantitative indicators (I_{MHi}), combining individual risk estimates (I_{Hi}) using existing literature methods. The road traffic, seismic, fire, and vehicle impact risks are considered for the computation of the total multi-hazard risk indicators (I_{MHi}). The goal was to propose a quantitative multi-hazard assessment approach, as opposed to the qualitative approach of the Italian guidelines, according to which ranking bridges belonging to the same class of attention is not an easy task. It has been shown that the prioritization process is influenced by the type of combination used for multi-hazard risk aggregation. The use of a multi-hazard approach based on the unbundled assessment of individual hazards helps to develop targeted intervention techniques, while increasing the level of knowledge for each bridge (i.e. targeted inspections) allows to obtain a more accurate multi-risk classification. To this end, for prioritization purposes, the efforts in increasing the resolution of the Italian guidelines could be their integration with more quantitative parameters, which may also permit the inclusion of extreme hazards (such as the herein-included fire and vehicle impact). Notwithstanding the promising results that were obtained with this preliminary study, future developments should aim to propose a more comprehensive multi-hazard quantitative method, also improving the multi-risk aggregation procedures, e.g., by using statistically calibrated weighting factors (C_{Hj}) and investigating the importance of uncertainties associated to the input data needed for the calculation of each single-hazard indicator on a final multi-hazard indicator.

The Italian guidelines for risk and safety evaluation of existing bridges: A case study

P.P. Rossi & N. Spinella

A. Recupero
Department of Engineering, University of Messina, Messina, Italy

ABSTRACT: After some catastrophic collapses of bridges, detailed guidelines on risk classification and management, safety assessment and monitoring of existing bridges have been issued in Italy in 2020. This paper presents one of the first experimental applications of these guidelines to a large stock of bridges of two highways located in the Sicilian region (southern of Italy). The first three levels of analysis recommended by the Italian Bridges Guidelines have been applied, and they comprise census, visual inspection and calculation of the so-called class of attention of bridges. The results of these analyses made it possible to collect an experimental database of 358 in-service road bridges, which has been stored and catalogued by means of a customized web application. The web application allows to organize and check data, make queries, processing and visualizing the results. The experimental results are described in detail and analyzed, underlining both abilities and limitations of the examined levels of analysis of the Italian Bridges Guidelines. Moreover, a group defect index is introduced to classify groups of bridges for which the same types of defects with different level of extension and intensity have been detected. It is a prioritization method which allows to plan the same type of maintenance intervention on a group of bridges, more than on a single bridge, reducing economic and social costs.

1 INTRODUCTION

Bridges are critical components of transportation infrastructure, because they provide essential connections for users and services. They may deteriorate quickly, due to the lack of maintenance and/or the increase of traffic load. Therefore, the probability of collapse, as well as the associated economic and social costs, grows rapidly. Almost the Italian territory is prone to several natural hazards, like earthquakes, landslides, and floods. Furthermore, the infrastructure heritage of Italy is one of the oldest in Europe. In the past, only a few Italian regions and handlers have made investments on the management and risk assessment of bridges by means of partnerships with academic research groups or experts in order to obtain support for activities of safety verification of bridge structures or develop their own guidelines (Zonta & al., 2007, Limongelli & al., 2022a, Limongelli & al., 2022b). The Polcevera bridge collapse in 2018 (Calvi & al., 2018) has raised the management and maintenance of bridge to an issue of utmost interest in the country.

In 2020 the Italian Ministry of Sustainable Infrastructure and Mobility (MIT) issued the Italian Bridges Guidelines (IBG) for the classification and the risk management, safety evaluation and monitoring of existing bridges (MIT, 2020). The main scope of the IBG is to ensure a standard and uniform method for the assessment of the level of risk of existing bridges and, then, to plan the monitoring and maintenance activities. The IBG propose a multi-level approach (levels from 0 to 5) with growing degrees of detail. The approach considers different

DOI: 10.1201/9781003483755-342

risks associated with structure-foundation, earthquakes, landslides and floods. The first level of analysis of IBG aims to obtain an inventory of the examined bridges; the second aims to achieve an evaluation of the degradation conditions of bridges by means of visual inspections. The third level allows to determine, for each type of risk, the Class of Attention (CoA) of each bridge. The CoA provides an indicator for the handler to establish the subsequent actions on bridges (i.e. assessment or planning of monitoring systems).

The recent literature about the IBG is mainly focused on the first levels of analysis (from L0 to L2). For instance, Scalbi & al. (2002) presented an application of IBG to a set of sixteen Prestressed Concrete (PC) bridges located in the Lombardia and Calabria regions. As result of the use of the IBG, the authors highlighted the relevance of the maintenance plans in the through-life management of the structure. Zizi & al. (2023) applied the first three levels of analysis of the IBG to a set of sixty road bridges of the Province of Caserta (located in the south of Italy). Based on their results, the authors proposed a preliminary risk model suitable to define an inspection priority ranking.

This article presents the results of the first three levels of analysis of the IBG on more than 350 road bridges of two highway sections in Sicily, a region located in the south of Italy. This campaign was commissioned in the recent past by the handler, the Consortium of Sicilian Highways (CAS), and is one of the first experimental campaigns performed in Italy on a large stock of bridges based on the IBG (MIT, 2020, 2022). The analysis of the results is intended to highlight pros and cons of the IBG. Moreover, a global defect index is introduced as a tool for prioritization of interventions on bridges. It allows handlers to outline a plan of similar interventions on large groups of bridges. Carrying out the interventions suggested by the proposed approach, the number of bridges that need a detailed and expensive analysis (higher than L3 in the IBG) can be reduced.

The authors note that the analyses presented in this paper refer to the entire stock of bridges, without any reference to the single bridge. The use of the results of census and visual inspection is authorized by the data owner (CAS). Based on the results of the visual inspections, the CAS has carried out proper restoration works on their bridges to ensure adequate safety levels.

2 THE ITALIAN BRIDGES GUIDELINES

The IBG implement a multilevel approach. It encompasses six levels of analyses (from L0 to L5) which require different activities as summarized below:

- L0. Inventory of the main characteristics of the bridge and collection of the available documentation;
- L1. Visual inspection of the structure in order to recognize defects and structural and geometric characteristics of the bridge, as well as geo-morphological and hydraulic characteristics of the area;
- L2. Estimation of the CoAs based on hazard, vulnerability and exposure parameters determined at levels L0 and L1. The level of CoAs [structure-foundation (CoA-SF), seismic (CoA-S), landslide (CoA-L) and flood (CoA-F)] may be high, medium-high, medium, medium-low or low. Once the level of the CoAs has been determined, actions are planned. In particular, specific inspection campaigns are mandatory for bridges with medium or medium-high CoAs whereas accurate structural assessments (L4) are required for bridges with high CoAs;
- L3. Preliminary assessment of the structure in order to recognize the need for a detailed analysis of L4. The numerical calculations required at level L3 aim to estimate the minimum safety level required by the codes at the time of construction of the bridge compared with the safety level required by the current code NTC18 (MIT, 2018).
- L4. Accurate assessment of the bridge according to NTC18 and IBG.
- L5. It is currently not described in the IBG.

This study focuses on the first three levels of the IBG (L0, L1 and L2) which are related to the classification of risks and management of interventions. The visual inspections carried out on the two sections of the Sicilian highways were intended to evaluate the structure-

foundation and seismic risks only. As a consequence, the CoAs related to the other risks (CoA-L and CoA-F) are not evaluated and discussed in this paper.

case study

2.1 *Description of the stock of data*

As a demonstrative case, the procedures of the IBG have been applied to a stock of bridges of two sections of the Sicilian highways managed by CAS. These bridges belong to the highway named A18, which connects the towns of Messina and Catania (east side of the Sicily Island) and A20, which connects the towns of Messina and Buonfornello (north side of the Sicily Island). Highways A18 and A20 are more than 50 years old because they were built in the early 1970s. The east side of Sicily has been involved by relevant seismic events (i.e. the Messina strait earthquake in 1908). Nevertheless, the bridges that were built before the '70s were designed without significant seismic provisions.

2.2 *Collection and management of the database*

The inventory and visual inspection activities have produced results in the form of photos and spreadsheet files. At first, these data have been checked by means of an automatized protocol in order to find eventually gross errors due to the inspection activity. For example, the most common errors concerned: the coordinates of the bridge location and the structural type of the bridge deck [sometimes PC bridges were catalogued as Reinforced Concrete (RC) one]. The lack of a predetermined list of allowed responses and the absence of a clear guide to some of the questions included in the forms have caused these kinds of mistakes. In addition, values of intensity and extension factors equal to 0.2, 0.5 or 1 were provided by the inspectors also when the forms allow only a specific value (i.e. 1).

The revised data have been collected in a large database. To create, read, update, delete and quickly select and analyze portions of the database, a customized web application has been built (Costantino & al., 2023).

2.3 *Web application*

The web application includes several components. Each component runs specific tasks, i.e. inventory of bridges, compilation of inspection forms and computation of CoA. All data are stored server-side on a MySQL relational database. An application Program Interfaces (APIs) system allows the exchanges of data between client and server. In addition, data can be imported or exported in MS Excel and/or JSON format.

2.4 *Main characteristics of considered bridges*

The bridges are in number of 142 and 216 on highways A18 and A20, respectively, and have been grouped as a function of the deck material, i.e. RC, PC or Steel-Concrete (SC). As

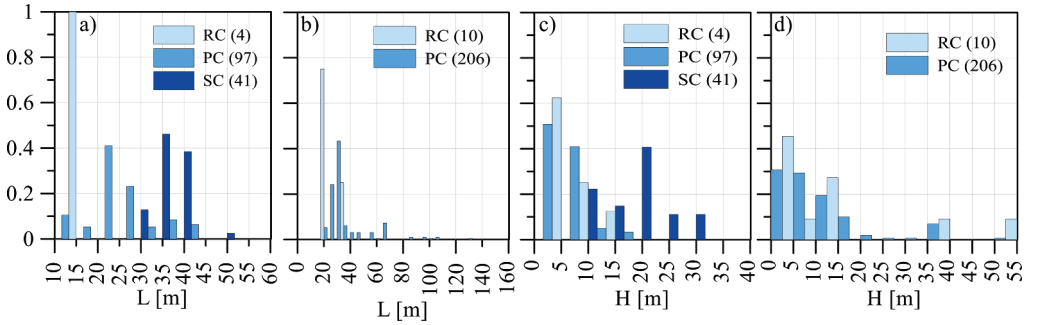

Figure 1. Relative frequency of the length of girders (L) and the maximum height of piers (H) for (a, c) highway A18 and (b, d) highway A20, respectively.

regards the PC bridge decks, pre-stressed strands were mostly utilized on highway A18, while post-stressed strands were used on highway A20.

Figure 1 shows the relative frequency of the values of girder length and maximum pier height grouped for the highway sections (A18 and A20) and for the type of the deck material considered (RC, PC or SC). The girder length of the bridges on highway A18 is mostly in the range between 20 and 30 m. Instead, the girder length of the bridges on highway A20 is mostly in the range between 35 and 40 m, but, in some cases, it exceeds 100 m. The maximum pier height is strictly related to the morphology of the landforms which characterize the territory. The maximum pier height is about 30 m for some bridges of the highway A18 and is over 50 m for some bridges of the highway A20.

3 RISK ANALYSIS

The CoA of a bridge is a function of hazard, vulnerability, and exposure for each risk considered in this work: structure-foundation and seismic, respectively. Risks are analyzed according to primary and secondary parameters described in the IBG.

In particular, the hazard relative to the structure-foundation risk depends on the maximum permissible mass of vehicles and on the frequency of transits of commercial vehicles. Therefore, the handler has provided the data regarding the transit of all vehicles along the considered sections of the highways and, then, an analysis of traffic has been performed. The average of the transits per day was always high for the A18 highway, while on the highway A20 the average of the transits per day was medium from toll-gates 1 to 14 and low from toll-gates 14 to 28. Similarly, the exposure depends on the average daily traffic and average span length, alternative routes and bypassed entity.

The hazard associated with the seismic risk depends on the local characteristics of the ground, both in terms of Peak Ground Acceleration (PGA) and subsoil stratigraphy. The former has been provided by the inspectors based on the national seismic hazard map, the latter has been assumed as the worst condition in accordance with the standard code. The exposure to seismic actions is simply estimated as equal to the one estimated for the structure-foundation risk or it is corrected if the bridge has a strategic function in case of emergency.

The vulnerability of both types of risk considered, structure-foundation and seismic, is mainly estimated as a function of the level of defectiveness as explained in the next section.

3.1 *The level of defectiveness*

The level of defectiveness is determined from the results of the visual inspections and based on the criteria indicated in the IBG. For each type of element, the IBG provide a list of pre-established defects with a different grade of importance (G) from 1 to 5. Each defect is identified by the inspector by means of a level of extension (k_1) and intensity (k_2) factors and, where applicable, indicating if the detected defect can affect or not the statics of the bridge. Moreover, the IBG indicate a list of Critical Elements (CEs), like half-joints, prestressing tendons and extensive crack pattern, which are particularly prone to degradation phenomena and, then, they can significantly affect the structural behavior of the bridge. According to the authors the list of CEs reported in the IBG is not exhaustive. Owing to this, it has been integrated considering also movements undermining bridge foundations (ril_fond_1), diagonal (ca-cap_10) and crushing cracks (ca-cap_13), bending of rebars (ca-cap_17), breakage of the prestressing bars or anchorages failure (cap_12) and oxidation of prestressing wires (cap_8).

Selecting the results of the inspection activities, which were catalogued by means of the web application, it has been possible to know how many times (N) a defect has been detected on the considered group of bridges at a certain level (0.2, 0.5 or 1.0) of k_1 or k_2. The number of times a defect has been detected is $N_{ki,l}$, where $i = 1, 2$ and $l = 0.2, 0.5$ or 1.0. For instance, Figure 2 shows $N_{k1,l}$ and $N_{k2,l}$, which are referred to the defects detected on the primary and secondary beams of the PC decks of highway A18. The defects detected on the PC beams mainly involve the external surface of the PC beams and are: water traces due to inefficient rainwater drainage systems (dif-gen_1), passive (ca-cap_1) and active (ca-cap_2) humidity

spots, erosion of the external layer of concrete (ca-cap_3), spalling of the concrete cover (ca-cap_5) and presence of oxidized and corroded rebars (ca-cap_6) (Figure 3).

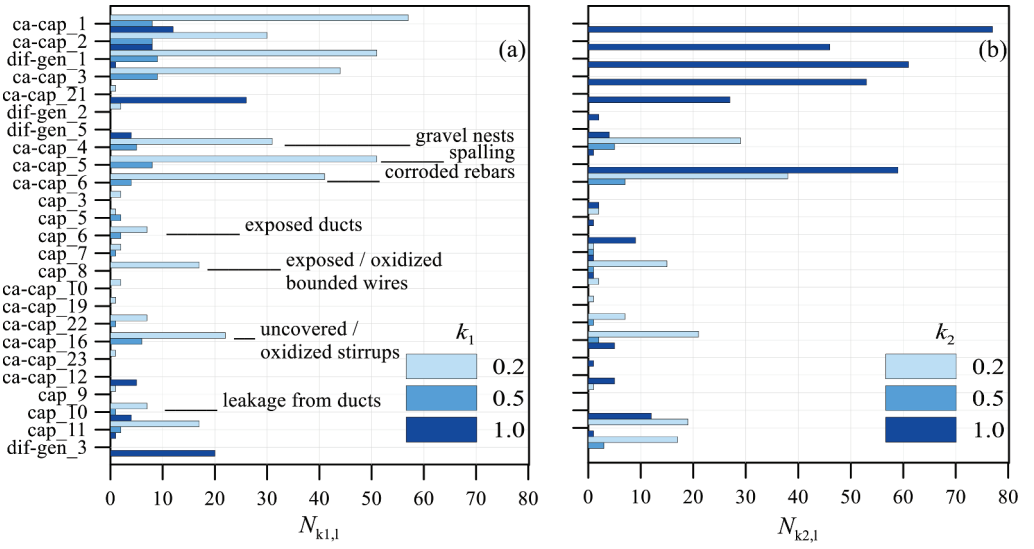

Figure 2. Number of defects detected on "PC primary and secondary beams" of bridges on highway A18 at different (a) extension and (b) intensity grades.

Figure 3. Photos of some defects detected on PC beams.

4 CLASSES OF ATTENTION

The CoAs have been calculated for each bridge of the highways A18 and A20 using hazard, vulnerability and exposure. The possible combinations of values of these components of risk are indicated in the IBG, which report five different tables for each level of hazard (high, medium-high, medium, medium-low and low), and allow the estimate of the CoA following a procedure described by means of flow charts.

Figure 4 summarizes the results of the calculations in terms of structure-foundation (CoA-SF) and seismic CoAs (CoA-S). The bar charts show that the CoA-S is generally higher than the CoA-SF for the bridges of both highways considered. It can be explained because the hazard related to CoA-SF depends on the traffic loads frequency and is higher on highway A18 than on highway A20. By contrast, the seismic hazard is influenced by the seismicity level of the zone of the bridge in terms of both PGA and soil class. The exposure to CoA-S is higher than the one to CoA-SF due to the strategic function of the bridges in case of earthquakes.

The application of the IBG to the stock of bridges considered returns that 56 and 114 of the 358 bridges have been classified as in high CoA-SF and CoA-S, respectively. Therefore, a more detailed and more onerous investigations would be required.

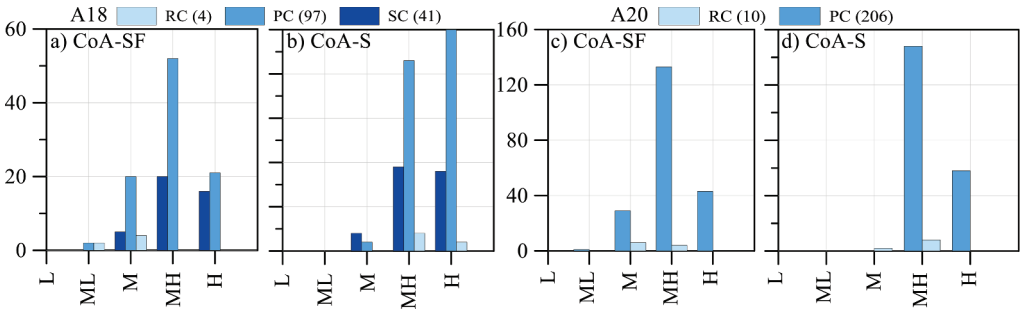

Figure 4. Structure-foundation (SF) and seismic (S) classes of attention of bridges: (a, b) highway A18 and (c, d) highway A20.

Furthermore, bridges with problems due to their structural type and /or material (i.e. bridges with post-tensioned strands) should be preliminary subjected to special inspections and, as a consequence of that, the level 4 of analysis could be necessary to some other bridges with consequent costs often not compatible with the budget of the handler.

5 A SIMPLE INDEX TO PLAN INTERVENTIONS

The prioritization index proposed in this section is based on the principle that management companies, in order to reduce economic and social costs, are generally inclined to carry out the same type of maintenance intervention on a group of bridges, more than on a single bridge. Therefore, the data concerning the defects detected by visual inspection have been analyzed to identify the defects that are mostly influential on the level of defectiveness of the group of bridges. The elaboration of data leads to obtain a Group Defect Index (GDI) inclusive of extension, intensity and importance grades of defects.

First, two indexes (K_1 and K_2) are first calculated for each defect detected on the considered group of bridges to incorporate the weight of the extension or intensity grade factor (k_1 and k_2) of the examined defect. The two indexes are calculated by means of the following relation:

$$K_i = \frac{\sum_l l \cdot N_{ki,l}}{N_b} \tag{1}$$

where i indicates extension ($i = 1$) or intensity ($i = 2$) factors, $N_{ki,l}$ is the number of times a defect with assigned values of the extension or intensity factor ($l = 0.2$, 0.5 or 1.0) has been detected in the group of bridges and N_b is the number of bridges where the specific defect could be detected.

To take into account also of the grade of importance of the defect, the GDI of a defect is defined as:

$$GDI = (G/G_{max})\sqrt{K_1 K_2} \tag{2}$$

$G_{max} = 5$ being the maximum grade of importance of defects. The GDI returns a value between 0 and 1. The higher the GDI value, the greater the influence of the defect in the level of defectiveness of the group of bridges examined. The GDI does not depend on the number of bridges considered because K_1 and K_2 are normalized with respect to N_b, and then it can be used to prioritize interventions.

For instance, in Figure 5 the defects of the PC and RC beams of the bridges on highway A18 have been considered and the GDI has been calculated. The defects with the highest GDI

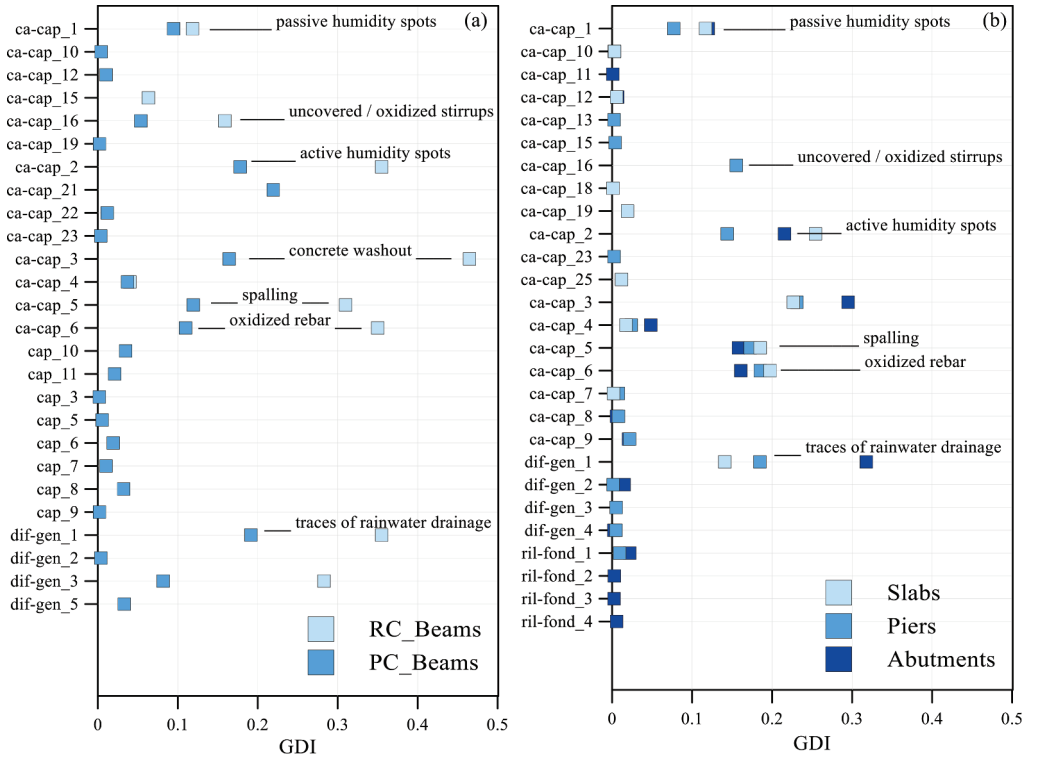

Figure 5. Group defect index for bridges of highway A18: (a) PC and RC beams, (b) slabs, piers and abutments.

values involve the concrete surface of the beams, as previously observed. In detail, the highest values of GDI are related to water traces due to inefficient rainwater drainage systems (dif-gen_1), passive (ca-cap_1) and active (ca-cap_2) humidity spots, erosion of the external layer of concrete (ca-cap_3), spalling of the concrete cover (ca-cap_5) and oxidized and corroded steel bars (ca-cap_6). The defects on slabs, piers and abutments of bridges on highway A18 (Fig. 6b), characterized by the highest values of GDI (≈ 0.35), are practically the same as those of PC and RC beams. In particular, the GDI values of the weightiest defects on slabs, piers and abutments range from 0.10 for traces of rainwater drainage (dif_gen_1) of concrete slabs to about 0.35 for concrete washout (ca-cap_3) of abutments. Defects characterized by deterioration due to erosion of the external layer of concrete (ca-cap_3) of slabs and piers and oxidized steel bars (ca_cap_6) of concrete piers have values of GDI between 0.15 and 0.20. These results highlight an overall high priority of interventions needed to mitigate the effects of inefficient rainwater drainage systems, on RC beams as well as on slabs, piers and abutments.

6 CONCLUSIONS

The paper presents the experimental results obtained applying the methodology proposed by the Italian guidelines on existing bridges. The procedures have been applied to a bridge stock of 358 bridges located along two highways of Sicily Island (south of Italy). The data acquired by visual inspection activities have been stored in a web application to expedite the analysis.

The results of the visual inspections have led to the main conclusion that the most common defects detected on the considered bridges involve cracking and spalling of the concrete cover of the reinforced and prestressed concrete members and are basically due to the lack of maintenance of the structures during past decades.

Moreover, the application of the Italian guidelines to the stock of bridges considered, has allowed outlining the following main observations and proposals:

- The role of the critical elements is significant on the results of the visual inspections because it leads to high levels of defectiveness and, then, to high levels of the Class of Attention. Therefore, to more accurately estimate the effects of a critical element on the level of defectiveness of the bridge, the authors suggests that the effects should be related to the effective level of degradation of the critical element as a function of extension and intensity grades of the defect.
- The structure-foundation and seismic classes of attention are high in 22% and 36% of the inspected bridges. Therefore, a detailed structural and seismic assessment activity on a large number of bridges is mandatory.
- A Group Defect Index has been suggested and it allows owners to cluster groups of bridges through aggregation of data referring to the detected defects in a single numerical index. The proposed index can be useful to plan interventions on groups of bridges and optimize the economic and social costs.

ACKNOWLEDGEMENTS

The authors thank the Consortium for the Sicilian Highways (CAS) that has authorized the use of the data of census and visual inspection of the examined bridges. The research study has been supported by the University of Catania within the research project "DU.SO.CA.P. – Durabilità e SOstenibilità delle strutture in Cemento Armato e Precompresso" 2020/2022 PIA.CE.RI". Moreover, the studies presented here have been carried out as part of the activities envisaged by the Agreement between the High Council of Public Works (CSLLPP) and the ReLUIS Consortium implementing Ministerial Decree 578/2020 and Ministerial Decree 240/2022. ABSTRACT: In recent years, technology has made it possible for us to have a better view and understanding of existing conditions. One such aspect is the use of Unmanned Aircraft Systems (UAS) and Photogrammetry to create photorealistic reality models, which have yielded significant benefits by allowing inspectors, bridge maintenance personnel, and engineers to have a clearer view of what is happening on critical infrastructure and to also perform many of the tasks virtually that would have previously required expensive travel, access equipment, and manual labor. Not to mention the impact on the normal operations of a transportation infrastructure asset (reduced availability and safety). In this paper, we will provide a demonstration of these capabilities and how Transportation Owners and Engineering Firms are starting to apply them on projects to see tangible benefits in terms of costs, time, environmental impact, and safety.

1 INTRODUCTION

In recent years, technology has made it possible for us to have a better view and understanding of existing conditions of our transportation infrastructure. One such technology is the use of Unmanned Aircraft Systems (UAS) and Photogrammetry to create photorealistic reality models, which have yielded significant benefits by allowing inspectors, bridge maintenance personnel, and owners/operators to have a clearer view of what is happening (as-is condition) on critical infrastructure and to also perform many of the tasks virtually that would have previously required expensive travel, expensive access equipment, and extensive manual labor. Not to mention the impact on the normal operations of a transportation infrastructure asset (reduced availability and safety for the users).

There is a significant opportunity to harness additional benefits using virtual and augmented reality (VR and AR). By allowing multiple users to access structures and to view them at a real-world 1:1 scale, we can start to collaborate on bridge projects without everyone being physically on-site. The opportunity to conduct virtual inspections incl. performance prediction and the ability to conduct better Quality Assurance/Quality Control means that we can derive much higher quality, consistent, and objective data that can lead to transparent and better decisions and outcomes. This becomes ever more important as the inventory of bridges and structures that are close to and beyond their design service life continues to grow. It is not sustainable to replace all these structures, and all owners and operators need to develop an optimal strategy to inspect and maintain them.

Introducing a digital twin for bidirectional communication is not new to infrastructure engineering. For decades real time sensor-based updating of Finite Element Models for offshore jacket structures have been performed which again formed the basis for risk-based inspection planning. The digital twin can be local (e.g., cracking of certain area) or global (e.g., deformation of an entire structure). The qualification and assurance of digital twins based on Finite Element Models is described in ref. (DNV, 2020). Somewhat similar to

DOI: 10.1201/9781003483755-343

offshore jackets, bridges are also large infrastructure objects that are often difficult to access and often require complex analyses. Digital twins of bridges have also been used for some time, e.g., for analysis of various hazard scenarios (e.g., strike of lightning on stay cables) so the owner/operator can prepare in advance and thereby increase network resiliency.

Integration of digital technologies and tools in current bridge management workflow needs to be intuitive, reliable, flexible and support transparent decision-making. This holds for new bridges with BIM models, birth certificates (digital as-constructed information) etc. but also for existing bridges with all the challenges that comes with these structures.

Technologies, such as UAS, Photogrammetry, VR/AR, Machine Learning as an application of Artificial Intelligence (AI-ML), and Internet of Things (IoT) can allow us to do more with less and still ensure safe operations of these critical infrastructure. In this paper, we will discuss and demonstrate capabilities and how infrastructure owners and operators and their consultants are starting to apply them on projects to see tangible benefits in terms of costs, time, environmental impact, and safety. Easy access to as-is information may also pave the way for innovative and sustainable structures, materials and inspection and maintenance approaches with yet unproven track record.

Establishment of a photorealistic model is described (chapter 2), followed by a summary of the benefits from an immersive inspection workflow and having a photorealistic model in general (chapter 3). Introducing a second and third layer of new technologies on top of the photorealistic model - virtual and augmented reality (chapter 4) and artificial intelligence and machine learning (chapter 5) is also discussed.

2 ESTABLISHMENT OF PHOTOREALISTIC REALITY MODELS

In Denmark and elsewhere it is common to use a traditional hierarchy of inspections, comprising routine, principal, and special inspections as primary source of information on bridge condition and performance. In particular, principal inspections, often performed within a 5-year interval, should be performed within an arms-length reach of all surfaces according to national codes and guidelines. This principle implies difficult access on major bridges (often coast to coast) by use of rope access and/or underbridge inspection gantries. Performing such inspections comes with a risk to the bridge users (due to traffic restrictions) as well as the inspection personnel working at heights and/or near water. Furthermore, this inspection type is labor-intensive and costly – especially when dealing with major bridges.

In recent years, several bridge owners and their consultants have with success implemented a UAV-based immersive inspection workflow on some of their major bridges. The immersive inspection workflow often starts with a drone flight where RGB and for concrete bridges often also thermal images are obtained. The aircraft could be a DJI M300 RTK or similar. RGB and thermal images might be captured simultaneously with a DJI Zenmuse H20T camera (20 MP zoom camera, 12 MP wide camera and 640x512 px radiometric thermal camera) or similar. The temperature difference between night and day should be minimum 5 degrees for optimum use of the thermal images for detection of concrete delamination, honeycombing etc. The latter defects are otherwise only obtainable using hammer tapping and/or by use of NDT equipment at the concrete surface. It is generally recommended to use the same device for RGB and thermal image capturing respectively during the entire operation.

Real time kinematic positioning (RTK) is used for geo reference of the pictures, which is a 3D representation of the image location in real time. For other bridge structures, a surveyor establishes separate fix points on the structure for geo reference. It must be acknowledged that GPS signal is limited below bridge girders and when flying in their interior. The drones operate in a predefined flightpath at approx. 15 m from the bridge structure. The flight path is determined from weather conditions, drone capability (tight spaces), light conditions, quality of sensors (cameras), restrictions due to traffic, fix points for image reference, etc., which requires domain knowledge within reality capture. Careful planning is key. It is expected that flightpaths can be semi-automated in the future. Automated flight paths can also be of use, when performing a second future reality model.

The imagery is captured with an overlap of approximately 70-80%, which creates a highly detailed 3D mesh. The mesh is then overlayed with the RGB and possibly thermal photos. In special vulnerable zones such as concrete half-joints and splash zone of concrete piers, imagery is captured with an overlap of 80 % for more detailed 3D mesh. It requires domain knowledge within bridge condition management (vulnerable zones, damage mechanisms, resolution needed for defect finding, etc.) to establish a detailed 3D model suitable for immersive inspection. Usually, all pictures are stored as part of the reality capture model and the reality model can be used for easy navigation to the best picture displaying the area of interest.

Using the reality capture model an immersive inspection can be performed at the office. This allows for collaboration between the inspector and various experts if needed be.

Furthermore, immersive inspection allows for the inspector to be well rested and to be able to go back-and forth between locations of interest. Defects and repairs can be annotated on the reality capture model for easy communication between consultant, owner and contractor and all captured data are stored for easy reuse – maybe in connection with defect prognosis at or after the next principal inspection. The use of a reality capture model increases objectivity, transparency and flexibility, i.e., they allow for better decisions.

Furthermore, one or several trained artificial intelligence (AI) models for defect detection are being used. They assist the inspector during virtual inspection especially at vulnerable zones (could be a concrete crack-overlay that highlights flow of forces at half-joints or beneath bearings). Based on the finding from immersive inspections the owner can launch targeted special inspections if certain defects need a more thorough investigation using non-destructive or destructive testing.

Along with the reality mesh, it is quite valuable to be able to add data from other sources that have historically been kept in either a paper format or digital format but on a different/siloed platform. One such example is building information modeling (BIM) data that could be added to the model to give more information from the original design. For an older bridge, this data might not exist. But consultants and owner/operators are more and more seeing the value of putting information into the model that shows all of the historical data made throughout the lifecycle of the bridge. Also, a BIM model could be helpful when inspection data lead to rehabilitation or replacement plans.

3 BENEFITS OF IMMERSIVE INSPECTIONS AND PHOTOREALISTIC MODELS IN GENERAL

Application of immersive inspection comes with a range of benefits. The most important benefits are listed below in random order:

- Reality capture models allow for efficient information sharing, cooperation, and communication between consultant, owner, and contractors.
- Reality capture models provide a good reference point for daily operation of major bridges, e.g., during planning of maintenance works at meetings between various stakeholders (contractors, consultant, and owner).
- Reality capture models can contain and present: 'birth certificates' (as-constructed information), condition assessments as a snapshot in time (incl. warranty inspection i.e., condition at year zero), information of performed and planned repair works and monitoring data. It is seen that a reality capture model represents a snapshot in time information and needs updating when important activities take place (inspection and repair works).
- Combining reality capture models established at different times allows for better prognosis and transparent decision-making. This benefit is not capitalized from day one.
- Immersive inspections decrease the need for labor-intensive inspections and costly access equipment.
- Immersive inspections increase the safety for inspection personnel (less time exposed to traffic, working at heights and near water) as well as asset users (risk of accidents due to traffic restrictions).

- Decrease of inspection costs, maybe not during the first inspection due to establishment of the reality model, but during the following inspections (entire bridge or element-clusters at major bridges).
- UAV's can carry different equipment and in the same flight, e.g., RGB photo for photorealistic models and thermal photo for identification of concrete delamination, honeycombing etc. – and with the current development pace it is expected that more equipment will come.
- No need for manual description of defect location. This may reduce manual labor, increase precision when a special inspection is launched, increased possibility of prognosis and add transparency in decision-making.
- Inspection can be performed by well rested personnel with the possibility of going back and forth between locations (did we miss a repeatable defect?).
- Decrease of environmental impact (detour, congestion, trucks on site for inspection gantries and for traffic restrictions with lights).

There are also some challenges and barriers for people using this digital technology:

- Reality capture and structural experience is required, i.e., domain knowledge is required. Experience with reality capture modelling comprises flight paths for reality capture models of high quality, drone types and carry-on equipment, lighting needed and max wind speed. This is an area of fast development where flightpaths assistance/automation is becoming available. Structural experience comprises reality model resolution needed for defect detection (again dependent on deterioration process and material) and understanding of vulnerable areas that are of special interest (either prone to deterioration or limiting the capacity of the structure in question). Artificial Intelligence assisted defect detection experience comprise knowledge on the accuracy of models, needed training etc.
- Speed and model quality can be obstacles because immersive inspections are always compared to visual inspection. If areas are difficult to reach (often the case for major bridges) speed will not "be a problem". Furthermore, reality capture models usually store all photos, i.e., quality should not be a problem if the reality capture model is established with 70-80% overlay which is generally recommended.
- Introduction of new technologies and tools in organizations comes with a cost and requires new skills. However, a cost-benefit analysis should pave the way for implementation, at least for bridges with difficult access.
- Storing of information should be 'balanced'. It must be decided what data/information should be stored directly in the reality capture model for efficient presentation and decision making and what data should be stored or kept in the bridge management system (BMS), database or a structural health monitoring system (SHMS). A link between the reality capture model and BMS and possibly other systems is key. Similar questions arise regarding new structures and their BIM model.

4 VIRTUAL AND AUGMENTED REALITY

A reality model lets bridge experts see the model from anywhere and easily move around to see different angles of a large bridge structure that would otherwise be hard to reach and comprehend. Once the model is made, there is usually little extra work needed to view it on mobile devices like phones, tablets, or even augmented reality (AR) and virtual reality (VR) headsets. While looking at reality meshes on a desktop is well known, the AR/VR tools offer a chance to improve the workflows, get more information and enhance collaboration among stakeholders.

Virtual Reality (VR):

Virtual reality offers a way to simulate the experience of a physical visit to a bridge site while allowing the user to easily navigate views of the entire structure. Inspecting bridge components such as the top of a bridge pier would be hard to reach, and present issues related to required equipment, traffic management, safety risks and travel time to and from the site.

Furthermore, viewing the model in VR allows the user to view at a 1:1 scale and then quickly switch to a zoomed in overhead view of the overall structure.

The VR environment provides a realistic viewing experience with enhanced features, and the added advantage of being able to co-experience it with other project stakeholders who may be geographically distant. It is plausible to envision multiple engineers evaluating the seriousness of a bridge inspection problem, while looking at the flaw in actual size from different offices.

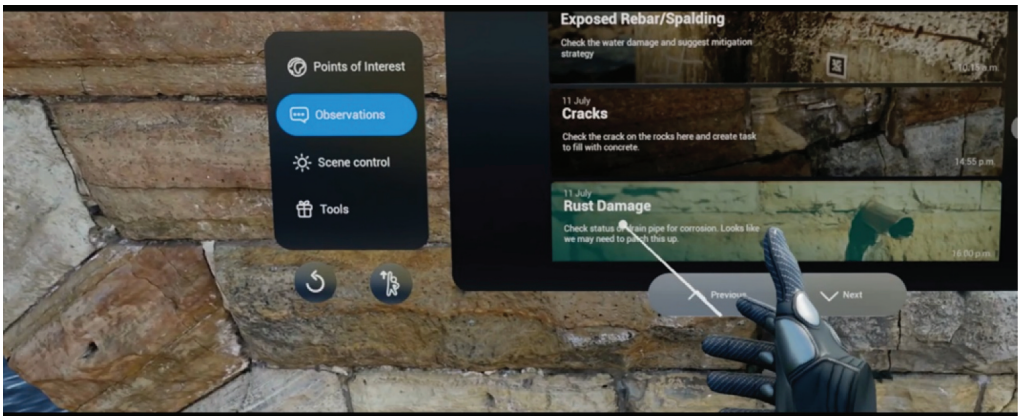

Figure 1. Using a VR app to remotely annotate observations.

Another potential for this technology is in the realm of public involvement, which is a key element in bridge operation and management. Through traditional data and deliverables, it can be difficult to convey how traffic will be impacted by inspection and maintenance projects to public motorists who depend on that infrastructure. Through a combination of a design and reality model data along with VR technology, we can offer more effective visualizations, which makes it significantly easier to convey impacts for a public that is not used to seeing 2D plans, cross-sections, or engineering details.

Augmented Reality (AR):

While virtual reality can bring the bridge to the office, augmented reality can now bring digital data into the field. Recently, AR hardware has been developed that is integrated into personal protective equipment, like hardhats so that personnel in the field can safely use the equipment and combine the insights and usability of the reality mesh with the inherent value of being able to physically view the bridge components.

We can envision many use cases for AR, but these 3 are the most apparent:

Viewing hidden design components – Often the as-built drawings that are provided at the completion of a project can be lacking in information, unreliable or in a format that is difficult to valuably use to make maintenance decisions. Being able to visualize hidden features like rebar or buried utilities against the backdrop of the physical structure empowers professionals to have a more complete picture and make more informed decisions. This is accomplished by integrating an accurately georeferenced model into the AR view. It should be noted that for many older structures, this information may not be readily available, and more work and data acquisition may be required to identify hidden components and convert the data to a digital format. However, AR presents this potential advantage for future design and construction projects. Integrating AR and building data-rich models into current workflows will pay dividends well into the future.

Comparing inspection or design notes while onsite – An accurate high-resolution reality model presents the opportunity to create annotations and inspection items in the office that can be subsequently viewed onsite as georeferenced locations on the model. Integrating these notations into the AR viewable model allows inspectors to leverage the benefits of the reality

model while in the field. The notes created in the office can be verified and amended in the field with the backdrop of the physical structure.

Visualizing potential rehabilitation/replacement components – Similar to integrating existing hidden BIM design components into a reality view, the ability to physically walk the bridge and view proposed design items at a 1:1 scale can provide a more complete picture and help identify clashes or potential construction challenges. Unlike the hidden design components, the ability to integrate new BIM components into an existing model does not present the same technical or logistical challenges and is a feature that can be easily added throughout the maintenance lifecycle of a bridge.

The potential for AR to revolutionize the way we see our infrastructure is certainly there, but there are also technical challenges that must be addressed. While AR technology continues to mature, VR technology is already mature enough to deliver significant benefits to everyone involved in infrastructure projects ref. (Bentley, 2021).

As an early proof of concept of Augmented and Virtual Reality, Microsoft HoloLens 2 (HL2) has been used along with Microsoft Azure Remote Rendering (ARR) technology to stream reality data to the headset device. The streaming service requires a strong and stable network connection with a minimum requirement of 40 Mbps download and 5 Mbps upload. The HL2 comes with a version of Windows, which has a familiar user interface for most users. The headset requires an initial configuration to calibrate the device for each user and can also use their retina for login purposes. For the HL2, an application (App) was developed and deployed, which can integrate with single-sign-on (SSO) systems to access 3D models that reside in cloud services. A proof-of-concept project between COWI and Bentley was conducted where a HL2 App was used to stream reality data from a cloud service.

The process for this immersive visualization required the user to first generate a QR code from a web application, which then allowed the use of the HL2 device to read and then launch the application to access that specific model. The App allows the user to view the model in table (small) scale as well as full (1:1) scale. The hologram of the reality capture model can be moved, rotated, and extended with the use of gestures and finger movements. The 1:1 scale allows the user to fly around in the model giving access to areas that would be difficult or impossible to do on-site. Within the App it is also possible to inspect the structure and annotate maintenance items and observations. A pin is placed for each of these annotations and details can be added either by writing on the hologram keyboard or by dictating the text. These annotations can then be synchronized to a web application for further collaboration with other users.

Figure 2. Using HoloLens 2 at site (upper right picture is the AR-image as seen by the inspector).

5 ARTIFICIAL INTELLIGENCE AND MACHINE LEARNING

Bridge inspections can be a tedious yet risky task. An inspector must correctly spot, measure, and categorize damage processes and defects such as deck cracking as part of a thorough bridge inspection. The data they collect is useful for bridge inspection reports and for maintenance and design purposes. Inspectors have to visit the site and examine every part of the bridge to assess condition/performance and report it properly in the system.

Artificial Intelligence can help make the workflow better by providing assistance to the inspectors. Some examples have appeared with machine vision technology that lets inspectors get a more consistent and objective understanding of issues, such as cracking, spalling, or corrosion.

For instance, to solve the problem of finding cracking on bridge decks, we can use thousands and thousands of images. These images can come from regular inspection photos, from a dataset that is open to the public, or from drone images, to train a detector that can find cracking on bridge elements. The AI-ML detector can go through all the 2D images to detect and then mark the cracks in the photos. A post-processing cleaning step can find and remove known false positives. The reality capture model should be based on pictures of similar resolution as used for training of the AI-ML models. This allows for the best defect detection.

Figure 3. Sample of a cracked concrete surface (left) and crack-overlay (right).

Each 2D image with the crack information can then be sent to software to create a 3D mesh, which can then project the identified cracks on the surface of the deck. This 3D view lets the user quickly assess the overall state of the bridge without having to zoom in on the reconstructed model. Even before getting the actual analysis and numbers, this lets the user evaluate the condition qualitatively with little effort.

These auto-detected cracks can also be turned into 3D-lines, which can then let us interact with them as individual cracks that can be edited, deleted, or extract information about their geometry. Some examples of the type of analysis that can be done include individually selecting each crack and instantly getting the length, selecting all of the cracks to get the total crack length and even more importantly crack width in the chosen area – both options relevant for pavement repair but not very interesting for concrete bridges.

While cracking on concrete bridges is a good use case, other types of defects can also be found using this workflow. For example, spalling is a very common (and troublesome) issue on large concrete structures. Spalling is a big issue for infrastructure owners because 1) it may weaken the structure integrity, 2) even when it does not, it greatly increases the chances for more spalling to happen and other elements to degrade (like rebars in reinforced concrete, which then corrode when exposed to humidity) and 3) concrete may hit underpass traffic.

Because spalls affect areas rather than lines like a crack would do, new types of detectors are needed to find them. There are some challenges, such as the AI model not being able to find the exact boundaries of spalling areas and the tendency to produce a lot of false positives.

As the goal of such automated inspection is to assist engineers in their task, a few of these false positives can be accepted, however, a high number of mistakes is problematic, because it would require a lot of time from the engineer to exclude them and would lead to a general distrust of the AI system. Using several new AI techniques, detectors for spalling are now able to not only put a rectangular bounding box around the area of concern, but can also highlight the affected areas accurately, so that you can get a much better measurement of overall spalling.

Besides using machine vision for supporting inspections, AI-ML has the potential power to help our industry move at a faster pace from reactive to preventative or even cognitive maintenance. For example, with the emergence of Internet of Things (IoT) sensors that can collect a large amount of data about a bridge's performance over time, we can not only use this information to alert us when the readings are out of range, but we can use the time-series data to predict performance. This type of analysis could be supporting us to move from the traditional scheduled-based inspection and maintenance to risk-based inspection and maintenance.

6 CONCLUSION

Digital technologies have a lot of potential to improve the way we do bridge inspections and maintenance. They can help us collect more consistent data and analyze it faster and more effectively, which can benefit bridge owners, inspectors, and the public who use them. Some of the early users of tools and technologies like UAS, AI-ML, and IoT have already seen benefits, such as: less field time, more reliable data for analysis, better bridge repair suggestions, better communication and cooperation, lower costs, and less environmental impact by using less equipment. Technology is advancing quickly, and this is only the start. In the immediate future it is foreseen that we will have more trained defect detection models for various materials, image resolution, lighting conditions etc. and efficient integration of data from various sources (crow sourcing from connected cars, satellite data, sensors/IoT on the structure, etc.). But technology is not enough to change the way we manage our bridges. We also need to train people to use these technologies and we need to update our processes so that we can use UAS more confidently and regularly in our operations and trust the power of AI-ML to help our bridge engineers make the best choices on how to maintain our growing number of structures that are aging beyond their expected design life.

Digital transition in asset management – Virtual inspections of bridges

N.L. Barnes
COWI A/S, Kongens Lyngby, Denmark

E.D. Hartwich
The Danish Road Directorate, Fløng, Denmark

ABSTRACT: In Denmark, bridge managers are obligated to conduct principal inspections every sixth year. Today, most inspections of bridge structures are outsourced to consultancy companies performing visual inspections on-site, facing challenges such as traffic restrictions, subjectivity and consistency in documentation, and difficult access- and working conditions. However, the ongoing digital transformation of O&M of bridges offers viable solutions through the integration of technical equipment including drones, sensors, software, etc. in the inspection process, leading to significant environmental, economic, and technical benefits. By employing high-quality RGB photogrammetry and thermal imagery captured by drones etc., a Reality Capture Model, a visual Digital Twin of the structure, is generated. The COWI Virtual inspection software facilitates principal inspections with AI-aided defect detection enabling multiple specialists to annotate damages or defects directly on the RCM and revisit the bridge structure when necessary. Additionally, the thermal imagery, when combined with RGB photos, enables the detection of delaminations, honeycombing, and water ingress in concrete structures. In 2023, a virtual principal inspection of the pylons on the Faroe Bridges and the Queen Alexandrines Bridge is conducted. This paper presents key findings from pilot projects to complete virtual inspections and highlights the benefits and challenges associated with the transition to virtual inspection methodologies and future AI-driven- and performance-based asset management.

1 INTRODUCTION

The digital maturity of the construction sector was reported as very low back in 2016 (McKinsey 2016). Compared to other industries there seems to be great potential in terms of both technical and economic benefits of the digital trasition in the construction sector. In the recent years there have been a great focus on the Operation and Maintenance (O&M) of bridges originating from e.g., bridge collapses, increasing environmental focus, and the attention to service life and Life Cycle Cost of structures and materials accelerating the digital transition.

In Denmark, the asset manager is obligated to conduct visual inspections every sixth year to maintain the level of safety, foresee critical defects, and avoid costly repairs. Most of the inspections are outsourced to consultancy companies performing traditional inspections. The traditional inspections are carried out with rope-access or from a lift or platform challenged by e.g., traffic restrictions, high initial costs, subjectivity, and consistency in documentation (Moore et al., 2001), and access - and working conditions.

The use of Unmanned Aerial Vehicles (UAVs) has accelerated in the construction sector in within both inspections and supervisions of structures. The high-quality sensors, Real Time Kinematics (RTK), and improved software have made it possible to establish detailed 3D-meshes and Reality Capture Models suitable for virtual inspections. RGB Photogrammetry and AI-aided defect detection is used to detect visual defects e.g., cracks, corrosion, etc.

DOI: 10.1201/9781003483755-344

and thermal imagery is used to detect e.g., delamination, loose repairs, honeycombing, and water ingress. UAV-based photogrammetry has proven safe, cost-, and technically efficient on multiple bridge projects with the use of both RGB and thermal imagery (Lindberg et. al, 2022 and Sandager Jensen 2023).

The digital transition within asset management and O&M is rapidly improving, and this paper provides key findings from pilot projects to complete virtual principal inspections performed today and the prospects within performance-based asset management and predictive maintenance.

2 ASSET MANAGEMENT OF BRIDGES

The inspections are performed according to general procedures and manuals for principal inspections. The observations from the principal inspections are noted on tablet or paper and documented in a report including selected photos (primarily the founded defects). In addition, the observations are translated into a condition rate for each structural element (intermediate piers, abutment, pavement, bearings, etc.), according to the codified procedures. The inspector also provides a timing and cost estimates of needed repair or replacement works, and the asset manager plans for future repair work based on this principal inspection report.

The visual inspection is cost-effective when performed by qualified personnel. However, the documentation rely on subjectivity as only selected defects are reported. The inspector should also be able to separate visual defects from critical defects and acknowledge when to upgrade the principal visual inspection to a special inspection and perform non-destructive tests or service life assessment, load capacity assessment, proof-loading, etc.

An essential aspect of asset management is determining the 'optimal point in time' for repair or replacement of structural elements based on the inspection data and condition rating considering the Key Performance Indicators (KPIs) reliability, availability, safety, economy, and environment relevant for bridge management when considering service life of bridges (COST TU1406, 2018 and Linneberg, 2020). Structural Health Monitoring Systems (SHMS), bearing capacity (Finite Element modelling), and defect modelling is key input to the decision making regarding long term maintenance strategies. It requires Artificial Intelligence to objectify and find the strategies and the optimal point in time for repair and replacement of structural elements.

The traditional inspections are reported by the inspector into existing Bridge Management Systems (BMS), which cannot accommodate the integration of different data sources. Such improvement of the current portfolio BMS incl. full integration of a risk-based management system considering multiple maintenance strategies (and KPIs) is technically challenging and costly. Therefore, the digital transition is only improved gradually.

2.1 *The Danish Road Directorate*

The Danish Road Directorate is the asset manager of the Danish state roads and adjacent civil structures including bridges. They have shown increasing interest in UAVs and a more cost-effective alternative to traditional inspections the recent years. As bridge maintenance costs continue to rise, this has become a priority. Consequently, several pilot projects exploring the possibilities of UAVs, Digital Twins, and virtual inspections were initiated in 2019. One such project involved the collaboration between the Danish Road Directorate and COWI A/S in 2020. The main focus was to establish a Reality Capture Model of the Faroe Bridges (presented later in this paper). This model was intended for general operational purposes and to facilitate the principal inspection of concrete emergency walkways.

The pilot project marked the beginning of an ongoing collaboration between the Danish Road Directorate and COWI A/S. As case studies in this paper, the recent principal virtual inspections of the Faroe Bridges and the Queen Alexandrines bridge are examined. Notably, both bridges cross water, presenting significant potential for cost-effective inspections when utilizing UAVs.

One of the challenges facing the Danish Road Directorate is the large number of relatively small and easily accessible structures for which the state is responsible. When considering the establishment of Reality Capture Models for these smaller structures, careful assessment of the costs versus the value they can create is essential. In addition to their applications in the operational phase, RCMs can also yield valuable information for future road and bridge projects during the planning and construction phases, thus enhancing the overall data foundation for the Danish Road Directorate.

3 CASE STUDIES

Two case studies from Denmark have been selected to illustrate the utilization of UAVs, Reality Capture Models, and the general workflow when working with virtual inspections: The Faroe Bridges and The Queen Alexandrines Bridge. Both bridges have been part of pilot projects prior to complete inspections which is described in further details in the following presentations of the two bridges.

3.1 *The Faroe Bridges*

The Faroe Bridges connect Falster and Zealand via the Faroe Island in Denmark. These bridges opened to traffic in 1985 and is carrying four lanes of highway traffic. The connection consists of a cable-stayed bridge in the south, connecting Falster to Faroe. It has a length of 1,726 m, a main span of 290 m, and a clearance from the sea of 26 m. In the north, there is a concrete beam bridge (orthotropic steel box girder) connecting Faroe to Zealand, with a total length of 1,596 m and a clearance from the sea of 26 m (The Danish Road Directorate, 2023).

The Danish Road Directorate owns and operates the bridge, while COWI A/S has provided consultancy services related to its operation and maintenance. The cable-stayed bridge is shown in Figure 1. In 2020, the Danish Road Directorate commissioned COWI A/S to establish a Reality Capture Model of both bridges, used for general operations and principal inspection of concrete emergency walkways (spanning over 6.5 km) and bridge piers (34 in total).

In total four UAV flights were conducted for the pilot project: The first flight established reference points. The second flight established RGB photogrammetry for the entire model. The third flight obtained close-up photos of emergency walkways, and the fourth captured close-up photos, including thermal imagery of all bridge piers.

The inspection was carried out in an early edition of COWI Virtual Inspection. Following a virtual visual inspection with RGB-imagery and thermal images, an inspection of six bridge piers using rope access were carried out. The inspectors found the same significant defects (delaminated areas of similar size) as the virtual inspection alongside minor defects as cracking and poor in-situ grouting of voids from the removal of scaffolding. Furthermore, the virtual inspection discovered a few defects in the splash zones that were not accessible during the rope access inspection. In 2023, a principal inspection of the two pylons of the cable stayed bridge is conducted.

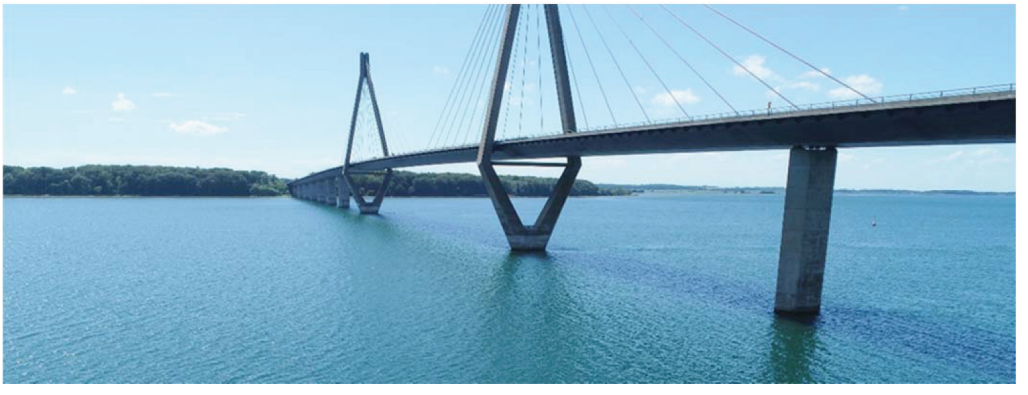

Figure 1. The Faroe Bridges (Cable Stayed Bridge in South).

3.2 *The Queen Alexandrines Bridge*

The Queen Alexandrines Bridge, also known as the Moen Bridge, connects Zealand with Moen in Denmark. The bridge opened to traffic in 1943 and is carrying two lanes of traffic and two pedestrian walkways. It has a total length of 745,5 m, with a main span of 127,5 m and a clearance from the sea of 26 m (The Danish Road Directorate, 2023). The construction is an open arch bridge with five approach spans cast in reinforced concrete on each side of the main arch span constructed in steel.

The Danish Road Directorate is responsible for owning and operating the bridge, with consultancy services provided by COWI A/S for its operation and maintenance. The Queen Alexandrines Bridge is shown in Figure 2. In 2022, the Danish Road Directorate commissioned COWI A/S to establish an RCM of one approach span. The model was integrated into COWI Virtual Inspection as part of a pilot project for visual inspections.

The Reality Capture Model of the bridge was based on both RGB – and thermal imagery captured simultaneously with the use of a drone, without any traffic restrictions. The principal inspection was carried out using annotations in the model to illustrate visible damages e.g., cracks, spalling, organic growth, graffiti, etc. The annotations are directly linked to the specific area of the model and are easy to revisit to e.g., consult or verify with a specialist. In 2023, a Reality Capture Model of the bridge is established as part of a principal inspection of the entire bridge.

Figure 2. The Queen Alexandrines Bridge.

4 DATA COLLECTION

In 2023, the Reality Capture Models of the two bridges are established using similar methods. The models are created by processing RGB-images captured with a drone trough photogrammetry. The captured pixels ranges from 1.2 to 7.8 mm. In addition to the visual surface, thermal images are also simultaneously captured. The drones follow a predefined flight path, approximately 15 m from the bridge structures. The flight path is dependent on weather conditions, drone capability (e.g., tight spaces which require a drone capable of bumping into the structure), light conditions, quality of sensors (cameras), restrictions due to traffic, fix points for image reference, etc., which requires domain knowledge within reality capture. When operating in Denmark, the drones are not allowed to pass or fly above traffic lanes without permission.

To ensure accurate geo-reference, real-time kinematic positioning (RTK) is utilized for the Faroe Bridges, providing a 3D representation of the image locations in real time. For the

Queen Alexandrines Bridges, a surveyor establishes separate fixed points on the structure for geo-referencing purposes.

Typically, the imagery is captured with an overlap of approximately 70%, resulting in a highly detailed 3D mesh. In vulnerable zones (e.g., splash zone), imagery is captured with an overlap of around 80% to produce an even more detailed 3D mesh. This mesh is then overlayed with the RGB photos. The creation of a detailed 3D model suitable for visual (virtual) inspection requires domain knowledge within bridge condition management, considering factors such as vulnerable zones, damage mechanisms, and the necessary resolution for defect detection.

5 VIRTUAL INSPECTIONS

5.1 *Workflow of virtual inspections*

The RGB-images are processed in commercial Bentley software to establish the Reality Capture Model. The models with adjacent RGB- and thermal images are then imported into the COWI Virtual Inspection tool. It is a web-based platform where the virtual inspections are carried out. The platform allows the users to manually annotate defects, use AI for defect detection, attach files or URLs to the model or defect, and generate a principal inspection report of annotated defects. The workflow of the two case studies is elaborated in the following.

5.1.1 *The Faroe Bridges*

The pylons of the Faroe Bridges are established as two separate RCM-models and imported with adjacent RGB- and thermal images into COWI Virtual Inspection. The COWI Virtual Inspection platform is shown with the northern pylon in Figure 3. The screen of the platform is split into three showing the model, annotations, and the images. A double click on the model will give the user the 30 best images in the picture panel.

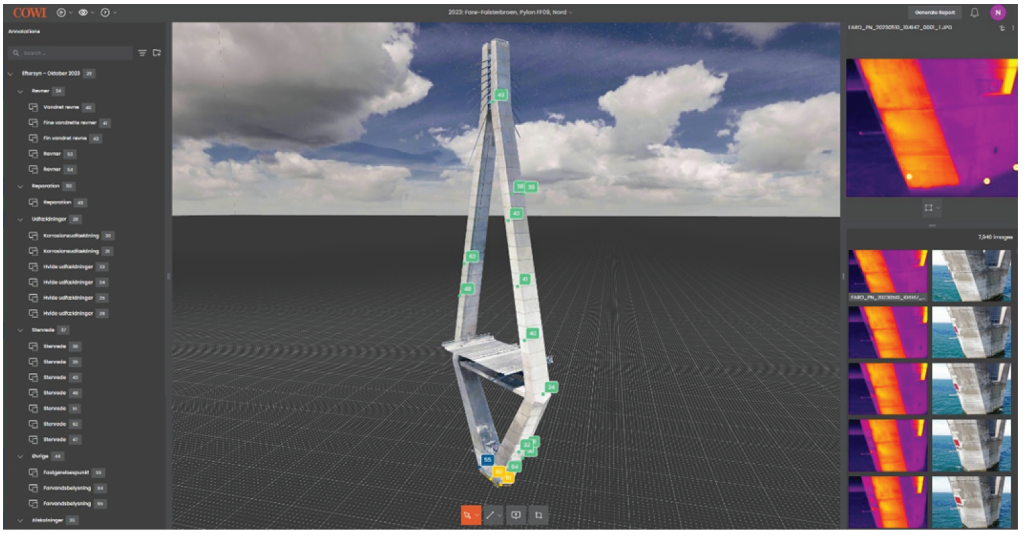

Figure 3. Pylon of the Faro Bridges in COWI Virtual Inspection.

A principal inspection is carried out using manual annotations to illustrate visible defects e.g., cracks, spalling, corrosion, coating defects, etc. The defects are registered with severity level 1-5 (green to red), a short description, recommended action, and custom tags (location). The defect annotations are linked to the specific area of the 3D-model and are easy to revisit e.g., consult

or verify with a specialist. Thermal imagery identifies areas that have a temperature difference down to 0.1-0.2 degrees Celsius compared to the surrounding structure.

The thermal imagery is primarily used to screen the concrete surface above the highway for possible delaminations to ensure safety for the drivers passing the bridge. In the splash zone thermal imagery is also used to detect spalling and loose repairs in the splash zone where cathodic protection is established. A principal inspection report is generated in COWI Virtual Inspection with all the annotated defects and two adjacent images: Overview and close-up image of the annotated defect.

The virtual principal inspection is combined with a manual inspection of the interior concrete surfaces of the pylon. A pilot project was carried out using the same method with image processing based on RTK, but it was not optimal with the plain concrete surface and no GPS in the pylons. Instead, the manual inspection is supported with drone videos and imagery from inaccessible areas inside the pylon. Both inspections are collected in a general inspection report with overall summary of defects and recommendations.

5.1.2 *The Queen Alexandrines Bridge*

The Queen Alexandrines Bridge is established as two separate RCM-models: Span 1-6 and 7-12 and imported with adjacent RGB- and thermal images into COWI Virtual Inspection. The COWI Virtual Inspection platform is shown with model of span 7-12 in Figure 4.

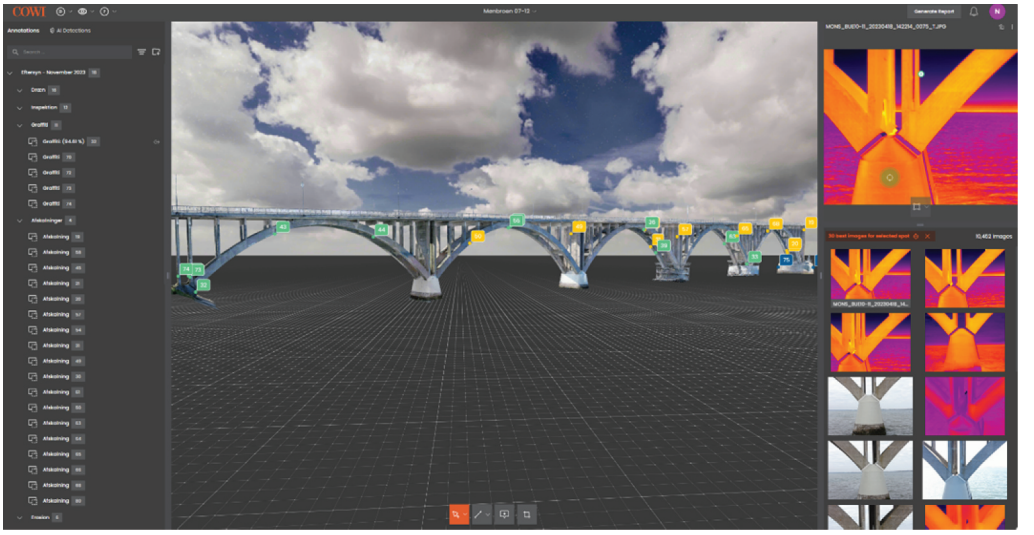

Figure 4. Span 7-12 of the Queen Alexandrines Bridge in COWI Virtual Inspection.

The approach of the virtual inspection is similar to the one carried out for the pylons of the Faroe Bridges. However, AI defect detection is implemented in the beginning to screen the bridge structure for cracks, graffiti, and corrosion. The defect detections are rated true og false to train the general AI-model, and the AI detection is moved to the annotations for the principal inspection if it is within the scope of the inspection. An example of an AI-detected crack is shown in Figure 5.

The AI-models are in general trained with the mindset, that false positives are accepted (they are sorted out during the manual visual inspection), but a false negative of a given size or in vulnerable regions (e.g., shear cracks in bridge half joints) is not accepted. In addition, it is important to use AI models that are trained for similar damage types and image resolution.

The thermal images are primarily used to screen the concrete surfaces on the main arches for possible delamination and loose concrete repairs. A principal inspection report is generated in COWI Virtual Inspection with all the annotated defects.

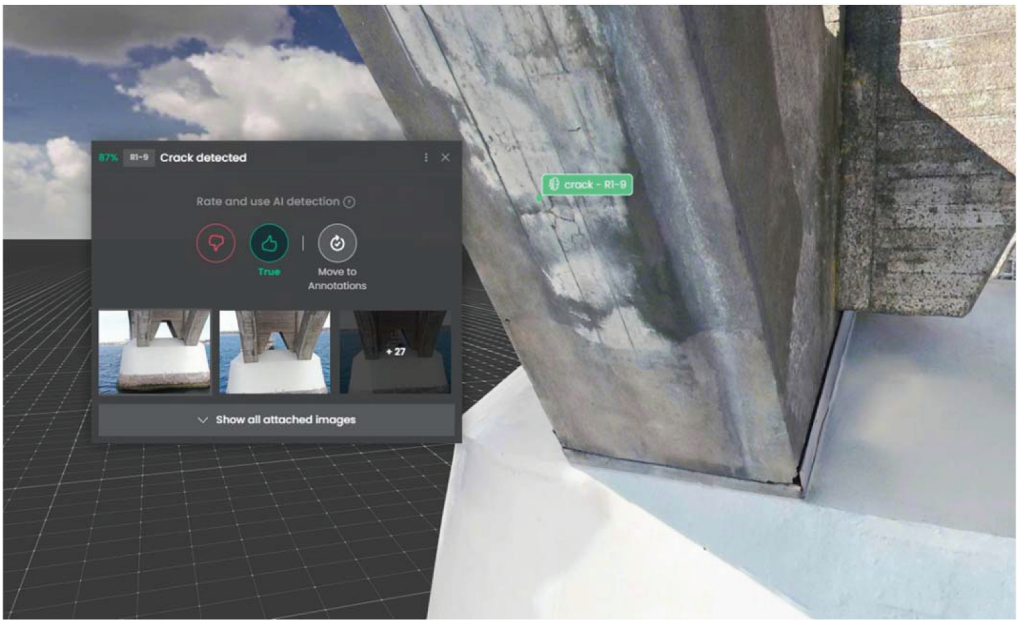

Figure 5. Example of an AI-detected crack in soffit of concrete arch of the Queen Alexandrines Bridge.

The virtual inspection is combined with a manual inspection of the interior and structural elements above road level as pavement, dams, railings, and main span including embankments. The main span consists of a steel arch with hangars and trusses. That type of structure is problematic when establishing an RCM-model with image processing and the drone images are instead used to supplement the manual inspection of the main span. Both inspections are collected in a general inspection report with overall summary of defects and recommendations.

5.2 *Advantages and challenges*

The COWI Virtual Inspection platform allows multiple specialists to take part in the visual inspection leading to transparency in decision-making and less subjectivity. The bridge is inspected with well-rested personnel, and it is possible to revisit structural elements to look for repetition patterns in defects or consult a specialist.

At the Queen Alexandrines Bridge it is not profitable to do a principal inspection of the entire bridge every fifth or sixth year. The bridge is constructed with arches and columns, which are difficult to inspect from a lift, platform, or rope-access. The RCM-model gives a great visual model of the entire structure. If necessary, it is easy to point out structural elements or areas where a special inspection should be caried out. The Danish Road Directorate can access the model and hereby get full documentation of the bridge inspection, not only selected defects. Beside the models, the images, annotations, and the 3D-model is handed over in open-source formats to the DRD, which makes it possible for them to access the data from other platforms.

The Reality Capture Model may also be used to e.g., annotate daily operation jobs for operation personnel, plan future repair works, etc. The model creates a solid foundation for collaboration with all stakeholders incl. owners, contractors, and consultants without being present at the bridge site and without possible traffic restrictions.

Though many advantages have been pointed out, some challenges remain: The data collecting process still requires highly trained personnel to establish a detailed photo-realistic 3D model and depends on the quality of sensors (cameras etc.), traffic laws, and restrictions when flying with UAVs, flight plans, lighting conditions, weather, and temperature (when using thermal imagery).

The implementation of the Reality Capture Model in 'codified' procedures and manuals, and in current BMS software remains one of the greater challenges. The digital transition requires more performance-based assessment and not only codified procedures and traditional reporting. The Danish Road Directorate is openminded and has agreed to do separate inspection reports to upload in their Bridge Management System.

6 FUTURE PERSPECTIVES

When working with O&M of older bridges as the two bridges presented in the case study, the drawings, images, structural verification reports, etc. from construction are rarely well-documented. The establishment of an RCM-model gives full documentation of the older bridge as a first step in O&M. The same applies for a newly constructed bridge. It can both work as supervision in collaboration with the contractor or as a 'Birth Certificate' of the bridge. The bridge owner has a great focus on the BIM-models to be handed over as part of the As-built information. It might be the time to demand a Reality Capture Model, which gives full documentation of the structure with defects from the beginning and works as a solid foundation for future O&M activities.

Companies specialized in BIM have acknowledged the great potential for digitalization within Operation and Maintenance (O&M). It is competencies like this that will take the RCM-models to the next step with integration of both BIM-models and FE-models and improve the quality of the O&M ensuring repairs and replacement of structural elements at the 'optimal point in time'.

7 CONCLUSIONS

It requires domain knowledge within bridge condition management and reality capture to establish a detailed 3D model suitable for visual (virtual) inspection. With improved sensors, software, and UAVs, the data collection -and integration process still becomes less time consuming and more cost beneficial. Virtual inspections performed on Reality Capture Models delivers less subjectivity and full 3D documentation in an improved workflow with full transparency. In addition, UAV-based inspections increase bridge availability, and increase safety for bridge users and workers.

The workflow of Virtual Inspections is continuously improved as seen in the two case studies from pilot projects to principal inspections with both RGB and thermal imagery to detect visual and certain non-visual defects. However, it is important to acknowledge the limitations and move on to a special inspection when needed.

The integration of the Reality Capture Model within the principal inspection regime improves workflow, ensure full documentation, and supports finding the 'optimal point in time' to repair and replace structural elements considering multiple Key Performance Indicators for bridge owners and operators.

Norwegian coastal bridges

T. Kvamstad
COWI AS, Trondheim, Norway

H.A. Moe
COWI AS, Oslo, Norway

I.A. Lervik
Møre and Romsdal County Molde, Norway

ABSTRACT: Due to Norway's topography with fjords and islands the demand for bridges is high. The age of these bridges, specifically those constructed between 1960 and 1990, coupled with harsh climate and exposure to seaborn chloride, indicates an anticipated increase in the need for maintenance in the near future. This paper give insight in challenges the asset managers of Møre and Romsdal county is facing. This is illustrated by the case studies of Remøy bridge from 1967 and Runde bridge from 1982. The result of a special inspection by COWI demonstrates how different maintenance strategies is needed based a detailed investigation of the deterioration state. The Remøy bridge will rely on a strategy of Controlled Detoriation to maintain an acceptable Safety level. For the Runde Bridge the rehabilitation strategy is to extend service life by investment in new and modern cathodic protection systems. To be able to inspect and perform maintenance to the bridges in a sustainable way, new technologies must be taken into use and further developed. In this paper drone inspections with thermal images, NDT inspection of post-tensioned strands and rehabilitation with cathodic protection will be discussed.

1 INTRODUCTION

Norway has the second-longest coastline in the world, measuring 100,915 km when including all the islands. With its topography characterized by fjords extending up to 205 km into the country and approximately 300 islands with permanent residents, there is a high demand for bridges.

In general, Norway's regional policy since World War 2 has aimed to reduce centralization and promote development across the country. A crucial aspect has been ensuring access to healthcare, schools, and transportation networks for all citizens. As part of this effort, the construction of bridges to replace ferries has been prioritized, even in areas with relatively few permanent residents. The coast is home to important export industries within the maritime industry, seafood industry, and power-intensive industries. These industries rely on bridges that are open and with high load-carrying capacity.

Coastal areas of Norway are home to over 7,000 public road bridges, where the majority are reinforced concrete bridge (Bruaas, T.). The first reinforced concrete bridges were built in the 1920s, and the number of bridges constructed annually increased rapidly and peaked in the 1970s. According to the BRUTUS database, which catalogs Norwegian public bridges, approximately 60% of the bridges have either already reached, or will soon reach an age, where extensive maintenance is required. The main challenge faced by bridges in coastal areas is corrosion of the reinforcement due to the presence of chlorides. Seawater and air born chlorides can result in pitting corrosion, which deteriorate the health state and safety of the structures. The required concrete cover thickness for bridges has varied over the years since the first regulations were

DOI: 10.1201/9781003483755-345

established in 1926. From 1973 to 1988, it reached its lowest at 25 mm - 30 mm (Bathen, L 2021). Considering that this period coincided with the peak in the construction of new bridges, we anticipate a rapid increase in corrosion-related damage in the coming years.

Post-tensioned bridge technology gained popularity in Norway, particularly for longer span bridges along the coast. The industry faced challenges, particularly with grouting. However, significant improvements in grouting quality were achieved following the release of the first version of the Norwegian Concrete Association (NCA) publication number 14 in 1986. Several bridges with insufficient grouting from before 1982 have been identified. With the recent release and implementation of the NPRA Report number 718 "Post-tension concrete bridges - Inspection manual" in 2021, more bridges with corrosion on post-tensioned reinforcements are expected to be discovered.

The high costs involved and the challenge of keeping bridges open with only limited closure times due to lack of alternative routes require the application of new technologies. Several major older bridges are single lane and may be the only access point to a community and industry. Closure for more than a few hours has high user inconvenience cost and, in some cases, not acceptable.

The Norwegian bridge owners are obligated to seek sustainable solutions when managing their bridge portfolio. To keep the existing bridge for as many years as possible will in most cases be the correct solution. The decision of whether a bridge should be strengthened, maintained or go through controlled deterioration has to be based on LCA and LCC with input of sufficient data.

2 MØRE AND ROMSDAL COUNTY MUNICIPALITY

In the Norwegian Public Road association, a bridge is a traffic carrying element spanning more than 2,5 m. In Møre and Romsdal county road network, there are a total of 1021 structures that are managed according to the national bridge management regulations. This includes 872 road bridges, 50 pedestrian and bicycle bridges, 56 ferry docks, 34 avalanche protection structures, and nine loose material tunnels/tunnel portals that bear traffic loads.

The bridge management regulations require regular inspections, to ensure control over the condition of these structures. Currently, three percent of the road bridges in the county road network have severe damages/deficiencies that pose a threat to the bridge's bearing capacity or the safety of the users, as shown in Figure 2. There is a significant maintenance need for road bridges. The main reasons are the age of the bridges, how they were constructed, and the environment they are exposed to. A national goal of a 100-year lifespan for bridges was established around 1990. This goal resulted in much stricter requirements regarding concrete composition, concrete cover, and considerations for the environment in which the structure is placed. These stringent requirements do not apply to structures built between approximately 1960 and 1990. The regulations at that time were based on a lifespan of 50-60 years. Figure 2 shows that 60 percent of the county road bridges in Møre and Romsdal were constructed during that period.

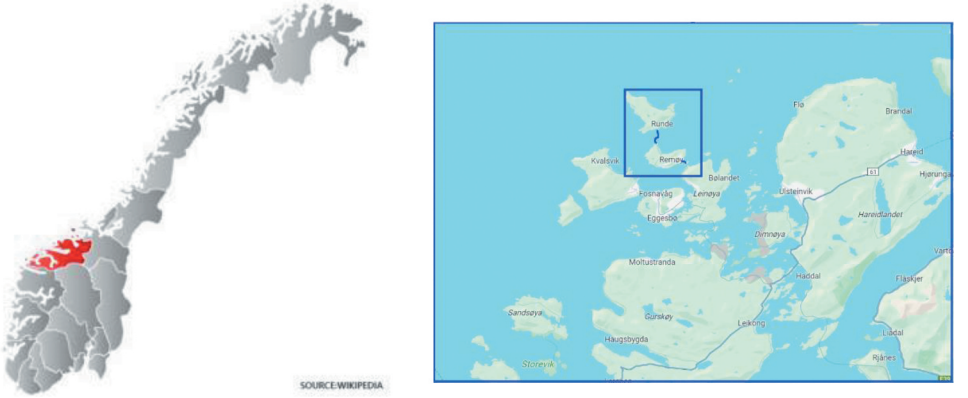

Figure 1. Left: Map of Norway and Møre and Romsdal County Municipality showed in red. Right: Location of Remøy Bridge and Runde Bridge outlined in blue (Map: Wikipedia).

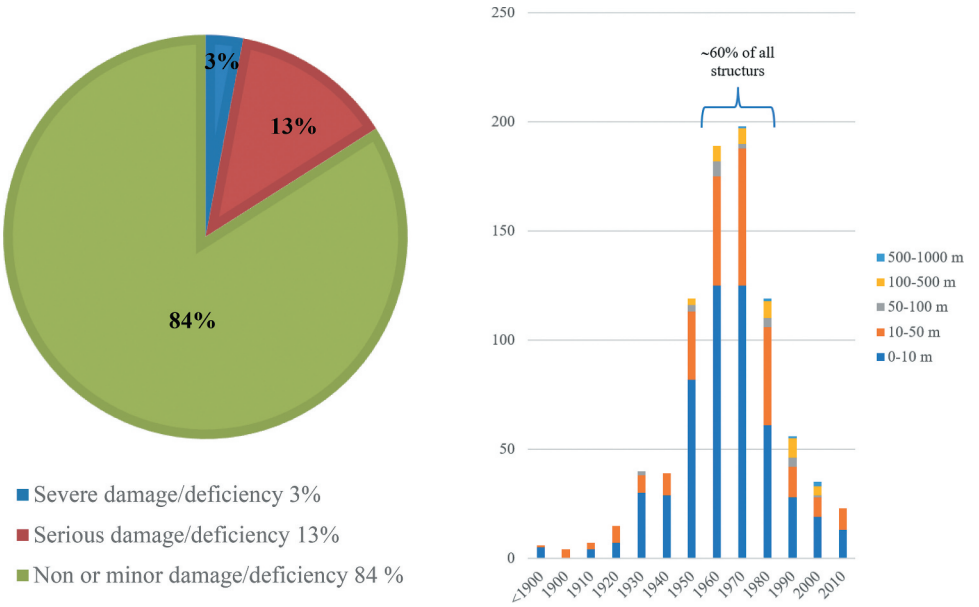

Figure 2. Road Bridges in Møre and Romsdal County. Left: Condition. Right: Year of construction.

Møre and Romsdal county situated on the coast of Norway is characterized by its challenging geography, islands, fjords and mountain areas, combined with scattered settlements. Despite of this, Møre and Romsdal is one of the country's largest export counties. According to the National Exportation Report from 2022, the export per employee of the county was 700 000 NOK. This is almost four times the export intensity of Innlandet County and more than double the export intensity of Oslo. The high export intensity is driven by significant exports from the maritime industry, seafood industry, and power-intensive manufacturing in the region (Menon Economics, 2023). Hence, it is of vital importance to have an operational road network with high bearing capacity.

Knowing that over half of the total bridge length pr. meter built between 1960-1990 is located over the sea, this indicates a significant need for major maintenance or replacement of bridges in the coming years. The leading repair method for large reinforced concrete bridges in coastal areas is cathodic protection (CP) systems. As CP rehabilitation is an expensive investment, it is crucial to apply the correct repair strategy and method. Amount of damaged concrete to be replaced is often a key cost driver. This leads to time consuming inspections and field work, including visual inspections and surface testing with hammer sounding.

3 CASE STUDY

Møre and Romsdal County's challenges and need for investments in bridge operation and maintenance is illustrated by the case studies of the Remøy and Runde, located at the coastline in the south-western part of the region. The bridges carry a single lane of traffic and a narrow pedestrian walkway, and is the only access to the islands Remøy and Runde, see Figure 1. The Remøy bridge opened to traffic in 1967, with a 2023 annual average day traffic (AADT) of 1000. The Runde bridge opened to traffic in 1982 where it replaced the previous ferry connection to Remøy, with a 2023 AADT of 300 (Vegkart.no).

Both bridges are situated in harsh climates, exposed to deterioration from chloride driven corrosion. In 2023 Møre and Romsdal FK commissioned COWI AS to perform a special inspection of both bridges. The purpose of the inspections was to recommend a short term and long-term maintenance strategy. An overview of the inspection program is listed in *Table 1*.

Table 1. Special inspection program conducted for the Remøy and Runde Bridge, June 2023.

	Remøy	Runde
Under Bridge Lift Access *(night closure of traffic)*	x	x
Rope Access *(night closure of traffic)*		x
Drone inspection with Reality Capture Model and Thermal images	x	x
Visual inspection and Sound hammering	x	x
Chloride samples (RCT-method)	x	x
Concrete core testing	x	x
NDT (Non-Destructive Testing) of PT-reinforcement	x	x
Inspection and data collection of Cathodic protection system	x	x
EKP measurement to assess ongoing corrosion		x
Local inspection of ongoing corrosion on reinforcement	x	x

3.1 *The Remøy Bridge (1967)*

The Remøy bridge is a 340-meter-long slender beam bridge opened to traffic in 1967. The bridge consists of 20 spans, a T-shaped beam cross section with varying height. The 40 m main span and adjacent side spans are prestressed with Dywidag bar system. The need for a ship navigation clearance of 17-meter results in high slender columns, as well as steep slopes.

As a combination of the harsh climate conditions and the design rules at the time of constructions with limited concrete cover, the Remøy bridge today is at a state of rapid increasing deterioration. The slender design has few reserves with regards to bearing capacity.

The inspection by COWI concluded that Remøy bridge has extensive concrete damages mainly due to chloride driven corrosion and that the damages developed from last inspection. Photos from drone inspection was important when comparing to previous inspections and assessing the rate of deterioration. Also, the cathodic protection system does not function as intended anymore. Although a load capacity check shows sufficient bearing capacity on short term, the location and shape of cracks on the main beam indicate that they may have occurred due to high loading.

Figure 3. The Remøy bridge. (Photo: COWI AS).

The recommended strategy for Remøy bridge is controlled deterioration and the county need to invest in a new bridge within 5-15 years. The reason for this is both the high chloride content and rapid development of damages, but also the lacking robustness that is required to perform maintenance at the same time as it is traffic on the bridge.

On a side note, the bridge has a slightly longer twin bridge, the Nerlandsøy bridge, build at the same year where damages have yielded the need for a replacement, and a new bridge is under construction and opens to traffic in 2025. The total cost for the new Nerlandsøy bridge is estimated to 850 MNOK. The need for a high-bridge due to the Norwegian Coastal Authority sailing lead requirements is a key cost driver.

3.2 *The Runde Bridge (1982)*

The Runde Bridge from 1982 is a post-tensioned concrete box girder bridge, where the main span of 118 m is constructed as an extradosed cantilever girder. The bridge lands on a 1,2 km long mole, and the sea currents around the mole and pillars leads to heavy currents. The asset manager has informed that the snow plough runs over the bridge to remove seaweed after heavy storms.

The Runde Bridge is located in extremely harsh climate, facing the open Nordic Sea to the west. The severe chloride impact has led to increasing deterioration from concrete damages and corrosion. At the end of the 1990's the bridge was in need for a corrosion protection system, and early 2000 a Cathodic protection system was installed at bottom slab of the girder, as well as on most pillars.

The inspection conducted by COWI AS showed increasing deterioration, and a non-functioning CP-system that needs to be replaced on both pillars and underside of bridge-deck. Due to the robust design of the box girder, no damages with consequence for the short-term bearing capacity was identified. To reach this conclusion it was vital to investigate the state of non-visual parts as cast-in post-tensioned tendons. This inspection of PT-tendons was conducted as non-destructive testing (NDT) based on ultrasonic pulse combined with local inspection.

The single-lane traffic as well as heavy wind led to difficult and expensive inspection, and hence will lead to an even more difficult and expensive repair. Result show that, depending on strategy chosen, the Møre and Romsdal county will face an investment of between 30 MNOK and 80 MNOK to extent the service life.

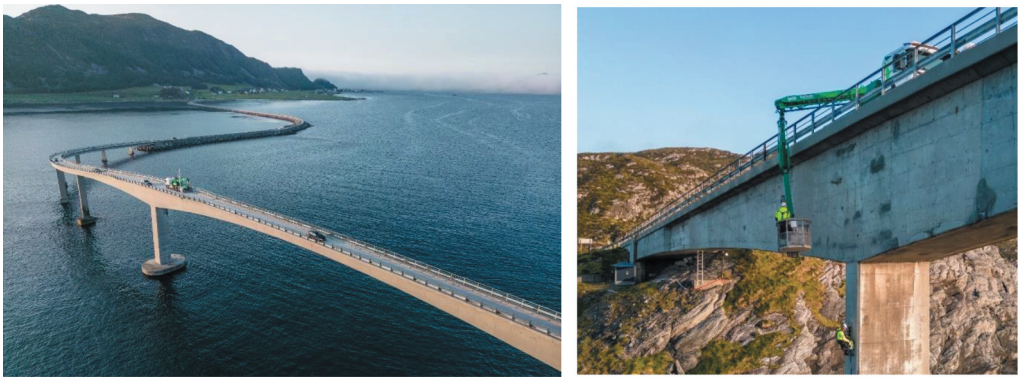

Figure 4. The Runde Bridge (Photo: COWI AS).

4 CHALLENGES AND OPPORTUNITIES

4.1 *Controlled deterioration*

When selecting a repair and rehabilitation strategy for a deteriorating structure – including a controlled deterioration strategy - the estimate of the remaining lifetime is often based on experience. To avoid serious bridge failures a conservative estimate must be used when predicting the remaining lifetime. Additionally, the effect on the extension of lifetime because of various repair and rehabilitation option is associated with some uncertainty due to the lack of an efficient tool to proper evaluate the effect. This uncertainty with respect to the remaining lifetime – and the effect of repair and rehabilitation options – means that there is a lack of information when determining the optimal bridge rehabilitation strategy, which may often lead to a non-optimal spending of budgets.

When a bridge such as the Remøy bridge undergoes a controlled deterioration strategy it is vital to have the required and updated information on the current deterioration of the bridge and an estimate on the development of deterioration – concrete, reinforcement, and

post-tensioning system. A controlled deterioration strategy is maintained by maintaining the load bearing capacity, so an updated load bearing capacity model and a trustworthy model of the current and future deterioration is vital. Only when having this, is it possible to evaluate the needs for actions from the current day and until a replacement bridge is in place. as well as consequences for on delaying the replacement on:

- Safety and robustness associated with the condition and load-bearing capacity
- Increased cost to inspection routines
- Increased costs associated with load-reducing measures
- Increased cost to acquiring knowledge to maintain safety (data collection, calculations)
- Socio-economic consequences (traffic regulations, closure time for inspections and maintenance work)

The actions required in this period may range from doing nothing, perform new inspections to update and validate the deterioration model, local strengthening projects, local repair projects to slow deterioration, reduction of allowable loads on the bridge and so forth.

4.2 *Virtual inspections*

As a pilot project initiated by Møre and Romsdal County, a Reality Capture Model was included in the inspection program for Remøy and Runde bridge. The Reality Capture 3D models and inspection software were delivered by the drone inspection specialist company Axess Digital AS. COWI AS contributed to the flight plan before data collection and conducted the virtual inspection reporting in the Axess Bridge software.

A Reality Capture Model offers a visual overview of the bridge and full documentation for future operation and maintenance activities. A Reality Capture Model is established from RGB images captured primarily with Unmanned Aerial Vehicles (UAVs) as drones etc.

In addition to the visual surface, thermal images are simultaneously captured. The drones follow a predefined flight path, approximately 15 m from the bridge structures. The flight path is dependent on weather conditions, drone capability (e.g., tight spaces which require a drone capable of bumping into the structure), light conditions, quality of sensors (cameras), and fix points for image reference. The imagery is captured with an overlap of approximately 70%, resulting in a highly detailed 3D mesh, which is then overlayed with images to create a visual digital twin. The models with adjacent RGB- and thermal images are then imported into commercial software for inspections. The platform allows the users to manually annotate defects and generate a report of annotations. An example is shown for Runde bridge in Figure 5.

Figure 5. Rundebru in axess inspection app with annotated defects and adjacent images.

The thermal imagery is used as a supplement to the RGB photos and can identify areas with temperature changes at the surface of the concrete e.g., delamination, certain cracks and joints, concrete repair, and water ingress which may not be visible on RGB photos.

Using UAVs leads to reduced traffic disturbance and a short time on site which overall reduce the initial cost e.g., truck mounted under bridge inspection units, rope access, lifts, etc. for visual inspections. The virtual inspection is a good starting point for special inspections, offering a visual overview of the entire bridge before collecting concrete cores or dust samples for further material analysis, manual inspection with hammer test using rope-access, etc. of a limited part of the bridge. It provides full documentation with less subjectivity compared to manual inspections on site.

4.3 *Cathodic protection rehabilitation*

The use of impressed current cathodic protection as part of rehabilitation strategies for the bridges in the coastal areas started in the late 1980′ties and early 1990′ies. At the Runde bridge an extensive cathodic protection system was installed in 2001/2002. Protection was applied to 6 of the 8 pillars and the entire bottom of the concrete box girder. For the pillars a carbon fibre-based anode mesh embedded in 3-5 mm cement mortar was installed on all external surfaces, whereas discrete drilled-in anodes (3 mm diameter TI-MMO rods) embedded in a graphite paste were installed in the bottom plate from the inside of the box girder. A modular rectifier and monitoring system was installed inside the box girder. Compared with traditional TI-MMO mesh embedded in sprayed concrete both anode types allowed for at faster and more effective installation as the mesh on the pillars was only covered with a thin (3-5 mm) mortar and all discrete anodes were installed from inside the box girder eliminating traffic nuisance and the need for scaffolding. In terms of the anode types used the installation was considered a pilot project as the performance was not well known.

After installation, operation and maintenance inspections were carried out at regular intervals to evaluate the performance of the system, and particularly the adopted anode systems. Over the first decade, it was observed that the current output from the carbon fibre mesh decrease significantly over the years, and it was reported that samples of the anode mesh collected from the structure showed signs of deterioration. Also, it was from observations suggested that the low current output was also a result of failing anode mesh connections. Also, the performance of the discrete drilled in anodes was observed to decrease over time. This was observed to be a result of drying out of the graphite paste causing both a high electrical resistivity and shrinkage reducing the contact to the concrete surrounding the anodes. From the inspection performed in 2023 it was concluded that the system no longer provided any protection that could be considered when evaluating the remaining service life of the bridge.

Approximately, at the time of installation of the system at Runde bridge, a cathodic protection system was also installed at the Remøy bridge nearby. Here cathodic protection was applied to all pillars and the bottom side of the bridge deck. Due to the slender design of the bridge an anode conductive paint was chosen as anode system in order not to increase the weight of the bridge. The conductive paint system was one of the first generations where silver wires were used as primary anodes/current distributors. A good performance of the anode system was observed over the first approximately 10 years. However, since then the performance in terms of the current output has decreased gradually due to mainly spalling of and cracks in the conductive paint as well as rupture of the primary anodes (silver wires). Similar to Runde bridge it was in 2023 concluded that the system no longer provided any protection that could be considered when evaluating the remaining service life of the bridge.

Despite the need for testing novel anode systems as well as other components for cathodic protection systems the experiences from Runde and Remøy bridge clearly demonstrate that proven technologies and materials should be used when applying cathodic protection to the many bridges at the Norwegian west coast. Not only are the bridges and thus cathodic protection systems exposed to the extremely harsh climate at the west coast meaning that the materials used should highly durable. But also, the costs of maintenance, repair and eventually replacement are high due to the often remote locations and harsh climate making construction work difficult.

Development within cathodic protection systems has during the recent years been focused on rectifier and monitoring systems with a trend going in the direction of automated cloud based systems. This allows for a better performance monitoring of the systems and optimised maintenance and repair.

When designing and planning future cathodic protection systems for these bridges it should be ensured that all embedded and difficult to access/replace components such as anode systems, reference- and monitoring electrodes, cables and wires have the longest service life possible. For traditional TI-MMO based anode systems this is often +50 years. Other components such as reference electrodes, wires and cable have a somewhat lower service life, typically not longer than 25 years. As a result of this the installations should be designed and installed allowing for easy replacement of all components expected to be replaced during the design service life of the cathodic protection system. To optimise performance monitoring and maintenance automated rectifier and monitoring systems with remote access or cloud solutions combined with data management should be considered for future installations. For these systems the service life is most often not defined by the service life of the electronics itself, but rather limitations in use, repair, and maintenance due to outdating. Thus, the risk of testing novel systems is limited compared with e.g. anode systems.

5 CONCLUSIONS

The bridge owner must rely on detailed knowledge about degradation rates and available repair methods to maintain their bridge portfolio in a sustainable manner. The challenges and need for future investment in bridge maintenance and inspections are illustrated by asset manager Møre and Romsdal County and the case studies of Remøy bridge and Runde bridge. These illustrate how chosen repair strategy requires advanced bridge inspection methods, including visual inspection with challenging access, data collection from material testing, as well as NDT-inspections of post-tensioned cables.

The case studies also serve as examples of different maintenance strategies based on the deterioration state, age and access. The Remøy bridge will rely on a strategy of Controlled Detoriation to maintain an acceptable Safety level. For the Runde Bridge the rehabilitation strategy is to extend service life by investment in new and modern cathodic protection systems. Both bridges show how the County face major investments, especially when related to annual average day traffic of the road network.

With the increasing volume of aging bridges, there is an urgent need to develop new technologies and methods for inspection of bridges. Drone-inspection enables efficient access to structures, with high resolution images and thermal camera/infrared technology to identify delamination and corrosion. These technologies are still evolving, and further research in these areas will be necessary.

Virtual supervision of the new Storstrøm Bridge: Status and potential with CVI

T. Norsk
COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: The New Storstrøm Bridge, currently under construction, is comprised of 44 prefabricated girders manufactured onshore, which are then shipped and assembled with the pierheads offshore. Usually, all bridge constructions have a Principal inspection every six years, which also applies to this bridge. Unlike other construction projects the strategy for the New Storstrøm Bridge is to inspect and repair any minor initial defects on the elements before they are mounted offshore. For this strategy the COWI Virtual Inspection (CVI) routine is used. The CVI software facilitates Principal inspections using Reality Capture Models (RCM) and makes it possible to revisit the bridge structure without having to visit the structure on site.

This project, utilizing CVI benefits, supports the digitization of Principal Inspection procedures and the product (RCM model). In the long run, it can merge with the digital twin of the structure, serving as a baseline for future operational and maintenance procedures.

1 INTRODUCTION

The New Storstrøm bridge is a bridge under construction comprised of 44 prefabricated girders manufacture onshore, which are shipped and assembled with the pierheads offshore. On Figure 1 a visualization of the new Storstrøm Bridge is shown. The new Storstrøm Bridge will replace the old Storstrøm Bridge from 1937, which has served its design lifetime and has an outdated design. The New Storstrøm Bridge is part of the new rail line from Copenhagen to Germany, where the Femern Belt Tunnel between Denmark and Germany is currently under construction.

The bridge is approximately 4 km long with a span of approximately 70 m between pier heads and with an average clearance to sea at 26 m. It will be a two-lane bridge for vehicles together with a two-lane railway crossing that starts at Masnedø and connects with Orehoved on Falster, see Figure 1. This paper introduces the progress of the New Storstrøm bridge with CVI and the future possibilities introducing a digitalization tool.

Figure 1. Illustration of the new Storstrøms Bridge and alignment for the new and old version (from wwww.vd.dk).

DOI: 10.1201/9781003483755-346

The bridge is under construction and almost half of the girders have been cast and mounted offshore pr. December 2023, see Figure 2.

Figure 2. New Storstrøm bridge with indication of progress of project (from wwww.vd.dk).

The plan is that the project is complete by 2026 to be a part of the new route from Germany to Scandinavia through the finalization of the Fehrman project.

For creating the best possible departure of the bridge inspections are performed and repair strategies are formed on a very early stage a short time after casting and hardening of the girder elements. Instead of doing manual inspection it is planned to use the project as a Pilot project for a more digital approach, introducing COWI virtual inspection CVI.

2 COWI VIRTUAL INSPECTION

Usually, inspection of major bridges is performed from a permanent inspection platform, by boat or using rope access. This provides several challenges regarding traffic access and working conditions, dependency on weather, high initial cost (lifts etc.) and difficult conditions for onsite documentation. Furthermore, manual inspection is very time consuming when dealing with major structures and with any uncertainty of the inspection, the inspection worker would be required to go on site again, resulting in lost time and higher expenses.

Using drones to take high-quality RGB photogrammetry supplemented with thermal imagery of the structure a Reality Capture Model (RCM) can be generated for the purpose of inspecting the structure from a computer instead of on site.

The RGB-images are processed in commercial Bentley software to establish the RCM model.

The captured pixels ranged from 1.2 to 7.8 mm. The drones follow a predefined flight path, approximately 15 m away from the bridge girder structure. The flight path is dependent on weather conditions, drone capability (e.g., tight spaces), light conditions, quality of sensors (cameras), fix points for image reference, etc., which requires domain knowledge within reality capture.

By generating a high-quality RCM, the construction only needs to be visited once with drones and afterwards the RCM can be utilized via computer and inspected by multiple people if needed.

CVI is the software platform, where the RCM models can be review and notes can be tagged to individual locations in the model.

CVI brings significant flexibility to the project for both inspection workers and the quality assurance process, allowing the digital model to be examined in the office.

CVI is a part of the ongoing digital transformation for Operation and Maintenance (O&M) that the industry is undergoing at the moment.

2.1 *Benefits from using CVI on the Storstrøm Bridge*

To heighten the quality of the Storstrøm bridge it was decided that CVI would be used in the early stages of the construction of the bridge. See the following list for the overall benefits of using CVI for the Storstrøm bridge:

- Due to the size of the project, it is optimal to be able to inspect the construction from a computer (allowing several specialists to analyse the bridge without visiting site)
- Each individual girder is split into its own RCM model, which allows for a detailed analysis for each girder separately.When the bridge is completed, all these individual models will be collected into at single model of the whole bridge.
- A benefit with CVI on the Storstrøm bridge compared to other major bridges is that it is under construction, so the drone flying has no challenges regarding traffic or pedestrians.
- Possibility to visit the bridge as many times as needed without having to visit site.
- Easy access for visual inspections on areas that might be difficult or impossible to visit on site.
- Overview of photographic data of each element on the bridge stored and easy accessibility for this data through a RCM model.

2.2 *Disadvantage from using CVI on the Storstrøm Bridge*

The disadvantages with using CVI on the bridge is listed below:

- Slightly more expensive to initialise the process of doing the virtual inspection as well as being labour intensive (highly trained personnel is needed to capture photos and generating RCM models)
- There is a certain time window to do the virtual inspection, otherwise the bridge girder elements are shipped offshore. This would result in additional cost to perform the virtual capture and if needed the actual repairs to possible defects identified on the elements. However, due to the speed of the girder construction onshore and the girders being shipped onshore, it has been necessary to do the drone inspection offshore as well. Using current technology, the drone inspection has been able to be done from onshore and has therefore not resulted in additional inspection costs.

3 CVI ON THE NEW STORSTRØM BRIDGE

It was decided that the New Storstrøm bridge is part of a pilot project for usage of CVI on major bridges in Denmark. The first RCM model of the Storstrøm bridge was conducted in early 2023. An external company was hired in to perform drone inspections on the bridge, preferably while the girder elements are still located on land after casting. Here both RGB image and thermal capture is performed from the drones, which is later handed over to COWI to be used in CVI as RCM models.

From the RCM models it is fast and easy to inspect each girder. Additionally, the model allows for quality check of the reported defects from other experienced inspection engineers. It is observed that after casting of the prefabricated girders some minor errors such as honeycombing, cracks (with or without deposit) or delamination is present.

The identified defects are subsequently mapped within CVI, enabling the generation of a report and later an appropriate repair strategy can be created.

Since it is a pilot project, the inclusion of extra inspections after casting, along with the subsequent repair strategy and the actual repair of elements, is still being integrated into the inherent workflow of the Storstrøm Bridge construction. However, as of now, it has not become a seamless part of the natural workflow.

Incorporating the routine into the workflow during the initial phase is expected to result in cost and time savings over the lifespan of the structure. Addressing repairs in the early stages can help prevent more extensive repairs that might become necessary later, ultimately averting structural failure.

3.1 *Example from CVI – Bridge girder G13S*

Girder G13S is used as an example from the Storstrøm Bridge project. From Figure 3 a snapshot is seen from the software including listing of the different noted defects in the structure. A colour table is used for different condition rating, from 1 (least severe defects) to 5 (more severe defects):

- Green for least defect severity of 1
- Yellow for severity of 2
- Orange for defect severity of 3
- Light red for defect severity of 4
- Red for worst defect severity of 5
- Blue for unknown severity or to highlight a query to the supervision team.

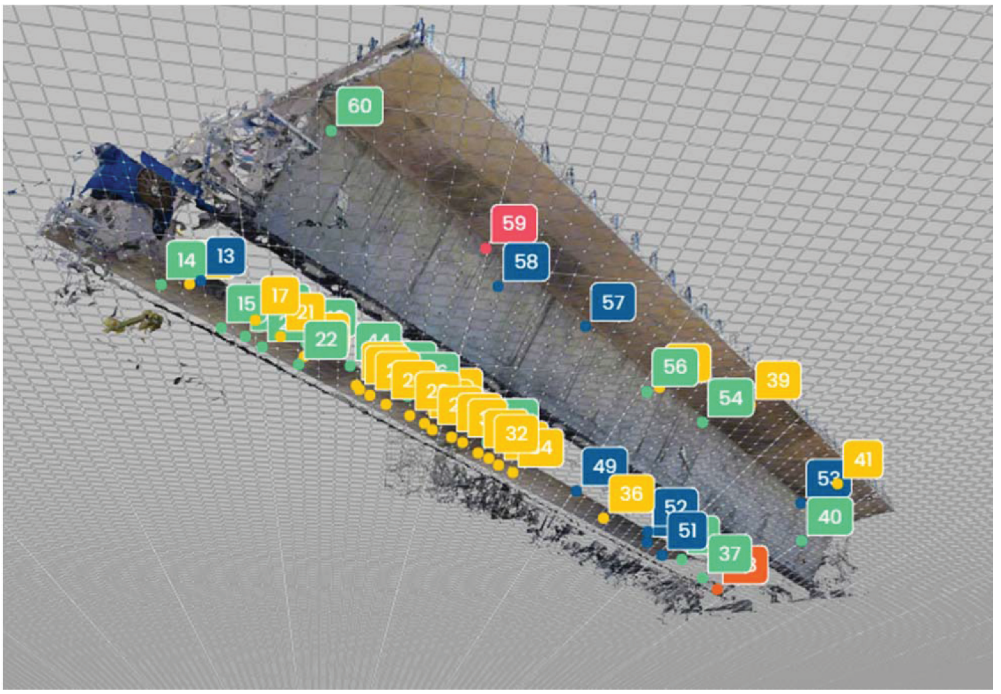

Figure 3. Snapshot of girder G13S from CVI representing recorded defects.

In this example some minor defects are found and placed in CVI with varying severity. Many of the defects are of similar nature, one example is that cracks are forming on the wings of the structure with a cross-sectional direction. From Figure 4 an example can be seen of

a cross-sectional crack on the wing of the girder G13S, which is flagged in CVI with a defects severity of 2.

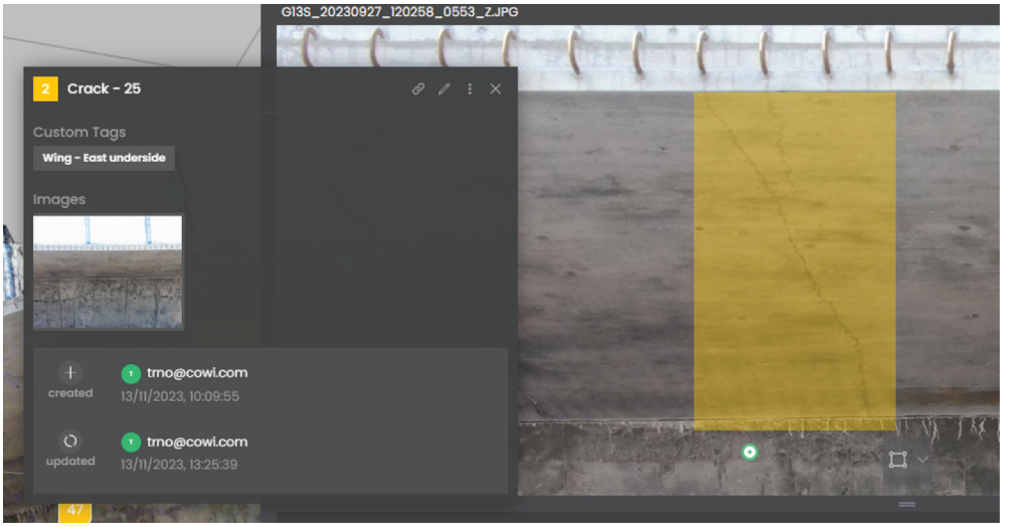

Figure 4. Snapshot of crack from G13S on the Eastern wing underside.

The whole RCM model, seen on Figure 3, consist of lots of individual high-quality photos merged together to a 3D model, which is packed into a manageable model. The registration of defects is done on photos and not in the overall RCM model. A photo used for a registration is seen on Figure 4. The RCM model for this girder consist of approximately 2000 high-quality photos (RBG and thermographic).

All registered "defects" are not defects in the common understanding. In this approach "defects" refer to minor initial defects that needs to be repaired before handover of the bridge to the bridge owner – and – it refers to "defects" which are discolouring, cracks planned during construction, minor casting defects that do not require repair og remediation. However, for future drone based inspections, this is vital knowledge. This means that all "defects" have been treated during construction and they do not need to be reevaluated during future inspections.

3.2 *Reparation strategy*

After conducting a virtual inspection on a single girder, a report can be created and exported using CVI to showcase defects in a preferred format, such as arranging them from most severe defects to least severe defect or organizing them based on their specific locations. This report can work as a presentation of the virtual inspection that has been perform and a repair strategy can be discussed with the contractor. The RCM model itself can also serve as a tool to identify and discuss individual defects during a live meeting with the contractor.

3.3 *Corporation with the contractor*

The utilization of RCM models facilitates smoother collaboration between the contractor and consultant. The digital model serves as an excellent navigation tool, eliminating the need to locate defects on-site. Moreover, the ability to navigate through a model within minutes contrasts with the hours required on foot, addressing accessibility concerns. It is easier to pinpoint exactly where the defect is from the RCM models and prepare the repair strategy with the contractor.

3.4 *Status on the use of CVI on the Storstrøm Bridge*

As of November 2023 a total 20 girders have been virtually captured and uploaded to the CVI software. Several of these have been through the first round of checking.

4 FUTURE USE OF CVI

There are several opportunities to further develop CVI, as listed below:

1. Developing the automatization part of the program using AI image recognition to limit the need of personnel to quality assure the results. This is not in the pipeline for this project, but is under development – and expected to be used later on and before handover of the bridge
2. Combining the RCM model part of CVI with the digital twin of the structural model together with structure defects registrations to have a more developed BIM model for future requirements from clients.

4.1 *Possibility with automated AI image recognition of defects*

CVI represents a significant advancement in more intelligent methods of digitizing work performed during inspections, traditionally conducted by field personnel. Taking the next step towards smarter inspection methods involves incorporating AI for the detection of structural defects seen through CVI. Currently, the process of defect recognition through AI is still in progress, but there is potential to achieve fully automated inspection through the integration of CVI and automated AI defect recognition, which might be possible in the next couple of years. This would have to be quality assured by comparing a traditional inspection through CVI with an AI inspection.

In the grander scheme, the integration of CVI and AI reflects a strategic move towards a future where infrastructure inspections are seamlessly fused with state-of-the-art technologies, paving the way for safer, more efficient, and technologically advanced projects in the realm of structural assessment and maintenance and mitigating human mistakes.

4.2 *Using the RCM model for advanced BIM models*

Introducing the reality capture model into a digital twin would allow for the next generation of BIM models and could benefit the operation and maintenance process of a construction lifetime. Even the development of a structures defect could be captured automatically comparing RCM models from different moments in time and a repair strategy could be developed and executed on the right time. This would be beneficial for economy optimization, structural safety and green transition (optimising when to repair).

5 OPERATIONAL BIM

In modern day a lot of focus is on operational BIM and digital twins. With CVI a huge step is taken towards the first point of operational BIM, but with a bit more development the two can be combined, such that the images and notes in CVI could be combined with a real BIM model.

It is not exactly known where the future of BIM is heading and what format will be the main format, but it is certain that more information will be required in models. For operational BIM there is not captured any information on operation and maintenance in complex BIM models. This could be a future aspect of the CVI tool to incorporate defect and note tagged RCM model into digital twins of the real structure.

6 CONCLUSION

Incorporating CVI into the building process of the Storstrøm bridge seems like an advantageous way to create lots of data for the bridge on the concretes initial condition. It also serves as a way of quickly identifying problematic areas to be repaired, such that the bridge can have a departure without initial concrete defects. Collaboration with the contractor using CVI as a tool to present and discuss defects works smoothly.

The integration of the Reality Capture Model within the principal inspection regime improves workflow, ensure full documentation, and supports finding the 'optimal point in time' to repair and replace structural elements considering multiple Key Performance Indicators for bridge owners and operators.

Sustainability monitoring of cable systems

J. Laigaard Jensen, J.F. Melén & I.F. Alcover
COWI A/S, Kongens Lyngby, Denmark

ABSTRACT: Corrosion is a major threat to the sustainability of cable bridge systems. Corrosion is probably the largest threat to exceedances of bridge owner's maintenance budgets just as corrosion is a persistent threat to the sustainability of the cable-borne bridges. Many years of experiences with different generations of cable systems shows that water ingress is a problem both with respect to main cables, suspenders and cable stay lower anchorages. As the cable system as such is a primary non redundant part of the structural system, such durability issues may be costly to mitigate and may reduce the sustainability of the bridge as a whole. In order to handle proactively such threats, the paper presents cases and discusses the pros and cons of different monitoring approaches. Monitoring in this context may be inspection, testing or continuous automatic monitoring. Based on hand-on experiences, the paper reviews different monitoring approaches.

1 INTRODUCTION

1.1 *The corrosion challenge of cable borne bridges*

The world assets of medium-sized and large bridges comprise a large population of cable borne bridges which provide important infrastructure links. Hence, to keep the infrastructure fully functional, the integrity of these bridges must be maintained. The cable systems of the bridges are non-redundant and are thus a critical structural system to maintain. As the bridges are generally large and expensive assets, their integrity is also an important element of the sustainability of the infrastructure both with respect to environment and socio-economic costs.

Although cable vibrations are often considered as a major problem of cable systems, experiences show that, from an operation and maintenance point of view, the threat of corrosion is a problem of at least the same magnitude if the economic consequences are considered, Laigaard et al. (2012). Corrosion is triggered by the combination of water and oxygen accelerating further if impacted by chlorides from e.g. road de-icing salts. As gravity generally controls water ingress, water ingress and corrosion are generally a problem related to lower anchorages of cables.

Records of experiences show that corrosion of cable systems on many occasions have caused the need for replacement or large rehabilitation works on the entire cable systems, e.g. Andersen (1999), Bloomstine & Zinck (2016), Laigaard et al (2016). With the focus on cable stays and suspension bridge suspenders, this paper will highlight some important cases and describe the causes, the monitoring, and the handling of cable corrosion problems. The challenges of water ingress and corrosion in cables are described generally in e.g. Laigaard et al. (2017).

2 SCENARIO WITH LACK OF SUSTAINBILITY

2.1 *Sustainability of cable-borne bridges*

Cable borne bridges have been used for major crossings for far more than hundred years. Figure 1 shows an approximate overview of the age distribution of existing cable borne

DOI: 10.1201/9781003483755-347

bridges. The two plots show that about 60% of all cable borne bridges are more than 20 years old and about 40% of the bridges were inaugurated from 1960 to 2000. Hence, in the future there will no doubt be a significant need for monitoring and maintaining the corrosion exposed cable systems. As an illustration, it may be recalled that the use of steel ropes goes back to about 1830 and the first bridge to use galvanized wires was Brooklyn Bridge opened in 1883 However, the use of black steel has continued well into the 20th century and corrosion protection may not yet have reached a stage of perfection.

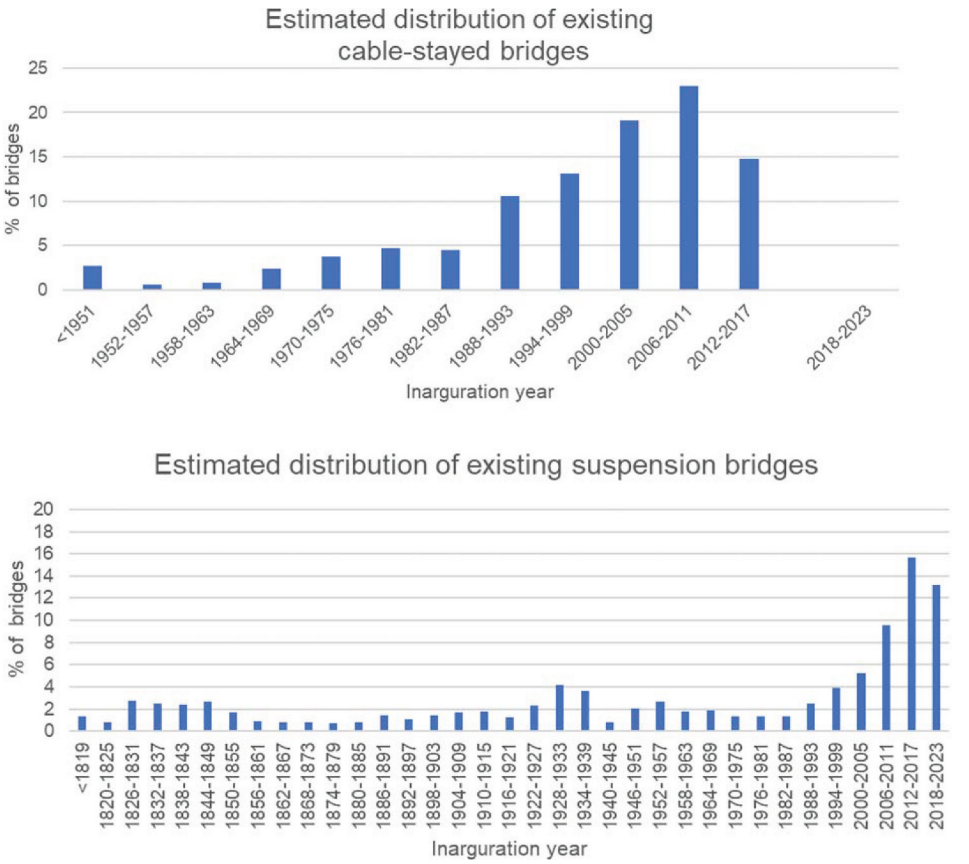

Figure 1. Age distribution of suspension bridges and cable stay bridges based on data from https://structurae.net/en/structures/bridges (November 2023).

The service life of the cable systems of such bridges may be subjected to discussion. However, for a modern bridge hardly any manufacturer or designer warrants a cable service life of more than 100-120 years, which often will be the formally stated service life of the bridge.

Based on experiences from the last two decades, a cautious estimate of cable service life could be suggested to be around 60 years even when new bridges are being designed. The cautiousness in giving service life estimates is somewhat illustrated by the fact that modern bridges are designed with replaceable cables to allow for replacement before the end of the service life of the bridges themselves. Hence, the suggested 60 years' service life for a cable system is somehow not up to date with the novel sustainability agenda. Based on the above-mentioned age distribution, it may therefore be concluded that today's owners and consultants are looking into a major challenge regarding extending an ambition of a 60 years' service life to a much longer service life. Here it should be noted that due to the nature of corrosion, the handling of this challenge is an urgent problem. This is illustrated in Figure 2, which

shows that, in some cases, corrosion of a cable stay may develop quire rapidly over only 6 years. Hence, it is evident that there is need for detecting and monitoring corrosion in cable system in due time before complete replacement is required.

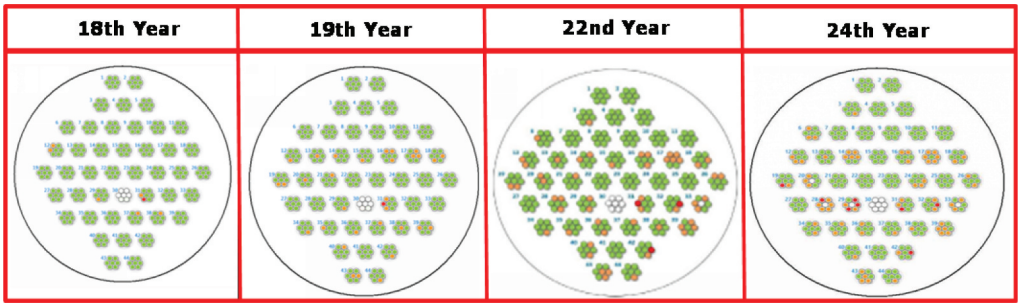

Figure 2. Example: development of corrosion in parallel strand cable anchorage based on ultrasound testing. green: uncorroded; orange: corrode; red: broken (Laigaard. et al. 2022).

The scenario outlined stresses the need for monitoring strategies of the cable condition allowing for:

- A systematic and persistent approach on monitoring the condition of cable stays and suspenders to maintain and prolong their service life as much as possible.
- Sufficient early detection of irreversible corrosion degradation to allow for replacement of cables one by one without costly and time-consuming temporary strengthening arrangements. Such arrangements will be needed when many cables have reached a severe corrosion degradation at the same time.

2.2 *Monitoring of corrosion condition*

Corrosion monitoring of the condition of cables will be the main topic in the following sections which will consider the following categories of monitoring:

- Visual inspection (manual or by endoscopy, photogrammetry, infrared techniques)
- Non-Destructive-Testing (ultra-sound, magnetic flux techniques, chemical analysis of water samples)
- Destructive Testing (inspection, metallurgy assessment and tensile testing)
- Permanent automatic continuous monitoring (vibration, acoustic emission)

The challenges of monitoring the corrosion condition will depend on the cable system, which for modern bridges may comprise the following cable systems, Gimsing & Georgakis (2013):

- Spiral strands – predominant used in sixties and seventies.
- Fully locked coil – predominant used in fifties, sixties, and seventies.
- Grouted parallel wires – predominant used in sixties, seventies, and eighties.
- Parallel seven wire strands - predominant used from mid-nineties.

2.3 *Examples of corrosion cases*

There are numerous reports on cases with cable corrosion for the four types of cables described above and there are good reasons to assume that several existing bridges are being operated and maintained without awareness of an on-going risk of water ingress and corrosion. This is understandable as it is difficult to inspect and document corrosion problems in cable systems before the problems have become serious and detectable by visual inspection. Unfortunately, this often means that problems often have grown into a size making them costly to mitigate. In some very unfortunate, but few cases, the difficult detection may even result in having severe bridge failures.

Table 1 shows several selected examples of cases which have led to significant costs with need for cable replacements, traffic restrictions/closure and unwarned cable failures. Many of these older generation bridges have had a significant shorter service life than the above suggested 60 years' service life of modern bridges. Figure 3 shows examples of cable failures after only 16-19 years of service life.

Table 1. Overview of bridges with records of corrosion problems in cable systems. S: Suspension Bridge; CS: Cable stay bridge.*) Approximate year of awareness of corrosion issue.

Bridge	Bridge type	Year	Cable type	Year of corrosion detected	Mitigation
A.L. McDonnald Bridge	S	1955	Spiral strands	**2015-2017**	Replacement
Strömsund Bridge (S)	CS	1956	Locked coil	2014	Replacement

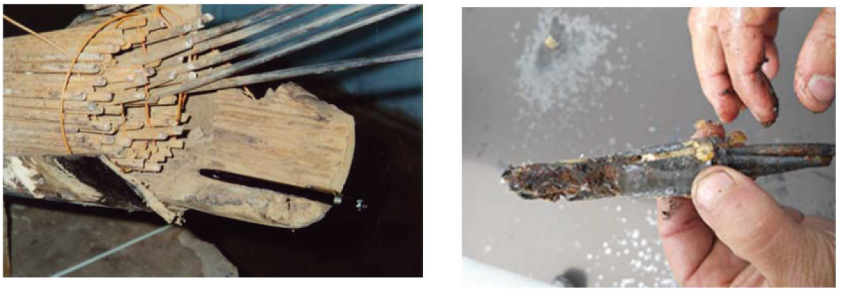

Figure 3. Examples of cable failures: left: 19-year-old parallel wires in grout of suspender. right: 16-year-old modern parallel strand.

3 VISUAL INSPECTION

3.1 *Visual inspection*

Visual inspection will rarely be able to detect corrosion in cables due to very limited access for inspecting the most exposed part of the cable wire (Figure 4). Most visual positive detections of

corrosion will not occur before irreversible corrosion damages have taken place. Only in cases where lower anchorage systems are quite open and easily accessible, it will be possible to detect corrosion. However, in some cases with parallel strand systems, it may be an option with a jack to extract a cable strand to inspect the anchored position for signs of corrosion. Hence, the primary objective of visual inspection is mainly pro-active maintenance of sealings, drainage and other elements in the multi-level protection systems of cable systems. Figure 5 illustrates examples of such inspection objectives. For the free lengths of cable systems, visual inspection may be efficient in detecting defects in paint, cable tubes and embedment in cement/grout. For such cases, visual inspection may be assisted by use of infra-red cameras equipped on drones or robots.

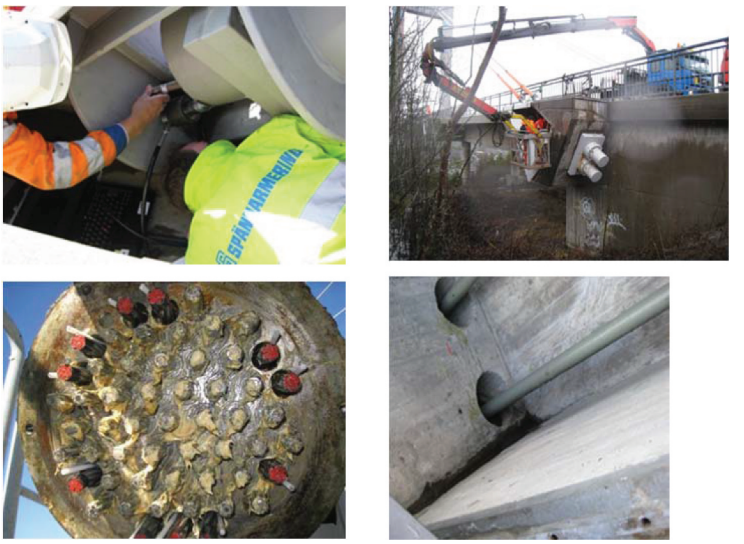

Figure 4. Access condition will rarely allow direct visual contact to the anchorage point in the lower anchorage which is most exposed to corrosion. left: parallel strand anchorage. right: locked coil anchorage.

Figure 5. Visual inspection of drainage, sealings and barriers against water ingress may considered as primary objective of visual inspection. left: parallel strand anchorage. right: locked coil anchorage.

4 TESTING

4.1 *Non-destructive testing*

Non-destructive test methods relevant for cable stays and suspenders for detecting corrosion may be summarized to comprise:

- Testing of coatings and grout by a Schmidth hammer or similar may provide insight in signatures of cavities of defects in the coatings and grout.
- Magnetic flux induction may be relevant in the cases where there may be a corrosion risk along the free length of the cable. This will be the case where parallel wires are embedded in a grout or cement solid. Having said this, the severe corrosion risk could often still end up being on odd locations not suitable for using magnetic flux method.
- Ultrasound may be applied as a very efficient tool for assessment of corrosion and wire ruptures of parallel wire strands. Figure 6 shows an example of the use of ultrasonic testing for a cable stay bridge. The reliability of ultrasound may be as high as 80% for detection of strands with broken wires, (Laigaard et al. (2022).

Figure 6. Ultra-sound testing applied on parallel strand system at lower anchorage.

4.2 *Destructive testing*

Destructive testing of cables may be carried out to obtain an in-depth understanding of the actual corrosion and possibly provide a basis for calibrating NDT methods. This may involve on-site testing as well as dismantling of cable elements with subsequent testing in laboratory. One often activity will be to do tensile testing of corroded cable segments to assess their capacity. Figure 7 shows an example with subtraction of cable strands from a bridge with subsequent tensile testing and calibration with ultrasonic testing carried out on bridge. This case

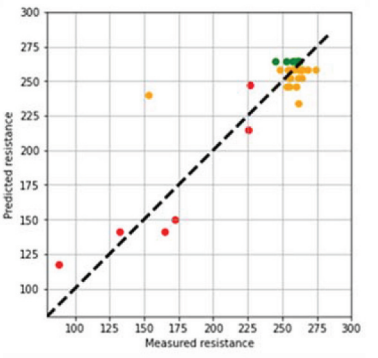

Figure 7. Results of tensile testing of segments of parallel strands with subsequent calibration with the ultrasound testing carried out on bridge Laigaard et al. (2022).

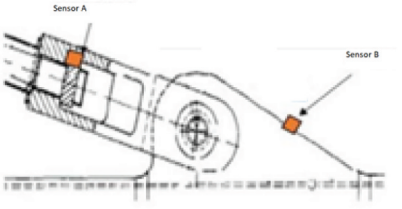
resulted in an increased reliability of the ultrasonic testing carried out and estimation of tensile resistances of strands/stays based on the results of periodic ultrasonic tests.

5 MONITORING

Monitoring methods may comprise a range of options with somewhat different objectives:



- Use of corrosion cable strand dummies in anchorages to provide early warning of corrosion. Periodic inspection of such dummies may reveal early signs of corrosion. This may provide early warnings of corrosion in a cable system. The only limitation is that the cable anchorage system design needs to have space allowing the use of dummies subjected to the same exposure as the installed cables Laigaard et al. (2017).
- Measurement of moisture due to water ingress or condensation. Some cable systems, which may be difficult to visually inspect, may still allow the detection of moisture by use of sensors having spacings and cavities as part of their lower anchorage design. This may allow continuous monitoring of moisture and thus assessment of the corrosion risk and the effect of different mitigations Parodi et al. (2024)
- Periodic chemical assessment of water tapped from the anchorage can provide indication of on-going corrosion and thus raise the need for further assessment. However, this may also only provide a somewhat late indication of corrosion as a significant amount of corrosion indicators have to be present in the tapped water.
- Vibration testing may be used to observe changes in natural frequencies. However, this will almost always only provide a very late detectable indication of corrosion.
- Acoustic emission by sensor measuring the dynamic impact response induced by the failure of individual wires. If signal noise from normal loading in the cable system can be removed by signal processing, the method can provide information about the occurrence of individual wire ruptures by measuring the sound wave propagation due to energy release caused by wire rupture. However, the method is only of interest as an alarm system for bridges, which already have a severe corrosion problem in the cable system.

a) Use of cable dummies

c) Tapping of water for chemical analysis.

b) Acoustic monitoring of cable anchorage for detection of wire ruptures.

Figure 8. a) Use of cable dummy for monitoring of corrosion, b) acoustic monitoring as mean for detecting wire or strand failure, c) water tapping for chemical testing for traces of corrosion from cable wires.

6 CONCLUSION

The existing population of cable borne bridges shows that there is a significant challenge regarding corrosion monitoring of the cable systems. The cable system of many of the existing bridges can be expected to have a service life which will be significantly shorter than the bridges themselves. This both will cause a burden regarding sustainability, costs of operation and maintenance and may also cause reduction of the infrastructure capacity over significant periods of time.

For this challenge, there should be a focus on developing corrosion monitoring of cables further. Firstly, for making pro-active maintenance to extend the service life beyond the current state-of-the-art ambition, which this paper has suggested to be of the order of 60 years. Secondly, further development of corrosion monitoring will also be of great significance in postponing the time of replacement by prudent mitigation actions. Any extension of service life will support the need for a more sustainable bridge infrastructure.

For meeting these challenges, the paper points to a need for further development of corrosion monitoring for the cable systems using the concepts of: Inspection, Testing and Monitoring as shown in Figure 9. The corrosion monitoring of cable systems is far from a simple task. No method alone is sufficient to monitor the condition of a cable system. However, the paper shows that different tools together may form the basis for developing corrosion monitoring of cable systems further with the aim of providing pro-active maintenance in due time and extend service lives further and obtaining control when weaknesses have caused severe corrosion problems.

ABSTRACT: This paper presents a summary of the service life of The Tjörn Bridge. The focus is highlighting deviations of the expected maintenance, replacements, and upgrades from the expected service life of the bridge. The objective is to identify the bridge components and operational conditions, which often may be deviating from the expected planned service life in connection with the design of a bridge. The Tjörn Bridge being a 366 m span cable stay bridge from 1981 has reached an age where maintenance tasks have started to increase. Some tasks, such as general degradation of paint, pavement, joints etc., have been in line with expectations, whereas other have been unexpected and thus called for mitigation. The Tjörn Bridge was constructed over a record short duration of 18 months as it replaced the old bridge which collapsed due to a ship collision.

1 INTRODUCTION

1.1 *The service life of Tjörn Bridge*

This paper describes the service life of the Tjörn bridge and significant events and decisions in the service life from 1981 until today (2023) to investigate how the actual life of the bridge may deviate from what was planned and expected when the bridge was decided and carried out.

The Tjörn Bridge, shown in Figure 1, is located 50 km North of Göteborg in Sweden in a temperate climate, Kahmann (1982). Figure 1 shows that the bridge is 645 m long with a main span of 366 m. Cable stays are painted locked coil cables of 46 m to 160 m lengths with diameters ranging from 77 mm to 108 mm arranged in pairs. The bridge forms the major fixed connection between the island of Tjörn and the mainland via the two islands Almön and Källön. The bridge was opened in 1981 after only 18 months of construction, as it replaced an arch bridge, which collapsed on 18th January 1980 due to a ship collision with the loss of 8 lives. On January 31, 1980, a new bridge was decided. Tender was carried out and on June 19, 1980, a contractor was chosen, and the bridge was opened for traffic November 9, 1981, where design, procurement and construction had been finalized. The winning tender had the 3rd lowest price but with the fastest execution time, which was decisive for the selection.

1.2 *Bridge design, construction and operation*

The Tjörn Bridge, being 42-year-old, gaps over at least two generations of owners, contractors and consultants and it is therefore very relevant to ask how the bridge's service life turned out compared to the original intentions and expectations regarding operation and maintenance of the bridge.

Looking into the service life of bridge components and the operation and maintenance carried out, it may provide some insights into how the actual service life turned out. It may reveal if the bridge, after decades of operations, have met expectation when they were planned, tendered, and the bridge commissioned. Of course, this could be considered as a somewhat

DOI: 10.1201/9781003483755-348

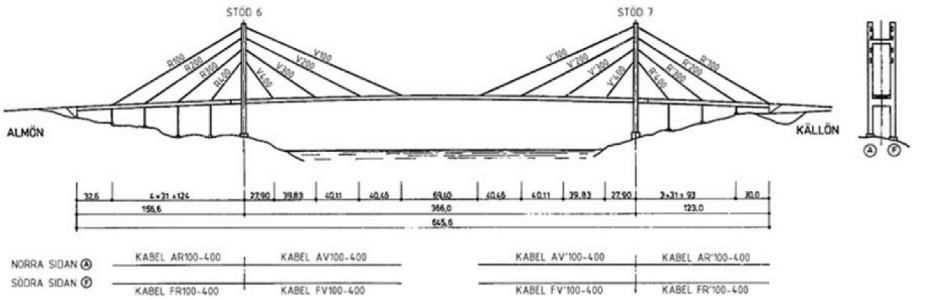

Figure 1. Overview of the Tjörn Bridge.

academic question, as the involved professionals rarely will be the same persons after several decades have passed. However, it may still be interesting to pursue the answers to the question, as there could perhaps be room for improvements in the way we plan, design, construct, commission, operate and maintain bridges.

When bridges are designed, the service life and level of required maintenance are directly or implicitly considered with expectation on:

- The service life and level of required maintenance considered both for individual bridge components and for the bridge. In modern terms this is accomplished through service life design but has in the past been carried out through use of proven concepts and materials although there have been periods where new concepts and materials have been introduced with unintended consequences. As simple and well-known examples the use of new concrete mix recipes (e.g. alkali chisel), new cable stay system and post tensioning system (corrosion due to water ingress), reinforced concrete exposed to deicing salts (insufficient concrete cover), could be mentioned.
- Construction quality which per experience often is challenged in tenders exposed to e.g. tough price competition and accelerated project time schedules or unclear tender requirements. Once a weakness is introduced in the phase of design and construction, it is a well-known experience that this weakness will trend to follow the bridge over long period of time with a potential significant impact on inspection, maintenance, service life and overall, its sustainability. In addition, it may in some cases happen that bridges suffer from lacking maintenance attention due to lack of organization, funding or simply just manpower.

Considering the owners, their consultants, and contractors in many ways control the life of the bridge throughout its service life, there are good reasons to look back and see if we can learn something or if there has been circumstances out of our control when the bridge has ended up in another way than anticipated when the bridge was decided. However, before looking at what may have deviated from expectation, it may be necessary to start with what was likely to be expected from the service life of a bridge like Tjörn Bridge.

2 THE EXPECTED SERVICE LIFE OF TJÖRN BRIDGE

There is no knowledge of anybody who can describe the expectations to the service life of the Tjörn Bridge when it was designed and constructed, Brodin (1984, Kahmann & Koger (1982). Instead, we have referred to more than forty years old written descriptions and design calculations. It was designed during an era before the concept of service life design, life cycle cost and sustainability were on the agenda and basically, we can only look back and evaluate what we think would be the expected service life of the design and the applied materials.

Based on today's standards, the bridge would have been required to have a service life of at least 120 years in accordance with SS-EN 1992-1-1. Prior to the development of Eurocode there was a more informal expectation that bridges should last at least 100 years. Table 1

shows what we with today's insight would expect to be the service life of the different main components of a new bridge. The irreplaceable elements would be expected to have a service life of minimum 100 years. From the descriptions of the bridge design and construction, the state-of-the-art durability precautions were part of the design, and it was designed to last a considerable number of years. However, no explicit durability design was carried out with a holistic view both with respect to interaction among bridge components and the life cycle from design, construction to operation.

It may be noted that the definition of service life does not consider the development of inadequate functionality due to changes operational needs compared to the intentions in the applied design. Examples could for instance be a change of configuration of road lanes, a need for larger bearing capacity, noise screens etc.

Table 1. Expected service life of bridge main components.

Selected main components	Overall service life	Maintenance
Concrete piers and pylon	120	Not replaceable
Concrete girder	120	Not replaceable
Orthotropic deck	120	Not replaceable
Cable system	60	Replaceable
Bearings	50	Replaceable
Expansion Joints	30	Replaceable
Edge beam	80	Replaceable
Pavement	25	Replaceable
Deck membrane	60	Replaceable
Barriers	40	Replaceable
Railings	40	Replaceable
Lift	20	Replaceable
Gantry	20	Replaceable

3 THE ACTUAL SERVICE LIFE OF TJÖRN BRIDGE

Overall, it may be anticipated that all bridges have components which last unexpectedly short but nevertheless it is interesting to study the reasons for why the service life became shorter, which in our case is demonstrated for the Tjörn Bridge. Subsequently this may be brought further by benchmarking of group of bridges. Hence, the achieved service life of main bridge components to now, can be compared with expected service and the reasons for unforeseen short service lives can be scrutinized to identify the roles of design deficits, lack of construction quality or maintenance carried out or changes in the operation of the bridge.

Table 2 shows actual service life experiences until 2023 based on listing of recorded maintenance carried out on the bridge from 1982. The table shows the achieved service life for bridge main components with identification of components with unexpectedly short service life. By color identification the maintenance of components is marked with the group of bridge components it belongs to.

The table indicates that the following types of components may at some point of the more than 40 years' service life have experienced an unexpected shorter service life:

- Parts of the concrete
- Components of cable system
- Orthotropic deck welds
- Structural Monitoring System installed due to need for wind assessment for planning of a reconfiguration of deck cross section (new barriers and jump prevention parapets).

In the following, reasons explaining the achieved service life of these four bridge components will be investigated.

Table 2. Overview of maintenance history from 1982 to 2023. Maintenance data from Swedish Transport Administration (Trafikverket). Comment on service life: "Expected" and "Unexpected" compared to design expectations.

2022	Inspection gantry overhaul	40	Expected
2023	Cable replacement	41	Unexpected
2023	Welding repairs deck	41	Unexpected

4 CASES OF EXPERIENCED SHORT SERVICE LIFES

4.1 *Repair of concrete edge beam*

Although the repair of concrete appears somewhat early with a service life of 14 years, it may not have been a complete surprise that the edge beams of the bridge was the most vulnerable component needing repair due to the use of de-icing salts. The applied concrete mix and a concrete cover may very likely have been state-of-the-art at the time in 1981. However, it appears reasonable to assume that the eighties (the time where the bridge was designed and constructed) had significant less focus on durability than in the following decades, where considerably more attention was given to concrete recipes and choice of concrete cover, Johansson & Johansson (2007). Hence it is considered that the current state-of-the-art with improvements in design over time have resulted in considerably more durable edge beams than obtained in 1981.

4.2 *Replacement cables stays after 35 years.*

Table 3 shows that cable stays of the bridge have been replaced in a program running since 2015. As indicated in Figure 2, the reason was that through inspections it was found that the lower anchorages of the cables in the approach spans over a longer period appeared to have been exposed to water due to lack of sealing against water as well as blocked drainages. The corrosion led in 2013 to the rupture of some wires in two of the lock coiled cables with wires, which were protected by hot dipped galvanized wires and a paint coat on the cable. The short service life of 34 years compared to an expected service life of at least 50 years may be attributed to:

- Lack of designed access to the lower anchorage is likely to have made it difficult to carry out inspection and maintenance.
- Lack of drainage caused by construction tolerances not providing sufficient room for drainage in some anchorages.

The corrosion of the cables was mitigated by improved access to lower anchorages, 1:1 replacement of cables but with extruded HDPE sheeting instead of paint and with improved water drainage. In addition, safety of the bridge during the replacement program was ensured by a safety assessment of the bridge with corroded cables. In total these mitigation works can be considered one of the largest costs in maintenance carried out so far. The details of replacement of the cables are described in Table 3 (Jensen et al. 2016). The cables of the approach spans were given highest priority as they were the most critical ones regarding the bridge global integrity.

Table 3. Overview of cable replacements on Tjörn Bridge.

Year	Number of cables	Position
2015	2	Eastern approach span
2019	14	Eastern approach span
2021	16	Western approach span
2024	8	Main span
To be planned	24	Main span

4.3 *Repairs of orthotropic steel deck structure*

Some fatigue cracks were identified after 38 years of services, which is quite early considering that the overall service life of the deck would be expected to be at least 100 years. In 2018 the results of a load capacity assessment showed insufficient fatigue capacity of the orthotropic steel deck (12 mm deck plate with 24 6 mm throughs spanning 4 m). This initiated the execution of an inspection program, which in total until 2023 have led to the identification of four cracks:

- Two cracks in welds in mouse holes between cross girder and through no. 14 and 15 at diaphragm no. 27. These cracks are small and kept under observation.

Figure 2. Condition of lower cable anchorage in 2013.

- One potential Crack at a stiffener against the deck plate at diaphragm no, 32 - 33. The crack could probably be attributed to inadequate welding and has been repaired.
- One crack in the bottom of the through no. 9 between diaphragm no. 90 and 91. The crack may have its origin from the construction and had been repaired.

The causes for the cracks have been evaluated to be due to quality issues from construction with several locations with the poor welding quality not meeting nowadays standards. These observations combined with the results of the fatigue evaluation of the bridge means that there are some concerns for occurrence of fatigue cracks in the future. At the same time, it may be noticed that traffic has increased from approximate 12200 (1980) to 19210 Average Daily Traffic (ADT) (2019), which also will contribute in detrimental way. Hence these concerns have been addressed through a continued inspection and repair program. For now, the extent of the mitigation program is moderate but over time there will be a risk of further development of cracks.

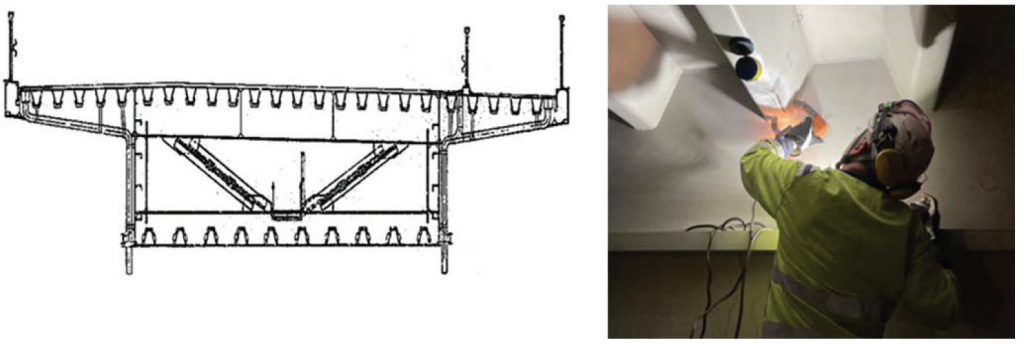

Figure 3. Left: Deck cross section. Right: Repair of crack at through-diaphragm interface.

4.4 *Wind assessment by structural monitoring system (SHMS), numerical calculations and wind tunnel testing*

In 2020, it was decided to carry out a wind investigation with the objective of assessing the wind response of the bridge deck ahead of an upgrade of the bridge. This service life activity may not be considered as a maintenance activity as such but rather an operation assessment and upgrade of the bridge. The assessment comprised the installation of a structural monitoring system as well as a detailed study of wind performance of the deck through a finite element calculation, aerodynamic simulations and wind tunnel testing. There were two reasons for the assessment carried out:

- Investigation of the overall aerodynamic properties of the deck as a basis for planning a future reconfiguration of the bridge railings (barriers, suicide prevention fences) including road lane division. For the original and a future configuration of the bridge deck, assessment of aerodynamic performance of the bridge was carried out by simulation of the aerodynamic

stability by COWI in-house software DWMFLOW and finite element modal analysis with subsequent verification through wind tunnel testing. The investigation was supplemented by results from SHMS, among other damping estimates. The latter confirmed the observed vortex shedding with 169 mm amplitudes and 3.6% log. Dec damping at winds of 13 m/s. The investigation was supplemented by results from SHM, among other damping estimates. The results of the assessment have shown a reconfiguration of deck cross section is indeed feasible and may even improve the aerodynamic performance of the bridge.

- In addition, the assessment has served as a clarification of the concern of occurrence deck vibrations raised by traffic and maintenance personnel. The deck vibrations are identified as vortex-induced oscillations which occur at certain wind conditions with wind roughly perpendicular to the bridge with 10-minute average wind speeds of 12.5 m/s and 14.5 m/s with frequency of occurrence of 0 to 7 days per year. These observations match well the predicted wind speed for vortex induced oscillations in the bridges first order vertical bending mode from wind tunnel test. Results from installed structural monitoring system verified the frequency and magnitude of these deck vibrations (Figure 4) and is used to continuously evaluate the need for any mitigation. The SHMS has now a permanent purpose in observing the wind response of the bridge to support the safe operation of the bridge. Currently the SHMS is a stand-alone system but in the longer perspective, the owner pursues a strategy on having such systems on several major large cable borne bridges in Sweden to support the operation of the bridges.

The need for this wind assessment with installation of SHMS was of course never foreseen when the bridge was planned and designed. Overall, the wind assessment may be said to have been triggered by the fact that:

- Traffic has increased from approximate 12200 (1980) to 19210 ADT (2019) which may have led to less tolerances for perceived insecurity through e.g. occurrences of large deck vibrations.
- In society, there has been a development of a non-acceptance towards the occurrence of suicides with jumps from bridges over time.
- Pylons have through capacity assessment turned out to be sensitive the loss of a cable stay combined with development of heavy traffic has led to higher requirements to traffic barriers.

5 DISCUSSION & CONCLUSION

With Tjörn Bridge as an example, the paper has compared the actual service life from the bridge inauguration in 1981 with what was expected when the bridge was planned, designed and constructed. The bridge was as an replacement established over only 18 months, and overall it may be concluded that the bridge has performed very much in line with the service life expectations except for a few durability challenges due to weaknesses in the design and construction quality and some changes in the operational conditions of the bridge.

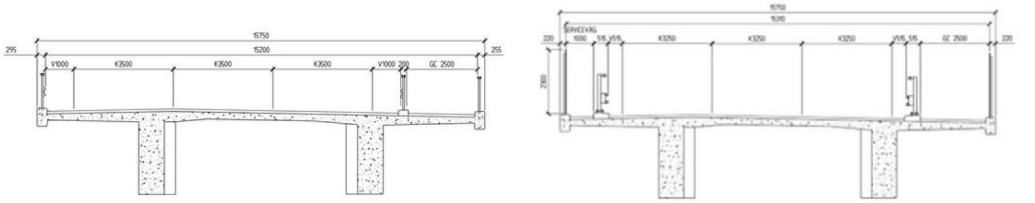

Figure 5. Left: Existing deck cross section. Right: Investigated future deck cross section.

5.1 *Durability challenges*

The bridge has overall performed quite well except for the problems with corrosion of cable stays. The durability challenges have overall been quite conventional with the somewhat early needed repairs of the concrete edge beams probably as the most unexpected. Nevertheless, the corrosion of the cable stays has been a significant cost in the service life of the bridge. The reason for this may be attributed to weaknesses in the design concept, which also has been experienced on other bridges with similar cable systems e.g. Saul & Humpf (2007). This design weakness has combined with deficits in construction quality led to failure in obtaining the intended drainage in the lower cable anchorages and thus resulted in the severe corrosion problem. The problem has been mitigated by a replacement program for all cable stays.

5.2 *Operational challenges*

Changes in operations have also challenged the operation and maintenance of the bridge in two ways:

- Increased traffic loads compared to design assumptions, have due to some deviations in quality of deck welding resulted in some fatigue cracks in the orthotropic steel deck. These challenges are now handled by an inspection program and follow-up repairs.
- More dense traffic has also had operational consequences on the bridge deck. Firstly, a larger focus from society on the need for parapets preventing people from jumping from the bridge triggered the need for an aerodynamic assessment (incl. installation of a SMS) of a deck reconfiguration with a jump prevention parapet. Secondly, pylons vulnerable to loss a cable stay combined with heavier traffic has pointed to a need for upgrade of the road barriers together with a reconfiguration of the deck cross section. Thirdly, it may be noticed that over there the years has been a development on attention on driving conditions being influenced by wind, which also has been addressed by the installation of a structural monitoring system.

5.3 *How to handle the unexpected service life*

The above isolated deviation from the expected service life may not easily be handled. However, it underlines the need for focusing on establishing a sound basis for the design and construction of a bridge, where focus should not only be on complying with standards but also on robustness and risks in the operation and maintenance phase of the service life of the bridge.

Moisture monitoring in cable anchorages before and after dehumidification

ABSTRACT: Water presence in lower cable anchorages has been a long-term challenge on the Uddevalla Bridge in Sweden, as on several other cable-stayed bridges. To find an ultimate solution to the possible corrosion development, a moisture monitoring system has been installed in two selected anchorages. Over 1½ year, the system has provided the base of data required for tracking the formation of condensation, the mechanisms of water ingress and the efficiency of the drainage ways. All the above has also been assessed in relation to different interventions carried out on the anchorages. The monitoring system is currently used to evaluate the effectiveness of a prototype dehumidification system, designed to ensure an internal relative humidity below 40%, which will eliminate the risk of corrosion development. A potential way forward is to develop the moisture monitoring system into a digital twin, enabling to extrapolate the moisture assessment to all anchorages of the bridge.

1 INTRODUCTION

Lower cable anchorages of cable-stayed bridges are often subject to the challenge of water ingress during the service life, which implies a significant risk of corrosion for the cable strands. For Uddevalla Bridge (Sweden – see Figure 1), water ingress has been a long-term challenge and although several preventive measures have been adopted, the problem remains and the concern regarding corrosion has not been resolved (Laigaard et al, 2017).

Since the discovery of water in the lower cable anchorages already in 2000 – year of inauguration – the bridge owner Trafikverket (Swedish Transport Administration) has followed the conditions of the cables closely. After more than 20 years of operation, it was decided to investigate in detail the issue and its causes, with the aim of finding an ultimate solution. In order to carry out a continuous investigation throughout different seasons and environmental conditions, it was therefore decided to design and install a moisture monitoring system.

COWI has procured and installed the monitoring equipment (May 2022) and performed the subsequent data processing and interpretation. The system has been installed on two anchorages – specifically identified as 101V and 115V – selected as representative of all other anchorages (see Figure 1).

The recorded data have been processed and analyzed to monitor the parameters directly related with moisture throughout the different seasons, with special focus on mapping the causes behind the presence of water. This includes an effort in differentiating the moisture generated by air condensation from the moisture associated with rain ingress, as well as checking the watertightness of the anchorage casings, tracking the water flows, and validating the efficiency of the drainage ways.

Figure 1. Photos of the Uddevalla Bridge, one of the monitored anchorages (101V) and one of the Leaf Wetness Sensors on the cable wires.

The information gathered by data analysis has been used to design and calibrate a prototype dehumidification system, installed on the two monitored anchorages at the end of May 2023. After the installation, the data obtained from the monitoring system acquired the additional objective of evaluating the dehumidification system effectiveness, before possibly extending its installation to all stay anchorages of the bridge.

The following sections present in detail the hardware and setup of the monitoring system, the approaches for data analysis and interpretation, the main results, and the conclusions – along with the potential way-forward.

2 MONITORING SETUP

The monitoring system has been procured, installed on site, and programmed for data acquisition and communication by COWI. The layout of the system is described in the following. Table 1 and Figure 2 should be referred to, for details regarding hardware and sensor positions.

The monitoring system features air temperature sensors, relative humidity (RH) sensors, surface temperature sensors and Leaf Wetness Sensors (LWS).

The air temperature and RH sensors have been installed on the inside of the protection pipe of the anchorages, with the aim of identifying the air conditions in the anchorages and to provide the basis for calculating the dew point in the condensation assessment (see section 4).

The surface temperature sensors have been installed on the wire surface, on the protection pipe surface (both internal and external) and on the DAU cabinet (hidden from solar radiation, for correlation with the surface temperature measured on the anchorage), with the aim of providing a full overview of the surface temperatures and, consequently, of the formation of condensation.

LWS are normally used in agriculture for monitoring wetness conditions in greenhouses and are designed to mimic the thermodynamic and radiative properties of real plant leaves. In that context, the LWS data are normally meant to be interpreted binarily – i.e., as "dry" or "wet" – as in the standard agricultural application there is no need for quantitative wetness data proportional to the amount of water on the sensor. For this reason, deploying LWS to monitor moisture and water flow in stay anchorages was initially considered experimental, without any ambition of capturing anything more precise than a simple binary indication on presence/absence of water. Nevertheless, as shown in the following sections, it has been proved that LWS data can be highly more informative than expected, and that data trends can be used to differentiate the wetness due to condensation from the wetness due to water flow – see section 5.

The LWS have been installed at strategic positions (on the wires, on the surface of the protection pipe and in the base pipe) to track the water flow paths. Special solutions have been

adopted to make sure that the water flowing on a surface instrumented with a LWS would not "skip" the sensor's surface – e.g., by applying silicon to guide the water flow onto the sensor surface, as shown in Figure 1. At each anchorage, one of the LWS (LWS4) has been installed outside on the DAU cabinet, which is exposed to rain, to serve as a rain sensor.

Table 1. Details of the monitoring hardware.

Leaf Wetness Sensor	Campbell Scientific	LWS DECAGON	4
Data Acquisition Unit	Campbell Scientific	CR1000X	1

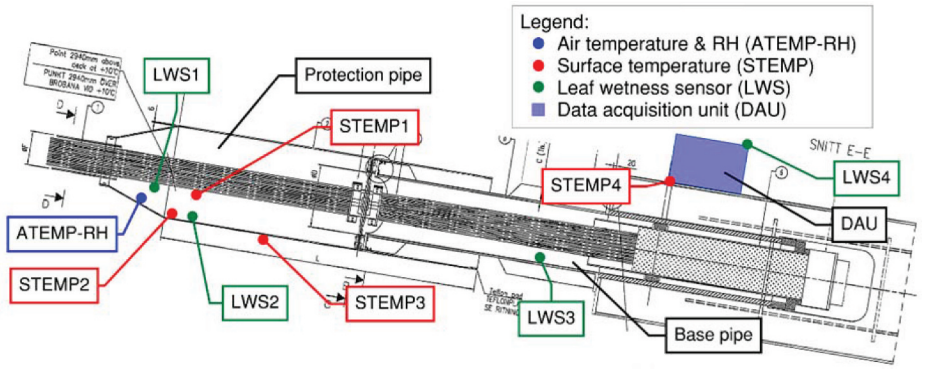

Figure 2. Layout of the monitoring system, identical in the two monitored anchorages 101V and 115V.

3 DATA PROCESSING AND VALIDATION

The data obtained from all sensors have been analyzed to understand, to the extent possible, the behavior of humidity and temperature conditions in the monitored anchorages, while keeping into account the execution of interventions and the geometrical differences between the two anchorages.

As an example, extracts of air temperature, air relative humidity (RH) and surface temperature data are shown in Figure 3 to Figure 5.

Figure 3 shows a noticeable difference both in air temperature and RH during the warmest hours of the day, especially in summer, between the two anchorages. It has been interpreted that this phenomenon is related to the different size and inclination of the two anchorages. Specifically, the air inside of anchorage 101V – smaller and more inclined – is more efficiently heated and dried than in anchorage 115V, especially under more intense solar radiation during summer days.

The analysis of the surface temperature sensors has provided information on how the different surfaces (of wires, protection pipe and base pipe) are subject to temperature variations with a timing consistent with their position. As an example, Figure 4 shows how the outer surface of the protection pipe in anchorage 101V is heated earlier and more efficiently during the first sunny hours of the day, while the internal surface, as well as the wires, are heated with a delay of several hours. In general, the temperature of all anchorage and wire surfaces show – at different times of the day – higher peaks compared to the data from surface temperature sensors on the DAU cabinet hidden from sun radiation. This highlights that the sun radiation has a significant impact also on the distribution of the surface temperatures, in addition to the effect on air temperature and RH as mentioned above.

The measured data have also been used to test the effects of different interventions on the anchorages. As an example, Figure 5 shows an extract of the wetness data from LWS2 (installed on the internal surface of the protection pipe). On December 21st, 2022, the gaiter sealing at the top of the protection pipe (see example in Figure 8) was removed from anchorage 101V. Given that LWS2 would normally provide values around 170 mV when dry, it appears evident that the removal of the gaiter sealing has caused an increase in the recorded wetness peaks during all the following rainy periods.

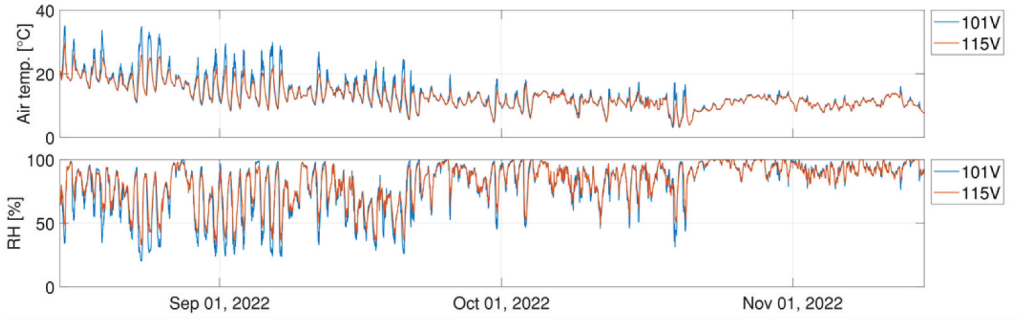

Figure 3. Time series of air temperature and RH in both anchorages.

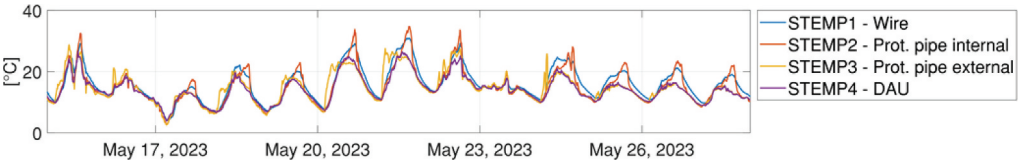

Figure 4. Time series of surface temperature data in 101V.

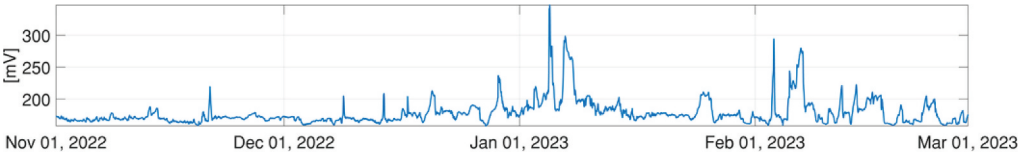

Figure 5. Time series of wetness measured by LWS2 (on protection pipe internal surface) in 101V.

4 CONDENSATION ASSESSMENT

Air temperature, RH and surface temperature data have been used as basis to track the situations in which the conditions triggering the formation of condensation would be met on the different surfaces of the anchorages.

More in detail, the air temperature and RH data have been used to calculate the dew point of the air enclosed in the anchorages. The dew point is defined as the temperature below which air must be cooled to become saturated with water vapor (RH≥100%), assuming constant air pressure and water content. Hence, if a surface has a temperature below the dew point, the air will condensate when it gets in contact with this surface. The measured surface temperature data have therefore been used to assess when condensation can form on the instrumented surfaces.

An example of the outcome of this assessment is shown in Figure 6, where the difference between surface temperature and dew point is plotted. Values below zero identify situations where the conditions for condensation are met. The data are extracted from a period in which an

airtight bellow sealing had been installed between protection pipe and base pipe of 115V (January 2023 – see example in Figure 8), but before the installation of the dehumidification system (May 2023). This means that the air conditions inside 115V were sealed and isolated from outdoor conditions, which caused a significant increase of RH in the anchorage and, consequently, a more intense formation of condensation compared to 101V – as evident from Figure 6.

The results of the condensation assessment obtained throughout time have been summarized by calculating the percentage of time per month with formation of condensation on the internal surfaces of the anchorages. The outcome is shown in Figure 7. As expected, the formation of condensation becomes more intense during the winter months, due to higher RH and lower temperatures. These summary results have also been useful in identifying the effects of the interventions carried out on the anchorages, e.g., the above-mentioned installation of a bellow sealing on 115V before the installation of the dehumidification system, which implied a big gap in the formation of condensation between the two anchorages starting from January 2023.

5 WATER INGRESS ASSESSMENT

The data recorded with the LWS have been used as basis to assess the magnitude of the water ingress issue during rain. As anticipated in section 2, although LWS were initially expected to provide purely binary information (i.e., sensor "dry"/"wet"), LWS data have proven to be significantly more informative if the focus is on the wetness trends in time (see Figure 9). Firstly, it has been possible to identify the formation of condensation as a slow and gradual increase of wetness that can be developing through several hours. On the other hand, the start of water flow has been associated with sudden "jumps" in the wetness readings. It shall be noted that, given the nature of the wetness measurements, it is only possible to identify when the water flow starts – i.e., when a jump in the data is produced – but not the duration of the water flow. This is because the wetness produced by a water flow after its initiation is affected by the continuity of the rain, it can be easily confused with the wetness produced by condensation, and the drying time can be heavily affected by the air humidity.

As part of the water ingress assessment, all data recorded during the monitoring period have been analyzed to seek sudden jumps in the wetness data due to the start of water flow on the different surfaces instrumented with LWS. The results have been summarized in a similar fashion to what was done for the condensation assessment (see section 4), by calculating the percentage of time during which water flow is initiated during rainy days. The results are shown in Figure 10. For clarity, as the data are available with a frequency of 10 minutes, the above-mentioned percentage has been calculated as the ratio between the number of 10-minute intervals with a jump in wetness and the number of 10-min intervals in which the readings from LWS4 (installed outside of the anchorage and serving as a rain sensor) are above a certain threshold, i.e. when the sensor is wet due to rain.

LWS2 (installed on the surface of the protection pipe) is the sensor recording the highest rate of water flow. Given the position of LWS2 at the top of the protection pipe of both anchorages, this water flow is considered directly produced by rain ingress from the top of the protection pipe. Anchorage 115V appears to be the most sensitive anchorage to rain ingress.

LWS3 (in the base pipe) records a higher water flow rate than LWS1 (on the wires), which has come as a surprise when interpreting the data. As a matter of fact, the water flow recorded by LWS3 would be expected to be equal to or less than the water flow recorded at LWS1, since the main – and possibly only – path enabling rain leakage into the protection pipe to reach the base pipe should be through the wire surface. An explanation for why this expectation has not been met may be that the water flow recorded by LWS3 is not caused by the rain ingress at the top of the protection pipe, but by the condensation formed on all anchorage surfaces and then flowing down into the base pipe. This mechanism is more evident in 101V than in 115V, which is due to the different size of the two anchorages. Specifically, the drops of condensation formed on the protection pipe or wires of 101V need to flow for a shorter distance before dripping into the base pipe. To conclude, it is considered that only a minor portion – if not negligible – of the water flow recorded in the base pipe is directly produced by rain ingress at the top of the protection pipe.

The effects on rain ingress associated with different interventions on the anchorages have also been assessed. For example, it has already been described in section 3 how the removal of the sealing gaiter at the top of the protection pipe of 101V in the end of December 2022 has caused an increase in the water flow rate in the following months – which can also be noticed in Figure 10.

A significant increase in water flow rate is also noticed from January 2023 in 115V. This is most likely related to the installation of the bellow sealing between base pipe and protection

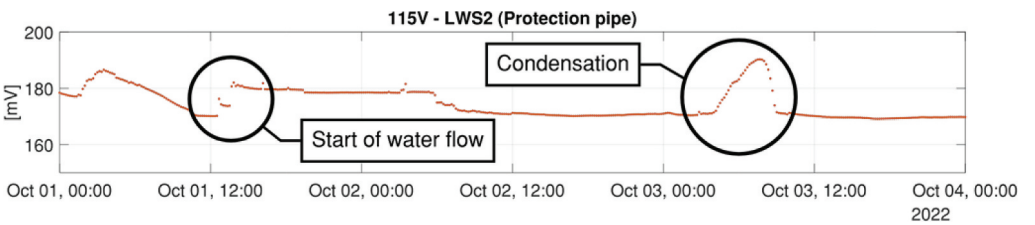

Figure 9. Example of wetness readings associated with start of water flow and with condensation.

pipe at the end of December 2022, which has triggered a very intense formation of condensation – as described in section 4. It is highly plausible that such an intense formation of condensation eventually produces a notable water flow.

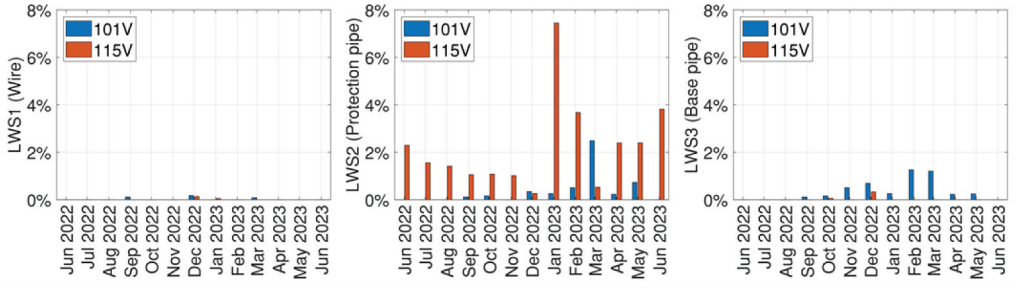

Figure 10. Summary of percentage of time in which water flow is initiated during each month.

6 EVALUATION OF PROTOTYPE DEHUMIDIFICATION SYSTEM PERFORMANCE

In order to mitigate the issue of the water presence in the lower cable anchorages, Trafikverket has decided to install and test a prototype dehumidification system in each of the two monitored anchorages. The monitoring system has therefore acquired the additional objective of validating the efficiency of the dehumidification system before it is possibly extended to dehumidify all anchorages of the Uddevalla bridge.

This process is currently ongoing, and the dehumidification system is being calibrated to achieve the desired air conditions inside of the anchorages, namely a relative humidity below 40%, which is expected to eliminate the formation of condensation and to facilitate the drying process of the water potentially leaking into the anchorage during rain.

In general, the efficiency of the dehumidification system is tracked by simply comparing the RH measured inside of the anchorages and the RH measured by the nearest SMHI (Swedish Meteorological and Hydrological Institute) weather station in Gothenburg. As an example, the plot in Figure 11 shows an extract of the RH readings from anchorage 101V, where the impact of the dehumidification system is already evident right after its installation.

The evaluation of the dehumidification system's performance is currently ongoing, and the system is being calibrated to achieve the desired effect. To this aim, optimal settings for dry air production will be identified after the system has been operational for a certain period in airtight anchorages, protected from weather conditions.

7 CONCLUSION AND FUTURE DEVELOPMENT

This paper has presented the main outcomes of the moisture monitoring system installed on two selected lower cable anchorages of the Uddevalla bridge.

The monitoring system, procured and installed by COWI (including programming of data logging and communication), continues showing an excellent performance in providing data of high quality. The initially moderate expectations regarding the experimental deployment of Leaf Wetness Sensors (LWS) have been exceeded, as a base of highly informative data have been collected, allowing to map the paths of water flows and the efficiency of the drainage ways.

Specific assessments have been carried out to investigate the magnitude of the main issues behind the presence of water in the anchorages, namely condensation and rain ingress. Both assessments have resulted in monthly summaries estimating the percentage of time affected by the two issues.

Based on both raw and processed data, the effect of different interventions on the anchorages has been successfully evaluated, identifying changes in air conditions and water flow intensity inside the anchorages.

Finally, the performance of a prototype dehumidification system is now being monitored since its installation at the end of May 2023 on both monitored anchorages. The efficiency of the dehumidification system can be tracked by comparing the outdoor relative humidity with the one measured inside the anchorages, while its operation is being calibrated to achieve the desired objective of an internal relative humidity below 40%.

Among the future developments of the monitoring project, the possibilities for extrapolating the data from the monitored anchorages to all the other anchorages are being investigated. After more than a year of continuous monitoring, air temperature, humidity and surface temperature data are available for all seasons, which constitutes a quite complete basis of data under diverse weather conditions.

As described in section 3, the trend of air temperature, humidity and surface temperature are strongly correlated with the geometry – i.e., size and inclination – of the anchorages. It is therefore considered that air temperature, humidity, surface temperature, and, as a consequence, the condensation rate, can be extrapolated from the monitored anchorages to all other anchorages, by considering their geometry.

A less straightforward operation may be the extrapolation of the water ingress results, as they directly depend on the watertightness (i.e., leaks and imperfections) of each anchorage. A possible way-forward to obtain a basis for the extrapolation could be to perform inspections on all anchorages and rate their watertightness.

All the above initiatives for future development converge into the general idea of establishing a digital twin that would enable estimating the consequences of environmental conditions, mitigation, and other changes with respect to the extent of the water presence issue. This digital twin approach may provide an efficient way of assessing the exposure to corrosion risk for all anchorages, based on their geometry.

Analysing ultrasonic testing data to optimise stay cable maintenance

A. Boyez & R. Percy
COWI UK Limited, London, UK

J. Laigaard Jensen & I. Farreras Alcover
COWI A/S, Lyngby, Denmark

ABSTRACT: Corrosion caused by water ingress is a significant risk for parallel-strand cable systems lower anchorages. When this risk is realised on a bridge, implementing a robust maintenance strategy is needed to ensure safety and minimise operational impacts. This makes ultrasonic reflectometry a valuable tool for bridge owners since it can estimate the condition of individual wires from the anchorage.

Sixense's UScan® has been applied to the stay cables of Pont de Normandie since 2012, and since COWI started advising the bridge operator CCIT-SE in 2019, complementary testing and analysis has allowed to assess the reliability of ultrasonic testing and to maximise the value of ultrasonic testing data.

The paper builds on this experience to discuss how ultrasonic testing can be used to inform stay cable maintenance and replacement and proposes further steps to better enable proactive maintenance that minimises costs and operational impacts while extending the life of stay cables.

1 INTRODUCTION

Stay cables on major long span bridges are critical components within primary load paths, historically with limited or no redundancy. While more modern bridges are usually designed to permit one or two stay cables to be temporarily absent, earlier bridges may either have no redundancy or cater only for a single stay to be removed, typically under reduced traffic loads. The majority of stay systems use spiral strand or parallel strand systems: the later has become more widely used and is the one considered in this paper.

Corrosion of the wires making up stay cable strands may lead individual wires and strands to fail, threatening the integrity of stay cables. Considering their limited redundancy, water ingress prevention is a design priority, but corrosion remains a possibility, so that effective methods for corrosion detection become critical. Indeed, without data on the extent of corrosion, bridge owners and operators cannot accurately assess the bridge's reliability or efficiently plan stay replacements.

In this context, stay lower anchorages are problematic as they combine susceptibility to water ingress with limited access. Most of the length of strands within the anchorage is not visible beyond the anchorage plate, leaving Non-Destructive Testing (NDT) as the only option to determine the extent of corrosion before wire and strand failures become apparent.

This paper explores the use of periodic ultrasonic testing data to inform safe operation and maintenance of cable-stayed bridges subject to stay lower anchorage corrosion. Context on the issue is provided and the testing method presented before practical applications of data analysis and visualisation from COWI's work on Pont de Normandie are presented. Finally, short-term and long-term optimisation of stay condition testing and management is discussed.

DOI: 10.1201/9781003483755-350

1.1 *Corrosion in parallel strand stay cable lower anchorages*

The top right of Figure 1 shows the cross-section of a typical parallel strand stay cable: multiple strands are arranged in parallel to approximate a circular cross-section, and generally protected by an outer high-density polyethylene (HDPE) sheath. Modern steel strands are typically formed of 7 high-strength steel wires, which, for corrosion protection, are individually galvanised. The complete strand is then covered with wax and an extrusion of high-density polyethylene (HDPE) - refer to the bottom left of Figure 1.

At the anchorages, strands are separated and individually anchored using steel wedges, which requires removing the HDPE extrusion (refer to top left of Figure 1). This leaves the strands and constituent wires more vulnerable to corrosion (refer to centre left of Figure 1). Anchorages are often injected with wax, but this further mitigation does not always prevent water ingress.

This weakness to water ingress is particularly relevant at the lower anchorage since gravity will help water find a way past imperfect and aging seals into the anchorage, and this is indeed where many corrosion issues have been documented in stay cables (Jensen 2017).

1.2 *Inspection, testing and monitoring of stay cable lower anchorages*

The challenge with corrosion in parallel strand stay cable lower anchorages is the difficulty to view or reach the location where corrosion is most likely to occur, that is within the length of strand not protected by HDPE, as this area is either within or beyond the anchorage plate. Some options for inspection, testing and monitoring are discussed below:

1. Stay cable checks: when a strand breaks, it may pierce or distort the stay's outer sheath and become visible. While checking for this is easy to implement, it provides only partial information after a breakage.
2. Anchorage visual inspection: signs of corrosion, missing wires or missing strands may be identified from the anchored end. This requires access, preparation (removal of the anchor cap and wax), and potentially restoration (reinjection of wax), and is more likely to provide information when the corrosion process is advanced.
3. Endoscopy: in theory, a fiberscope thin enough to be inserted between the strand and its anchorage hole should allow to check for signs of corrosion along the exposed strand length. In practice, residual wax makes it impractical. Requirements for this method are the same as for visual inspection.
4. Acoustic emissions monitoring: in theory, this continuous monitoring identifies wire breaks when they occur, building an incremental picture of the stay degradation. In practice, any downtime could lead to wire breaks being missed, and false negatives and false positives are a possibility that must be accounted for in assessing the output. Acoustic emissions monitoring requires 2 sensors per stay to determine/confirm the location of breakage, an acquisition network and specialist signal interpretation, but once installed access should not be needed other than for maintenance. This cannot provide information on pre-existing stay condition.
5. Ultrasonic reflectometry: this test, further described below, provides a snapshot of the absolute corrosion level of each wire. It requires access, preparation (removal of the anchor cap and wax, machining of the wires) and restoration (reinjection of wax).

Destructive testing of loaded strands is to be avoided considering their structural function. On the other hand, failed or replaced strands can be extensively tested, which yields valuable information on the accuracy of testing and monitoring techniques and on strand properties. This will not however directly inform the condition of the remaining strands.

1.3 *Challenges of stay replacement*

Stay replacement involves several challenges, including traffic restrictions, which may be necessary for public and worker safety and structural capacity; and the removal of elements such as protective covers and sheaths, stay damping devices, and ancillaries such as monitoring sensors, cabling and lighting.

These challenges, together with works set-up costs, make stay replacement a complex and costly operation, especially when a low number of stays is replaced. Forward planning and

maximising stay life are therefore essential to reduce maintenance costs and environmental impact.

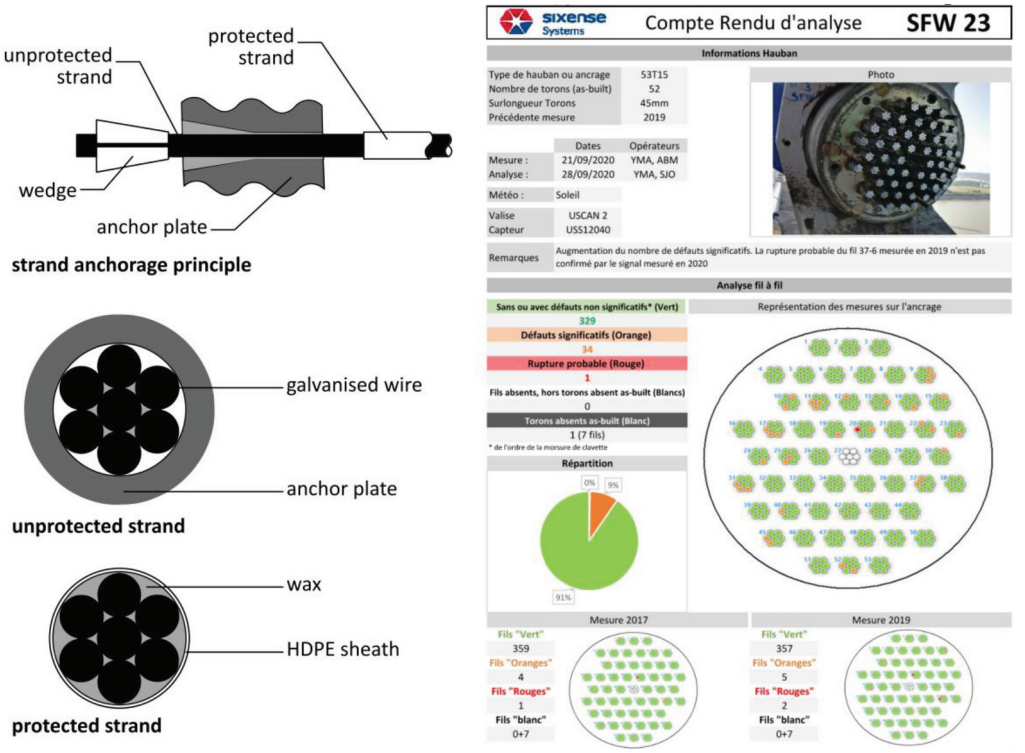

Figure 1. Left – strand anchorage section and cross-sections of the unprotected and protected sections of the strand. Right – results of UScan® testing of a Pont de Normandie stay before its replacement in 2020.

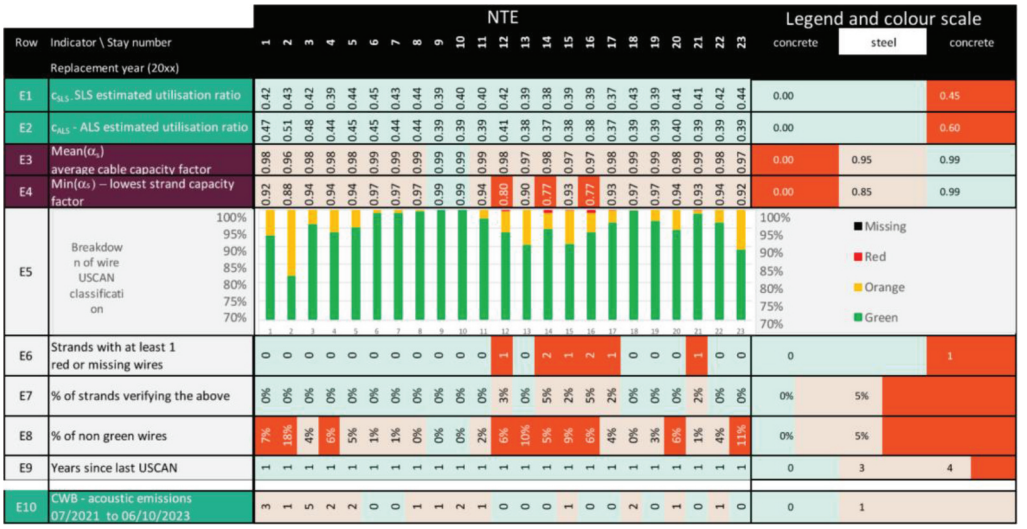

Figure 2. Extract from COWI's Pont de Normandie summary table bringing together all available stay information, including UScan® and stay condition indicators derived from it.

Table 1. Colour classification used by Sixense to report UScan® results from Pont de Normandie stays.

Wire colour classification	Signal reflection	Meaning
Green	None/poor	A defect such as corrosion is unlikely.
Orange	Significant	A defect such as corrosion along the wire is likely.
Red	High	A failure along the wire is likely.
White	N/A	Wire physically absent but was present at construction.
Black	N/A	Wire absent from construction, by design.

2 ULTRASONIC REFLECTOMETRY TESTING OF PARALLEL-STRAND CABLES

Ultrasonic reflectometry is a non-destructive test that can be applied to detect flaws in steel wires and steel strands. An ultrasound is emitted at an anchored end, and the recorded response signal is analysed to identify flaws such as surface corrosion or ruptures.

The ultrasonic guided wave reflectometry applied to stay cables further discussed below, UScan®, has been developed and patented by Gustave Eiffel University (UGE) and Sixense (Laguerre et. al 2011, 2020).

2.1 *Requirements and output*

For parallel-strand cables, UScan® can be applied to individual wires. The wave is generated and detected by an ultrasonic transducer held in contact with the wire end, which requires preparation so that the wire section is clean, flat, and orthogonal to the strand axis. Signal can be detected for ranges between a few decimetres and a few metres, which covers the length of wire most susceptible to corrosion in an anchorage. The signal is then analysed to classify individual wires into categories (see Table 1 for the wire colour classification used by Sixense).

The right side of Figure 1 illustrates how Sixense typically reports UScan® test results for parallel-strand cables – it provides useful contextual information on top of the classification of each wire, such as the date of measurement and processing, results from previous investigations, and a picture of the anchorage at the time of inspection.

2.2 *Consistency and reliability*

UScan® is subject to uncertainties and errors from multiple sources including, in no particular order, ultrasonic equipment calibration, wire surface preparation, signal contamination, stay/strand/wire mislabelling, signal interpretation process, erroneous data entry. Since its inception, the UScan® methodology has been refined to eliminate or mitigate some of the above (e.g., measuring each wire twice), however cross-checking throughout the process remains essential to maximise data quality.

Stay replacements provide an excellent opportunity to establish the reliability of ultrasonic testing: the classification into corrosion categories from a detailed visual inspection of removed wires can then be compared with wire classifications from a recent UScan® test. It should be kept in mind however that the results of such an exercise only apply to an instance of UScan® and cannot be fully generalised to other instances if the test methodology changes.

3 ANALYSIS OF USCAN TESTING DATA FROM PONT DE NORMANDIE

3.1 *History of ultrasonic testing on Pont de Normandie*

The discovery of 2 broken strands in one of the bridge's stay cables in 2010 led to investigations that established the cause as corrosion in the lower anchorage. In parallel, the lower anchorages of other stays were visually inspected, revealing some corrosion but no visible ruptures. The limited information to be gained from visual inspection triggered a research and development for better testing methods which culminated in the selection of ultrasonic reflectometry.

In 2012/13, UScan® was applied on Pont de Normandie to test the bridge's 184 stay cables. Since 2017, a rolling program to test all stays over 4 years has been ongoing.

The observation of strands breaking out of their stay aerodynamic sheath in 2018 and 2019, in combination with UScan® results, prompted the replacement of a further 3 stays in 2020. This was used as an opportunity for testing of the replaced stays, including tensile resistance tests and cross-checking of UScan® wire classification (see Table 2).

Other related activities have included the evaluation of the stays' design loads, and a trial acoustic emission monitoring system with 2 acoustic sensors per stay has been running since July 2021.

COWI became involved as a consultant to the bridge owner in 2019 and has since been working with UScan® data and other sources to provide meaningful information. The bridge is operated by CCIT Seine Estuaire (CCITSE), concessionaire for the French state.

3.2 *UScan® data quality and reliability assessment*

Although the responsibility for UScan® data quality lies with Sixense, several data quality checks can be conducted by other analysts. Such checks include verifying the consistency of information provided on individual stay reports. While these may be basic, they can identify mistakes that would impact the analysis, and are easy to automate – it makes sense to perform them as reports are generated. Incorporating similar consistency checks with other sources of information (e.g., composition of stays from construction records) is also beneficial.

The next level of checking involves the comparison of successive measurements on the same stay. Since the true wire condition can only degrade over time, the expectation is that individual wires can only evolve in the following order, although colours might be skipped: green, orange, red and white. In Laigaard (2022), such a method is presented. It relies on encoding the colour classification of wires constitutive of a strand into a scalar that increases with corrosion. If this number decreases between two successive measurements of a strand, at least one of the results must be erroneous. Although the error might come from multiple sources, aggregating the results of this method for stays tested at the same time can reveal trends that are likely to be due to differences in UScan® measurement or processing. Conversely, a reduction in the prevalence of non-physical evolutions of UScan® wire classifications over multiple campaigns would point to the reliability of UScan® increasing over time.

The best way to assess the reliability of UScan® data is to compare it with visual inspection results from replaced cables. Such a comparison exercise was undertaken during the replacement of 3no. Pont de Normandie stays in 2020, the results of which show a good correlation between UScan® and visual inspection (see Table 2 and Laigaard (2022)).

These results are recast in Table 3 on the basis that UScan® is a test to detect wire breaks, showing that UScan® in 2020 could reliably classify a wire into dichotomous "un-broken" or "broken" categories (being correct 97% and 71% of the time respectively). A similar analysis focused on UScan® as a test to detect corrosion reveals that it correctly places a wire in the "intact" category 87% of the time, and in the "corroded" category 50% of the time. This lesser performance is explained by the allusiveness of early corrosion and can be mitigated by data processing strategies. Overall, the above results are impressive and show UScan® is altogether a reliable method to assess wire condition.

The quantification of UScan® reliability informs the interpretation of the data and can even be explicitly taken into account using Bayesian probabilistic modelling to infer the actual

Table 2. Breakdown of UScan® wire category counts based on laboratory visual inspection categories for 971 wires from the 2020 replacement of 3no. Pont de Normandie stays.

Visual inspection levels*	Green	Orange	Red
Levels 1, 2 & 3	720	69	3
Levels 4, 5 & 6	102	21	7
Level 7	5	20	24

* Levels are grouped to match the UScan® colour categories.

condition. It should be noted however that this quantification corresponds to UScan® performed at a certain point in time and that changes to the methodology are expected to have an impact on its reliability.

Table 3. Alternative breakdown of the results shown in Table 2.

Visual inspection levels*	Green+Orange*	Red+White*
Levels 1-6	912 [97%]	10 [29%]
Level 7	25 [3%]	24 [71%]

* Category groups correspond to un-broken or broken.

3.3 *Meaningful indicators and data visualisations*

UScan® data is discrete categorical data with high granularity (every wire in a stay is attributed a category), which can make interpreting and summarising it difficult. Some of the strategies used by COWI's to achieve this are discussed below.

The first strategy is aggregation, an example of which is the use of normalised stacked bar plots reflecting the total count of wires in each colour category within a stay (see Figure 2). This plot allows to see the proportion of wires likely to be corroded or broken within a stay but also to compare it across stays, which helps clearly identified which appear to be in the worst condition. Another example of aggregation is the definition of colour categories for strands based on that of its constitutive wires. Such a strand categorisation makes sense for two reasons: first because remedial action cannot be taken on individual wires, and second because corrosion in a wire means the whole strand is likely to be exposed to water and corrode eventually.

The second strategy is encoding, i.e. transforming categorical data into numerical data, which makes ranking and aggregating easier. An example of encoding is the strand Damage Indicator (DI) defined in Laigaard (2022), which captures the colour categories of 7 wires making up a strand into a scalar that increases with the signs of corrosion. Another example is the definition of a strand capacity factor that estimates the proportion of tensile resistance maintained by a strand using the UScan® classification of its constitutive wires. This relies on a linear regression model fitting tensile testing data to UScan® results for a sample of strands from the 3 stays replaced in 2020, see Laigaard (2022).

The third strategy is the focus on meaningful indicators and synoptic data visualisations, exemplified by Figure 2. Along the rows, it shows estimated utilisation ratios, capacity factors, underlying UScan® results, condition indicators, contextual information and Acoustic Emission results. Along the columns, it shows stay cables according to their location. Discrete conditional colour formatting helps to highlight hotspots. While it summarises and juxtaposes a lot of information, it is designed to remain readable, so that it can serve as a tool for contextualisation, comparison and prioritisation. Figure 2 shows only one fan for readability, but the full version shows the 8 stay fans of Pont de Normandie in an A3 sheet of paper, condensing a large amount of information digestible manner.

3.4 *Degradation rates and predictive models*

While Figure 2, reading like a snapshot of the condition of the stay cables, is a useful tool for management, it has limitations. The first is that it shows the latest available UScan results, which on Pont de Normandie can be up to 4 years old and are necessarily asynchronous. This must be kept in mind when interpreting it, which is why the age of the underlying UScan is indicated. The second is that it doesn't offer forecasting information, which would benefit long-term planning. Options to address this latter issue include the characterisation of degradation rates and the definition of predictive models, both informed by historical data. Pros and cons of potential empirical and Bayesian approaches to both options are discussed below.

An empirical approach could be to plot the historical evolution of a numerical condition indicator for a stay, and to extrapolate the future evolution on this basis. This method can be

refined by using statistics (e.g., averaging the rate for all stays), by grouping individuals (e.g., making the rate conditional on the current condition) or by exploiting the granularity of the data (e.g., looking at strand degradation rates rather than stay degradation rates), and the physics of degradation can help inform the refinement used (one could for instance expect that different stays will see different degradation rates due to differences in exposure to water). While implementation can range from simple to complex depending on the level of refinement, the empirical approach is limited by two considerations: first, UScan® is susceptible to censoring (the exact time of a change in wire condition between two measurements is uncertain), and second, UScan®, although generally reliable, can and does misclassify wire conditions, as seen in Table 2 and Table 3. While an empirical approach can be informative if the associated uncertainty is kept in mind, quantifying this uncertainty is difficult.

A Bayesian modelling approach can elegantly deal with the limitations of empirical approaches and inherently quantifies uncertainty within the model structure. It is possible to bake into such a model that UScan® measurements are discrete observations of condition and that the true wire condition can only degrade with time. Both misclassification probabilities as inferred from laboratory testing data and variability within stays and strands can be incorporated. A trained model can flexibly estimate the true condition, which can be used to derive relevant condition indicators, and provides the associated uncertainty, making it an ideal tool for long-term planning. Multiple candidate model structure can be considered, ideally informed by corrosion process modelling.

4 STAY CABLE MAINTENANCE OPTIMISATION USING ULTRASONIC TESTING

4.1 *Extent and frequency of ultrasonic testing*

As discussed in the previous section, ultrasonic testing of stay cables' lower anchorages enables a range of analyses that can inform stay cable maintenance. While the minimum amount of data necessary will depend on the analysis, the reliability and value of these analyses can only increase with more ultrasonic testing data and other relevant information from inspection, testing, design and assessment, the acquisition of which comes at a cost for the bridge operator.

The ultrasonic testing regime must balance operational and financial costs of ultrasonic testing with the need for informative analysis outcomes. The following elements should be considered:

1. Testing costs: whether direct or indirect, many factors can influence them. Testing more stays per ultrasonic testing campaign is likely to reduce costs but operational constraints can limit the extent of the campaigns (weather, concurrent maintenance works). Costs can be expected to reduce over time as experience is gained, but only to an extent, unless specific process improvements are developed and implemented.
2. Condition knowledge: if the extent of corrosion is unknown, testing all stays to establish a benchmark should be a priority. Conversely, if the condition is understood, the frequency of testing should be proportional to the known corrosion level.
3. Stay criticality: the frequency of testing should be proportional to the criticality with respect to safety and structural integrity, to be informed by specific assessments.
4. Confidence in testing and data analysis: as confidence in ultrasonic data and derived results such as degradation rates or projection increases, the frequency of testing could be reduced.

On Pont de Normandie, the outcome of these considerations is a rolling program where a quarter of the stays (46 stays) are tested each year (so that no result is ever older than 4 years), complemented by more frequent testing of stays exhibiting the worst condition. This serves the dual purpose of keeping results up to date and of accumulating more data to enable more advanced analysis, while ensuring the condition of the most degraded stays is monitored closely.

4.2 *Ultrasonic testing informed maintenance decision making*

Conceptually, ultrasonic testing informs two aspects of stay cable lower anchorage corrosion: detailed results for individual stays allow to determine the local severity of corrosion, while an

overview of results for many stays informs the global extent of the issue. Up-to-date knowledge of the extent and local severity of corrosion, combined with understanding of bridge-specific circumstances, allows stakeholders to answer the following questions:

1. Should traffic restrictions, mitigation measures, contingency plans be prepared/implemented?
2. Should further testing be conducted, what should it target and what should its extent be?
3. Should complementary monitoring (e.g. acoustic emission monitoring) be considered?
4. Should selected strands or stays be replaced, and how soon?
5. Should corrosion prevention measures (such as dehumidification) be considered?

Figure 2 is an example of how to design ultrasonic testing data visualisation to facilitate the identification of the local severity and global extent of the stay lower anchorage corrosion issue, making it a useful tool to inform maintenance decision making. Its usefulness is further enhanced by the integration of further information such as stay utilisation levels, corroded strand resistance and acoustic emission monitoring. It is part of a report that is updated every time new UScan® results become available.

4.3 *Optimising replacement planning*

Bridge operators are typically working under tight budget constraints, so that they might be limited in their ability to replace stays within a given period. This, combined with sustainability considerations, makes optimising replacement planning a high priority.

A major obstacle to optimal planning is imperfect and incomplete information at the time decisions are made. A reasonable reactive replacement strategy, such as replacing the worst stay based on current information whenever new information becomes available, might prove far from optimal if the replaced stays were adjacent and would have had enough capacity to be replaced in a single, delayed operation, at a significantly lower cost. In this example, a better understanding of the relationship between the condition of a stay and the associated urgency of its replacement could lead to a better replacement strategy and an extended stay cable life.

For the issue considered here, investigations complementary to ultrasonic testing, although associated with a cost, enable further value to be obtained from ultrasonic testing: specific assessments of stay loading and redundancy can inform the criticality of individual stays, laboratory testing of replaced stays can quantify the reliability of ultrasonic testing and link condition with capacity, and complementary monitoring such as acoustic emissions monitoring have the potential to increase the robustness of the condition assessment.

For Pont de Normandie, COWI prepared a stay management plan that covered the above points. This document, periodically updated to take into account new information, provides a high-level summary and recommendations on the stay corrosion issue to enable proactive maintenance.

Replacement planning could be further optimised by the ability to estimate current and future condition based on available data. Such predictions might be valuable even if they are not particularly refined provided they can highlight a range of realistic scenarios that can be specifically assessed in terms of criticality (e.g. 3 adjacent stays might need to be replaced at once, or 8 stays might need replacing in 3 years).

COWI is working on a proof-of-concept Bayesian model that incorporates UScan® historic data, mis-classification rates, and the physics of degradation to provide estimates of current and future actual condition, and quantify their uncertainty. Such a model would evaluate the probability of a given replacement scenario occurring within a defined timeframe. If successful, this would be an excellent tool to optimise replacement planning.

5 CONCLUSION

The difficulty of assessing strand condition within stay lower anchorages, combined with the limited redundancy of stay cables, makes corrosion a significant challenge for cable-stayed bridge. For parallel strand stay cables, ultrasonic reflectometry testing can be a solution to

this problem. A testing strategy cognisant of the bridge's specificities and incorporating information from complementary analysis, assessment, monitoring can enable proactive maintenance that extends the life of stay cables and minimises operational and financial costs.

The management of Pont de Normandie's stay lower anchorage corrosion using UScan® testing illustrates the benefits of this approach: the bridge owner now has a reliable means of assessing stay condition as well as synoptic data visualisations to help inform decisions, and can look forward to condition predictions that quantify uncertainty to better inform long-term planning.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Chambre de Commerce et d'Industrie Seine Estuaire (CCITSE) for their support and for giving permission to publish this paper, as well as Sixense for their assistance in reviewing this paper.

The maintenance project of the special anti-seismic devices of the longest Italian bridge

A. Greco
Speri Spa, Rome, Italy

A. Lupoi
Sapienza University of Rome, Rome, Italy

ABSTRACT: The *elastoplastic damper* devices are frequently used to control the seismic response of structures and, in particular, of continuous bridges. Unlike other anti-seismic devices, the elastoplastic dampers are seismic restraints with *hysteretic elastoplastic* response capable of controlling the horizontal force level and of dissipating energy due to the earthquake. Sometimes such devices are coupled to *temporary* constraint devices, which are hydraulic type (shock-transmitters) generally. In case of seismic action, the hydraulic device is able to transmit the forces to the elastoplastic damper, while in case of service load, it does not offer resistance and allows the movements. Due to their performance characteristics, the elastoplastic dampers coupled to shock-transmitters have been used to control the seismic response of the longest Italian bridge, located on A12 highway in Tuscany Region. The paper shows the details of the maintenance project of the devices of the bridge, with a focus on the causes of any and all damage which have been detected during the surveillance.

1 INTRODUCTION

The article deals with the assessments and the choices regarding the improved maintenance project of the bearing and anti-seismic devices of the longest Italian bridge, which is located on the A12 highway, in Tuscany Region.

The abovementioned maintenance project of anti-seismic devices was part of a wider intervention strategy, which has been developed on the basis of certain damage found through the monitoring activity on the bridge's devices. This monitoring activity was made necessary due to (i) the significant length of the bridge (9 km), and (ii) the wide number of the anti-seismic devices (1047 units), and (iii) the peculiarity of such devices, consisting of elastoplastic dampers and oleo-dynamic components coupled to each other.

Moreover, the monitoring activity of anti-seismic devices was useful to constantly check the state of the anti-seismic devices and to arrange a proper intervention plan which will be adopted over the years in relation to the levels of the monitored damage. The limits of these levels have been identified in advance and throughout numerical analysis. The main benefit of this approach has allowed us the optimization of the costs related to the project.

For the sake of completeness, we have also carried out a safety static and seismic assessment of the bridge before starting the maintenance project of the devices, which has confirmed their compliance with Italian technical standards required by D.M. 17/01/2018. The outcome of this assessment was crucial as we have opted for a maintenance project of the anti-seismic devices rather than replacing them completely.

The article also describes the depth-analysis on the reveled damage which affecting the anti-seismic devices, and which has been carried out with the aim at better understanding the causes of such damage. This analysis has allowed us to consider within the project, the proper measures to have to be adopted for improving the functionality and the durability of all such devices.

DOI: 10.1201/9781003483755-351

In conclusion, we would like to point out that the maintenance of the devices, rather than their replacing, was opted on the basis of three factors: i) the positive outcome of the safety assessment; ii) the increasing of residual service life of the devices up to 50 years obtaining in this way the same service life of a new devices; iii) the lower costs of the maintenance interventions compared to a full replacement.

2 THE BRIDGE

2.1 *Description of the bridge*

The bridge was built in 1993 and it is located on A12 Italian highway. The length of the bridge is 9619 m, and it is considered the longest Italian's bridge (Figure 1).

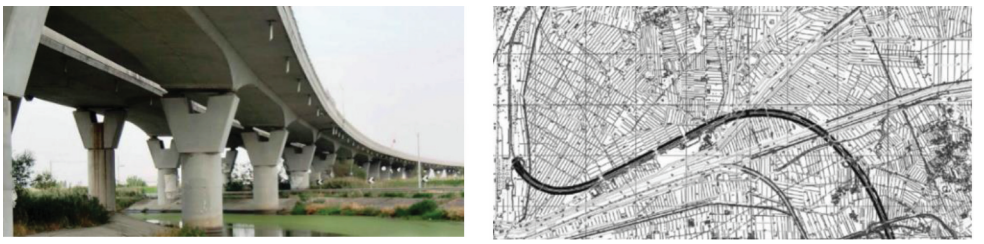

Figure 1. View of the bridge (left); cadastral plan of the bridge (right).

The bridge consists of no.27 continuous deck with separate carriageways; no.230 piers and no.2 abutments. The single deck consists of no.10 spans: the eight internal spans are 45 m long, while the two external ones are 33 m long. The single deck, of 12,25 m width (11,25 m for driveways), is built with the *incremental launching method.* Each single span is characterized by parabolic profile (from 2,3 m to 1,1 m) with *precast* concrete plate section. The pre-stressing system of the decks consists of 21ϕ7 with a ultimate tensile strength f_{ptk} and yield tensile strength $f_{p(0.1)k}$ equal to 1800 MPa and 1600 Mpa, respectively. The piers and foundations are in ordinary reinforced concrete, with a cubic resistance of R_{ck} 45 MPa and 55 MPa, respectively. Pier stems are characterized by a circular or rectangular section and a variable height ranging from 4,1 m to 13,6 m. Foundations piles are 65-70 m long with a ϕ1200 diameter do due the poor characteristics of the soil.

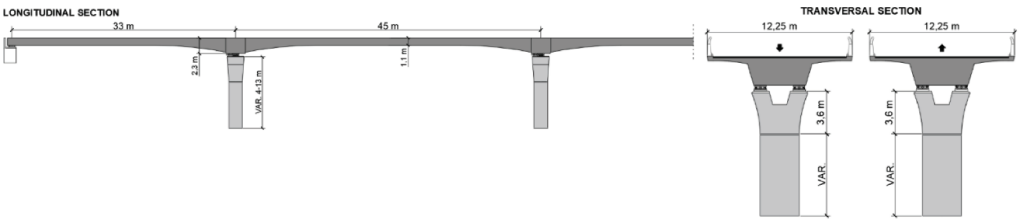

Figure 2. Longitudinal (up) and transversal (down) sections of the bridge.

2.2 *Bridge bearings and anti-seismic devices*

The deck is connected to the piers by special devices which have a dual function: the vertical load transfer and the seismic protection. The total number of the devices, considering the two carriageways, is equal to 1047, no. 2 for each pier of the bridge. The constraint scheme of each continuous deck is characterized by two fixed type devices located in the central pier, two free sliding type devices installed on the two external piers and two longitudinal sliding type devices on the remaining eight pears (Figure 3) which are coupled to hydraulic devices (shock-transmitters).

The latter devices ensure the longitudinal movement in case of service load (thermal action, creep, shrinkage, post-stress relaxation), while the transversal movement are bounded.

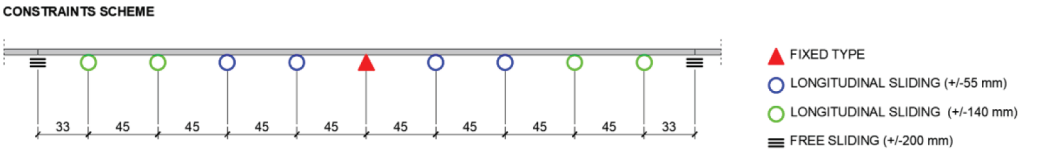

Figure 3. Constraints scheme.

Fixed and longitudinal device are able to transmit the horizontal forces through elastoplastic element characterized by *tapered* shape (also called *tapered pin*). These elements are developed to dissipate a rate of seismic energy by yielding and guarantying many stable hysteresis loops [1], [2]. The yielding force and ductility of such *tapered pin* are defined precisely.

The details of the longitudinal special device of the bridge, coupled to oligodynamic device, are shown in Figure 4.

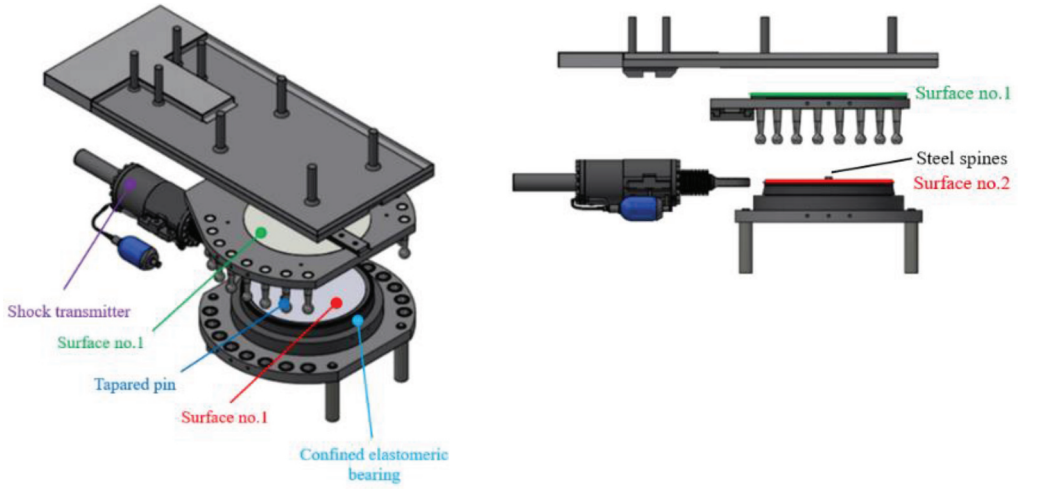

Figure 4. Tridimensional view (left), details (right).

The main components of the special device are the following:

1. Confined elastomeric bearing which is able to transmit vertical load.
2. Dissipative components which consist of no.16 *taperd pin* (built with stainless steel AISI 304) which dissipate seismic energy by yielding and hysteresis loops.
3. Hydraulic device (shock transmitter) connected both to the deck and to dissipative components. In case of seismic action, the hydraulic device has the ability to transmit the forces to the elastoplastic damper, while in case of service load, it does not offer resistance but allows the movements.
4. No.2 sliding surfaces made of PTFE which are characterized by low friction (the surface no.1 is highlighted in green in Figure 4, while the surface no.2 is highlighted in red color);
5. No.2 steel spines characterized by circular diameter and by made of S355 which are able to transmit service breaking action only.

The device allows a different performance which depends on the type of action. In particular, the sliding occurs at the surface no.1 or no.2 in case of service load or seismic action,

respectively. In case of seismic action, the steel spines break, and the hydraulic device transmits the force to the dissipative components which start their hysteresis loops by deformation.

The braking action transmission is ensured by steel breakage spines which allow to spread the forces in all devices of the continuous deck.

In terms of construction, the hydraulic device (shock-transmitter) consists of a piston sliding in a cylinder, filled with silicone or any other kind of oil. The piston is equipped with seal in order to separate the cylinder in two parts [3].

The hydraulic circuit is characterized by two valves with two calibrate orifices (one on the pressure side and the other one on the vacuum side) through which the fluid flows. In case of service loas, the orifices are opening, while for seismic action, the orifice on the pressure side closes and ensures the transmission of the forces.

The circuit is also connected to an external nitrogen accumulator which pressure is dependent of the outside temperature. The nitrogen accumulator is able to compensate the volume of oil in the cylinder, which is variable, due to its compressibility.

The shock-transmitters of the bridge, ones of the first type on the market, is rigidly connected to the deck of the bridge, while its piston is connected to steel sliding plate of the bearing by cylindrical hinges. These kinds of connections only allow the rotation in the horizontal plan as opposed to the ones currently in use which also allow the rotation in all planes (spherical hinges).

The dissipative components, as stated earlier, consist of no.16 *taperd pin* developed to dissipate a rate of seismic energy by yielding and guarantying many stable hysteresis loops. The total yielding force is equal to 640 kN (40 kN for each pin) which corresponds to a displacement equal to 8 mm. The maximum displacement to failure is equal to 70 mm (Figure 5).

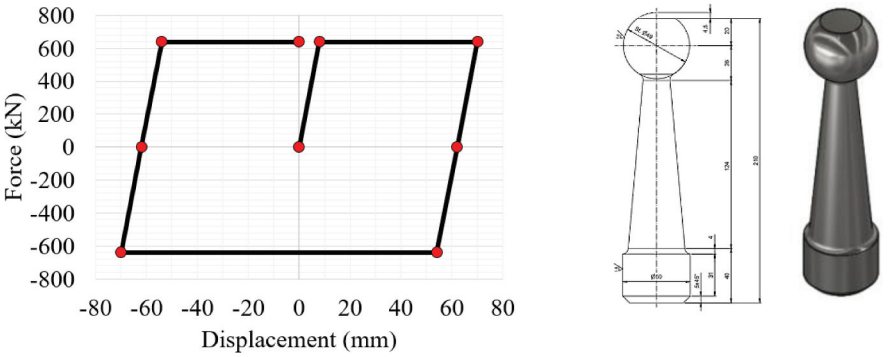

Figure 5. Diagram Force/Displacement of no.16 *elastoplastic taperd pin* (left); detail of the single taperd pin (right).

The performance parameters of all devices are shown in the Table 1 below.

Table 1. Performance parameters of the devices of the bridge.

	Vertical Load	Long. load	Transv. load	Long. displacement	Transv. displacement
Tipo	kN	kN	kN	mm	mm
Fix	12000	640	640	-	-
Longitudinal sliding	12000	640	0	+/-140 (+/-55)*	-
Free sliding	4000	-	-	+/-200	+/-200

* The excursion capacity is equal to +/- 140 mm or +/-50 mm for the longitudinal sliding device located at external or internal side respectively (Figure 3).

3 DAMAGE ASSESMENT AND CAUSES ANALYSIS

3.1 *Damage assesment*

During the bridge monitoring activity were detected multiple types of damage on the bridge's devices in the latest years. Such damage mainly interested the hydraulic devices and the elasto-plastic components, while the elastomeric confined bearings are very preserved.

Below we have listed the main damage captured by on-site inspection followed by photographic details (Figure 6):

a) Elastoplastic tapered pin deformed or broken.
b) Oil leakage from the shock-transmitters.
c) Circuit of the hydraulic device lockout.
d) Deterioration of the sliding PTFE surfaces and loss of planarity.
e) Oxidation of the metallic components.

Figure 6. Mainly damage of the devices.

3.2 *Causes analysis*

Firstly, an assessment of the damage has been carried out with the aim at better understanding the causes of such damage. This assessment was helpful to evaluate and then to adopt the most appropriate measures for restoring and improving the functionality and the durability of the bridge's anti-seismic devices.

The outcome of the assessment has revealed that the main cause of the damage to the device consists of lockout of the hydraulic circuit of the shock-transmitters which leds the deformation or the breaking of the tapered pin for service load.

In particular, have been identified two different behaviors:

i. Malfunctioning of the hydraulic circuit.
ii. Reaching the displacement limit stop of the device.

With regard to letter (i), the main cause of the malfunctioning of the circuit could be the orifices obstruction of the calibrate valves and in particular, the sliding of the piston in the cylinder wears out the seal and such wearing causes the releases of elastomeric particles which obstruct the orifices of the valves (without protection filter) by blocking the device (Figure 7).

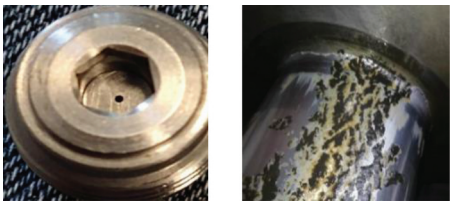

Figure 7. Calibrated orifices of the valves (left); particles of the seal in floating in the oil (right).

The valves are the most important elements of the system as well as the activation velocity of the device, which should be the same in both push directions of the piston (i.e. pressure and vacuum direction). Therefore, the tolerance of orifices' diameters shall be deemed crucial as such tolerance should be the same for both orifices of the valves and, if possible, for the all devices of

the bridge as well. The different activation velocity of the oleodinamic device might lead a delay time in their response by causing damage to themselves and to the bridge.

With regard to letter (ii), it is possible that certain oleodinamic devices might have reached the displacement limit, due to the thermal and rheological effect [4], and then consequently the blocking of the devices should have occurred. In fact, the numerical analysis of the bridge, which will be presented clearly in the next chapter no.4, will show that the maximum displacement of one device could be equal to 62,8 mm (12,8 mm due to thermic action, 50 mm due to rheological effect) and, therefore, greater than its own capacity which is 55 mm (Figure 8).

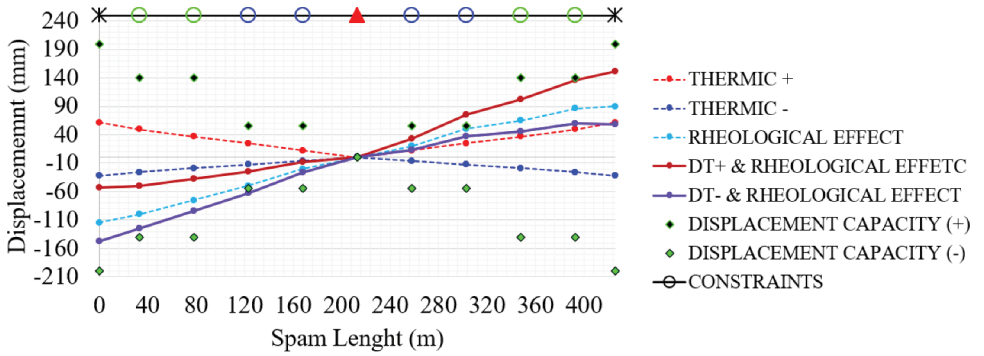

Figure 8. Thermal and rheological displacement of the device of the single continuous deck.

Additionally, it was possible to identify contributing factors by the assessment which factors may have been decisive for the damage detected on the bridge's devices:

iii. Type of the connection of the piston of the shock-transmitters to the bearing steel plate. In particular, the connection of the devices consists of cylindrical hinges only allows the rotation in the horizontal plan and not the one in the vertical plane, as clarified in chapter 2. This aspect could have arisen a parasitic bending moment and – consequently – an high pressure on the seals of the piston and their deterioration (Figure 9). The modern devices, in fact, are characterized by spherical hinges instead of cylindrical hinges in order to avoid these latter negative effects.

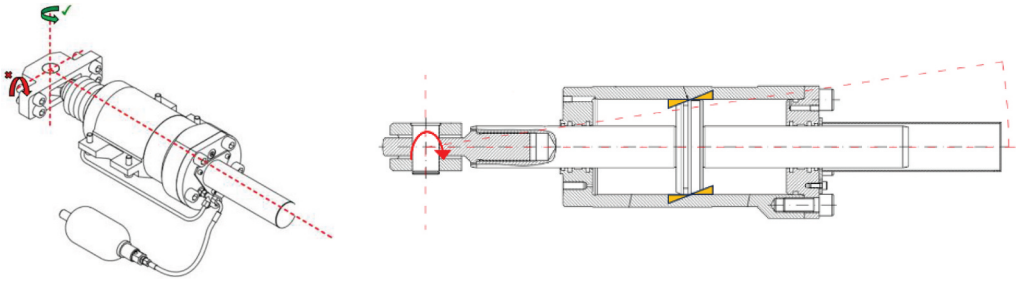

Figure 9. Cylindrical hinges of the device (left); negative effect of the blocked rotation on the seals of the piston (right).

iv. Deterioration and consequently loss of flatness of the PTFE surface of the bearing which could have increased the friction resistance and caused the deformation of the tapered pin for service loads.
v. General deterioration of all components due to the exposure to atmospheric agents.

4 NUMERICAL ANALYSIS

As preliminary phase of the maintenance project of the devices, a safety static and seismic assessment was carried out and it has confirmed their compliance with Italian technical standards required by D.M. 17/01/2018. The outcome of such seismic assessment was crucial to evaluate and then to opt for a maintenance project of the anti- seismic devices rather than for their complete replacement.

The response of the bridge (and its special devices) has been captured by FE model, managed with the support of the SAP2000 code (Figure 10). The model represents the single typological deck of the bridge which consists of no.10 spans and no.11 piers (total length equal to 426 m).

Decks and piers are modelled with frame elements [5], while the shock-transmitters interposed between deck and each pier are modelled with elastoplastic links. Such links are characterized by law governing performance of tapered pin (Figure 5). In addition, the model considers the construction phases by a specific *staged construction*, including the different response of the special anti-seismic devices for service or seismic loads.

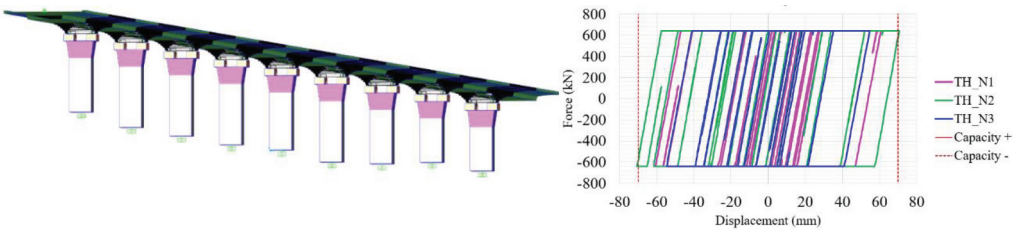

Figure 10. FE model of the typological deck of the bridge (left); hysteresis loop of the elastoplastic devices (right).

The dynamic response of the structure is estimated by carrying out dynamic non-linear analyses with direct integration [6]. Seismic input is applied by displacements time history with a duration equal to 20 s in the three directions of the seismic action and characterized by 8000 steps of 0,0025 s. The thermic and rheological action are considered by equivalent thermic load applied to the deck, while the traffic loads have been modeling by moving load. Figure 10 shows the typically hysteresis loop of the elastoplastic device obtained for the seismic action. The graph outlines that the maximum displacement of the elastoplastic devices is within the range of their capacity excursion. This positive response, as already pointed out in the preamble of this chapter 4, has allowed us to opt for a maintenance project of the anti-seismic devices by avoiding their radical substitution.

5 THE MAINTENANCE PROJECT OF THE DEVICES

The main goal of the maintenance project, which is the object of this paper, was the restoring and the improvement of the functionality of the special anti-seismic devices of the bridge and the adoption of the proper measures to increase their durability. On the basis of the monitoring activity of anti-seismic devices it has been arranged an intervention plan which will be adopted over the years in relation to the levels of the monitored damage with the aim at optimizing the maintenance costs.

The maintenance project has identified two main cases of intervention:

a) In case of tapered pin deformed or broken (or poor general state of preservation): the project provides for the full replacement of special devices, including all their relevant components (elastomeric confined bearing; elastoplastic components and hydraulic device).

b) In case of tapered pin not damaged (and good general state of conservation): the project only provides for the maintenance of the hydraulic devices (shock-transmitters).

Regarding the case (a) the main action that needs to be considered is the raising of the bridge which is, however, an operation much expensive. Due do this latter aspect, the initial choice to rebuild the *tapered pin* was excluded. Therefore, the intervention involves the full replacement of the devices with other ones which are characterized by the same performance but built according to the requirements of the current standards. In particular, it is required that the new devices have (i) the "CE" marking, and (ii) the connection with spherical joint, and (iii) the orifices of the valves with protection filter which shall be characterized by appropriate tolerances of their diameters. The new devices which have been installed on one pier of the bridge recently are shown in Figure 11.

Figure 11. New devices installed on one pier of the bridge.

Regarding the case (b), it was defined an accurate procedure in order to restore the oleodinamic devices. The procedure provides for the restoring of all components of such devices, in particular the replacement of the oil and the insertion of a filter in the calibrated valves' orifices, together with the complete replacement of such valves, to capture the potential particles which may be in suspension in the oil. In addition, the procedure requires an accurate preselection and coupling of the valves by specific algorithm with the aim at ensuring the tolerance of the diameter of the orifices within the range provided by current standards (<5%). This approach permits to have the same activation velocity in both push directions of the piston (i.e. pressure and vacuum direction) and for all devices of the bridge.

We should also point out that the checking tests on no.20 calibrated valves' orifices (with a diameter of 0,4 mm as per project), which were performed during the disassembly of certain devices of the bridge, have shown that the value of the current tolerance of their diameters is equal to +/-0,1 mm. This means that the tolerance is approximately equal to 56% versus 5% required of current standards.

Subsequently, the cylinder shall be painted according EN ISO 12944 (C5M) and the devices' stems shall be double chromed. All devices will be tested according EN 15129 before their reinstallation on the bridge. Regarding the assembly phases, particular care must be taken to the excursion adjustment of the device, considering the thermic displacement at that time. Rheological displacements, instead, are now stabilized to 30 years from the construction of the bridge and, therefore, they can be overlocked.

6 CONCLUSION

The article has showed the assessment of the damage and the details of the maintenance project related of the special anti-seismic devices of the longest Italian bridge, which consist of elastoplastic dampers coupled with shock-transmitter. The preliminary assessment of the damage detected on the devices has permitted to identify the main causes of such damage and to consider, within the project, the proper measures to have to be adopted for improving the functionality and the durability of all such devices.

On the basis of the project that was carried out and which was detailed in this work, we might point out the following main aspects:

1. The adequate tolerance of the diameter of the valves' orifices is relevant to ensure the greatest performance of the hydraulic devices. A low value of such tolerance in fact permits to

have the same activation velocity in both push directions of the piston (i.e. pressure and vacuum direction) and for all devices of the bridge. This aspect allows to avoid potential at hydraulic devices and at the whole structure, as well.
2. The presence of the filter protection of the valves' orifices of the hydraulic devices is decisive to avoid their obstruction, the blocking of such devices and any further damage both to the devices and to the bridge.
3. It is crucial the connection of the hydraulic devices to their support by spherical joint in order to avoid parasitic bending moment and – consequently – high pressure on the seals of the piston and their deterioration.
4. It is decisive a correct estimate of the thermic and rheological effects on the continuous bridges and their devices, to choose the compatible excursion capacity of such devices and to avoid permanent damage both to them and to the bridge. Regarding this matter, it is important to consider the correct adjustment of the device during the assembly phase.
5. The continuous monitoring of the bridges' behaviour and their devices is the best approach to plan the intervention strategy over the time and to optimize the maintenance costs.

Experiences with repair of fatigue cracks in an orthotropic steel deck, New Little Belt Bridge, Denmark

P.L. Sørensen & N. Bitsch
COWI A/S, Kongens Lyngby, Denmark

J. Præst
The Danish Road Directorate, Copenhagen, Denmark

ABSTRACT: Since 2017 a numbers of fatigue cracks, at approximately 160 locations, has been observed in the orthotropic steel deck of the New Little Belt Suspension Bridge in Denmark. The bridge was in 2017, 47 years old, and this was the first time to observe fatigue cracks in the steel deck of the bridge girder. For a bridge owner this can be a crucial observation, as it is well known that repair of fatigue cracks in orthotropic steel decks can be difficult to repair in a proper way and the repairs are normally costly. More to that it is difficult to foresee how this will develop, as the kilometres of welds and number of fatigue prone details are enormous. Despite the difficulties and uncertainties, the bridge owner needs to consider the related crack repair costs in budgeting of the O&M costs in the remaining lifetime of the bridge.

1 INTRODUCTION

The Little Belt Suspension Bridge carries the E20 motorway over the crossing between the island of Funen and the mainland of Jutland, connecting east and west Denmark. The bridge was opened in 1970 and it carries three lanes of traffic in each direction. The average daily

Figure 1. Overview of New Little Belt Suspension Bridge.

DOI: 10.1201/9781003483755-352

traffic numbers have seen a steady increase since the opening, from around 15,000 vehicles to around 100,000 vehicles at present which is close to maximum capacity.

The suspension bridge has a main span of 600 m and two side spans of 240 m for a total length of l,080 m, see Figure 1. The approach spans have a total length of 620 m, giving a total length of l,700 m for the entire connection.

The superstructure is a closed steel box girder with a width of 33.3 m and a height of 3.0 m. The inside of the steel box girder is protected from corrosion by means of dehumidification. As this bridge was the first in the world to have this system installed, it was decided to also apply a paint system as backup. This paint system has a base layer that contains lead and a tar asbestos based top coat. After 50 years there is no sign at all of corrosion, even not at the non protected surfaces.

The width of the carriageway and paved area is 26.6 m. The pylons are ll8 m tall and made of reinforced concrete.

The suspension bridge has altogether six (6) expansion joints, as the bridge girder is divided in three (3) independent sections, two (2) side span sections and one (1) main span section.

During a general visual inspection in 2017, indications of fatigue cracks in the orthotropic steel deck were observed for the first time. A special inspection was performed and the indications of cracks were confirmed by NDT. Eddy current testing (ET) and ultrasonic testing (UT) methods were used.

2 DECK STRUCTURE

At the time of design of New Littlebelt Suspension Bridge in the mid 1960′es there was only very limited experience with wearing surface on orthotropic steel decks (OSD) in Denmark. Danish codes and regulations for bridges were based on the allowable stress method and no fatigue analysis was required to be performed.

However, some experiences from Great Britain and West Germany with OSD's were available and both the Client and the designers were, already at that time, very aware that fatigue was an issue that should be taken into consideration, and so several work groups were formed with the task of finding an optimum pavement to be used on the OSD and to find the best welding methods. Several tests were also completed to verify the composite effect between pavement and OSD and assist in the selection of details and welding procedures during the bridge design. For instance, it was decided to select an automatic submerged arc welding procedure for the vital trough deck weld, as this method would yield fewer welding defects compared to a manual welding process and it possesses better fatigue performance. Test results reported in [2] confirm this.

The final design was an orthotropic steel deck structure with closed troughs that act as the upper flange in the closed steel box girder. The troughs have a height of 250 mm, thickness of 6 mm, width at the deck of 300 mm and spacing of 600 mm, see Figure 2. Troughs are welded with a part penetration butt weld with up to 2 mm root gap. The plated bulkheads have

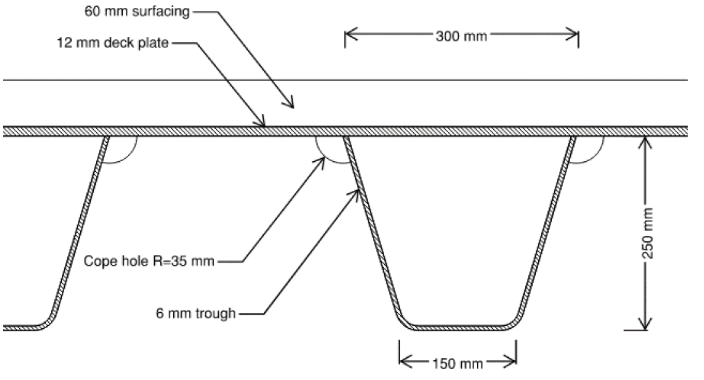

Figure 2. Trough layout.

a spacing of typically 3.0 m, but the spacing can vary down to 1.0 m at site connections. There are no cope holes in the transverse bulkheads at the bottom of the troughs, but there are R=35 mm cope holes at the trough to deck weld, ref. (COWI 1970).

On top of the 12 mm steel deck is a wearing surface with a total thickness of 60 mm. The original surfacing on the OSD was composed of the following layers:

- Adhesive primer
- 4 mm waterproofing
- 25 mm bearing course, Mastic Asphalt 0/8 mm
- 30 mm wearing course, Mastic Asphalt 0/12 mm with 8/12 mm embedded chippings.

The original surfacing had a very good durability and was first partly replaced in 1999/2000 were 5 mm of the bearing course and the entire wearing course was replaced with a 35 mm Stone Mastic Asphalt (SMA) layer. The SMA layer was then replaced again in 2013/2014. Full replacement of the pavement is planned to be executed in 2026 – 2027.

3 ANALYSES

Longitudinal cracks in the pavement close to the central node were observed in 2016, ref. (Ferreras et al. 2017). To evaluate the effect of a damaged pavement on the fatigue life of the OSD, two (2) different analytical methods were undertaken of a section of the OSD.

The first method consisted of a finite element analysis. An accumulated fatigue damage of D=0.7 after 100 years of usage was estimated with composite effect included for the trough deck weld near a bulkhead. The accumulated fatigue damage without composite effect was calculated to D=5.0 which simulate a fully cracked pavement.

The second method consisted of data analysis from a monitoring campaign that included nos. fifteen (15) strain gauges and pavement temperature sensors. This method had the advantage of being based on actual traffic loads and included the temperature influence on the composite effect. The fatigue damage was estimated to D=0.35 after 100 years of usage.

Assuming some composite effect from the pavement, no fatigue cracks should be expected in the bridge service life in areas that is not influenced by the impact from the expansion joints. However, if there is no composite effect due to deterioration of the pavement, fatigue cracks must be expected in the trough deck welds throughout the bridge during the service life.

4 OBSERVED CRACKS IN 2017

During a general visual routine inspection in the summer of 2017, indications of fatigue cracks in the orthotropic steel deck were first observed. The superstructure contains many kilometers of welds, and the visual inspections primary focus was on welds close to the expansion joints under the slow lane with spot checks further away from the expansion joints. These locations were selected based on the following criteria's:

- Structural details that will cause high stress concentrations.
- High local stresses and a high number of wheel passages from heavy vehicles.
- Additional impact factor from heavy vehicles passage of expansion joints.
- Experience from fatigue damage in similar structures.

The paint system with its orange base layer and black top coat provided a good background where crack indications stood out quite clearly, see Figure 3. There were however some concerns that small fatigue cracks could develop, hidden by the asbestos based top coat and thus not observed in a visual inspection. This concern was addressed by performing NDT inspections later in 2017.

All crack indications were in the through to deck plate welds in through nos. 14 and 17 which correspond to the typical wheel positions of heavy vehicles in the slow lane, see Figure 4.

All crack indications were also located close to the bulkheads after the expansion joints in the driving directions.

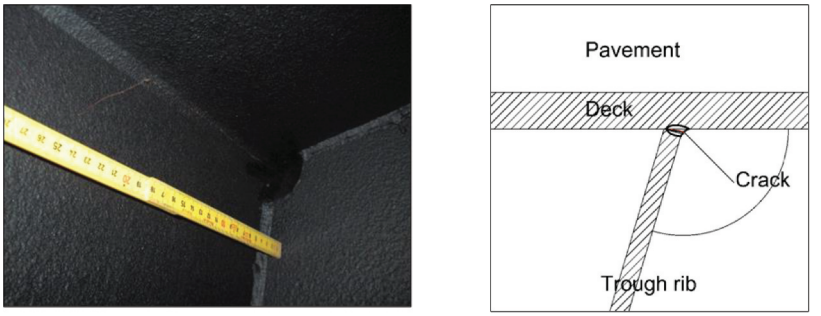

Figure 3. Fatigue crack indication in trough to deck weld.

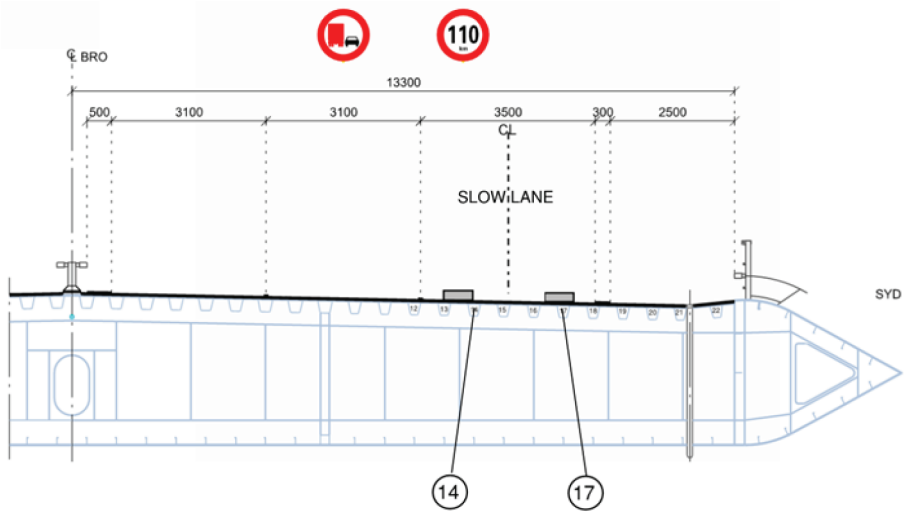

Figure 4. Cross section with typical wheel locations of heavy vehicles.

Following the general visual routine inspection, a program for the execution of a special inspection, with particular focus on the fatigue cracks, was prepared. Meetings with NDT experts from FORCE Technology were held and it was decided to use ultrasonic testing (UT) and eddy current testing (ET) in the special inspection.

A special inspection with assistance from FORCE Technology was performed later in 2017 with NDT methods. The crack indications were confirmed and areas without crack indications nearby were also tested with negative results. It was thus confirmed to a certain extent, that no hidden cracks, that could not be observed by visual inspection, were present.

A total of ten (10) cracks were found with a total length of approx. 2.5m. The cracks initiates at the weld root near the bulkhead cope hole and propagate through the weld bead to the face. They are often termed through bead cracks. They extend away from the bulkhead for approx. 150 – 200mm and then turn down into the parent metal in the trough rib, until they reach a position in the trough rib where the crack driving stress is sufficiently small. There were not any indications of cracks initiating at the root and extending up into the deck plate.

Seven (7) cracks were limited to the trough deck weld and would typically extend 50 - 100mm on each side of the transverse bulkhead. Three (3) had developed to a length of typically 150 – 200mm on each side of the transverse bulkhead and had then continued down in a skew angle into the parent metal in the trough rib as shown in Figure 3 left above. All the three (3) long cracks were in the same area after an expansion joint and on the left side of trough no. 14.

5 STUDY OF REPAIR METHODS

A study of repair methods was performed in the spring of 2018 based on COWIs experience from similar bridge structures with fatigue damage and published articles on the subject. A total of eleven (11) options was identified, that could be used either alone or in combination:

1. Do nothing.
2. Move traffic lanes approx. 0.6m.
3. Drill stress relieving holes at crack tip of cracks that have continued down into trough rib.
4. Strengthening of troughs by bolting a steel plate over one weld.
5. Strengthening of troughs by bolting a steel plate over two welds.
6. Strengthening of troughs by filling the troughs with a filling material, such as polyurethane.
7. Weld repairs from inside of the box girder.
8. Weld repairs both from inside and outside of the box girder.
9. Weld repairs from inside combined with bolted splice plates on the deck.
10. Bolted splice plates on the deck plate combined with bolted splice plates on the trough ribs.
11. Replace asphalt surfacing with high strength concrete overlay with steel fibers.

The options were compared and ranked, based on several parameters such as documented effect, impact on total bridge dead load, ease of execution, impact on traffic on bridge and economy.

Based on the limited number of cracks detected and COWIs successful experience with crack repair by welding, it was decided to go ahead with option 7) "Weld repairs from inside of the box girder". This method does not change the stiffnesses of the deck structure or introduce additional weight and can be performed without the need to close traffic above repairs, which was of very high importance to the bridge owner, the Danish Road Directorate.

The unit price of weld repair was initially estimated to 9,000 USD per nos. and it was expected, that the unit price could be reduced if the number of repairs was increased. A large part of the cost of option 7) is due to removal of the toxic paint system. Therefore option 4) was also seriously considered as the paint system does not need to be removed except very locally and this option is generally considered cost effective. However, it was not selected due to lack of documented long-term fatigue performance.

6 MOCKUP

As preparation for the weld repairs, it was decided to manufacture two (2) mockups of troughs, deck plate and surfacing, see Figure 5 - left, where a preproduction test, including weld preparation and welding, could be tested under near realistic conditions. Welds shall be performed without backing and particularly the weld repairs in the trough rib is considered difficult to execute. It was decided to use a multi run Tungsten Inert Gas (TIG) welding procedure specification because high quality welds by experience can be achieved with TIG welding, due to the excellent weld bead control.

The welds on the mockup was tested by both radiographic testing (RT), ultrasonic testing (UT), magnetic particle testing (MT) and macro examination. All with good results. Furthermore, surfacing temperature was measured to max. 250°C directly above the trough deck plate weld repairs. The adhesive primer is damaged at temperatures around 180°C and was therefore damaged over a width of approx. 3cm above and along the weld repairs. Thus local damage and possible local repair of the surfacing must be expected with this repair method.

A method statement for the weld repairs was prepared based on the experiences obtained from the preproduction test. The main tasks were:

- Preparation
  - Removal of paint.
  - Coordinate temporary traffic markings. It was necessary to close the emergency lane locally to bring personnel and equipment into the box girder.
  - Coordinate with NDT inspector.

- Removal of crack and weld preparation
  - Removal of crack and weld preparation with grinder and rotating file.
  - Check with VT/MT that crack tip is removed.
- Welding
  - Perform horizontal weld in position “horizontal overhead” (PD) from bulkhead and out on both sides.
  - Perform weld in trough rib in position “vertical down” (PG) on both sides. Both vertical up (PF) and vertical down (PG) had been tested on mockup with PG giving the best results.)
- NDT
  - Check weld with VT/RVT/MT/RT.

It was decided to drill two (2) Ø16mm holes in the trough rib on the opposite side of the weld repair, so remote visual testing (RVT) of the weld repair could be carried out with an endoscope, see Figure 5 - right.

Figure 5. Mockup – left. Two (2) Ø16 holes for RVT – right.

7 WELD REPAIR CAMPAIGN

Weld repairs were carried out late in 2018 based on the method statement and the WPS and with full traffic in the roadway lane above. All repairs were welded by the same expert TIG welder. The results were generally good and a typical weld repair is shown in Figure 6 - left.

A crack indication was found by RT in one (1) of the trough weld repairs, see Figure 6 – right, and this was then cut away and repaired again with satisfactory result. The remaining nine (9) weld repairs were satisfactory in the first repair.

The weld repairs were in total quite time consuming because the cracks were scattered over four (4) locations and thus personnel and equipment had to be moved four (4) times. With

Figure 6. Weld repair of trough deck plate weld left, crack indication in trough weld repair right.

taking down and setting up traffic markings, movement to a new location could take almost a full day. Also the NDT inspector was not present full time and one day hold time before NDT could be performed had to be respected. With all in place the welding in itself did not take long for the expert TIG welder.

The unit cost for a weld repair ended up to approx. 6,500 EUR per nos. with a rough split of 25% for removal of paint and 75% for NDT, weld repair and traffic markings.

Some of the lessons learned were:

- Great care should be exercised with the weld preparation and the root gap should not be too large.
- High quality pictures of the root side of weld repairs, could be obtained with a flashlight and the camera from a mobile when put in front of the two Ø16 holes. Much higher quality than by endoscope, see Figure 7.
- Only expert TIG welders should be used, and welder should preferably practice on a mockup before actual production welding.
- Allowing traffic above the weld repairs increased the weld duration slightly, but from an overall perspective, this had little impact on the total duration.
- Cracks shall preferably be repaired before they turn down into the parent metal of the trough side.

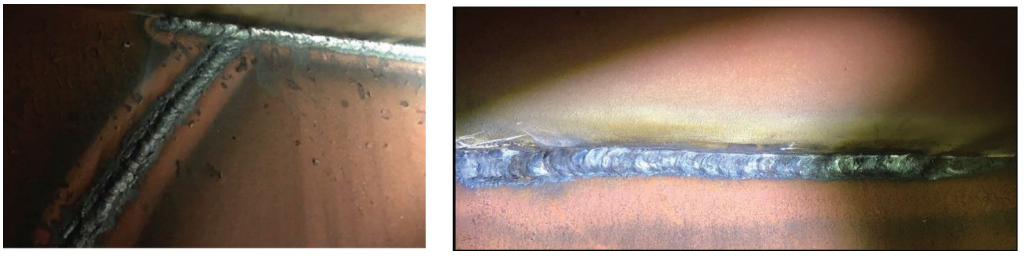

Figure 7. Root side of weld repair, first repair left and last repair right.

8 FOLLOW UP ON WELD REPAIRS AFTER 2018

Since 2018 visual inspections has been carried out every year and afterwards all observed fatigue cracks have been repaired. The repair works has been tendered out and agreements made with a contractor for a 3-year repair period.

It has in the tendering process been found beneficial to specify five (5) types of repairs, characterized by the length and the location of the fatigue crack. The unit cost in 2023 for a weld repair is in average approx. 3,000 EUR per nos. with a rough split of 20% for removal of paint and 80% for NDT, weld repair and traffic markings. Compared to 2018 prices a reduction of 54%. The costliest fatigue crack repair is 3,800 EUR.

70% of the fatigue cracks are observed at an early stage (Type 1), where the fatigue crack is limited to the deck to trough weld. The next 27% fatigue crack observations (Type 2) are observed when the fatigue crack is extended from the deck to trough weld, down (10 – 100 mm) in the trough side.

A visual inspection supplemented with NDT methods was performed approx. one (1) year after the weld repairs. No crack indications were found in any of the weld repairs.

However, three (3) new trough deck plate bead through cracks were observed and confirmed by MT. These newly discovered cracks were located before the expansion joints in trough nos. 14 and 17. The areas before the expansion joints have not been in similar focus, as the areas after the expansion joints, in earlier visual inspections and it is therefore not known how long they have been there.

The continuous discovery of new cracks highlight the necessity for conducting visual inspection on a regular basis in areas under the slow lanes. The dynamic effect on the front axles of

a lorry passing the expansion joint will also have a dynamic impact back on the rear axles that have not yet reached the expansion joint that need to be considered.

The remaining fatigue life of the trough deck weld under the fast lanes is likely several decades and need only be spot checked every five years.

9 CONCLUSION

The steel box girder of New Little Belt Bridge contains close to 100km of trough to deck plate welds and it was fabricated during a time where the knowledge of fatigue assessment of steel bridge deck details was much less developed than today. Also, modern welds are generally of higher quality than the welds on the New Little Belt bridge. The deck plate and trough thickness are smaller than current Eurocode recommendation and ultimately, and from that point of view, it is only a matter of time before fatigue cracks will start to appear. However, it depends very much on the original weld execution quality, pavement condition and traffic loads if cracks will start to develop on a large scale within the bridge service life. General fatigue issues thus could represent an enormous potential cost for the bridge owner.

At present, after fifty-three (53) years of operation, at total of one hundred and fifty-seven (157) fatigue cracks have been detected in the trough to deck weld close to the bulkheads, see heatmap in Figure 8. Most cracks have been located close to the expansion joints and beneath trough nos. 14 and 17 which correspond to typical wheel positions of heavy vehicles in the slow lane, see Figure 4.

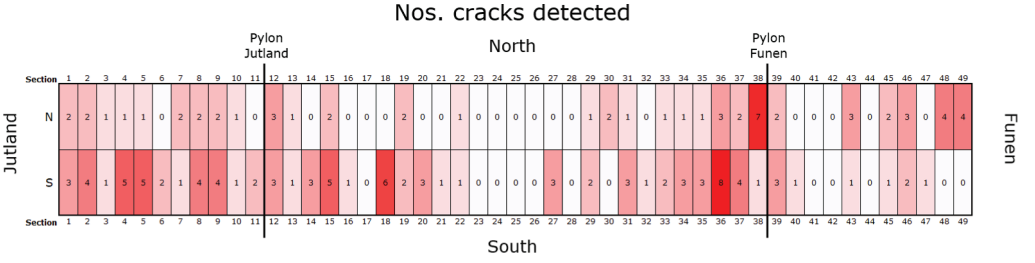

Figure 8. Heatmap of cracks per December 2023.

All the discovered fatigue cracks from the period 2018 – 2023 have successfully been repaired by welding based on a method statement that was prepared after preproduction tests on a mockup.

The expansion joints cause an additional impact that roughly can be estimated to a 30% increase of wheel loads for pavements of good quality. As the fatigue life is a function of stresses to the power of five (5), it is very vital that the pavement and expansion joints are continuously kept in good condition.

Because heavy vehicles are restricted to driving in the slow lanes and lighter vehicles does not cause fatigue damage, it is anticipated that the remaining fatigue life of the trough deck weld under the fast lanes is likely several decades.

The organization, O&M operations and inspections of the 1915Çanakkale Bridge

F. Aytekin
Çanakkale Motorway and Bridge Construction Investment and Operation Inc., Turkey

A.M. Kızılkaya
Intertoll Turkey Operation and Maintenance Inc., Turkey

ABSTRACT: The 1915Çanakkale Bridge provides the crossing of the Dardanelles between Gelibolu-Lapseki as part of the 101-kilometer long Malkara-Çanakkale Motorway. The 1915Çanakkele Bridge is the longest suspension bridge in the world with a main span of 2023 meters, symbolizing the 100th anniversary of the Republic of Turkey, and featuring the world's tallest towers at a peak height of 334 meters with the addition of Seyit Onbaşı artillery shell figures to the 318-meter steel tower height. The1915Çanakkale Bridge is a world record bridge that was built in a record time of just four years providing an alternative route to the busy city of İstanbul. The long main span combined with extreme wind loads and possible earthquakes, put engineering capabilities to the test. The O&M sub-contractor organization, inspections, and monitoring systems offer an intriguing case study. Operational since March 18,2022 the 1915Çanakkale Bridge and Malkara-Çanakkale Motorway Project critical for enhancing regional connectivity.

1 INTRODUCTION

The Malkara-Çanakkale Motorway and 1915Çanakkale Bridge Project represent a monumental engineering accomplishment that has significantly enhanced Turkey's transportation infrastructure. This visionary project was conceived as an essential component of the 101-kilometer Malkara-Çanakkale Motorway, which has now been brought to fruition with the construction of the 1915Çanakkale Bridge. The bridge spans Çanakkale Strait (Dardanelles) between Gelibolu and Lapseki connecting Europe and Asia. Not only it is a testament to exceptional engineering prowess, but it also holds deep symbolic significance as it commemorates the 100th anniversary of the Republic of Turkey.

Figure 1. 1915Çanakkale Bridge.

DOI: 10.1201/9781003483755-353

1.1 *Strategic importance*

The countries within the region have constructed railways and integrated motorways across Anatolia, Caucasia, and Asia to support the development of the Silk Road. This historical trade route originates in the Far East and extends all the way to Europe, along the "Middle Corridor" To facilitate this, they have taken important steps to develop a multi-directional transportation network on the Asia-Europe-Middle East axis and implemented projects to develop transportation.

As a result, mega projects are being built in an integrated manner. The 1915Çanakkale Bridge is of great importance in this regard. It not only connects mega-projects such as Yavuz Sultan Selim Bridge, Northern Marmara Motorway, Osmangazi Bridge, North Aegen Port, and Gebze-Orhangazi-İzmir Motorway but also increases the benefits and importance of this corridor.

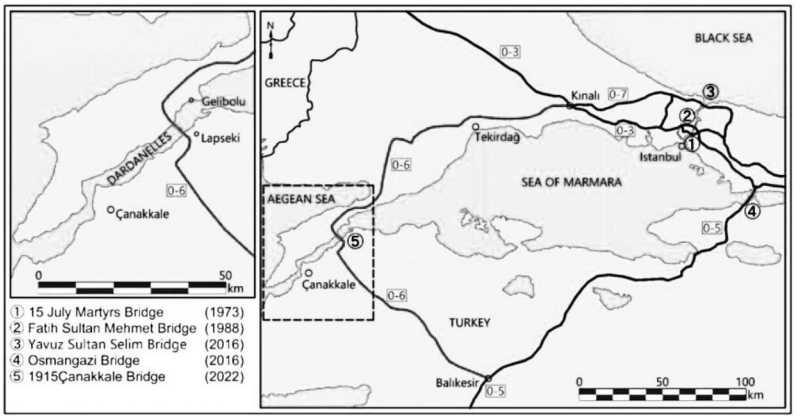

Figure 2. Transportation network between mega-projects (Til 2023).

1.2 *Design basics*

The Bridge faces several challenges including aerodynamics, ship traffic, seismic activity and adverse soil conditions. To address the windy conditions, a wind-resistant twin-box steel girder design is being implemented. The tower foundations are designed to withstand intense ship traffic and seismic hazards. The construction timeline requires fast-track construction methods, influencing the overall design approach.

Figure 3. Twin-box steel girder deck.

The deck arrangement was finalized following wind tunnel testing aimed at enhancing traffic comfort through the implementation of wind barriers. Prefabricated parallel wire strands

were used for main cables and high-grade steel was used for the tower to reduce the quantities and consequently construction time and seismic mass.

1.3 *Organization, information*

The General Directorate of Highways commissioned the 1915Çanakkale Bridge and Motorway Project to a Turkish-Korean joint-venture in 2017 within the framework of the public-private partnership model. Limak and Yapı Merkezi from Turkey and Daelim and SK E&C from Korea make up this joint-venture named DLSY JV which established a joint-venture company specific to the project, under the name of Çanakkale Motorway Bridge Construction Investment Management Inc.

Project Length: 101 Km. (88 km Motorway + 13 km Link Road)

Duration: 16 Years 2 Month 12 Day (Construction + Operate) (5 Years 6 Month Construction+10 Years 8 Month 12 Operation Day)

Appointed Company: Çanakkale Otoyol Yatırım ve İşletme A.Ş. Contractor: Daelim – Limak – SK – Yapı Merkezi

Operator Company: Intertoll Turkey Operation and Maintenance Inc

2 ORGANIZATION AND PARTNERSHIP MODEL

2.1 *Organization structure*

The Kınalı-Tekirdağ-Çanakkale-Savaştepe Motorway Project Malkara-Çanakkale section, including the 1915Çanakkale Bridge, has been commissioned by the General Directorate of Highways to a Turkish-Korean joint-venture under the name of Çanakkale Motorway Bridge Construction Investment Management Inc. The joint-venture has been awarded a Build-Operate-Transfer contract for the project.

Intertoll Turkey Operation and Maintenance Inc. is the O&M sub-contractor related to the operation and maintenance project Malkara-Çanakkale section, including the 1915Çanakkale Bridge is part of Intertoll Europe, an independent infrastructure developer, operator & maintenance provider, and toll operator with its head office in Budapest, Hungary.

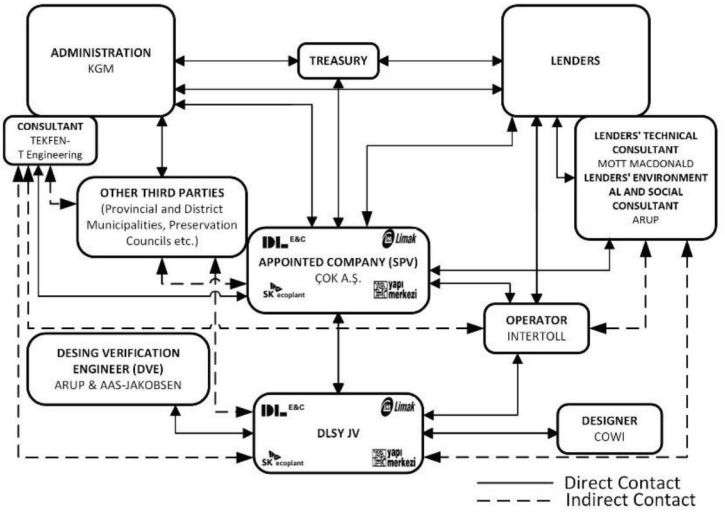

Figure 4. Organization scheme.

2.1.1 *Public-private partnership model*

Public-private partnership (PPP) generally refers to the implementation of investments and services through a contractual agreement, involving the sharing of costs, risks, and returns between the public and private sectors. Originally conceived as a means to secure financing for national infrastructure projects, PPP has evolved into a model emphasizing the effective managerial capabilities of

the private sector. In this framework, the public sector is strategically positioned to focus on areas such as investment coordination, overarching planning, supervision, and policy formulation (T.C. Kalkınma Bakanlığı 2012).

3 INSPECTIONS AND MAINTENANCE

3.1 *Inspection and maintenance protocols*

Inspection and maintenance activities are arranged according to the relevant specification of the General Directorate of Highways, I&M manual by the bridge designer and suppliers O&M manuals. Inspection and maintenance activities are classified into five types "routine inspections/maintenance", "principal inspections", "special inspections" "major maintenance", and "surveying". These types of help organize the activities involved in keeping equipment and infrastructure safe and working well.

Routine I&M tasks are typically carried out with a frequency of weeks, months or annually. The nature of the work is visual inspection and ad-hoc maintenance by walking or driving on the bridge. Routine I&M performed by the permanent I&M personnel.

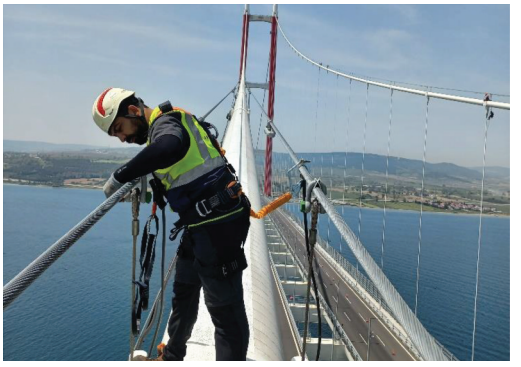

Figure 5. Main cable routine inspection.

Table 1. Suspension Bridge and Approach Viaducts routine inspection plan.

Routine inspection of substructure	Routine inspection frequency
Tower foundation elements above the sea level	Annually
Tower (Outside)	Annually
Tower (Inside)	Annually
Anchor Blocks (Outside)	Annually
Anchor Blocks (Inside)	Annually
Concrete Piers	Annually
Routine inspection of superstructure	Routine inspection frequency
Steel Deck Exterior	Annually
Steel Deck (Inside)	Annually
Main Cable System	Annually
Hanger Rope System	Annually
Bearings	Semi-Annually
Expansion Joints	Monthly/ 3 Monthly/Semi-Annually
Surfacing, Pavement, Maintenance Walkway	2 times a month
Concrete Deck Exterior	Annually
Concrete Deck (Inside)	Annually
Routine inspection of substructure	Routine inspection frequency
Barriers, Parapets, Wind Barriers and Ancillaries	2 times a month
Access Facilities	The relevant access structure during the inspection
Hydraulic Buffers and End Stops (Structural Parts)	Annually
Drainage System	Semi-Annually

Figure 6. Concrete surface visual inspection by using drone.

Principal inspections comprise a closer visual inspection with the objective of assessing the current condition of the structure, reviewing the development of defects, and assessing and planning the need for maintenance. Principal inspections are carried out at fixed intervals, which are typically defined as intervals of 5 or 10 years in the designer manual.

Figure 7. Principal inspection of bearings.

Special inspections normally involve the use of specialist personnel and equipment to conduct and evaluate measurements and testing. They are typically initiated based on the conclusions of principal inspections or routine I&M, where the results indicate the need for special inspections to clarify the condition of the structure and the need for repair. After extreme events with potentially large structural consequences for example fire, earthquake, ship impact high winds and vehicular collisions.

3.2 *Maintenance strategies*

In addition to adhering to the recommendations outlined by the supplier's O&M manuals a maintenance plan has been developed with the primary objective of preserving and maximizing the structural integrity and service life of the suspension bridge. The maintenance program comprises both routine and ad-hoc interventions for addressing any identified damages during inspections to ensure the bridge's stability throughout its lifespan.

Table 2. Suspension Bridge and Approach Viaducts routine maintenance plan.

Routine maintenance of the bridge elements	Maintenance Frequency
Litter collection (Anchorage Blocks (Outside), Revetment, Abutments)	Semi-Annually
Litter collection (Anchorage Blocks (Inside), Piers (Inside))	Annually
Litter collection (Suspension Bridge Decks (Inside))	Annually
Litter collection (Approach Viaducts Decks (Inside))	Annually
Litter collection maintenance walkway	Annually
Cleaning of expansion joints	2 times a month
Cleaning of bearings	Annually
Cleaning of drainage system	Semi-Annually
Cleaning of road elements	Maintenance Frequency
Cleaning of traffic signs	When needed
Cleaning of guardrail and wind barriers	When needed

Figure 8. Cleaning of expansion joints.

3.2.1 *Winter maintenance*

During the winter, meteorological data are monitored which have been taken from the General Directorate of Meteorology and outsourced services for winter maintenance, and preventive maintenance work is initiated for the suspension bridge when the asphalt temperature taken by patrol on site drops below 2°C. Urea solution is used to prevent the negative effect of NaCl on the steel surface of the suspension bridge. If snowfall is normal and urea solution can melt the snow, snow ploughing is not performed. Under extreme conditions, if the solution used is not sufficient to melt the snow on the bridge, snow ploughing is also carried out in all 3 lanes. In cases where the width of the shoulder is not sufficient to accumulate snow due to heavy snow conditions, winter maintenance is carried out with snow ploughing in 2 lanes only, as there is no shoulder on the bridge section. It is planned to use magnesium chloride and corrosion inhibitor solution at temperatures too low for urea solution to function.

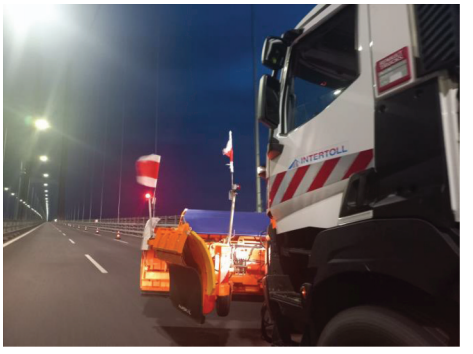

Figure 9. Preventive winter maintenance.

4 CONCLUSION

In conclusion, the paper provides a comprehensive overview of the organization, operations, and inspections of the 1915Çanakkale Bridge, a monumental engineering achievement that significantly enhances Turkey's transportation infrastructure. The 1915Çanakkale Bridge emerges as an unparalleled engineering marvel, proudly claiming the title of the world's longest suspension bridge with its extraordinary 2023-meter main span. Positioned as a pivotal component within the extensive 101-kilometer Malkara-Çanakale Motorway, this iconic structure transcends its physical dimensions, embodying Turkey's rich history and commemorating a century of the Republic.

The strategic significance of the 1915Çanakkale Bridge is evident in its role connecting major projects such as the Yavuz Sultan Selim Bridge, Northern Marmara Motorway, Osmangazi Bridge, North Aegean Port, and Gebe-İzmir Motorway, contributing to the development of modern Silk Road. The organization and partnership model, implemented as a public-private partnership, reflects effective collaboration between Turkish and Korean entities.

The section on inspections and maintenance outlines a comprehensive approach to ensuring the longevity and safety of the 1915Çanakkale Bridge. The protocols for inspections and maintenance strategies showcase a meticulous and proactive maintenance plan.

In summary, the 1915Çanakkale Bridge stands not only world record in terms of its impressive dimensions but also as a testament to the successful project management, innovative engineering, and effective public-private collaboration. The operational and maintenance practices detailed in this paper reflect a commitment to ongoing safety, functionality, and regional connectivity facilitated by this extraordinary infrastructure project.

Traffic wind hazards on the Storebælt East Bridge and mitigation

A. Larsen, L.F. Pedersen & N. Bitsch
COWI consulting engineers, Kgs. Lyngby, Denmark

F.R. Gottfredsen
Sund & Bælt, København V, Denmark

ABSTRACT: The present paper gives an account of theoretical and experimental work carried out for identifying and improving the wind traffic climate for vehicles crossing the Storebælt bridge. The theoretical work involved development of the balance model for wind overturning and a survey of stability parameters for various classes of road vehicles. The experimental work involved wind tunnel tests for determination of aerodynamic coefficients to be applied in the theoretical balance model yielding revised wind restrictions for vehicles travelling the bridge.

1 INTRODUCTION

The wind climate experienced by the traffic crossing cable supported bridges is influenced by structural components such as pylons, anchor blocks, crash barriers and other equipment rising above the roadway. These elements create local zones of increased wind speed or shelter relative to the approach wind speed well upwind of the bridge. Abrupt changes in the wind speed requires responsive counter steering by the driver to maintain the driving path. Also, excessive momentary wind loads may cause overturning of light high sided vehicles. A statistical survey of wind related vehicle accidents encountered on the Storebælt East Bridge revealed that 33 out of 56 accidents recorded in the period 1998 - 2019 happened in the vicinity of the pylons and the anchor blocks involving overturning of light and high sided box trailers town by private cars, commercial vans or lorries, Figure 1.

The fact that most of the wind related accidents involved overturning of light high sided vehicles initiated a theoretical and experimental investigation into the wind hazards and wind screens and traffic restrictions for mitigation.

2 SIMPLE THEORETICAL BALANCE MODEL FOR WIND OVERTURNING

A vehicle travelling at a constant speed V in a wind field having a local speed U and a direction β with the travel path will be met by a relative wind speed V_r at inflow angle α, Baker (1991), Figure 2, left:

$$V_r = \sqrt{(V + U cos\beta)^2 + (U sin\beta)^2}$$
$$sin\alpha = \frac{U sin\beta}{\sqrt{(V + U cos\beta)^2 + (U sin\beta)^2}} \quad (1)$$

The forces acting on the vehicle is the restoring moment of gravity $M_g = ½Bmg$ about the lee wheel contact point and an overturning moment due to the wind $M_w = 1/2\rho V_r^2 LHz_a C_M$ where C_M is the aerodynamic overturning moment coefficient. C_M is a function of the inflow

DOI: 10.1201/9781003483755-354

Figure 1. Wind overturning accident near the pylon involving a small empty box trailer towed by a car.

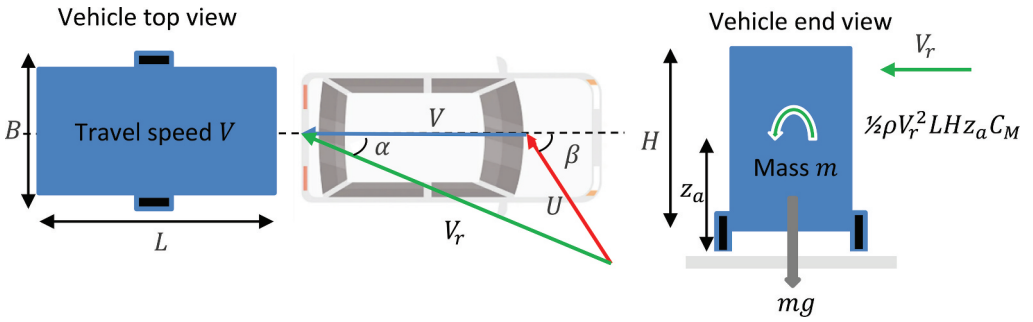

Figure 2. Characteristic dimensions, wind speeds and forces acting on a travelling vehicle.

angle α and is often well approximated by sinus function $C_M(\alpha) = C_{M90} sin\alpha$ for box shaped high sided vehicles (Baker, 1991) with C_{M90} being the nominal value for cross winds. C_{M90} is to be determined from wind tunnel tests for the vehicle types in question.

The relative wind speed at which the vehicle is expected to overturn is obtained by equating the overturning moment of the side wind force and the restoring moment due to gravity:

$$1/2Bmg = z_a 1/2\rho {V_r}^2 LHC_M \Rightarrow {V_r}^2 = \frac{S}{C_{M90}\, sin\,\alpha} \tag{2}$$

where $S = Bmg/\rho LHz_a$ is the stability parameter combining the width of the wheelbase B, the length and the height of the vehicle L, H, the height of the aerodynamic center z_a above the roadway mass, the mass m, the air density ρ and the gravity acceleration g as illustrated in Figure 2.

Inserting (1) into (2) allows the overturning condition to be expressed as function of the vehicle speed V, the wind speed U and wind direction β:

$$U^4\left(1 + \left(\frac{V}{U}\right)^2 + 2\left(\frac{V}{U}\right)cos\beta\right) = \frac{S^2}{C_{M90}^2}\frac{1}{sin\beta^2} \tag{3}$$

which must be solved numerically for the general case. In the case of cross winds, $\beta = 90$ deg. (3) reduces to the analytical expression:

$$V_{OT} = \frac{1}{U}\sqrt{\frac{S^2}{C_{M90}^2} - U^4} \tag{4}$$

where V_{OT} (m/s) is the travel speed at which the vehicle is expected to overturn when subjected to a local wind speed U (m/s). Numerical solutions to (3) reveals that it displays a shallow minimum for $\beta \approx 70$ deg. as is also reported in Baker (1991). Using (4) instead of (3) overestimates the travel speed by approximately 4% at $\beta \approx 70$ deg. A fair approximation for practical applications.

Application of (4) for investigation of the traffic crossing the Storebælt East Bridge requires that the stability parameter S and the overturning moment coefficient C_{M90} are determined.

3 STABILITY PARAMETER

The stability parameter S combines the vehicle size and inertia properties of the overturning as discussed above. The stability parameter for different types of vehicles crossing the Storebælt bridge was determined from vehicle manufacturers and providers databases.

The many and diverse vehicles crossing the bridge were divided into commercial and private categories.

The commercial vehicle category included high sided truck trailers empty or full, vans, mini-buses, city busses and tourist buses.

The private vehicle category included small and large high sided box trailers, caravans, auto campers, large, midsize, and small passenger cars and sports utility vehicles (SUV).

The survey revealed a certain variation in the numerical value of S depending on model and make. Based on the variability of the stability parameter within each vehicle group it was decided to define a characteristic value S_c as the mean S_m minus one standard deviation S_σ to be applied for stability calculations. The characteristic stability parameter for commercial vehicles such as vans, mini busses and city/tourist busses falls in the range $1500 < S_c < 2500$ whereas the characteristic stability parameter for private vehicles like passenger cars and SUVs falls in the range $2500 < S_c < 5600$.

The lowest and thus most critical stability parameters are found for large and small commercial or private box type trailers, Table 1. The small and popular box trailer which can be rented at most service stations, home improvement retailers and large furniture stores in Denmark displays the lowest characteristic value $S_c = 480$ making it the most vulnerable vehicle with respect to wind induced overturning.

Table 1. Stability parameters for typical high sided commercial and private vehicles.

Vehicle type	Truck trailer – empty	Large box trailer - empty	Caravan	Small box trailer - empty
				
Stability parameter				
Mean S_m	1490	1000	1100	700
Standard deviation S_σ	140	300	100	220
Characteristic $S_c = S_m - S_\sigma$	1350	700	1000	480

4 OVERTURNING MOMENT COEFFICIENT

The overturning moment coefficient for wind constitutes the aerodynamic parameter necessary of evaluation of vehicle overturning travel speeds to be determined from wind tunnel testing. It is noted that C_{M90} appearing in (4) refers to the local wind speed U meeting the vehicle at a given section of the travel path. The local wind speed experienced on a bridge is dependent on the shelter

or speed up effects caused by bridge components located upwind of the vehicle. To obtain the best possible estimates of the overturning moment coefficients from the wind it was decided to measure the overturning moments M_w acting directly on a generic box trailer model located at different locations on models of representative parts of the Storebælt East Bridge and to refer the overturning moment coefficient, now termed C_M, to the speed U_0 of the undisturbed wind approaching the bridge model: $C_M = M_w/1/2\rho U_0^2 LHz_a$. The consequence of this choice is that C_M now becomes a function of the shape of the vehicle as well as its position on the bridge.

4.1 *Wind tunnel tests*

The wind tunnel tests were carried out at FORCE Technology, Kgs. Lyngby, Denmark. The models of the Storebælt East Bridge included λ_l = 1:30 scale deck/pylon and deck/ anchor block assemblies and was tested with and without local wind screens arranged as vertical picket fences having an open area ratio of 50%, Figure 3. All tests were run in turbulent flow of 10% intensity characteristic for the Great Belt site. The approach wind speed U_0 was measured by a pitot tube situated at deck level and well upwind of the bridge models.

The vehicle model was chosen to represent a generic box trailer having full scale dimensions L = 2.3 m, H = 2.8 m, B = 1.3 m and z_a = 1.6 m. The vehicle model was mounted on a heigh frequency force balance having a first resonance frequency of 25 Hz. The vehicle/force balance assembly was inserted in pits in the slow lane of the bridge deck model at preset distances from the pylon or anchor block such that the top of the model mount was flush with the roadway leaving a 0.2 m gap to the trailer bottom plate, Figure 3, bottom.

All measurements reported were made for cross winds (β= 90 deg.) at a model scale approach wind speed of U_{0ms}= 8 m/s taking 60 sec. time histories of the overturning moment M_w.

Data processing involved low pass filtering of the recorded timeseries at 17 Hz to avoid contamination of the measured signals by the force balance resonance. Assuming a full scale wind speed of U_{0fs} = 25 m/s the time scale of the tests is obtained as $\lambda_t = \lambda_l U_{0fs}/U_{0ms} \approx$ 1:10 indicating that the 60 sec. sampling period is a good representation of standard meteorological averaging period of 10 min. and capable of resolving gusts down to approximately 1 sec. full scale.

Bottom: Model box trailer located in the slow (windward) lane. High frequency balance/model assembly.

4.2 *Wind action at the pylons without wind screens*

Figure 4. top right, displays an excerpt of the C_M time series measured at a position 7 m from the center line of the 9 m wide pylon, i.e., at a position approximately one vehicle length before entering the shelter zone. The times series is converted to full scale time by applying the

time scale λ_t. It is noted that the mean value of the overturning moment coefficient is approximately 1 (horizontal line) whereas the peak reaches 2.7 and the minimum 0.17 within the 10 sec. time window displayed. Video recordings of overturning box trailers indicates that the overturning is a fast process of 1 – 3 sec. duration thus governed by the peak value of C_M.

The Fourier transformation of the time series (below, right) displays a wide band signal slightly decreasing with increasing frequency and a prominent narrow band peak at the non-dimensional frequency $fD/U_0 = St = 0.12$ where $D = 9$ m is the cross-section dimension of the pylon leg. The broad band signal is interpreted to be due to random turbulence. The narrow band peak at $St = 0.12$ is identified as the Strouhal Number for von Kármán vortex shedding from a square section prismatic structure as proposed in EN1991-1-4. The large variation of C_M due to the vortex shedding action in the vicinity of the pylon is believed to be a significant ingredient in the frequent overturning accidents close to the pylons. Following (4) a factor 3 increase of C_M yields a 70% reduction of the approach wind speed at which a vehicle overturns.

The spectral composition of C_M suggests that the peak value can be obtained as the sum of the mean value C_{Mm}, the standard deviation of the contribution from the vortex shedding $C_{M\sigma vtx}$ and the standard deviation of wide band turbulence $C_{M\sigma wb}$:

$$C_{Mp} = C_{Mm} + \sqrt{2}C_{M\sigma vtx} + 3.5C_{M\sigma wb} \tag{5}$$

Application of (5) to the spectrum in Figure 4 yields $C_{Mp} = 2.34$ while the absolute maximum value of the time series is $C_{Mmax} = 2.4$ thus supporting the spectral summation.

It is interesting to note that the relatively high speed of the vehicle compared to the relative slow time variation of C_M (a period of about 3 seconds) means that some vehicles may experience a quiet situation when passing into or out of the near wake of the pylon whereas other vehicles may enter or exit the pylon wake when the overturning moment is at its peak. A vehicle travelling at 80 km/h will travel 22 m in one second. From the time trace of C_M it is observed that a vehicle entering the pylon wake at time about 412.5 will experience a moment overturning coefficient $C_M < 0.5$. Contrary, a vehicle entering the wake at time 414.5 will experience an overturning coefficient $C_M > 2.0$.

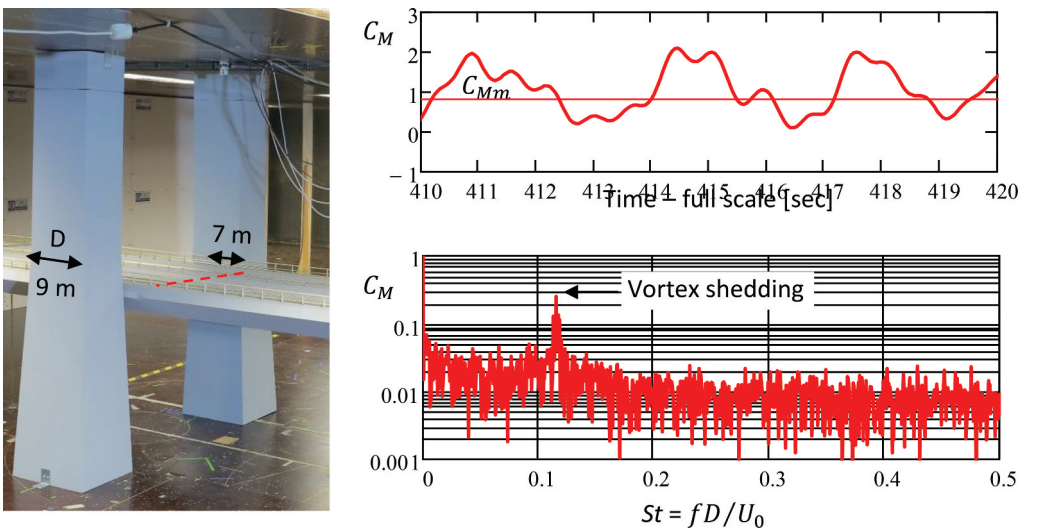

Figure 4. Full scale time trace and frequency spectrum obtained at a position 7 m from the center line of the pylon. As built situation without local wind screens.

4.3 *Overturning moment coefficients at the pylons and effect and extent of the wind screens*

The discovery of the effect of wind band turbulence and narrow band vortex shedding close to the pylon suggested that shielding of the vehicles by wind screens may reduce the mean wind

loading and break up the coherent vortex patterns in wind flow. To this end the model wind screens were fitted to the pylon/deck and anchor block/deck models, Figure 3.

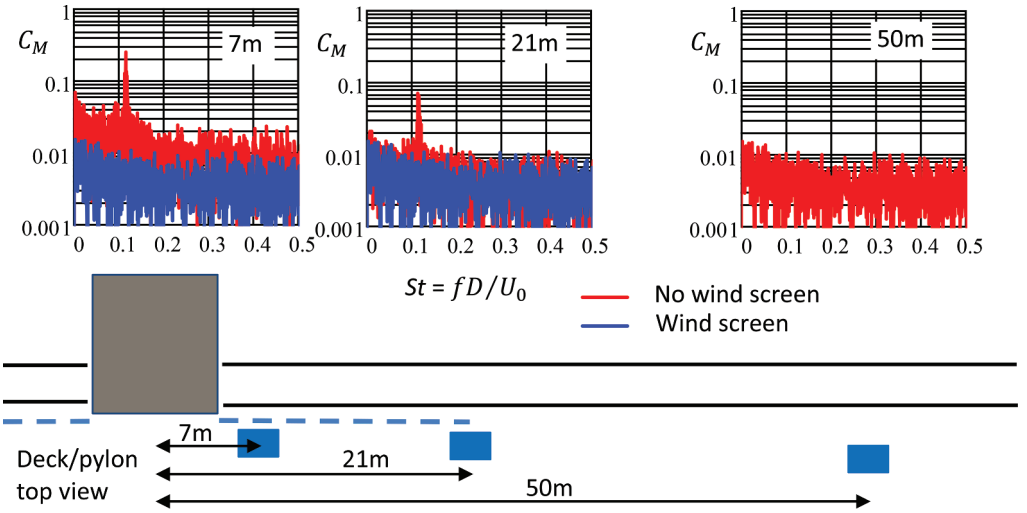

Figure 5. Moment coefficient spectra at positions 7m, 21m and 50m from the pylon center line.

Figure 5 shows spectra of overturning moment coefficient measured at 3 positions of the model vehicle 7 m, 21 m and 50 m from the center line of the pylon. The spectral distribution for the as built situation without wind screens shows that the magnitude of the vortex peak as well as the wide band contribution decreases when moving away from the pylon. At the position 50 m from the pylon the vortex peak has completely disappeared. At a position 21 m the vortex peak has decreased by a factor of 5 relative to the 7 m position and the wide band contribution is roughly at the same level as at the position 50 m from the pylon center line. This finding suggested that a wind screen extending approximately 21 m each side of the pylons would control the vortex shedding loading on passing vehicles.

Overturning moment coefficients measured at 7 m and 21 m before and after fitting of 3.5 m tall, 20 m long wind screens having an open area ratio of 50% show that the wind screens are very efficient in decreasing the peak C_{Mp}, the mean C_{Mm} and the dynamic components $C_{Mdyn} = \sqrt{2}C_{M\sigma vtx} + 3.5C_{M\sigma wb}$ of the overturning moment coefficient, Figure 6.

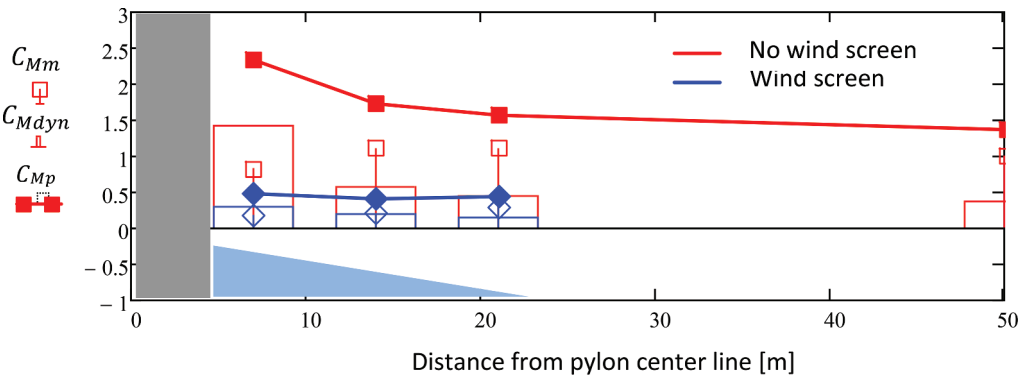

Figure 6. Mean (⊔), dynamic (⊓) and peak (▬) overturning moment coefficients as function of distance from the pylon center line following (5).

4.4 *Overturning moment coefficients at the anchor blocks*

The two anchor block structures of the Storebælt East Bridge, Figure 3, form triangular structures rising approximately 6 m above the roadway at each side of the bridge girder forming the transition from the 4.4 m deep suspension bridge girder to the 7.5 m deep girders of the approach bridges. The similarity between the shelter zones at the pylons and the anchor blocks suggests that it is desirable to fit identical wind screens from the anchor block extending into the suspension bridge side spans. The operation and maintenance of moveable traffic barriers situated at the point of transition from the anchor blocks to the approach bridges would be rendered difficult by the presence of the wind screens. Thus, it was desirable to omit the wind screens at this location.

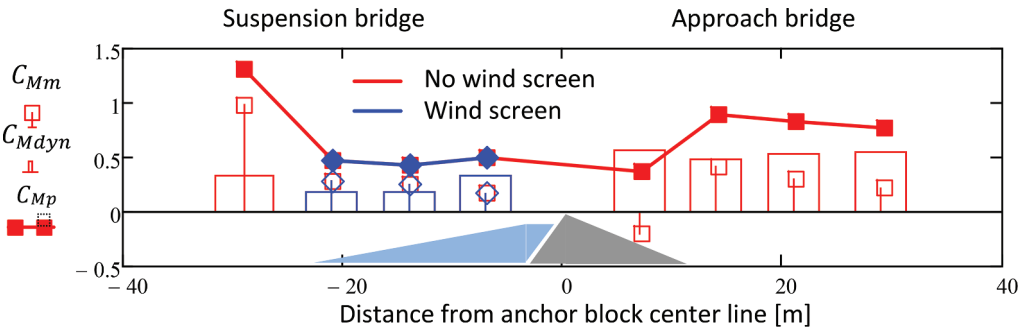

Figure 7. Mean ( ), dynamic ( ) and peak ( ) overturning moment coefficients as function of distance from the pylon center line following (5).

From Figure 7 it is noted that the wind screens at the suspension bridge side of the anchor block reduces the overturning moment coefficients as efficiently as is the case in proximity of the pylons. At -29 m onto the suspension bridge side span and past the wind screens, C_{Mp} = 1.31 which for practical purposes is identical to C_{Mp} = 1.37 measured at the 50 m position in the deck/pylon model, Figure 6. At 29 m onto the approach bridge it is noted that C_{Mp} = 0.77, about 60% of the peak overturning moment coefficient measured at the identical position on the suspension bridge. It is speculated that this effect is due to the larger section depth of the approach bridge which diverts parts of the of the wind flow otherwise impinging on the trailer model.

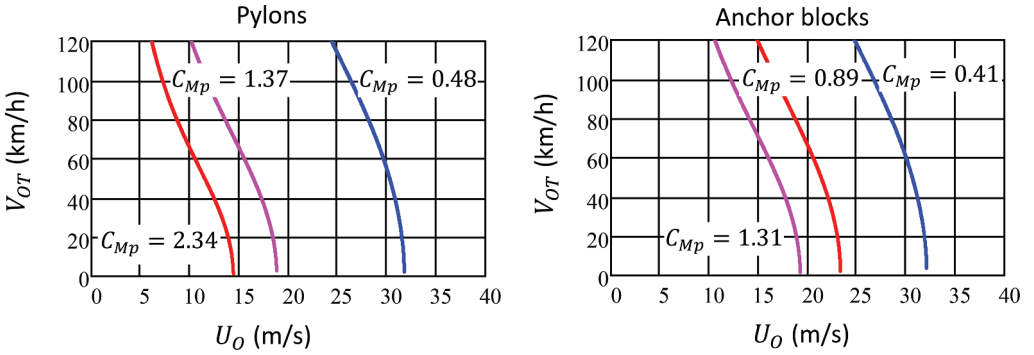
5 OVERTURNING WIND SPEEDS

The theoretical travel speed speeds V_{OT} (km/h) as function of the approach flow wind speed U_0 (m/s) are calculated from (4) using the characteristic stability parameter S_C = 480 (Table 1) and peak moment coefficients C_{Mp} obtained from the wind tunnel tests, Figure 8.

Small box trailers are allowed to travel at a maximum speed of 80 km/h on highways and thus also on the Storebælt bridge. Thus, it is a appropriate travel speed for evaluating the corresponding approach wind speeds at which the vehicle is expected to overturn.

From Figure 8 (left) it is noted that the small box trailer is at risk for overturning at an approach wind speed of 9 m/s at a position 7 m from the center line of the pylon if wind screens are not fitted, C_{Mp} = 2.34 (red curve). In presence of the wind screes the estimated overturning wind speed becomes 28 m/s at this position proving the efficiency of the wind screens (blue curve). At some distance from the pylon center line (50 m, C_{Mp} = 1.37) the approach wind speed for overturning becomes 14 m/s at a travel speed of 80 km/h (magenta curve) which must be considered as a theoretical limiting wind speed for the small box trailer travelling on the bridge.

On approaching the anchor blocks from the approach bridges, Figure 8 (right) the minimum approach wind speed for overturning is 18 m/s, C_{Mp} = 0.89 (magenta curve). When passing the shelter of the anchor blocks and the wind screens the approach wind speed for overturning



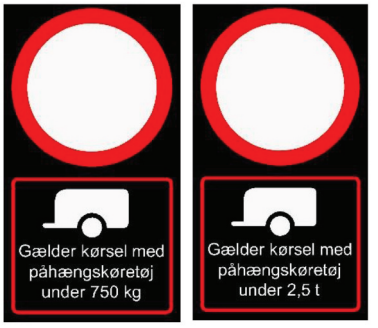


Figure 8. Calculated travel speeds for overturning V_{OT} as function of the approach wind speed U_0 on the suspension bridge (left) and approach bridges (right).

increases to 28 m/s, C_{Mp} = 0.41 (blue curve). On exit of the wind screens on the suspension bridge the approach wind speed for overturning becomes 14 m/s, C_{Mp} = 1.31 (magenta curve) at the travel speed of 80 km/h. This evaluation demonstrates that the approach bridges provide better sheltering of the traffic than the suspension bridge does. Also, the evaluation supports the decision not to install wind screens at the approach side of the anchor blocks.

6 TRAFFIC RESTRICTIONS AND SIGNS

Calculation of vehicle travelling speeds for overturning were carried out for various classes of vehicles leading to implementation of a set of revised wind related restriction for crossing the Storebælt bridge. The new restrictions are summarized in Table 2 along with the new sign boards developed for enforcing the restrictions in high wind situations. The approach wind speed referred to in Table 2 is the wind speed component normal to the bridge alignment.

Table 2. New traffic restrictions based on wind tunnel tests.

Approach wind speed	Restrictions	New Sign boards	
< 10 m/s	No restrictions	Small box trailer	Large box trailer
10 – 15 m/s	Small box trailers not allowed - (weight below 750 kg) Other vehicles: Speed limit 110 km/h		
15 – 20 m/s	Small, large box trailers and Caravans not allowed - (weight below 2.500 kg) Other vehicles: Speed limit 90 km/h		
20 – 25 m/s	Small, large box trailers and Caravans not allowed - (weight below 2.500 kg) Other vehicles: Speed limit 70 km/h		
25 m/s	Bridge closed

ABSTRACT: To study the fatigue crack propagation mechanism at Haibach hole for orthotropic steel deck, the multi-scale whole-bridge digital twin model was established based on a highway-railway dual-purpose bridge case study. The digital fatigue test of the Haibach hole was carried out based on fracture mechanic theory and the eXtended Finite Element Method (XFEM). The welding process numerical simulation near Haibach hole was performed. The result shows there is the high residual tensile stress at the cutout edge. The cracks at diaphragm cutout edge and weld toe at U-rib propagation were simulated coupled with the effect of multi-stress field. The result shows that the crack could not be in the plane but will deflect a certain angle during the propagation process. The cumulative strain energy release rate result reveals that the fatigue cracks at Haibach hole edge are I mode crack and I mode crack at U-rib weld toe.

1 INTRODUCTION

Orthotropic steel deck is widely used in bridge construction because of its excellent mechanical properties, convenient construction and environmental protection (Wang *et al.*, 2015). However, due to its complex structural form, the orthotropic steel bridge deck inevitably introduces welding defects and welding residual stress in the manufacturing process, and there is wheel loads directly acting on the steel bridge deck during operation. These factors make the fatigue cracking problem of orthotropic steel bridge deck very serious (Wang & Feng, 2009).

Relevant researchers mostly use the method of physical fatigue test to study fatigue property of orthotropic steel deck (Wang *et al.*, 2017, Fisher & Barsom, 2016). Physical fatigue test, especially full-scale fatigue test, can directly observe the fatigue crack propagation behavior and obtain the corresponding fatigue strength.But the physical fatigue test cycle is large and the cost is high. The digital fatigue test provides a new way for the fatigue research of steel bridge. A refined numerical model of fatigue details of orthotropic steel bridge deck is established, and the information of different stages of physical real bridge is mapped to the numerical model to construct a digital twin model of fatigue crack propagation.

Traditional finite element method is widely used in the current digital fatigue test of orthotropic steel bridge deck. Liu et al. (Liu *et al.*, 2016) established finite element models from the component and segment scales respectively, predicted the fatigue crack propagation path, evaluated the number of cyclic loadings, and proved the reliability of the fracture mechanics parameter analysis of the three-dimensional solid model. Wang et al. (Wang *et al.*, 2019) established a three-dimensional fracture mechanics model of riveted steel bridge before and after reinforcement, and considered the effect of corrosion fatigue. The results show that this method can well evaluate the residual fatigue life of riveted steel bridge under the coupling

DOI: 10.1201/9781003483755-355

effect of corrosion and fatigue. Zong et al. (Zong *et al.*, 2015) used FRANC3D to simulate and analyze the fatigue crack propagation of CT specimens based on the theory of linear elastic fracture mechanics, and obtained the residual life of fatigue cracks more accurately.

When the traditional finite element method is used to simulate the crack propagation, it is necessary to divide the grid repeatedly after the crack propagation. Repeated meshing reduce the computational efficiency. Belytsehko et al.and Moës proposed the extended finite element method (XFEM) (Belytschko & Black, 1999, Moës *et al.*, 1999), based on the partition of unity finite element method (Melenk and Babuska, 1996). This method can well solve the disadvantages of the traditional finite element method. Based on XFEM, Chen et al. (Xiang *et al.*, 2022) studied the fatigue life calculation under the condition of double crack propagation, and analyzed the influence of the angle between the crack and the roof, the initial crack size and the aspect ratio of the crack on the fatigue crack propagation behavior. Wang et al. (Wang *et al.*, 2017) established a segment model of orthotropic steel bridge deck, considering the influence of welding residual stress, and realized the fatigue crack propagation of main details based on numerical fracture mechanics and XFEM.

In the existing research, the segment model is used to carry out the digital fatigue test and the simulation of welding residual stress is mostly small-scale simulation, which is different from the actual welding situation in the factory. Therefore, it is necessary to put forward reasonable boundary conditions of welding residual stress simulation corresponding to the actual situation. Moreover, there is less research on the Haibach cutout fatigue property. With the development of traffic, more and more railway bridges use Haibach cutout as the form of digging cutout in the diaphragm of orthotropic steel bridge deck, and the force is complex. Therefore, the propagation mechanism of typical fatigue cracks at the top deck-U rib-diaphragm Haibach cutout detail under multi-field coupling needs to be clarified. In this paper, an orthotropic steel bridge deck in a highway-railway bridge is taken as the case study, and the digital twin model of this whole bridge is established. The welding process is simulated, and the actual welding boundary conditions are adopted. Considering the multi-field and the fatigue crack propagation behavior is researched. The propagation mechanism of typical fatigue cracks at the Haibach cutout of the top deck-U rib-diaphragm under multi-field coupling is revealed.

2 CASE STUDY AND NUMERICAL MODEL

2.1 *Case study*

A continuous steel truss bridge is taken as the case study. This is a highway-railway dual-purpose bridge. The height is 12m and the width is 30.5m of the steel truss girder. The main body of the steel beam is made of Q370q steel. As shown in Figure 1, the thickness of the roof of the deck is 16mm; the longitudinal stiffener adopts a closed trapezoidal section. The thickness of the longitudinal rib web is 8mm, the thickness of the top deck is 10mm, the top width is 300mm, the bottom width is 180mm, the height is 280mm, the diaphragm cutout radius is 20 mm and the spacing is 600mm. The cut-out form of the diaphragm is Haibach cutout. The full penetration fillet welds

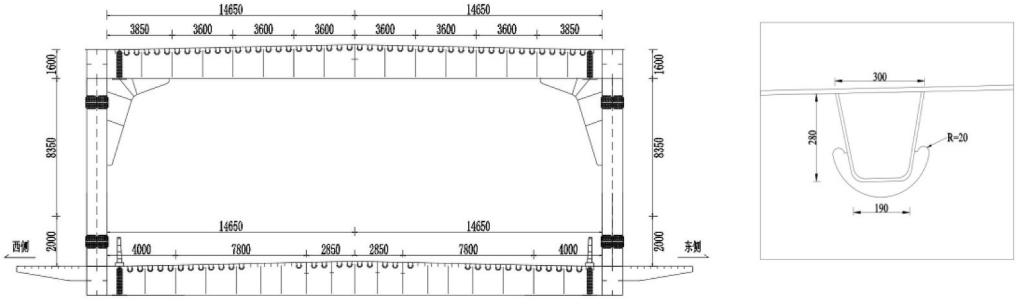

Figure 1. Structural dimensions of steel bridge deck.

are used for the connection welds between the orthotropic steel top deck and the U-rib, and the connection welds between the diaphragm plate and the U-rib.

2.2 *Digital twin model*

Taking into account the calculation cost and calculation accuracy, the cross-scale sub-model modeling method was used to establish a full-bridge digital twin model. At the full bridge scale, the main truss, stiffening string, upper deck system and lower deck system are simulated by beam element. Five internode lengths were selected to establish a 68m long segment steel truss girder substructure, which was simulated by shell element. The key parts containing fatigue cracks are simulated by solid elements. In the cross-scale model, the main girder segment model and the welded sub-model adopt the shell-solid coupling constraint, and the beam element model and the main girder segment model adopt the coupling constraint. According to the bridge span arrangement and the bearing arrangement, the continuous beam boundary constraint is applied in the numerical model. The cross-scale full-bridge model is shown in Figure 2.

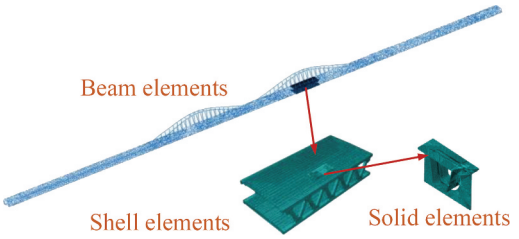

Figure 2. The cross-scale full-bridge model.

3 SIMULATION AND ANALYSIS OF WELDING PROCESS

The influence of residual stress at the weld on the fatigue performance cannot be ignored. The researchs of relevant scholars show that there is a large residual stress at the connection weld (Wang *et al.*, 2013). In this paper, a numerical model of fatigue details at the weld of U-rib and diaphragm is established for thermal-mechanical coupling analysis. This lays a foundation for the simulation of crack propagation under multi-field stress coupling.

3.1 *Welding simulation model*

The welding simulation solid sub-model shown in Figure 3 is selected in the connection area of U-rib and diaphragm. The width of the sub-model is 600mm, the longitudinal length is 200mm, the height is 400mm, the thickness of U rib is 8mm and the thickness of diaphragm

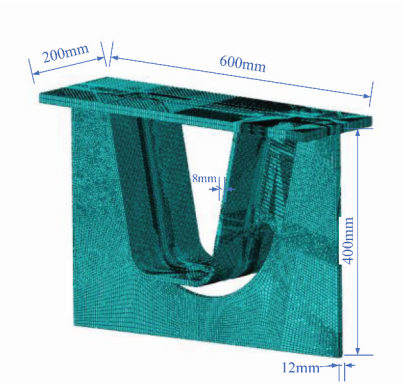

Figure 3. Welding analysis model.

plate is 12mm. The mesh size is refined to 1mm at the connection details of the U-rib and the diaphragm to ensure the calculation accuracy of the residual stress field and the matching degree between the mesh size and the initial crack size during the subsequent fatigue performance analysis. At the same time, taking into account the computational efficiency, the grid size gradually changes smoothly from 1mm to 8mm from the focus area to the outside. The eight-node hexahedral heat transfer element is used to calculate the temperature field, and the eight-node linear hexahedral element is used to calculate the residual stress field.

3.2 *Welding simulation method*

In the simulation of the whole welding process, the 'birth and death element method' is used to simulate the filling process of multi-pass welds, and the welding residual stress analysis of U rib-diaphragm connection weld is carried out by sequential coupling method. In the thermal analysis, the stress on the 'dead element' and its constraint on the adjacent elements are also close to zero. During the welding process of the diaphragm and U-rib connection weld, the weld element set is continuously activated with the movement of the welding heat source. In the process of thermal analysis, only thermal boundary is needed. However, when analyzing the welding stress field, it is necessary to apply mechanical boundary conditions in the welding model to ensure that the structure does not appear rigid body displacement and does not constrain the free deformation of the weld. The boundary conditions of the welding residual stress model are shown in Figure 4. Welding heat input and welding heat source model are the main influencing factors of welding temperature field. This paper assumes that the thermal efficiency η is 0.75 and adopts the double ellipsoid heat source model (Goldak *et al.*, 1984).

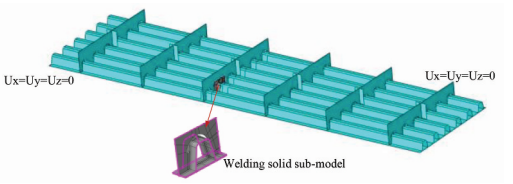

Figure 4. Boundary conditions of welding residual stress model.

3.3 *Welding residual stress analysis*

Taking the welding temperature field as the external load, the stress boundary conditions of the whole welding process are set up to carry out the thermal analysis of the whole welding process. The welding residual stress around the weld has reached or approached the yield value of the steel, indicating that the welding residual stress has a great influence on the stress distribution of the fatigue details of the Haibach cutout.

In order to analyze the distribution characteristics of welding residual stress, three paths are selected for analysis, which reflect the transverse direction of the weld toe and the diaphragm cutout edge. The distribution of welding residual stress is shown in Figure 5. The transverse residual stress at the weld toe is the largest near the weld toe, and gradually decreases away from the weld toe. The distribution trend is similar to the vertical residual stress distribution. Under the action of vehicle load, the detail has a combination of tensile-tensile stress cycle and welding residual stress, resulting in fatigue failure of the detail. It can be seen that there is a large welding residual tensile stress along the edge of the Haibach cutout, and it shows a trend of increasing first and then decreasing, and the stress at the later welding is significantly greater than the stress at the earlier welding, indicating that the welding residual stress at the earlier welding will be reduced during the later welding process. The welding residual stress reaches the maximum at about 50mm from the weld toe at the edge of the Haibach cutout, and the maximum can reach 350MPa.

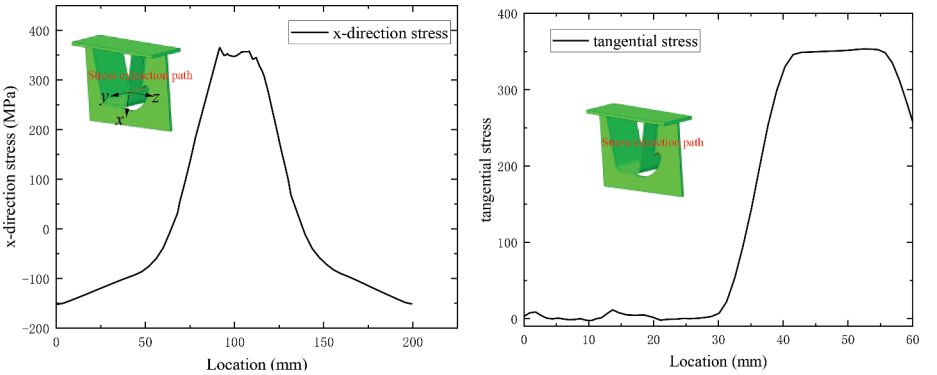

Figure 5. Welding residual stress distribution.

4 FATIGUE CRACK PROPAGATION SIMULATION

4.1 *Extended finite element method*

Based on the partition of unity finite element method, Belytsehko and Moës proposed a new calculation method in 1999. The finite element method (XFEM) allows the crack to be independent of the grid, and there is no need to re-divide the grid during the crack propagation. XFEM introduces the enrichment function into the displacement function of the traditional finite element method, and reflects the discontinuity of the crack by strengthening the degree of freedom of the element nodes around the crack. The enrichment function includes the crack tip asymptotic function and the jump function, and the two-dimensional plane grid with cracks.

4.2 *Fracture mechanic theory*

Under the action of fatigue load, the rate of change of crack length a and cycle number N is called the fatigue crack growth rate, and the da/dN-ΔK curve describes the fatigue growth performance of the material. The da/dN-ΔK curve in double logarithmic coordinates can be obtained by constant amplitude fatigue test on the central crack tensile specimen or compact tensile specimen with sharp notch and prefabricated crack. As shown in Figure 6, the curve can be divided into three regions (Paris & Erdogan, 1963):Zone I is the low rate region of fatigue crack growth. When ΔK is less than the lower limit value ΔK_{th}, the fatigue crack will not expand, and ΔK_{th} is the stress intensity factor threshold of fatigue crack growth. Zone II is the medium rate zone of fatigue crack propagation, in which the fatigue crack propagates stably. There is a good linear relationship between lg (da/dN) and lg (ΔK), and the linear relationship is the famous Paris formula. Zone III is a high-rate zone for fatigue crack propagation. In this zone, crack propagation will expand rapidly, and then the structure will fracture. Usually, the contribution of this zone to life is not considered.

In order to directly apply the strain energy release rate calculated by VCCT method and improve the calculation speed of fatigue crack propagation simulation, the composite crack propagation power criterion is adopted, and its expression is (Xu & Yuan, 2009):

$$\frac{G_I}{G_{IC}} + 1.9\frac{G_{II}}{G_{IIC}} + 2.1\frac{G_{III}}{G_{IIIC}} = 1.0 \tag{1}$$

Among them, G_I, G_{II}, and G_{III} are type I, type II, and type III strain energy release rates; G_{IC}, G_{IIC} and G_{IIIC} are type I, type II and type III critical strain energy release rates, respectively.

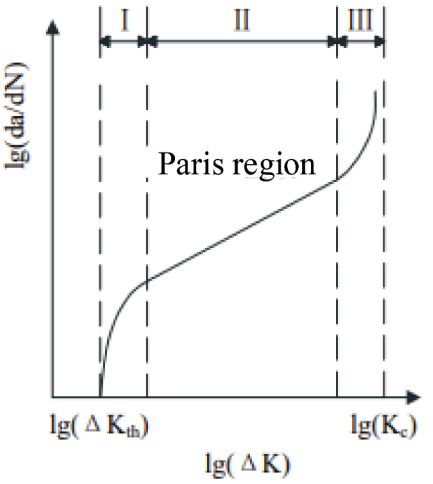

Figure 6. D*a*/d*N*-Δ*K* dependence.

4.3 *Fatigue crack growth analysis*

4.3.1 *Fatigue crack propagation at the weld toe of the U-rib side of the U-rib and diaphragm connection weld*

The initial crack at the weld toe of the U-rib side is a semi-elliptical crack, and its fatigue crack ruler is a_0/c_0= 0.5mm/1mm. The initial crack plane is along the thickness direction of the U-rib, the short half axis of the crack is in the thickness direction of the U-rib, and the long half axis is at the weld toe of the U-rib side. With the increase of loading times, the crack propagates longitudinally along the U-rib, and the angle between the crack and the U-rib weld is formed due to the influence of welding residual stress, as shown in Figure 7. When the number of cycles reaches 2.65 million, the crack penetrates the U-rib web plate, and the crack remains semi-elliptical shape. After that, the crack shape gradually expands from plane to both ends to space arc shape. The strain energy release rate at the crack tip is extracted and the strain energy release rate curve is drawn, as shown in Figure 8. It can be seen that the value of G_{I} is greater than G_{II} and G_{III}, and G_{II} and G_{III} are less than 10 % of G_{I}, and their effects are negligible. This shows that the cracks are mainly type I cracks, and the effects of type II and type III cracks can be ignored. It can be concluded that the fatigue crack at the weld toe of the U rib side of the U rib-diaphragm connection weld is a type I crack.

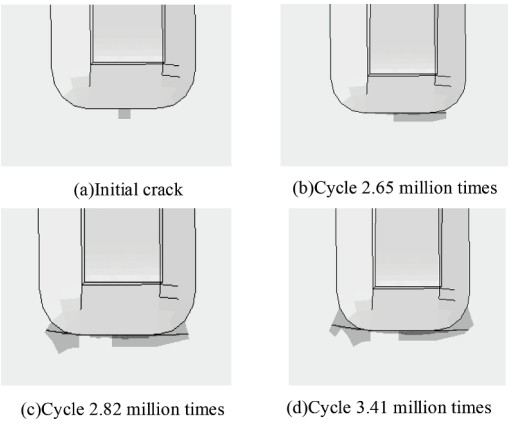

Figure 7. Fatigue crack propagation at weld toe of U rib side.

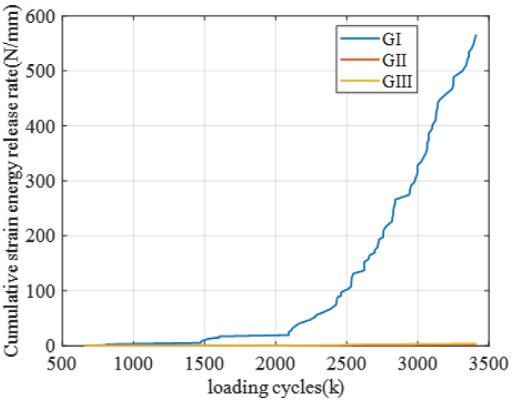

Figure 8. Cumulative strain energy release rate of fatigue crack propagation at weld toe of U-rib side.

4.3.2 *Fatigue crack propagation at the edge of Haibach cutout*

The initial crack at the edge of the diaphragm is 1/4 elliptical crack, and the initial crack size is a_0/c_0=0.5mm/1mm.The initial crack plane is along the thickness direction of the diaphragm, the short half axis of the crack is in the thickness direction of the diaphragm, and the long half axis is in the normal direction of the edge of the diaphragm. The fatigue crack propagation at the edge of the diaphragm hole is shown in Figure 9. When the cumulative cycle of fatigue wheel load reaches 2 million times, the crack propagation direction remains in the normal direction of Haibach cutout edge. When the number of cycles reaches 6.73 million, the crack propagation direction is not in the initial direction and begins to deflect. After that, the crack propagation direction gradually deflects to the diaphragm. The cumulative strain energy release rates G_{I}, G_{II}, and G_{III} at the side weld toe of the diaphragm during crack propagation are shown in Figure 10. It can be seen that the cumulative strain energy release rate changes slowly at the initial stage of crack propagation, and gradually increases with the increase of cycle times. It shows that in the initial stage of crack propagation, the tensile-tensile stress of the initial crack is small and the crack propagation rate is slow. After that, due to the multi-field coupling effect, the tensile-tensile stress at the crack gradually increases, and the crack growth rate begins to increase. The value of G_{I} is greater than that of G_{II} and G_{III}, and the values of G_{II} and G_{III} are less than 10 % of G_{I}, and their effects can be ignored. This shows that the cracks are mainly type I cracks, and the effects of type II and type III cracks can be ignored. It can be concluded that the fatigue crack at the Heibach notch is a type I crack.

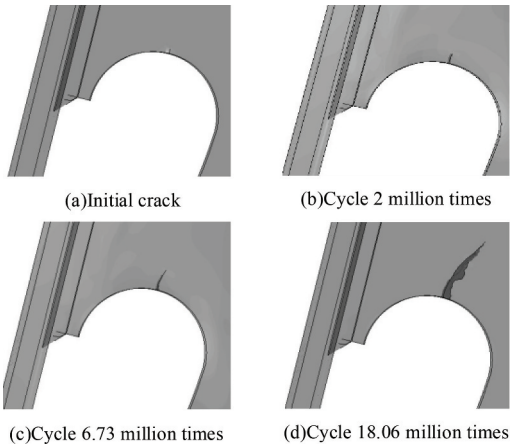

Figure 9. Fatigue crack propagation at Haibach cutout.

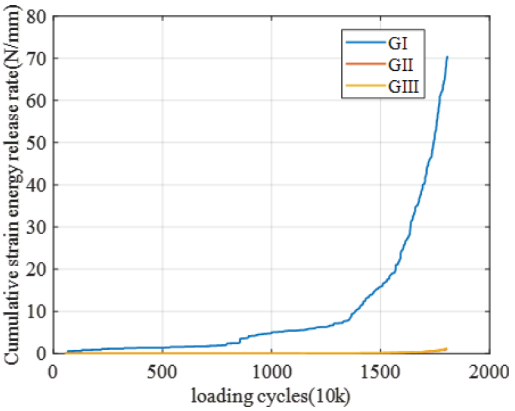

Figure 10. Cumulative strain energy release rate of fatigue crack propagation at Haibach cutout.

5 CONCLUSION

1) In this paper, a multi-scale full-bridge digital twin model was established. The global model is simulated by beam element and truss element, the sub-model and steel deck is simulated by shell element, and the sub-model of top deck-U rib-diaphragm is simulated by solid element. The fatigue problem of steel deck can be studied under multi-field coupling.
2) There is a large welding residual stress in and around the weld, which is close to the yield strength of the steel. There is a large residual tensile stress at the top deck-U rib-diaphragm excavation detail group. It can be concluded that the welding residual stress has a non-negligible effect on the fatigue performance of the steel bridge deck.
3) Coupling with the multi-field stress, based on the XFEM, the digital twin simulation of the typical cracks at fatigue-prone details of Haibach cutout was carried out. The results revealed that the fatigue crack at the weld toe of the U-rib side of the U-rib and diaphragm connection weld is a type I crack and the fatigue crack at the Haibach notch is type I crack.

ABSTRACT: The steel truss girders with double-deck are widely used in long-span suspension bridges due to its superior mechanical properties and traffic capacity. However, the fatigue mechanism of such bridges under multi-lane loads is uncertain. In order to clarify this issue, full size digital fatigue test considering detail welding residual stress (WRS) is carried out. Based on the theory of Extended Finite Element Method (XFEM) and the Linear Elastic Fracture Mechanics (LEFM), the fatigue crack propagation law of the details is researched. The results show that the WRS of the fatigue-prone detail is close to the yield strength of the steel. Thus, the influence of WRS should be considered in the fatigue assessment. Then, the cracking of fatigue details is caused by out-of-plane distortion under the multi-field coupling effects. Moreover, the fatigue cracks are Mode I-II-III combined cracks dominated by Mode I through analysis of fracture parameters.

1 INTRODUCTION

The double-deck steel truss girder is widely used in long-span bridges due to its high spanning capacity, large traffic volume and superior structural performance. For the double-deck truss girder, the joints intersect many members such as chords, web members and crossbeams, resulting in a more complex force transmission path. With the improvement of welding technology, full-welded integral joints are gradually used in steel truss girders instead of splicing joints. It has a high degree of factory manufacturing and superior overall mechanical performance. However, there are many fatigue-prone structural details in the welded integral joints, and initial defects such as large welding residual stress (WRS) and deformation are also introduced during the welding process. The vehicle loads are transmited to the truss by crossbeams. The bending moment generated at the end of the crossbeams will drive the joints and chords to twist. Therefore, out-of-plane distortion will occur in the connecting area between the crossbeams and the joints. Distortion-induced fatigue cracks initiate and propagate under the cyclic vehicle loads, severely threaten service safety and life of truss girder bridges.

DOI: 10.1201/9781003483755-356

Current research methods on fatigue performance in the field of steel bridges mainly include two aspects: (1) Carry out physical fatigue tests to evaluate the fatigue strength of sturcture details (Wei et al. 2017, Wang et al. 2022); (2) Conduct fatigue assessment based on in-situ monitoring of real bridges (Wang et al. 2013). However, the cost of physical fatigue testing is high, and it is difficult to fully ensure that the stress state of the physical model is consistent with that of the actual structure. During in-situ monitoring of real bridges, fatigue cracks are always shielded and scattered. It is difficult to monitor fatigue cracks at joints accurately in real-time. With the continuous development of computing science, the numerical fracture mechanics method that combines fracture mechanics with Extended Finite Element Method (XFEM) has gradually been applied to fatigue analysis of bridges (Wang et al. 2017). By establishing a multi-scale full-bridge numerical model, WRS and initial defects are introduced in the fatigue detail, fatigue cracks propagate under the action of vehicle cycle loads, and the fatigue cracking mechanism of structural details is studied (Wang et al. 2022).

In this paper, a multi-scale numerical fatigue model of a long-span suspension bridge with double-deck is established, and the sequential coupling method is used to simulate the WRS of the crossbeam-joint structural detail sub-model. Based on linear elastic fracture mechanics (LEFM) and XFEM, crack propagation analysis is carried out under the multi-field coupling effect of dead load, live load and WRS field to explore the cracking mechanism and propagation behavior.

2 MULTI-SCALE DIGITAL FATIGUE TEST MODEL

The suspension bridge of 2180 m main span with double-deck steel truss girder is selected as the research object. Both upper and lower decks adopt a multi-crossbeam system, which is arranged in eight-lane layout each deck with a total width of 43.6 m. The standard section length of the steel truss girder is 16 m, the height of the upper and lower chords is both 1.7 m, and the width of the chord is both 1 m.

By the analysis of the moving load of the whole bridge and the identification of fatigue sensitive details, the joints in the about L/5 region are determined as the most unfavorable fatigue control joints for evaluation. The layout of the whole bridge is shown in Figure 1.

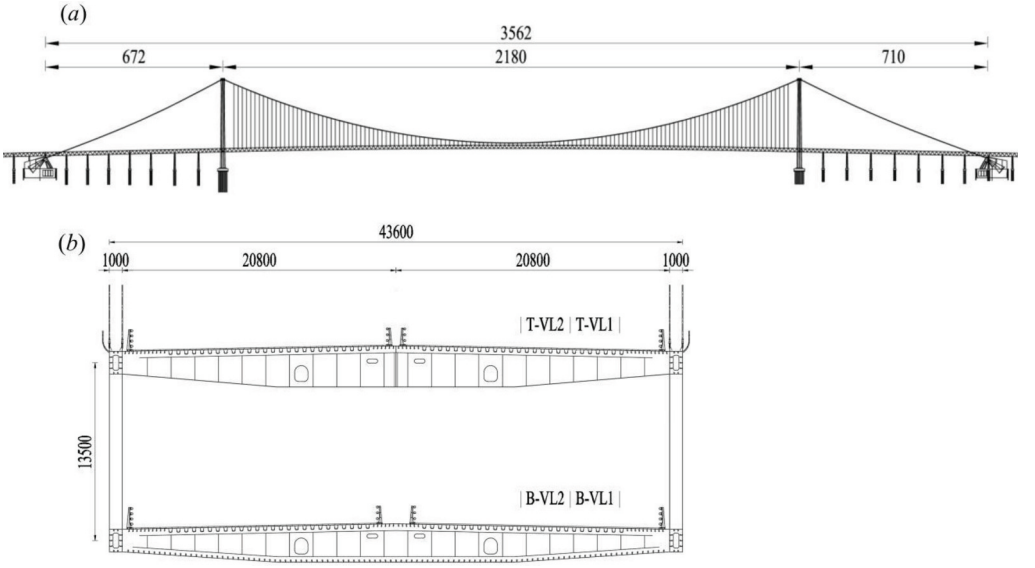

Figure 1. The layout of the whole bridge: (*a*) bridge elevation (Unit: m); (*b*) cross section of stiffing girder (Unit: mm).

In order to fully reflect the stress state of the joints in whole bridge and ensure calculation efficiency and accuracy, multi-scale finite element model of suspension bridge is established, containing SOLID element sub-model considering the detailed geometric configuration. Solid sub-model is embedded into the SHELL element model of five standard segments by means of "Shell-Solid Coupling". The whole bridge model including main cables, hangers, towers and truss girder is simulated by BEAM/TRUSS elements. It is constrained with segment SHELL element model by "Coupling" means to realize force transmission and displacement constraints. Initial crack is semi-ellipsoidal, whose length is 2 mm and depth is 0.5 mm.

The solid mesh size at the crack insertion position is accurate to 1mm. In order to improve the computational efficiency, mesh transition technique is used to increase the mesh size from 1 mm to 8 mm. The multi-scale calculation model is shown in Figure 2.

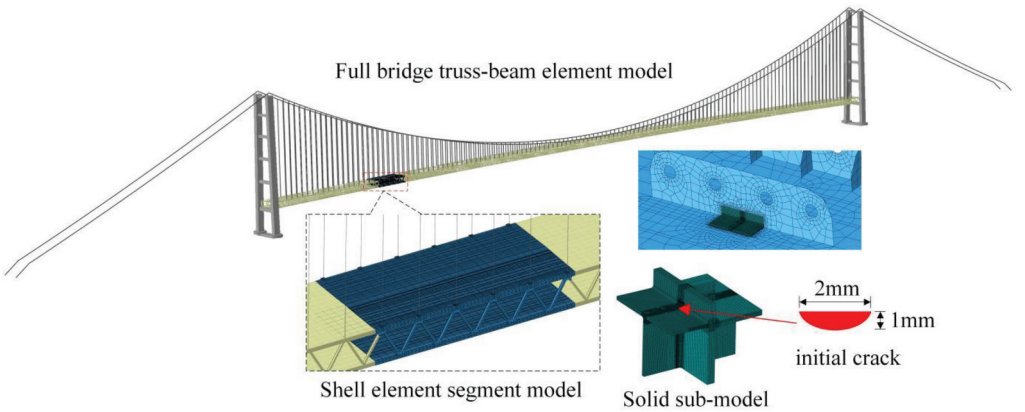

Figure 2. Multi-scale FEM of the suspension bridge.

3 WRS SIMULATION

3.1 *Welding simulation method*

The WRS field of the solid sub-model in welding process is calculated by sequential coupling method. The truss adopts Q355 steel, and the deck system adopts Q420 steel. The thermal-physical and thermodynamic performance parameters of Q355 and Q420 steel are defined respectively (Sun et al.2016). The welding wire and the corresponding base metal use the same material property. Due to large thickness of plates, welds are simulated by multi-layer and multi-pass welding means. A rational cooling interval is set between two adjacent layer welds to ensure an appropriate interlayer temperature. The passivated elements are gradually activated to simulate the travel process of the welding.

Firstly, welding temperature field is calculated. The solid sub-model element attribute is set by eight-node hexahedron DC3D8. In the welding process, the double ellipsoid heat source model is selected as the heat input model to convert electric energy into heat energy, which is expressed (Goldak et al. 1984) as:

$$q_r(x,y,z) = \frac{6\sqrt{3}f_r Q}{\pi^{3/2}abc_r}\exp\left\{-3\left[\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{(z-z_0-vt)^2}{{c_r}^2}\right]\right\}\ (Z \geq 0) \tag{1}$$

$$q_f(x,y,z) = \frac{6\sqrt{3}f_f Q}{\pi^{3/2}abc_f}\exp\left\{-3\left[\frac{x^2}{a^2}+\frac{y^2}{b^2}+\frac{(z-z_0-vt)^2}{{c_f}^2}\right]\right\}\ (Z<0) \tag{2}$$

where f_f and f_r are constants of the heat deposited in the front and rear quadrants; Q is the heat input per-unit time; v is the welding speed; t is the welding time; z_0 is the position of the heat source in the z-direction at the beginning. The heat source model geometric parameters a, c_f and c_r are independent and they can have different value.

Based on results of the temperature field, the WRS field is calculated. Temperature field is applied to the solid sub-model as a predefined load. On the basis of the original solid sub-model mesh division method, element type is modified to an eight-node hexahedron C3D8R, and activation order of weld elements is guaranteed to be consistent with the thermal model. Symmetrical mechanical boundary constraints are used on the edges of the solid sub-model.

3.2 *WRS analysis resluts*

In the process of welding thermal analysis, it is necessary to adjust the input of current, voltage and the heat source model size to ensure that welds can be fully penetrated. The melting point of steel and welding wire is 1450℃.

Figure 3 shows temperature field distribution of the welding process. The color of the area where the temperature exceeds 1450℃ is eliminated. It can be seen that the molten pool above 1450℃ can penetrate the cross section of the welds, which further indicates that the parameter setting of the heat source model is reasonable.

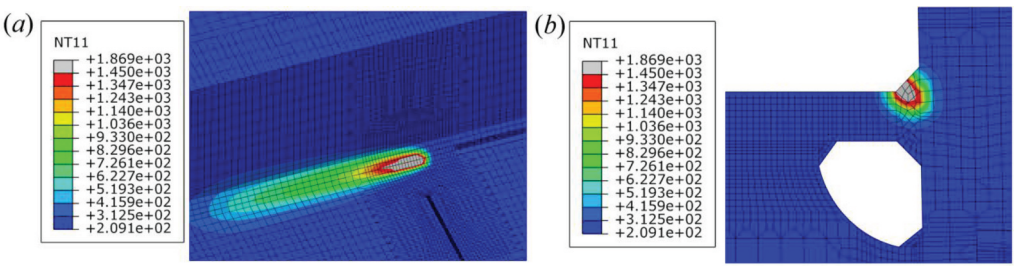

Figure 3. Temperature field distribution(Unit: ℃): (*a*) Molten pool plane; (*b*) Molten pool section.

Based on results of the temperature field, the WRS field is calculated. WRS distribution results of different paths are extracted, as shown in Figure 4. It can be seen that WRS is tensile stress closed to the yield strength. As the welding goes on, WRS of the previously weld decreases, indicating that the subsequent welding process will affect the WRS distribution in the previous welding area.

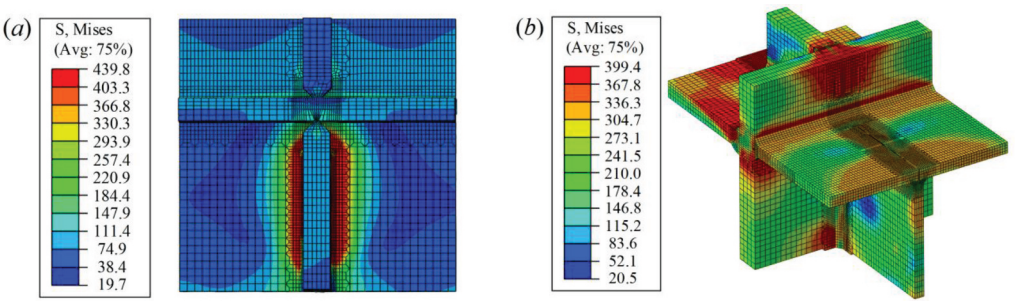

Figure 4. WRS field distribution (Unit: MPa): (*a*) welding process; (*b*) welding completion.

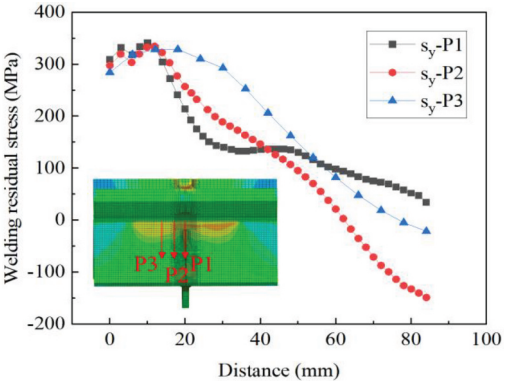

Figure 5. WRS distribution along different path.

The WRS in the vertical weld toe direction under different paths at the extracted details is shown in Figure 5. It can be seen that the farther away from the weld toe, the WRS gradually decreases. The WRS of P2 begins to transform into compressive stress at 58 mm from the weld toe, whose gradient is the largest of three paths.

4 DETAIL STRESS RESPONSE ANALYSIS

4.1 *Fatigue vehicle load*

In order to analyze the stress response of the fatigue details of the joints under the action of live load, the fatigue load model II (FLM II) from the *Chinese Specifications for Design of Highway Steel Bridge* (JTG D64-2015) is selected as the fatigue load. FLM II is consisted of double vehicles with 40 m center distance. Single vehicle is six-axis truck which weighs 425kN. Each wheel load area is 0.20 m×0.60 m. Regardless of the stiffness contribution of the 75mm thick asphalt pavement layer to the structure, it is treated as a secondary load on the bridge deck. Single wheel load area is diffused to the steel bridge deck through the asphalt pavement layer at an angle of 45°, so the calculated area of a single wheel load is 0.35 m×0.75 m.

4.2 *Analysis of stress response results*

The joints of the double-deck truss girder intersect with multiple members such as hingers, chords, crossbeams and web members. Due to three-dimensional spatial lane distribution feature, the FLM II on different lanes will have different effects on the details of joints. It is necessary to comprehensively consider the stress response of the details caused by different loading cases. Different combinations of double-deck lane loads are designed to determine the most unfavorable loading cases, as shown in Table 1. Based WRS field and the dead load stress field, the stress response of the details under different loading modes is calculated, as shown in Figure 6. When the rear axle of the FLM II is just acting on the crossbeam connected to concerned joint, stress at the details reaches the peak. The stress amplitude of details under Case 3 is the largest, reaching 46.3 MPa. Effect of bottom lane loading cases on top joint details can be ignored from fatigue damage perspective.

Load cases	FLM 2 loading lane
Case 1	T-VL1
Case 2	B-VL1
Case 3	T-VL1+T-VL2
Case 4	B-VL1+B-VL2
Case 5	T-VL1 +B-VL1

5 DIGITAL FATIGUE ANALYSIS

5.1 *Methodology*

Cracks cannot directly pass through the element when using traditional finite element method. And the mesh needs to be re-divided at every step of propagation to make crack surfaces and the element edge match each other, resluting extremely low calculating efficiency. XFEM introduces the enrichment function in the displacement approximation function to reflect the geometric discontinuity problem in crack propagation. The displacement function equation in the XFEM is expressed (Belytschko et al. 1999, Moes et al. 1999) as:

$$u(x) = \sum_{I \in \mathrm{P}} N_{\mathrm{I}}(x) \left[u_{\mathrm{I}} + \underbrace{H(x) a_{\mathrm{I}}}_{\mathrm{I} \in K_{\Gamma}} + \underbrace{\sum_{\alpha=1}^{4} F_{\alpha}(x) b_{\mathrm{I}}^{\alpha}}_{\mathrm{I} \in K_{\Lambda}} \right] \tag{3}$$

Where a_{I} is additional degrees of freedom (DOF) of the penetrating element; b_{I}^{α} is additional DOF of crack tip element; K_{Γ} is penetrating element nodes set; K_{Γ} is crack tip element nodes set.

5.2 *Crack propagation path simulation*

FLM II wheel load position of the most unfavorable loading case is selected for cyclic loading. Calculation results of crack propagation path with and without considering WRS field are extracted seperately, as shown in Figure 7. It can be seen that crack deflects along the length and depth direction under cyclic loading without considering WRS field. After considering WRS field, the crack propagation path and morphology basically do not change, indicating that the WRS field has no effect on the crack propagation morphology.

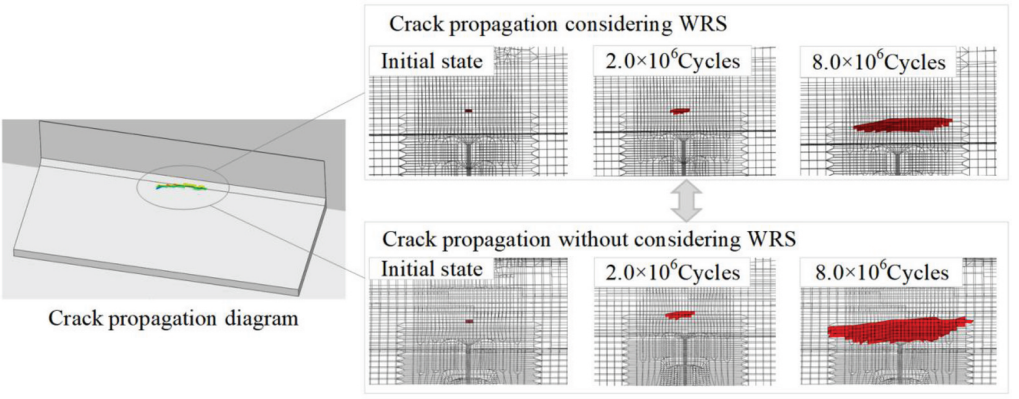

Figure 7. Crack propagation path comparison with and without considering WRS.

Further analysis shows that without considering the WRS, the crack extends 54 mm along length direction and 10 mm along depth direction under 8 million loading cycles. When considering the WRS field, the crack extends 76 mm along the length direction and 14 mm along the depth direction, basically penetrating the plate thickness. Crack growth rate considering WRS field is about 1.4 times than that without considering WRS field.

5.3 *Analysis of cumulative strain energy release rate*

The strain energy release rate (SERR) during crack propagation is calculated based on the virtual crack closure technique. Cracks will propagate when meeting $G_{th}<\Delta G<G_{pl}$. By calculating the SERR during crack propagation, mechanism and law of crack propagation are further analysed. The cumulative SERR under crack propagation with and without considering WRS field is extracted respectively as shown in Figure 8. It can be seen that in the process of crack propagation, ΣG_I is much larger than ΣG_{II} and ΣG_{III}, and the three forms of cumulative SERR with or without WRS are basically the same. In the process of crack propagation, the proportion of ΣG_I in the total SERR increases rapidly. However, ΣG_{II} and ΣG_{III} increase slowly, where (ΣG_{III} /ΣG_I) is about 2.0 times and 1.5 times of (ΣG_{II}/ΣG_I), corresponding to the crack propagation with and without considering WRS, respectively. It shows that the proportion of ΣG_{III} increases considering the WRS. The fatigue cracks are Mode I-II-III combined cracks dominated by Mode I, consistent with the crack growth paths.

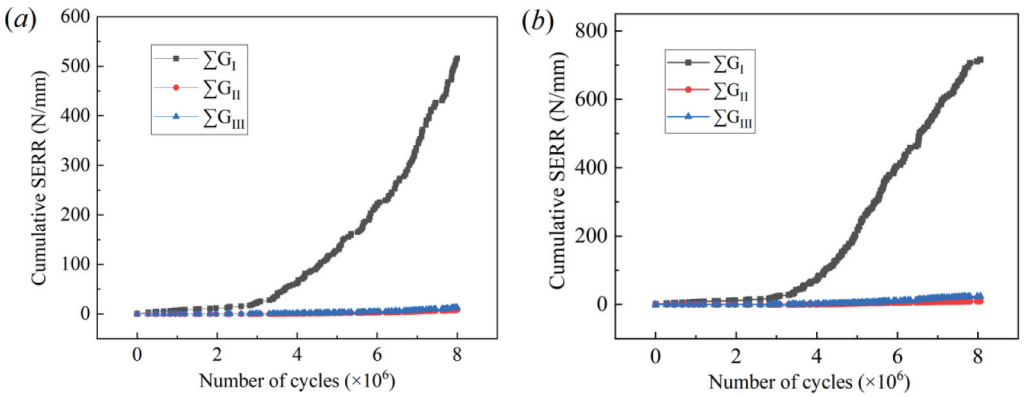

Figure 8. Cumulative SERR during the crack growth simulation: (a) without considering WRS; (b) considering WRS.

6 CONCLUSION

The digital fatigue analysis of integral joints in double-deck steel truss girder of long-span suspension bridge based on LEFM and XFEM methods is studied and applied in this paper. By establishing a multi-scale numerical model of the whole bridge, the dead-live load stress field and the WRS field are introduced to simulate the fatigue crack propagation, and crack propagation law is further revealed. The specific conclusions are as follows:

(1) According to the calculation results of WRS in multi-layer and multi-pass welding, the WRS of the detail reaches 320 MPa, which is about 90.1% of the yield strength. The post-welded weld can reduce the WRS of the previous weld.
(2) It is calculated that the most unfavorable vehicle loading position of the joint fatigue details is that the vehicle heavy axis acts directly above the crossbeam connected to the concerned joint, while the effect of the bottom-layer vehicle on the top-layer joint details can be ignored.
(3) Based on the calculation results of cumulative SERR, $\sum G_{\mathrm{I}}$ is much larger than $\sum G_{\mathrm{II}}$ and $\sum G_{\mathrm{III}}$, and the proportion of $\sum G_{\mathrm{III}}$ increases while WRS is considered. The fatigue cracks are Mode I-II-III combined cracks dominated by Mode I, consistent with the crack growth paths.
(4) Crack growth rate considering WRS field is about 1.4 times than that without considering WRS field, indicating that the influence of WRS cannot be ignored in the fatigue analysis of welding details.

Change detection using Bayesian multivariate linear regression

R.J. Hollamby & I.F. Alcover
COWI

ABSTRACT: For civil engineering infrastructure, the objectives of monitoring are often to quantify current performance behavior and seek to detect changes in behavior or status that could be attributed to component damage or degradation. For structures, responses such as displacements and stress changes are often strongly influenced by the effects of wind loading, traffic and temperature, the latter presenting via correlated daily and seasonal variations between structural components, often of differing materials. Displacements due to temperature change can be significant, and loading imparted by traffic is often only indirectly measured. In contrast, comparatively small deformations of the structure can be expected due to component degradation or localized failure. Without a principled approach to data analysis there is a risk that such subtle changes will be go unnoticed due to the complex daily, seasonal, and random volatility of the variable actions.

Through monitoring two long span bridges in Normandy, France, COWI have developed analysis methods that use measured data from several different sensor types to deliver insights with regards to the defined monitoring objectives. Bayesian multivariate linear regression has been found to be a versatile and scalable model class for predicting structural responses, owing to its compatibility with the linear system theory by which structures are typically analyzed. In this class of model, action-related measurement channels (e.g., temperatures, wind speeds) are typically used as regressors, with response measurements being the dependent variables. Response predictions obtained from deployed models serve to contextualize new measured data and identify anomalous responses. Sophisticated model variants, in which some of the parameters are time-varying, can serve to expose any long-term trends or changes that may be evident, yet otherwise masked, within the measured data. This approach constitutes an efficient automated methodology for processing large data quantities that scales well. Inferred model parameters deliver information that is relevant for digital twinning and asset management purposes. The practical application of this methodology is illustrated via a few case studies analyzing real data.

1 INTRODUCTION AND MOTIVATION

The following generic objectives are commonly encountered when working with structural monitoring data from civil engineering infrastructure:

1. Is the structure behaving as predicted? *Design verification/behavior characterization*
2. Is the behavior of the structure changing over time (months, years)? *Long term trend/degradation monitoring*
3. Can we identify rare events/unusual occurrences? *Anomaly detection*

The above are important for proactive asset management, to keep infrastructure functional and safe and give advance warning of any degradation or impending failures that could occur, so that component replacements and/or other interventions can be made.

DOI: 10.1201/9781003483755-357

The responses of civil engineering infrastructure, such as displacements and stress changes, are usually strongly influenced by the combined effects of wind loading, vehicular traffic and temperature, the latter typically presenting via complex variations and temporal lags between structural components. For long span bridges, displacements due to temperature can be very significant; often movement ranges more than 1m are witnessed as structural temperatures increase from Winter to Summer. In contrast, comparatively small deformations of the structure can be expected because of component degradation or localized failure. Without a principled approach to data analysis, the daily, seasonal, and random volatility of these variable actions can easily mask the temporal variations that are of interest, per the generic objectives listed above.

2 BAYESIAN MULTIPLE LINEAR REGRESSION

2.1 *Formulation for use with metric data*

Multiple linear regression is one of the oldest and simplest regression analysis techniques within the field of Machine Learning. But despite its simplicity it represents a convenient mathematical model that has wide applicability in the analysis of structural monitoring data, owing to its compatibility with the linear (or linearised) theory by which most civil engineering structures behave and/or have been designed.

A more versatile variation of the traditional deterministic multiple linear regression model is a Bayesian multiple linear regression model, which can be written in its most elementary form as:

$$\mathrm{Y}_t = [\beta]X_t + \alpha + \varepsilon$$

where X_t is a vector of n regressor variables at time t, Y_t is the vector of m dependent, or response, variables at time t, $[\beta]$ is the gradient matrix of shape $[m,n]$, α is the bias/intercept vector and ε is the process noise vector. In this most elementary form, $\varepsilon \sim Normal(0, [\Sigma_\varepsilon])$, where $[\Sigma_\varepsilon]$ is a diagonal covariance matrix formed from standard deviations vector σ_ε.

The advantage of this model structure is that each of the parameters are physically meaningful. For example, the gradient coefficients that form $[\beta]$ express the proportional influence that each of the regressor variables has on the dependent variables. In a bridge engineering context, these will typically be the influence of wind, traffic and temperature on responses such as displacement, rotation or stress. Once inferred such gradients are readily compared vs Finite Element (FE) model predictions e.g., of displacement due to temperature and/or wind separately, i.e., facilitate FE model calibration.

2.2 *Extensions to the basic formulation*

The metric formulation above can be extended in several ways, also summarized in Table 1:

- α can be allowed to vary with time t, be this via a step-change at unknown time $t=t_1$, a ramp trend or other pre-defined or inferred temporal variation, or simply by adopting a different α parameter for different time intervals, e.g., monthly
- σ_ε can be allowed to vary with time also. Where this is being included to account for unmeasured inputs, such as vehicular traffic, it would be natural to adopt a different σ_ε parameter on weekdays and during trafficked hours.
- Alternative noise models for ε could also be adopted. For example, rather than using a Normal distribution, a Students T-distribution could be used, such that the model structure may then be termed *Robust* Bayesian Multiple Linear Regression, [1], since parameter estimation is less sensitive to outliers in the measured data.

Besides tracking real changes in the bias of responses, use of time-varying bias can help accommodate, identify or be tolerant of small offsets that can occur due to routine monitoring

system maintenance activities, e.g., disconnection and remounting of sensors. Having used the data to infer offsets attributed to such activities, suitable corrections to the measured data can be made, to correct for these effects.

Terms in $[\beta]$ would not normally be varied with time since this would imply a change in system responsiveness to loading actions. Notwithstanding this, there is no technical reason why $[\beta](t)$ couldn't be adopted, except doing so would give increased potential for over-fitting and poor model generalization, especially when other model parameters are also allowed to be time varying. Having estimated parameters via Bayesian inference, a useful back-substitution is to determine the posterior distribution in the reference response vector, Y_{ref}:

$$Y_{ref}(t) = [\beta](t)X_{ref} + \alpha(t)$$

where the regressor vector X_{ref} is defined to have suitable reference values. For example, zero entries when considering variable actions such as wind or temperature difference, or 15°C (of other suitable annual average value for the site) when considering absolute structural component temperatures. Suppose Y were a vector of position coordinates. Evaluating Y_{ref} in this way naturally defines the "reference positions at a uniform temperature of 15°C in zero wind", i.e., the reference positions compensating for the effects of wind and temperature. In many applications this is itself is a useful metric to have inferred from the measured data. Furthermore, considering the variation of $Y_{ref}(t)$ provides a natural answer to facilitate the review of the existence of long-term trends. Since $[\beta]$ is usually treated as time-invariant, $Y_{ref}(t)$ is just a re-positioning (ideally centralizing) of the $\alpha(t)$ offset within the space represented by the variables comprising X. Thus, changes in $Y_{ref}(t)$ are inferred exogenous changes attributable to variables not included in X.

A further use of this model is to evaluate the posterior predictive distribution in the response vector $\hat{Y}(t)$. This is useful for contextualizing new data and for the detection of anomalies. These could be short-term outliers, attributable to incidents such as traffic jams, or more persistent deviations of the measurements from model predictions.

Table 1. Extensions to the basic linear regression formulation and their practical applications.

Parameter		Practical applications
Posterior predictive responses	$\hat{Y}$(t)	Data contextualization; predict responses given measured actions, X(t)
		Anomaly detection; significant differences between predicted responses $\hat{Y}$(t) and measured responses Y(t) (residuals)
		Model evaluation: identify situations in which current model does not perform well, to seek to improve model
Time-varying bias or reference response	α(t)	Long-term trend detection
	or	Inference of offsets due to reinstallation of sensors
	Y_{ref}(t)	Assessment of abrupt changes following events taking place at known time t
Time-varying gradients	$[\beta]$(t)	Assessment of long-term changes in responsiveness to loading actions
Time-varying noise	σ_s(t)	Account for time-varying influence of traffic, if not measured directly and included in X

It should be noted that whilst in general it is common for the variables comprising X to be metric variables, such as wind speed and temperature, the framework of the linear model can be easily generalized to include dichotomous or categorical regressor variables, as may often be encountered when working with measured data from infrastructure. Similarly, through appropriate selection of inverse link function, the dependent variables can also be of non-metric type. Refer application examples below and [2] for further details of generalized linear models.

Similarly, it should be noted that a generalized linear model is applicable in any situation where a model structure is linear *in the parameters*. For example, power law relationships between X and Y, as are encountered when considering wind responses for example, can be inferred according to a linear model by transforming both X and Y using logarithms.

Whilst often X may comprise measured physical data, e.g., wind speed measurements from anemometers, stress changes from strain gauges or temperature measurements from thermocouples, this is not essential. For example, suppose the natural frequencies of the structure have been identified via one of the methods of Operational Modal Analysis. For flexible structures these data will routinely be found to vary with temperature and other loading (wind/traffic), hence it is natural to wish to seek to subtract-off these effects via determining the 'reference' natural frequencies (e.g., at 15°C and when subject to no wind or traffic), to examine if these are changing meaningfully with time (months, years).

Regarding adjudging for *significant* changes, the Bayesian approach provides an expressive means of assessment. For example, suppose we define a model with a step-change bias $\alpha(t)$ as follows:

$$\alpha(t) = \alpha_1 for\, t < t^*$$

$$\alpha(t) = \alpha_2 for\, t t^*$$

whereby the switch time t^* may in some applications be defined as a constant, or otherwise via a suitable prior (e.g., Uniform distribution, bounded by start/end times of monitoring period). By evaluating the posterior distribution in $\Delta\alpha = \alpha_2 - \alpha_1$ we can conduct Bayesian hypothesis testing to assess the significance of the change. Similarly, if t^* is not defined via a constant we can review for a grouped posterior on the switch time at which the unknown change in bias $\Delta\alpha$ occurred.

In summary, a Bayesian Multiple Linear Regression model, especially when extended as described above, proves a good choice when working with structural monitoring data, owing to its inherent compatibility with the linear theory of structures and the way in which its parameters can be used to deliver on monitoring objectives.

2.3 *Software implementation*

Modern probabilistic programming packages such as Stan, JAX and PyMC can be used to naturally define this model, including any of the variants listed above. PyMC, [3], has been used by the author since this Python-based package interfaces well with associated data analysis and provides an especially clean syntax and other supporting functionalities that promote debugging and clear communication of the intent of the model. Having defined parameter prior distributions (either informative or weak, according to any univariate or multivariate probability distribution) together with the model structure as described above, inference of the model's free parameters is conducted via Markov Chain Monte Carlo (MCMC) sampling, by using advanced gradient-based inference engines such as No U-Turn Sampling (NUTS) as implemented by PyMC. This provides samples from the joint posterior distribution in the parameters.

Regarding the obtention of joint posterior parameter samples, this proves especially useful when the variables comprising X are strongly correlated, as is often found to be the case with structural temperature measurements, e.g., from steel and concrete bridge components. In such cases the joint posterior distribution in the influence parameter terms in $[\beta]$ will exhibit strong correlation, which makes these harder to interpret in isolation, but this doesn't undermine the usefulness of the model otherwise. Notwithstanding this, useful projections to evaluate temperature differences and average temperatures are nonetheless useful for restoring the physical interpretability of such parameters.

3 APPLICATION EXAMPLES

For over 4 years COWI have been responsible for the analysis and interpretation of monitoring data recorded from two major cable-supported bridges in Normandie, France: Pont de

Normandie and Pont de Tancarville, see Figure 1. These structures are instrumented with hundreds of sensors that measure environmental conditions (such as structural temperatures, wind speed & direction) and bridge responses (such as position, displacement, inclination, tension force, and strain). Monitoring objectives are diverse but cover each of the main classes of problem listed in the Introduction.

In the sub-sections below some examples of how Bayesian multivariate linear regression has been applied to assist the interpretation of data and the management of these structures.

Figure 1. Pont De Normandie (left, center) and Pont de Tancarville (right).

3.1 *Pont de Normandie: Geometry and stay load review following stay cable replacement*

Following concerns regarding their condition three stay cables on Pont de Normandie were replaced, between June 2020 and December 2020. Stay replacement involved de-tensioning existing stays and then successive tensioning operations to install new stay cables. Such operations would result in a redistribution of load within the remaining stay cable system as well as temporary vertical (Z) displacements of the deck. Data from the monitoring system was used to verify that the works had not permanently altered the distribution of loads within the stay system or the vertical position of the deck.

Four of the remaining stay cables have been instrumented since the original construction of the bridge using load cells. These devices record the absolute tension force sustained by the strand to which they are affixed. For a given instrumented stay, 3 or 4 strands are instrumented. In addition, the bridge is instrumented with GPS receivers, from which XYZ displacements in a bridge-aligned coordinate system are calculated relative to datum positions. Structural temperatures of typical deck and pylon cross-sections are measured. Two anemometers positioned close to midspan measure wind speed and direction.

From linear regression analysis using data prior to the stay replacement works it was established that the 10-minute-mean strand tension for a given stay could be predicted reasonably accurately given the 10-minute-mean structural temperatures and 10-minute mean wind statistics. Various candidate models were considered, with model performance and generalization (overfitting) assessed using distinct training and test datasets, each comprising data from a minimum of 3 months. The most parsimonious model uses the effective steel deck temperature (itself a weighted average from 7no deck temperature sensors) and the transverse component of mean wind speed -squared as regressors. To largely eliminate the influence of traffic, which is not itself monitored directly, only data recorded at 03:00am (when traffic is invariably light) was included in the analysis.

To use such data before, during and after the works an extension of the linear regression model structure was required. The bias vector $\alpha(t)$ was allowed to vary at pre-defined monthly intervals; this was sufficiently granular given the works programme and furthermore some fine-tuning of the assignment of the monthly bias parameters to data was made, given known key dates. During stay replacement gradient parameters [β] would not be expected to vary and

hence are modelled as time-invariant. Similarly, σ_s, which represents the goodness-of-fit of the model in this context, was also modelled as time-invariant. Each of the parameters are arrays i.e., allowed to be distinct for each of the instrumented stay cables.

Posterior distributions in all model parameters were inferred using MCMC and NUTS as implemented by PyMC. Reference responses Y_{ref} were defined at X_{ref}=[15,0] i.e. 15°C uniform deck steel temperature and zero transverse wind speed. In this application $Y_{ref}(t)$ is of greatest interest, a key conclusion being to determine whether the Y_{ref} after completion of the works differs significantly from Y_{ref} prior to the works (recall that Y includes both stay load and deck displacement response channels).

Figure 2 presents time series plots of the measured data from regressor X and dependent Y variables. Posterior predictive stay loads $\hat{Y}(t)$ determined according to the model structure and X(t) data are overlaid via median curves and prediction bands, which represent equal-tailed 90% credible intervals. Monthly-varying reference loads $Y_{ref}(t)$ parameters are shown via right-hand vertical axes, these evaluated based on $X_{ref} = [15, 0]$, i.e., 15°C deck temperature and zero transverse wind speed.

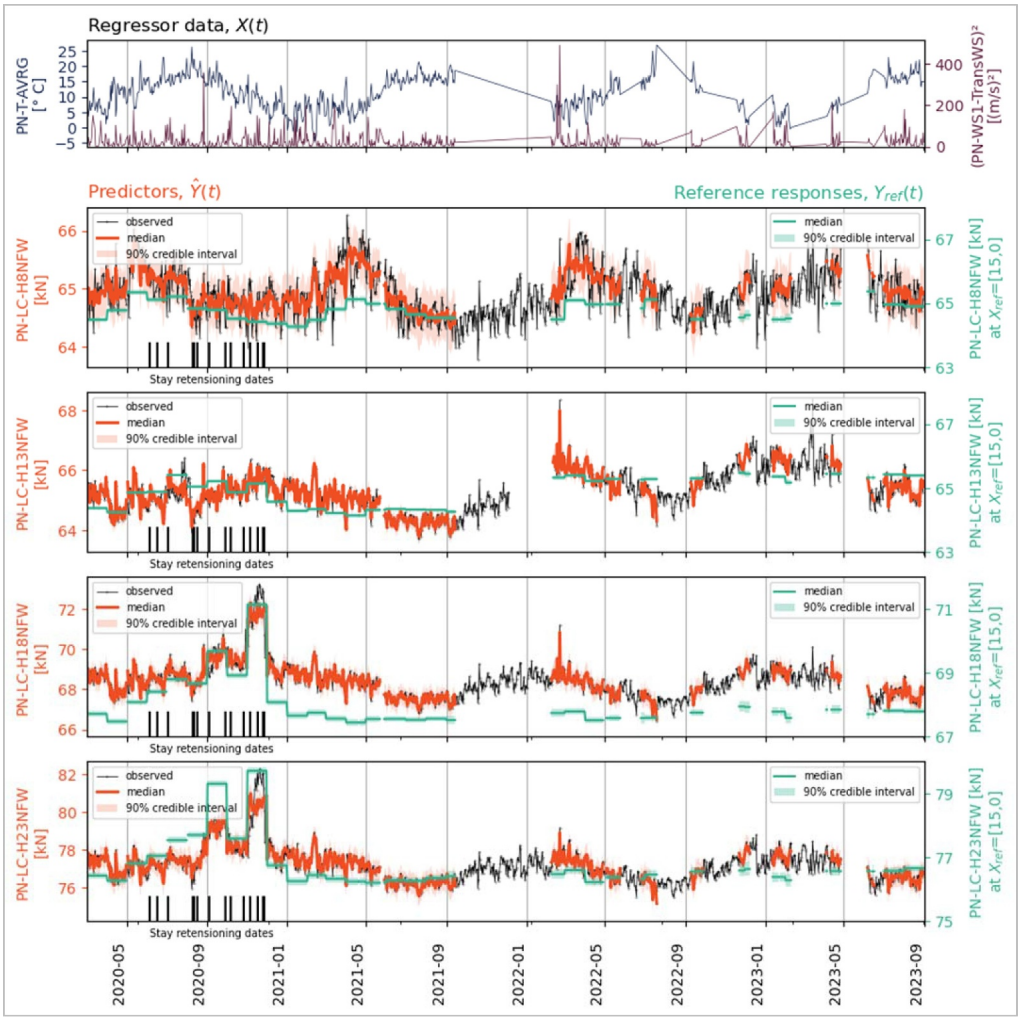

Figure 2. Time series of measured and predicted 10-minute mean stay load data, given measured temperature and wind speed data (refer top subplot). Time series of reference stay loads are plotted via right-hand vertical axes. Key dates in the stay replacement works programme are overlaid for context.

Some responses were hardly influenced by the stay replacement works (e.g., H8NFW strand forces; this stay cable is remote from those replaced) but others were temporarily disturbed yet return to their pre-works values following completion of the stay replacement works. This provided quantitative evidence to reassure the owner-operator of the bridge that the works had not permanently altered the geometry of internal strand forces of the bridge.

3.2 *Pont de Normandie: Correlation of stay wire break events vs environmental conditions*

Each of the 184 stay cables of Pont de Normandie have been monitored using acoustic emission (AE) monitoring, as part of a set of proactive stay management plan, which also includes periodic use of ultrasonic non-destructive testing, laboratory tests and visual inspections, in response to concerns about corrosion at their lower anchorages. Since 2021 AE monitoring has been delivered by Mistras, who classify filtered AE waveforms to identify events compatible with wire breaks. Such events are denoted "Confirmed Wire Breaks" (CWB) with discrete data giving their time of occurrence and stay anchorage.

It should be emphasized that the count of CWB events per year is small. COWI have been engaged to review the data and assess its implications for structural condition. This includes a review of correlations with measured environmental data, e.g., measured temperatures and wind speeds. Other AE monitoring systems have suffered from false-positive events at times of strong rainfall, hence reviewing for dependence on rain conditions was also important.

To explore the correlations in the data a generalized linear regression model was formulated as follows:

- *X* data include discrete wind speed categories, in 5m/s bins, and a Boolean raining/not raining channel, this being classified from the measured rainfall rate data.
- *Y* data are the integer counts of CWB events per hour, aggregated across all stays. *A vector Y could have been used by adopting different aggregations, e.g., distinct for each stay or sum of counts within a stay fan, but this was not done.*
- Metric CWB rate parameters [λ] take the place of the gradients [β] in metric formulation. [λ] is a tensor with multiple dimensions; two in this application, to define joint wind speed and raining/not raining categories respectively. *This would be extended to additional dimensions if different aggregation levels were used.*

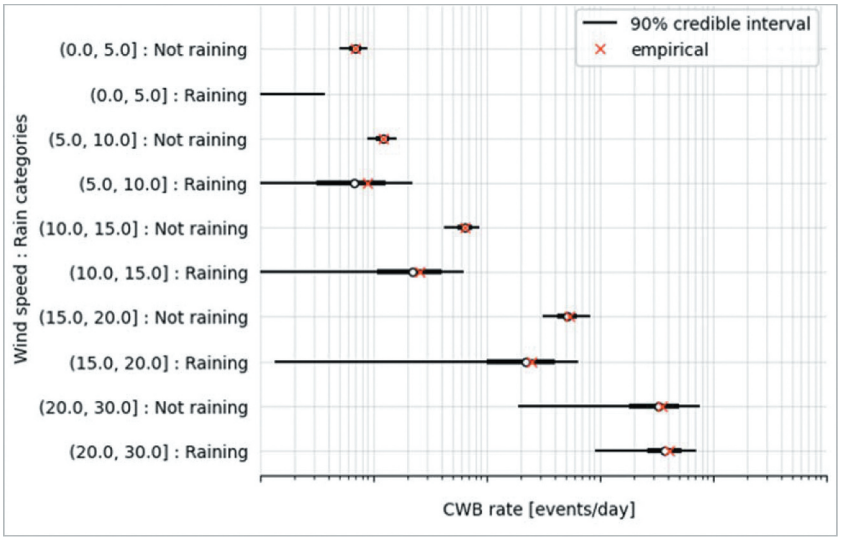

Figure 3. Posterior Distributions On Conditional Cwb Rate Parameters For Joint Wind Speed [M/S] And Rain Categories. Please Note The Horizontal Scale Has Been Obscured For Reasons Of Confidentiality.

- Poisson distribution is used as inverse link function. I.e., the observed CWB count data is regarded as a realization of a Poisson process with parameters [λ], with appropriate [λ] selected according to enumerated wind & rain categories of each data point in X, i.e., each hour of data.
- Weak priors were assumed for the model parameters, i.e. [λ], to let posterior distributions be inferred freely given the data only.

This provides a principled means of analysis that makes use of diverse data and respects their distinct types. Different quantities of data in the various joint categories are reflected in the posterior distributions in [λ] inferred; greater uncertainty is found for under-represented joint categories. The posterior distributions can be compared (refer Figure 3) and directly deliver insights; in this case it was shown that CWB events occur at significantly increased rate as wind speed increases. Furthermore, the presence of rain was shown to not have a significant modifying effect, the posterior rate parameters for a given wind speed category overlap.

3.3 *Pont de Tancarville: Post-fire assessment*

A further application of linear regression came following a major fire on the road deck of Pont de Tancarville in 02/09/2022. A truck lost control, crashed and caught fire, coming to rest adjacent to one of the suspension hangers. Given the intense heat from the fire there was concern that the hanger could have been irreversibly damaged by this event.

Immediately following the fire, the bridge was closed to all traffic, this being diverted considerably via Pont de Normandie. COWI provided advice to the owner-operator (CCITSE) on procedures for conducting a robust post-fire assessment of the crossing prior to its reopening. One aspect of this was to review the monitoring system data, which recorded both the vibrations resulting from the truck's impact and the bridge deformations before, during and after the event.

One aspect of that data review was to apply linear regression analysis to check for any abrupt change in response e.g., vertical displacement following the fire, using techniques like those described in Section 3.2. No significant step-changes in reference positions of the deck or pylon were noted, which provided reassurance when considered in conjunction with findings from close visual inspections.

4 CONCLUSIONS

As demonstrated through application examples, despite its simplicity Bayesian multivariate linear regression has been shown to be a versatile model class that is well suited to the analysis of structural monitoring data. The physical interpretability of its parameters lends itself to FE model calibration, due to its compatibility with the linear theory of structural behavior. Comparison of predicted and measured responses allows for automated detection of anomalies. Use of time-varying parameters can allow subtle long-term change in response to be exposed, which may otherwise be masked by daily and seasonal variations in response attributable to changes in environmental loading. Generalized linear model structures can be used to deliver similar benefits using diverse data types (metric and nominal).

ABSTRACT: Transportation infrastructure demands reliable, cost-effective, environmentally friendly, and safe solutions. It is, therefore, crucial to leverage both the knowledge gained from current practices and the potential offered by emerging technologies. This paper uses the scoring system approached in the INFRACOMS project to offer a framework for asset managers and technology providers to identify areas of improvement and make informed decisions regarding selecting and implementing remote condition monitoring solutions. We focus on two technologies for bridges, like bridge weigh-in-motion and digital inspection and centre around four areas: data analysis, visualisation and integration and potential for practical decision-making. Technologies are evaluated based on their intended use, acknowledging that some may have multiple applications due to novel sensor installations or data interpretation/visualisation methods. Consequently, a technology may undergo multiple appraisals within this system. We showcase the benefits of the scoring system, alignment with specific use cases, and potential for broad applicability.

1 INTRODUCTION

The application of consistent, reliable information is a key component of highway asset management. The information and the tools to help interpret and apply data have continuously evolved. However, National Road Authorities (NRAs) are not yet fully exploiting their potential in the highway environment. By bringing these components of sensing and measurement together, NRAs could better understand highway assets and improve reactive and proactive asset management decisions.

This paper describes a scoring system to appraise new technologies mapped for bridges and pavements in the INFRACOMS project (www.infracoms.project.cedr.eu/). INFRACOMS is

DOI: 10.1201/9781003483755-358

a CEDR Transnational Road Research Programme Call 2021 project (July 2022 – June 2024). It aims to equip NRAs with the capability to leverage the technological evolution in data/ monitoring.

The first action in the project consisted of identifying the information needs, gaps, and priorities of different NRAs in terms of their data collection and monitoring approach and a list of current and emerging measurement technologies. This is reported in Deliverable D1.1 Current Practice, Future Need and Gap Analysis (Arvidsson et al. 2023a).

Commonly used appraisal methodologies that can be used to evaluate the effectiveness, suitability, and potential impact of new technologies for an organisation include Technology Readiness Levels (TRLs), Cost Benefit Analysis (CBA), Life Cycle Cost Analysis (LCCA), Risk Assessment, and Multi-Criteria Decision Analysis (MCDA). Elements of these commonly used methodologies are included in the INFRACOMS Appraisal Methodology.

The INFRACOMS Appraisal Methodology is designed around technology use cases, that is, a particular application of a technology by an NRA. Some technologies may have more than one technology use case within an NRA. In general, each technology use case should be subject to a separate appraisal, as their costs and benefits, risks and limitations will be different. The appraisal methodology was designed and fine-tuned by applying it to several examples of emerging technologies. INFRACOMS will ultimately deliver a Technology Database and a Technology Appraisal Toolkit to CEDR. The database will comprise appraisals and will be the subject of a future publication.

In this paper, a sequence of appraisal methodology developed within the INFRACOMS project is presented and applied to two different technologies. They were mapped as promotional case studies. First, Section 2 presents a concept of the appraisal methodology, following its technical scoring system in Section 3. Section 4 is intended to apply the scoring system for two technologies: Bridge Weigh-In-Motion (BWIM) and COWI Digital inspection platform (CVI). For each technology, a brief description is given, followed by comments on the scoring results and emphasis on future areas of improvement. In the last chapter, the main conclusions from the paper are drawn.

2 APPROACH OF THE INFRACOMS PROJECT

The proposed INFRACOMS Appraisal Methodology is presented in Figure 1. The processes shown in orange boxes represent the core components of an INFRACOMS appraisal. The blue boxes are filtering and prioritisation processes, representing the ways in which the methodology can be tailored to individual NRAs.

An INFRACOMS appraisal has three (3) core processes with increasing levels of detail and complexity: a Pre-Evaluation, an Evaluation, and a Case Study. These core processes apply at the level of the technology use case. Although the appraisal focuses on a specific technology use case, the Pre-Evaluation and Evaluation stages are still considered generic and useful to any NRA considering applying that technology in a similar use case. Case Studies are normally conducted with an individual NRA and are more focused.

The pre-evaluation process is a high-level analysis of the anticipated benefits, limitations and costs and an assessment of the readiness level of the technology for a particular use case from the supplier's perspective. It also scores the technology for the particular use case against the key imperatives of the NRA. Pre-evaluation should be accomplished quite quickly (in perhaps 2 – 3 hours). It would require general knowledge of technologies and their applications and an understanding of the potential applications of the NRA.

The evaluation process is a more detailed breakdown of the technology's benefits, limitations, and cost factors within the proposed use case, including a more in-depth technical evaluation and an assessment of the steps required to implement it in an NRA. It provides an assessment of the readiness level of the technology from the NRA's perspective. Evaluation would take longer (perhaps 2 – 3 days of inputs). It would require input from a specialist or expert in the field and discussion with the technology supplier to gain a full understanding of the technology and its potential application for an NRA. Detail information on this can be found in Arvidsson et al. (2023b).

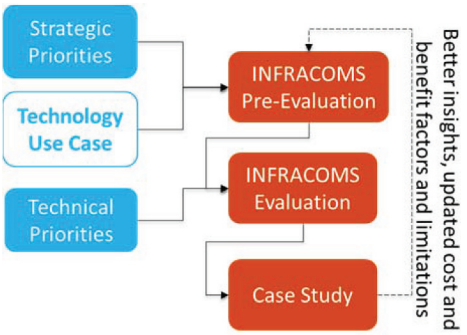

Figure 1. The concept of the INFRACOMS appraisal methodology.

Both the pre-evaluation and evaluation processes also consider the strategic and technical priorities of the NRA. The NRA must establish Strategic Priorities concerning the key imperatives that the NRA wishes to address using emerging technology. Four key imperatives were established in the first action of the project (Arvidsson et al. 2023a): safety, environment, socio-economic, and availability. The NRA must establish Technical Priorities to define its technical priorities concerning the capabilities for using and integrating technology. Four key components that were identified for use in a technical evaluation are (Arvidsson et al. 2023b):

- The need for associated data analysis
- Ease of data visualisation
- Potential for improvement in decision-making
- Ease of data integration.

The ranking between these priorities may differ for different NRAs. A technology may be less relevant for an NRA when it does not address any of the priorities.

3 INFRACOMS SCORING SYSTEM

The current paper focuses only on the technical evaluation of a technology found in the INFRACOMS appraisal methodology. The appraisal components in the technical evaluation include the following items as specified above: The need for associated data analysis, ease of data visualisation, potential for improvement in decision-making, and ease of data integration. Appraisal regarding cost and implementation in an NRA's organisation is for example, not considered in this paper.

The INFRACOMS technical appraisal includes a simple scoring mechanism to allow for the comparison of technologies. The above four components are scored from 1 (lowest) to 5 (highest), indicating the level of technological maturity and potential for improvement. Before scoring, the technology must be described in a specific format to inform the evaluator adequately. An example of the scoring mechanism for the appraisal of data visualisation can be seen below in Figure 2. There are 4 items that should be scored for data visualisation, namely:

- Does the technology come with a visualisation platform?
- Can visualisation data be extracted?
- Current state and prognosis?
- Compliance with client visualisation requirements for decision support?

The concept is that the evaluator will choose a box from each column that they believe best aligns with the current technology from their perspective. The final score is the average of all four items.

A radar diagram where each 'spoke' represents the technical score for a component provides a concise interpretation of the strengths and weaknesses of the technology in each of the

technical evaluation areas. Two practical examples of the scoring system are provided in the next chapter.

DATA VISUALIZATION				
DESCRIPTION OF ANALYSIS:				
FINAL SCORING	DOES THE TECHNOLOGY COME WITH A VISUALISATION PLATFORM?	CAN VISUALIZATION DATA BE EXTRACTED?	CURRENT STATE AND PROGNOSIS	COMPLIANCE WITH CLIENT VISUALIZATION REQUIREMENTS FOR DECISION SUPPORT
5 – Visualization provides complete information for decision support / gap closure	Yes, Technology comes with clear and useful visualisation platform. The platform requires some basic training.	Yes, The visualized data can easily be extracted and used for further analysis	The visualization provides information of current state and prognosis can be easily visualised within the platform	The visualization provided gives sufficient and clear information for decision support and open for future developments
4 – Visualization provides complete information for decision support, but some traning are required to interpretate visualization	Yes, Technology comes with clear and useful visualisation platform but the visualization requires detailed technical training to interpret results	Yes, The visualized data can easily be extracted and used for further analysis	The visualization provides information of current state. Prognosis and trends needs to be done manually but this does not require expert staff.	The visualization provided gives sufficient and clear information for decision support
3 –A visualization will provide information for decision support but work is required to develop this	No, But proper visualization/interpretation can be made using simple plotting tools which can generate 2D/3D plots. No specialized staff needs to develop the visualisation platform	Yes, Data can be extracted and used for further analysis but some work are needed to extract the data	The visualization provides information of current state. Prognosis and trends needs to be done manual but this work do not require expert staff.	If the data are visualized it provides sufficient and clear information for decision support
2 – Visualization provides information for decision support, but expert staff are required to interpret visualization	Yes, Technology comes with clear and useful visualisation platform but the visualization requires expert to interpret results	Yes, The visualized data can be extracted and used for further analysis but work from expert staff are needed to extract the data	The visualization provides information of current state. Prognosis and trends needs to be done manual by expert staff.	The visualisation provides information for decision support.
1 – Visualisation only provides partial information for decision support and expert staff are needed to interpret	No,In order to make proper visualisation complex programming are required (e.g. 3D-'as-is'-model based on photogrammetry, possibly paired with AI for automated identification of defects). Expert staff needs to develop the visualisation platform	Yes, The visualized data can be extracted and used for further analysis but work from expert staff are needed to extract the data	The visualization provides information of current state. Prognosis and trends needs to be done manual by expert staff.	The visualisation only provides partial information for decision support; there is a need for additional information

Figure 2. Scoring sheet for data visualisation.

4 APPLICATION OF SCORING SYSTEM

4.1 *Bridge Weigh-in-Motion system*

Bridge Weigh-In-Motion (BWIM) enables measuring the axle and gross weights of vehicles passing over a bridge in the free flow traffic (Moses, 1979, Žnidarič et al. 2017). This technology is based on the dynamic response of the bridge due to moving vehicles in terms of strains, measured with different sensors strategically placed under the bridge. The acquired data is then processed using specialised algorithms to estimate the vehicle data, i.e. gross vehicle weights, axle weight, axle spacing, velocity, etc. Data and information obtained by the BWIM system can be used for two different areas:

- Heavy traffic management.
- Bridge safety assessment.

One significant application of BWIM systems lies in managing heavy traffic. These systems identify overweight vehicles, ensuring the protection of road infrastructure. Moreover, by eliminating the need for vehicles to stop at weigh stations, BWIM facilitates smoother traffic flow. Additionally, it contributes valuable statistical data for traffic policymaking (Figure 3, left).

BWIM systems are also crucial for bridge assessment services, particularly in performing Soft Load Testing (SLT). SLT offers a cost-effective and efficient alternative to traditional load tests by utilising free-flowing traffic data without road closures. This method provides essential parameters for bridge assessment, including strains, influence lines (Figure 3, right), load distribution factors, and dynamic amplification factors.

The effectiveness of BWIM in both heavy traffic management and bridge safety assessment was evaluated using the INFRACOMS scoring system, providing insights into its efficiency and practicality in real-world applications.

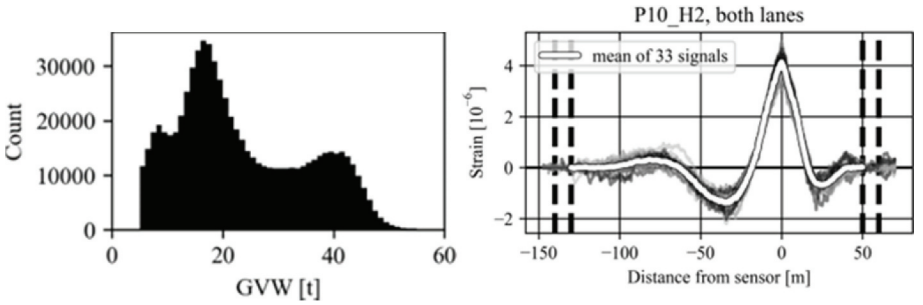

Figure 3. Gross vehicle weight (GVW) and strain data obtained by BWIM for Heavy traffic management (left) and for Bridge Safety assessment (right) (Hekič et al., 2022).

4.1.1 *Scoring results*

As mentioned, BWIM technology offers several layers of data and can be used for both pavements and bridges. The technology scoring was performed similarly, addressing pavement management and bridge management issues. Our findings show that BWIM scores, if we evaluate average ranking values of 2.5 for bridge safety assessment and 4.2 for heavy traffic management (Figure 4). Remember that a score of 5 is reserved for technologies that have achieved full development with little to no room for further advancement.

Although modest, the average score of 2.5 assigned to BWIM in bridge safety assessment has much potential to increase its score. The data for heavy traffic management scores particularly high in Data Visualization and Data Integration, indicating that it is well-suited for comprehensive analysis and seamless synthesis with other data sets. Conversely, the bridge safety assessment data shows lower performance, especially in Data Analysis and Data Integration, suggesting that while it is sufficient for practical decision-making, there is substantial room for improvement in its analytical and integrative capabilities. This suggests that while BWIM has significant capabilities, it demands additional involvement and advanced expertise from bridge engineers to enhance its relevance and improve its standing on the scoring scale.

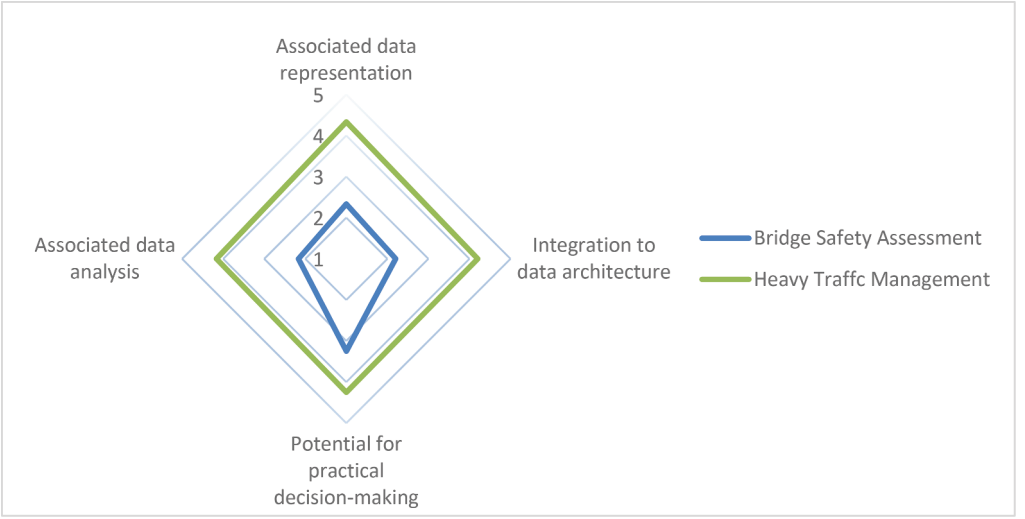

Figure 4. Scoring results for the B-WIM technology are shown on a radar diagram for two different applications.

4.1.2 *Future potential*

The future of BWIM technology is at a promising juncture, with vast potential for enhancing the operational efficiency of road networks. It is an indispensable tool in dual areas, such as Heavy traffic management and Bridge safety assessment. As described in Section 4.1.2, the B-WIM technology already automates key technical aspects like data analysis, visualisation, integration, and practical decision-making. However, for bridge safety assessment services, a gap remains in achieving the desired level of automation for its full practical deployment.

Looking ahead, the modular architecture of the BWIM system harbours the capacity for substantial upgrades, potentially transforming it into a comprehensive Structural Health Monitoring (SHM) system. Its ability to connect a diverse array of sensors and draw a direct correlation between vehicle impact and the consequent structural response — deformations, accelerations, or displacements — sets it apart from other SHM systems. Integrating bridge assessment expertise can unleash the full spectrum of BWIM capabilities, making it an even more powerful instrument in the infrastructure monitoring and maintenance domain. The future enhancements are not just incremental but could mark a paradigm shift in how bridge health is monitored, with BWIM technology offering this advanced step.

4.2 *Digital inspection platform*

The lifetime of structures such as bridges depends on how good we are at maintaining them. If we can postpone decommissioning, we can save massive amounts of time and natural as well as financial resources. An important step in extending the lifetime of structures is to perform reliable and accurate inspections. Traditional inspections are challenged by traffic restrictions, high initial costs (rope access, platform, lift, etc.), subjectivity, and consistency in documentation and working conditions. Establishing a Reality Capture Model or Virtual Twin is important in optimising inspections and moving towards a digital transition within bridge asset management. The model is created from photogrammetrically processed images efficiently collected using camera-mounted unmanned aerial vehicles (UAV).

Within the INFRACOMS project, a case study of digital inspection was taken into account, where COWI's Virtual Inspection platform (CVI) was used. It uses of UAV and artificial intelligence to create a given structure's virtual twin and detect deterioration. The data reveals the structural condition, enabling you to plan for and handle issues while they are still minor and easy as well as inexpensive to correct. By gathering all data in one platform, you can access the full overview from any location and perform your virtual inspections from the office.

First, drones capture high-quality images of the entire structure's surface, which are used to create a photorealistic 3D model. Using a combination of normal colour photography and thermographic images enables you to see "hidden" defects not always visible to the naked eye,

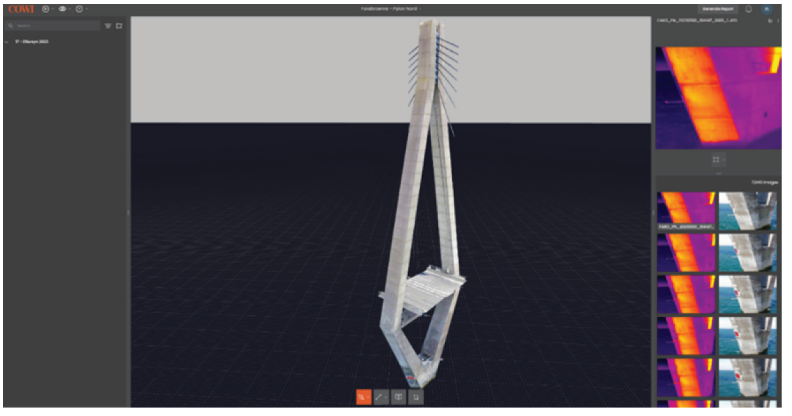

Figure 5. The COWI Virtual Inspection platform illustrates the bridge pylon, where a thermographic camera is used to detect hidden defects.

like delaminated concrete or water seepage. Next, the data is processed, and artificial intelligence is used to detect the defects. Bridge inspection experts then qualify the defects that require repair or further follow-up. All information is gathered in a web-based platform, where data can be shared or revisited at any time.

Inspections using drones on large bridges can significantly reduce the need for lifts, boats, climbing, and rappelling equipment and thereby optimising the inspection process both in terms of safety cost and reliability

Drones with thermography camera provide greater possibility to collect data from the entire structure than hammer tapping, which often only collect data from selected random samples (Figure 5). Direct coupling between photos and geographical position facilitates tracking the development of defects at later stages. Unlike in traditional surveys, where defects are often grouped and only one or few typical pictures are taken for each group, in the COWI Virtual Inspection Platform, pictures are taken for every individual defect.

4.2.1 *Scoring results*

The CVI platform is scored using the INFRACOMS scoring system in the Figure 6. The INFRACOMS scoring is done on a case where the CVI platform was used on a large bridge in Europe.

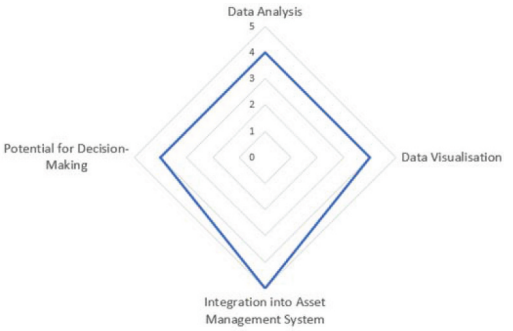

Figure 6. Scoring results for the COWI virtual inspection platform on a radar diagram.

Data visualisations - A 3D Reality Capture Model is created automatically by CVI containing annotated defects and it also includes all RGB – and thermal images. By clicking on any part of the generated 3D model, the 30 best images for the selected spot are shown in a picture panel. In addition, a conventional PDF report is generated in CVI. The report includes a written summary and an auto-generated description of findings based on annotations with additional photos of the defects

Data analysis - Crack detection is performed automatically using a well-trained AI algorithm. An expert, however needs to review and confirm be identified cracks.

Integration into asset management system - In the current case, the data from CVI was not integrated into an existing asset management system. All collected data, including analysis results and expert assessments, where centralised in a web-based platform, facilitating seamless collaboration and data sharing among stakeholders

Potential for decision making - Structural experts need to evaluate the severity and repair urgency of detected defects, enabling informed prioritisation for efficient maintenance planning to ensure that repairs are made at the optimal point in time. Future RCM models can be compared to previous models to identify new defects and defect development to ensure that repairs are made at the optimal point in time. The CVI will improve the quality assurance (QA) process since you have a complete view of the structure and not only pictures taken at locations which are selected by the engineer who is performing the inspection.

4.2.2 *Future potential*

Trials are currently being conducted using smartphones to broaden the use of CVI to smaller structures. While smartphone cameras possess adequate resolution, challenges persist in achieving a finely detailed resolution crucial for precise positioning. This high level of detail is essential for generating a functional 3D model while merging the captured images.

5 CONCLUSIONS

This paper has presented a scoring system for the technical evaluation of technologies which can be used in remote bridge monitoring applications. This scoring system is part of the technology appraisal concept developed within the framework of the INFRACOMS project. It focuses on four key areas: data analysis, data visualisation, decision-making potential, and data integration. These criteria are crucial for assessing the viability and effectiveness of technologies. Two technologies were mapped as appropriate for showcasing the scoring system, i.e. bridge weigh-in-motion systems and digital inspection platforms.

Our findings reveal that each technology has distinct strengths and limitations, as evidenced by the case studies. For instance, bridge weigh-in-motion systems demonstrate high utility in heavy traffic data management but indicate a need for improvement in bridge safety assessment applications since, at this point, it requires the full engagement of the bridge safety assessment experts. This understanding is critical for bridge owners and asset managers to make informed decisions that align with their strategic and technical priorities. Digital Inspection Platform already provides benefits for the landscape bridges at this stage. On the other hand, to scale its application for the whole bridge stock, there should be development in the area of smartphone usage and simplification with respect to the importance of the structure in the whole transport network.

Looking ahead, this scoring system lays the groundwork for more advanced studies and the integration of emerging technologies in the field of bridge or asset management. It holds the potential to guide future research, fostering innovations that further enhance the efficiency, safety, and sustainability of infrastructure management.

ACKNOWLEDGEMENTS

We acknowledge financial support from the Slovenian Research Agency through the research programme No. P2-0273 and Slovenian Motorway Agency (DARS) to provide data for the case study analysis.

Regional impacts of natural disasters on road bridges in the Philippines

M.J. Adarne & M. Henry
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: Bridges serve as a vital infrastructure that links the Philippines' island and mountainous regions and promotes trade, quality of life, and movement of people. However, these bridges are susceptible to natural disasters such as typhoons, earthquakes, and floods, representing significant hazards and resulting in temporary or permanent disruptions to the economy and people's lives. Therefore, this research aims to assess the impact of natural hazards on road bridges in the Philippines at the regional level by analyzing two years of government-collected data for 2020 and 2021. It will investigate the physical damage that these natural hazards bring to bridges, as well as the financial losses incurred by bridge infrastructures due to these natural calamities and compare the results across regions. Understanding the effects of natural disasters and how they vary between regions will help agencies responsible for bridge management in developing a strategy to mitigate those effects and prepare for the economic implications.

1 INTRODUCTION

The Philippines has placed a significant emphasis on infrastructure development in recent years, acknowledging its critically important purpose as the foundation of the economy, a driver of social activities, and a facilitator of increasing levels of interconnection among various regions, islands, cities, and provinces. Infrastructure investment increased from 3% of GDP on average between 2011 and 2016 to over 5% in 2018, with the goal of reaching over 6% (MGS Insurance, 2022). To facilitate the movement of people, goods, and services throughout the archipelago, roads and bridges connect metropolitan centers, remote provinces, and rural communities in the sixteen regions of the Philippines. The transportation of products and tourists across regions sustains economic growth by supporting industries, agriculture, and tourism. In addition, these infrastructure projects will ensure that rural populations not only benefit from better connections to essential services such as healthcare and education but also facilitate access to these benefits for rural people (DPWH Atlas, 2022). In all sixteen regions, roads and bridges stimulate socioeconomic development by promoting integration and seamless connectivity.

Bridges serve an essential role in connecting islands and regions while also playing an important part in natural calamities and disaster preparedness. One of their critical tasks is to maintain a connection with areas impacted by disasters, making them a vital lifeline during these times of need. By providing connectivity, bridges facilitate rapid emergency response activities and contribute to saving lives and minimizing the impact of disasters on affected communities (Utilities One, n.d.). Therefore, bridges are needed to support rapid emergency response activities, especially when access to crucial services, rescue operations, and critical operations is hampered due to the isolation of certain islands, cities, and areas. However, it should be noted that these crucial infrastructures are not immune to the adverse impacts of natural disasters. This vulnerability is underscored by the country's notable position as the 8th

DOI: 10.1201/9781003483755-359

highest on the global risk index and its designation as the 9th most disaster-exposed country, according to the World Risk Report (World Risk Report, 2021). In 2021, the country's total cost of damages caused by natural disasters exceeded 60 billion pesos or 1.1 billion USD (Statista, 2021). The speed at which a nation recovers from a disaster is influenced by its level of development (Taghizadeh-Hesary et.al, 2019). Developing countries, like Philippines, are generally more susceptible to and more severely affected by natural disasters of all varieties than developed countries. As a result, the average citizen's welfare is further compromised (Cavallo et.al, 2009).

The present study aims to identify regions susceptible to various types of bridge damage resulting from natural disasters through data collection. Data was obtained from the Bureau of Maintenance (BOM) of the Department of Public Works and Highways (DPWH) regarding natural disasters that have damaged bridge infrastructures in the Philippines, together with the estimated cost of damages for the years 2020 and 2021. Data cleaning was done, and different types of bridge damage caused by natural disasters were identified, together with an estimate cost of damage. The results offer significant contributions to future readiness efforts by facilitating the development of mitigation strategies that allocate and prioritize resources strategically, with a particular emphasis on bridge structures that are susceptible to damage in areas susceptible to disasters.

2 RESEARCH METHODOLOGY

2.1 *Research data*

This study used data from BOM, DPWH obtained from 16 Regional Offices (R.O) and reported by their corresponding District Engineering Offices (DEO). The condition of the bridge structure prior to the occurrence of natural disasters is not determined. However, the damages that occurred to bridge structures prior to natural disasters are collected and reported. The geographic location of each region within the Philippines is illustrated in Figure 1. Following natural disasters, the maintenance division of DEO conducts an inspection, records the physical damages subjectively, and estimates the cost of such damages. These damages typically consist of road slips, potholes, landslides, scouring, base failure, bridge and road protection damage, and other infrastructure-related issues.

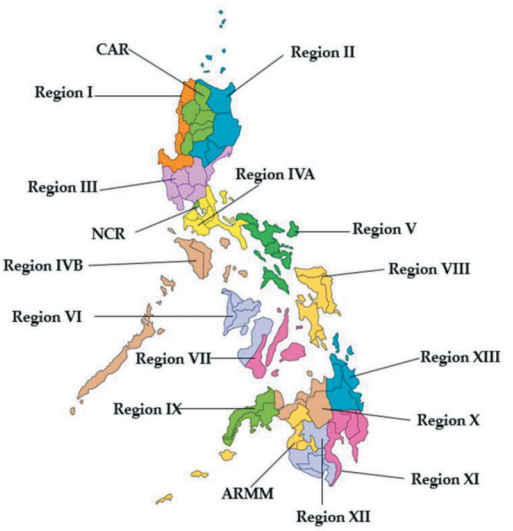

Figure 1. Map of the Philippines with regions (Nnadari et.al 2021).

2.2 *Description of damages*

In 2020 and 2021, 82 different types of bridge structure damages were identified as the result caused by natural disasters. The damages were categorized into three distinct groups: the superstructure damages group contained 37 different types of damage, the substructure damages group contained 17 different types of damage, and the bridge protection damages group contained 28 different types of damage. This categorization facilitated the identification of the specific components of the bridge structures that were most susceptible to damage in the event of such natural disasters.

2.2.1 *Superstructure*

The upper portion of the bridge comprises structural elements above the bearings that support the deck, and these damages can potentially compromise the bridge's stability (Fontanez, 2021). Since this section is always exposed when infrastructure is damaged by natural disasters, this section of the bridge is more susceptible to damage.

2.2.2 *Substructures*

Damages that affect the structural components below the bearings, including piers, abutments, and foundations, are referred to as substructure damages (Fontanez, 2021). This particular section of the bridge is frequently subjected to flooding and scouring caused by excessive rainfall. In addition, the materials typically used in this area consist of masonry and concrete, which are susceptible to deterioration under various natural conditions.

2.2.3 *Bridge protection*

To ensure the bridge's longevity and avoid damage, structures that protect them from natural disasters are important. To prevent structural damage from natural disasters, it may be necessary to install riprap slope structures, stone masonry, and scour preventative measures, all of which are expected to receive damage initially (Harasti et.al, 2021). Bridge protection is undertaken with the goal of helping preserve bridges.

3 RESULT AND DISCUSSION

3.1 *Road infrastructure damage events in 2020 and 2021*

The frequency of infrastructure damage for the years 2020 and 2021 is presented in Table 1. The data shows that natural disasters caused a greater number of infrastructure damages in 2020 as compared to 2021. It can be seen that there were 2,778 instances when infrastructures were damaged by natural disasters, with road infrastructure accounting for 1,670 (60%) of the total number of damage events, bridge infrastructure for 245 (9%), and other infrastructures, including flood control, school buildings, etc., comprising 863 (31%).

Table 1. Total number of infrastructure damages for the years 2020 and 2021.

Types of Infrastructures	2020	2021	Total	Percentage
Total data	1,473	1,305	2,778	100%
Road	832	838	1,670	60%
Bridge	147	98	245	9%
Other Infrastructure	494	369	863	31%

After cleaning the two-year data, 245 damage events of bridge structures were identified. Two damage events were determined to have missing data, making up 1% of the total number of damage events in the data. The absence of these two data points in the analysis can be attributed to the lack of specific information regarding the type and extent of the damage. While there were reported incidents of damage in the area, the exact details were not recorded. As a result, these

missing data points were not included in the analysis due to the absence of recorded information regarding the type and scope of the damage. Following that, considering the significance of traffic conditions during repairs, bridge structure defects were classified into three different groups: superstructure, substructure, and bridge protection, as previously explained. Additionally, it was discovered that while there have been recorded instances of bridge damage in Regions IX and XII, there are no reported incidents for the years 2020 and 2021.

As shown in Table 2, bridge structures were affected by four types of natural disasters over this period of two years. The frequency distribution of damage events indicates that typhoons caused the greatest number of road bridge damage in 2020 and 2021, accounting for 86% of the total, whereas tropical cyclones accounted for 11%.

Table 2. Number of occurrences of natural disasters that caused damage to bridge structures, N=245.

Natural Disasters	2020	2021	Total	Percentage
Tropical Storm	0	27	27	11.0%
Typhoon	141	70	211	86.1%
Continuous Rain	0	1	1	0.4%
Earthquake	6	0	6	2.4%

Although the overall data indicates that the bridge structures constituted a lower percentage of damage events, it is important to take a wider range of factors into consideration before concluding that they are less vulnerable. The particular information like the intensity of the impact of disasters, the kinds of damage, and the local conditions are all important factors in determining the vulnerability of the infrastructure.

3.2 *Regional distribution of bridge structure damage events*

Figure 2 illustrates that, in comparison to all other regions, Region V, Region VII, and Region II experienced the highest number of damage events in bridge structures as a result of natural disasters. Region V, also referred to as the Bicol Region, experienced 117 bridge-damaging events (48% of the total number of damage events in 2020 and 2021), and it's also been reported that the Bicol Region is characterized as having a significant number of potentially damaging wind speeds (Thinkhazard.org., 2020). In addition, its frequent cyclones and

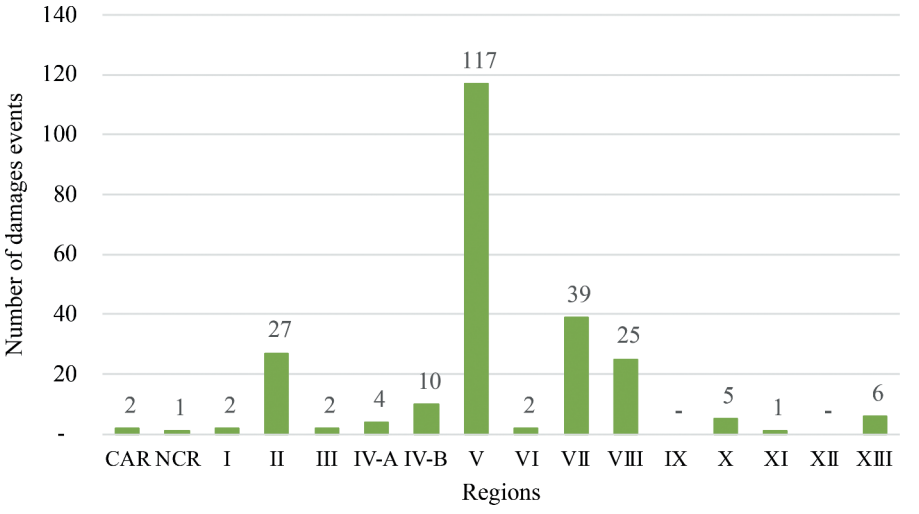

Figure 2. Number of bridge structure damage events due to natural disaster by region.

floods contribute to its location as one of the most disaster-prone areas due to its geophysical locations (preventionweb.net., 2022).

The Central Visayas region, specifically Region VII, experienced the second-highest number of damage events, with 39 events (16%) recorded in 2020 and 2021. This high incidence of bridge damage can potentially be attributed to the unique geographical composition of the area, which includes several outlying islands, one main island, and one smaller island. Additionally, the interior of the region's provinces is characterized by expansive highlands, while the coast features narrow strips of arable land. A significant portion of the province's land area, accounting for 62% of the total, is hilly and mountainous. Consequently, the susceptibility of bridges in this region to damage events may be heightened due to these geographical factors (Arkipelago, 2020).

Region II, generally known as Cagayan Valley, experienced 27 damaging events (11%) in bridge structures due to its geographical location along the Pacific Ocean, making it prone to frequent typhoons. The region's diverse topography, including plains, mountains, and a major river system (Cagayan River), contributes to heightened flooding risks and landslides, particularly during the typhoon season. Heavy rainfall is caused by the tropical environment and being in the path of typhoons, increasing these hazards. The region's economic reliance on agriculture increases the effects of natural disasters, making adequate risk mitigation and disaster preparedness measures critical (Cuntapay A.B., 2015).

3.3 *Physical damage to bridge structures due to natural disasters*

Since the physical or actual damage was divided into three groups, the percentage of damage for each group was calculated by dividing the number of actual damage occurrences within that group by the total number of damage events recorded during the specified period. As per data in Figure 3, the largest number of damage to bridge structures in 2020 and 2021 in the Philippines was found for superstructures, which was observed in 45.7% of the damage events. This indicates that superstructures were most susceptible to damage during this time frame. Bridge protection incurred the second-highest percentage of damage at 44.4%, while substructure damages incurred the least at 21.8% of the total damage event.

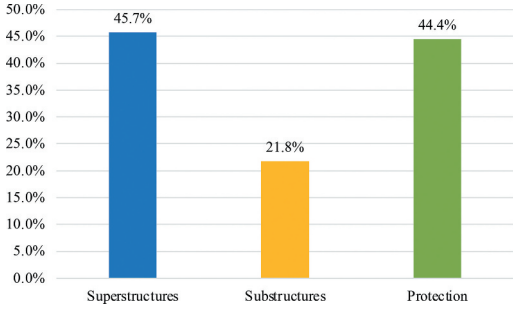

Figure 3. Percentage of damage events for which each type of damage was observed.

After a thorough analysis of the regional implications of bridge damages, it is evident that Region V greatly impacted the structural integrity of bridges. During the combined period of 2020 and 2021, Region V accounted for 18.1% of superstructure damage, 8.2% of substructure damage, and 17.7% of bridge protection damage, as depicted in Figure 4. These percentages were derived by calculating the actual group of damages experienced by Region V, divided by the total of 243 recorded damage events within the specified time frame. Additionally, Region V is the one that is most impacted by all three categories of disasters. This illustrates how much the bridge structures in this area were impacted by natural calamities. Region VIII, which accounted for 8.6% of superstructure damage, follows closely to Region V in terms of superstructure damage. However, Region VIII's substructure and bridge protection damages were comparatively smaller, making only 1.2% of the overall damages. It's interesting to take into account that, at 8.2%, Region VIII came in second for contributing to damages to bridge protection. These results

demonstrate how susceptible bridges in Region V are to natural calamities and the necessity of preventive measures and specific attention to increase their resilience. It also highlights how important it is to take certain geographic areas into account when developing mitigation strategies for reducing and dealing with natural disaster-related bridge damage.

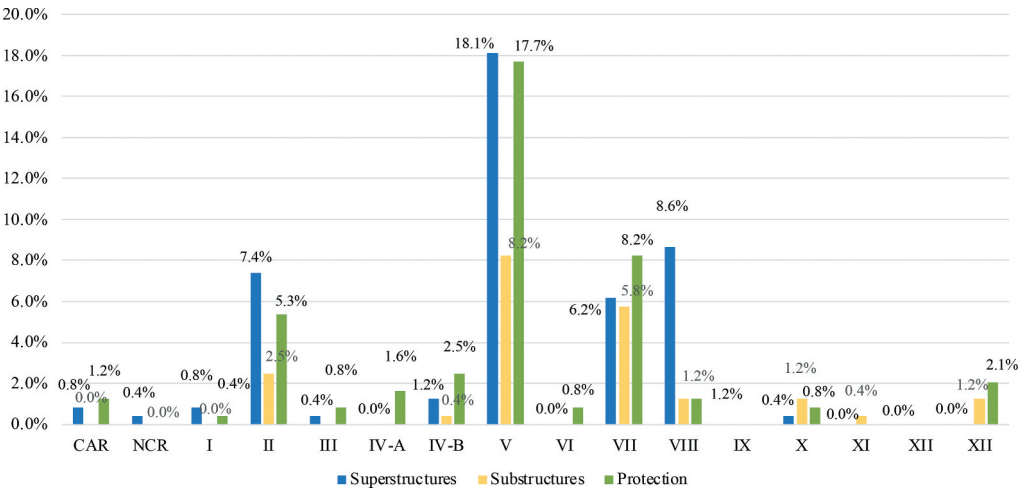

Figure 4. Percentage of damage events in each region for which each type of damage was observed.

3.4 *Estimated cost of damages to bridge structures*

Figure 5 shows the total estimated cost of damages to bridges caused by natural disasters in each region for the years 2020 and 2021. It can be observed that Region V suffered the highest estimated cost of damages, amounting to Php 1,254.1M, followed by Region II with Php 252.8M and Region VII with Php 160.0 M. Evidently, Region V has the highest estimated cost of damages as well, given that it suffered the highest percentage of damages, as shown in Figure 3. After reviewing Figure 3, it becomes apparent that Region VII incurred a greater proportion of cost damages in comparison to Region II. However, an examination of the financial implications of these impacts, as illustrated in Figure 5, shows an interesting finding. Despite Region VII experiencing a greater number of natural disasters and sustaining a larger number of damages in Figure 2, it was actually Region II that incurred a higher estimated cost of damages than Region VII.

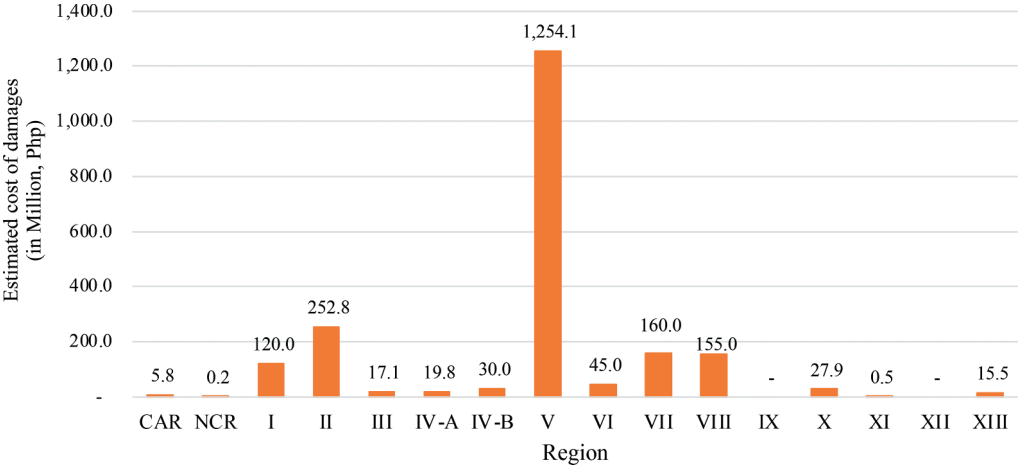

Figure 5. Percentage of the estimated cost of damage per region in the year 2020 and 2021.

One possible explanation for this discrepancy is that the severity and scale of the disasters in Region II were more significant. Even though Region VII had a greater frequency of events, factors such as the severity of typhoons, the vulnerability of infrastructure, and the specific types of natural disasters can all contribute to variations in the economic impact on different regions. All these factors must be considered when evaluating the economic impacts of natural disasters on different regions. Merely estimating the amount or percentage of the damages sustained might not offer a comprehensive understanding of the actual cost incurred. Gaining insight into the socioeconomic factors that extend beyond mere frequency may help in a more accurate assessment and mitigation of the financial impact of natural disasters in particular regions. By considering the severity and specific characteristics of natural hazards in each region, policymakers and stakeholders can develop more targeted strategies to mitigate the economic impact of future disasters and allocate resources effectively for post-disaster recovery and reconstruction efforts.

4 CONCLUSION

Based on a study investigating the impact of natural disasters on the infrastructure of the Philippines in 2020 and 2021, it was found that bridges experienced less damage than road structures. In addition, bridges also had a lower occurrence of structural damages when compared to road structures. These findings highlight the relatively better resilience of bridges in the face of natural disasters as compared to road structures. Moreover, the comparative susceptibility of bridge structures to road structures depends on various conditions, relying solely on the percentage of damage events may not accurately represent the structures' overall vulnerability.

In terms of damage distribution among regions, Region V has seen much more extreme damage events, with the greatest impact on bridge structures, resulting in a significant number of damages. As a result, this region suffered the most damage to bridge structures and the highest estimated cost of damages compared to any other region.

Another key observation is that Region II experienced more severe financial implications despite having a lower number of damages to bridge structures compared to Region VII. This suggests that the severity of the damage in Region II was greater. It is essential to note that the number of damages does not always correlate with the financial losses, as factors like damage type, severity, and location can significantly influence the financial implications.

Furthermore, when assessing the impact of natural disasters on different regions, it is important to consider the economic growth and overall state of each region's economy. Road authorities must evaluate multiple factors, including geographic location, magnitude of the natural disasters, current economic conditions, and infrastructure status in the affected regions. Taking a comprehensive approach will help in developing evidence-based strategies and efficiently allocating resources for future loss mitigation and post-disaster recovery.

Examining the economic factors provides a broader understanding of the financial implications of the damages. The growth and stability of a region's economy can influence the ability to fund repairs and recovery efforts effectively. Regions with stronger economies may be better equipped to allocate resources towards infrastructure repairs, while regions with weaker economies may face more significant challenges in addressing the damages. Hence, policymakers and stakeholders should analyze these underlying factors rather than solely relying on the number of damages. By taking a holistic approach, they can develop evidence-based strategies and allocate resources efficiently. This comprehensive perspective will help mitigate future losses and facilitate a more effective post-disaster recovery.

The research promotes awareness and knowledge of transportation infrastructure damages and the cost implications of road infrastructure damages caused by natural disasters. This paper will provide useful information to experts, relevant government agencies, construction industries, and the general public in order to decide on appropriate countermeasures or mitigation strategies for the transportation infrastructure and to better prepare the budget for the future maintenance of road infrastructures, allowing for a quick and timely response during and after natural disasters. Additional data from previous years will also need to be incorporated into the research to investigate the overall pattern of road infrastructure damage caused

by natural disasters. Furthermore, it is strongly advised to conduct additional regional studies and consider the condition of each road infrastructure as well as the magnitude of natural disasters to acquire a greater understanding of road infrastructures and create possible solutions on how to reduce the vulnerability of road infrastructure.

5 RECOMMENDATION

Investing in high-resolution camera-equipped drones can significantly benefit the Regional and District Engineering Office of DPWH in the Philippines for assessing bridges after natural disasters. Drones offer a cost-effective and efficient solution, providing a comprehensive aerial view and real-time data capture of bridge conditions in affected areas. Equipped with LiDAR sensors, these drones allow for detailed 3D scanning of bridge structures, facilitating accurate evaluation of damages. By swiftly deploying drones, the DPWH can make timely decisions regarding repair and rehabilitation efforts, optimizing resource allocation within budget constraints. This technology enables faster response efforts, facilitates prioritization of maintenance activities, and ultimately aids in the speedy recovery and functionality of bridges in the aftermath of natural disasters, enhancing disaster preparedness and resilience efforts.

ACKNOWLEDGMENT

The authors would like to thank the Japan International Cooperation Agency (JICA) for their support through the Road Asset Management Platform (RAMP), the Shibaura Institute of Technology (SIT) for providing the environment for the research, The Department of Public Works and Highways (DPWH), Philippines for sharing the data and information needed and the Unified Project Management Office (UPMO), DPWH for their warm support.

Improved structural assessment of Newport Bridge using smartphone-based technologies

J. Winkler
Digital Engineering Solutions – DES & AtkinsRéalis, Warsaw, Poland

N. McKay
AtkinsRéalis, Stockton, UK

C. Hendy
AtkinsRéalis, Epsom, UK

ABSTRACT: The ongoing operation & maintenance costs regarding physical infrastructure are extremely high and asset owners continue to experience budgetary constraints. One of the biggest challenges is a lack of practical tools and low-cost solutions for structural health monitoring. However, developments in smartphone technologies have opened new opportunities for optimizing bridge inspection including rapid data collection on asset health. Bridge inspectors can use smartphones during visual inspections vastly improving accessibility and efficiency. The Tees Newport Bridge is a vertical-lift road bridge in England. Bridge inspection revealed that the bearing and bearing support steelwork had failed leading to joint displacement and impact on road users crossing the bridge. AtkinsRealis was called to carry out the assessment and evaluate bridge safety. This paper shows how smartphone-based applications were used for scanning, creating 3D photogrammetric models and monitoring of bridge deformations to understand structural response to the bearing failure. To the authors knowledge this is one of the world's first examples where regular smartphones were used for generating the 3D model of a complex bridge and also for capturing and analyzing structural displacements with mm-accuracy. Low-cost, smartphone-based tools are potentially game-changing with respect to structural health monitoring and asset condition reporting, enabling engineers and clients to manage their assets as efficiently and safely as possible.

1 INTRODUCTION

1.1 *Description of structure*

Tees Newport Bridge is located between the A66 and the A19 and carries the A1032 two lane dual carriageway and associated footpaths over the River Tees with Stockton-on-Tees to the west and Middlesbrough to the east. The structure comprises 11 spans and was constructed circa 1934. Lifting span is simply supported, 80m long between the centres of the bearings and approximately 20m wide. It comprises a pair of primary Pratt trusses with curved top chords, connected by bracing frames. The span is connected to lifting girders which are suspended by 80 steel cables (or "ropes"), in 8 groups of 10, which pass over sheaves at the top of the towers and connect into counterweights on the other sides. There are four groups of cables and two counterweights at each corner of the lifting span. The roadway is carried by a steel frame deck comprising secondary transverse girders spanning between the primary trusses, with longitudinal tertiary girders between each transverse girder. Quaternary transverse girders span between the tertiary longitudinal girders to provide support to the mass concrete, non-composite deck (Figure 1).

DOI: 10.1201/9781003483755-360

Figure 1. The Tees Newport Bridge.

1.2 *Context and client issues*

During the mid 20th Century the bridge was in constant use and would be lifted twice daily. However, this gradually declined, and upon the construction of the Tees Barrage approximately 1.5 miles upstream, the need for lifting the deck ceased. The last known lift occurred on 18th November 1990. The route over the bridge nevertheless continued to see large volumes of traffic. North shore industry along the bank of the Tees saw much commuter traffic and this continued throughout the latter part of the century, even following the construction of the A19 Tees Viaduct that crosses the river just south-west of Tees Newport Bridge. Daily traffic volumes continue to be high with Annual Average Daily flows of circa 20,000 vehicles.

In 2023, bridge inspection revealed that the bearing and bearing support steelwork had failed leading to joint displacement and impact on road users crossing the bridge. In addition, the condition of other key elements including the remaining bearings, buffer mechanisms and lifting cables became a concern as the support conditions changed following the bearing failure (Figure 2). Reports of "locking off" the bridge deck following its last lift in 1990 indicated that load in the cables may have been removed or reduced. Subsequent inspection of the tower steelwork indicated that this wasn't in fact accurate. Angles connected to the tower legs above the main deck prevented the deck from lifting excessively. However, with only upward movement restricted and a gap of around 40mm between deck and angle lock off, the deck was still carried by the vertical cable runs passing over large sheaves at the head of each tower and connecting to the counterweight system. The counterweight system was indeed finely balanced with approximately 90% of the total permanent load from the deck passing into the cables. The remaining 10% supported on the rocker bearings and transferring approximately 20 tonnes of load into each supporting pier.

Failure of the north-west bearing and support steelwork led to downward displacement of the deck and this was seen along the comb joint across the width of the bridge at this end. With the deck so finely balanced and significant load taken by the cables, any forward mitigation would need more comprehensive understanding of associated movement under live load. As an immediate measure traffic was directed away from the north side of the bridge through lane closure and towards the central section of the bridge. The finely balanced support conditions and complex structural arrangement presented a logistical headache when considering potential mitigation methods.

2 SPECIAL INSPECTION

The initial bridge inspection was followed up with special inspection (SI) of the bearing and this was carried out by AtkinsRealis in April 2023. The inspection identified the full extent of

Figure 2. Inspection images of the cables and the bearing assembly post-failure.

the problem in terms of collapsed stool and fracture throughout most of the stool width. In addition, there was a clear gap at the head of the bearing indicating that the deck was supported entirely on the cables at this corner. The inspection also considered the condition of the fixed end bearing assemblies at the east end of the bridge and the corresponding condition of the south-west bearing at the free end. Whilst the condition at the fixed end indicated corrosion of key elements these remained relatively intact and serviceable. The bearing assembly at the south-west corner however indicated similar deterioration mechanisms as that at the north-west corner although not as severe. Nevertheless, it was clear that stabilizing the deck under load as an initial measure would require work to both corners at the west end of the bridge.

To support the SI a 3D photogrammetric scan was undertaken using LIDAR enabled iOS device. Inspectors carried out the scan from below the bridge obtaining access to the pier head. Scanning included pier head, bearing and original buffer assembly. Access to the south of the assembly was restricted by the deck steelwork however sufficient data was obtained from the remaining 3 sides of the assembly. The scan has enabled holistic condition appraisal of the assembly as well as basic measurement of key dimensions including collapsed bearing stool height, gap between bearing and deck soffit, deck steelwork dimensions, etc. The 3D scan has proved invaluable in supporting the contractor in designing and locating temporary jacks as well as providing valuable data for the replacement bearing design.

3 MOBILE DIGITAL IMAGE CORRELATION (DIC) SURVEY

Understanding of the deck movement under load was critically important and this was true to understand structural response post bearing failure but also structural response to temporary jacking. As such, monitoring was required. In advance of jack installation and more comprehensive physical monitoring, deployment of mobile Digital Image Correlation (DIC) was carried out. AtkinsRealis started to use DIC technology in structural health monitoring in 2014 (Winkler et al. 2014) and continue to expand the use of this technology in recent years

(Winkler et al. 2022). AtkinsRealis carried out a basic movement monitoring for all four corners of the bridge in May 2023.

3.1 *Methodology and equipment*

The method uses a smartphone mounted on a tripod, at a static position. The phones camera picks up two points, a static point used as a datum and an active point which moves under dynamic load. The ISO certified software developed by Digital Engineering Solutions (DES) records a video of the load moving over the bridge and calculates the relative displacement between the static and active points and presents the information on a graph of displacement against time (Figure 3).

Figure 3. Mobile Digital Image Correlation (DIC) survey.

The survey (data collection and video analysis) was carried out successfully using a regular smartphone by an engineer with no prior monitoring experience proving scalability and easiness of use of the smartphone based DES technology. Survey was susceptible to shadow at a pixel level, however it can be considered a useful in determining the extent of movement above and below the bridge, under normal traffic.

4 RESULTS

4.1 *North-West corner*

Figure 4 shows movement of the north-west corner buffer while Figure 5. shows peak movement of the expansion joint (approx. 10mm) at the nearside lane position.

The results support the theory of the movement being predominantly at the north-west and south-east corners. At the north-west corner, it was noted that the range of movement under heavy traffic was not sufficient to close the approximately 60mm gap above the northwest bearing, suggesting the deck is predominantly free and supported on the buffer, acting as a spring support, in combination with the cables.

4.2 *Full scale monitoring*

Deployment of full scale structural health monitoring was conducted before the jacking operations at the north-west corner of the bridge. Preliminary findings from the mobile DIC survey indicated the extent of movement expected at each corner both upward and downward in response to traffic load. It is clear when comparing the full monitoring output to the DIC output that the magnitude of movement under load is consistent.

Figure 4. North-West corner buffer movement.

Figure 5. North-West corner expansion joint movement.

5 CONCLUSIONS (KEY BENEFITS & SUCCESS FACTORS

Bridge inspection of the Tees Newport Bridge revealed that the bearing and bearing support steelwork had failed leading to joint displacement and impact on road users crossing the bridge.

AtkinsRealis was called to carry out the assessment and evaluate bridge safety. It has been demonstrated that smartphone-based applications can be successfully used for scanning (15 min to capture images), creating 3D photogrammetric models and monitoring of bridge deformations to understand structural response to the bearing failure. Ease of deployment of mobile DIC and early value of movement information in supporting the decision to keep the bridge open to traffic should be emphasized. To the authors knowledge it was one of the world's first examples where regular smartphones were used for generating the 3D model of a complex bridge and also for capturing and analyzing structural displacements with mm-accuracy. Low-cost, smartphone-based tools are potentially game-changing with respect to

structural health monitoring and asset condition reporting, enabling engineers and clients to manage their assets as efficiently and safely as possible.

Artificial intelligence to identify defects on bridges inspected by drone

S. Flawinne
Public Service of Wallonia, Liège, Belgium

ABSTRACT: Drones and artificial intelligence are fast-growing technologies that offer considerable potential for the inspection of large, high-rise structures, such as viaducts. Drones can lead to safer and more economical inspections. Several years ago, Belgium's Service Public de Wallonie (SPW) began carrying out full drone inspections of its major structures. This survey includes photos, 3D model, orthomosaics of defects and database of defects.

The advantages of drone inspection are numerous. It allows precise visualization of hard-to-reach areas, as well as global analysis directly from orthomosaics. It also enables full digital documentation of the defects via the database.

However, the number of defects identified on large-scale structures can be extremely large. Manual detection of all these defects is time-consuming. So the SPW is now working with an artificial intelligence solution that can automatically identify defects in the structure on photos and positioning defect contours on 3D CAD models of the bridge.

1 INTRODUCTION

Drones are an emerging technology that holds significant potential for inspecting tall and large structures such as bridges and viaducts. Compared to traditional visual inspections, the use of drones can be safer and more cost-effective, avoiding indirect costs associated with road closures and the rental of inspection lifts. However, detection of all the defects identified on large-scale structures can be extremely time-consuming. Artificial intelligence is a solution that can help solve this operation much faster and more efficiently.

2 INSPECTION OF LARGE BRIDGES BY DRONE

To assess the feasibility and limitations of using drones for inspecting large structures, the Public Service of Wallonia has initiated test projects on four viaducts.

For each viaduct, a drone inspection was conducted, including:

- Capturing photos of each defect
- Creating a 3D model through photogrammetry
- Generating orthophotos with defects outlined and sorted by layers, all at a millimeter-scale photo resolution
- Compiling a database documenting all defects by type and location

The requested ground sample distance (GSD) for both photos and orthophotos is a minimum of 1mm. This means that each side of a pixel in a photo or orthophoto will have a maximum length of 1mm. The GSD will be calculated using the Equation 1 below: $R = Tp{*}H/p \leq 1\ (mm)$

Where:

- R is the ground sample distance (GSD)
- Tp is the size of the photosite in mm (pixel size on the sensor of the camera used)

DOI: 10.1201/9781003483755-361

- H is the maximum distance in mm between the camera during measurement and the structure being photographed
- p is the focal length used in mm

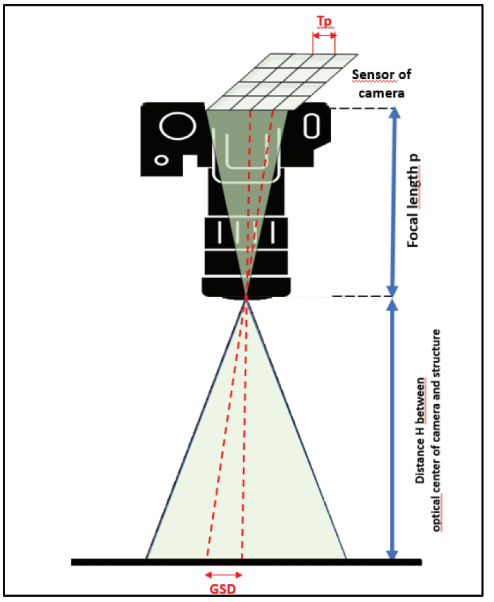

Figure 1. Calculation of ground sample distance (GSD).

The four inspected viaducts are the Onoz, Remouchamps, Sécheval, and Horion viaducts. These viaducts are of high significance in the Walloon Region and have substantial dimensions, spanning over numerous traveled roadways. Their sizes range from 300m to 1 km in length. Table 1 provides a description for each viaduct, including the deck size and the type of structure.

Table 1. Deck size and type of structure of each viaduct.

Bridge name	Deck size	Type of structure
	m^2	
Onoz	23638	Concrete girder bridge
Remouchamps	33770	Steel girder bridge
Sécheval	19630	Steel girder bridge
Horion	8430	Steel girder bridge

The Figure 2 illustrates each of the four viaducts.

Several different drones were used for photo capture, but, in general, the characteristics of the drones used were fairly consistent, namely:

- Weight ranging between 10 - 15 kg
- Flight autonomy between 40 and 60 minutes
- Excellent resistance to wind and turbulence
- Obstacle avoidance sensor system
- Three-axis stabilized camera gimbal capable of pivoting vertically from +90 to -90°

The last point is crucial because it's necessary to have a camera that can be oriented upwards to capture the underside of the deck, which is often the most important and complex part for inspecting large viaducts. However, most commercial drones do not offer such a solution.

Figure 2. Illustration of each viaduct.

The cameras mounted on these gimbals were often models with a full-frame 36x24mm sensor and a resolution ranging from 24 to 45 megapixels. The focal length often varied around 50mm.

Based on the camera's characteristics, it is possible, through Equation1, to calculate the necessary distance between the structure and the camera to achieve a minimum resolution of 1mm. This calculated distance showed that the camera had to be positioned between 5 and 8 meters from the photographed surface.

To construct 3D models of the structure as well as orthomosaics, a photogrammetric process is required. Photogrammetry involves creating accurate 3D models of objects and environments using photos taken from different angles. Once scaled, distance measurements on the 3D model or its 2D projection (orthomosaic) can be made. Figure 3 schematically illustrates the transition from photographs (represented by the blue rectangles) to a comprehensive 3D photogrammetric model.

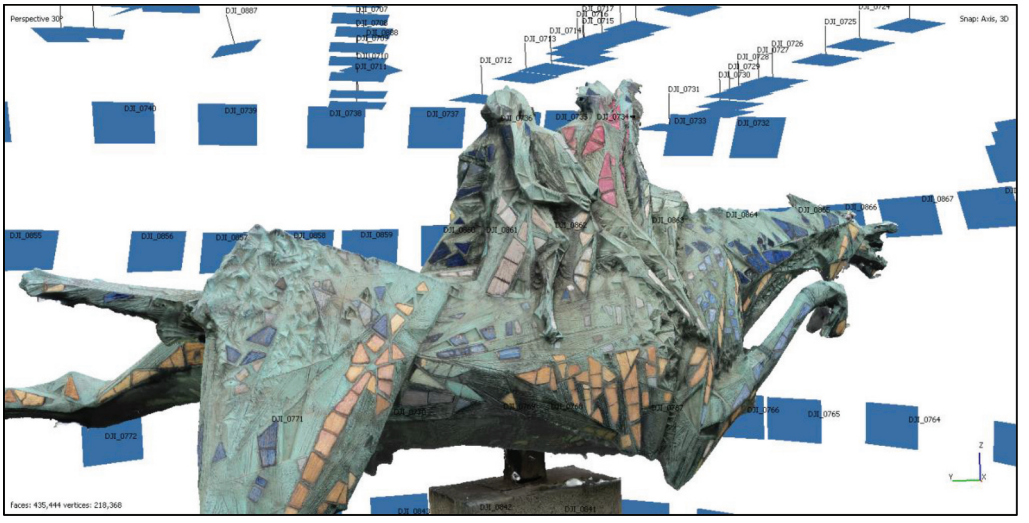

Figure 3. Transition from photos to 3D model.

An absolutely necessary condition for creating a 3D model through the photogrammetric process is to have an overlap (common area) between two successive photos. This overlap must be a minimum of 60% on the same strip (usually 80%) and a minimum of 20% between strips. Therefore, each taken photo will only have 20 to 40% of the area not yet captured compared to the previous photo in the same strip.

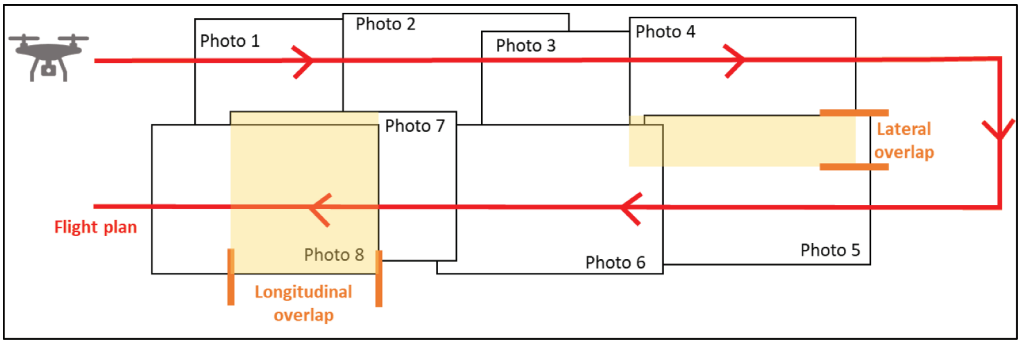

Figure 4. Overlapping of photos.

The photogrammetric process, therefore, entails a significant increase in the number of photos required to create a 3D model and orthomosaics compared to the number of photos needed to simply capture the entire structure. Table 2 indicates the number of photos taken for each bridge and the number of defects identified in these photos.

Table 2. Number of photos taken by drone and number of defects identified.

Bridge name	Number of photos	Number of defects
Onoz	30141	5418
Remouchamps	19271	2712
Sécheval	4355	2702
Horion	9585	3927

From these photos, a photogrammetric 3D model is created. This model is projected in a reference direction to generate orthophotos of various elements of the structure. The orthophotos are then analyzed to identify each defect. These defects are then listed in a database, along with their location, size, and type of defect. Figure 5 illustrates the different steps of analysis.

Layers are drawn on the orthophotos at the defect locations to visualize them directly. Each color represents a type of defect. Figure 6 shows, for example, the orthophotos with colored layers for each of the piers and undersides of the spans of the deck of the Onoz viaduct.

The advantages of such drone inspections have proven to be manifold. Such an inspection on large structures allows for precise visualization of hard-to-reach areas and a comprehensive analysis of large sections of the structure directly through orthophotos. Moreover, it can be conducted more quickly and with fewer risks for inspectors. It also enables accurate digital documentation of detected defects through the database.

While conducting a drone inspection of a large viaduct proves highly advantageous for helping asset managers synthesize and assess the bridge's condition, several important aspects can be considered drawbacks:

- Current regulations prohibit the overflight of traveled roadways by drones of such weight. Therefore, it is necessary to close and divert traffic beneath the structure during flight operations.

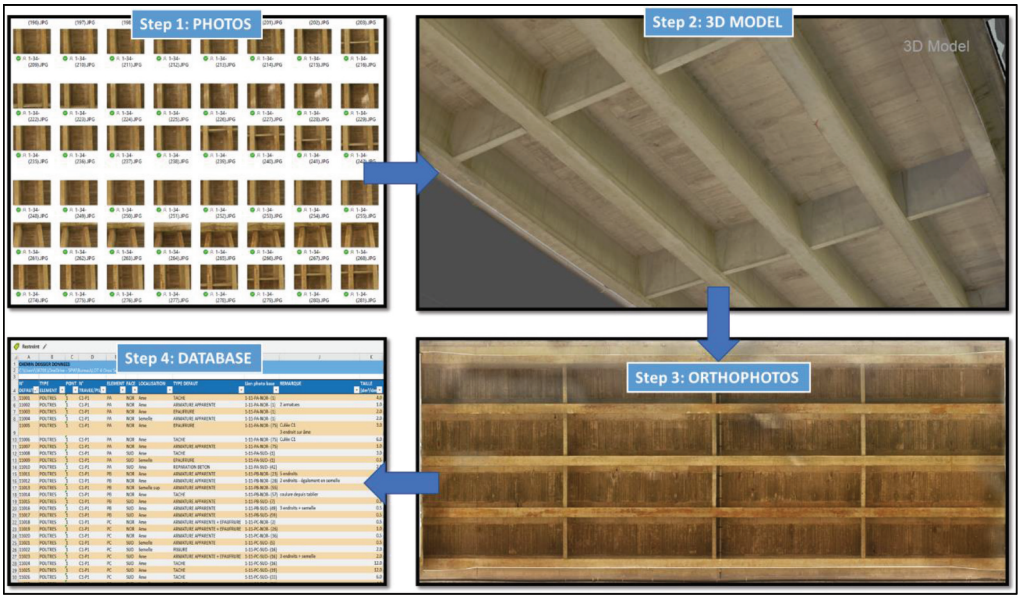

Figure 5. Different steps of analysis. Onoz viaduct.

Figure 6. Orthophotos of Onoz viaduct with layers on the defects.

- The number of defects observable in photos taken at close range on a large structure is extremely high. The time required for analyzing this amount of data and creating layers and a database is consequently very high.
- Inspections of each structure are mandated every three years. It is not feasible to conduct a complete drone inspection with such regularity. Therefore, conventional inspections are performed between two drone inspections. But, the time required to link the defects from such an inspection to those from the mass of defects captured by drone is significant.

3 ARTIFICIAL INTELLIGENCE FOR VIADUCTS INSPECTION BY DRONE

If the technology doesn't provide leverage on regulations, it's not the case for the last two issues raised. Indeed, working with an artificial intelligence solution can solve those problems by automatically:

- identifying defects in the structure on photos. The AI categorizes these defects, estimates their size and annotates the contours of the defects on the photos
- positioning defect contours on 3D CAD models of the bridge
- finding a defect already identified during a previous inspection, and estimating the change in defect size from two successive inspections

In the first phase, SPW worked with an artificial intelligence, developed by the company Dynamic Infrastructure, capable of automatically recognizing each type of defect on a structure, regardless of the category, such as:

- Cracks
- Moisture stains
- Rust stains
- Visible corroded reinforcements
- Gravel nests
- Spalls

On each photo analyzed by the AI, defects were outlined and tagged according to their type. Figure 7 displays the tags of defects automatically identified by the AI on several photos (the colors do not indicate the type of defect but rather their severity).

Figure 7. Tags of defects automatically identified by AI.

To assist the structure manager in analyzing the bridge, the defect detection cursor was adjusted with a strong tolerance. This means that the AI is configured to, in case of uncertainty, tag a defect even if it is not one. This scenario is, however, quite rare since the correct detection rate of the AI used is 99%. However, this approach ensures that all existing defects are effectively identified (which may not have been the case with a defect detection cursor set to low tolerance).

As the goal is not to rely entirely on AI, a human eye must review the tagged photos to validate the AI results. However, it is much simpler and faster to identify tagged defects that are not defects than the reverse. Currently, an experienced operator can, in this way, check hundreds of photos in one or two hours.

The operator takes advantage of this phase to assign a chosen severity level to defects they deem appropriate. Consequently, defects are not only classified by type but also by severity.

Still in the first phase, the AI solution used can automatically link and identify the same defect from one photo to another. It calculates the relative evolution (in percentage) of the defect's size or intensity from one photo to another, even if the photo is taken from a different angle. This allows for automatic detection of whether defects have changed in size from one inspection to another. Figure 8 illustrates an example of defect evolution identified by the AI.

Figure 8. Example of defect evolution identified by the AI.

While the solution proposed by AI at the end of the first phase already brings many benefits, there are still some limitations that ideally should be addressed to significantly improve the impact of AI. Indeed, at this stage, it is not possible to:

- Measure the absolute size of a defect
- Automatically position the defect in 3D on the structure for a general overview

These capabilities were possible with drone inspections but required significant manual work to synthesize the data. The idea, therefore, was to enhance the process offered by AI by recreating the process of a drone inspection but in an automated way. In a second phase, the AI has been reworked by Dynamic Infrastructure to automate this process.

The concept is to use this new process on a series of major structures. The steps are as follows:

1. Drone photo capture of the structure with overlap
2. Identification of defects in the photos by AI
3. Creation of a low-quality photogrammetric 3D model. This model is used to calculate the size of defects and position them on a CAD 3D model.
4. Projection of the outlines of identified defects onto the 3D model. The CAD model is lighter than the photogrammetric model and therefore easier to navigate. Clicking on the outlines reveals the characteristics of the defect.

Figure 9 illustrates the ongoing development process for the Onoz viaduct.

This new process overcomes the limitations imposed by AI in the first phase (no calculation of absolute defect size, no positioning on a 3D model). Furthermore, once this process is completed, it is entirely possible for future inspections to capture simple photos of defects from any location and without overlap. The AI will then be able to link the defects photographed during this new inspection to the defects already identified and positioned on the 3D model previously. It can also automatically verify if the defect has increased in size. It is simply necessary that the initial photo capture of the bridge processed by the AI is done in a way that

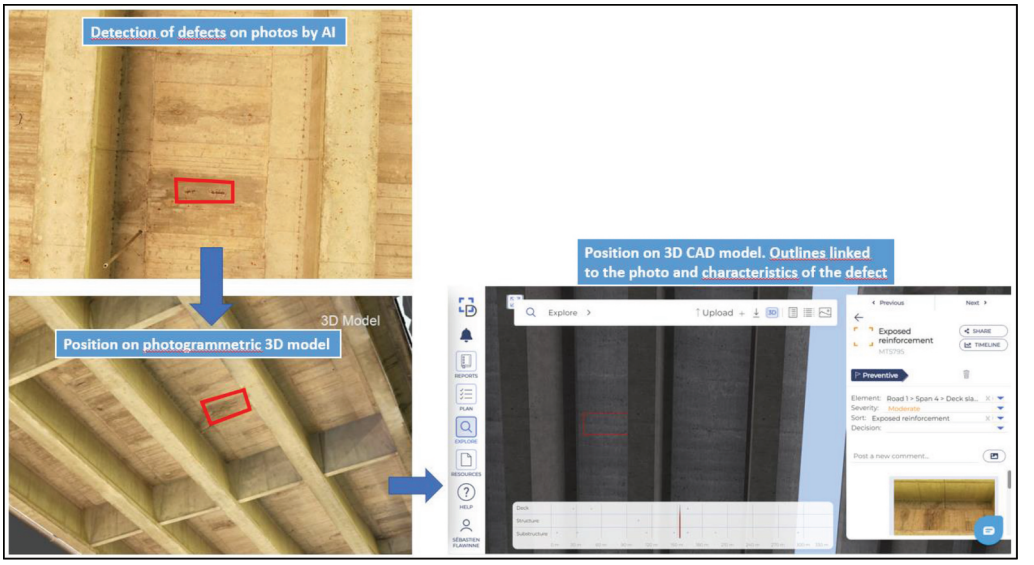

Figure 9. Process of automatic inspection of major structures by AI. Onoz viaduct.

allows for the creation of a photogrammetric 3D model, meaning taking a significant number of photos to ensure the necessary overlap (this photo capture can be done using drones or other methods).

That's why SPW reserve this process for major structures that involve a significant analysis time and that will be greatly facilitated by this method.

4 CONCLUSIONS

As a manager of infrastructure assets, the inspection of major structures by drones offers numerous advantages. Four viaducts have been inspected using this tool, and the results have been conclusive. The quality of photos at close range, the ability to quickly visualize all defects on orthophotos, and the creation of a database for a detailed analysis greatly facilitate the decision-making support for the asset manager.

The limitations of such inspections are more on the side of drone operators, who must undertake significant work to capture and, most importantly, sort and format all the data. To overcome these difficulties, the implementation of a tool using artificial intelligence to automatically perform the identification and categorization of defects greatly eases the operators' work. A human eye is still necessary to verify the results. However, by combining drone inspections with powerful AI, the inspection and analysis of major structures are significantly simplified and comprehensive.

Service Public de Wallonie, Direction de l'Expertise des Ouvrages, Belgium

J. Winkler
Digital Engineering Solutions – DES, Poland | AtkinsRéalis, UK

ABSTRACT: The Service Public of Wallonia (SPW) oversees 6,000 bridges in Belgium, relying on specialized departments for their operation and maintenance.

Structural Health Monitoring (SHM) is crucial for managing aging infrastructure. To achieve that goal SPW began to use a camera-based monitoring system. The system is compatible with all commonly available cameras (including smartphones) and enables precise monitoring of structural displacements with no traffic disruption.

This paper shows the outcome of 2-year long structural health monitoring campaign. The camera-based system was used on the Lincent Bridge, where settlement caused concrete beams to become trapped. The monitoring system initially employed conventional sensors, resulting in inconclusive results. In 2021, SPW introduced solar-charged cameras, revealing that the expansion of beams was pushing one of the abutments.

The DES system, showing over 90% correlation with temperature sensors, provided unique insights unattainable through conventional methods. These findings were instrumental in assessing the situation and initiating necessary renovations.

1 INTRODUCING THE ISSUE

The structure in question is a highway bridge located on the E40 (connecting Liège to Brussels) near Lincent. It consists of two similar bridges, each with slightly different widths, corresponding to traffic flow in opposite directions. These bridges span over a local road.

With a total length of 25 m, the structure comprises a deck section with longitudinal beams covering 15 m, followed by a frame bridge section for the remaining 10 m.

During the structure inspection, SPW observed that certain longitudinal beams were compressed between the frame and the abutment. This observation indicates the presence of unforeseen movements within the structure. It's essential to highlight that this compression primarily stems from settlement issues, with temperature effects exacerbating the situation. It is also crucial to emphasize that the compression is concentrated in specific areas at the end of the beams.

Topographic surveys were conducted to assess whether any parts of the structure had potentially shifted from the original construction plans. It was observed that the frame bridge had tilted from its original position, resulting in the pushing and compression of the longitudinal beams between the abutment and the frame.

Before undertaking the costly rehabilitation measures proposed by a consulting firm to restore the structure to its original state, SPW wanted to ensure that the situation was still evolving.

An initial instrumentation campaign using traditional sensors (inclinometers, displacement sensors, etc.) was conducted. However, the results from this campaign proved to be complex and challenging to analyze, preventing SPW from determining the overall behavior of the structure.

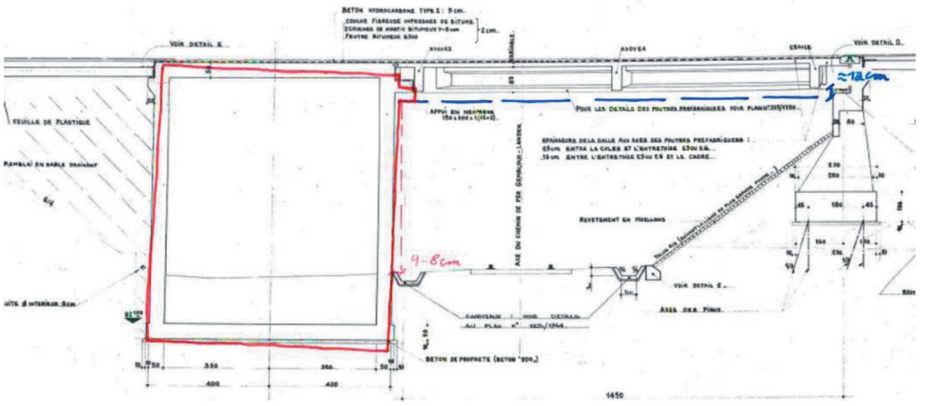

Figure 4. Displacement of the frame and beams.

2 ISSUES ENCOUNTERED WITH TRADITIONAL INSTRUMENTATION

In 2020, the traditional instrumentation campaign commenced, incorporating linear displacement sensors, inclinometers, temperature probes, and strain gauges installed on-site, with data transmitted via telemetry.

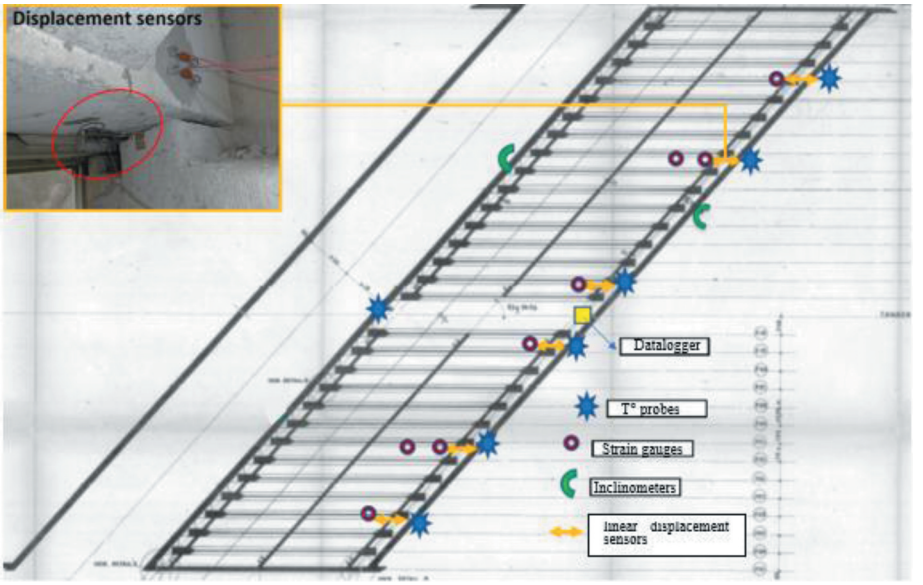

Figure 5. Distribution of traditional instrumentation.

Inclinometers placed on the frame revealed that the frame had ceased to tilt, exhibiting only slight cyclic movements around 0.03°, attributed to temperature variations. The challenge arose in determining how the abutment behaved concerning the beam movement, adding complexity to the study.

The displacement sensors at the beam-abutment junction provided movements perfectly correlated with temperature suggesting that the beam wasn't constrained in its movements according to the coefficients of expansion. Surprisingly, the coefficient of expansion derived from these values was twice the expected value, which is unexpected given the contact between the beams and the abutment.

It is noteworthy that these results were obtained based on a single temperature probe within the structure (at a depth of 15cm). In this instance, temperature gradients were not calculated, as this study did not aim to undertake such complexity.

The abutment is also equipped with inclinometers, and their results proved equally intriguing. Data analysis uncovered a partial correlation with temperature, with maximum displacements reaching 0.15°, equivalent to a 16 mm displacement at the top. This movement significantly exceeded that of the frame. These findings present a contradictory scenario, as while the beams are theoretically free to expand, the inclinometers suggest a pushing motion against the abutment.

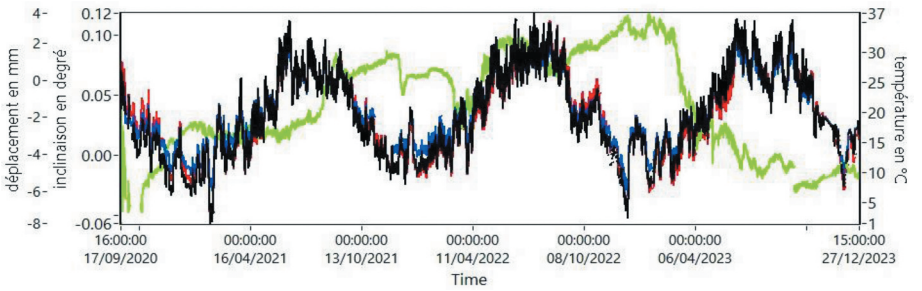

Figure 6. Temperature curve (red); beams displacement (black and blue); Abutment's rotation (green).

The issue stems from using linear displacement sensors, focusing on relative displacement studies (between the abutment and the beam, for example). The overall complex movement of the structure led to sensor results unsuitable for in-depth analysis. The possibility of the beam undergoing rotational movement upon contact with the abutment makes interpreting results from linear sensors particularly challenging.

Given this complexity, a comprehensive study of the overall movement of different elements was necessary for a profound understanding. Consequently, SPW adopted an innovative approach, exploring the use of Digital Image Correlation (DIC).

While this method has proven effective in laboratory settings (Winkler et al. 2014, Winkler et al. 2015) its application in the field remains underutilized but holds promise as an alternative solution (Winkler & Hendy 2017).

3 IMPLEMENTATION OF DIC INSTRUMENTATION

The DIC method is ideal for tracking the evolution of displacements over time. To implement this instrumentation, two surveillance cameras, powered by solar panels, were installed on the back wall of a railway bridge located 30 meters from the structure under investigation.

Figure 7. Camera-based system powered by solar panels.

These two cameras provided an overall view of the Lincent Bridge (frame, beams and abutment). Two cameras were necessary to capture all elements due to their restricted field of view (FOV). Nonetheless, the study could have been conducted with a single camera filming the entire scene but with a lower precision. SPW used cameras to observe the 2D displacements (in the image plane) of various points on the structure. These points facilitate the study of the following elements:

- The frame itself
- The longitudinal beams
- The abutment
- A point outside the structure considered fixed

On-site, these different points were marked with circular targets with a diameter of 5 cm.

This instrumentation remained in place from November 2021 until September 2023. During this period, images taken at regular intervals (every hour) by the cameras were directly transmitted to FTP owned by SPW. Consequently, DES Vision Software was used to conduct the displacement study.

Figure 8. Positions of cameras and their FOV.

4 STUDY IN THE DES SOFTWARE

The displacement study was conducted in two parts. The first part aimed to determine whether the frame section of the structure continued to tilt. The second part focused on understanding how the abutment behaved in relation to the movement of the longitudinal beams.

On-site, the traditional sensors installed during the initial instrumentation attempt were still in place. These sensors were utilized to validate certain results.

4.1 *Study of the frame movement*

The investigation into the frame's movement constituted the initial step in the analysis process conducted in the DES Vision Software. This study determined that there were no changes in the inclination of the frame. The results aligned with those obtained from the inclinometers.

Analyzing the frame's movement was the easier part of the study. The subsequent focus was on determining whether the DIC study conducted in DES Vision Software could provide insights into the abutment's movement.

4.2 *Study of the abutment movement*

To conduct this study, SPW chose to examine the displacement of three distinct points in the image, located respectively on the abutment (orange dot), one of the longitudinal beams (red dot), and the pier (purple dot) on which the beams rest. The displacement of these points was

studied relative to a point considered fixed within the image (the bridge's stone parapet represented by a blue dot). The study is conducted in a "relative" manner, but it effectively examines the overall movement of a single element.

Figure 9. Selected points for conducting the study.

The study of the abutment displacement provided values with a very good correlation with temperature (around 90%) and an expansion coefficient approaching expected values.

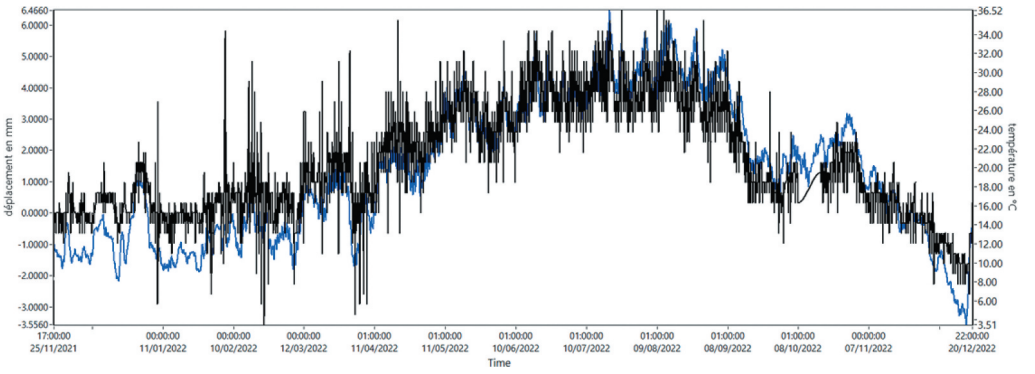

Figure 10. Abutment's displacement curve from DES (black) and temperature curve (blue).

SPW then focused the attention on studying the displacement of beams and the abutment. The results provided by Digital Image Correlation (DIC) reveal a perfect correlation between the movement of the beams/pier and the motion of the abutment.

Indeed, the beams and pier exhibit similar motion patterns in response to temperature variations. This motion is attributed to the contraction/expansion of the beams during different temperature cycles.

Consequently, these beams exert force against the abutment, a phenomenon not explicable by traditional sensors. This underscores the importance of augmenting conventional instrumentation with DIC for a comprehensive understanding of the structural dynamics.

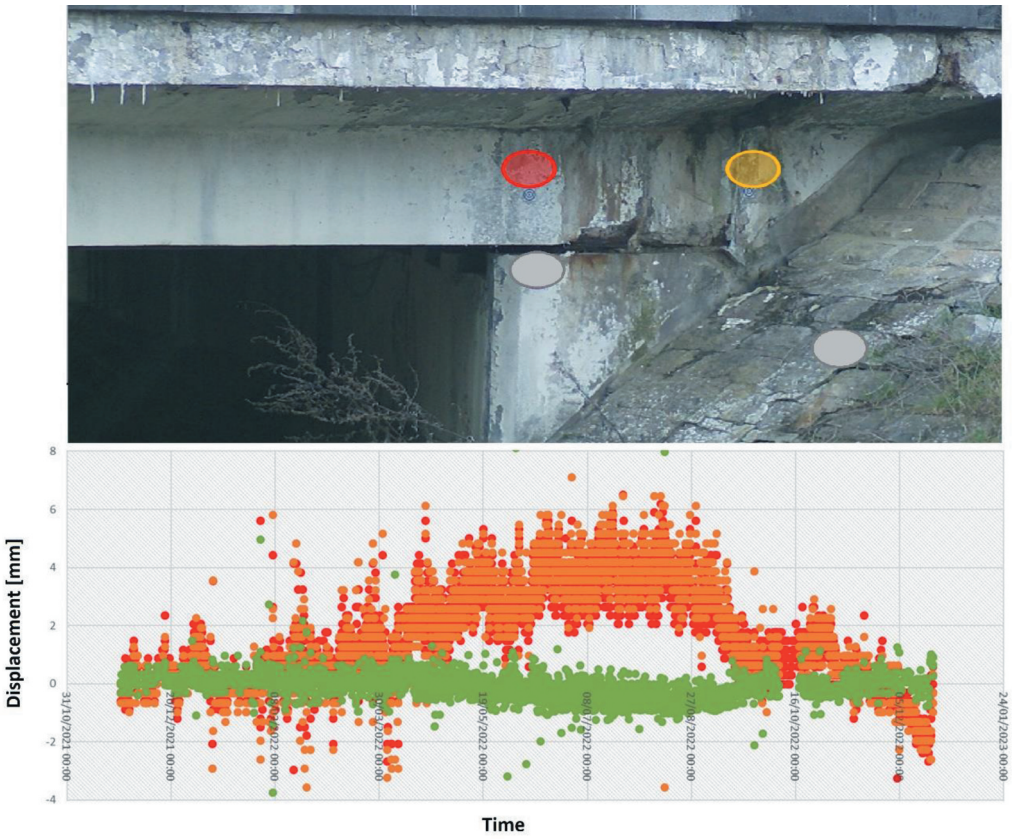

Figure 11. Displacement of the beam (red), displacement of the abutment (orange) and difference between them (green).

5 CONCLUSION

In conclusion, the study using Digital Image Correlation (DIC) proved to be an effective method for assessing the complex displacements of the Lincent Bridge. The installed cameras provided data for analyzing the movements of the frame, longitudinal beams, and abutment. This approach offered a complementary perspective to traditional sensors, providing precise information on absolute displacements.

By integrating the DIC method into the instrumentation toolkit, SPW overcame the limitations of traditional sensors and gained a more comprehensive understanding of the bridge's behavior. This innovative approach proved valuable for making informed decisions regarding the management and rehabilitation of the structure.

ABSTRACT: This paper discusses the life-cycle assessment (LCA) of concrete trough bridges, which make up about 20% of Sweden's railway bridge inventory. The LCA focuses on environmental impact and considers European Union emission regulations. It uses a 7.20m x 3.10m railway bridge in Rättelöv, Sweden, as a case study, along with a similar structure in Colombia. The study includes embodied carbon calculations, covering materials production, construction, use, and disposal. Approximately 70% of emissions occur during materials production and bridge use, with a focus on STA construction processes. While alternative life-cycle profiles weren't extensively explored, changes in working actions' schedules were considered. Additionally, a life cycle cost analysis (LCCA) was conducted, highlighting emissions from materials production, construction, and reconstruction as significant contributors. Recommendations and discussions for the Colombian case were proposed due to limited regional emission data.

1 INTRODUCTION

The focus of infrastructure project analysis can vary depending on the primary objectives of the decision-maker. The choice of analysis method, such as determining service life, assessing environmental impact, conducting life-cycle cost analysis (LCCA), optimizing schedules, or enhancing networks, depends on the specific goals of analysis. In the context of bridges, historically, costs have been the primary driving factors behind both past and current processes. For example, Leiva-Maldonado et al., (2023) and Leiva-Maldonado & Bowman, (2023) present current developments for superstructure selection based on LCCA. Regarding service-life extensions or maintenance scheduling, different approaches considered various aspects of bridge construction methods and technologies (Bouhaya et al., 2009; Du & Koroumi, 2013; Zhang et al., 2011). However, life-cycle assessments (LCA), is a method to determine public policies based on environmental load and impact are scanty and far apart in time. O P Gibbons & J J Orr, (2020) indicate that the carbon reduction potential decreases as the project stages develops. The higher reduction potential can be achieved in the planning and design stages, close to 100% and 80% respectively. Therefore, this research serves as a valuable tool for decision-makers during the planning process and may be advantageous for the involved agencies. Specifically for Swedish bridges, Hammervold et al., (2013) presented a comparative environmental

DOI: 10.1201/9781003483755-363

LCA case study, where different bridge material types were considered (structural steel, structural concrete, and wood). This research is one of the earliest and most important made about LCA specifically for bridges located in the Scandinavian peninsula, stating that is possible to decide upon environmentally effective design alternatives, a target of emissions and environmental impact, which is more than relevant in current practices.

Based on experience and research, some broad principles for conducting LCA (Collings, 2006): First, the initial environmental impact is proportional to its initial cost, and second, the long-term environmental burden will be approximately proportional to the amount of maintenance required. Thus, bridge structures with less working actions during its service-life would also be structures with less environmental burden in the future. In other words, even though the LCA could be made, if data is not available to calculate the environmental impact, the LCCA could be used as an indirect method to select the design option with the less environmental impact. Therefore, and specifically talking about LCCA, to determine the true cost of a bridge structure, the cost to build, inspect and maintain the bridge over the entire lifespan of the bridge, is needed. This involves not only the estimation of initial costs, but also future costs, so called "long term costs". This is a better measure of the real cost of a bridge, rather than the initial, or first cost.

There are few data or prior published studies regarding the life-cycle cost of entire bridge structures in Sweden and those are focused mainly on road bridges. However, there are approximately 4000 railway bridges in Sweden managed by the Swedish Transport Administration (Trafikverket), of which a common construction type is the reinforced concrete trough bridge (RCTB -close to 20%-), which is a structure that consists of a slab carried by two longitudinal main beams which transfer loads towards the supports (Gustafsson, 2021). A substantial number of the RCTB structures are approaching the end of their service lives which consequently implies that the replacement of some of these bridges can be expected in the near future (Åkergren, 2021). A comprehensive analysis focused on the LCC and the LCA as a complementary tool of structural behavior analyses, is of the most relevance to preserve and optimize agency budgets and environmental impact.

Some researchers have approached this problem in the past, for example, Du & Koroumi, (2013) made the LCCA comparison of two different railway superstructure options including the environmental performance, concluding that the slab reinforced concrete (RC) option has a better environmental performance over all due to the implementation of easier maintenance working actions. On the other hand, other studies focused the attention on the environmental footprint of specific working actions, such as deck replacements as described by Zhang et al., (2011). It can be seen in the literature that the existing research treated the environmental impact issue for different materials and working actions. However, no evidence of a comprehensive approach to perform an analysis for a specific bridge type but also to apply such techniques into the analysis of railway bridges such as RCTB have been found.

Therefore, a study to evaluate LCA and LCCA in railway bridges, specifically in the ones considered the most common (RCTB) would be useful for efficient, cost-effective, and environmentally responsible future planning. In this document, a first approach to this problem is presented, determining both the LCCA and LCA of a RCTB structure. Additionally, a comparative analysis is presented for a similar structure (reinforced concrete -RC- bridge) located in Colombia. Hence, different challenges and aspects of LCCA and LCA applied to Colombian structures are discussed, making a "roadmap" for future developments and research in the region.

2 METHODOLOGY

The present preliminary study is divided into two main analyses, one focused on the LCA and the second on the LCCA. However, both analyses were done for the RCTB, the case of the RC bridge was performed only for the input data available. The primary obstacle to implementing both methods arises from the insufficient regional information. Therefore, a discussion about the minimum requirements needed is presented in each section.

2.1 *Environmental life-cycle assessment*

There are different methodologies to compute LCA as stated by Hammervold et al., (2013). For example, and specifically for Nordic bridges, software's called *BridgeLCA* and *BridgeLCC* were developed to calculate LCA and LCCA respectively (*ETSI Project III - Task Group 5*, 2013), using *SimaPro* and the *Ecoinvent* database. Nonetheless, in this research the approximation proposed by The Institution of Structural Engineers is used (O P Gibbons & J J Orr, 2020). The guide supports the sustainability objective to achieve net-zero carbon emissions by 2050. As stated in the appendix of the guide, the process proposed involves more databases than the ones used in *BridgeLCA*, including Ecoinvent, EPD Norge among others. The method uses different factors in production, service, and end-of-life phases. The environmental impact of this guidance refers to its carbon dioxide equivalent emissions ($kgCO_2e$), also known as global warming potential (GWP). The best practice is to consider whole life embodied carbon emissions (Stages A – D in the guide, see Figure 1). Consequently, minimization of embodied carbon emissions is achieved contemplating future emissions, including end of life scenarios, reusability, and recyclability. The general approximation is described in Equation (1). In the case of minimum or unavailable data for stages B-D, the minimum analysis must be made considering only stage A because those emissions will be released before 2050. Additionally, uncertainties are higher for stages B – D. Also, most embodied carbon emissions are associated with stage A, which means that most of the reductions can be achieved in this time frame. Therefore, careful consideration of Environmental Product Declarations (EPD) of construction products is needed.

$$\begin{aligned} kgCO_2e = {} & ECF_{A1-A3} + \sum_{j=1}^{n} ECF_{A4,j} + \sum_{i=1}^{n} ECF_{A5W,i} + EC_{A5a} + ECF_{B1-B3} \\ & + \sum_{k=1}^{n} ECF_{B4,k} + ECF_{B5} + EC_{C12} + \sum_{k=1}^{n} ECF_{C34,l} + \sum_{k=p}^{n} ECF_{D,p} \end{aligned} \tag{1}$$

Where:

$kgCO_2e$ =	Life-Cycle total embodied carbon
ECF_{A1-A3} =	Embodied carbon factor for stages A1 to A3 (product phase)
$ECF_{A4,j}$=	Embodied carbon factor for stage A4 for the *j*th material
$ECF_{A5W,i}$=	Construction waste embodied carbon factor for the *i*th material
EC_{A5a} =	Embodied carbon from construction site activities
ECF_{B1-B3} =	Embodied carbon factor for stages B1 to B3
$ECF_{B4,k}$=	Replacements emissions for the *k*th material
ECF_{B5} =	Refurbishment emissions factor
EC_{C12} =	Demolition and deconstruction emission factor
$ECF_{C34,l}$=	Waste processing and disposal embodied carbon factor for the *l*th material
$ECF_{D,p}$=	Reuse emission factor (stage D)

2.2 *Life-Cycle Cost analysis (LCC)*

To determine the life-cycle cost, detailed information, and data on the bridge initial costs and long-term bridge inspection, repair, and maintenance costs are needed. Consequently, and with the aim of presenting and comparing different options (not only for bridge construction but also for bridge maintenance) the costs of a single life-cycle event will be projected back to obtain the net present value (NPV). The comparison of such NPV's will be used for selecting the most cost-effective Life Cycle Cost Profile (LCCP) for trough bridges. LCCP's was also considered to determine the environmental impact of all the options considered. It is important to remark that structural behavior of the superstructure type is needed prior to the LCCA, this information is vital to understand the possible deterioration and the feasible maintenance/preventive/rehabilitation schedule for different deterioration degree. However, since structural behavior is out of the scope of this research, information of such will be assumed based on previous research (Åkergren, 2021;

Gustafsson, 2021; Thun et al., 2006). Additionally, LCCA implementation in the Swedish infrastructure (road bridges) is presented in multiple research (Du & Koroumi, 2013; Safi et al., 2012, 2013, 2015). The general model is presented in Equation (2) (Leiva-Maldonado & Bowman, 2023), where the discount rate (i) and the service life (SL) of each option, and the time of execution of each working action (t) are considered in design costs (CD), construction costs (CC), inspection costs (IC), maintenance costs (MC), rehabilitation costs (RC) salvage costs (SV), and user costs (UC).

$$\mathrm{BLCCA}_{(i,SL)} = \mathrm{CD}_{(i,t)} + \mathrm{CC}_{(i,t)} + \mathrm{IC}_{(i,t)} + \mathrm{MC}_{(i,t)} + \mathrm{RC}_{(i,t)} + \mathrm{UC}_{(i,t)} + \mathrm{SV}_{(i,t)} \quad (2)$$

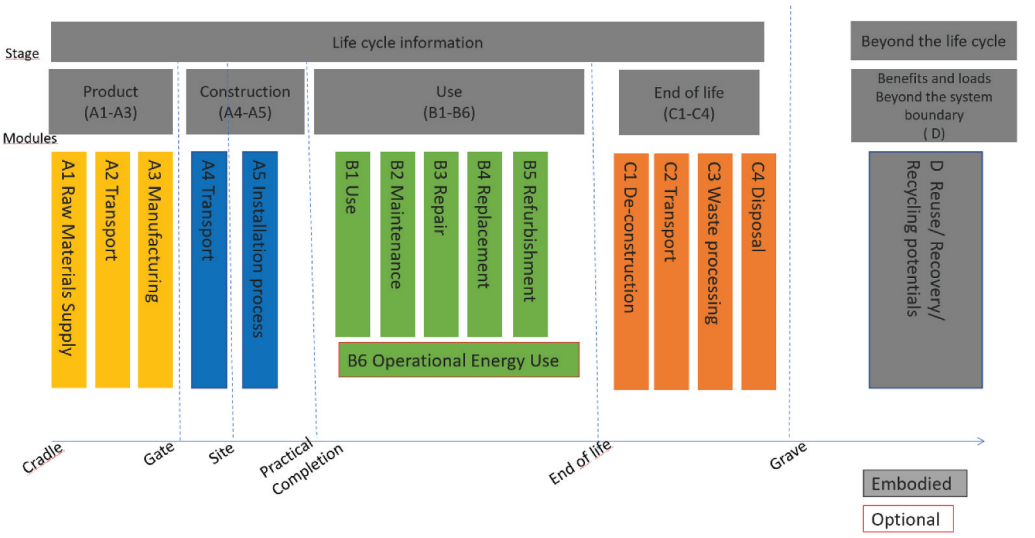

Figure 1. BS EN 1578 Life-cycle stages (O P Gibbons & J J Orr, 2020).

3 CASE OF STUDY

Trough bridges are built as a slab suspended between two longitudinal main edge-beams that carry the loads towards the support. The structure typically forms a "U-shape" which allows to be filled with ballast to distribute loads from the sleepers, rails, and traffic. The traffic load is transferred to the ballast using sleepers on which the rail is fastened. According to Trafikverket, the most common sleeper type in Sweden is the concrete sleeper which is used in almost 71% of the tracks. Figure 2 shows an example of a RC trough bridge located in Rättelöv in Sweden.

The structure used is the Lautajokki bridge, an RC trough bridge with a longitudinal span length of 7.20m and width of 3.10m (reinforcement and geometrical details are presented in the appendix of the research made by Gustafsson, (2021)). Bill of materials showed that 9.36m^3 (22.470kg) of concrete, 1.860kg of reinforcement steel, 462kg of wooden formwork, 864kg of UIC60 steel rails, 310kg of normal concrete sleepers (0.20x0.20x2.65m^3 every 0.60m) and 24.028kg of crushed stone ballast was needed for the construction of the superstructure.

A separate discussion is needed for the Colombian considerations. Due to the lack of railway development, few structures can be catalogued as railway bridges, and those are mainly structural steel superstructures (Márquez, 2017). However, similar bridge types can be seen in slab road bridges. Therefore, to make impactful research for the region, road bridges must be the focus of the investigation. However, as stated by the *International Trade Administration* \(International Trade Administration, 2023), Colombia launched a railway master plan to develop cargo and passenger railway lines. Thus, estimation of LCA and LCC in through bridges could be useful to support this master plan.

Figure 2. RC trough bridge located in Rättelöv, Sweden (Åkergren, 2021).

4 LCCA

For the LCCA analysis, costs related to the different service-life activities are needed. Different sources were used to determine costs, not only for construction but also for future working actions. However, it is important to remark that for more precise computations, historical cost records can be used, with them, probability density functions (PDF's) could be fitted. Those PDF's will be used for a stochastic model (Monte Carlo Simulation) that considers the inherent probability of cost estimation. Nonetheless, for this preliminary research historical records are not available. Therefore, cost estimation was modeled as a PERT distribution with a minimum and maximum value of 0.75 and 1.25 times the reference values presented in Table 1 respectively. Additionally, a similar model was used for the discount rate, which expected value was assumed as 3.5% (*BridgeLCC*).

Table 1. Construction cost (CC) and future working actions costs estimation.

For the future working actions, Trafikverket experience and recommendation given by Safi, (2013) were considered and are presented in Table 1. As a result, the LCCP presented in Figure 3 was used. However, as described by Sinha et al., (2009), the action year of each activity depends on the bridge condition of that year and the budget availably. The action year can vary from 2 to 5 years depending on bridge condition. Therefore, for this analysis, for repair, replacement and rehabilitation activities, a Poisson distribution was modeled with a minimum and maximum value of "action year $\pm$ 5years" respectively. For the MC simulation, a licensed program developed by *Palisade*^{TM} called *@RISK*® was used. The number of iterations (10000) employed corresponds to the stabilization of the mean and variance of the output variables. A pseudo random number generator (Mersenne Twister) and a Latin Hypercube sampler were utilized. Results of the simulation and the sensitivity analysis are presented in Figure 4. This study only considers superstructure analysis, substructure depends on local

conditions and specific site variables. In addition, user costs are also omitted due to the same conditions.

The main limitation encounter for the Colombian analysis is the lack of reliable scientific information or comprised official costs databases. The Colombian national road institute (INVIAS) has spare available data that needs to be gathered, cleaned up, and organized, to make the LCCA computation. Additionally, maintenance and inspection schedules are not normalized, and depend on the local authorities and constrained budget allocations. On the other hand, bridge service life needs a separate discussion. According to the local Colombian bridge standard design code (CCP14), the service-life for bridge structures is 75 years, however, no scientific research was found that analyze condition ratings or bridge inspections to predict future conditions. Conversely, Sweden base information regarding service-life can be obtained from different researchers (Racutanu, 1999; Safi, 2013), which indicates a service-life of 100 years. Nonetheless, a comprehensive study about deterioration rates including current practices is also needed.

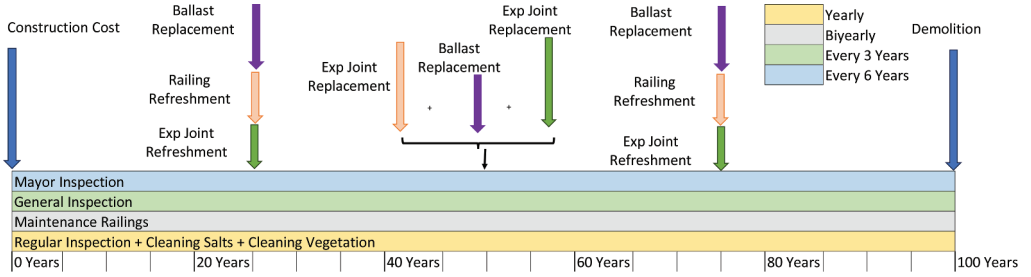

Figure 3. LCCP - Reinforced concrete trough bridges.

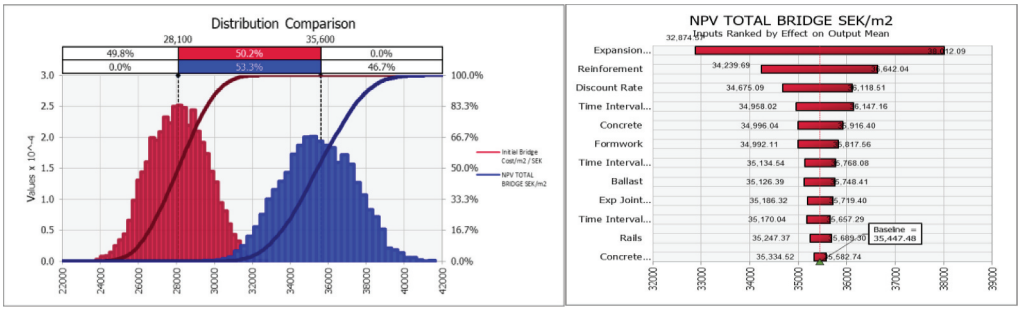

Figure 4. Simulation results and sensitivity analysis for total bridge cost per area.

5 ENVIROMENTAL LCA

As described before, considering data from specific EPD's is key to accurately computing the environmental emissions. Declarations vary depending on geographical location. For this analysis, EPD Norge and EPD Latin America databases were considered. Sweeden EPD's according to O P Gibbons & J J Orr, (2020) are dictated by the International EPD database, meaning that the closest accurate data is the one mentioned in the basics of this sections. Bridge quantities presented in Table 1 and maintenance schedule presented in Figure 3 were used for the computation of emissions. Nevertheless, EPD's depends severely on the productions processes of the companies making the declaration. Therefore, variability is inherently elevated. Hence, to make standardized LCA, minimum CO_2 emissions for each stage must be established by regional authorities. Where minimum CO2 emissions data are not available, recommendations from O P Gibbons & J J Orr, (2020) were used.

Specifically, for the presented analysis, the following variables were considered for each major stage. Emission for stage A1 to A3 were obtained from the EPD's described before. Transportation computed in stage A4 are based on local measurements, for the Sweden option, basic emission were taken from Uppenberg & Åhman, (1998), additionally, for the Colombian analysis, research made by Agudelo et al., (2021) was considered. Particularly, for the Colombian case, and as mentioned before, railway development is limited, therefore, only dump truck material transportation was used. Moreover, for locally produced materials 50km transportation was assumed, for national products 300km, for non-transoceanic international material 1.500km and finally, for transoceanic importation 10.000km, as suggested by O P Gibbons & J J Orr, (2020). Conversely, for demolition (C2) only 50km local transportation was assumed. Stages C3-C4 namely waste processing disposal emissions were taken from each material EPD. In cases like reinforcing bars and ballast from the Swedish option, and all materials except reinforcing bars and formwork in the Colombian case, no emissions were reported in the EPD's, therefore, a minimum of 0.013kgCO_2 per unit was contemplated. Reuse and recovery (D) emissions were also reported as the EPD's for each material. Finally, stage B only considered subsection B4 since use and maintenance (B1-B4) emissions are considered marginal (inspections and cleaning as presented in Figure 3). Stage B5 is only considered when planned changes in use are defined at the conception of the project. Operational carbon emissions (B6-B7) could be impactful for buildings, however, for infrastructure projects as bridges, those emissions can be neglected. Results of the LCA are presented in and Figure 5.

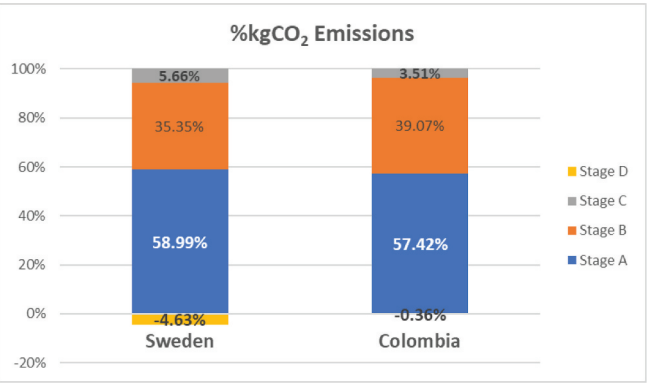

Figure 5. LCA CO_2 total emissions.

6 CONCLUSION

A first approximation to LCCA and LCA for Swedish railway reinforced concrete trough bridges was presented. Also, a parallel analysis for the same structure was performed for the Colombian case. Monte Carlo simulations were executed for the LCCA, using PERT and Poisson PDF's only for the original case. The lack of railway development in Colombia as well as the minimum or inexistent behavior or cost information made the LCCA unfeasible. However, the Colombian major railway master plan makes this preliminary study of total interest for the region. A LCCP was proposed for RCTB, including inspection, maintenance and replacement working actions. Sensitivity analysis showed that the most impactful variables of the analysis are dictated by material costs and the discount rate. On the other hand, LCA was performed for both options. Specific EPD's and transport emissions for each region were used. Results showed that higher emissions are expected for the Colombian structure. Results are driven by the greater emissions presented in material production and internal transportation. Again, the lack of railway Colombian development make internal transportation by dump trucks mandatory, which significantly impact the emissions outcome. Finally, as

presented in the LCA, most of the emissions are reported during production, and replacement phases (Stage A – 58% – and B –35%–), meaning in those activities it is expected to have more potential of emission reductions.

Reducing the climate impact (GWP) from bridges in a Danish highway project

J. Olesen & P.G. Pedersen
COWI A/S, Kongens Lyngby, Denmark

C.V. Scholten
Vejdirektoratet, Hedehusene, Denmark

ABSTRACT: This article focuses on the analysis of the carbon emissions of different concrete road bridges together with possibilities of reducing their carbon footprint. Reducing carbon emissions is of increasing importance to owners, consultants and contractors alike, the whole industry is in transition to reduce their impact. Infrastructure projects have a significant carbon footprint due to the large quantities of consumed materials.

A key focus for the project owner, The Danish Road Directorate, is to reduce the carbon emissions from the construction of Kalundborg Motorway Stage 3. For the road bridges in the project, a life cycle analysis is made comparing the carbon emissions of different types of concrete bridges. The potential savings in carbon emissions from choosing the concrete bridge type is significant and the results of the analysis are highlighted and elaborated in this article.

1 INTRODUCTION

Sustainability, especially lowering of the carbon footprint (CO_2e), is a focal point in the design, tendering, and construction of the Kalundborg Motorway Stage 3, Regstrup-Kalundborg. In this the project, several analyses have been conducted on the influence of different bridge types on the carbon footprint. This includes road bridges, pedestrian bridges, and wildlife crossings. These analyses were carried out during the outline and project proposal phases and will continue during the detailed design phase.

Figure 1. Left: Location of project in Denmark (red box). Right: Alignment plan, the Kalundborg Motorway Stage 3, from Regstrup to Kalundborg (red line).

DOI: 10.1201/9781003483755-364

Bridges have a significant carbon footprint due to their size and thereby use of construction materials. This article includes examples and results from specific analyses conducted on the project "Kalundborgmotorvejens Phase 3, Regstrup-Kalundborg".

The Kalundborg Motorway Stage 3, from Regstrup to Kalundborg, is part of the Danish Infrastructure plan 2035, "Danmark Fremad"/"Denmark Forward", (Ministry of Transportation, 2021). The project consists of 20 km of road widening and 10 km of new road. The project includes 26 major structures, including 2 new pedestrian bridges, 11 new road bridges, 6 new wildlife crossings, and 7 existing structures, as well as 17 smaller structures (small wildlife crossings/pipes).

The Danish Road Directorate (Vejdirektoratet) are the owner of the project, and COWI are the consultant. The project is expected to be tendered in 2024-2025 and completed by 2028.

It is one of the first projects where the Danish Road Directorate focuses on minimizing the carbon footprint of structures such as bridges as well as other civil structures. Minimizing the carbon footprint is an unavoidable area of focus, especially considering the Danish goal of a 70% CO_2 reduction by 2030 compared to 1990. This target is from The Danish Climate Act (Ministry of Climate, Energy and Utilities, 2019). Carbon reduction is an area of focus for clients, consultants, manufacturers, and contractors alike. There are significant developments in the construction industry in this area, and therefore the article also provides details on the status of the industry's progress and direction.

2 THE ANALYSIS ON THE PROJECT

With a larger number of bridges (20+), there is significant potential to reduce the carbon footprint. Analysis is conducted in the concept design and project proposal phase of the project. It focuses on a predetermined location within the project. This location is representative to a larger portion of the bridges in the project. The road bridges in the analysis are assumed to be constructed with concrete. The analysis solely focuses on the carbon footprint of the structures but should be seen as part of the overall effort to minimize the project's carbon footprint.

At the specific location 7 different possible types of bridge layouts are identified, including both overpasses and underpasses (OP/UP). In addition, the bridge types also differ in terms of the number of spans, with either 1, 2, or 4 spans. The designs also vary depending on the type of the abutment, with either vertical walls/abutments close to the edge of the under passing road or sloping embankments (verges) under the bridge end. These types are referred to as closed/open bridge-ends which is what is seen from a user perspective passing the bridge. In Figure 2 below, the 7 different bridge types investigated are illustrated.

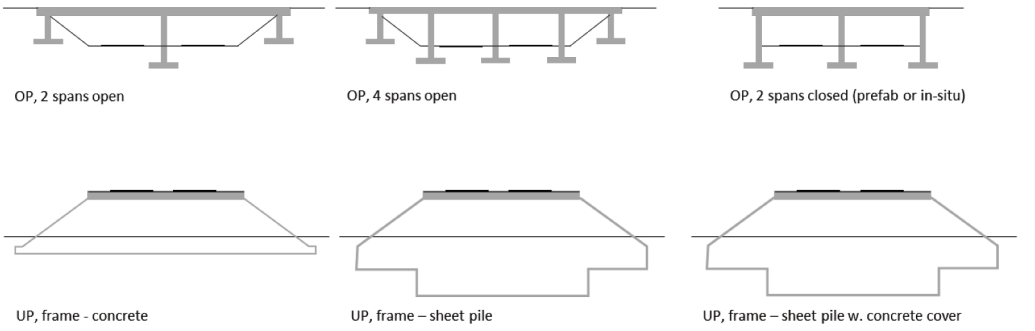

Figure 2. The 7 bridge types in the analysis (the "OP, 2 spans closed" is investigated with both prefab concrete beams and in-situ cast concrete deck).

The analysis is conducted using the Danish Road Directorate and Banedanmark's joint life cycle assessment tool, InfraLCA. Life cycle assessments are evaluations of the overall climate and environmental impacts of one or more material/ product throughout their entire life cycle.

In this analysis, the focus is solely on the carbon footprint (GWP). The GWP is calculated in CO_2-equivalents, which is the impact from greenhouse gasses calculated as an equivalent amount of CO_2. When conducting such analyses with organizations like the Danish Road Directorate or Banedanmark, the tool InfraLCA is commonly used.

The aim was to use the predefined data in the program, including; emission factors, transport distance, and service life, to keep the analysis as generic as possible. However, some inputs must be adjusted to provide a reasonable basis for the analysis that aligns with the project's assumptions. The program and other details of the analysis are not further discussed here.

The version of InfraLCA used (version 2.11) includes the following life cycle phases: A1-A3, A4, (A5) & B4 (cf. EN 15804). Phases A1-A3 represent raw material extraction, transportation, and production of the material/product. Phase A4 represents transportation, for example, from the factory to the construction site. Phase A5 represents the construction phase, this is not included in the analysis due to insufficient incorporation in the utilized version of InfraLCA. Phase B4 represents replacement at the end of the lifespan. It is noted that the newest version of InfraLCA additionally includes phase C (demolition and disposal) and phase D (reuse). The analysis conducted generally includes the following categories: concrete, concrete elements, reinforcement, prestressing reinforcement, sheet piles, soil anchors, pavements, insulation, and earthworks.

In the project, various options for carbon reductions are considered in the project's different phases, these are reflected in the CO_2-evaluation. The process is shown in Figure 3 below (the figure reflects the project's progress according to the Danish Road Directorate's project phases, phase 1-6).

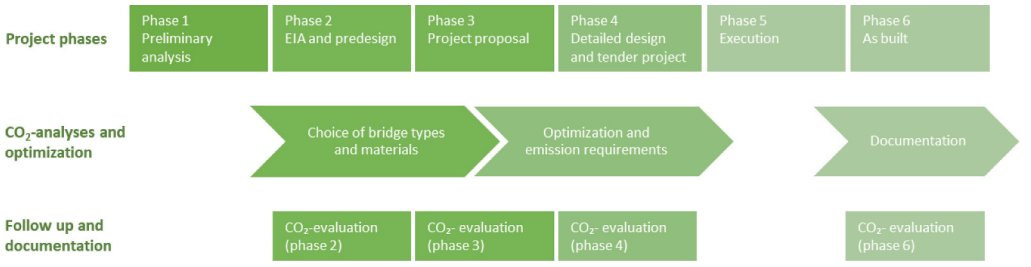

Figure 3. Process for carbon reduction throughout the design lifecycle - consultant CO_2-evaluation for each larger structure in the project.

The Danish Road Regulation, "Design Basis for Bridges" (Danish Road Regulation, 2023) Section 3.2, has been updated to outline the requirements for implementation of carbon reducing measures during the design phase. These requirements reflect the strategy of the Danish Road Directorate to reduce carbon emissions from structures they build and own.

The choice of bridge type and materials is the first step in reducing the carbon footprint of these structures. The next step is to optimize the selected bridge type during the detailed design phase, typically by reducing the quantity of materials. Emission requirements (in tenders) and other execution guidelines are then incorporated into the tender material and used in throughout the execution.

3 RESULTS

In Table 1, the results of the analysis of the 7 bridge types are shown, the results are divided into life cycle phases and include a summation of all life cycle phases. An indexing in relation to the 2-spans bridge (lowest footprint) has also been conducted to facilitate comparison.

As seen in Table 1 (A1-A3, A1-A3/Index), there are relatively large differences in the total carbon footprint of the different bridge types based solely on the footprint from the production of materials. Particularly, the underpasses (UP) have a high carbon footprint. This is mainly due

Table 1. Results from the analysis in InfraLCA of the 7 bridge types. Total [t CO_2e].

Bridge type	A1-A3	A4	B4	Sum (A1-A4+B4)	Index* (Sum, A1-A4+B4)	Index* (A1-A3)
	[t CO_2e]				[-]	
OP (overpasses), open						
2 spans	234	351	36	620	1.0	1.0
4 spans (short)	273	354	36	663	1.1	1.2
4 spans	291	355	39	685	1.1	1.2
OP, closed						
2 spans (prefab)	350	356	23	729	1.2	1.5
2 spans (in-situ)	367	359	23	749	1.2	1.6
UP (underpasses)						
Frame (concrete)	403	325	20	748	1.2	1.7
Frame (sheet pile)	427	333	20	780	1.3	1.8
Frame (sheet pile + conc.)	503	335	20	859	1.4	2.2

*Relative to the result of "2 spans open"

to the assumed location and the narrow crossing road (approx. 10m), which applies to several bridges in the project. The UP and closed type OPs will require larger walled substructures, which have a negative impact on the carbon footprint. However, the results for the different types can be influenced by the width of the bridge. For a wider highway bridge, the carbon footprint of the substructure will be relatively smaller compared to the superstructure for these bridge types.

Furthermore, the results for materials transport (A4) are noteworthy. The primary contribution to this phase is the transportation of soil, especially for the bridge approach embankments. When constructing on flat terrain, significant amounts of soil are involved. It should be noted that the chosen location in this project is a particular case, and the amount of soil at this location is considerably larger than the average amount for the project as a result of special bridge approaching embankments. The footprint of soil transportation at this location is just below 300 t CO_2e, while on most other locations of the same size in the project, it is around 100 t CO_2e due to significantly smaller approach embankments structures.

Maintenance/partial replacement (B4) of a bridge account for a smaller portion of the footprint since concrete bridges require minimal maintenance. The primary differences in these results come from the replacement of pavements where there are differences in road and bridge deck areas for the different bridge types.

To make comparisons and establish requirements, there is a need for some benchmark values. In the Table 2 below, the CO_2e footprints are presented per square meter of bridge deck area. Both for the total bridge deck area and per square meter of "crossing area". "Crossing area" defined as the area overlapped by underpassing and overpassing road. The latter benchmark value has the advantage of being based on a constant (crossing area) which is independent of the bridge type for a specific location.

As seen in Table 2, the clear differences observed in the total carbon footprint are also reflected when calculated per area. The variation is significant for the results per square meter of bridge deck, while it eliminates the variances between bridge types and is (relatively) smaller for the result per square meter of crossing area. However, it is evident that the choice in bridge type for this specific location has a significant influence on the overall footprint. It is expected that the carbon footprint per bridge deck area/crossing area will become an important way to measure the carbon footprint of bridges.

It should be noted that the carbon emission factors for primary materials such as concrete, reinforcement, prestressing reinforcement, sheet piles, etc., have a crucial impact on the results and, therefore, the comparison of bridge types. Therefore, careful selection of emission factors is important.

From this analysis, the results indicate that the 2 spans open bridge has the lowest carbon footprint among the investigated bridge types.

Table 2. Results calculated pr. m² bridge deck/crossing area.

Bridge type	A1-A3 [t CO_2e]	Bridge deck area, [m²]	(A1-A3) [kg CO_2e/m²] (deck area)	Crossing area [m²]	(A1-A3) [kg CO_2e/m²] (crossing area)
OP (overpasses), open					
2 spans	234	506	462	254	921
4 spans (short)	273	506	540	254	1075
4 spans	291	548	531	254	1146
OP, closed					
2 spans (prefab)	350	326	1074	254	1378
2 spans (in-situ)	367	326	1126	254	1445
UP (underpasses)					
Frame (concrete)	403	286	1409	254	1587
Frame (sheet pile)	427	286	1493	254	1681
Frame (sheet pile + conc.)	503	286	1759	254	1980

3.1 *Analyses of other structures in the project*

Similar analysis was conducted on other types of structures within the project with the aim of minimizing the overall carbon footprint of the project's structures. This included an analysis of the wildlife bridge, for several large wildlife passages, in addition to a footbridge where several materials and bridge types are analysed and investigated.

Figure 4. Rendering of a possible wildlife crossing on the project.

3.2 *Other bridge related carbon emissions*

During construction, many activities lead to carbon emissions. These can include test drilling, cooling/heating at concrete casting, lowering of groundwater, operation and maintenance in addition to traffic-related factors.It is generally more challenging to quantify these emissions, and many of them are not yet included in the analysis conducted by commonly used tools such as InfraLCA.

Further analysis has been undertaken to identify and quantify carbon emissions for aspects related to bridge design and construction that are not accounted for in InfraLCA calculations. These was focused on detours and traffic congestions during bridge construction works.

The results indicate that detours and traffic congestions can have a significant impact on the total carbon emissions, and in some cases the carbon emissions associated with detours and traffic congestion may exceed the carbon footprint of the bridge itself.

These considerations highlight the complexity of calculating the total carbon footprint of a structure and emphasize the importance of conducting an overall assessment as early as possible in the project, considering all relevant factors.

4 OPTIMIZATION POTENTIALS AND WORK FOR FUTURE PHASES

In the next phase of the project (detailed design), further carbon reducing measures will be implemented. This includes investigating the following:

- Cut outs/voids in structural parts
- Ribbed structural parts
- Varying thicknesses
- Differentiation of concrete types/strengths
- Optimizing surfacing/materials on slopes beneath bridge
- Stressing reinforcement vs. height of structure
- Optimization of the layout of the substructure

In the tender documents, requirements for minimizing the carbon footprint will be imposed on the contractor's execution. These requirements can include:

- Soil management
- Emission requirements for materials/products
- Construction site management requirements
- Construction machines fuel type
- Maximum transport distances
- Reuse of interim structures
- Minimization of waste and spills
- Recycling and reuse

These optimization opportunities and quantification aim to minimize the overall CO_2 footprint of the project and promote sustainable construction practices.

4.1 *Challenge requirements, norms, and standard practices*

There are high demands placed on materials, design, and execution when constructing structures with long lifespans (120 years). If the goal of 70 % reduction in carbon emissions is to be achieved, there is a need to adjust more parameters than investigated here. This includes, but is not limited to, the choice and composition of materials, which should be considered, researched, and tested to determine the necessary requirements to ensure these lifespans, not only in terms of material selection but also during designing and execution.

However, it is crucial to ensure that the durability of the structure is not compromised in the attempt of lowering the carbon emissions, as it may otherwise result in higher carbon emissions due to subsequent repairs than what is gained from optimization. Additionally, there will be a greater need for the maintenance of existing structures and allowing for increased reuse in various contexts.

5 THE POTENTIAL REDUCTION AND PERSPECTIVES

The described analysis and presented results should be seen as a study in projects phases 1-3 (see Figure 3), where aspects such as materials, type of structures, and initial optimization are analysed. Additionally, there is room for further optimization in the detailed design phase and the possibility to establish carbon requirements in the tender material for compliance during

construction, as reflected in Figure 3. When setting requirements or comparing products, environmental product declarations (EPD) are essential. EPDs are declarations that contains information on several environmental impacts from a specific product or material, and this is how the global warming potential, measured as carbon emission, is documented. The trend is that EPDs are becoming increasingly demanded as documentation for the materials and products used in larger quantities within infrastructure projects.

If the bridge type with the lowest footprint (2 spans open) is considered, there is expected potential for further reductions in carbon footprint in the next phases, as described below. Currently, it is estimated that there is a possibility of reducing carbon emissions in phases A1-A3 by around 10 % by minimizing material consumption, especially concrete and reinforcement.

Maximum emission requirements for the most common materials are expected to further reduce the carbon footprint by approximately 15-20 % in phases A1-A3. Refer to Table 3 below.

It should be noted that transportation (A4), especially earthworks and transportation of soil, is expected to shift towards electric or hydrogen-powered vehicles, leading to a movement towards zero emissions.

Looking towards 2030, it is anticipated that concrete for construction purposes will have a carbon footprint of around 200 kg CO_2e/m³, while reinforcement will be around 375 kg CO_2e/t due to advancements in material technology (projection estimates from Vejdirektoratet). This would reduce the total reduction for phases A1-A3 by 45 % compared to the "basic-case" 2022 estimates for the "2 spans open" bridge.

Table 3. An approximate assessment of the carbon footprint for the 2 spans open bridge type over time.

Year	1990 (baseline)	2022 (basic case)	2022 (optimistic)	2030 (expected)
Estimates of emissions factors (concrete/reinforcement)	-	392 kg CO_2/m³ 1060 kg CO_2/t	353 kg CO_2/m³ 600 kg CO_2/t	200 kg CO_2/m³ 375 kg CO_2/t
A1-A3 [t CO_2e]	360*	234	175**	130***
A1-A3 [kg CO_2e/m^2 bridge deck]	711*	462	346**	257***
CO_2-reduction compared to 1990 baseline	0%*	35%	51%**	64%***

*Estimate based on industry experience (Teknologisk Institut, 2020).
**Based on possible emission values.
***Estimates based on expected approximate emission values.

In Table 3, during the period from 1990 to 2030, there is an estimated CO_2e reduction of nearly 65%, suggesting that the climate goal of a 70% CO_2 reduction by 2030 is not unrealistic but requires continued development and effort.

It can be added that there is a natural limitation in reducing carbon emissions in concrete in the short term, as about half of the carbon emissions come from the chemical process when cement clinker is heated. To further reduce the footprint of concrete, Carbon Capture Storage (CCS) can be a possibility. CCS is to capture and storage the CO_2. There are also opportunities in changing/new concrete compositions. For reinforcement/steel, there are already technologies (SSAB) that, in the long run, will be able to produce steel using hydrogen and green electricity with a CO_2e emission close to 0.

6 CONCLUSION & GOING FORWARD

Civil structures in infrastructure projects have a significant carbon emission. It is clear, that analysing the necessary type of bridge structure for a specific location can have a significant positive impact in lowering the total environmental impact. In this specific location the

differences were up to a factor 2. However, this will vary depending on the specific location and size of crossing. Therefore, it is important to choose the right type of crossing where possible in respect of other project constraints.

It is also clear, that the large amounts of earth moved has a significant impact on the overall carbon emission. Detailed plans for earthworks are important in reducing the overall carbon emissions.

Looking at the goals for the carbon emissions in Denmark (Ministry of Climate, Energy and Utilities, 2019), there is still way to go when focusing on bridges.

When the process of deciding if something should be built, what should be build and how it should look, the process of optimising the defined structure starts (build nothing, build less, build clever, build efficiently). To reach our goals, it is very important to have a continued focus in this phase as well, as we have an opportunity to reduce the carbon emission further.

A lot of initiatives and development is ongoing in the industry, and if large infrastructure projects shall be a reality in the future, it is important to maintain this ongoing development.

Static behavior of steel-concrete bridge under pier girder consolidation

Wei Xie & Qingtian Su
Tongji University, ShangHai

ABSTRACT: There are some advantages of steel-concrete composite bridge in the case of pier girder consolidation, such as greater overall stiffness, less maintenance work. However, the combination zone of composite girder and concrete pier which needs to transfer bending moment, shear force and axial force is under complicated stress state. Combined with Sutai expressway project in Tongxiang, this paper conducts research on its static behaviour. Firstly, stress distribution law of the structure during construction and service stage is studied by establishing an overall three-dimensional solid model, and the influence of some structural system parameters on its static behaviour is analysed. Then, a local model which minutely simulates the combination zone of composite girder and concrete pier is established to reveal the failure mechanism by nonlinear finite element analysis, and effects on stiffness, ultimate capacity and failure mode are investigated by varying shear span ratio, embedded depth of steel plates and reinforcement ratio. The conclusions obtained in this paper can provide references for the same type of bridges.

1 INTRODUCTION

During the service period of bridge bearings, numerous problems may arise, including deflection, disengagement and deterioration[1-2]. The typical life expectancy of bridge bearings ranges from 15 to 20 years. However, improper construction or maintenance methods can significantly shorten this lifespan. Consequently, it becomes necessary to repeatedly close the traffic and replace bearings within the designated bridge lifespan, thereby increasing the later maintenance expenses. Furthermore, bridge overturning accidents resulting from overload phenomena occur frequently in China, yet the current study on tensile bearing remains relatively limited. In soft soil foundation areas, the constraint effects of shallow soil on pile foundations are not significant, therefore, pier-girder consolidation structures can be considered to solve the above problems.

In recent years, the steel-concrete composite girders have been widely applied in the simply supported bridges since the merits of concrete compressive strength and steel tensile strength can be efficiently utilized. Additionally, compared with concrete girders, steel-concrete composite girders exhibit less noticeable shrinkage and creep effects, making them a more suitable choice for the superstructure.

The combination zone of composite girder and pier is a typical stress disturbance zone, characterized by complex stress distribution and force transmission mechanisms. In recent years, many scholars have carried research on the mechanical behaviour of this joint. [3-4] have proposed an innovative beam-to-pier joint, and respectively studied the joint response under monotonic and cyclic loading. [5-6] have proposed a deck-to-pier connection structure suitable for earthquake-prone areas based on the German specifications, and studied the differences between the two structural systems of pier-beam consolidation and non-pier-beam consolidation through experiments. [7] has studied the seismic performance of the joint between steel-concrete composite girder and concrete pier under cyclic loading through

DOI: 10.1201/9781003483755-365

a double cantilever model test. [8] has dis-cussed the seismic characteristics and failure mode of beam-to-pier joint through shaking table test and finite element analysis.

2 ENGINEERING OVERVIEW

The simply-supported system to rigid-frame system is adopted for the Tongfu viaduct bridge, which is implemented by post pouring concrete cross beam. This paper takes it as engineering background, the span layout of which is 3×30m. Figure 1 shows the cross section at pier. The height of pier is about 10~20m.

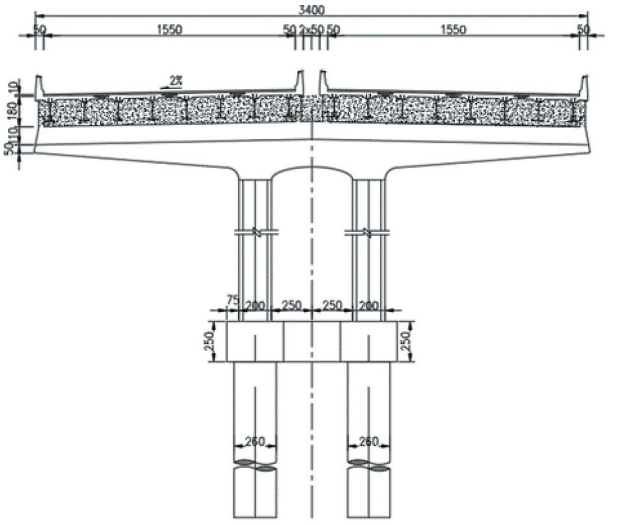

Figure 1. Cross section at pier (unit: mm).

The beam-to-pier joint is as Figure 2 shows. The connection between steel and concrete is achieved by adopting perforated plates and welding studs. The concrete slab in the hogging moment zone tends to crack, so two methods are employed to address this issue. The first method involves adjusting construction sequences. Initially, the steel girder and concrete slab are prefabricated and assembled in the factory, then erected in place. Subsequently, the concrete cross beam is poured to connect main girder and pier. The second method is to pour an ultra-high performance concrete (UHPC) layer, with a thickness of 100mm, within a range of 6m at the top of pier.

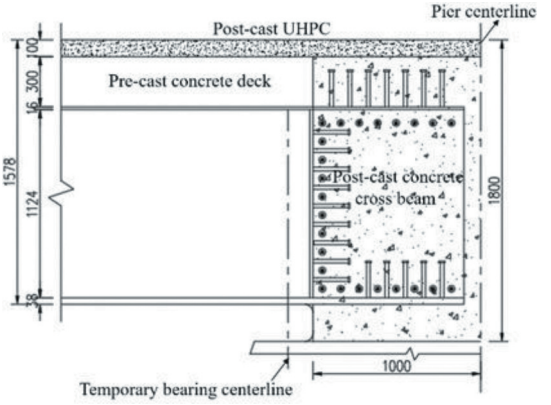

Figure 2. Beam-to-pier joint (unit: mm).

3 NUMERICAL SIMULATION

This paper establishes an overall three-dimensional solid model to study the overall mechanical behaviour of steel-concrete composite bridge in the case of pier girder consolidation during construction and service stages, and studies the influence of some structural system parameters. Due to the fact that the combination zone of composite girder and concrete pier is under complicated stress state, it is essential to establish a detailed local model to investigate its stiffness, ultimate capacity and failure mode by nonlinear finite element analysis.

3.1 *Overall mechanical behaviour*

3.1.1 *Finite element model*

This paper establishes an overall three-dimensional solid model by the general finite element software ANSYS for stress analysis, as Figure 3 presents. In this model, steel plates are simulated by SHELL93 element, while concrete components are simulated by SOLID95 element. The actual construction process of the bridge is considered in the calculation. The steel girder and concrete slab are prefabricated and combined in the factory, and then erected in place. Subsequently, the concrete cross beam is poured to connect main girders and piers. The EKILL and EALIVE commands are used to simulate the construction process. The boundary conditions of the model during service stage are as follows, displacements in Y and Z direction are restricted on both sides of steel bottom plates, and nodes at the bottom of piers are restricted in all directions. The dead load, vehicle load and the effect of temperature, foundation displacement and concrete shrinkage and creep are considered in the finite element calculation. The most unfavorable condition is found through combination of load effects.

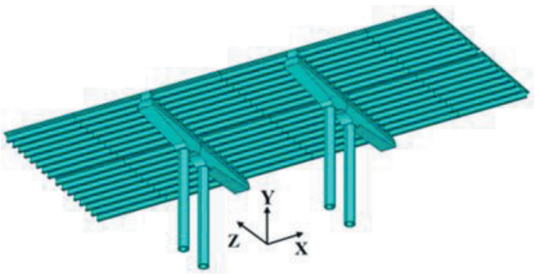

Figure 3. Three-dimensional solid model.

3.1.2 *Numerical results*

Through combination of load effects, the following three cases are determined. Case 1: the hogging moment zone is under the most unfavorable state; Case 2: the midspan area of the side span is under the most unfavorable state; Case 3: the midspan area of the middle span is under the most unfavorable state.

Figure 4 presents the longitudinal normal stress distribution of the structure under Case 1. It can be seen from Figure 4(a) that the maximum tensile stress values 13.0MPa and occurs at the upper edge of the junction section of main girder and concrete cross beam. It demonstrates that pouring UHPC at the surface of hogging moment zone is essential. Figure 4(b) shows that the closer to the outer lane, the greater the compressive stress of the concrete cross beam is. This is mainly due to the fact that eccentric loading is considered when arranging the vehicle load. The maximum compressive stress reaches 32.4MPa, which is caused by stress concentration. Figure 4-(c) shows that tensile stress of top plate in the middle of the side span is 98.1 MPa, and the compressive stress of bottom plate is 70.2 MPa.

Maximum longitudinal normal stresses of different components are listed in Table 1. It should be noted that the maximum stresses of steel plates given in the table are obtained in the

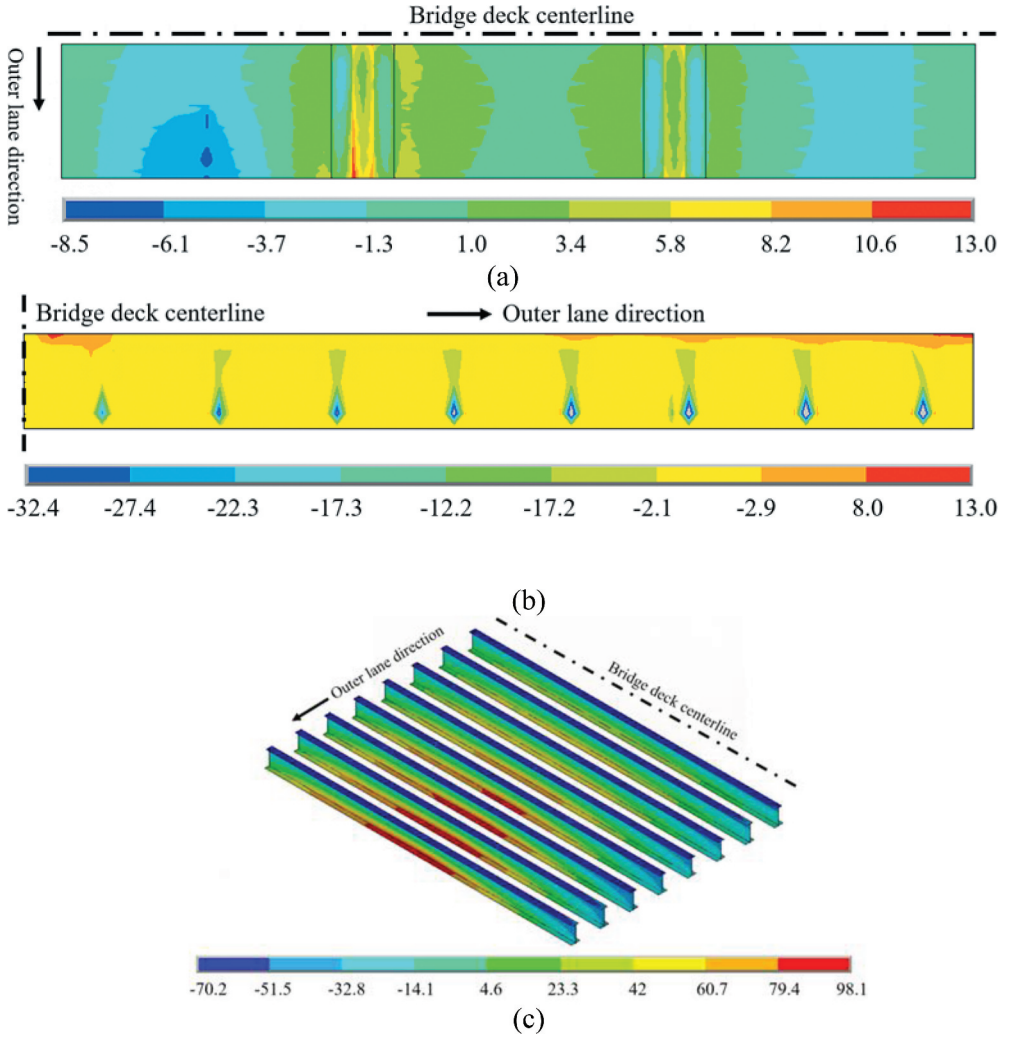

Figure 4. Longitudinal normal stress distribution of (a) concrete slab; (b) concrete cross beam and (c) steel plates of side span under Case 1.

midspan region. The stress of concrete slab reaches 13.0MPa, while that of steel structure is far less than the material limit. It can be concluded that the stress state of concrete slab in the hogging moment zone plays a crucial role in the design of steel-concrete composite bridge in the case of pier girder consolidation.

Table 1. Maximum longitudinal normal stresses of different components (unit:MPa).

		Side span		Middle span	
	Concrete slab	Top Plate	Bottom Plate	Top Plate	Bottom Plate
Case 1	13.0	-70.2	98.1	-64.6	17.9
Case 2	10.3	-54	113.5	-48.0	26.0
Case 3	9.9	-51.3	53.9	-50.2	80.7

Note: Positive number represents tensile stress, negative number represents compressive stress.

3.1.3 *Parameter study*

Effects on the static behaviour of the structure are investigated by varying span, pier height and the longitudinal length of concrete cross beam in this paper. The parameter study only con-siders the effects of dead load and vehicle load.

Figure 5 illustrates the longitudinal tensile stress distribution of the upper edge of concrete slab under different span, pier height and longitudinal length of concrete cross beam. When the span changes from 20m to 40m, the maximum longitudinal tensile stress of the upper edge of concrete slab increases from 5.5MPa to 16.8MPa. In addition, it can be seen from Figure 5-(a) that length of tensile area of concrete slab is about 0.4L. When the pier height changes from 10m to 50m, the maximum longitudinal tensile stress of the upper edge of concrete slab near the side span decreases from 10.7MPa to 10.1MPa, that near the middle span increases from 8.0MPa to 8.2MPa. It can be concluded that pier height slightly affects stress distribution of the upper edge of concrete slab. With the increasing of the longitudinal length of concrete cross beam, the longitudinal tensile stress of the upper edge of concrete slab within the concrete cross beam area decreases, while that outside the concrete cross beam area increases. When length of concrete cross beam changes from 0.6m to 2.0m, the maximum longitudinal tensile stress of the upper edge of concrete slab changes from 12.3MPa to 10.3MPa.

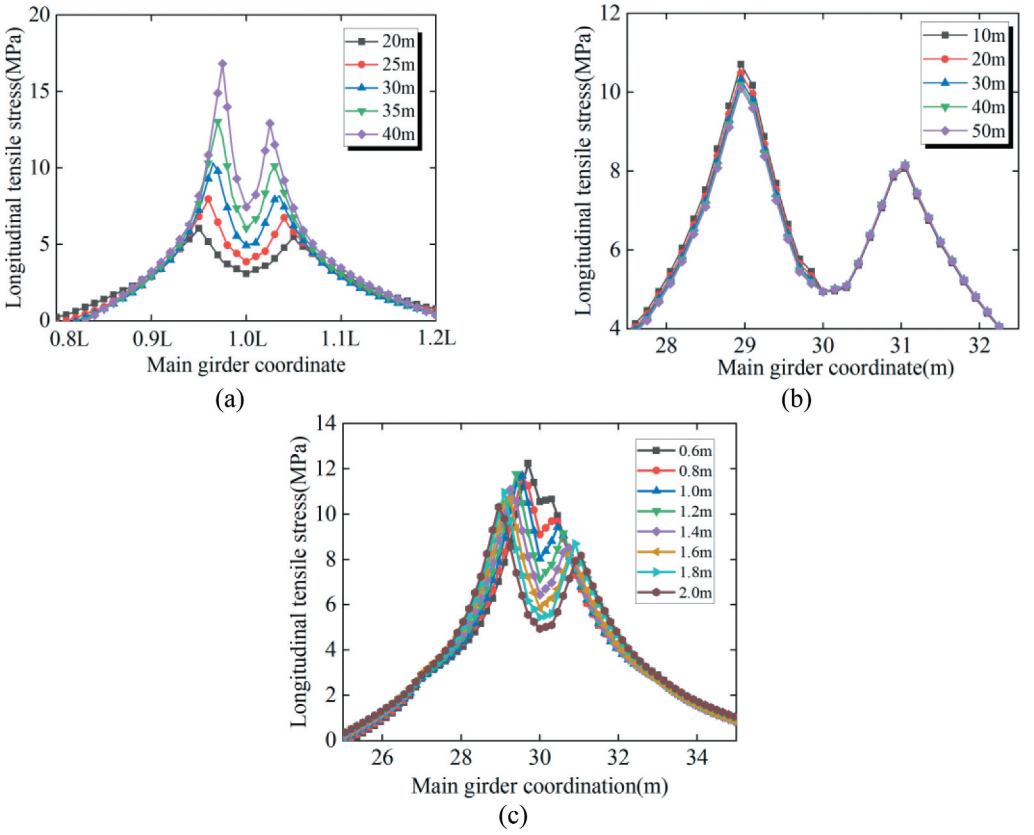

Figure 5. Longitudinal tensile stress distribution of the upper edge of concrete slab under different (a) span; (b)pier height and (c) longitudinal length of concrete cross beam.

3.2 *Local mechanical behaviour*

3.2.1 *Finite element model*

This paper establishes a local model which minutely simulates the combination zone of composite girder and concrete pier, as Figure 6 shows. The longitudinal length of the local model

is taken as length of the hogging moment region. In this model, steel plates are simulated by shell element, and loaded plates, the UHPC layer, concrete slab and cross beam are simulated by solid element. Rebars simulated by truss element are embedded in the concrete. Concrete and steel plates are tied together. The boundary conditions of the model are as follows, nodes at the bottom of concrete cross beam are restricted in all directions. Displacement-controlled loading is applied on both sides. Dynamic explicit analysis, which can increase the calculation speed, is used to numerically solve the iterative equation.

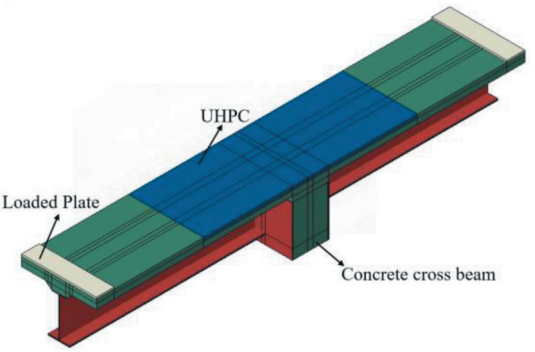

Figure 6. Local model.

The concrete damaged plasticity (CDP) model is employed to simulate the mechanical behavior of the concrete. For C50, the stress-strain relationship of C50 is referred to the current specifications of China, and for UHPC, the stress-strain relationship in tension is referred to Gao[9], and that in compression is referred to Wang[10], as Figure 7 shows. The classic bilinear model is adopted for reinforcement bars and steel plates.

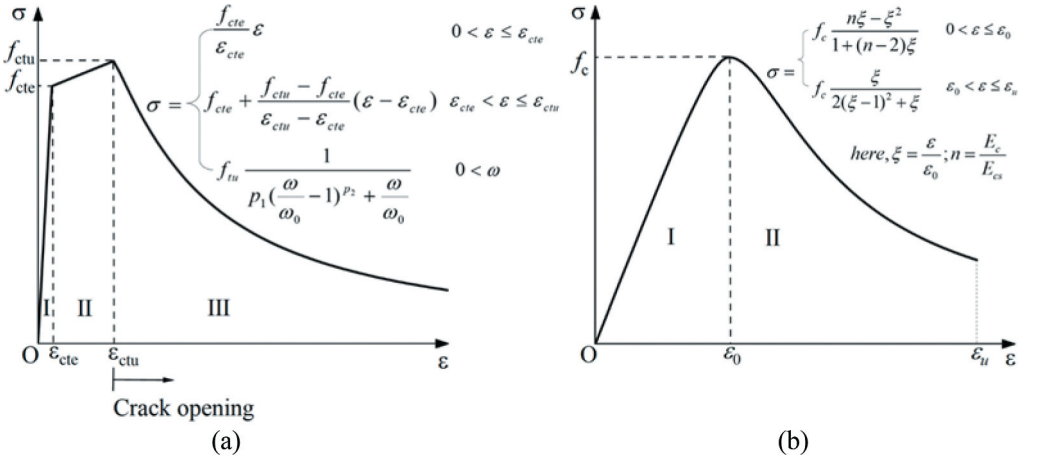

Figure 7. Constitutive models of UHPC: (a) tension; (b) compression.

3.2.2 *Numerical results*

Figure 8 demonstrates the load-displacement relationship of the structure. It is found that with the increasing of load, the cracking of normal concrete layer is earlier than that of UHPC layer on the surface. When the load reaches 466kN, the maximum tensile stress of C50 concrete reaches 2.64MPa, and the beginning of C50 concrete damage marks the end of the linear elastic stage. The UHPC layer begins to crack under a load of 600kN. The failure mode of the structure is the yielding of longitudinal rebars. The ultimate bearing capacity corresponding to the peak point is about 1468kN, and the corresponding vertical displacement is 37.0mm.

The longitudinal stress of rebars at the peak point reaches 400MPa, but steel bottom plates have not yielded, and the Mises stress values 332MPa. Figure 9 shows the concrete tensile damage at the peak point. It can be seen that severe damage happens to normal concrete compared with UHPC. The concrete cross beam also suffered tensile damage, which may be due to the fact that steel plates are embedded in the concrete and the relative displacement is not allowed.

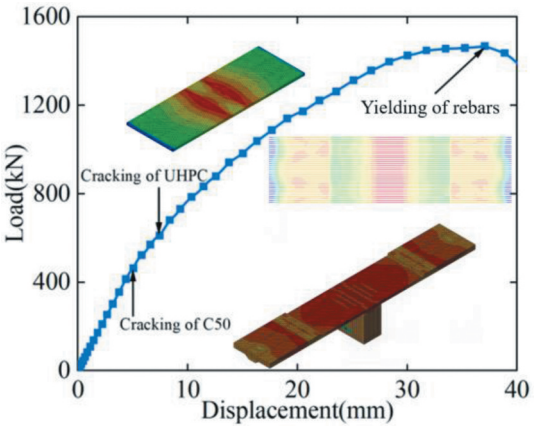

Figure 8. Load-displacement relationship.

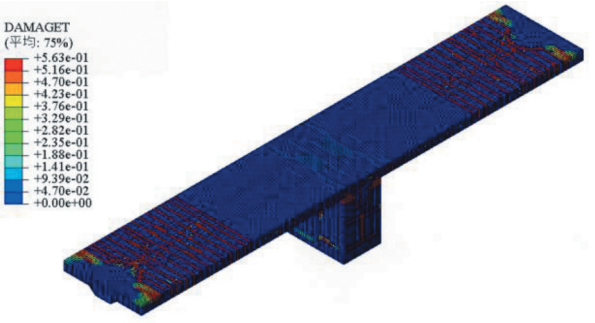

Figure 9. Concrete tensile damage at the peak point.

3.2.3 *Parameter study*

Effects on the static behaviour of the structure are investigated by varying shear span ratio, embedded depth of steel plates and reinforcement ratio in this paper. Table 2 lists the detailed parameters of the local model.

Table 2. Detailed parameters of local model.

Parameters	values
Shear span ratio	**3.8**, 3.2, 2.2, 1.6, 1.0.
Embedded depth	0.15m, 0.25m, **0.35m**, 0.45m, 0.5m.
Reinforcement ratio	0.88%, 1.04%, 1.2%, 1.36%, **1.68%**.

Note: Bold number indicates the parameters of the standard model.

The change of shear span ratio is achieved by varying the cantilever length on both sides. The shear span ratio mainly affects failure mode of the structure. When the shear span ratio is

less than 1.6, shear failure occurs in the structure, which is manifested by yielding of web, as Figure 10 shows.

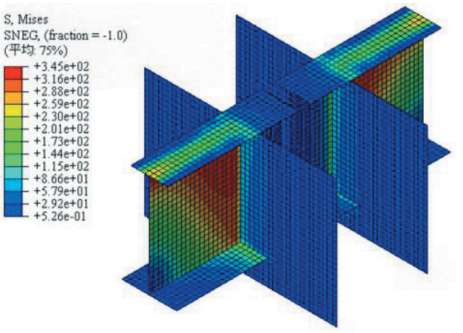

Figure 10. Failure mode.

Figure 11 shows the load-displacement relationship of structure under different embedded length of steel plates and reinforcement ratio. When the embedded depth of steel plates changes from 0.15m to 0.50m, the ultimate bearing capacity increases from 1333kN to 1639kN. When the load is less than 983kN, the load-displacement relationship of the structure under different embedded depth is almost identical, which is mainly due to the fact that the concrete cross beam begins to damage in a wide range when the load is greater than 983kN. With the increasing of reinforcement ratio, the stiffness and ultimate bearing capacity of the structure both increase. When the reinforcement ratio changes from 0.88% to 1.68%, the ultimate bearing capacity increases from 1282kN to 1490kN.

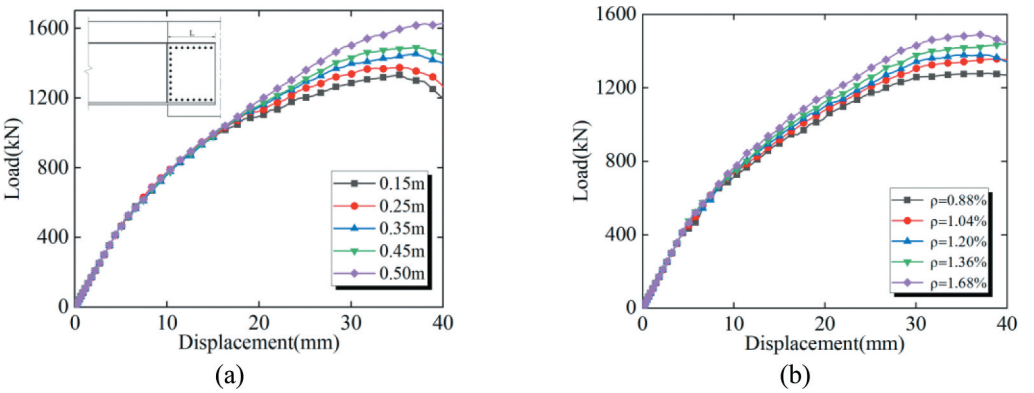

Figure 11. Load-displacement relationship under different (a) embedded length of steel plates and (b) reinforcement ratio.

4 CONLUSIONS

Based on the above investigations, the main conclusions are

(1) Stress state of concrete slab in the hogging moment zone plays a crucial role in the design of steel-concrete composite bridge in the case of pier girder consolidation.
(2) With the increasing of span, the longitudinal tensile stress of the upper edge of concrete slab increases.With the increasing of pier height, the maximum longitudinal tensile stress of the upper edge of concrete slab near the side span decreases, while that near the middle span increases. With the increasing of the longitudinal length of concrete cross beam, the longitudinal tensile stress of the upper edge of concrete slab within the concrete cross beam area decreases, while that outside the concrete cross beam area increases.

(3) With the increasing of load, the cracking of normal concrete layer is earlier than that of UHPC layer on the surface.
(4) Shear span ratio mainly affects the failure mode of the structure. When the shear span ratio is less than 1.6, shear failure occurs in the structure, which is manifested by yielding of web, and when the shear ratio is more than 1.6, bending failure occurs in the structure, which is manifested by yielding of longitudinal rebars.
(5) With the increasing of embedded depth of steel plates and reinforcement ratio, the ultimate bearing capacity of the structure both increase.

ABSTRACT: Roadway transportation systems contribute significantly to global Green House Gas (GHG) emissions. Although there has been significant progress in identifying how to reduce embedded GHG in construction, we do not know how efficient our decisions are in creating sustainable welfare. To achieve this knowledge, it is necessary to investigate how structures contribute to economic growth, life safety, resilience and sustainability, relative to their associated embedded GHG emissions. In the present paper a framework is provided on how the GHG efficiency of different strategies for roadway bridge design and integrity management may be modelled and quantified. The application of the framework is illustrated on an example considering typical design decisions for ordinary concrete highway bridges and it is shown that optimal decision in this respect have the potential to reduce embedded GHG emissions by a factor of two.

1 INTRODUCTION

The urgency to mitigate climate change has made the reduction of carbon emissions a global imperative, particularly in the short to mid-term. Civil structures and building structures play a big role in global greenhouse gas emissions. The global embodied GHG emissions from construction amounts to nearly 20% of global emissions caused by human activities (Faber, 2020). At the same time, infrastructure is expanding rapidly across the globe, driven by economic growth and increasing urbanization. This expansion brings significant environmental challenges. As critical elements of infrastructure, the construction, maintenance, and operation of civil structures, hereunder concrete bridges are significant contributors to global greenhouse gas emissions, particularly CO_2 emissions. This necessitates a focused effort to understand and mitigate the carbon footprint associated with the lifecycle of concrete bridges– as one example. To enable the construction industry to engage effectively in redesigning best practices, it is necessary to shift the focus of leading principles. These principles should be grounded in achieving the desired functionality of the built environment with maximum efficiency, especially in terms of minimizing environmental impacts like CO_2e emissions (all greenhouse gas emissions converted to the equivalent effect of CO2 on climate change), rather than relative to costs alone. To redesign best practices in this regard, however, necessitates that we are able to:

DOI: 10.1201/9781003483755-366

– Assess the efficiency of structural designs and strategies for structural integrity management in providing the desired functionality relative to associated effects on impacts to the environment, reliability/safety and economy.
– Understand the trade-offs between life safety, economy and reductions in impacts to the environment (at global and local scale) under different strategies for the development of societal infrastructure with respect to quality and quantity.

Presently, knowledge on these two points is very sparse; in fact no previous study of such nature has been identified by the authors.

The present paper focuses on the modeling of the relationship between bridge construction and integrity management decisions and their impact on associated life-cycle costs and embedded CO_2e emissions. Bridge structures made by reinforced concrete are addressed in the present paper but the general approach presented may be easily adapted to structures made of other materials. To investigate how different strategies for design affect the life-cycle cost and embedded CO_2e emissions, different design scenarios are explored by altering the cross section, material type, target reliability, and cover depth. Our analysis aims to support decisions for design of concrete bridges, contribute to decision making at political, regulatory, and operational levels on how to ensure and optimize sustainable and affordably safe development of infrastructure.

2 DECISION SUPPORT FRAMEWORK FOR BRIDGE MANAGEMENT

2.1 *Brief introduction of the decision support framework*

This framework is established based on previous research (Nishijima & Faber, 2009) in which optimal strategies for the development of infrastructure systems was addressed from the context of socio-economic optimization. In the present paper, focus is on the modeling of the relationships between the decisions related to the quality and quantity of the bridges and the consequences in terms of life-cycle cost and embedded CO_2e emissions during the life-cycle of the structures. In this framework, the quality of the structures is considered as the reliability/safety and durability of the structures and the quantity of the structures are considered as the material consumption such as the consumption of concrete and steel. There are trade-offs between the decisions on the quality and quantity of the structures considering the life-cycle cost and embedded CO_2e emissions as consequences. Decisions which may improve the reliability/safety level of the structures could lead to higher material consumption. Opting for higher reliability/safety in structural design reduces the probability of failures, thereby decreasing the expected embedded CO2e emissions from replacements or repairs caused by failures, but the higher material consumption may also at the same time be associated with a higher emissions.

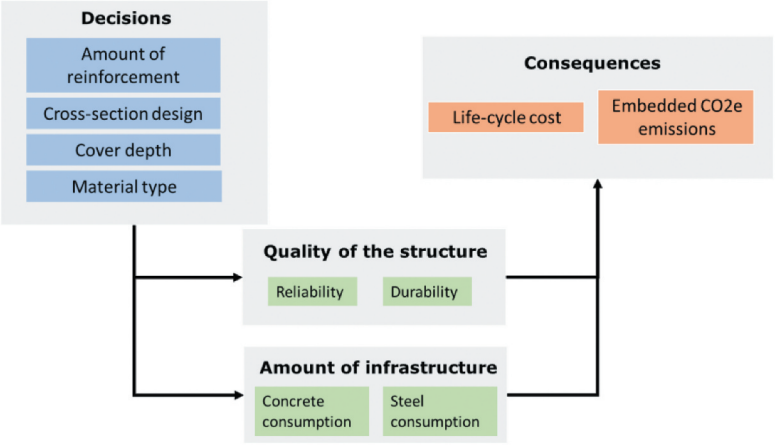

Figure 1. Principal relationships between decisions on the quality and quantity of bridges and consequences with respect to embedded CO_2e emissions and life-cycle cost.

2.2 *Modeling of failure events*

2.2.1 *Failures due to extreme operational loads*

The approach utilized for calibrating design codes, as demonstrated by Faber & Sorensen (2003), is adapted to model the failures due to extreme operational loads. In this way, instead of modeling structures in detail, only the failure modes relating to different types of materials and load cases are considered.

For purposes of simplicity, and without loss of practical relevance, it is assumed in the design process of the bridge girder cross section that the pre-stress reinforcement is designed to carry all the dead load. As a consequence the event of failure of the cross section is modelled as the event that the tensile force from the live loads in the mild reinforcement is larger than the yield capacity, which is expressed as:

$$g(z) = z \times F_{\mathrm{y}} - F_{\mathrm{load,l}} \tag{1}$$

where $F_y = f_y \times A_{\mathrm{s}}$ represents the tensile capacity of mild reinforcement, f_y is the yield strength of the mild reinforcement and A_{s} is the area of the longitudinal reinforcement; $F_{\mathrm{load,\ l}}$ is the tensile force from the live loads; z is the design parameter (e.g., cross-section parameter) which is adjusted such that the annual probability of failure is equal to a given target value $P_{\mathrm{f}}^{\mathrm{T}}$.

It is acknowledged that pre-stressing cables possess additional capacity which, under realistic conditions, would contribute to the ultimate capacity of the structure in response to live loads. However, in the present paper, we adopt this simplification to facilitate straightforward, preliminary estimates of the environmental impact, specifically in terms of CO2 emissions, associated with varying levels of safety. More detailed model of the limit state should be introduced in the future work.

The probabilistic model for the parameters entering Equation (1) are given in Table 1.

Table 1. Uncertainty model for the considered failure mode.

Basic variable	Distribution	Mean	CoV
Tensile capacity (F_y)	Log-normal	1	0.07
Tensile force from the live loads ($F_{\mathrm{load,l}}$)	Gumbel	1	0.3

2.2.2 *Modeling of degradation*

Research into the probabilistic modeling of deterioration processes has received considerable attention. The report by Duracrete (1999) provides a comprehensive review of the current understanding as it pertains to reinforced concrete (RC) structures compromised by chloride-induced reinforcement corrosion. Different limit state functions describe different condition states, which are related to the serviceability and the safety of the structure.

In the present paper, a simplified model is utilized to describe the ingress of chlorides into concrete (Malioka,2009), which is expressed as:

$$C(z,t) = C_s\left[1 - erf\left(\frac{z}{2\sqrt{tD}}\right)\right] \tag{2}$$

where $C(z, t)$ represents the chloride concentration at a distance z from the concrete surface at time t, C_s represents the the surface chloride concentration, D represents the chloride diffusion coefficient and $erf(\cdot)$ is the error function.

Corrosion will essentially begin when the chloride level at the depth of the reinforcement will exceed a critical threshold level, C_{CR}. Assuming both the surface chloride concentration and the diffusion coefficient as constant, the time till corrosion initiation, T_{CI}, at the first layer of reinforcement may be determined as follows:

$$T_{CI} = \frac{d^2}{4D}\left(erf^{-1}\left(1 - \frac{C_{CR}}{C_S}\right)\right)^{-2} \tag{3}$$

where d is the cover depth, which replace z in Equation (2), $erf(\cdot)$ is the inverse of the error function and can be expressed for computational purposes as:

$$erf^{-1}(\cdot) = \frac{\Phi^{-1}(\cdot)}{\sqrt{2}} \tag{4}$$

The limit state function for visible corrosion at time t can be expressed as:

$$g_{CV}(t, \mathbf{X}) = T_{CI}(\mathbf{X}) + T_V - t \tag{5}$$

where $\boldsymbol{X}$ is a vector that includes all the stochastic variables in the limit state function, T_V represents the time from corrosion initiation to visible corrosion. As suggested by Johnsen et.al. (Johnsen et.al., 2003), T_V is estimated as 10 years.

The deterioration of concrete structures is a random phenomenon that shows significant spatial variability. In the present paper, the model proposed by Straub et.al. (Straub et.al., 2009) is utilized. To model the spatial variability in concrete structures, areas with similar characteristics are grouped into zones. It is assumed that there is no interdependency between different zones. Then the zones are further discretized into elements. To assess the size of these elements, as well as their dependency structure, a study of the correlation length or radius of the parameters governing the degradation process must be carried out. In Straub (2009), the correlation length is identified as 80 cm.

Table 2. Uncertainty model for the degradation model.

Basic variable	Unit	Distribution	Mean	Std. dev.
d	mm	Log-normal	45/50/55	8/9/10
D	mm²/ year	Log-normal	μ_D	24
C_s	Weight-% of concrete	Log-normal	μ_{C_s}	0.04
C_{CR}	Weight-% of concrete	Normal	0.1	0.03
μ_D	mm²/ year	Normal	30	3
μ_{C_s}	Weight-% of concrete	Normal	0.24	0.02

2.3 *Life-cycle analysis*

Life-cycle assessment (LCA) is extensively utilized to evaluate the energy and environmental impacts throughout the lifespan of products and services. This is particularly relevant in the context of civil structures, which encompasses various stages such as material production, construction, maintenance, operation, and end-of-life (ISO 14040, 2006). These stages correspond to the A1 to C4 categorization in Life Cycle Assessment, see Figure 2.

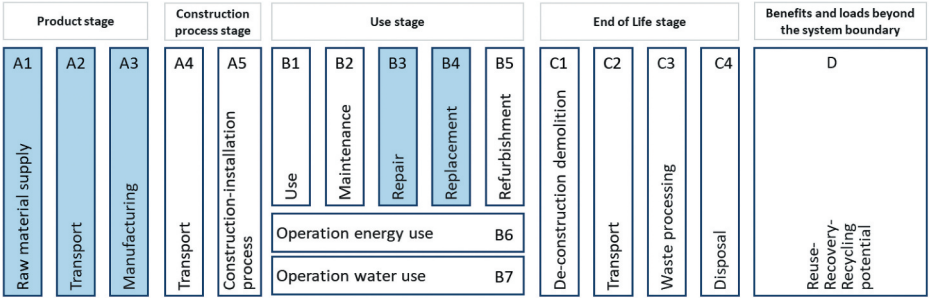

Figure 2. Life-cycle stages (ISO 14040, 2006).

2.4 *Life-cycle cost and embedded CO_2e emissions*

Considering different decisions related to the design and integrity management of the bridges, the life-cycle cost $E[C_T]$ can be expressed as:

$$E[C_{\mathrm{T}}\ (\mathbf{a})] = E[C_{\mathrm{C}}\ (\mathbf{a})] + E\left[C_{\mathrm{Repair}(\mathbf{a})}\right] + E\left[C_{\mathrm{Replacement}}\ (\mathbf{a})\right] \tag{6}$$

where **a** is the vector that represents the decision variables, $E[C_{\mathrm{C}}\ (\mathbf{a})]$ is the initial cost depending on the design decisions which lead to different material consumption and construction cost; $E\left[C_{\mathrm{Repair}(\mathbf{a})}\right]$ represents the repair cost, which depends on the decisions related to the degradation process of the structures such as cover depth and inspection and repair plan; $E\left[C_{\mathrm{Replacement}}\ (\mathbf{a})\right]$ represents the replacement cost which depends on the reliability of the structures.

The life-cycle embedded CO_2e emissions can be expressed as:

$$E[E_{\mathrm{T}}\ (\mathbf{a})] = E[E_{\mathrm{C}}\ (\mathbf{a})] + E\left[E_{\mathrm{Repair}(\mathbf{a})}\right] + E\left[E_{\mathrm{Replacement}}\ (\mathbf{a})\right] \tag{7}$$

where $E[E_{\mathrm{C}}\ (\mathbf{a})]$ is the embedded CO_2e emissions at the production phase (A1-A3), which also depends on the design decisions which lead to different material consumption; $E\left[E_{\mathrm{Repair}(\mathbf{a})}\right]$ represents embedded CO_2e emissions from the repairs (B3) (assuming embedded CO2e from inspection being minimal and somewhat similar for all scenarios) and $E\left[C_{\mathrm{Replacement}}\ (\mathbf{a})\right]$ (B4) represents the emissions from replacement. The considered stages in the life-cycle analysis are highlighted in Figure 2. It should be noted that the emissions calculated here are all expected values, which are the results after taking into account the uncertainty of the system. They are not directly calculated emissions in a given scenario.

3 ILLUSTRATIVE EXAMPLE

3.1 *Introduction of the example bridge*

The example bridge is a two-span continuous bridge, see Figure 3, and the detailed superstructure cross-section for the basic case is shown in Figure 4.

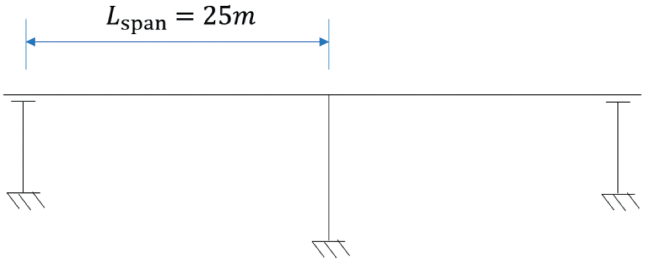

Figure 3. Two-span continuous bridge.

In the following, only the superstructure of the bridge is being considered.

3.2 *Design scenarios*

In the example, various design scenarios are explored by altering the cross section, material type, target reliability, and cover depth. Consequently, 18 distinct design scenarios are examined. Scenario 1 is the basic case shown in Figure 4. More scenarios could be investigated, but some of the most obvious are investigated here. These scenarios are indeed possible and reasonable, but some of them ar not allowed due to existing codes and guidelines. Even though these scenarios are not all currently implemented in practice, their inherent potential emphasize the needs for changing these regulations.

The first group of scenarios encompasses those with a reliability/safety level equivalent to the basic case, characterized by a failure probability, $P_f^T = 10^{-6}$. These scenarios are introduced as follows:

– Using a new type of cement, "FUTURECEM", which is a more sustainable cement based on the LC3 technology, can possibly reduce the CO_2e emissions significantly while

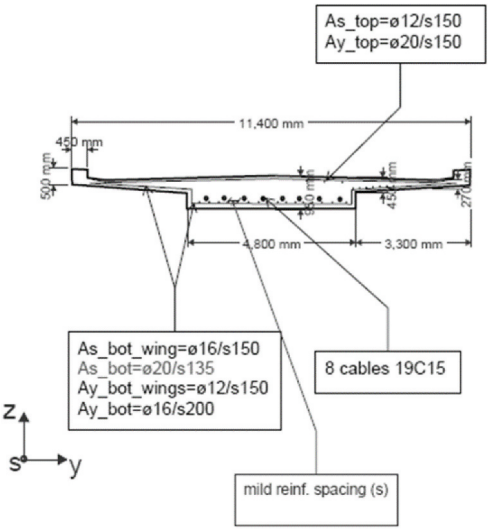

Figure 4. Cross-section for the basic case.

maintaining high performance, and is currently being implemented in various construction projects (Scenario 8).

- Using LC3 (Limestone Calcined Clay Cement), which is an environmentally friendly concrete technology that combines calcined clay and limestone to reduce clinker content, thereby lowering CO_2e emissions while possibly maintaining or enhancing the performance of traditional Portland cement (Scenario 9).
- Cut outs in the cross section, a technique involving intentional voids or openings in structural elements, effectively reduces concrete consumption. To maintain the bending capacity, this scenario necessitates an approximate 10% increase in the consumption of mild reinforcement (Scenario 10).
- Using lower strength concrete, C30. To preserve the bending capacity in this scenario, it's necessary to increase the consumption of mild reinforcement by about 5% (Scenario 11).
- Using recycled concrete. By repurposing concrete from the demolished structures, the aggregate and clinker in the concrete can be substituted by the recycled This approach reduces the consumption of raw materials and lowers CO_2e emissions (Scenario 12).
- Reduce the cross-section height with 10cm. To maintain the capacity, this scenario necessitates an approximate 30% increase in the consumption of mild reinforcement (Scenario 13).
- Reduce the cross-section height with 20cm. To maintain the capacity, this scenario requires an approximate 75% increase in the consumption of mild reinforcement (Scenario 14).
- Reduce the cross-section height with 20cm and using high-strength mild reinforcement (700 Mpa). To maintain the capacity, this scenario requires an approximate 40% increase in the consumption of mild reinforcement (Scenario 15).

Then different reliability levels are considered, which are calibrated according to Equation (1). Scenarios related to lower reliability/safety level ($P_f^T = 10^{-5}$) are considered as follows:

- Reducing mild reinforcement based on the basic case (Scenario 2).
- Using low strength concrete (Scenario 3).
- Reduce the cross-section height with 10cm (Scenario 4).
- Reduce the cross-section height with 20cm (Scenario 5).
- Reduce the cross-section height with 20cm + 700 MPa reinf. (Scenario 6).
- LC3 concrete + Reduce the height of the cross section with 20cm + 700 MPa reinf. (Scenario 16).

Scenarios related to higher reliability/safety level ($P_f^T = 10^{-7}$) are considered as follows:

– Increasing mild reinforcement based on the basic case (Scenario 7).

Finally, to investigate the effect of cover depth, on basis the basic case (cover depth is 45mm), two other scenarios are considered by reducing or increasing the cover depth by 5 mm.

3.3 *Results*

Figure 5 shows the expected value of life-cycle total emissions. The emission factors utilized in the example come from InfraLCA, a tool developed by the Danish Road Authority (2021). The emission factors for the FUTURECEM and LC3 are assumed according to the research in Antoni et al. (2012) and the report from Aalborg Portland (2020).

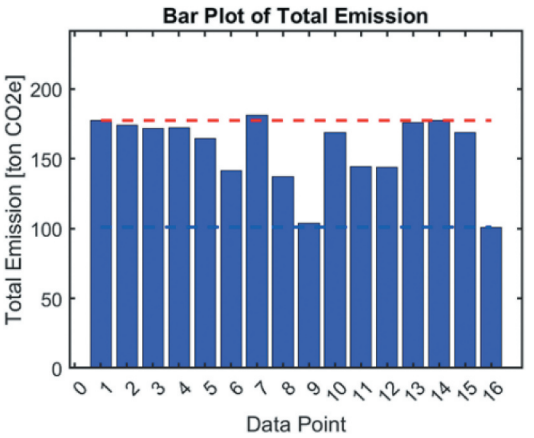

Figure 5. Expected value of life-cycle total emissions (A1-A3 + B4).

It is observed that all scenarios with lower reliability/safety levels have been observed to reduce embedded CO2e emissions when compared to the basic scenario, conversely, the scenario with higher reliability/safety level is associated with an increase in embedded CO_2e emissions compared to the basic scenario. Keeping the basic-case reliability/safety level, it is still possible to reduce emissions by utilizing low emission materials such as LC3 and FUTURECEM or utilizing high strength steel. Scenario 16 can reduce emissions by more than 40%. Additionally, there is a minimal difference in the total cost across the various scenarios.

By calculating the expected value of life-cycle total costs, it is found that there is a minimal difference in the total cost across the various scenarios - within a margin of 5%. The purpose of the calculation here is to estimate the cost difference due to changes in material type, material consumption, and reliability level. Since many materials are not yet available on the market, the results here are based on assumptions.

Table 3 shows the results about expected value of total embedded CO_2e emissions for different cover depths. It is observed that increasing the cover depth by 5mm can reduce the annual embedded CO_2e emissions (yearly emissions) by 20% compared with the basic case. It is important to understand that this does not imply a reduction of total emissions at the initial point.

Table 3. Expected value of CO_2e emission with different cover depth.

Cover depth	Emission (production (A1-A3)) [t CO_2e]	Expected value of emission from major repair (B3) [t CO_2e]	Expected value of total CO_2e emissions (A1-A3 + B3)	Life [yr]	Annual carbon emission [t CO_2e/yr]
40 mm	175.21	2.67	177.88	100	1.78
45 mm	177.36	3.88	181.24	135	1.35
50 mm	179.91	5.96	185.87	175	1.06

4 CONCLUSION

The efficiency of roadway bridge design and strategies for structural integrity management in providing the desired functionality relative to associated effects on impacts to the environment, safety and economy are assessed. This study demonstrates that there are multiple strategies to effectively reduce embedded CO_2e emissions in civil structures. The utilization of lower strength concrete (scenario 6 and 11), incorporation of high strength steel (scenario 5 and 15), and the use of low emission materials (scenario 8, 9, 12, and 16) have all shown promising results. Notably, these strategies have the potential to decrease emissions by more than 40%. Additionally, increasing the concrete cover thickness (the concrete outside the reinforcement), while also initially increasing the embedded CO_2e emissions during the production phase, has the long-term benefit of reducing the frequency of major repairs and extending the lifespan of structures, thereby reducing annual embedded CO_2e emissions. The findings of the present study emphasize the vital necessity for industries to expedite the qualification of new materials for various uses and exposures. It's imperative that this information is shared swiftly and incorporated into new policies, codes, standards, and guidelines.

Fatigue design of continuous thermite-welded rail

Y.C. Park & J.Y. Lee
Department of Civil Engineering, Inha University, Incheon, Republic of Korea

ABSTRACT: Since continuous rails are made by welding a certain length of rail, there is a pos- sibility that fatigue cracks may occur due to train passage. Since thermally welded long rails are constructed in the field, there is a higher probability of welding defects compared to other welding methods. Therefore, the fatigue life of continuous rails can be determined by the fatigue life of thermite-welded connection. In this study, the fatigue life of thermite-welded continuous rails presented in existing studies was verified. The fatigue strength of thermite-welded continuous rails was evaluated based on linear elastic fracture mechanics by analyzing the existing experi- mental results. The fatigue life and crack shape at failure were used to obtain the initial crack size for crack growth analysis. The stress intensity factor range threshold utilized to obtain the fatigue limit is determined by the stress ratio. Changes in residual stress due to seasonal temperature changes cause changes in the stress ratio acting on the rail, and therefore changes in the fatigue limit occur depending on the season. Considering these features, a fatigue design method for ther- mite-welded continuous rail is proposed.

1 INTRODUCTION

Fatigue cracks in rails can be caused by welds or by friction between the rail and the wheel. Welds are particularly susceptible to fatigue cracking due to inherent nature of welding, with large re- sidual stresses and micro-discontinuity at the interface of the weld and the rail. Welding methods for rails include flashbutt welding, gas tack welding, thermite welding, and submerged arc weld- ing. Among them, thermite welding is a method of joining rails by installing molds on the rails in the field, which has the advantage of simple welding equipment, no need for power equipment, and short welding time, but it has the disadvantage of quality deviations depending on the skill of the operator, low strength of the welded part as a casting, and a lot of padding in the web and lower part of the rail. In particular, it can be considered the most vulnerable to fatigue cracking because the fatigue strength is lower than other welding methods due to the strength of the casting and the presence of the filler metal.

Several studies have experimentally characterized the fatigue performance of thermite-welded connection. The fatigue strength of thermite welds has been studied experimentally by Ishida (1990) and Park (2016). The experiment conducted by Ishida (1990) was a full-scale rail fatigue test for thermite-welded connection with the purpose of studying the relationship between rail surface irregularities and rail bending fatigue life. The test method was a four-point bending fatigue test, and the results of the test are shown in Figure 1. The test conducted by Park (2016) was a full-scale rail fatigue test for thermite-welded connection for the purpose of studying the rela- tionship between rail surface irregularities and rail bending fatigue life. The test method is a three- point bending fatigue test, and the results of the test are shown in Figure 2.

As shown in Figures 1 and 2, S-N curves for various probability of fracture were presented based on the linear-log scales of the stress range and number of cycles to failure. As per linear elastic fracture mechanics, crack growth rate is linear to the stress intensity factor when both are illustrated in log-log scale. Thus, S-N curves for welded connections recommended in many fa- tigue design guidelines are in the form of log-log scale, so that both Ishida (1990) and Park (2016) are violating the basic rule of linear elastic fracture mechanics.

DOI: 10.1201/9781003483755-367

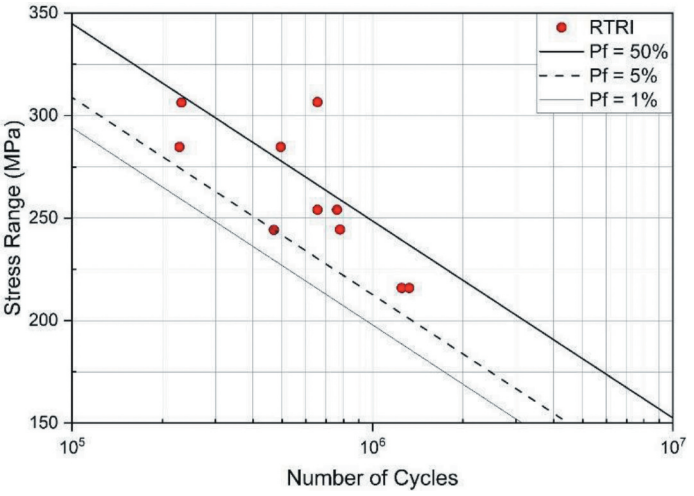

Figure 1. Fatigue test results conducted by Ishida (1990).

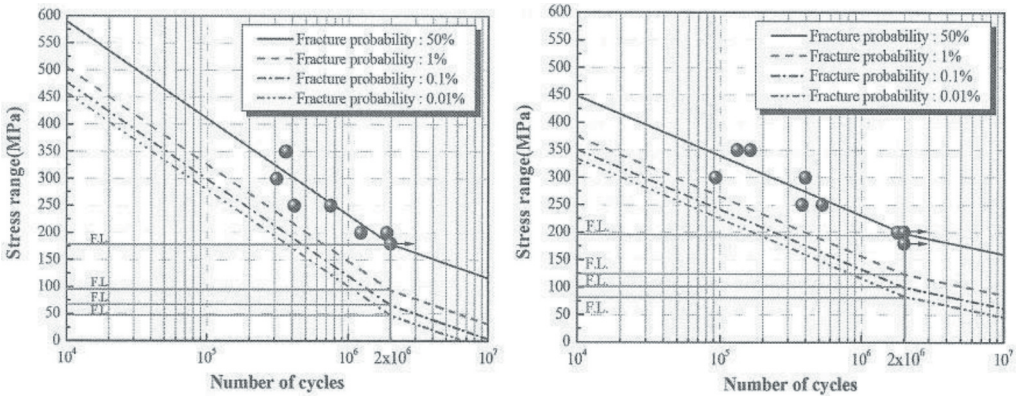

Figure 2. Fatigue test results conducted by Park (2016): (a) 50 kg/m rail; and (b) 60 kg/m rail.

The maintenance guidelines for continuous rail in Korea are divided into rail replacement cy- cles based on rail wear by rail type and cumulative tonnage. The criteria for rail replacement consists of the degree of wear, cumulative tonnage and visual inspection. The rail replacement criteria items that are currently applied are reviewed from a linear elastic fracture mechanics per- spective for a more reasonable rail life assessment.

A method of determining the fatigue life of the thermite-welded rail was developed by simulating different crack growth under repeated loading based on linear elastic fracture mechanics. Fatigue crack growth simulation was performed based on the fracture surface data from previous fatigue tests (Park 2016), and the expected initial crack size was estimated. Based on the fatigue test data, S-N curves for 5 and 50% of the probability of failure on log-log scale.

2 S-N CURVE OF THERMITE-WELDED RAIL

Fatigue test data for thermite-welded rail was collected from various documents and are shown in Figure 3 (Ishida 1990, Park 2016, Sung 2021, Yang 1998). Fatigue life of 51 specimens with the stress ranges from 100 to 450 MPa. No significant difference was observed from the new and used rails and 50 kg and 60 kg rails.

S-N curves for the probability of failure *Pf* of 50% and 5% were estimated, and those were:

$$P_f \ of \ 50\% : \log N = 15.25 - 3.92 \log S_r \quad (1)$$

$$P_f \ of \ 5\% : \log N = 14.88 - 3.92 \log S_r \quad (2)$$

where, N = fatigue life; and Sr = stress range.

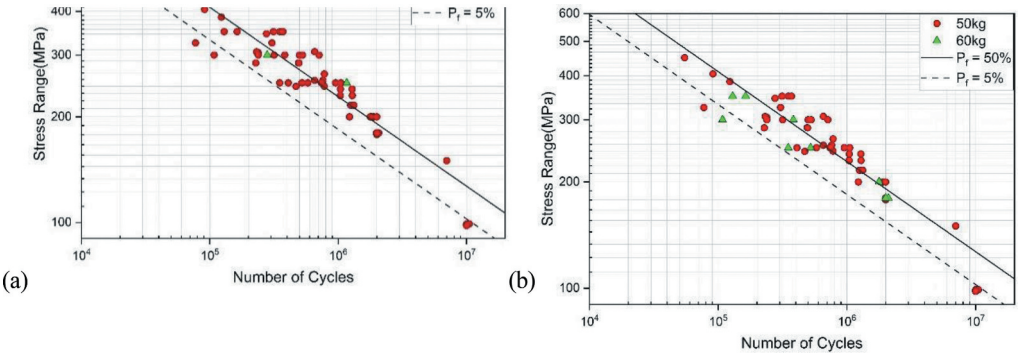

Figure 3. Fatigue test data of thermite-welded rail and S-N curve: (a) comparing used and new rail; (b) comparing 50kg and 60 kg rail.

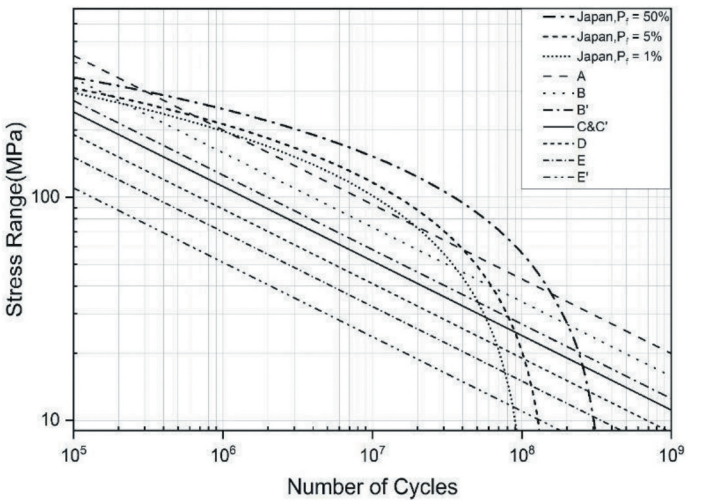

Figure 4. Comparison of S-N curves from AASHTO (2020) and Ishida (1990).

Figure 4 shows the S-N curve by probability of failure from Ishida (1990) and the S-N curve from AASHTO (2020) on a log-log scale. As shown in this figure, for stress ranges where exper- imental or regression data are available, fatigue life is likely to be severely under-estimated for sections in the lower stress range. The plotting of fatigue life against stress range on a linear scale follows a trend from the early days of fatigue research in the 19th century, and even then it was known that the relationship between stress range and fatigue life was not linear, but exponential, so it is a clear error to plot the S-N curve on a linear-log scale as in previous studies. It is consistent with the theory of linear elastic fracture mechanics that the S-N curve of steel has a linear rela- tionship in the stress range higher than the fatigue limit on the logarithmic scale. Since the fatigue tests in the previous studies were conducted at a stress range of 200 MPa or higher than the actual stress range, the fatigue life at stress ranges beyond the data used in the regression analysis is not reliable, but it is judged to be linear in

this range according to the results of fatigue tests of other structural steel joints and the theory of linear elastic fracture mechanics.

Under normal conditions, the stress range developed by the traffic of train is less than 100 MPa. However, all fatigue tests were conducted at the stress range greater than 100 MPa. To construct robust fatigue design curve including the fatigue limit, fatigue test data which includes the stress range at lower stress range level is required. Unfortunately, fatigue test data is not available for lower stress range levels, analytical approach based on linear elastic fracture mechanics (LEFM) was performed to estimate fatigue limit of the thermite-welded rail.

3 ESTIMATE FATIGUE LIFE AND FATIGUE LIMITS FOR THERMITE WELDS BASED ON LEFM

3.1 *Key factors affecting fatigue performance*

It has been known that the fatigue crack growth rate depends on the stress intensity factor range. When the stress intensity factor range is greater than the threshold ΔKth and less than the fracture toughness KIc, fatigue crack growth rate linearly increases as increasing stress intensity factor range in log-log scale (Figure 5). This relationship is called the Paris Law (Paris & Erdogan 1963). The following equation expresses the relationship:

$$\frac{da}{dN} = C \times (\Delta K)^m \text{ or } \log\left(\frac{da}{dN}\right) = \log C + m \times \Delta K \tag{3}$$

where a = crack size; N = number of stress cycles; C and m = material constants; and ΔK = stress intensity factor range.

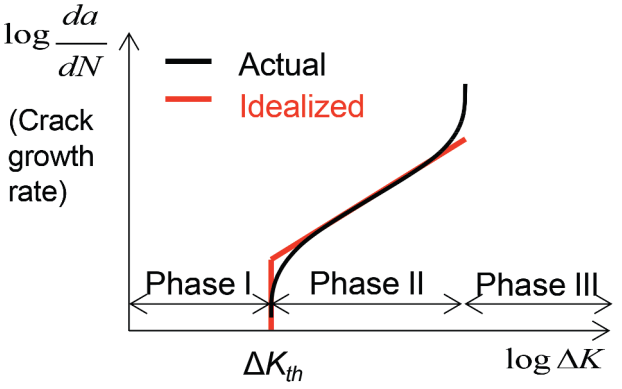

Figure 5. Relationship between crack growth rate and stress intensity factor range.

According to the Paris Law equation, the main factors affecting fatigue life are crack size, material constants and fracture toughness KIc. To determine these factors, test results conducted by Yang (1998) were considered. The material constants C and m and the fracture toughness KIc of the rail are tubulated in Table 1. The factors were measured from the upper and lower parts of rail. The values of the material constants were averaged, and lower value of the fracture toughness KIc was considered to be conservative. It should be noted that the averaged value of m = 3.7, which is the slope of the crack growth rate with respect to the stress intensity factor range, is close to the slope of the S-N curve shown in Figure 3 and Equations 1 and 2.

3.2 *Estimating initial crack size*

Initial crack size in the thermite weld was estimated from the test results conducted by Park (2016). As shown in Figure 6, width and depth of the fatigue crack were 54.0 and 17.6 mm,

Table 1. Material constants C and m and fracture toughness KIc of rail (Yang 1998).

Factors	Upper part	Lower part	Average
C	4.21×10^{-14}	7.10×10^{-17}	7.13×10^{-15}
m	3.2	4.2	3.7
KIc (MPa√mm)	1429	1398	–

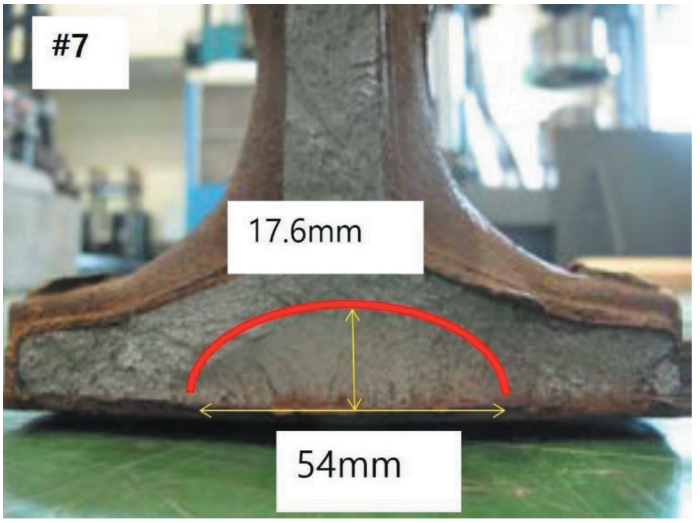

Figure 6. Fracture surface and fatigue crack of thermite-welded connection (Park 2016).

respectively. Applied stress range was 200 MPa with minimum stress of 30 MPa at the bottom fiber of the specimen, the fatigue life was 1.9 million cycles. Stress intensity factor was calculated at the deepest point of the crack and was 1423 MPa√mm. The fracture toughness KIc of 1398 MPa√mm was validated. Newman-Raju solution for elliptical edge crack was applied to calculate the stress intensity factor (Newman & Raju 1984).

Initial crack was assumed to be elliptical edge crack and the size was estimated by conducting crack growth simulation from the final crack to the initial crack using Equation 3. Estimated initial crack depth and width were 0.51 mm and 22.5 mm, respectively. The specimen shown in Figure 6 demonstrated the fatigue life close to the probability of failure of 50%. Thus, initial crack size which could provide probability of failure of 5% presented in Figure 3 was estimated to obtain conservative fatigue limit.

Range of the crack depth was assumed to be 0.7~1.3 mm, and aspect ratio of the initial crack (depth to width ratio) was assumed to be 1/200~1/50. The crack depth and the aspect ratio were divided into 30 levels, and crack growth simulation was conducted using Equation 3. To consider the effect of the stress range, stress ranges of 100, 200 and 300 MPa were considered.

Estimated initial crack sizes for various stress ranges are tabulated in Table 2.

Table 2. Estimated initial crack size for various stress ranges.

Stress range (MPa)	Crack depth (mm)	Crack width (mm)
100	1.21	62
200	1.10	59.3
300	0.98	51.5

3.3 *Estimating fatigue limit*

As shown in Figure 3a, fatigue life of used rails is not different compared to the new rails indicating fatigue cracking has not occurred on the rail in service. Since the train load on the rails is not highly variable, it can be assumed that these rails will not develop fatigue cracks no matter how long they are used. Therefore, knowing the fatigue limit, the stress range below which fatigue cracking will not occur in thermite-welded rail, can have a significant impact on the maintenance of rails in service.

The stress range at which crack growth may not occur when applying the initial crack size to estimate the fatigue limit was identified based on LEFM. According to Barsom & Rolfe (1999), stress intensity factor range threshold ΔKth, which can determine the fatigue limit, is determined by the following equation:

$$\begin{aligned} \Delta K_{th} = {} & 7(1 - 0.85R)MPa\sqrt{mm} && \text{for } R0.1 \\ = {} & 6MPa\sqrt{mm} && \text{for } R<0.1 \end{aligned} \tag{4}$$

where, R = stress ratio. The stress ratio is determined by the maximum and minimum values of the stress range. To determine the maximum and minimum stress, the actual stress acting on the rail should be determined, but it is very difficult to measure actual stress. As an alternative, fatigue limit for varying stress ratio was estimated. The fatigue limit was determined using following equation:

$$Sr = \frac{\Delta K_{th}}{Y(a)\sqrt{\pi \mathrm{a}}} \tag{5}$$

where, $Y(a)$ = correction factor. The fatigue limit obtained by varying the stress ratio from 0.1 to 0.6 for the stress range of 100 MPa are shown in Table 3.

Table 3. Fatigue limit at the stress range of 100 MPa.

Stress ratio	0.1	0.2	0.3	0.4	0.5	0.6
Fatigue limit (MPa)	163	148	133	118	103	87

4 CONCLUSION

To estimate the fatigue life and fatigue limit of thermite-welded rail, this study analyzed the re- sults of previous fatigue test results and estimated the initial crack size. Fatigue limit based on the linear elastic fracture mechanics was estimated considering the initial crack size and fatigue test results. The main conclusions of this study are follows:

(1) S-N curve for the fatigue design or the maintenance of the thermite-welded rail was proposed based on previous fatigue test results. S-N curve of thermite-welded continuous rail for the 5% probability of failure was $\log N = 14.88 - 3.92\log Sr$.
(2) The crack width and depth of the initial crack in the thermite weld, obtained by considering the size of the fatigue crack identified in the fracture surface of a fatigue tested specimen and the fatigue life for a 5% probability of failure, are approximately 0.98~1.21 mm and 51.5~62.0 mm, respectively.
(3) The fatigue limit was estimated by considering various stress ratios, and the fatigue limit was estimated to be approximately 90 MPa for the most conservative case, a stress ratio of 0.6.

The results of this study are based on previous experimental results and a number of assump- tions. In order to better characterize the fatigue properties of thermite-welded connection for ef- fective maintenance, it is necessary to further confirm the following points:

- magnitude of residual stresses around the weld after thermite welding
- range of stresses caused by vehicle traffic on the rails at various locations
- stress changes due to changes in the environment around the rails, such as tempera- ture changes, deflection of the bridge, rail lifting, etc.
- fatigue life when the range of stresses experienced by the rail is formed around the fatigue limit.

Risk-based evaluation of fire protection on cable-supported bridges

N.P. Høj
HOJ Consulting, Brunnen, Switzerland

M. Bjelkerud
RED Consulting, Oslo, Norway

H. Matre
Norwegian Public Roads Administration, Oslo, Norway

ABSTRACT: The procedure and practical application of a risk-based evaluation of the fire exposure, fire impact and fire protection of cable supported bridges is presented.

The goal is to adapt fire protection to the actual risk of the individual structure. Whereas it may be sufficient to follow guidelines and common practice for more modest structures, larger cable supported bridges may benefit from a specific study based on the actual structure and exposure.

1 INTRODUCTION

The main steps in a risk-based evaluation include: hazard identification, estimation of probabilities and consequences, aggregation of the risk picture and evaluation of acceptability and risk reducing measures.

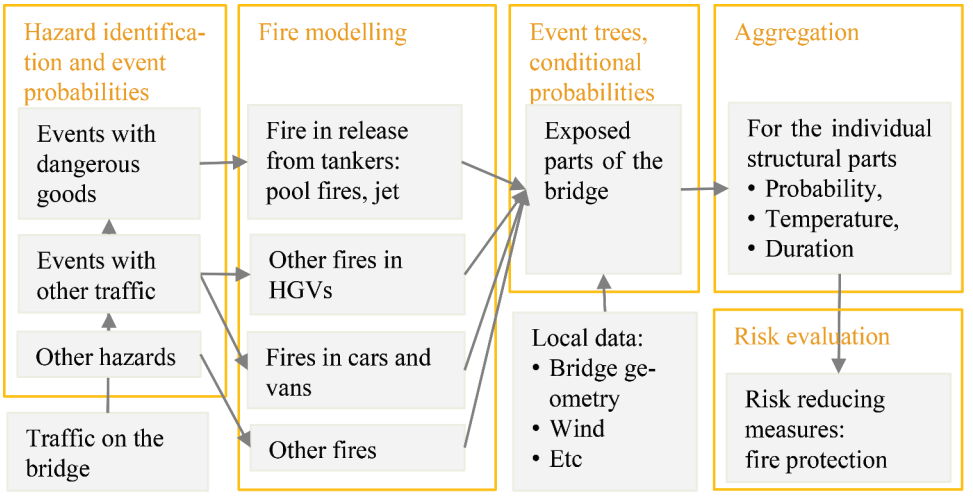

Figure 1. Structure of the risk-based evaluation of fire protection.

DOI: 10.1201/9781003483755-368

2 HAZARD IDENTIFICATION

The first step identifies the main scenarios: fires in dangerous goods transports, in other trucks or vehicles, and fires from other sources. The estimation of the probabilities is dependent on the traffic volume, the traffic composition, and an estimate of the local basic events probabilities. Local conditions which indicate increased or reduced incident probabilities need to be taken into account. The timely development of traffic and incident rate will have to be considered, and either a reference year can be decided or the development over time can be integrated.

Whereas the statistical basis for accidents on road and fires in tunnels is well represented in literature and in public statistics, the event probabilities for various types of fires on bridges need to be based on assumptions and estimates. The data for events with dangerous goods are available for open roads and for tunnels. With the focus on the most severe fires in dangerous goods, these data can be applied for bridges as well. A more comprehensive and generally accepted basis may be established and shared internationally by authorities and scientists.

The main initial events distinguish fires in road vehicles as results of accidents and "spontaneous" fires, igniting without prior accidental events.

Furthermore, the fires are distinguished with respect to fires in light vehicles (cars and vans), heavy goods vehicles (HGV) and transports of hazardous (flammable) goods.

The fires in dangerous goods are modelled as pool fires (flammable liquids spill on the road and ignited) and jet fires (flammable liquids or gasses released from pressure tanks and ignited). Other fires in general flammable solids may be modelled separately for the various substances, alternatively a model can be adapted and made representative for the various solid substances.

Other hazards may include fires in buildings or other infrastructure near the bridge or, for bridge over waterways, fires in vessels under the bridge. Also fires in the technical equipment in the bridge, lightning, and sabotage (and similar) have been identified as hazards. The effect of these types of hazards are not discussed further in this paper.

The probability of these initiating events will need to be established.

Further detailing in the hazards include the circumstances of the fire, i.e., the location of the fire, the wind and other meteorological conditions during the fire, the size of the leak, etc. These circumstances are modelled in terms of event trees and based on initial event probabilities and conditional probabilities for the circumstances, the probability of each scenario of the event tree is determined.

3 FIRE MODELLING

3.1 *Pool fires*

In the present paper the fire modelling is focused on pool fires and jet fires. As the first step in the model for pool fires, the release is modelled. Some of the relevant parameters are: the type of liquid (for example: petrol or diesel fuel), volume and geometry of the tank, diameter/size of the hole in the tank, location (height) of the hole.

$$\dot{m} = A_d \cdot C_d \cdot \rho \cdot \sqrt{2 \cdot g \cdot h_V} \tag{1}$$

where
C_d = release coefficient (= 0.6)
A_d = hole area (m^2)
g = 9.81 m/s^2
h_V = the height of the liquid in the tank
ρ = mass density of the fuel (kg/m^3)
Petrol: ρ = 700–800 kg/m^3
Diesel fuel and similar: ρ = 830–950 kg/m^3

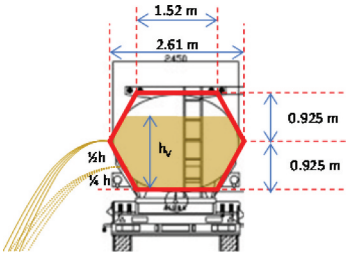

Figure 2. Example of release from a tanker.

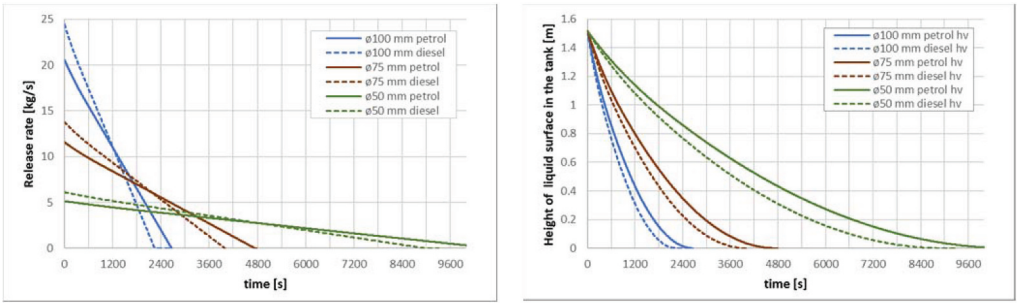

Figure 3. Release rate and height of liquid surface as function of time for a 40 m^3 tank (shown in Figure 2).

Based on the results presented above the average release rate and the duration of the release can be determined for various hole diameters (ø50 mm, ø75 mm and ø100 mm), locations of the hole (¼ h, ½h) and petrol and diesel fuel. The results vary from long durations with low release rate (say, ø50mm, ½h, petrol: duration 2000 s, avg. release 5 kg/s) and vice versa (say, ø100mm,½h, petrol: duration 500 s, avg. release 18 kg/s).

The area of the pool resulting from the release is dependent on the combustion rate and the drainage. The arrangement of the drainage system and the geometry of the bridge deck on the determines the effective mass from through the drain grate.

$$A_1 \approx \frac{l_{w1}}{\sin(\arctan(c/g))} \cdot 2.4 \cdot V^{0.46} \tag{2}$$

where V = the release rate in l/s
c = the cross slope
g = the gradient
l_{w1} = the distance from the release to the kerb
$A_2 \approx \frac{d}{2} \cdot \frac{(V - V_{comb})^{0.5}}{c}$, where
d = the distance between the drain grates

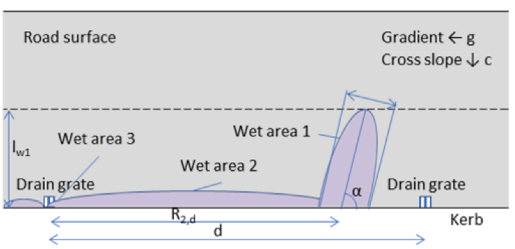

Figure 4. Formation of pools on the bridge deck with drain grate and kerb.

V_{comb} = the combusted volume of fuel for A_1+A_2

With a similar formula (subtracted the drained volume) a third pool will form if the first drain grate has insufficient capacity for V–V_{comb}.

The heat release from the fire is calculated (simplified) as:

$$\dot{Q} = \dot{m}'' \cdot A \cdot \Delta H_c \approx A \cdot 2.64 MW/m^2 \tag{3}$$

where

$\dot{m}''$ = the combustion rate (for petrol 0.055 kg/(m^{2}s))

ΔH_c = the combustion heat (for petrol 48 MJ/kg)

The generalised flame length is based on circular pools. Based on the areas determined from the principles in Figure 4 an equivalent pool diameter, D_{pool}, is determined as function of release rate, distance to the drain grate and the geometry of bridge deck and drainage system. In the actual case equivalent diameters in the range 7 – 16 m^2 were estimated.

Various estimations have been proposed for estimating the flame length as function of the pool diameter. The empiric relation proposed by Heskestad, 1995 expresses the length as function of the heat release and diameter:

$$L_{flame} = 0.235 \cdot \dot{Q}^{2/5} - 1.02 \cdot D_{pool}$$

Without wind the flame is considered to be vertical and cylindrical. The wind velocity, u_w, will influence the direction and reach of the flame.

$$cos\theta = 0.7 \cdot [u^*]^{(-0.49)}, \text{if } 0.7 \cdot [u^*]^{-0.49} \leq 1 \tag{4}$$

$$cos\theta = 1, \text{ if } 0.7 \cdot [u^*]^{-0.49} > 1 \tag{5}$$

Where

$$u^* = u_w / u_c$$

$$u_c = g \cdot m'' \cdot D_{pool} / \rho_{air}$$

u_w = the wind velocity (m/s).

$$\frac{D'}{D_{pool}} = 1.5 \cdot Fr^{0.069}; \text{ where } Fr = \frac{{u_w}^2}{g \cdot D_{pool}} \tag{6}$$

Hereby:

$$x = sin\theta \cdot L_{flame} + D' + 1/2 \cdot D_{pool} \tag{7}$$

$$H = cos\theta \cdot \left(L_{flame} - \left(D' - D_{pool}\right)\right) \tag{8}$$

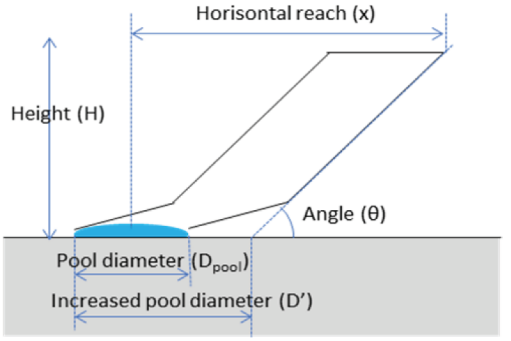

Figure 5. Determination of horizontal and vertical reach of flames.

With these calculations the vertical and horizontal reach of the flames and the fire durations have been determined as function of location on the bridge deck, hole size and location, liquid type and volume, drainage, and wind speed. The exposure of the various structural components of the bridge is investigated in event trees.

3.2 *Jet fires*

Jet fires occur when flammable liquids or gasses are released from pressure tanks and ignited. The pressure in the tank (and hereby the release rate) depends on the surface of the fluid in the tank in relation to the hole. When the surface of the liquid has come under the hole, the release required evaporation, and the pressure and release is reduced (RWS, 2005).

$$L_f = 18.5 \cdot m^{0,41} \ [m] \tag{9}$$

$$D_f = 0.1 \cdot L_f \ [m] \tag{10}$$

$$m_{liq} = \varphi \cdot m_{Bernoulli} = \varphi \cdot A_d \cdot \ C_d \cdot \sqrt{2 \cdot dP \cdot \rho}$$

$$m_{gas} = \ A_d \cdot \ C_d \cdot \psi \cdot \sqrt{(2 \cdot p^2 \cdot M_W)/(R \cdot T)}$$

where
dP is the pressure difference tank– atmosphere
ρ is the mass density of the gas
A_d is the hole area
C_d is the release factor = 0.62
φ is empirically 0.75
ψ is empirically 0.48

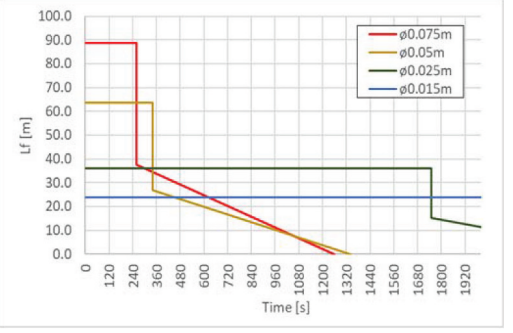

Figure 6. Example of determination of flame length from a jet fire in propane (40 m^3 tank, hole at ½h).

The flame from a jet fire is a concentrated beam, the direction of the release is determined by the location of the hole, the wind may bend the direction and the length of the flames are assumed to grow with 33% in tailwind and reduce 15% in headwind.

With these calculations the reach of the jet flames and the fire durations have been determined as function of location on the bridge deck, hole size and location, liquid type and volume, drainage, and wind speed. The exposure of the various structural components of the bridge is investigated in event trees.

4 EVENT TREES

The event trees are detailed with the exposure of structural components, depending on the randomised fire location, the flame size, direction and temperature, the bridge geometry, and the local meteorological conditions. The structural components of a suspension bridge are considered: the main cable, one or more hangers, the pylon and the bridge deck.

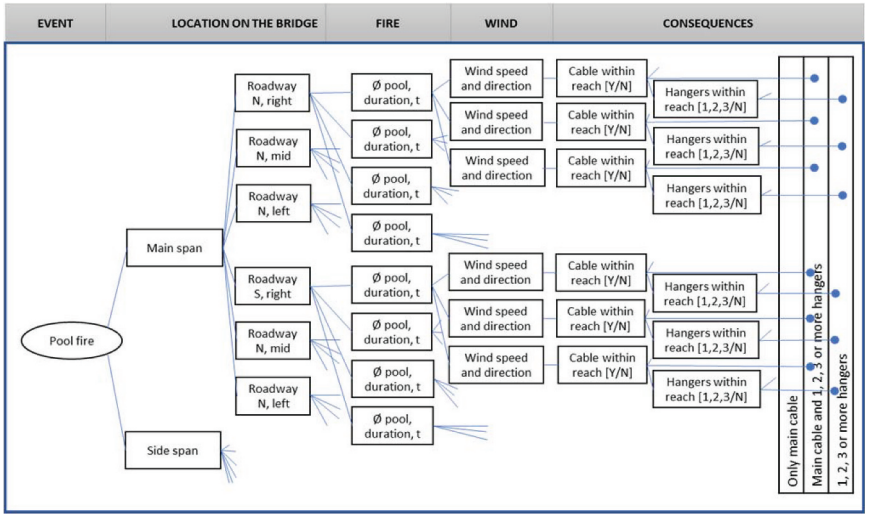

Figure 7. Part of (a simplified) event tree for exposure of main cable and hangers to flames from a pool fire.

Event trees are methodologically quite simple, however, with many variables, event tree grow rather large and difficult to oversee. In Figure 7 a simplified part of the event tree for pool fires is illustrated. In the event tree the location of the fire between the Northern roadway and the Sothern roadway are distinguished because the bridge in the present example is not symmetrical. Side span and main span is distinguished because hangers are only placed on the main span. For jet fires similar event trees are established. Furthermore, event trees for the exposure of the pylon (and the girder) are established from the same basic principles.

As part of the event tree evaluation all the conditional probabilities will have to be established, for example the probability of various locations on the fire, probability of various fire events, probability of wind speed and – direction (wind rose) etc.

In addition to this the main consideration is to which degree the various structural elements are exposed to the flames. This exercise requires the geometrical calculation of the reach of the fires from the specific location and the distance to cable, hangers, pylons etc.

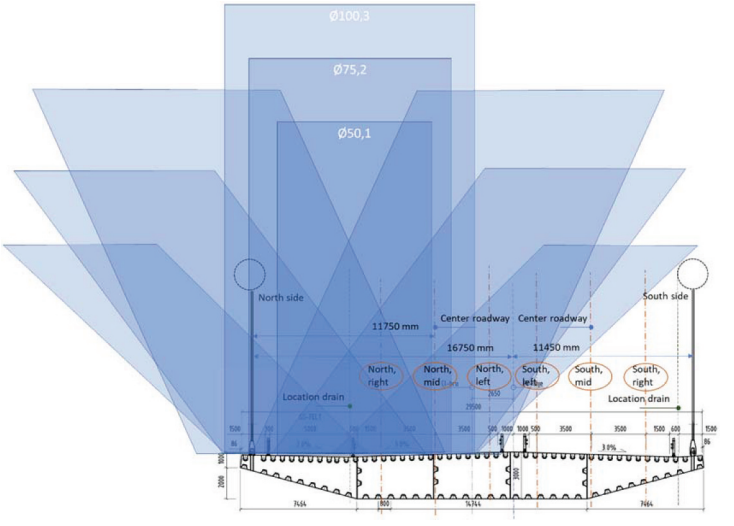

Figure 8. Principal illustration of the flames from severe pool fires at one location and with wind speeds of -4 m/s, 0 and 4 m/s transversal on the bridge deck.

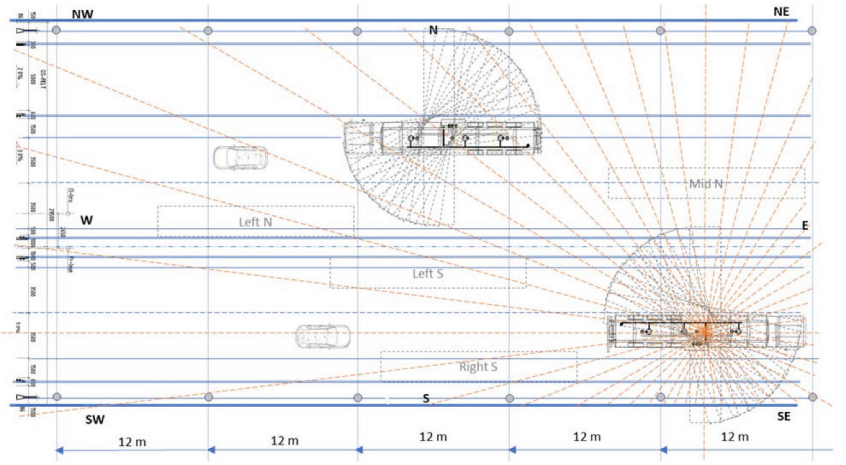

Figure 9. Principal illustration of the flames from jet fires at one location and the horizontal distances to hangers.

5 AGGREGATION

For each of the structural components (cables, hangers, girder, pylons), the exposure is determined as probability, duration, and temperature.

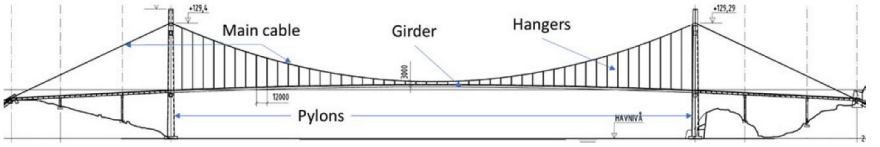

Figure 10. Main components of the suspension bridge.

5.1 *Main cables, hangers and pylons exposed to pool fires*

Based on a large number of scenarios combining hole size, location of the bridge cross section, wind speed, wind direction etc. and the associated conditional probabilities, it can be determined that approximately 30% of all pool fires on the bridge have a flame length and direction which will engulf the main cable. With the event probability of a pool fire, the annual exposure probability of any of the two cables is estimated to 3 E-06 in the present case. The asymmetric design makes one side slightly more exposed than the other. This exposure probability is determined for the reference year, and it will be dependent on the timely development of the traffic and the event rates.

The hole size determining the release is correlated with the duration of the fire. Hence, a relation between exposure probability and duration can be established as shown in Figure 11.

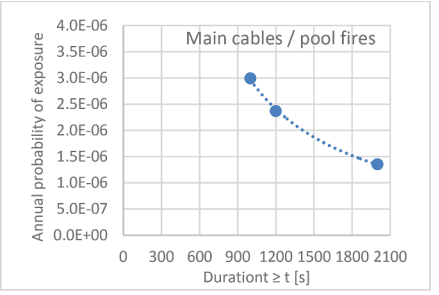

Figure 11. Annual probability of exposure and duration of pool fires engulfing the main cable.

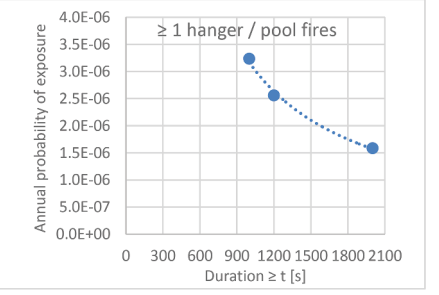

Figure 12. Annual probability of exposure and duration of pool fires engulfing at least one hanger.

In similar aggregations of scenarios as for the main cable, it can be determined that approximately 40% of all pool fires on the bridge have a flame length and direction which will engulf the at least one hanger. The design of the bridge without hangers in the side span has of course a major influence on this figure. With the event probability of a pool fire, the annual exposure probability of any of the two cables is estimated to 3.3 E-06 in the present case.

The hole size determining the release is correlated with the duration of the fire. Hence, a relation between exposure probability and duration can be established as shown in Figure 12.

The exposures shown in Figure 11 and Figure 12 are very similar, however, the criticality of the exposure differs significantly. On one side the exposure of a hanger to a high flame temperature will relatively quickly heat up the entire hanger and change the strength and stiffness of the hanger, whereas the main cable may only be heated on the surface and remain a significant part of its strength and stiffness after a fire. The exposure of the main cable may lead to repair but not to replacement, whereas the hanger more likely will have to be replaced after the exposure.

On the other side the bridge is designed so that one or more hangers can be replaced. A failure of a hanger is hereby not a failure which endangers the structural stability of the bridge. In the present case, the bridge design has taken into account that up to three hangers are lost without impairing the integrity of the bridge.

For this reason, it is important to calculate the probabilities of ≥2, ≥3, ≥4, etc cables exposed to the pool fire. In the present case it was determined that the probability decreased with approximately a factor 10, when one more hanger was considered. The annual probability of more than 3 hangers exposed to a pool fire is therefore approximately 100 times less than shown in Figure 12.

Similar calculations can be made for the exposure of the pylons to pool fires, but as the probability of a fire located on the bridge within reach of the flames from a pool fire, is about a factor 10 lower for the pylon as it is for the main cable.

5.2 *Main cables and hangers exposed to jet fires*

In spite of the much longer reach of flames from jet fires, the probability of reaching the main cable is significantly lower than for the pool fires because the width of the flames is narrow, and the direction is most likely horizontal. Horizontal jet flames will in most part of the bridge not reach the main cable. On the other hand, the hangers are more exposed on a larger part of the bridge.

With aggregations of event probability and conditional probabilities, the relation between annual exposure and duration can be established as shown in Figure 13 and Figure 14.

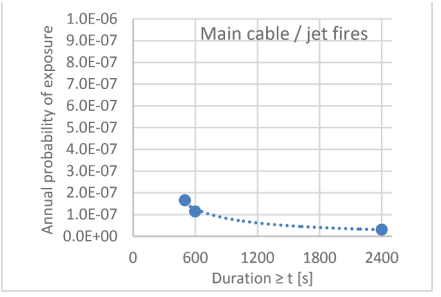

Figure 13. Annual probability of exposure and duration of jet fires engulfing the main cable.

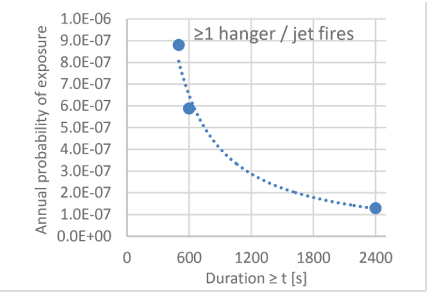

Figure 14. Annual probability of exposure and duration of jet fires engulfing at least one hanger.

The probabilities of ≥2, ≥3, ≥4, etc cables being exposed to the jet fire decreases with approximately a factor 2 when one more hanger is considered. The longer reach of the flames results in a relatively higher share of cases where several hangers are affected. On the other hand, the annual probabilities are very low.

The lower part of the pylon may also be exposed to flames from jet fires, and even the bridge deck may in some circumstances be exposed to jet flames. The probabilities for these exposures are in the order of magnitude as for the main cable.

5.3 *Other vehicle fires*

Other vehicles fires may be modelled in a similar way. Fires in cars and light vans are much more likely, but the exposure of the structural components will be limited. Fires in HGVs may potentially result in severe fires. As part of the studies of the present bridge these fires were preliminarily equivalated with adapted small pool fires. Based on these studies it was found that the main cable at midspan and near the anchor blocks can be reached by 6 m high flames, which may occur with an annual probability of over 1 E-04. The probability of fires in HGVs reaching more than two hangers is much lower.

5.4 *Discussion*

Most fires have little impact on the structural behaviour and the main consequence will be repair and reinstatement. In some cases, the structural integrity may be compromised. The probability of these events is very low, but, on the other hand, the consequences can be extraordinarily high.

The vulnerability of the bridge is dependent on the degree of redundancy and robustness in the structural system. The reserves in the components' capacities and the material fire behaviour are important as well.

6 RISK EVALUATION AND FIRE PROTECTION

The last step in the analysis is the risk-based evaluation of the effect measures and the costs of these in order to arrive at a cost optimal decision.

According to the national bridge guideline, accidental loads with annual probabilities over 1E-04 cannot be disregarded. In the present example, fire loads for HGV fires should be further considered and/or designed for. The design may evaluate whether the heating from the flame temperature of e.g. the main cable is exceeding a level, where fire protection is necessary for the exposed areas, or whether the integrity is not affected, and reasonable repairs can be performed after a severe fire.

For the pool fires and jet fires the possible consequences of the heating may be more severe, but the annual probabilities found in the study were all under 1E-04. It should be noted that the guideline does not state that accidental loads with annual probabilities under 1E-04 must be disregarded. In some cases, the consequence of failure can be so severe in terms of material loss (possible bridge collapse), loss of lives, traffic disturbance etc., that also events with small probabilities are worth to consider in a risk-based approach. In these considerations, the expected consequences (i.e., the expectation value in terms of probability times consequences) is transformed into monetary values and compared with the expected costs of various risk reducing measures. If the benefit of reducing the consequences exceeds the costs, then the risk reducing measure should be implemented. The lower the probabilities of the events are, the more difficult it will be to identify relevant cost-efficient measures.

Based on the results of the studies, it was identified that expensive safety measures may most likely not be cost efficient. The study was performed before the final design, and the possible safety measures were merely identified and discussed roughly based on the likely efficiency. Cost efficient safety measures may involve fire protection of the most exposed parts (fire insulation, fire paint or similar) or shielding against the flames.

7 CONCLUSION

A method for risk-based evaluation of fire and fire design of large cable-supported bridges. The method includes, modelling of the bridge, the specific geometry of the bridge, the traffic on the bridge, the local event rates. Furthermore, it includes hazard identification and modelling of the events in terms of event trees with associated conditional probabilities. The aggregation of the results leads to establishment of probabilities and duration of fires. The exposure is determined as the time, when the structural components are impacted by the flame temperature. Finally, these results are used to determine whether the design can be adapted and/or further cost-efficient safety measures need to be implemented.

For the actual case, the required safety measures could be limited to selected, most exposed areas, for which safety measures with relative low costs could be applied.

Maintenance strategies by the Swedish Transport Administration

F. Olsson
Swedish Transport Administration, Gothenburg, Sweden

ABSTRACT: The Swedish Transport Administration, Trafikverket, manages approximately 17,000 road bridges and 4,000 railway bridges. The Bridge and Tunnel Management System (BMS) provides support throughout the process from construction to assessment and prioritization of measures. The BMS is also used by a majority of Swedish municipalities. Beside the BMS there are guidelines that support the Bridge officers through the different stages such as inspection, planning, prioritization and finally performance of maintenance measures.

1 ASSET MANAGEMENT

This article will describe how the Swedish Transport Administration works with maintenance of structures during the whole life-cycle.

The Bridge Management System (BMS) that the Swedish Transport Administration uses supports management of not only bridges, it also gives support for managing other important structures such as retaining walls, troughs, ferry quays, tunnels and rock walls. Most of the Swedish counties and other big infrastructure owners also use this BMS.

Within the Swedish Transport Administration there is a formalized handover of new structures such as bridges from the building project to the asset steward. Correct as-built information in right time gives good opportunities for a cost-effective asset management.

The first main-inspection of a bridge is made short before it is open for traffic. After that all bridges are inspected close at hand at least every six years. If needed the interval of inspection is shorter. For some critical components and types of bridges there can be extra inspections in between the main inspections.

The inspections are carried out according to a special methodology and the bridge inspector assesses both the physical and functional state of the bridge.

All bridges that are in need of any condition-based maintenance measures within the next 6 years must have an individual strategy. For bridges that are in need of complete reconstruction the corresponding time is 12 years. Specified major bridges such as suspension bridges and cable stay bridges must have an individual strategy that covers at least next 20 years.

For road bridges the predetermined maintenance such as keeping the bridges free from dirt and vegetation is procured in integrated bridge maintenance contracts, contract time 3-5 years and 600-1,000 bridges/ contract. The contracts also include a contractor organization that can perform corrective maintenance.

2 INFORMATION OF THE ASSETS

2.1 *Type of assets stored in the Swedish Bridge Management System (BMS)*

The bridge and tunnel management system supports users in the management of bridges, tunnels and other structures. Bridge owners, consultants, planners etc. receive support and information about structures through the system.

The BMS contains a searchable database containing the structures that are registered. In the database, users can register new data and update information. One of the great benefits of

DOI: 10.1201/9781003483755-369

managing structures in the BMS is the ability to carry through effective measures for each individual structure. The BMS provides control over the condition of bridges, tunnels and other structures and information on what needs to be done to maintain or improve their standard.

The Swedish Transport Administration, municipalities in Sweden, Stockholm Public Transport, the Port of Gothenburg and others use the BMS for the management of their structures, and it is the Swedish Transport Administration that manages the system. The system is industry-wide and is used by many different actors such as consultants, contractors and administrators.

Outside the Swedish Transport Administration there are more than 20,000 structures, owned by the municipalities and some other major infrastructure owners in the BMS. Most of those structures are bridges.

Table 1. Structures owned by Swedish Transport Administration. Registered in the BMS.

	Number of structures	
Structure	Road	Railway
Bridges	16,860	4,535
Tunnels	319	520
Rock slopes	27,995	5,294
Culverts (≤ 2.0m)	-*	20,608
Retaining walls	460	103
Troughs	62	51
Ferry quays	123	-
Noise barriers	-*	624
Other structures	224	78
Total	46,043	31,813

*For the road-system noise barriers and culverts with largest span ≤ 2.0 m are not managed in the BMS.

During the 60s and early 70s there were many big infrastructure projects and many major bridges were built during this period, eg the bridge from mainland Sweden to Oland, the Alvsborgs bridge in Gothenburg and the bridges on the Essinge route in Stockholm. This means that a large part of the Swedish bridge area now has reached the age of 50-60 years and these bridges need fundings for bridge maintenance.

During the 90s there were also many new bridges built, It can be explained by recession were the state wanted to stimulate the construction industry by building new highways.

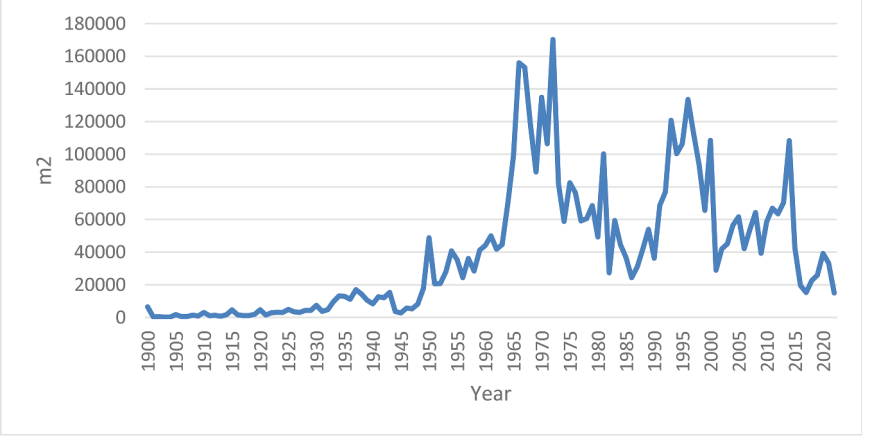

Figure 1. Bridge surface built each year, and still in traffic. (Bridges in the road-system).

2.2 *New and updated information about the assets*

Within the Swedish Transport Administration there is a formalized handover of new asset-information from building projects to asset-managers at the maintenance and operational departments. A plan for handover is established before any contracting-works have started. There are designated persons who have the role as handover-coordinators representing the building department and receiving-coordinator representing the maintenance and operational departments. These two roles support the building projects to deliver correct information in correct time in each of the management-systems that the Swedish Transport Administration uses.

When the contract-works are finished, approved and all information is handed over there is a formal receiving. This also means that the maintenance department takes the responsibility for conducting warranty inspections and having contact with the contractor if there are any problems that occur during the time of warranty.

3 INFORMATION ABOUT CONDITION

3.1 *Inspection*

The first inspection of a new bridge, tunnel or other structure is made before it's taken in traffic, second inspection before end of warranty (5 years). After that all bridges are inspected at least every six years, shorter intervals may be considered if the condition of the bridge is poor. Bridge inspections is a service contracted by the Swedish Transport Administration to external consultants with specialized expertise in the field. The inspections are conducted according to a specific methodology, and both the physical and functional condition of the bridge are assessed. The methodology is described in the BMS. The inspections are registered directly in the BMS as structured data. There for there are rarely any inspections-reports being written. The Swedish Transport Administration (2021), TRVINFRA-00213 Standard for inspection of bridges and other structures.

The functional condition is evaluated based on several parameters: the functional properties of the structural part, the functional requirements set during the design, the current and previously measured values, and the expected future deterioration of the damaged structural part.

The identified deficiencies are classified based on whether they affect the bridge's load-bearing capacity, traffic safety, durability, or other factors. The condition is described using the condition classes 0, 1, 2, or 3:

3: Deficient function at the time of inspection 2: Deficient function within 3 years 1: Deficient function within 10 years 0: Deficient function beyond 10 years

Bridges with damages in condition class 3 regarding traffic safety or load-bearing structural elements should be investigated within three months. Inspections form the basis for planning maintenance measures such as painting, replacement of parapets, railings, and waterproofing, as well as reinvestment.

3.2 *Special inspections*

Special inspections and damage investigations are carried out when required to follow up or study in detail individual structural parts/elements or damages.

For specific bridges/ bridge-elements the guidelines require that special inspection must be carried out in between the main-inspections.

For prestressed concrete bridges built before 1980, the main inspections shall be supplemented by special inspections of prestressed structural parts. This special inspection shall be carried out every three years.

For road bridges with modular expansion joints older than 20 years the main inspections shall be supplemented by special inspections of the joints. This special inspection shall be carried out every three years for road bridges with a traffic of > 10 000 vehicles per day.

4 PLANNING AND PRIORITIZATION

4.1 *Planning*

In the BMS there is a specific module that supports the bridge manager in planning of measures on structures. The planning is registered in the BMS. Planning aims to describe the overall action needs for a structure to ensure expected functionality at the lowest life cycle cost. In object planning, various action strategies are analyzed to find the strategy that provides lowest societal cost to maintain existing or restore the original functional standard. Based on external needs, object planning may also involve improving the functional standard. Object planning and the selected action strategy form the basis for short-term planning and the specification of requirements for the design and procurement of measures.

Within planning and prioritization there are guidelines and regulations published by the Swedish Transport Administration. Swedish Transport Administration (2021), TRVINFRA-00214 Standard for object-planning of bridges and other structures.

A main strategy (S1) is to be established for a structure with need for measures within each planning period. The S1 strategy should include all actions during the remaining lifetime of the structure, up to a maximum of 60 years, and conclude with a reconstruction (reinvestment) if such measure is expected within a 60-years period. The first action in S1 should have a validity period during which the S1 is intended to be carried out. No conflict with applicable delivery standard is allowed for the S1.

A structure with S1 strategy should also have an associated S2 strategy. S2 should describe the consequences if actions according to the S1 are not carried out within the validity period and is used to calculate the profitability of the S1. S2 may come into effect no earlier than the year after the expiration of the validity of the S1. S2 should further more have a validity period of 1 year. The profitability factor for the measure is calculated as follows: Profitability factor = (S2 total - S1 total)/S1 production

Table 2. Planning period is decided as below.

Category	Planning period
Structures with need of a condition based maintenance measure	6 years
Structures with a need of reconstruction (reinvestment)	12 years
Structures with planned improvement or risk reduction	12 years
Structures within category Major bridges*	20 years

*Suspension bridges, cable stay bridges and a handful of other major bridges.

4.2 *Prioritization*

When each structure with need of measures within the planning period has a main strategy (S1) and an associated S2, there has to be a comparison between different bridges and measures. When the overall need for funds is greater than the allocated funds, this has to be done. The BMS planning-module supports this by calculating which measures that are most cost-effective in

Table 3. Prioritization of measures on structures in the road system.

Priority	
1	Inspections and predetermined maintenance
2	Corrective maintenance on bridges with deficient functional condition
3	Maintenance measures on major bridges, moveable bridges and tunnels
4	Condition based maintenance on other bridges and structures. To support this allocation, the BMS planning-module is used. Since the socio-economic costs of different strategies are evaluated, high traffic roads are valuated higher than low traffic roads
5	Rock-slopes

a life-cycle cost perspective, the higher profitability-factor the better. All planned structures are presented in a list with measures and which year, within the validity period, they should be carried out. This list works as input for new projects in the maintenance plan. There also has to be taken into account other costs such as inspection and predetermined maintenance as well as other known local conditions and dependencies that exist.

5 MAINTENANCE MEASURES

Finally, after the prioritization there is a list of objects that shall be carried out the next four years within the budget that is given. By the end of each year there is a formal handover from the planning departments the executing departments. The executing departments are of course involved during the planning.

Bigger repairs are often contracted individually and smaller repairs can be contracted in groups (2-5 objects) so that the contract value at least reaches 5 MSEK. Bridge repairs are mostly procured as execution contracts.

The pre-scheduled maintenance is procured as Integrated bridge maintenance, which is a turn-key contract. There are 23 Integrated bridge maintenance contracts and they are geographically spread over the country. The predetermined maintenance consists of clearing of vegetation and cleaning (removal of de-icing salt, dirt etc). These contracts also include immediate corrective maintenance such as traffic damages and other unforeseen incidents, for instance due to extreme weather. They can also include same common repairs such as repair or replacement of edge beams and parapets, expansion joints or water proofing layers.

Almost 30% of the total budget for road-bridges goes to reinvestments, from small culverts and steel-pipe bridges to larger bridges.

6 MAINTENANCE MEASURES

Finally, after the prioritization there is a list of objects that shall be carried out the next four years within the budget that is given. By the end of each year there is a formal handover from the planning departments the executing departments. The executing departments are of course involved during the planning.

Bigger repairs are often contracted individually and smaller repairs can be contracted in groups (2-5 objects) so that the contract value at least reaches 5 MSEK. Bridge repairs are mostly procured as execution contracts.

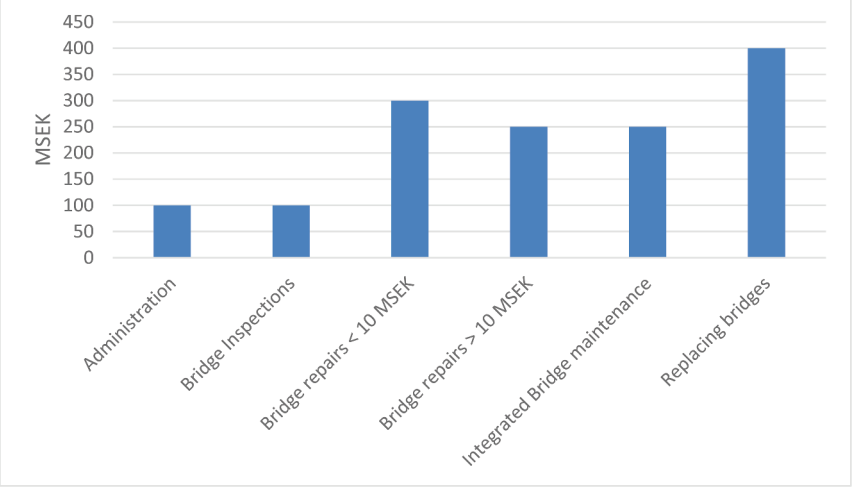

Figure 2. Costs of bridge maintenance in the road system, approximately 1,400 MSEK/ year.

The pre-scheduled maintenance is procured as Integrated bridge maintenance, which is a turn-key contract. There are 23 Integrated bridge maintenance contracts and they are geographically spread over the country. The predetermined maintenance consists of clearing of vegetation and cleaning (removal of de-icing salt, dirt etc). These contracts also include immediate corrective maintenance such as traffic damages and other unforeseen incidents, for instance due to extreme weather. They can also include same common repairs such as repair or replacement of edge beams and parapets, expansion joints or water proofing layers.

Almost 30% of the total budget for road-bridges goes to reinvestments, from small culverts and steel-pipe bridges to larger bridges.

7 CONCLUSIONS

A successful management of structures requires a successful management of working procedures. For a big organization such as the Swedish Transport Administration there must be guidelines that support the bridge officers so that decisions of maintenance measures are based on the condition and lowest life cycle costing. The Bridge Management System, BMS, is one tool that helps us to accomplish an effective asset management.

The procedures from inspections, to planning and prioritization must be easy to follow and well known in the organization. Keep it simple.

It's finally important that planned measures are carried out cost-effectively, that our tender specifications are transparent with a balanced risk distribution. The Swedish Transport Administration aims to be the supplier's first choice. We believe that is cost-effective for the Swedish Transport Administration and profitable for the suppliers.

Evaluation of post-tensioned bridges by state-of-the-art techniques

G. Rapaport
Ramboll Finland Oy, Kuopio, Finland

ABSTRACT: Based on the author's long experience, implementing suitable state-of-the-art non-destructive testing techniques in condition evaluation of post-tensioned bridges' invisible prestressing system is an essential approach for ensuring post-tensioned bridges' safe usage, long time durability and appropriate level of asset management. It also assists in determining the remaining service life of those bridges. There are thousands of aging post-tensioned bridges getting close the end of their service life. Due to reasons like environmental stresses, construction and maintenance faults the safe usage of bridges may be uncertain or even dangerous. In extreme cases this may lead even to sudden collapses of bridges.

Applying NDT techniques in post-tensioned bridges enables evaluation of the prestressing system grout injection, which is critical for the system durability and functionality. The introduced NDT techniques, ultrasound tomography and Impact-Echo, used together with slightly invasive investigations assist in this important evaluation.

1 INTRODUCTION

There is great amount of aging post-tensioned bridges, in many cases on critical transportation routes, built mostly in the 1960s-1970s. The condition of the bridges' prestressing system is usually unknown. Hidden faults and damages due to various reasons may threaten the safe usage of bridges. In some cases, the results might be catastrophic, causing a bridge collapse, as witnessed in 2018 when the Morandi Bridge in Genoa Italy suddenly collapsed.

Many post-tensioned bridges have reached renovation time or are getting close to the end of their designed service life. Their condition should be assessed and their safe usage should be verified. A serious challenge is that "traditional" inspection techniques do not provide any indications on the internal prestressing system even though it has a crucial role in the bridge load carrying capacity. It should be noted that at least part of the older post-tensioned bridges were planned as "fully prestressed structures" with only a small amount of regular reinforcement. Therefore a fault in the prestressing system is serious and possibly dangerous.

With correct implementation of suitable NDT techniques (ultrasound tomography and impact-echo) it is possible to evaluate tendon duct grout injection of post-tensioned structures. The injection grout (cementitious based) has a crucial role in protecting the prestressing steel against corrosion, which may cause dangerous damage mechanisms. The injection grout has also important structural role as will be explained. When considering these aspects it is obvious that successful grout injection is critical significance in ensuring the bridge safe and correct functionality.

NDT techniques also assist in pinpointing logical locations for applying invasive measures, i.e. opening of tendon ducts. The main purpose of the invasive measures is to confirm the NDT evaluation and to evaluate the condition of the prestressing system components.

Obviously, NDT techniques may also be applied to grout injection evaluation during construction of new post-tensioned bridges as a quality assurance measure. This ensures from the

DOI: 10.1201/9781003483755-370

beginning of the bridge service life its correct functionality and reveals possible problematic durability issues concerning the bridge prestressing.

The introduced NDT methods, used together with slightly invasive investigations, have already been successfully applied by the author in over 150 inspections of post-tensioned bridges in the past 15 years.

2 DURABILITY PROBLEMS OF POST-TENSIONED BRIDGES

A crucial factor affecting mostly the long-term durability of post-tensioned bridge prestressing steel is the success of the grout injection into the tendon ducts. The injected grout has two main roles:

- Providing permanent protection to the prestressing steel (high strength steel) against corrosion and preventing ingress of water, chlorides, air and humidity into the duct. Corrosion may cause at some point fractures of the prestressing steel due to Hydrogen Embrittlement and Stress Corrosion Cracking.
- Intermediating the prestressing forces from the prestressing steel to the concrete structure. Deficient intermediation of the prestressing forces to the concrete structure might result in reduced load carrying capacity of the bridge.

To provide sufficient protection to the prestressing steel the grout should be of adequate quality and thickness. This also demands correlation between the diameter of the duct and the amount of prestressing steel installed inside it. Obviously, proper injection work procedure and use of adequate injection grout mass is critical for the success of the injection.

The most acute durability problems are usually found at the prestressing system anchoring zones (moist and chloride stresses from leaking expansion joints and casting defects) and in the ducts' extreme low (water accumulation risk) and high points (leaking joints or waterproofing).

The risk caused by corrosion of prestressing steel, especially if chlorides are present (→ causing pitting corrosion), is severe because the steel is usually concentrated only in few tendons which provide most of the load carrying capacity of the bridge. If few tendons fail it can trigger a catastrophic sequence.

3 "TRADITIONAL" INSPECTION TECHNIQUES CONCERNING POST-TENSIONED BRIDGES

Traditional inspection techniques which are regularly applied in reinforced bridge inspections do not provide sufficient information concerning the condition of the internal prestressing system, which is the key factor of post-tensioned concrete bridges. Corrosion detection techniques such as the half-cell potential measurement and the electrical resistivity measurement are suitable for evaluating the corrosion process of regular reinforcement, not of prestressing steel (physical contact with the steel is also needed).

Opening ducts for ocular estimation of the prestressing system is risky and difficult as the exact location and depth of the duct is uncertain. Use of suitable Ground Penetrating Radar can assist to some extent in locating the actual positions of ducts, but it cannot reveal the success of ducts grout injection. Applying suitable NDT techniques is proven to be beneficial in these cases, as will be discussed here.

4 NDT TECHNIQUES SUITABLE FOR GROUT INJECTION EVALUATION OF DUCTS

This section shortly introduces the NDT techniques applied by the author in tendon ducts injection evaluation of post-tensioned bridges. More elaborate introductions can be found in different professional publications. Due to various reasons only injection evaluation of corrugated steel ducts which are close to surface can be reliably performed with NDT techniques.

4.1 *Ultrasound tomography*

Ultrasound tomography is suitable for concrete structures integrity evaluation usually when the concrete structure surface is reachable. Ultrasound tomography enables fast, accurate and sufficiently deep scanning from one surface of the concrete structure (Germann Instruments 2014). Experienced user of the system can perform quick onsite interpretation of the testing results. It is important to mention that tomography testing results' interpretation is based on relative comparison of the obtained testing results (there are no absolute thresholds). This is why the experience and understanding of the technique by the user are crucial when performing evaluations with this technique.

Ultrasound tomography is probably the most suitable NDT technique for grout injection evaluation of post-tensioned bridge tendon ducts. It is also useful in detecting and evaluating casting defects and in general a concrete structure's integrity.

The tomographer creates 3D representation of internal reflecting interfaces that may be present inside a concrete object. It is based on the ultrasonic Echo method using transmitting and receiving transducers in a "Pitch-Catch" configuration. It uses an antenna composed of an array of dry point contact transducers, which transmit into the concrete low frequency shear waves. The transducers are spring loaded to conform to an irregular surface. The effective scanning depth is about up to 0,5 m in heavily reinforced structures.

The testing results are presented in tomograms in 3D and different cross-sections by visualization software (Synthetic Aperture Focusing Technique algorithm based).

Detection of a defect with ultrasound tomography: if a defect inside a concrete object exists in the form of a sufficiently large concrete-air interface, a portion of the transmitted stress wave will be reflected by it and the reflected wave will arrive at the receiver sooner than reflections from the back wall. The SAFT software determines the location of a defect by analyzing the arrival times of the reflected pulses. When evaluating prestressing systems, continuous and intensive S-waves reflections along and at the depth of a duct might indicate voided duct.

4.2 *The Impact – Echo system (IE)*

The Impact-Echo technique is also suitable for concrete structure's integrity evaluation, usually when the concrete structure surface is reachable. Impact-Echo enables rather fast and deep yet pointwise evaluation. Experienced user of the system can perform quick interpretation of the testing results onsite, but a deep understanding of this technique is needed. The Impact-Echo technique is suitable for performing grout injection evaluation of tendon ducts (usually applied together with the ultrasound tomographer technique for increased reliability), for evaluating hidden defects inside the concrete, fracturs, delaminations etc.

The Impact-Echo testing method is also introduced in ASTM C1383-15 "Standard Test Method for Measuring the P-Wave Speed and the Thickness of Concrete Plates Using the Impact-Echo Method".

The impact-echo method is based on monitoring the periodic arrival of reflected stress waves (P- waves) and enable to obtain information on the depth of reflecting interfaces (e.g. void/defect). By that the integrity of a concrete object could be evaluated. The Impact-Echo components include mechanical spherical impactor source (different sizes of impactors are available), a high fidelity displacement transducer for measuring the surface displacement and a laptop with the Impact-Echo software needed for data acquisition, analysis and storage.

The technique principle: the impactor generates a short-duration pressure wave, which travels into the concrete and is reflected from the backside of a solid test object or from an internal anomaly. The P-wave is reflected sever-al times and the arrival of the reflected P-wave is detected by the displacement transducer on the test object surface. The impactor contact time is a function of the impactor diameter and is influencing the frequency do-main. The time domain waveform is converted to a frequency response (amplitude spectrum) using a FFT algorithm (a mathematical method to convert and presented data as function of frequency).

When evaluating prestressing systems, we look for dominant signal peaks at the depth and location of the tested tendon. If found at least at several spots along the duct → suspicious

indication. Similarly to grout injection evaluation by tomography system, also here appropriate understanding and experience in performing these types of tasks is required.

5 TENDON DUCT EVALUATION BY SLIGHTLY INVASIVE METHODS

It's always recommended to complement NDT by slightly invasive measures, when possible. Evaluation of a tendon duct with slightly invasive methods means opening a tendon duct and evaluating the different components of the prestressing system (see Figure 1 Left and Middle): the duct, the injection grout and the prestressing steel (strands). It is also possible to drill just slightly into a duct a small hole and to evaluate the duct injection by use of an endoscope (see Figure 1 Right), but in this case corrosion estimation of the prestressing steel is not possible.

NDT pinpoints logical locations of tendon duct opening. The opening should be done very carefully so it is a time-consuming process. Usually only 1-2 ducts will be opened per inspected bridge (at least in the first phase).

The main objectives of opening a tendon duct:

- Verifying NDT results.
- Verifying the exact duct location, its dimensions, material and condition.
- Evaluating the injection grout: quality, thickness, voids, chloride ion content evaluation (also of water if found inside the duct).
- Verifying the type of the prestressing system, dimensions of strands.
- Corrosion estimation of the prestressing steel (Räsänen & Salparanta 2003). In Finland, determining the corrosion classes: 0 (not corroded). . .4 (severely corroded).

Figure 1. Diamond drilling during opening of a tendon duct, opening of a tendon duct and exposing the injection grout (Left and Middle). Right: drilling by a small diameter drill-bit (d6 mm) few millimeters into a duct. Dry injection grout is visible.

6 EXAMPLE TEST CASES

This section presents some test cases demonstrating the NDT techniques and invasive measures in bridge inspection tasks the author was involved in.

6.1 *Test case 1*

About 150 m long prestressed concrete continuous box-girder bridge (Finland) built in 1968, see Figure 2 Left. The prestressing system type is KA Sigma Oval which is known to be sensitive to hydrogen embrittlement thus additional stresses such as faulty grout injection and corrosion of the prestressing steel are a real concern. The expansion joints of the bridge leak and de-icing salts are used here during wintertime.

Grout injection was evaluated at several locations of the bridge along 1,5 m of the theoretical locations of ducts. Applied NDT techniques were ultrasound tomography and Impact-Echo. Some of the NDT results for one of the anchorage zones (figure 2 Right) are shown in the Figure 3.

In the presented investigated zone ultrasound tomography revealed continuous and intense reflections along two scanned ducts and at their depth (ducts A and B). Nevertheless, "ringing" observed is the B scans at depth of about 175 mm from the concrete surface could indicate that the ducts are not completely empty of injection grout. Duct C is classified as non-suspicious according to tomography. The Impact-Echo test results at this investigation zone correlated well with the tomography results providing suspicious indications along ducts A and B (dominant signal peaks were detected along the duct and at the depth of the duct) and non-suspicious indications along duct C. According to the NDT results the duct A that was classified as "suspicious" was opened at a selected test point.

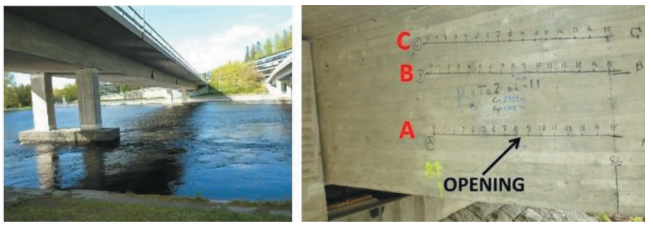

Figure 2. A side view of test case 1 bridge and the location of the presented investigation zone.

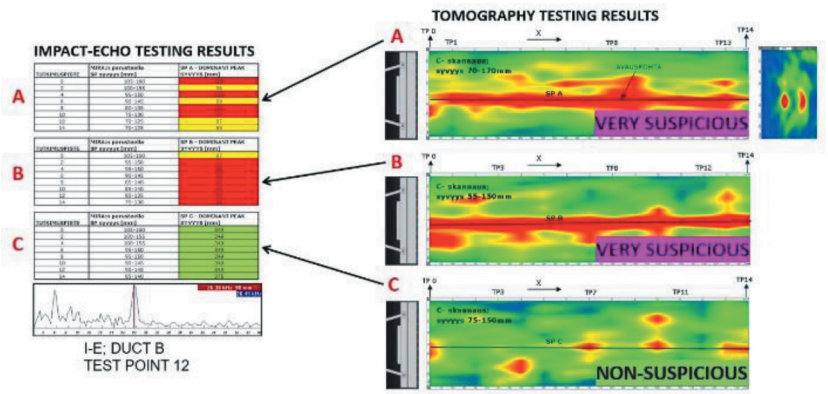

Figure 3. Ultrasound tomograms (C scans and B scan at a point along duct A) along investigated ducts A, B and C (See Figure 2) and Impact-Echo test point results summarized in a table (red-yellow colours are suspicious) and a dominant peak example at one test point.

Findings according to the opening of the duct (see Figure 4):

- The duct is partially injected (5 mm void). The injection grout is foamy and of low quality. The chloride content of the injection grout was <0,01 Cl^- % concrete weight → no penetration of chlorides from near leaking expansion joint has occurred.
- The prestressing steel corrosion class is estimated to be between 1 to 2 (light to mild). No pitting corrosion was observed.

6.2 *Test case 2*

About 102 m long prestressed concrete continuous box-girder bridge (Finland) built in 1971, see Figure 5 Left. The prestressing system is CCL 12 Ø 0,5" strands in each tendon duct. The expansion joints had been leaking intensively till the recent repair of the bridge. De-icing salts are frequently used during wintertime at the location of the bridge.

Figure 4. Voided duct. Light to mild corrosion of prestressing steel.

Figure 5. Side view of test case 2 bridge and the investigation zone related to the ultrasound tomography results presented in Figure 6.

Tendon ducts' grout injection was evaluated at various locations of the bridge along 1-2 m of the theoretical locations of the ducts, see Figure 5 Right. Applied NDT techniques were ultrasound tomography and Impact-Echo (partially). Some of the NDT results of one of the girders' anchorage zones are shown in Figure 6.

In the presented investigation zone the ultrasound tomography reveals continuous and clearly intense reflections along the scanned duct and at its depth. No "ringing" reflections were visible → very "suspicious" to be completely empty of injection grout.

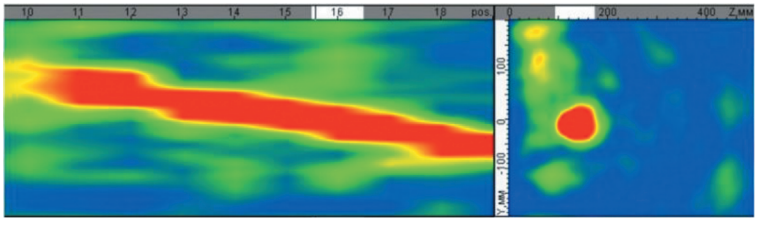

Figure 6. Side view of test case 2 bridge and ultrasound tomograms (C and B scan) along a duct and at the depth of the duct.

Opening of the tendon duct (Figure 7) revealed it is completely empty of injection grout and the prestressing steel is severely corroded (estimated Corrosion Class "3A"). Such a severe corrosion degree of the strands might significantly increase the risk of hydrogen embrittlement and/or SCC of the strands and therefore should be considered as a significant risk to the bridge durability.

Figure 7. Severely corroded prestressing steel in the opened empty duct.

7 CONCLUSIONS

Evaluation of tendon duct grout injection by applying suitable state-of-the-art NDT techniques and by performing slightly invasive measures at locations pinpointed by NDT results is proven to be beneficial in detecting substantial durability problems. These problems may pose risks to the prestressing system and affect the bridge functionality and sometimes its safe usage.

In some cases, acute faults were detected which required fast measures such as strengthening, setting traffic load limitations and even removal of bridges from service. Possibly some disasters were and will be avoided thanks to efficient evaluation of the prestressing system of bridges.

Applying these NDT techniques also during construction work of new bridges can ensure the post-tensioned system adequate quality from day zero and assist in preventing long term durability problems.

ABSTRACT: In this study, we have developed a digital inspection notebook in the bridge inspection process to prevent the oversight of damages and deterioration and ensure reliable inspections. Then, we evaluated and identified the challenges associated with the implementation of the digital inspection notebook in actual bridge inspections. By utilizing the digital inspection notebook, it became possible to display similar bridge damage cases and to record the inspection results on a 3D model of the bridge. This received positive feedback as it facilitated a better understanding of structural details and easier identification of areas susceptible to damages or changes. However, it was concluded that improvements are needed to enhance the usability in the field due to the complexity of equipment operation and increased input tasks on-site, as well as the difficulty of capturing images in narrow areas using the tablet device's camera. Based on the issues, we have improved the system in terms of the tool operation and showing of areas prone to damages or changes.

1 INTRODUCTION

Bridge Maintenance requires an establishment of a maintenance cycle consisting of inspection, diagnosis, measure and record which needs to be carried out continuously. That is, inspection within this maintenance cycle is a crucial first step in identifying any damage in the components, leading to subsequent diagnosis and measure. Therefore, inspectors responsible for conducting these inspections must possess sufficient knowledge and skills related to inspections and are required to appropriately report the condition of the bridge, which serves as the basis for the soundness through close visual inspection and similar methods.

On the other hand, bridge inspections may lead to "overlooking damage and deterioration" and "misjudgment of inspection results". The "overlooking damage and deterioration" occurs when the inspection is conducted, but crucial areas are missed, or when damage is overlooked due to a lack of knowledge regarding what constitutes damage. The "misjudgment of inspection results" is believed to arise from insufficient learning about similar damage cases and so on. Annual report of road maintenance in Japan (Ministry of Land, Infrastructure, Transport and Tourism. 2022) has reported significant variation in the proportion of damages classified as severity levels III (early measure stage) and IV (emergency measure stage) among different local authorities in bridge inspections. While the influence of regional characteristics is possible, there

DOI: 10.1201/9781003483755-371

is variability even in neighboring prefectures where the environment is considered to be similar. This suggests that "the overlooking damage and deterioration" and "misjudgment of inspection results" can be attributed to the knowledge and skills deficiency of the inspectors. To prevent such overlooking and misjudgment, it is necessary to understand areas prone to damages by referring to past inspection records of the target bridges and inspection results of similar bridges, and conduct inspections with the assumption of potential damages. However, many inspection records are primarily stored in paper format, and there is not a fully developed system that can be effectively utilized in the field. Therefore, there is a demand for the establishment of a system that allows on-site access to similar damage cases and past inspection records, enabling an understanding of critical inspection points for each bridge.

As mentioned above, the Ministry of Land, Infrastructure, Transport, and Tourism in Japan is actively promoting DX (Digital Transformation) in the field of infrastructure by harnessing data and digital technology. Various initiatives aimed at streamlining and improving the efficiency of maintenance and management using digital technologies, such as 3D data, are being undertaken by various public and private institutions. Kubota et al. (2021) developed a system for small-scale bridges without on-site signage of bridge names. This system utilizes RFID and QR codes to display the bridge name and a brief overview on tablet devices, with the goal of improving inspection efficiency, eliminating inspection errors and omissions, and enhancing the reliability of inspection results. Asai et al. (2018) investigated the construction of an inspection support tool that allows inspectors to annotate notes on images captured at the site using tablet devices, which are then displayed in an augmented reality (AR) space. Emoto et al. (2019) involves the development of a system that provides access to essential information for inspections, such as bridge specifications and inspection history, using augmented reality (AR) when scanning a bridge card with a smartphone camera. This system aims to enhance the efficiency of inspection tasks. Ibayashi et al. (2022) is working on the development of a bridge overview inspection system for small-scale bridges. This system enables inspectors to capture images of discovered damage using the built-in camera of a tablet device and automatically generate inspection reports.

As described above, in recent years, there have been efforts to develop systems that enable the acquisition of information related to bridge specifications and maintenance records as inspection support tools using digital data. However, there has been limited development of support tools focused on preventing the overlooking of damage, its diagnosis, and record. Therefore, the authors have developed a digital field notebook that prevents overlooking damage and deterioration in bridges and expects efficient and reliable inspections (Tai et al. 2023). In the present study, the developed digital field notebook was subjected to practical implementation and verification on real bridges. This process allowed the identification of the issues encountered and provided an opportunity to reflect on further development.

2 OVERVIEW OF DEVELOPED DIGITAL INSPECTION FIELD NOTEBOOK

In this chapter, an overview of the digital inspection field notebook developed by the authors are provided. The development of the digital inspection field notebook was carried out using the Unity game development software, which is a versatile tool used not only in game development but also in various other fields. Additionally, the chosen device for the digital inspection field notebook needed to have the following features:

- Portable for use in inspection sites
- Capable of capturing photos of inspection points
- Able to record inspection results
- Allows access to past inspection records and damage cases
- Capable of touchscreen operations (swiping, tapping, etc.)

In this study, a device that satisfies these requirements was selected, which is the Windows Surface Go3 with a weight of 544g, a 10.5-inch display, and an 8MP autofocus camera on the rear. The configuration of the digital field notebook system is shown in Figure 1.

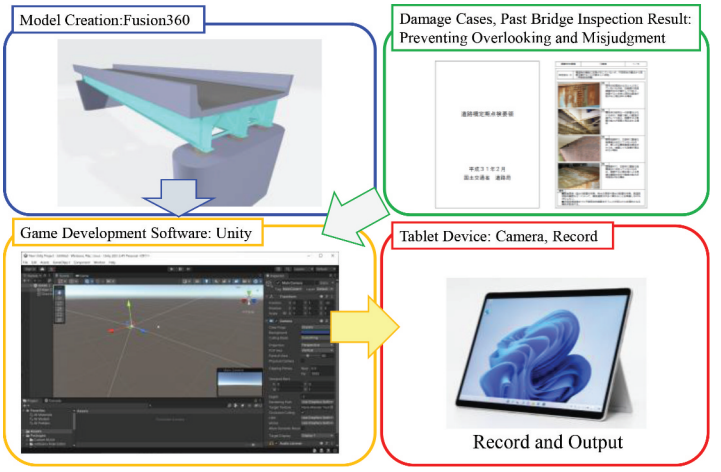

Figure 1. Configuration of digital field notebook system.

(1) 3D Bridge Model and Verification Function of Inspection Perspective
A 3D model of target bridge is created in VR space using the general-purpose 3D CAD software Fusion 360 by Autodesk. By creating 3D models for all bridge components, it becomes possible to conduct pre-inspection learning, confirming inspection points and inspection perspectives before the actual inspection. This allows for the visualization of inspection tasks and planning. Figure 2 depicts the general view of the bridge targeted for implementation verification and the created 3D model of the bridge.

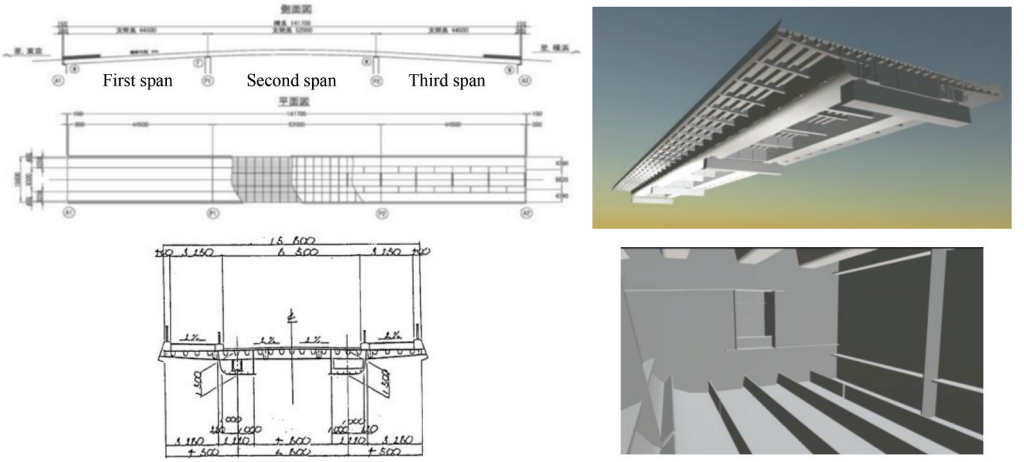

Figure 2. 3D model creation (a) Drawing of target bridge, (b) 3D model of target bridge.

(2) Confirmation of Similar Bridge Damage Cases and Prevention of Misjudgment
In bridge inspections, bridges with similar designs and construction environments often exhibit similar types of damage. Therefore, understanding damage cases from similar bridges and verifying the assessment of damage severity can help prevent misjudgments. While such verifications are commonly conducted as part of pre-inspection preparations, enabling on-site verifications, in addition to the preparatory phase, can contribute to preventing “overlooking damage and deterioration” and “misjudgment of inspection results”. This approach is believed to facilitate high-quality inspections.

Therefore, the digital inspection field notebook includes a feature that allows for the verification of damage cases and their assessment results from similar bridges. As illustrated in Figure 3, this feature compiles information on damage conditions and assessment cases as specified in the "Periodic Bridge Inspection Guidelines (Ministry of Land, Infrastructure, Transport and Tourism, 2019)". The included categories are corrosion, fatigue, fracture, deck plate, and others (such as bearing components or missing bolts). It also provides information on the target bridge's specifications and inspection considerations. Importantly, these pieces of information are customizable, allowing users to tailor them to the specific characteristics of the bridge under inspection.

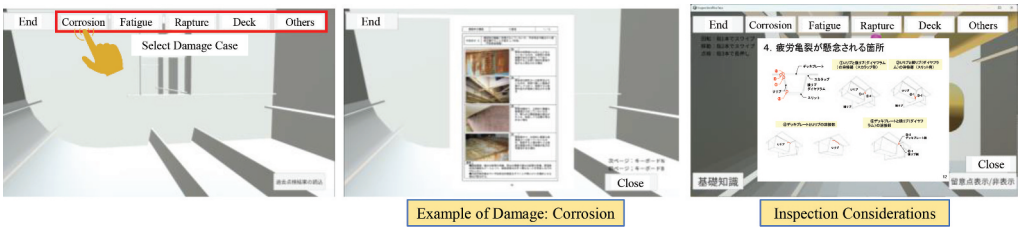

Figure 3. Confirmation feature for damage cases and inspection considerations.

(3) Verification of Past Inspection Records

When conducting inspections, it is of utmost importance to review past inspection records to identify areas where damage has occurred. Comparing the locations of damage or anomaly and assessing their progression and extent from previous inspection records is essential to prevent oversight and to make accurate assessments of the severity of damage. Therefore, to facilitate on-site verification of the occurrence, progression, and expansion of damage or deterioration, as shown in the example in Figure 4, the digital inspection field notebook has a feature that reads past inspection record data and displays markers in the form of spherical icons on the bridge's 3D model, indicating the locations where inspections were conducted. These spherical markers are displayed in different colors each time past inspection record data is loaded, allowing users to trace back through previous records to confirm damage or structural change data. As a result, during inspections at the site, inspectors can reference the occurrence of damage or deterioration from past inspection records, compare them with the actual damage, and prevent oversights or omissions during the inspection. This capability also allows for considerations regarding the progression of damage or deterioration when making assessments.

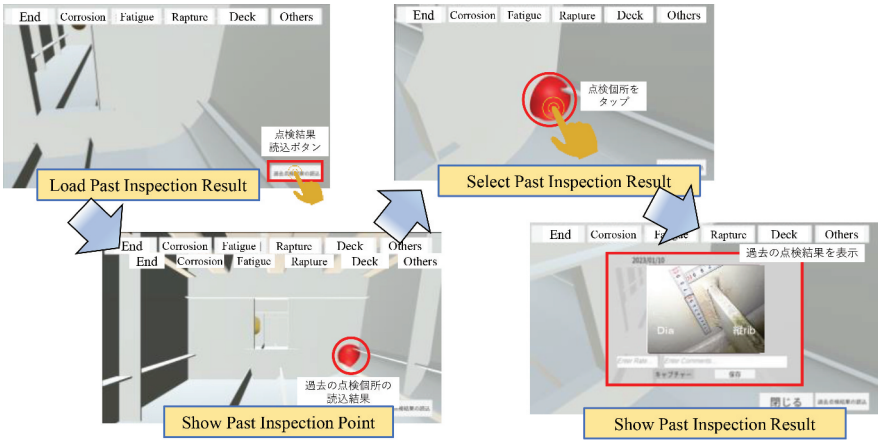

Figure 4. Feature for reviewing past inspection results on 3D bridge model.

(4) Record of Inspection Results

The ability to record inspection results is an essential feature in any field notebook, as accurate record enables proper diagnosis. In the digital field notebook, there is a function to capture photos using the rear camera of the Windows Surface Go3 device during inspections and record the inspection results. Specifically, as shown in Figure 5, users can tap on inspection points on the bridge's 3D model and choose to capture a photo. This action activates the device's rear camera, allowing for the photographing of the inspection point. After taking the photo, users can input information such as the component name, the damage severity classification, and commentsregarding the damage. This information is then saved as an inspection record. Once the inspection record is saved, similar to the inspection record verification feature described earlier, spherical markers appear on the bridge's 3D model. Users can tap on these markers to review the recorded content. As the markers are visually placed at the inspection points, it becomes easy to determine which locations have been inspected. This feature is valuable in preventing overlooking inspections.

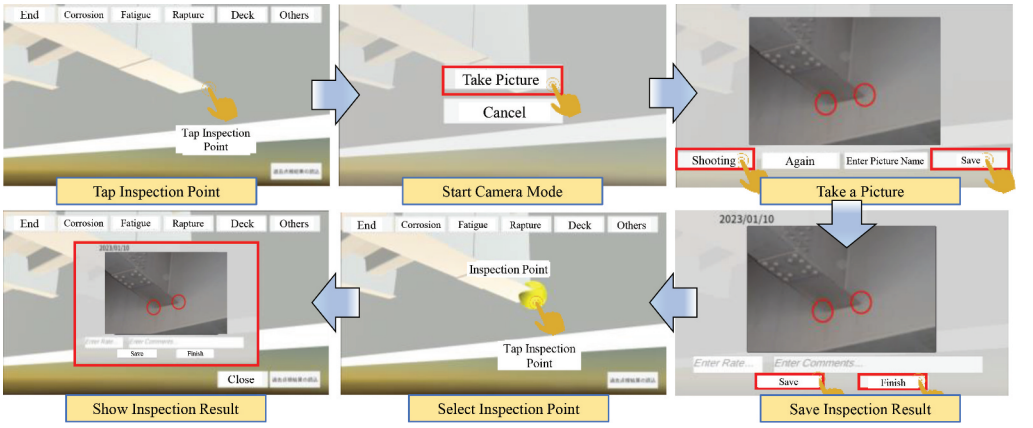

Figure 5. Record of inspection results.

3 IMPLEMENTATION OF DIGITAL INSPECTION FIELD NOTEBOOK

3.1 *Implementation testing method*

To validate the effectiveness of the digital field notebook mentioned above, an implementation test was conducted on the bridge illustrated in Figure 2. The testing method involved comparing the number of damage detections before and after implementing the digital field notebook. Specifically, the test involved two groups: one consisting of junior inspectors (with less than 3 years of inspection experience) and the other with mid-level inspectors (with over 10 years of inspection experience). For the test, the bridge's first and third spans were selected. Skilled inspectors with over 20 years of experience conducted visual inspections for these spans. Subsequently, the junior inspector group performed visual inspections on the third span before implementing the digital field notebook and the first span after implementing it. The mid-level inspector group inspected the first span before implementing the digital field notebook and the third span after implementation. The test aimed to compare the number of damage detections between skilled inspectors and junior or mid-level inspectors. The effects of implementation were evaluated through a questionnaire, and the results are presented in Table 1. The status of the implementation verification is illustrated in Figure 6.

Table 1. Questionnaire items and results.

For Pre-training

Figure 6. Situation of implementation.

3.2 *Results of implementation*

A summary of the inspection results from skilled inspectors and junior/mid-level inspectors before and after the implementation of the digital field notebook is presented in Table 2. In the first span, the detection rate of fine paint cracks, which are precursors to the development of fatigue cracks, improved from 38% for mid-level inspectors before implementation to 50% for junior inspectors after implementation. On the other hand, there were no detections of paint deterioration by junior inspectors after implementation, and neither group of junior/mid-level inspectors detected rust. In the third span, both mid-level and junior inspectors missed the paint cracks and rust discovered by skilled inspectors. In the case of paint deterioration, junior

inspectors before implementation had an 88% detection rate, which was superior to the 50% detection rate of mid-level inspectors after implementation. Since the targeted bridge in this test had a low occurrence of damage or deterioration within the box girder, the effects of implementing the digital field notebook were not clearly evident. To understand this factor, an analysis was conducted based on post-implementation questionnaires.

Table 3 shows the result of free description in questionnaire. Based on the results, it is likely that the application of the digital field notebook enhances pre-learning by providing a better understanding of structural details and making it easier to grasp locations prone to damage or deterioration compared to traditional drawings. However, the complexity of the field notebook's operation and the increased data input at the site may lead to a decrease in inspection efficiency and concentration, potentially not resulting in a clear improvement in inspection accuracy following implementation. Therefore, in the future, efforts should focus on improving usability, streamlining data input processes, and exploring equipment combinations to enhance inspection efficiency and concentration in the field. This will be crucial for the development of a more user-friendly system that effectively supports inspection activities.

Table 2. Comparison of inspection results before and after implementation.

First Span				Third Span			
	Type of damage	Number	Ratio		Type of damage	Number	Ratio
Skilled Inspector	Paint crack	16		Skilled Inspector	Paint crack	2	
	Paint degradation	3			Paint degradation	16	
	Rust	3			Rust	2	
	Total	22			Total	20

Table 3. Results of free description in questionnaire.

・**About Operation**
Radius of rotaion is too large.
Operation by finger is difficult.
Key plan is needed to identify current place.
・**About Data Input**
It's easier to operate when damage type can be selected from a dropdown.
Modification or re-editing function is needed.
・**About Photography**
Camera in the tablet device is not suitable to apply photography for narrow space.
It is difficult to come into focus by the tablet device.

・**About Usage effect**
It would be more efficient as it shows areas that should be inspected.
The tablet offers clear display screens, but it was not suitable for taking photos in particularly confined or challenging angles.
It could be a matter of getting used to it, but the operating the screen takes up so much attention that it can lead to a decrease in the focus on visual inspection of damages.
The visuals are easy to understand, and even after creation, others can intuitively understand the location of damages.
The 3D model is easier to understand the structure compared to drawings.
If it were possible to extract unfolded views and mark drawings from the 3D field book, it would lead to more efficient internal operations.

3.3 *Improvement of digital field notebook*

Based on the above results, the developed digital field notebook was improved. To reduce the overlooking the damage, The system added a feature to prevent overlooking of potential damage in critical locations by changing the color on the bridge's 3D model. For instance, in

the steel deck, there is concern about fatigue crack initiation from the welded joints of vertical ribs directly under the wheel load. Additionally, at field joints, being a site for on-site painting, there is a higher possibility of paint film degradation and corrosion compared to other areas. Therefore, as shown in Figure 7, the system visually highlighted such critical locations with potential damage or deterioration, allowing for easy visual recognition during pre-inspection and inspection.

Furthermore, the input method has been changed to screen buttons, adding a sketch feature on the 3D model, using dropdown menus for selecting damage levels, and incorporating a handwriting note feature (Figure 8). These improvements have enhanced usability. Implementation verification and continuous improvement are planned for the future.

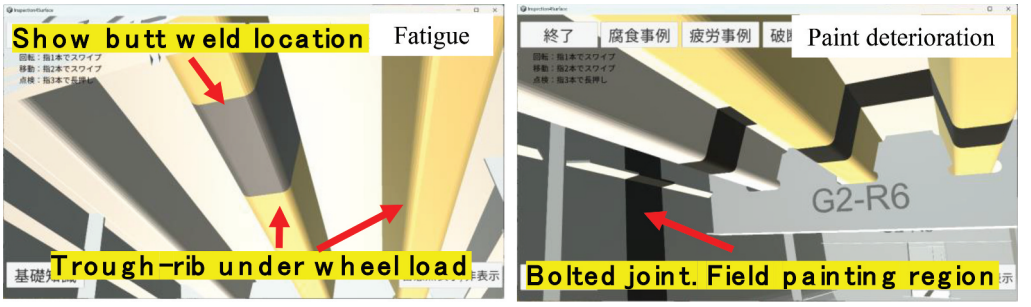

Figure 7. Examples of visually highlights such critical locations with potential damage.

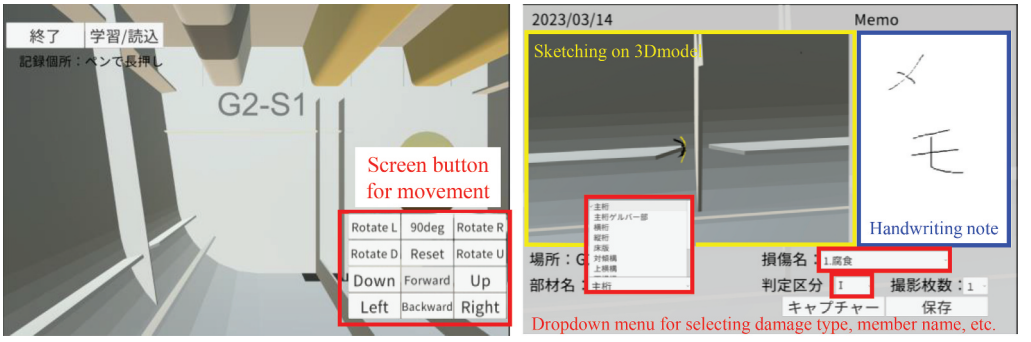

Figure 8. Example of improvement for the input method.

4 SUMMARY

In this study, the authors developed a digital inspection field notebook aimed at preventing the “overlooking of damage and deterioration” and “misjudgment of inspection results” in bridge inspections and ensuring efficient and reliable inspection processes. This system was implemented in actual bridge inspections, and an evaluation of its effectiveness and identification of issues were conducted.

By using the digital inspection field notebook, inspectors are able to display areas on the 3D model of the bridge in the tablet’s VR environment, based on damage instances from similar bridges where damage and deterioration are likely to occur. This feature enhances the understanding of structural details and locations prone to damage or changes compared to traditional drawings. However, there are challenges to be addressed, such as the complexity of equipment operation and the difficulty of capturing images in confined areas using the tablet’s camera.

To address these challenges, several improvements have been proposed, including changing the input method from tapping and swiping to button-based controls, implementing touchscreen pens for handwritten input, and streamlining data input through dropdown menus. These improvements is expected to reduce the workload in field inspections, ensuring that inspectors can concentrate on their work and preventing the overlooking of damage or deterioration. By directly inputting damage or change locations on the 3D model and enhancing the accuracy of inspection records, the system contributes to the advanced maintenance and management of infrastructure. The authors plan to work on further improvements to build a system that enhances inspection reliability and efficiency while reducing the workload on inspectors.

B. Hergart
Øresundsbron Konsortiet, Malmö, Sweden

ABSTRACT: The Øresund Fixed Link is a 15,9 km road and railway connection between the southerly Swedish city of Malmö and its neighbor across the Øresund strait, Copenhagen, in Denmark. The link, which opened in 2000, consists of an elevated bridge, including a high stay cable bridge, an artificial island, as well as a submerged tunnel. The operators of the link, Øresundsbron Consortium, have recently, as part of a comprehensive sustainability strategy, initiated a project for extending the service life of the link. The project, which is being carried out by researchers at Lund University, aims to develop decision support for service life extension of the bridge and tunnel structures to 200 years. The tasks include the identification, modelling, and analysis of service life relevant scenarios (as a basis for service life quantification) as well as decision scenario modelling and analyses considering possible future repair actions. A brief overview of the project is provided along with a general framework for service life quantification. Preliminary results for an example, concerning active corrosion initiation of the immersed tunnel roof, are also provided. This work highlights the potential benefits of industry-academic collaboration towards improved infrastructure operation and maintenance and, by extension, sustainability.

1 INTRODUCTION

1.1 *Background*

The proper operation and management of transport infrastructure assets is critical to ensure a well-functioning transportation network. Approaches to this have evolved and developed substantially over time. The focus early on was on repairing only when damage was observed (corrective maintenance) followed by developments towards preventative and then condition-based (or predictive) maintenance (Moubray 1997). More recently, emphasis has been on integrating risk or decision analysis-based methodologies to improve and optimize the management and operation of bridges and other infrastructure assets (e.g., Faber 2008, Björnsson et al. 2019, Thöns 2018). Recent research efforts have focused on the development and implementation of more advanced computational models for deterioration, identifying and calculating structural-performance indicators, evaluating life-cycle costs, and optimizing inspection, maintenance, and repair strategies (Sánchez-Silva et al. 2016, Zhang et al. 2021, Abdallah et al. 2022). However, the operational phase of built infrastructures such as bridges or tunnels is seldom, if ever, considered during design. Thus, ensuring continued operation, satisfactory performance, and structural safety over time can be a daunting and costly task for the bridge owner and manager.

The operation and management of medium to small scale infrastructure assets is commonly the responsibility of national or regional authorities, e.g., the Swedish Transport Administration

DOI: 10.1201/9781003483755-372

in Sweden or the Danish Road Directorate in Denmark. In these cases, the number of assets (bridges or tunnels) being maintained may be in the tens of thousands leading to a limited number of resources available for each individual structure. On the other hand, for larger scale infrastructures, such as the Millau Viaduct in France or the Øresund Fixed Link between Sweden and Denmark, ownership and management is the purview of a dedicated agency or company. In these cases, efforts are directed towards operating and maintaining a single large-scale infrastructure. In practice, it is commonly these types of structures that will, e.g., be equipped with expensive monitoring systems or employ state-of-the-art inspection technologies (such as drones) to support maintenance decisions. This is quite reasonable as the failure of these types of structures would result in very significant consequences; the collapse of the Polcevera Viaduct in Genoa in 2018 is a stark example of this (Calvi et al. 2019).

1.2 *Øresund Fixed Link (Øresundsbron)*

The Øresund Fixed Link, referred to locally simply as Øresundsbron, is a 15,9 km long road and railway connection between Southern Sweden and Denmark, see Figure 1. The link, which was opened to traffic in 2000, consists of a 7,8 km long elevated bridge, a ca 4 km artificial island, as well as a 4 km immersed tunnel. The bridge structures can further be subdivided into two approach bridges as well as a high stay-cable bridge to allow for transit of larger seagoing vessels. The bridge superstructure is a double-deck configuration with a lower steel truss supporting railway traffic positioned below a concrete slab for road traffic (Gimsing 2000a). The submerged (or Drogden) tunnel consists of 20 concrete tunnel segments on gravel bed foundation with immersion joints (Gimsing 2000b).

Figure 1. View of the Øresund Fixed Link (view from the artificial island Pepparholmen towards Malmö).

The link is owned and operated by the Øresundsbron Consortium, a company owned equally by the Swedish and the Danish state. The operators have a vision for the link to become the most sustainable infrastructure in the world. This vision is illustrated by four

targets: 100 extra year service life, 100% open for traffic, 100% free from severe accidents, and 100% free from CO_2. The strategies and main activities for approaching these visionary targets include a remarkable cut in energy consumption (by more than 55%) and installation of solar energy plants (now providing 45% of the needed electricity). The most sustainable action, however, is to prolong the service life of the link from the original design criteria which was 100 years. To support this action, an ongoing collaborative research project was recently initiated together with researchers at the Division of Structural Engineering, Lund University, Sweden. This paper briefly describes this project and describes methods for service life quantification. An example is also provided concerning reinforcement corrosion in the roof of the submerged tunnel.

2 SERVICE LIFE EXTENSION

2.1 *Background*

Extending the service life of infrastructures is an effective measure to improve sustainability by delaying or avoiding the need for expensive and resource-intensive replacements. The current design of these structures is often based on a design life of 100 years. The actual service life, which requires considering the operation phase, is limited by both technical and economic factors (Thöns et al. 2024). For the former, time-dependent considerations of structural safety and serviceability are central. Varying structural deterioration mechanisms, such as fatigue or corrosion, degrade structural integrity while the intensity and severity of certain hazards may also increase over time. Active measures to treat these risks are embedded in the management and maintenance of these structures, e.g., through preventive measures, periodic inspections, repairs, strengthening, etc. However, it is sometimes difficult, impractical, or impossible to avoid or repair certain structural damages, placing a technical limit on service life. Economic factors similarly place limits on service life if the required measures become too costly. In extreme cases, replacing the structure entirely may be the optimal solution. Another issue, commonly observed in practice, is obsolescence - when the structure is no longer deemed useful, e.g., owing to changes in the local transportation network (Mattsson 2008). However, this issue is difficult to consider a-priori and will not be discussed further in this paper.

2.2 *Collaborative project description*

In 2022, a collaboration was initiated between Øresundsbron Consortium and the Division of Structural Engineering, Lund University in Sweden. A pre-study was carried out to prepare a modelling basis for the service life management and service life extension to 200 years (Thöns & Björnsson 2023a, 2023b). The focus in the pre-study was on the structural components and systems of the link including the approach bridges, the high bridge, and the immersed tunnel. As of fall 2023, a continuation of the project is underway with the following objectives:

1. Modelling and analysis of service life relevant scenarios for different structural groups and deterioration mechanisms.
2. Service life quantification with repair strategies and additional information.
3. Quantification of service life extension costs and utilities.
4. Identification of efficient service life extending integrity management strategies.

The project is founded on methods of applied engineering and decision analysis research for the service life quantification and service life management as illustrated in Figure 2. The first step is to identify and model service life relevant scenarios for different structures and substructures considering relevant failure and deterioration mechanisms. Thereafter, the service life can be quantified provided time-dependent probabilistic models can be developed. At this stage it is also important to consider discrepancies or deviations from design assumptions as well as the current condition and loading on the structure (based, e.g., on previous inspections and repairs).

The remaining service life can then be determined based on compliance with corresponding target reliabilities as specified according to, e.g., JCSS (2001-2015) and ISO 2394 (2015).

Actions (such as, e.g., repair and strengthening) may be taken to extend the service life of the link and observations (i.e., information) can be used to update and predict the structural condition for the support of implementing these actions. These service-life extending strategies lead to economic and environmental benefits but may be costly and include potential structural risks. Furthermore, these strategies can be explicitly modeled and analyzed using a (pre-posterior) decision analysis framework. Finally, the analysis of the resulting decision scenarios allows for the identification of optimal service life extension and management strategies by maximizing the expected utility composed of potential benefits, consequences, and costs.

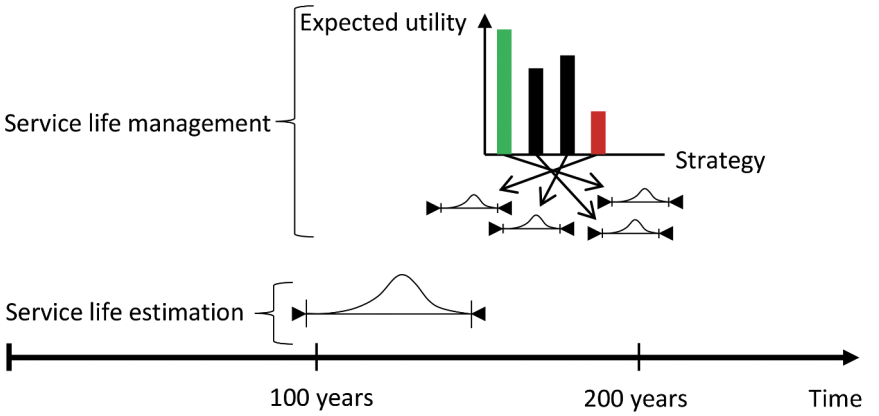

Figure 2. Visualization of the service life extension, service life management and decision-support model.

3 SERVICE LIFE QUANTIFICATION

3.1 *Introduction*

Determining the service life of an infrastructure is not a straightforward task and multiple approaches may be adopted. Herein, three will be briefly mentioned: (1) estimation by failure databases (of similar structures), (2) estimation by expert opinions, and (3) probabilistic modeling. For the first, published incident or failure databases can be utilized as a basis for estimating an average failure rate for a sample population with associated rates for different causes; see, e.g., Cook (2014). However, such estimates should be regarded with care as failure data is rarely complete, may contain incomplete or poor descriptions, etc. (Stewart & Melchers 1997). Furthermore, an average failure rate may be misleading as structures in general (and especially large-scale infrastructures) are unique; both with regards to their configuration and the circumstances to which they are enduring (e.g., loading history).

The second approach concerns estimations by synthesizing opinions from a group of experts. Established methods include expert elicitation (see, e.g., Ayyub 2001, Ioannou et al. 2022) and the Delphi method (see, e.g., Beiderbeck et al. 2021). Such approaches are useful in cases where uncertainties are high. However, as with using failure databases, the acquired results from expert opinions, which may be highly subjective, should be regarded with care. On the other hand, both the previously mentioned approaches may be useful in accounting for phenomena which are more difficult to model numerically (e.g., failures resulting from gross human errors).

Finally, an explicit probabilistic modelling of service life limiting scenarios can be carried out. Critical service life ending scenarios are identified, characterized by a structural condition that fails to meet safety standards and is unmodifiable. In other words, a condition that is

both unsafe and irreparable. Such a condition can be caused by technical or by economic limitations; see Thöns et al. (2024) for further details. The technical service life quantification relies on a probabilistic model including (1) a structural deterioration mechanism describing the time-dependent condition of the system, and (2) a criterion for when failure is reached. To illustrate this, the phenomenon of active reinforcement corrosion is presented in the next section.

3.2 *Reinforcement corrosion*

Active corrosion of reinforcement in concrete structures is a highly relevant deterioration phenomenon. Once active corrosion is initiated, the loss of load carrying capacity will occur as the steel area becomes reduced. Over time, this can lead to failure of a structural component or system. In this paper, we consider the initiation stage for active corrosion (without assessing the time-dependent structural reliability of a corroded RC structure). Thus, service life quantification based on these probabilistic models would require further assessing the impacts of this process to structural performance. On the other hand, they can provide a good starting point for prioritizing different service life ending scenarios, e.g., if the results indicate a relatively high or low probability of active corrosion for a critical structural member.

3.2.1 *Active corrosion initiation*

In a marine environment, corrosion can become active if both the concentration of chlorides at the rebars' level overcomes the critical threshold and the pH of the concrete surrounding the rebars is lower than ca. 9 (Melchers and Li 2009). This statement holds for sound concrete (no cracks developed).

Chlorides' concentration rises due to diffusion of chloride ions from the concrete surface, while a pH reduction is herein considered due to the carbonation process of concrete. Because carbonation is inhibited for submerged structures, the corrosion of submerged elements is, in this (preliminary) phase, neglected. Both processes are considered to develop independently, therefore the time to active corrosion (T_{ac}), or time needed for chlorides to reach the reinforcement (T_{ich}) and carbonation to advance (T_{ica}), can be estimated from:

$$T_{ac} = \max\left\{T_{i_{ch}}; T_{i_{ca}}\right\} \tag{1}$$

The subsequent sections describe the models adopted for each of these processes.

3.2.1.1 Chloride diffusion

The concentration of chloride ions at time t and depth x inside the concrete can be modelled using Fick's second law as follows:

$$C(x,t) = C_0 + \left(C_{s,\Delta x} - C_0\right)\left[1 - \mathrm{erf}\left(\frac{x - \Delta x}{2\sqrt{D_{app,c}(t)\cdot t}}\right)\right] \tag{2}$$

where C_0 is the concrete initial chloride content [wt.-%/c], $C_{s,\Delta x}$ is the chloride content at depth Δx [wt.-%/c], Δx is the depth of the convection zone [mm], $D_{app,c}(t)$ is the time-dependent chloride diffusion coefficient [mm^2/year], and $erf(\cdot)$ is the error function. The value of the apparent chloride diffusion coefficient $D_{app,c}$ can be evaluated from:

$$D_{app,c}(t) = k_e D_{RCM,0} k_t B(t) \tag{3}$$

where $D_{RCM,0}$ is the chloride diffusion coefficient [mm^2/year], k_t is the environmental transfer parameter equal to 1, and $B(t)$ is the ageing function. The environmental variable, k_e, can be determined according to:

$$k_e = \exp\left(b_e\left(\frac{1}{T_{ref}} - \frac{1}{T_{real}}\right)\right) \tag{4}$$

where b_e is the regression parameter [K], T_{ref} is the reference temperature equal to 293 K (20°C), and T_{real} is the temperature of the element or of the environment [K]. The ageing function is estimated from:

$$B(t) = \left(\frac{t_0}{t}\right)^a \tag{5}$$

where t_0 is the reference time (equal to 0.0767 years) and a is the ageing coefficient [-].

If the initial chloride content of concrete is considered equal to zero, the time needed for the chloride concentration to overcome the critical threshold at the steel (reinforcement) surface can be evaluated as follows:

$$T_{i_{ch}} = X_{ch} \cdot \left[\frac{1}{4k_e k_t D_{RCM,0} t_0^a}\left(\frac{c - \Delta x}{\text{erf}^{-1}\left(1 - \frac{C_{cr}}{C_{s,\Delta x}}\right)}\right)^2\right]^{\frac{1}{1-a}} \tag{6}$$

Eq. (6) is derived rearranging Eqs. (2-5) and replacing C_0 with the critical chloride threshold C_{cr} [wt.-%/c], and x with the concrete cover c [mm]. X_{ch} is an added variable that accounts for the model uncertainties.

3.2.1.2 Carbonation

The time to carbonation initiation is herein determined using an empirical model, see Eq. (7) (Silva et al. 2014).

$$T_{i_{ca}} = \begin{cases} \frac{c^2}{k_d^2} \text{ for } RH \leq 70\% \\ \frac{c^2}{k_w^2} \text{ for } RH > 70\% \end{cases} \tag{7}$$

In addition to the concrete cover c [mm], the following parameters are defined:

$$k_d = S_1 \cdot [CO_2] - S_2 \cdot EC - S_3 \cdot f_c + S_4 \tag{8}$$

$$k_w = S_5 \cdot [CO_2] - S_6 \cdot C_l - S_7 \cdot f_c + S_8 \tag{9}$$

Table 1. Carbonation model parameters.

4 EXAMPLE - REINFORCEMENT CORROSION IN IMMERSED TUNNEL ROOF

This example concerns active corrosion of reinforcement in the immersed tunnel roof of the Øresundsbron. A reduction in capacity of the roof section due to corrosion would be very severe as watertightness of the immersed tunnel element would be compromised. The results are preliminary and are related to the initiation of active corrosion, without considering the structural integrity of the tunnel roof as potential corrosion progresses.

For the inner surface of the tunnel roof (XD1), a type A concrete (Gimsing 2000b) is employed. The nominal cover is 50 mm with a tolerance of ±10 mm, the water-to-cement ratio is 0.45, and the characteristic compressive strength (f_{ck}) is 40 MPa. Input variables and distributions are summarized in Table 2.

The survival function, defined as the complement of the cumulative distribution function (1-CDF), for the T_{ac} variable is shown in Figure 3 for the studied example. The 90% survival probability is highlighted for illustrative purposes. In this example, utilizing higher survival probabilities (e.g., based on target reliabilities for ultimate limit state) is not suitable as the initiation of active corrosion would not lead to failure. Finally, a sensitivity analysis reveals that the concrete quality (strength), cover, and chloride content have the highest impact on the results; see Figure 4.

5 DISCUSSIONS AND CONCLUSIONS

Extending the service life of infrastructures is an effective measure to improve sustainability. Recently, the Øresundsbron Consortium have adopted this strategy for the Øresund Fixed

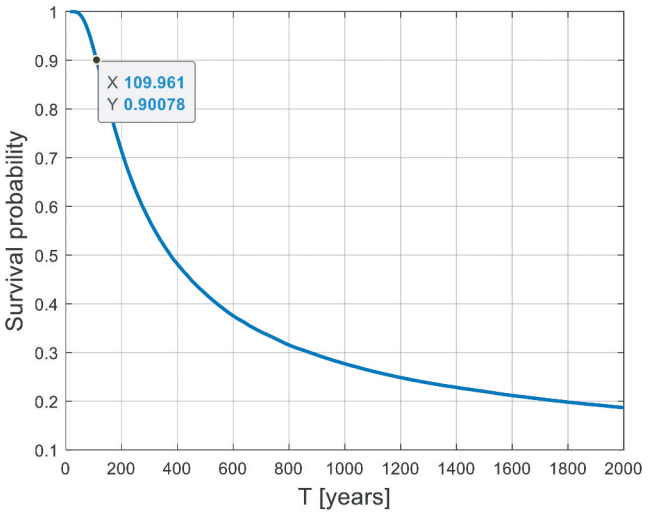

Figure 3. Survival function of the variable T_{ac} (time to active corrosion) for the inner ceiling of immersed tunnel (50mm cover).

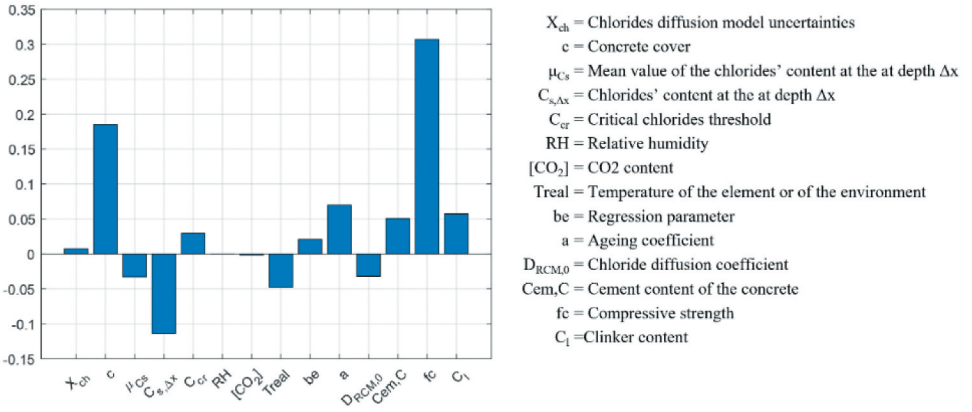

Figure 4. Spearman correlation coefficient of the input variables for time to active corrosion of the inner ceiling of the immersed tunnel (50mm cover).

Link located between south Sweden and Denmark. Specifically, the aim is to increase the service life from 100 years to 200 years. To support this, an industry-academic collaboration was established to implement current state-of-the-art research in the operation and management of the link. The ongoing research project aims to provide decision support for service life management and extension of the link. A first step in this direction concerns the development and implementation of probabilistic models for service life quantification. The provided example focuses on one deterioration mechanism (reinforcement corrosion) at a critical location in the link (the immersed tunnel roof). The preliminary results provide a basis for service life quantification which can then be extended to determine optimal maintenance actions and information acquirement strategies, providing direct decision support for the infrastructure operator. Investigations are ongoing concerning other deterioration mechanisms and critical sections/details, including steel fatigue of critical details of the bridge superstructure and at cable anchors.

Extending great belt bridge bearing service life using mobile computer vision

J. Winkler
Digital Engineering Solutions – DES & AtkinsRéalis, Warsaw, Poland

M.D. Havelykke & F. Bormlund
Sund & Baelt A/S, Copenhagen, Denmark

ABSTRACT: Our industry is facing a global problem with aging infrastructure. We need asset health data to extend service life of structures and thereby decarbonize our sector. Current structural monitoring tools are too expensive and not scalable enough. However, mobile computer vision technology has a potential to revolutionize structural monitoring by providing easy to use and affordable tools like regular smartphones. Great Belt East Bridge forms a part of the critical Scandinavian infrastructure. Inside the bridge anchor block there are several structural elements like bearings that ensure safe operation of the bridge. The bridge owner (Sund & Bælt) was concerned about the proper functioning of the bearings. This paper shows how Sund & Baelt technicians with no prior monitoring experience used a regular smartphone to capture and analyse bridge asset health data with sub-mm accuracy. The DES mobile app allowed for rapid data collection and analysis of the bearing behavior. The visual data obtained from the app triggered maintenance actions that ensured proper functioning of the bearings. Today, the mobile app for asset condition survey is used in connection with Sund & Bælt's operation and maintenance of the bridge. According to the bridge owner the mobile app has a potential to revolutionize bridge structural health monitoring worldwide.

1 INTRODUCTION

1.1 *Context and client goals*

The total value of the world's infrastructure is estimated at $50 trillion and ageing rapidly. Despite $70 billion spent on bridge maintenance alone there is a growing number of catastrophes in both developed and developing countries. The existing tools for monitoring and infrastructure management are usually too expensive and too complicated and therefore, most repairs are reactive and costly. The infrastructure will continue to develop and the constant reduction in maintenance budgets is posing serious challenges but at the same time creating an opportunity and a demand to introduce digital technologies. Sund & Bælt is Scandinavia's largest private infrastructure asset owner and has total responsibility for the operation and the maintenance of the Great Belt Bridge, Öresund Bridge (linking Denmark and Sweden) and Fehmarn Tunnel (world's longest immersed tunnel) Figure 1.

The Danish, state-owned holding company's strategy is to digitalize operations of the large infrastructure assets in collaboration with external technology partners like Digital Engineering Solutions - DES. The client have been using the DES mobile system and AtkinsRealis expertise to enhance their monitoring and measuring capabilities on the bridge. The data about structural performance (including damage detection) acquired by Structural Health Monitoring systems (Farrar & Worden, 2007) are used to develop maintenance strategies to

DOI: 10.1201/9781003483755-373

Figure 1. Sund & Bælt is Scandinavia's largest private infrastructure asset owner.

reduce operations costs and to improve reliability (Winkler & Hendy 2016, 2017). Sund & Bælt 2025 sustainable goals include:

- Reduction of operational costs: 2% per year
- Keeping constant cost level after 2024/2025 despite aging asset
- Maintaining quality and accessibility

1.2 *Structure description*

The Great Belt East Bridge has a central span of 1624 m with 535 m side spans and pylons reaching up to 254 m. The bridge carry a four lane motorway plus emergency lanes. 31 m wide welded steel box girder is continuous between the anchor blocks over the whole suspension bridge length (Figure 2).

Figure 2. Great Belt East Bridge.

The total length of the Great Belt Fixed Link is 18km long consisting of a road suspension bridge, a railway tunnel and a box-girder bridge for both road and rail traffic.

2 PROBLEM

2.1 *Bearing PTFE plate deterioration*

Inside the anchor block there are several structural elements like bearings that need to be monitored to ensure safe operation of the bridge. During one of the inspections it was noticed that the PTFE plate was getting worn out excessively indicating bearing malfunction (Figure 3).

Figure 3. Bearing and deteriorated PTFE plate.

The client was trying to identify the cause of the bearing problem. The first assumption was related with the mechanical issue (the friction between the PTFE plate and the bearing was potentially impacted as the plate was positioned on uneven stainless-steel plate). During a follow up inspection it turned out that the steel plate below stainless steel was deformed, causing local deformation. The second assumption was related with the bridge suspension span moving more than intended (due to f.x. increased traffic) and thereby inducing bigger movement on bearings.

The client decided to use the mobile app to capture additional monitoring data. It should be noted that there was a displacement sensor already installed on the bearing providing data on longitudinal movements. However, the client considered potential bearing rotation as a primary concern and wanted to gather visual data on the movement mechanism to better understand the overall behaviour.

3 SOLUTION

3.1 *DIC mobile app*

Mobile phones have never been just "phones." From camera to games, mobiles have always offered more than the standard calling experience. Now, the abilities of mobile phones have taken a new turn. Nowadays, smartphones come with superior-quality cameras. When integrated with computer vision and Digital Image Correlation (DIC) algorithms, these cameras can be used to provide professional services.

Computer vision give mobile devices the ability to see and process visual information like objects or images. Computer vision is becoming increasingly popular globally and is being applied in a wide range of industries. However, the application of mobile computer vision in structural health monitoring was virtually non-existent.

Sund & Baelt being one of the world's most innovative/digitally focused infrastructure asset owners was looking for smart solutions and recently adopted a technology that combines easiness of use, digitisation and flexibility in data collection & analysis. The technology was developed by DES - a pioneer in connecting AI with mobile computer vision for optimal structural monitoring (Figure 4).

Figure 4. Mobile DIC app developed by DES.

The method uses a regular smartphone mounted on a tripod, at a static position. Two setups for mobile monitoring were arranged: Setup 1 was used for capturing data on rotations while Setup 2 was used to simultaneously collect data on bearing movement (Figure 5). The mobile app system was collecting data for 2 days continually and the distance between a smartphone and the bearing was kept constant throughout the monitoring period. Light was provided by the client and the calibration procedure was done by implementing a known dimension into the software.

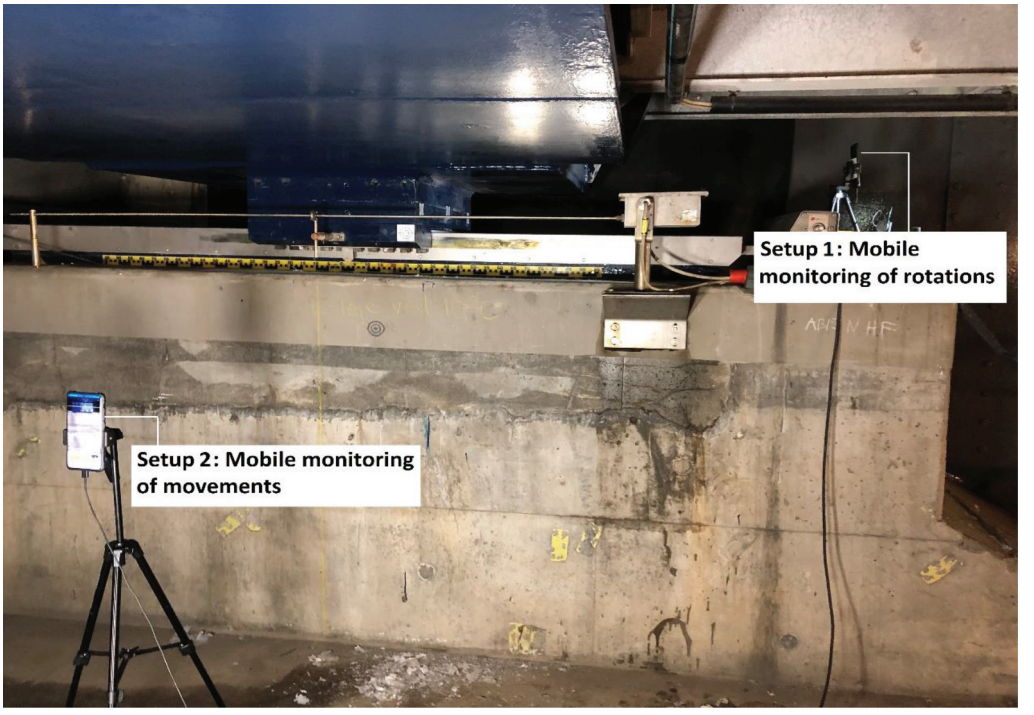

Figure 5. Mobile DIC setups for bearing monitoring.

Visual data acquired from the mobile setups were used to investigate bearing rotational movements (Setup 1). The results showed that there was no rotation of the steel part sitting on top of the bearing (Rotation 1 – see Figure 6) . However, the images collected over time clearly showed a rotation of the bearing plate (Rotation 2 – see Figure 6) and the subsequent rapid deterioration of the PTFE material. These results supported the assumption of an uneven steel plate affecting the behavior of the bearing.

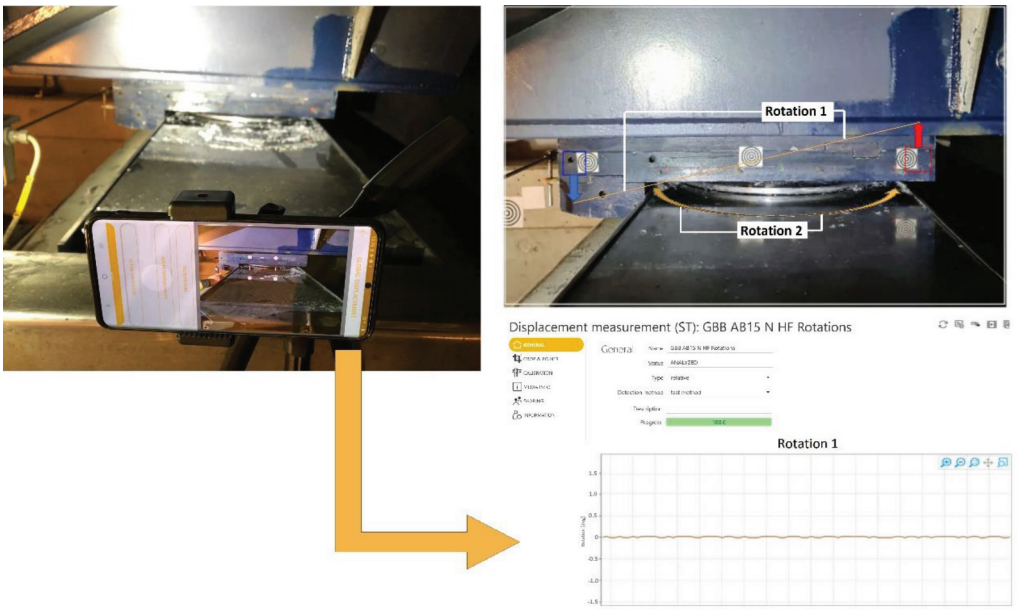

Figure 6. Setup 1: Mobile monitoring of bearing rotations.

To better understand the holistic bearing behaviour the mobile app was also employed to simultaneously collect data on movement (Figure 7). The results showed that the movement of the bearing exceeded the anticipated amount.

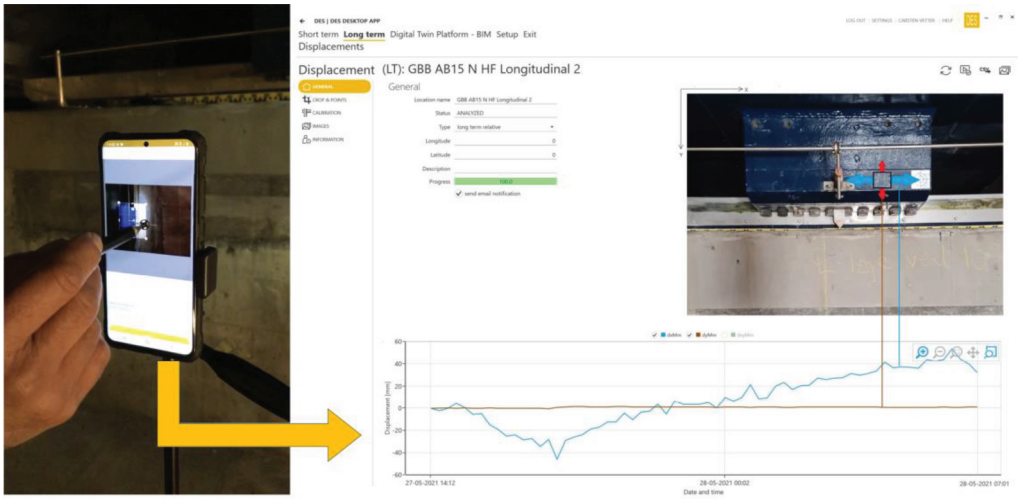

Figure 7. Setup 2: Mobile monitoring of bearing movement.

No specialist equipment or training was required to take and analyse the measurements. The mobile app uses AI and computer vision to analyse vidoes or images and the results are returned in as little as few minutes. The user sets the parameters for the capture and the algorithms incorporated into the app do the rest.

The mobile app measurements are highly accurate and have been validated multiple times against traditional equipment. A calibration certificate has been issued by an accredited laboratory according to the standards for European ISO 9513 and American ASTM E83-16.

4 MAINTENANCE ACTION

The client took two maintenance actions following the mobile app monitoring investigation. First was related with replacement of the stainless-steel plate to ensure proper bearing behaviour (no rotational movements) and replacement of the PTFE plate (Figure 8).

Figure 8. Maintenance action to replace the damaged elements of the bearing (PTFE plate).

Second maintenance action involved correction of the hydraulic pressure of the buffers to reduce bearing movement to allowable limits. The mobile app allows repetitive measurement for comparison purposes which showed that the bearing movement after the maintenance action and correction was as intended (23 mm at the highest point rather than 75 mm - see Figure 9).

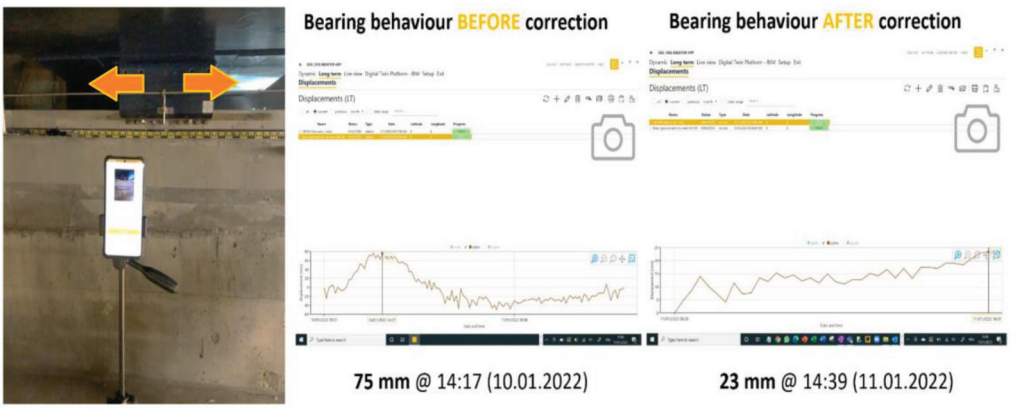

Figure 9. Movement of the bearing before and after hydraulic pressure correction.

5 CONCLUSIONS

Sund & Baelt is now able to take measurements anywhere along the bridge girder (more than 1.6 km long) using the DES mobile app. Previously, collecting additional monitoring data on expansion joints, bearings, decks or girders was too expensive. Traditionally, highly qualified experts along with specialized equipment are required for this level of monitoring. It also took a long time for the data to be analyzed and results produced. Now with the easy-to-use app functionality with its visual inspection and sub-millimeter measurement capability, accurate results can be acquired in a matter of minutes and available at the point of measurement if necessary.

The mobile app measurement triggered maintenance actions that ensured safe operation of the bearings and extended service life of critical structural elements.

Sund Baelt considers the mobile app SHM system as ground-breaking and disruptive technology that enables fundamental changes in the way bridge monitoring and asset management is carried out.

30 years' experience of optimizing the use of corrosion sensors

P.H. Møller
Ramboll, Hannemanns Allé 53, Copenhagen S, Denmark

S. Gjerding
Sund & Bælt Holding, Vester Søgade, Copenhagen, Denmark

ABSTRACT: For 25 years corrosion sensors at the concrete structures of the Great Belt Link in Denmark have been tested by various standard methods, but the results did not allow for a satisfactory evaluation of the corrosion in the splash zone, partly because of cathodic protection from anodes in the water installed at the Great Belt Link. The use of alternative/traditional inspection methods is difficult in the splash zone and therefore it was investigated if corrosion evaluation in this very important zone could be improved by optimizing the use of the corrosion sensors. The sensor setup was changed from separate sensor parts to all sensor parts being connected to the reinforcement which allowed detailed evaluation of the complex conditions in the splash zone governed by macro-cell corrosion and protection/prevention from the water anodes. Introduction of continuous monitoring allowed to document the influence from weather conditions on the corrosion conditions in the splash zone.

1 CORROSION SENSORS IN CONCRETE STRUCTURES, LITERATURE REVIEW

Around 1990 the main concept for corrosion sensors was introduced. The concept consists of sensor anodes arranged in a ladder system and the corrosion status of each sensor anode is mainly evaluated by measuring short-time (5 sec.) macro-cell current. The system layout, the measurement methods and 10 years' experience of the system is presented in (Raupach et al. 2000). The main purpose of this system is to determine the time of reinforcement corrosion initiation, but the measuring methods do not allow for evaluation of the corrosion rate after initiation.

To allow for taking account of the propagation phase methods for measuring corrosion rate after initiation were introduced. A review of relevant methods is presented in (Figueira 2017). Usually the Linear Polarisation Resistance (LPR) method is used, and a presentation and evaluation of the LPR methods is found in (Nygaard et al. 2012). Design of a sensor system and the results from continuous LPR measurements from 3 years field exposure is found in (Sørensen et al. 2013). The results from (Sørensen et al. 2013) showed an intermediate phase between the change of corrosion status from passive to active. During the intermediate phase status changes several times between active and passive. After the intermediate phase status stabilizes as active.

To measure corrosion rate at surfaces subjected to partial cathodic protection the sensor setup and the measuring methods must be adjusted. An example of such adjustments and the results from 10 years field testing is presented in (Møller et al. 2018).

Earlier corrosion systems were monitored by "snapshot" measurements, i.e., measurements with typical intervals between 1 and 5 years, but the long-term results (Sørensen et al. 2013) and (Møller et al. 2018) have shown that the results are significantly influenced by seasonal changes and fluctuations of corrosion status during the intermediate state between permanent active and permanent passive status. By a more "continuous" monitoring, e.g., measurement intervals between 1 hour and 1 week, interpretation of the results could be significantly more precise and reliable.

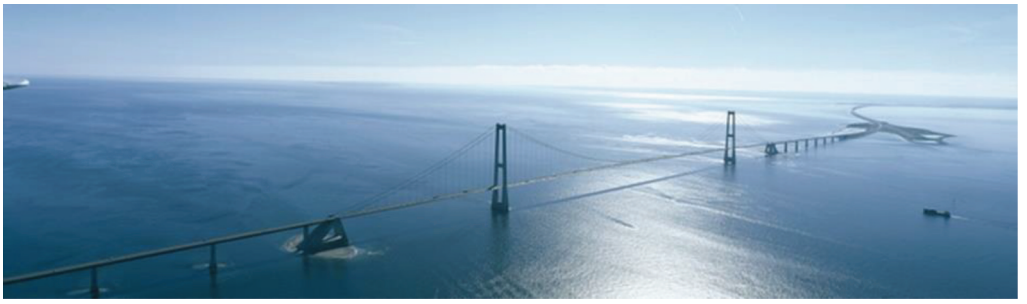

Figure 1. Great Belt Link, High bridge (front) and Low bridge (back).

2 CORROSION SENSORS AT THE GREAT BELT LINK

The Great Belt Link, see Figure 1, is 17 km long and consists of 7 km High bridge (road), 7 km Low bridge (road and rail) and an 8 km rail tunnel. At the 2 bridges a total of 222 corrosion sensors are installed and 224 sensors are installed in the tunnel. This paper only describes the sensors in the High bridge where sensors are installed at levels between -1.2 m and +14 m. In the splash zone sensors are installed at levels 0, +1.2 and +2.5 m. Sensors in casting joints are installed in level +4 m and + 12 m.

The sensor layout and the initial test methods for the Great Belt Link sensors are according to (Raupach et al. 2002). Measurements were planned to be performed as "snapshot" measurement campaigns at all sensors every 1-5 years. The purpose of the sensors was to determine the time for reinforcement corrosion initiation.

3 GOVERNING CORROSION CONDITIONS AT THE GREAT BELT LINK

To improve the corrosion evaluation by sensors the governing factors of corrosion development at the piers were inspected by traditional inspection methods. The main results were:

- The structures below water are corrosion protected by galvanic anodes to prevent corrosion in cracks formed during fabrication of the caissons. Surface based measurements showed that parts below level 0 m are fully protected by the water anodes and the parts just above level 0 m are partly protected. However above +2.5 m protection is low.
- Chloride measurements indicate that corrosion initiation is highly dependent of the distance to the water level, i.e., 100 years at water level but > 500 years 5 m above water level, see Figure 2.
- Above +4 m concrete AC resistance is so high, that risk of macro-cell corrosion is low. In the splash zone AC resistance is much lower and risk of macro-cell corrosion is thereby significantly increased.

The Great Belt Link is designed for a service life of 100 years but the possibility for an extension to 200 years is highly prioritized.

4 EARLIER RESULTS FROM CORROSION SENSORS AT THE GREAT BELT LINK

After conducting a few initial measurement campaigns, the results revealed that the electrochemical potential of the intended cathode (platinized titanium) was significantly reduced due to the high concrete moisture level in the lower splash zone and underwater zone. Consequently, the role of the intended cathode could shift to that of an anode in the context of the 5 sec. macro-cell current measurement method. As a result, it was concluded that the

interpretation of the original sensor measurements was unreliable for sensors located underwater and in the lower part of the splash zone.

Since chloride measurements clearly indicate that the highest corrosion risk occurs within the lower splash zone, the interpretation challenges in this area substantially diminish the value of the suggested sensor concept. Consequently, the 5 sec. macro-cell current measurements were replaced with LPR measurements, and a new measurement campaign was carried out. However, performing LPR measurements in the lower splash zone posed difficulties, leading to reduced reliability. Furthermore, LPR measurements do not account for the possible corrosion protection provided by the water anodes. The presence of such protection in the lower splash zone could significantly reduce corrosion, rendering a sensor system incapable of considering cathodic protection from water anodes less valuable.

Additionally, the relatively frequent manual measurements incurred non-negligible costs. Therefore, it was necessary to consider whether reducing the focus on sensor measurements in favor of traditional corrosion monitoring methods would be more practical.

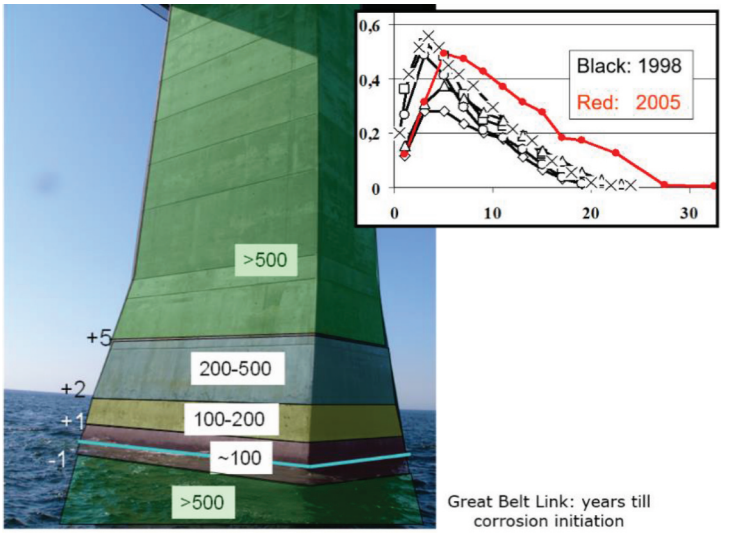

Figure 2. Time till reinforcement corrosion initiation (years) based on chloride ingress simulation.

5 OPTIMIZING THE RELEVANT SENSOR MEASURMENT METHODS

5.1 *General*

The traditional inspection showed that corrosion problems might arise within a 200-year service life in the zone between 0 meters and +4 meters. Outside this zone, the corrosion risk is very low. Therefore, corrosion measurements should be optimized for the zone between 0 and +4 meters. Experience has shown that repairing corrosion damage in concrete is very expensive. Consequently, it is highly important to prevent the development of corrosion damage that would necessitate concrete repairs. Cathodic protection is expected to be the most relevant prevention method, and the cost of cathodic protection depends significantly on where the anodes are being installed:

– Underwater installation costs are low, and maintenance costs are very low.
– Above approx. level +2 m installation costs and maintenance costs are moderate.
– Between 0 and +2 m installation cost are very high, and maintenance costs are also high.

The most relevant strategy for corrosion prevention in the zone between 0 and +4 m is to maximize protection from water anodes and only install anodes above +2 m when/if the prevention provided by water anodes is insufficient. To implement this strategy, sensor measurements should be able to address the following questions:

– When will corrosion be initiated in the zone between 0 and +4 m?
– What is the upper limit of corrosion protection from the water anodes?
– What is the upper limit of corrosion prevention from the water anodes?
– When must anodes above level +2 m be installed?

Within the zone between 0 and +4 m the traditional inspections indicate the following:

– Uniform corrosion can be relevant throughout the entire zone above water.
– Macro-cell corrosion can be relevant for æbetween 0 to +4 m but not likely above +4 m.
– Cathodic protection from water anodes is relevant for the zone up to +4 m but it is unlikely to be effective above this zone.

5.2 *Measurement of uniform corrosion rate*

At the Great Belt Link, the uniform corrosion rate is measured using the LPR method. This method is generally well accepted, and the requirements for testing equipment are relatively low. According to Nygaard et al. (2012), LPR is primarily measured through methods that induce a controlled current or methods that induce a controlled change in the steel potential. During earlier tests at the Great Belt Link, both types of LPR methods were tested to optimize their use in the splash zone. The main observations specific to the splash zone were as follows:

– Potential fluctuations are significant, during moderate to high winds (refer to Figure 4). However, even under relatively calm conditions, variations remain noticeable. To minimize the dependency on weather conditions, LPR measurements should be robust in the face of potential fluctuations.
– Polarization measured without compensation for Ir-drop can be up to 10 times higher than polarization measured with Ir-compensation. Therefore, precise compensation for Ir-drop is essential for accurate LPR results.

To achieve the highest robustness against fluctuating potentials, the simplest LPR method (galvanostatic) was selected. Signal strength was enhanced by allowing a high polarization voltage (20 mV) and a relatively long polarization time (60 seconds). Polarization and depolarization were recorded by an external logger with a scan rate of 3 Hz, enabling measurement of Ir-drop both when power was switched on and when it was switched off (see Figure 3). This approach aimed to test the reliability of the measurement.

The adjusted LPR equipment was tested. Originally the equipment was intended to be tested during both calm and wind weather conditions. Unfortunately, no tests were performed during any calm periods. As such the results of all tests are taken during windy weather conditions.

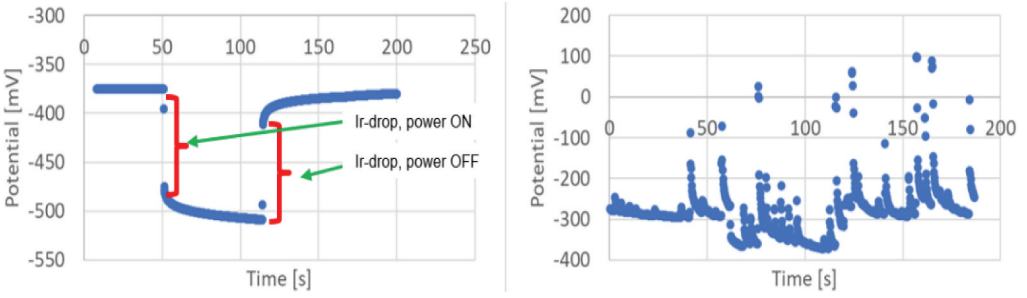

Figure 3. LPR-measurement level +1.2 m. Left: determination of Ir-drop. Right: sensor showing high noise.

The main results indicate that reliable LPR-measurements can be performed for levels above +1.2 m in most weather conditions, but for the critical sensors in levels 0 m and +1.2 m, measurements can only be performed in relatively calm weather.

5.3 *Testing measurement of cathodic protection methods*

According to the code for cathodic protection of concrete structures: ISO 12696:2022, Cathodic protection of steel in concrete (ISO 12696) the criteria for full cathodic protection are:

- The steel potential must be more negative than -884 mV (MnO_2/NaOH (0.5 mol/l))
- Depolarisation over a 24-hour period must be higher than 100 mV.

In addition, the protection can be evaluated from the design guidelines of ISO 12696:

- Cathodic prevention: current density should fall between 0.02 and 0.2 μA/cm^2.
- Cathodic protection: current density should fall between 0.2 and 2 μA/cm^2.

To establish cathodic protection each sensor anode is connected to the reinforcement by a separate cable.

The steel potential criterion can be tested directly by disconnecting the connection cable and measure the sensor anode potential with the reference electrode of the sensor. However, the calibration of these electrodes cannot be checked directly and therefore this measurement should be verified. Verification can be performed by handheld measurements (drop-cell) in the water.

To test the depolarisation criterion the connection cable is disconnected, and the anode depolarisation is measured over a 24-hour period.

The current density criterion is tested by measuring current flow through the connection cable.

5.4 *Macro-cell measurement*

Under real conditions, corrosion will start at a small area of the outer reinforcement and the other parts of the reinforcement will act as a cathode, possibly causing macro-cell corrosion. To simulate real corrosion initiation, the sensor anode should therefore be connected to the reinforcement. Through this connection both the influence from macro-cell corrosion and possible cathodic protection can be measured.

Each sensor anode is connected to the reinforcement through a separate cable, and by measuring the current flow in each cable the macro-cell corrosion can be measured. If current flow is negative, i.e., the anode is more negative than the reinforcement, the macro-cell corrosion rate can be calculated by Faradays Law showing that a current density of 1 μA/cm^2 corresponds to a corrosion rate of 11.6 μm/year. However, to determine the total corrosion rate, the local corrosion at the anode must also be considered. The local corrosion rate can be estimated from LPR measurements, but the sensor anode must be disconnected from the reinforcement and allowed to depolarize before LPR measurements are taken.

5.5 *Testing of cathodic protection and macro-cell measurement*

The most important outer anodes were connected to the reinforcement by separate cables. For one month, the current flow through these cables was monitored. Afterwards the anodes were disconnected and LPR and depolarisation was measured. Through this arrangement either the cathodic protection or the macro-cell corrosion is measured. If current flow is positive, cathodic protection current density is measured, and if current flow is negative, macro-cell corrosion is measured. Results are shown in Table 1.

Table 2. Main results from LPR-and macro-cell current testing.

Level/ orientation	Potential vs.		LPR, un-connected	Macro-cell corr.	CP current	1 h depo-larization.
	ERE10	Reinfor.				
	mV	mV	µm/year	µm/year	µA/cm^2	mV
+4 m/S	-350	-150	5	2 - 3		-84
+2.5 m/S	-180	-125	5	2 - 5		-55
+2.5 m/W	-100	+85	1-2	0 - 1	+0.05	+50

6 DISCUSSION

6.1 *Upper level of protective effect from anodes in water*

The sensor anodes at level +1.2 m W and +2.5 W were most likely in a passive state before the cathodic protection from the water anodes was established (green in Table 1) because anode potential is 100-200 mV higher than reinforcement potential. After connection, macro-cell corrosion was low <1-2 µm/year and 1 hour depolarisation was 40-50 mV, see Figure 4. Ramboll has compared depolarisation after 1 hour and 24 hours on other structures and it showed the following: At level +1 m 24- hour depolarisation was 3 times higher than 1-hour depolarisation. At level +3 m the 24-hour depolarisation was approx. 2 times higher than 1-hour depolarisation. It is therefore likely that the measured protection of the passive anodes fulfils the ISO 12696 100 mV criterion for full cathodic protection.

However, for the anodes showing signs of corrosion initiation (red in Table 1), before connection to the water anodes, the depolarisation is negative. This indicates macro-cell corrosion and no cathodic protection. This means that the reinforcement will not be protected, but instead connection to the reinforcement will seriously increase corrosion.

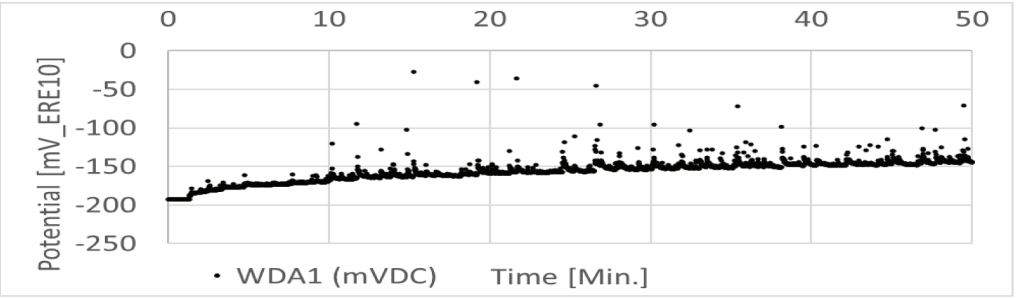

Figure 4. Level +2.5m W. 50 minutes depolarization. Depolarization is not finalized.

The measurements thereby indicate that the protection from the anodes in water can have a significant preventive effect up to level +2.5 m but cannot stop ongoing corrosion at level ≥+1.2m.

6.2 *Protection in and close to water*

The potentials of the 2 anodes at level -1.2 m and anode *0 m/W* at level 0 m fulfil requirements for full cathodic protection and according to ISO 12696 their corrosion rate is therefore negligible. However, the potential of the anode *0 m/S* at level 0 m does not fulfil the criterion, but the magnitude, development, and the depolarisation of the macro-cell current of this anode is very similar to the macro-cell current of the other 3 anodes, see Figure 5. For all 4 anodes current is high initially but is highly reduced after 1-2 days and reduces further to 0.01-0.04 μA/m^2. This very low current changes the natural corrosion potential of the anodes by 66 and 360 mV, which indicate that the cathode reaction (oxygen reaction) is highly restricted by poor oxygen access. The poor oxygen access is also responsible for the very low depolarisation rate of 2-3 mV/hour.

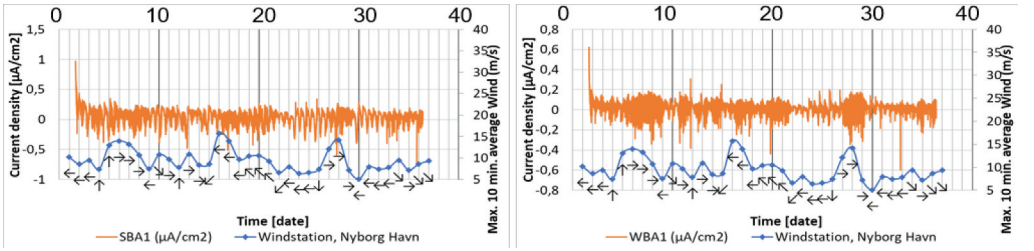

Figure 5. Macro-cell current. Left, level 0 S. Right Level 0 W. Same current size and development.

All 4 anodes in and close to water exhibits the same overall polarisation and depolarisation development and therefore all these anodes will most likely have the same negligible corrosion rate.

6.3 *Influence from macro-cell corrosion*

For actively corroding anodes at level +2.5 and +4 m (red in Table 1) a moderate uniform corrosion and a moderate macro-cell corrosion rate is measured after these anodes are connected to the water anodes. At the actively corroding anode at level +1.2 m, much higher corrosion rates of both uniform and macro-cell corrosion is measured.

The uncertainty of the measured LPR corrosion rate is expected to be quite high at +1.2 m and upwards, but for level 0 and below the uncertainty is expected to be extreme. For level 0 and below corrosion rates are most likely lower than 2 μm/year, but rates >50 μm/year are measured.

The macro-cell corrosion can be measured accurately. However, for the connected sensor anodes, the rate might be realistic for reinforcement corrosion, because anode/cathode ratio for the sensor anodes is lower than for the reinforcement. The measured influence from macro-cell corrosion is therefore expected to be overestimated. However, even if accounting for this incorrect anode/cathode ratio, the macro-cell corrosion at level +1.2m is expected to be very high.

6.4 *Intermitted protection and long-term protection development from water anodes*

In Figure 6 it is clearly seen that the protective effect from the water anodes is highly increased during high winds. The measurements indicate that high winds increase the upper limit of significant protection of actively corroding anodes from less than +1.2 m in calm weather to more than +2.5 m in high winds. To determine the accumulated benefit from the water anodes

it is therefore important to understand the effect of intermitted protection. ISO 12696 mentions this but it is not quantified. The depolarisation measurements indicate that intermitted protection can have a high effect for preventive protection, but the results are insufficient to draw solid conclusions.

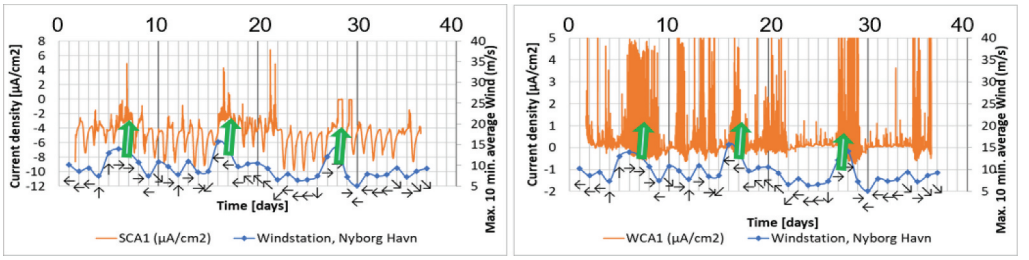

Figure 6. Relation between high wind (green arrows) and protective current from the water anodes. Left +1.2m S, actively corroding anode (macro-cell current reduced by wind). Right +1.2m W, passive anode (cathodic protection current increased by wind).

Regarding the long-term effects of establishing cathodic protection, the electric field caused by the protective current will generally slow chloride migration towards the reinforcement, and thereby increase time until the critical chloride concentration is developed at the steel surface and thereby delay corrosion initiation. Furthermore, cathodic protection reduces the aggressivity of the concrete at the steel surface by forming protective hydroxides and by removing aggressive chloride ions. Corrosion is expected to initiate when a given level of the $[Cl^-]/[OH^-]$ ratio is exceeded. The production of OH^- and the reduction of Cl^- by the cathodic protection thereby increases the critical chloride concentration. Corrosion initiation is thereby delayed because chloride migration is reduced, and a higher concentration must be established before corrosion starts. It is well known that the protective effect of cathodic protection will improve over time and the effect of the water anodes measured after just one month protection will most likely be increased significantly over the years.

7 SUGGESTED MEASUREMENT PROCEDURE FOR SENSORS IN THE SPLASH ZONE

Based on these results, the following measurement procedure is suggested:

- Base situation: all anodes are connected to the reinforcement and macro-cell current is monitored.
- At regular intervals each anode is disconnected, and 1 h depolarisation measured.
- After depolarisation LPR is measured whereafter anodes are reconnected to reinforcement

Due to very fluctuating conditions in the splash zone frequent logging is necessary for satisfactory monitoring of the conditions. For sensors >+4 m or <0 m frequent logging is not needed. To explore the possibilities of protecting the splash zone without anodes in the problematic zone 0 to +2 m it might be necessary to perform test installation of anodes just above +2 m and to test the effect of maximizing the protection from the water anodes, e.g., by more anodes.

8 CONCLUSION

The use of corrosion sensors for concrete bridges was analysed and concluded that the original test methods were unable to give a full picture of the corrosion in the splash zone. This is problematic since this zone mostly is governing for the condition of the bridges. Analysis

showed that the corrosion conditions in the splash zone are very complex and the usual evaluation from simple chloride ingress measurement are insufficient. Furthermore, it was found that installation of sacrificial water anodes could provide good corrosion prevention. The use of corrosion sensors was therefore optimized for the use in connection with water anodes.

The measurements indicated that macro-cell corrosion between outer- and inner reinforcement can accelerate corrosion highly. Measurements indicated that water anodes could prevent corrosion up to level +2.5 m, but that they might not stop ongoing corrosion even at level +1.2 m. This indicates the value of timely installation of water anodes. However, measurements showed that the corrosion conditions in the splash zone fluctuates highly, mainly from the sea waves, and to obtain a realistic picture of the corrosion conditions, continuous monitoring is necessary. Furthermore, the measurements indicate that corrosion might be highly reduced by poor oxygen access in the zone just above the water line.

For the concrete structures of the Great Belt Link, it is concluded that the main corrosion problem for obtaining 200-year service life is to prevent corrosion development without installing anodes in the zone 0-+2 m. The optimized use of the sensors can provide valuable information for designing this corrosion prevention. However, the full effect of these preventive measure is expected to improve over a long time and the monitoring period must therefore be long. Furthermore, the effect of the preventive measures fluctuates highly by the weather conditions and therefore detailed continuous monitoring is necessary. However, even with such detailed monitoring evaluation is difficult because the usual design models are insufficient for the fluctuating conditions in the splash zone. However, the monitoring can improve these models.

Digital technologies for bridge damage detection: Drones and AI for remote inspections

D. Buggiani, M. Malavisi & A. Baldacci
Movyon s.p.a, Roma, Italy

ABSTRACT: Transportation infrastructure have a considerable impact on the economic, social and political growth of nowadays society. In particular, highway bridges, due to their inherent vulnerability, are affected by aging and degradation processes over time, which lead to a loss of the expected performances. Periodic inspection is therefore essential to ensure their safety and serviceability. In common practice, defects assessment is performed through visual inspections carried out by engineers that come close to the bridges to perform the inspection. However, these activities are laborious, require huge cost and time and have significant safety implications. Moreover, there might be a wide disparity in the quality of visual inspections depending on the experience, knowledge, and competence of inspectors. To cope with these issues, the use of drones, can allow performing visual inspections, maximizing damage identification quality and minimizing costs as well as user safety. This work illustrates an innovative and powerful methodology to perform completely remote visual inspections using drones. In particular, a tool to perform remote inspections using the digital twin of a bridge is presented, combining state-of-the art 3D reconstruction methods with AI technologies for defects detection and high-resolution 3D rendering. The tool empowers inspectors with a Web application which improves and speeds up the process of defects detection, verification and tracking through time. We demonstrate significant improvements upon precision and recall of defects detection with respect to on-site inspections even in the most challenging cases. Significant experience from different Italian bridges is shown, confirming the opportunities and challenges of performing remote inspections applying the developed methodology.

1 INTRODUCTION

In 2020, the Guidelines for risk classification and management, safety assessment and monitoring of bridges have been issued in Italy as regulatory instrument for existing structures (MIT, 2022; Junwon Seoa, 2018). According to these guidelines and related operating instructions, every bridge must be subjected to visual inspections performed at regular intervals ranging from a minimum of 3 months to a maximum of 2 years, depending on the risk level of the bridge. Traditional inspections require experienced engineers to physically go on site and visually analyze all components of a bridge, in order to identify any defects or deterioration phenomenon and report it to the infrastructure manager. However, this entails strong impacts in terms of costs and time as well as social consequences on the highway operation caused by lane or roadway closures. Moreover, these activities involve considerable risks for safety of workers as well as an inaccurate, non-measurable and non-repeatable detection of defects, especially in hard to reach locations or parts of complex bridges, with inadequate lighting and conditions.

In recent years, many studies (M. Mandirola, 2022), (F. Giacobbe, 2018), (In-Ho Kim, 2022), (Jin Fan, 2019) have focused on the possibility of using Unmanned Aircraft System (UAS, according to the definitions proposed in the current European Union Regulations EU 2019/945 (EU, 2019)) commonly known as drones, equipped with different cameras and

DOI: 10.1201/9781003483755-375

sensor technologies, as an efficient and cost-effective support, or in some cases an alternative, for visual inspection activities, being able to reduce the impacts on traffic, costs, times and operators' safety in many inspection scenarios. Furthermore, drones have some advantages over conventional inspection practices regarding the inspection's quality, allowing quantifiable, measurable and repeatable defects identification over time (Junwon Seoa, 2018).

However, if, on the one hand, the use of drones appears to be a promising alternative for carrying out remote inspections on bridges in a safer and more efficient way, on the other hand the amount of data collected by the drone needs to be appropriately managed and made available to the inspector for carrying out the inspection as he would do on site. Indeed, UAS collect a massive amount of data during a flight, that require to be stored, postprocessed, analyzed and elaborated to be effectively used by structural engineers. (FHWA, 2021) underlined how appropriately manage data collected by drones can be one of the most challenging aspects of using this inspection methodology.

This paper describes a comprehensive practice-oriented approach and related platform, named ARGO 3D, for drones-based inspection. ARGO 3D is part of the larger ARGO asset management platform, developed by Movyon and Autostrade per l'Italia companies, for assisting highway and bridge managers in their choice of optimum improvements to the bridge network that are consistent with the national regulations, long-term objectives, and budgetary constraints.

The starting point for ARGO 3D platform is the standardization and control of all phases of bridges inspection process and data and, at the same time, the development of all the tools needed to use data collected during flights. Indeed, many research study were conducted regarding drone inspections, but there are still limitation in the standardization of the process, in the easy and effective use of data and in the availability of technologies able of covering the end-to-end remote inspection process. The developed platform solved these challenge problems by automating and integrating the entire bridge inspection procedure in a single easy to use inspection tool, perfectly aligned with Italian regulations.

The main contribution of the work is, thus, to propose drones-based inspection methodology and describe the innovative technological platform ARGO 3D, emphasizing how it is able to optimize the entire process, starting from inspection mission planning to data acquisition, processing and delivery, providing inspectors with all the tools needed to use data collected during flights and carry out bridge inspection in a much simpler and faster way than on the field.

2 BRIDGE INSPECTION USING DRONES: METHODOLOGY

This paper illustrates a methodology aimed at covering the whole end-to-end remote inspection process. The methodology has been fully implemented in the ARGO 3D platform. The term "inspection process" underlines the fact that there are several aspects that must be taken into account during bridge inspections, some related to field operations, other connected to some technical pre-process (e.g. digital twin creation or AI algorithms) and, finally, some related to the interaction with the platform users with the role "Inspector".

Before describing the proposed approach, some important pre-requirements that need to be considered before and during the data collection and necessary to obtain a suitably reconstructed 3D model are illustrated:

- a correct GSD (ground sampling distance), not too big if the focus is to be able to see same narrow defects (f.i. cracks), not too small otherwise the amount of data cannot be managed.
- a certain overlapping among pictures during the image collection, that allow to correctly reconstruct the 3D model with the less possible human interaction.
- a correct GPS positioning of the images.
- some GCP (ground control points) to be able to determine the correct roto-translation, scale and georeferenced 3D model.
- as much surface of the infrastructure as possible must be covered with pictures, since every not covered part cannot be reconstructed and, hence, cannot be represented in the digital twin.

Once the flights technical requirements have been defined, the proposed methodology includes, for each bridge to be inspected:

i. **Data collection** through a drone flight around the bridge, according to the standards preliminarily define. Collected data must be appropriately managed, with a process that ensures that all the information has the correct quality and completeness, and that the whole data chain is signed and not repudiable.
ii. **3D reconstruction of the bridge**, i.e. the digital twin, to be used to carry out remote inspection. A digital twin is a 3D virtual model of a bridge, obtained using photogrammetric techniques or LiDAR, that can be used to view structures from different perspectives and angles, as being on the structure itself.
iii. **Damage identification through AI algorithms**, where deep learning-based data analytics and modelling are applied for processing and analyzing drones images, pre-identifying damages on the structure.
iv. **Inspection planning and assignment** on ARGO 3D platform, so that the inspector in charge, the inspection date and all the information related to the inspection are univocally traced inside the platform.
v. **Remote inspection execution** by the inspector and in particular: (a) the inspector accesses ARGO 3D platform and is able to view the digital model of the bridge and the simplified 3D model side by side, with the defects identified by the AI algorithms and those from previous inspections already highlighted on the 3D model; (b) the inspector selects the bridge component to be inspected on the 3D simplified model; (c) using "drawing" tools, the inspector can trace a defect (or select one identified by AI algorithms) and select its type from a drop-down menu, in accordance with the list of defects provided by the Italian guidelines; (d) the identified defect is automatically associated with the selected component; (e) the system automatically sends an image of the defect to the central system to be stored; (f) when all defects have been identified, the inspector can close the inspection and all defects are stored in the platform.
vi. **Automatic inspection report production**: once the inspection is completed, the system produces a report that assesses the state of the infrastructure, in a format compliant with the current Italian Guidelines, digitally signed by the inspector.

3 ARGO 3D - BASED INSPECTIONS

3.1 *Asset registry and standard visual inspections*

Standard bridge visual inspections can be performed using ARGO platform, the extended technological platform for managing and monitoring infrastructure life cycle.

The platform contains the digital inventory of all the bridges of Autostrade per l'Italia network, which are decomposed in smaller components (beams, piers, abutments,..) and stored in an asset management system, following a four levels hierarchy that allows to have a unique and fully replicable way to store all the bridge information (Figure 1). Using the bridge registry data, ARGO can automatically build simplified 3D models, following the BIM format, used to have a visual representation of the bridge to, on the one hand, verify the correctness of all the geometric data stored in the platform and, on the other hand, "guide" the inspector during the inspection on site.

ARGO visual inspection tool allows to carry out on-site inspection activities with the support of a platform that:

- allows to plan the inspections, assign and execute them in a traceable manner.
- provides inspectors with a mobile app, that help the human to be sure to fulfill all the checks that are recommended by Italian guidelines and by the company in charge of the infrastructure. The mobile app, in fact, through the visualization of the simplified 3D model of the bridge, helps users to be sure to inspect all the components and report any defects found on the structure.

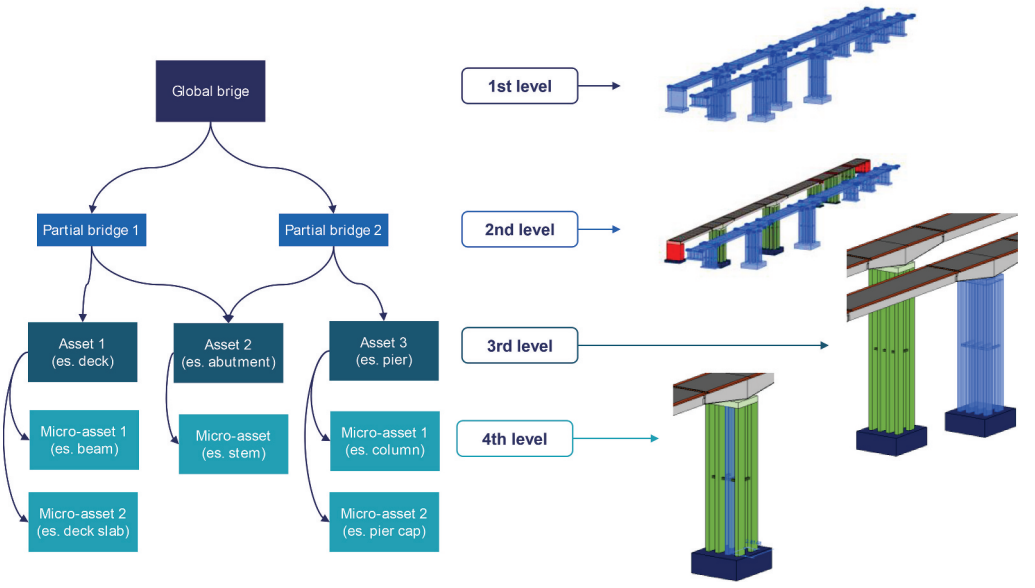

Figure 1. ARGO four-level hierarchy for the simplified 3D models.

- allows comparing over time the state of a defect, having easily available the information of the previous state of the same defect found during previous inspections.
- forces the user to upload images of all detected defects, in order to have a visual traceability of the state of the structure over time.

3.2 *Remote inspections tool*

Together with the tool supporting ordinary inspections, a part of the ARGO platform, called ARGO 3D, is specifically dedicated to remote inspections. More in detail, the platform allows to carry out inspections completely remotely, making available to the inspector all the tools that allow carrying out the activity exactly as if he were in the field but being comfortably in his office.

Indeed, the user, if a remote inspection has been assigned to him and after login in the platform, will see all the workorders whose he is in charge of, and, if the task is related to an inspection that can be performed remotely, he will access the web application "ARGO 3D".

As described before, there are some pre-requirements that must be covered in order to perform a remote inspection:

- All the pictures of the bridge must have been already collected during a drone flight.
- The digital twin of the bridge must already be reconstructed from the images (and eventually from laserscanner).
- AI inference must have been already executed over all the images that has been used for the 3D reconstruction.

Given that the requirements are fulfilled, when the user access "ARGO 3D", the tool allows to view the digital twin of the bridge, giving the inspector the possibility to rotate it, translate it and increase/decrease the zoom to literally "navigate" it; this first basic functionality actually enables the user to do the same thing he usually does during a visual inspection: look at the bridge.

The digital twin of the bridge can be viewed from any PC equipped with an Internet browser, without the need for dedicated workstations with special hardware features (e.g. very powerful GPUs). This is possible because ARGO 3D is a web application that exploits the principle of multiresolution, in order to progressively download the details of the infrastructure

required for the inspection, as you zoom in or out. In particular, every time the user zooms in to see a more detailed view of a component of the bridge, a set of more detailed textures and geometry features are download and shown into the web application. On the contrary, if the 3D model is viewed in a mono-resolution way, the web application should download the whole set of data (both for geometry and texture), that must match a strict tradeoff between something that is "detailed enough" to perform an inspection and something that can be downloaded and viewed in a browser without a too high memory consumption. This tradeoff, as can be easily imagined, can lead to a unfeasible configuration if the bridge is too big.

In addition to the mere visualization of the structure, since the purpose of this tool is to carry out visual inspections, it is possible to exploit the potential of the 3D model to identify defects on the bridge and draw the area of the detected defect directly on the surface of the solid. Once the presence of a defect has been detected, in fact, it is possible to locate it precisely using a drawing tool that allows to draw a polygon on the 3D geometry, identifying the area where the defect is located. This area can be measured with an accuracy equal to that of the 3D reconstruction.

Figure 2. Digital twin of a bridge.

Moreover, ARGO 3D contains the list of all the defects foreseen by the Italian Guidelines; this means that, once a defect has been identified and a polygon has been traced, the inspector can select the type of identified detect from a drop down list and perform a defect-type association, which is automatically stored in a specific database for subsequent analysis.

As is done for traditional inspections using ARGO mobile tablet application, each defect must be associated with a component of the infrastructure. To do this, the inspector can use

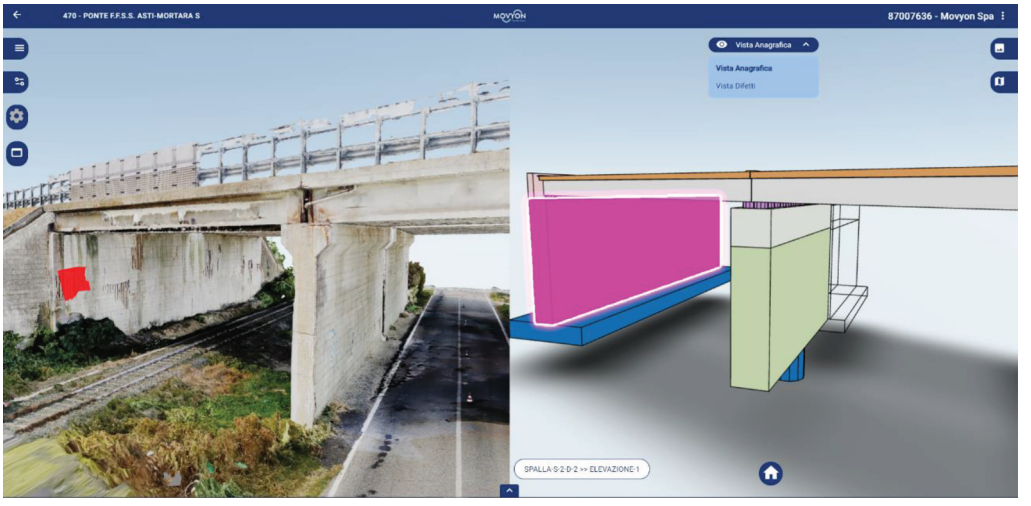

Figure 3. Digital twin of bridge and simplified 3D model, used for remote inspections.

the simplified 3D model of the bridge (the one automatically built from the digital inventory), which can be displayed in a side-by-side window, or, if available, use the digital twin previously segmented into components. In particular, in the last cited case, the application allows to use all the power of the simplified 3D model (strictly related to the digital inventory), in a seamless way, since its information are embedded in the digital twin.

3.3 *Automatic damage identification using AI*

Once the bridge surface images along a predetermined trajectory are collected, artificial intelligence algorithms can be used to automatically identify damages on the structure. Indeed, inside the ARGO 3D platform, the reconstruction of the digital twin is flanked by another fundamental process, which can be enabled before the inspector's intervention, i.e. the automatic detection of defects through the use of Artificial Intelligence (AI) techniques.

The use of modern deep convolutional networks for the semantic segmentation of images or the so-called 'object detection' (i.e. the identification of elements of interest by means of "bounding boxes") makes it possible to suggest, when the remote inspection application is opened, a series of defects that must then be confirmed or rejected by the human operator.

The automatic defect identification software, developed and integrated into ARGO 3D, is now able to recognize five classes of defects on concrete: cracks, exposed reinforcement, crawl spaces, efflorescence and moisture stains (work is underway to increase this number).Approximately 15,000 images (approximately 30% were synthetically generated) were used to train and then test the artificial intelligence algorithms, which are currently able to identify defects with very high precision.

Figure 4. Output of AI algorithms on the 3D model (left) and original image (right).

The usage of these algorithms, before the inspector activity begins, is intended to help him in his decision-making by showing not a 'blank' digital twin, but a digital twin with some suggestions, thus mimicking what is already being done in the medical field, where the use of AI as decision support for doctors in the interpretation of X-rays, CT scans, etc. is yielding excellent results (Scott J. Adams, 2021). This means that, when the inspector accesses the platform, what he sees is not the simple digital twin of the structure, reconstructed starting from the images collected by the drone, but a reconstruction of the bridge on which the main defects have already been pre-identified using AI, which he can confirm or modify. This represents a great time saving for the inspector and significantly reduces the human risk of "forgetting" some defect.

In addition, in order to speed up and optimize the process, the synergy between the collected pictures and the digital twin has been exploited, providing a dual and simultaneous AI-identified defects visualization on photos and bridge reconstruction model (Figure 4). In particular, making use of the knowledge about the position of the cameras and the projection of the images on the digital twin, defects suggested by the AI will be visible both on the photos and directly on the digital twin, providing a precise location of the defect in three dimensions and allowing inspector to perform geometric measurements. In this way, it will be immediate for the inspector to visualize what has been detected by the AI, correct it or add information.

This ability to precisely locate defects in three dimensions allows also the observation and analysis of defects history and the comparison among different surveys carried out over months or years, resulting in a powerful tool for predictive/forecasting analyses, to be used for optimizing maintenance and intervention planning.

3.4 *Towards merging ordinary and remote inspections*

In the transition from traditional on-site inspections to remote ones, carried out using ARGO 3D application, or in a possible alternation between the two types of inspections on a same bridge, it is essential to be able to use the information and data coming from both sources in a completely integrated way.

To achieve this goal, an algorithm has been implemented within ARGO 3D platform that, by leveraging on the tablet's GPS data and images characteristics, manages to 'record' the tablet's shooting position in relation to the digital twin model. The use of computer vision and AI algorithms then makes it possible to search for the same defect within the tablet photo and on the digital twin model, effectively linking the photos taken by the tablet with the digital twin.

The advantages of this approach are twofold: on the one hand, all the information saved during traditional inspections are recovered, and on the other hand, the defects reprojected on the 3D model are correctly labelled (because they are derived from human validation on the tablet). In this way, it is possible to reuse as much as possible all the information collected during classic inspections to strengthen and enrich what is shown in the 3D model.

3.5 *Data management*

As mentioned in the previous paragraphs, one of the main challenges associated with remote inspections is the organized management of a large amount of unstructured data collected during drones-based surveys, such as images, 3D models and point clouds.

In order to be able to manage this type and amount of data, ARGO 3D makes available to the user a graphical interface, that stands in front a back-office module, through which it is possible to upload data associated with an infrastructure, and, for those who have the appropriate role, to verify and validate this data.

The back-office module also includes a number of automatic checks that make certain validations of the uploaded data, e.g. checks on image quality, presence of location information (GPS) and checks that all raw files have been uploaded correctly.

Once the deliverables have been fully validated, the Digital Twin becomes usable in ARGO3D.

Another need that is covered by the back-office module is to be able to give the inspector completing a remote inspection reasonable certainty that the model he is operating on is actually reconstructed from images from a certain date.

To give this type of guarantee to the inspector, the module allows the person uploading the images and data, relating to a certain survey made on a certain date, to sign these data, thus making the entire chain from data collection to remote inspection traceable and non-repudiable.

3.6 *Conclusions*

This paper describes ARGO 3D platform, part of the larger ARGO platform, developed by Movyon and Autostrade per l'Italia, which aims to enable remote inspections of bridges.

The platform synthesizes the experience of digitization via mobile apps of the entire inspection process together with the new technologies of 3D models and digital twin, giving birth to a remote inspection tool that contains tools that enable: (a) data management and traceability (back office module), (b) the execution of inspections without the need for ad hoc workstations (web application with multi-resolution principles), (c) many capabilities to help the user in his decision making role (AI algorithms) and (d) the possibility to reuse all the information already available (recording tablet position with the 3D model).

Remote inspections performed with ARGO 3D are fully consistent with Italian Guidelines and, once finalized, are related to a detailed report signed by the inspector, and to a set of structured information (images, polygons that define defects and related metadata, etc) stored in the ARGO asset management platform.

Of course, many open points are still to be covered and investigated, and only a large-scale adoption of this tool, and consequently, of this approach, can confirm its effectiveness.

Service life strategies on hanger cables of the Great Belt Bridge

P. Holmstrøm, D. Lang, T. Friis & M.N. Svendsen
Rambøll Danmark A/S, Denmark

M.D. Havelykke
Sund&Bælt Holding A/S, Denmark

ABSTRACT: This paper will present the scenarios considered for replacement of hanger cables, including considerations from an operational perspective. In summary, the investments are made up front in terms of preparatory activities for future hanger replacements in case this is urgently required, as well as digital health monitoring and inspections enabling data-driven decisions on activities. For the case that a cable is lost (e.g., from a fire), urgent replacement would be desired. Preparatory activities include an engineered manual for handling forces and displacements of hanger replacements, detailing of bespoke equipment and sourcing of replacement hangers.

Global analyses to obtain hanger forces, girder deflections etc. are required in advance of hanger replacements, and thus these are made up front considering scenarios of partial or full hanger replacements with associated special traffic configurations.

A digital health monitoring system is used together with site inspections to give a longer warning for other replacement scenarios and enable data-driven decisions on mitigating actions to prolong the service life. After 25 years of service, the strategies for replacement have been re-assessed, taking into account the experience gained of the hangers in operation at this specific bridge through inspection, digital health monitoring and incidents on the bridge.

1 SERVICE LIFE IN GENERAL OF THE HANGER CABLES

1.1 *The Great Belt Bridge*

The Great Belt Bridge (Storebæltsbroen), inaugurated in 1998, is one of the largest suspension bridges in the world, with a main span of 1624m and hangers up to 177m in length. The suspension bridge is part of the 18km Storebælt Crossing which consist of the suspension bridge including approach viaducts, a twin box girder bridge and a twin bored railway tunnel. The structure is owned and operated by A/S Storebælt which is a subsidiary of Sund&Bælt Holding owned by the State of Denmark. A photo of the Great Belt Suspension Bridge is shown in Figure 1.

The hanger cables comprise of fully locked coil cables with HDPE sheathing and anchored in the ends by poured spelter cone type sockets. There are 176 hangers on the bridge in different lengths connecting the bridge deck girder to the main cables, and each hanger consists of two separate locked coil cable strands. In total 352 fully locked coil strands varying from 2m to 177m. The cable strands are installed in three different sizes (diameter/MBL) and with four different types of end socket configurations.

As it is assumed that replacement of hanger cables will be required at some point throughout the service life of the suspension bridge, the global structural integrity of the bridge is designed and prepared for replacement of the hangers, including sudden rupture of a single hanger from an accidental case. Any such replacement work will lead to traffic restrictions on the bridge, depending on the space required for the work site and structural safety of the bridge.

The top socket of the hanger strands is fixed to a cable clamp of the main cable, and the lower socket is placed inside the bridge girder and is accessible only from the interior of the girder. A further general description of the cable system can be found in Gimsing et al. (1998).

DOI: 10.1201/9781003483755-376

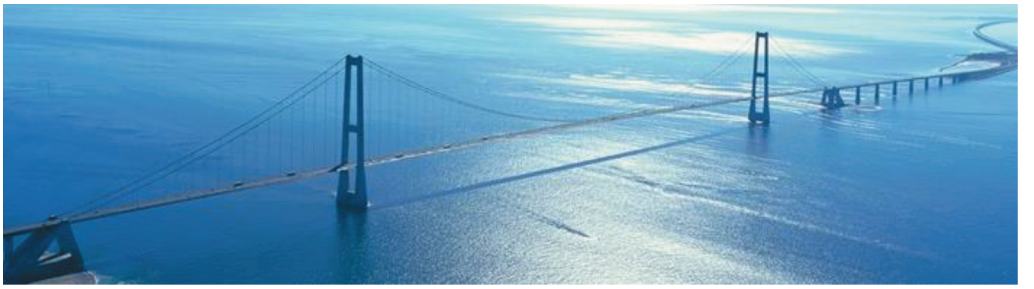

Figure 1. Photo of the suspension bridge of the Great Belt Crossing – also referred to as the East Bridge.

1.2 *Replacement scenarios*

Replacement of hangers would be required in case of fracture of the strand or damage to such an extent that the safety of the strand is compromised. For the Great Belt Bridge, the strategy for replacement depends on the root cause for replacement. Three different scenarios have been identified that would require replacement of one or more of the hangers depending on the type of damage on the cable. These three scenarios are listed in Table 1 and are described in more detail in the following. Some scenarios are likely to be more predictable than others.

Table 1. Replacement scenarios.

Root cause	Predictability	Expected no. of hangers to be replaced
I. Deterioration	Planned	All or most in same campaign
II. Fatigue	Semi-urgent	Selected 4 to 32
III. Accident	Urgent	One

I. *Deterioration of materials and corrosion*
Having a robust and well-proven design, the recurring inspections and investigations is expected to provide sufficient warning to secure the possibility of a well-planned replacement of the hangers. This general breakdown of material properties is considered to cover all hangers on the bridge equally, as the deterioration is assumed to be similar on all hangers, when a proper level of maintenance is kept. Thus, it is likely that all of the hangers are to be replaced in this scenario.

II. *Fatigue damage*
Fatigue damage of the strands is very difficult to detect until wire fractures occur, and given the expected location of wire fractures, these might even be difficult to detect using currently available none-destructive testing methods. Thus, this scenario might lead to urgent replacement of hangers in case of fatigue fracture. In order to mitigate this risk and predict the time for replacement, indirect monitoring of the fatigue damaged are installed as described in section 2. Replacement due to fatigue damage is likely to cover several hangers but not all – e.g. the ones longer than a certain length that are prone to heavy oscillations.

III. *Accidents on the bridge*
Accident scenarios are unpredictable by nature, and would cover fire incidents, explosions, collision from road, sea or air or other unpredictable types. It is assumed that these scenarios will lead to urgent replacement of a single hanger as these are expected to be local incidents.

This paper will not go into detail about deterioration of materials and corrosion as this is likely to be several years ahead still. The replacement work for this scenario will be a large campaign of replacing many hangers, that is assumed to be handled in due time in a well-planned schedule. The paper, thus, focuses on semi-urgent and urgent hanger replacement caused by fatigue and accidents, respectively.

2 RISK OF SEMI-URGENT REPLACEMENT AND SHMS

2.1 *The hanger monitoring*

Selected hangers undergo continuous monitoring using accelerometers to observe the oscillations of the cables, which have been identified to exhibit substantial oscillations intermittently Gjelstrup (2011). This monitoring initiative has been ongoing for approximately two decades. The current monitoring configuration involves accelerometer measurements in two horizontal directions on seven hangers situated around the western pylon. Specifically, all four hangers in position 2 from the pylon, along with hangers in positions 1, 3, and 4 to the southeast of the pylon, are subject to monitoring. These accelerometers are positioned 4.5 meters above the bridge deck and operate with a sampling frequency of 25Hz, which is feasible for cables on a bridge of this size, given the nature of vibrations relevant for analysis. A photo of a double stranded hanger with accelerometers installed above the damper is seen in Figure 2.

During 2023 and the beginning of 2024, the sensors within the hanger monitoring system are replaced, and additional sensors are introduced. As a general modification, the measurement height on the hangers is now adjusted to 10 meters above the bridge deck. In total, 10 hangers are monitored, and on one hanger, the setup is expanded to include 2 dual-axis accelerometers, 2 tri-axial accelerometers, and 5 dual-axis inclinometers. For more on the SHMS see Lollesgaard and Brøndum (2018) and Myrtue et al. (2021).

2.2 *Prediction of semi-urgent replacement (fatigue assessment)*

As previously outlined, a selected set of hangers is under constant surveillance, and the measurements are scrutinized with a focus on various aspects contributing to operational and maintenance considerations:

- *Surveillance and analysis of oscillation levels:*
  Utilized for planning, design, and evaluation of potential mitigation actions.
- *Estimation of fatigue lifetime:*
  Enables timely planning for potential replacement and assessment of the need for actions extending the lifetime.
- *Continuous monitoring of load distribution:*
  Provides insight into changes that could indicate damages, facilitating immediate detection and cost-effective measures. Enables surveillance of change in load distribution during replacement of hangers.
- *Surveillance of estimated hanger damping:*
  Continuous evaluation of performance of external dampers. Dampers with poor performance can be replaced to ensure longevity of the hangers.

The oscillations in the cables induce bending stresses and fretting wear at the ends, potentially leading to cable fatigue. Therefore, one of the primary motivations for hanger

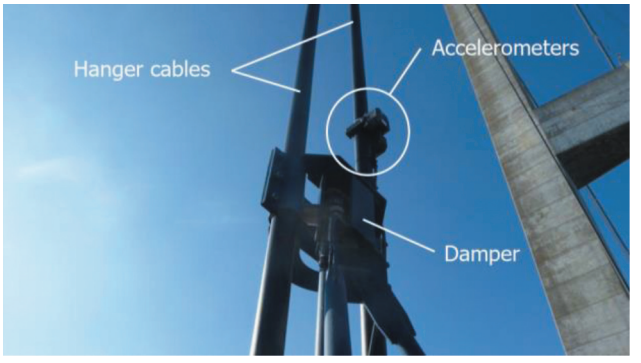

Figure 2. Photo of the double stranded hanger with accelerometers installed above the damper.

monitoring is to estimate fatigue damage resulting from these oscillations. The fatigue damage estimation involves several steps:

I. Virtual sensing to estimate stresses at critical positions.
II. Rainflow counting based on ASTM E1049-85 to determine stress ranges and count on an hourly basis.
III. Conversion of stress ranges and count into hourly damage values using an appropriate S-N curve and the Palmgren-Minor rule.
IV. Estimate of the fatigue lifetime based on the calculated fatigue damage.

Current estimates of the fatigue lifetime indicate a disappointingly low level. However, these calculations are considered conservative with an overestimation of stresses. In response, two actions have been initiated:

- Enhance of the measurement setup in spring 2023 to cover more hangers and increase sensor density on one hanger for a better understanding of vibration characteristics and thereby a reduction in conservatism in the fatigue damage estimation.
- Designing additional dampers for hangers in positions 3 and 4 from the pylons, complementing existing dampers installed in 2007 on the two longest hangers on each side of the pylons.

A pilot project has also been conducted to assess the feasibility of estimating the hanger tension forces from the acceleration measurements and thereby the load distribution between the hangers. The idea is to monitor the load distribution during replacement of hanger or immediate detection of potential damages large enough to cause elongation of a cable, which will cause a minor redistribution of the hanger forces. Potentially this can be detected immediately by the existing measurement setup and appropriate measures can be carried out in a timely and cost-effective manner.

The estimation of the hanger forces has been conducted by a continues estimation of the lower natural frequencies and mode shapes using automated operational modal analysis Friis et al. (2021), which have then been transformed into hanger forces by a model. In Figure 3, the tension force corrected for environmental and operational variations (EOV) (wind, temperature and traffic) is shown for one hanger for 2021 with moving average values and horizontal lines marking relative changes in tension force at 1%, 2%, and 3%. It is seen that the moving average of 7 days stay within the borders of a relative change of just 1% which indicate that there's potential to automatically detect damages that cause the load distribution to change 1% or more.

The hanger monitoring has already proven valuable for operational and maintenance purposes. It has illuminated vibration levels, identified potential future issues, and prompted timely and cost-effective actions to ensure current and future operational safety. Proactive

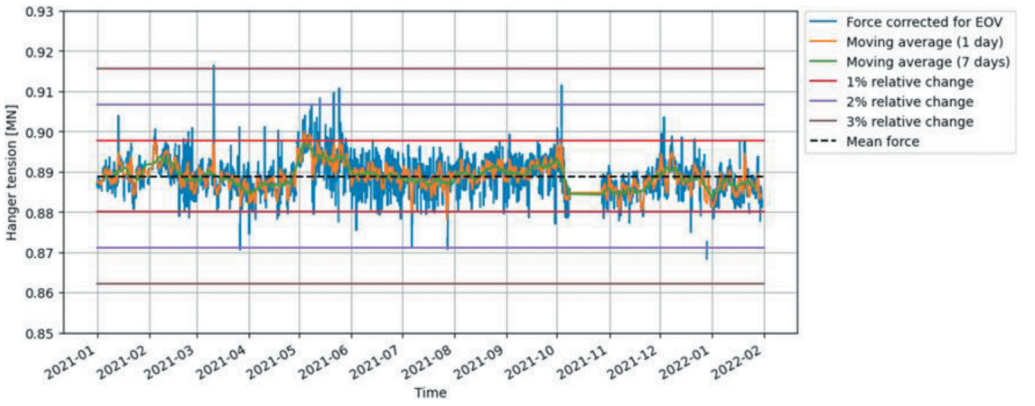

Figure 3. Tension force corrected for environmental and operational variations (EOV) for one hanger for 2021 with moving average values of 1 and 7 days and horizontal lines marking relative changes in tension force at 1%, 2%, and 3%.

Figure 4. Fire accident in 2020: (left) Truck on fire, (right) Undamaged hanger.

measures taken in the early stages of bridge life may contribute to extending its intended lifetime beyond the original design expectations. The reader is referred to Friis et al. (2023) for more on structural health monitoring of the Great Belt Suspension Bridge and the benefits for operation and maintenance.

3 RISK OF URGENT REPLACEMENT

In 2015, the general risk assessment of the bridge was revised using knowledge from the fire incidents on the bridge and other suspension bridges in Denmark. It was concluded that fire incidents are not as unlikely as assumed previously, and a general increased focus of fire incidents on major brides was included. Consequently, it was decided to install fire protection of the main cable during 2018/2019. Fire protection was not installed on the hanger cables, as the bridge is prepared for replacement of these.

In 2020, a near miss fire incident occurred at the hangers, when a truck fully loaded with bottles of cocktail liqueur caught fire. The truck was located close to one of the longer hanger cables, but luckily with a favourable wind direction. Hence no damage to the nearby hanger cables was observed. Photos from the incident can be seen in Figure 4.

After this near miss incident, it was decided to prepare an engineered technical manual for urgent replacement of hanger cables in order to be fully prepared for a similar case. One of the main challenges of urgent replacement is the lead time for sourcing a new hanger cable as these are bespoke at each location. Several concepts were investigated including having temporary hangers on stock, that can be adjusted in length and installed quickly until the permanent replacement hanger is available. But the result is to have a drum on stock of hanger replacement cable but with sockets installed at one end only and separate sockets ready for installation. If an accident occurs, the cable will have to be cut to correct length, the socket installed using resin socketing and installed permanently on the bridge. By this concept, bridge closure and traffic restrictions are kept to a minimum.

4 ENGINEERED MANUAL FOR URGENT REPLACEMENT OF A HANGER CABLE

In general, operation and maintenance of the Great Belt Bridge are handled using pre-defined technical instructions for the work that can be foreseen. These technical instructions cover various annual inspection works as well as replacement and repair of selected and critical members of the bridge. Several of these technical instructions were prepared when the bridge was built, and some are added or modified at later stages. After it has been acknowledged that urgent

replacement of the hangers might be required, as earlier mentioned, Sund&Bælt decided to prepare the technical instruction for replacement of hanger cables. This is made through a series of engineered manuals. To account for the many variations, a series of 5 manuals has been produced, each covering a range of the hangers such that the series account for all hangers.

The manuals can be viewed as a step-by-step guide to replace the hangers. The manuals describe which pieces of equipment is used at what times, what the expected loads and deformations are as well as how working areas are to be established on the bridge. All of this has been developed with a focus on minimal disruptions to the bridge users, as the bridge is critical infrastructure. The manuals therefore also include traffic limitations required for the different stages of the hanger replacement. The manuals are created with a reversibility principle, meaning that all steps in each procedure are fully reversible such that the replacement work can be terminated at any step, and the bridge reversed to its previous condition. This is an important safety principle in case unforeseen actions occur during the work.

4.1 *Global FE-model*

Replacement of any given hanger cable will impose a changed load distribution locally in the girder and in the nearby hangers, both for self-weight as well as for special load scenarios relevant for the temporary replacement situation. The quantification of force changes and deformations due to the various hanger replacement scenarios was performed using Ramboll's in-house FE-model of the bridge, developed in SOFiSTiK. The global FE-model is shown in Figure 5.

The model comprises a detailed, fully geometrical non-linear construction stage simulation, considering large displacements and geometric stiffness effects. The staged simulation produces an accurate calculation of main cable forces with large sag effects, as well as accurate hanger forces. This includes a special hanger force redistribution which was implemented as part of optimizations in the detailed design, essentially by transferring load from the (otherwise highly loaded) hangers next to the towers, to their adjacent hangers. The load transfer was achieved by making the hangers at positions 2 from the towers somewhat longer than the target geometry would otherwise prescribe, as well as making the hangers at positions 1 (adjacent to the towers) and positions 3 somewhat shorter. Similar adjustments were also made at the anchor blocks and all of these are represented in the model.

Influence-line analyses were an important part of the assessments. A control load, P = 100kN, moving longitudinally with steps = 10m along the bridge span was defined. The influence-line (i.l.) for the three different transverse positions shown in Figure 6a have been derived considering the situation of intact bridge: next to the south hangers, y = -13.5m (1), midway between the south hangers and the deck centreline, y = -6.75m (2), and next to the north

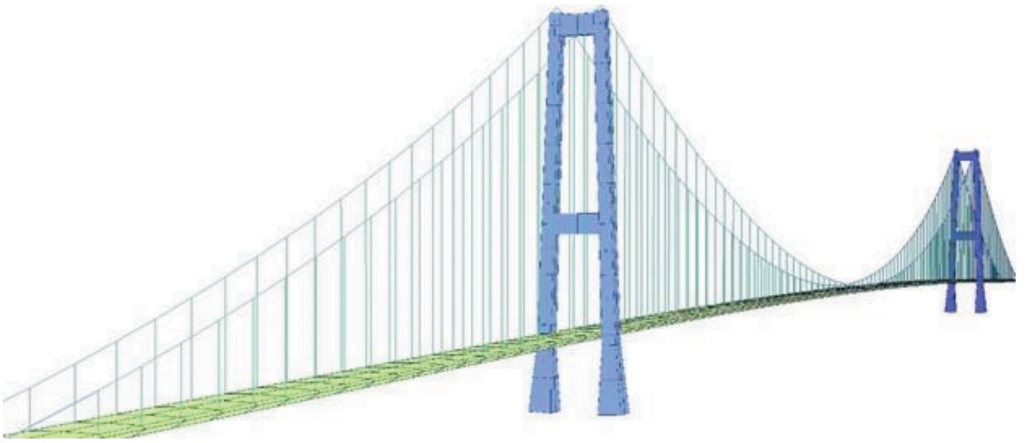

Figure 5. Ramboll's in-house FE-model of the Great Belt Suspension Bridge.

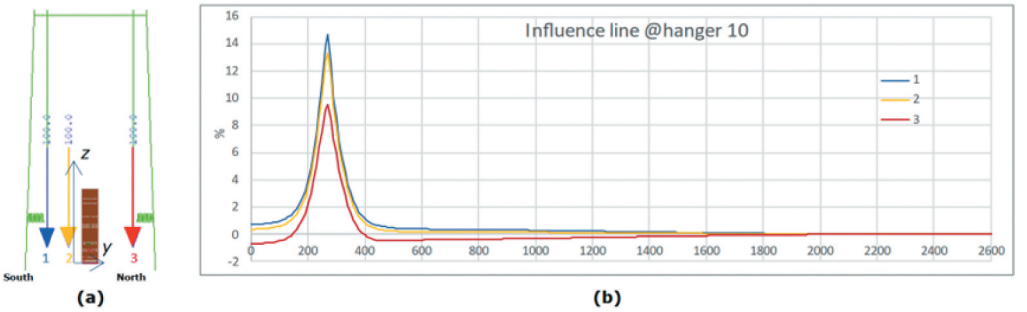

Figure 6. (a) Control loads in transverse direction. (b) Influence line of axial force in hanger no. 10.

hangers, y = 13.5m (3). The transverse distance between the hangers is 27m. It was concluded that the i.l.s are strongly affected by the transverse position of the loads, i.e. torsional effects are present. For example, Figure 6b shows the i.l. of the axial force in hanger no. 10, counting from the eastern anchor block.

A load located longitudinally between 0m to 180m is unfavourable for the force in hanger 10 if applied at position 1 or 2 counting from the pylons, whereas it is favourable in position 3. Position 1 and 2 produce similar i.l.s and position 2 was used for further analyses. Therefore, the traffic loads running on the north side of the deck will be defined on the i.l. for position 3, and the traffic loads running on the south side on the i.l. from position 2. For example, analysing hanger 10 south, it would take 15% of a load located at that hanger position and only 9% of a load located at the north side of the deck, as shown in Figure 6.

4.2 *Detailed design of equipment and replacement cables*

Replacing a hanger cable will be a challenging task which require meticulous planning and preparation. Even though the global structural integrity of the bridge is designed for replacement originally, the local structural effects and practical access issues must be considered too. In order to be prepared for an urgent replacement scenario, Sund&Bælt decided to invest in bespoke equipment designed to replace any hanger. Some of the main variations to consider in this design are:

- 3 different hanger diameters sizes (diameter/MBL)
- 4 different types of bottom sockets – 3 different principles to unload the hanger
- 4 different type of top sockets – 2 different principles of top anchorage
- Cable clamps varying in size and slope
- Hanger lengths in range of 2m to 177m
- Weight of hanger strands in range of 0.5 tonnes to 11 tonnes
- Hanger forces varying from 0.8MN to 2.9MN
- Varying deflection and movement when unloading

When one hanger is unloading it will shorten, the neighbouring hangers will elongate and the main cable will straighten. The sum of these 3 main contributions is the total extension which needs to be handled when unloading a hanger cable. The global FE-model of the bridge is used to quantify the extension and force to be handled at each location in order to design different types of unloading equipment.

As the hanger cables already are prepared for unloading from the girder interior, this concept is kept for the replacement scenarios. However, it was found that the total extension to be considered at some locations is larger than the free-space inside the girder, and consequently the unloading of the hangers has to be carried out by several jack strokes instead of one. The setups for unloading the hangers in both one and two strokes respectively are shown in Figure 7.

The equipment used for unloading the cable is also used for loading the replaced cable. The same applies for lowering/lifting the new cable. The bespoke equipment is procured and stored such that it is ready for use in case an urgent replacement is needed.

For the replacement work, the hangers are divided into categories of *short hangers* (<60m), which are readily accessible using a mobile crane, and *long hangers* (>60m) which are not accessible with a mobile crane or requires a mobile crane too large to fit on the bridge.

After the unloading of the hangers, the pin connecting the hangers to the main cable needs to be removed such the cables can be lowered onto the bridge deck and removed. For the short hangers a mobile crane can be used, while for the longer hangers a setup using strand jacks and a 'table' mounted on the cable clamps are used, refer Figure 7. The table, which is designed for the purpose, needs to accommodate the varying size and slopes of the cable clamps. Both short and long hangers are demounted using the same approach, where the hangers are lifted to unload the pin, and the pin is then removed and the hangers are lowered. The same approach is used for installation of the new cables, but in reverse.

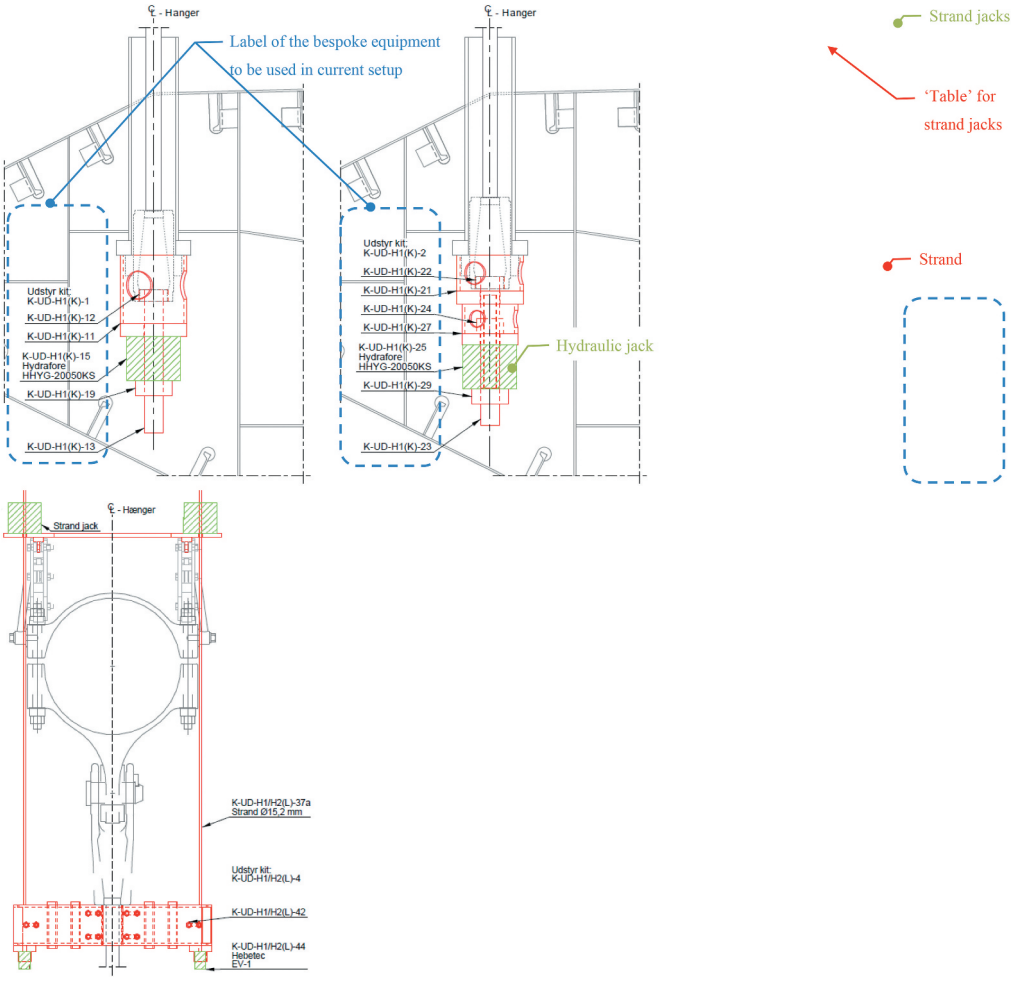

Figure 7. Typical setup for unloading hanger strands. (left) setup for short extension and (middle) setup for long extension. (right) Strand jacking from main cable.

5 CONCLUSIONS

SHMS on hanger cables can be used to get a better understanding of cable vibrations and these results may be used for estimation of remaining fatigue life. However, as it is an indirect method of determining the fatigue damage, uncertainties still remain. But it allows a downgrade of the predictability of fatigue fracture scenarios from urgent to semi-urgent when considering the service life strategy.

When preparing for replacement of hangers, knowledge of the magnitude of forces and displacements that shall be handled on site is crucial. The global FE-model is an important tool to obtain this.

Following accidental cases on the bridge, urgent replacement of hanger cables might be required, but these may typically have a long manufacturing lead time. To mitigate the time with traffic restrictions on the bridge, preparatory activities are being carried out in due time. These includes preparations of engineered manuals for the replacement work and sourcing of bespoke equipment and replacement hangers to keep on stock in case of an accident. One of the main issues is lead time required for a replacement hanger.

Data-driven maintenance of Bogibeel Bridge - large scale structural health monitoring

H. Gjelstrup, T. Bangsgaard & F. Houseini
Rambøll Denmark A/S, Copenhagen S, Denmark

ABSTRACT: The Bogibeel Bridge in India, spanning the Brahmaputra River, is a 4.94 km rail-cum-road bridge pivotal for Northeast India's infrastructure. Its design incorporates 41 spans with steel truss girders and a concrete slab. This paper focuses on the bridge's advanced Structural Health Monitoring (SHM) system, which employs around 920 sensors for continuous monitoring of key structural aspects like strain, temperature, vibration, and displacement. A critical feature of this SHM system is its integration with the bridge's asset management, allowing automated reporting and alarms based on data analysis for proactive maintenance. This innovative approach combines sensor-based data, cloud computing, and automated analytics to move maintenance from reactive to predictive, enhancing operational efficiency, safety, and cost-effectiveness. By early detection of structural issues, it ensures timely intervention, minimizing downtime. The adopted approach to the SHMS on the bridge, significantly improves safety, efficiency, and cost-effectiveness, demonstrating a pioneering model for smart infrastructure management.

1 BACKGROUND

The Bogibeel Bridge, India's longest rail-cum-road bridge, is not only a critical infrastructural asset spanning the Brahmaputra River in Assam but also a modern marvel of engineering for its blend of functionality and resilience. Completed in December 2018, this 4.94-kilometer bridge enhances Northeast India's transportation network and plays a vital role in national defense logistics due to its strategic location near the Assam-Arunachal Pradesh border.

The construction of the Bogibeel Bridge addresses strategic, economic, and social needs in Northeast India. It significantly improves connectivity within the region, reducing the distance between Dibrugarh and Guwahati by 55 km and linking key sections of the North-East Frontier Railway. This enhancement in connectivity boosts trade and economic activities while easing travel and congestion. Furthermore, the bridge's proximity to the Indo-China boundary in Arunachal Pradesh underscores its strategic military importance. The introduction of a state-of-the-art SHM system aligns with these strategic needs, ensuring the bridge's health and longevity through advanced monitoring and maintenance.

This paper examines the Bogibeel Bridge's innovative maintenance approach, focusing on its Structural Health Monitoring (SHM) system. This advanced system marks a paradigm shift in infrastructure maintenance, transitioning from reactive to proactive strategies by leveraging sensor technology and data analytics.

Traditionally, bridge maintenance relies on periodic inspections and manual assessments. Inspectors physically examine the structure for visible signs of wear, corrosion, or damage. This approach is often reactive, with repairs conducted in response to identified issues. While effective for detecting surface-level problems, it can miss internal or subtle structural weaknesses. Furthermore, manual inspections are labor-intensive and can lead to prolonged traffic disruptions. In contrast, the Structural Health Monitoring (SHM) system being employed on the Bogibeel Bridge offers continuous, real-time monitoring, allowing for proactive maintenance and early issue detection, thus enhancing safety and operational efficiency.

DOI: 10.1201/9781003483755-377

The paper aims to highlight the integration with asset management, and enhancements in safety and efficiency brought by the SHM system. The implementation of this system exemplifies a dynamic, responsive approach to infrastructure maintenance, setting a precedent for future large-scale projects.

2 BOGIBEEL BRIDGE STRUCTURAL DESIGN

The Bogibeel Bridge is a composite welded steel truss bridge with reinforced concrete, designed to carry a double line broad gauge railway on the lower deck and a three-lane road on the upper deck. The bridge comprises 41 spans, each measuring about 125 meters (End span, 33.4 meters).

The bridge's unique construction involved the creation of three distinct types of spans, in addition to the end spans. This design approach was necessitated by the bridge's deployment onto its pillars, which were the initial structures erected. The construction process involved welding multiple spans together and then pushing them onto the pillars. This method necessitated varying steel thicknesses, leading to the requirement of the three span types (labeled A, B, and C) along with the end spans. After positioning the spans accurately, the welds were removed, resulting in the bridge consisting of 41 individual spans. The picture in Figure 1 shows the Bogibeel bridge under the deployment of some of the spans.

The structural design of the Bogibeel Bridge, characterized by its repetitive span structure, uniquely facilitates the application of the Structural Health Monitoring (SHM) system. The uniformity in design across the 41 spans, each featuring steel truss girders and a concrete slab, allows for strategic deployment of the SHM system on select spans. This approach not only exemplifies efficient resource utilization but also ensures comprehensive monitoring. By selectively equipping spans with sensors, the SHM system can extrapolate data to assess the overall structural integrity, optimizing maintenance and ensuring the bridge's longevity.

Figure 1. Bogibeel Bridge under the deployment of span to the piers.

3 STRUCTURAL HEALTH MONITORING SYSTEM FOR BOGIBEEL BRIDGE

As the SHMS system is currently being implemented, the system overview, shown in Figure 2, is outlining the data flow and analysis process. The design is geared to leverage the bridge's repetitive span structure, enabling efficient sensor placement and data extrapolation for structural assessment.

The SHMS collects and conditions monitoring data from critical elements of the Bogibeel Bridge, providing temporary storage, data processing, system control, operation, and data management within the Structural Health Monitoring Control Room. At the time of writing this paper, the sensor installation is about to commence, which results in the absence of data from the system for this publication.

The system ensures the aggregation of critical data pertinent to the bridge's performance and enables future evaluations of the Bogibeel Bridge's structural health. The SHMS works in conjunction with visual inspections to facilitate targeted maintenance, enhance safety, identify

critical structural components, assess wear on moveable parts, and estimate the bridge's remaining lifespan. The architecture of the SHM system is depicted in Figure 2."

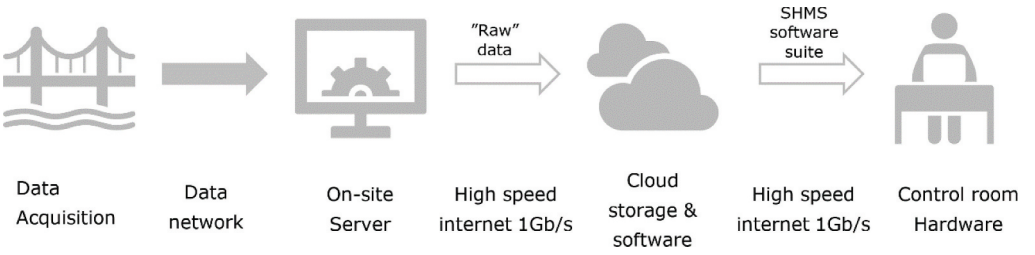

Figure 2. System overview.

The Structural Health Monitoring (SHM) system of the Bogibeel Bridge employs a comprehensive array of sensors, amounting to approximately 920 instruments, to ensure continuous and precise monitoring of the bridge's structural integrity. These sensors are strategically positioned across the bridge, mainly on four different spans, identified as Span A, B, C, and the south end span. They monitor a range of environmental parameters, operational and environmental loads, and the bridge's structural response. Figure 3 illustrates the different spans of the Bogibeel Bridge, including the sensor locations on all spans and piers.

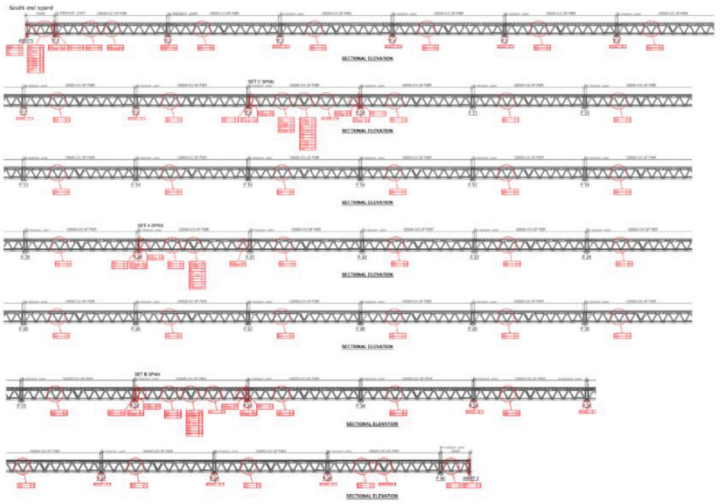

Figure 3. Overview of the different spans comprising the Bogibeel Bridge and the indication of sensor locations.

The SHM system for the Bogibeel Bridge includes a variety of sensors for monitoring environmental conditions, operational and environmental loads, and structural responses. Environmental sensors, such as Triaxial Ultrasonic Anemometers and Temperature & RH sensors, gather data on conditions impacting the bridge. Sensors like Dynamic Weigh in Motion sensors and Scour Monitoring Sensors track the loads affecting the bridge and its piers. To gauge the bridge's structural response, instruments like Load Cells and Accelerometers among others, measure aspects such as strain, load, acceleration, and corrosion.

These sensors are mainly positioned on four key spans, but all spans are equipped with accelerometers and GPS sensors to allow data extrapolation via numerical modeling, thus boosting the SHM system's effectiveness. Tables 1 through 3 detail the types and quantities of sensors installed on the bridge for various monitoring purposes.

Additionally, the SHM system incorporates a database with warning and alarm values to facilitate updates corresponding to changes in the bridge's condition. This database ensures a straightforward method for modifying important values when the bridge's structural characteristics change.

Table 1. The number of sensor and their type (Environmental Parameters).

Sensor/Instrument	Measurements	Qty.
Triaxial Ultrasonic Anemometer	Wind speed & direction in all directions	8
Visibility & Fog detector	Visibility	3
Pyranometer	Solar radiation	3
Barometer	Air pressure	3
Rainfall gauge	Rainfall rate & total rainfall	3
Temperature & RH sensor	Ambient Temp. & Relative humidity in air	12
Asphalt Temperature	Temperature	18
Concrete Deck Temperature	Temperature	18
Steel Deck Temperature	Temperature	45
Video Surveillance	Video surveillance	6

Table 2. The number of sensor and their type (Loads- Operational and environmental loads).

Sensor/Instrument	Measurements	Qty.
Dynamic Weigh in Motion sensor	Load of road traffic & speed	3
Sonic motion sensor	Train traffic detection	4
Scour monitoring sensors	Scour at piers	12

Table 3. The number of sensor and their type (Response Measuring sensors).

Sensor/Instrument	Measurements	Qty.
Load cell	Vertical Load on bearing	16
Static strain gauge	Strain in concrete	202
Dynamic strain gauge	Strain in structural steel	300
Accelerometer	Acceleration/ frequency of the girders	86
Displacement Transducer	Displacement of girder	28
GPS rover & reference stations	Deflection of girder	84
Tiltmeter & Inclinometer	Tilt of pier & rotation of girder	27
Corrosion sensor	Corrosion of concrete Rebar	40

4 DATA PRESENTATION AND ANALYSIS

All data from the SHM system is provided to the cloud-based SHMS software suite as "raw" data in SI units, with data preprocessing done on the data acquisition units (DAUs). Upon receiving data from the DAUs, the SHMS software suite can perform post-processing on both "online data" and "historical data." This process offers users options for displaying data in various formats, detailed below.

The terms 'online' and 'historical' data denote the real-time or stored data in the SHMS software, respectively, with 'online' data indicating immediate, live data and 'historical' data referring to records maintained on the cloud server.

Figure 4 illustrates the sensor locations on the Bogibeel Bridge and the alarm status for different sensor types. The left side of the figure shows an overview, while the right side zooms in on the response sensors. Users can access the latter by clicking on the corresponding row.

Similarly, detailed data for individual sensors can be accessed by selecting the sensor type. Figure 5 displays the SHMS software interface when the Load Cell option is selected, showing both the bridge location and a detailed view for better data origin understanding.

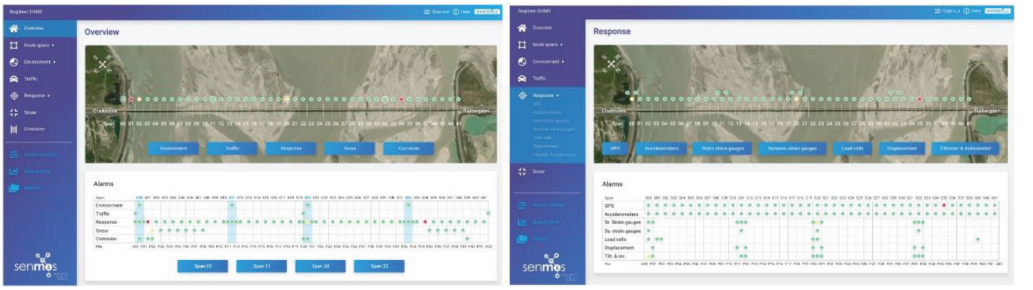

Figure 4. Overview of the sensor location and their alarm status in the SHMS software (Left) and a zoom in on the Response alarm status overview (Right).

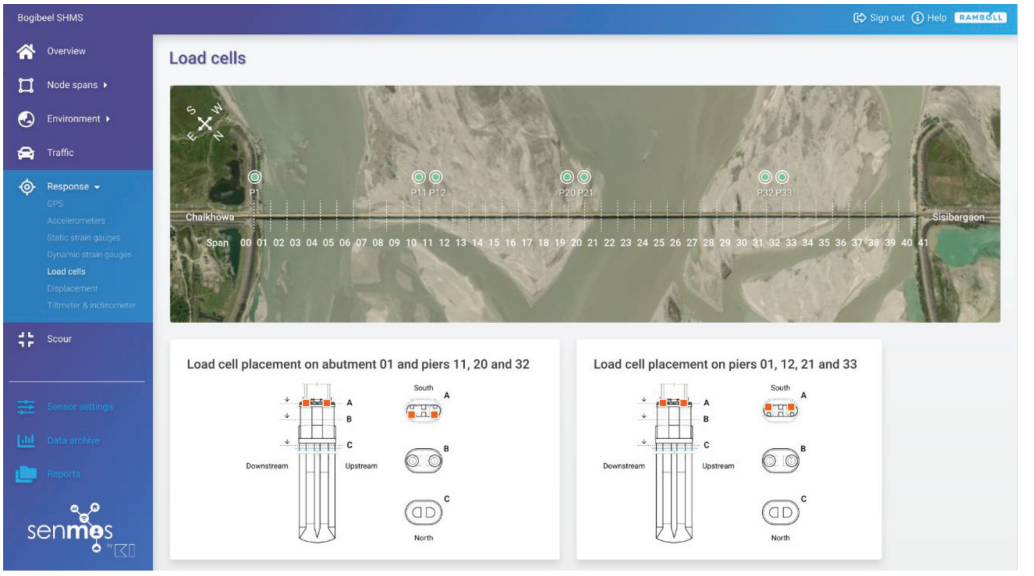

Figure 5. Detailed location information for the Load cells on the Bogibeel Bridge.

4.1 *Data presentation*

As previously mentioned, data is categorized into online and historical types. Table 4 provides an overview of the presentation options for these data types.

Each plot mentioned in Table 4 includes options for displaying limit characteristics. This feature allows for the visualization of both warning and alarm levels alongside measured data, offering an insight into the bridge elements' proximity to their utilization limits.

Figure 6 shows some examples of the mention plots. Here a correlation plot is seen to the left and rainflow and accumulated damage is seen to the Right. Example of the different limits are also shown in the plot.

4.2 *Analysis*

Post-processing scripts, as part of data analysis, are essential for creating desired data presentations. These scripts can be applied to both online and historical data. Table 5 outlines the available post-processing scripts for different data types.

Virtual channels can also be created as part of the analysis, which in the realm of data analysis for structural health monitoring plays a pivotal role in synthesizing complex insights from raw sensor data. These channels are not direct sensor outputs but are constructed through mathematical algorithms that manipulate and combine data from one or more physical sensor

Table 4. Data presentation.

Online data	Historical data
Images with displayed sensor values and alarm indicators.	Timeseries, with limit characteristics.
Tables with sensor values and alarm indicators.	Rainflow histograms, with detail class characteristics
Timeseries plots with online data.	Polar, with envelope characteristics.
– Online data scripts available with this graph is described in section 5.2 Post-processing scripts.	
Tables with latest sensor threshold	Histograms, with limit characteristics.
Tables with latest sensor errors (connection, configuration, and threshold errors)	Correlation, with envelope box characteristics
Online timeseries graphs with incoming values	Autocorrelation, with characteristics.
Historical graphs with a predefined specified period	Fatigue accumulation, with limit characteristics
Weather display for the region.	Accumulation over a set period, with limit characteristics
	Frequency plot, with limit characteristics.

Table 5. Post-processing scripts.

Online data	Historical data
Low-pass filter	Statistics (mean, max, min, std, accumulated change)
High-pass filter	Rainflow-counting and fatigue utilization
Band-pass filter	FFT/Spectral Densities
Moving average (ranging from sampling frequency to 1 hour) with associated statistical values	Cross-correlation and auto-correlation analysis
Simultaneous plotting of up to 256 channels	Combination of channels (virtual channels)
Gain and offset applied to sensor channels	Gain and offset applied to sensor channels

channels. By applying basic mathematical operations such as addition, subtraction, multiplication, a new channel is created—this composite channel encapsulates a specific aspect of the bridge's performance that cannot be captured by a single sensor. All post-processing scripts shown in Table 5 are thought to be usable on the virtual channels, just as if they were physical channels. For instance, if physical channels measure variables like strain and temperature independently, a virtual channel could represent the adjusted strain value that accounts for temperature effects, giving a more accurate indication of structural stress. This process of creating virtual channels enhances the interpretability of the data, allowing engineers to construct tailored indicators that are closely aligned with the bridge's unique monitoring needs. The

creation and analysis of such channels are crucial for the detection of subtle patterns or trends that signify potential issues, thereby enabling preemptive maintenance actions.

Using the post-processing scripts and virtual channels, warning and alarm systems can be configured to alert bridge owners to significant changes in the recorded data. Here the alarms are passed on to the management program SMART, which will be touch on in section 5 of this paper. For example, Figure 7 demonstrates a frequency check using defined intervals from the bridge's limit characteristics.

Figure 7. Frequency range check on example data for the Bogibeel Bridge.

5 MAINTENANCE STRATEGY

The new and innovating approach to the maintenance strategy is based on using the Specialized bridge asset management program SMART together with a link to the SHMS software where alarms and reports are automatically uploaded to SMART and placed under the correct hierarchical member in SMART. Figure 7 shows a schematical setup for this process and which data flows from the SHMS to SMART.

The Alarms and reports send from the SHMS software will create item/job in SMART which will then be a part of the maintenance planning for the bridge. The automation of placing reports and alarm in the SMART bridge management program will optimize the workflow by providing asset managers access to the information. Having the information under the right structural members and placed in the job interface in SMART is providing an easy way to prioritize the work needed on the bridge, that being "normal" maintenance, checking alarms/sensors or anomalies reported in the automated reports from the SHMS.

The implementation of the SHMS with the aim of integrating its data into the SMART software is a strategic move that enhances the usability of the information gathered by the SHMS. By integrating SHMS data as native data within the SMART system, it ensures seamless workflow and utilizes the established capabilities of the SMART system for efficient task management. This integration allows for an optimized use of SHMS data, making it more accessible and actionable for users, thus enhancing overall maintenance efficiency and decision-making for the bridge.

The optimization will help lower the cost of maintaining the bridge over its lifetime. Comisu et al. (2017) explore the structural health monitoring systems of bridges, indicating the potential of permanent monitoring systems to reduce the operating costs of inspections and maintenance by 25%, and to reduce the overall life costs of bridges by 10% by applying lifetime prediction models.

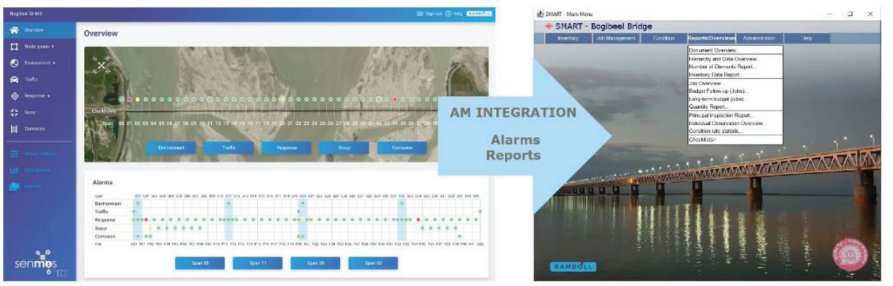

Figure 8. SHMS cloud software and its integration with the assets management software SMART.

6 FUTURE PERSPECTIVES AND INNOVATIONS

Structural Health Monitoring (SHM) systems in bridge maintenance is pivoting towards predictive methodologies where Deng et al. (2023) review the current developments in structural health monitoring within the last five years. Apart from this review of exiting sensor and data handling/analysis technologies and enhanced sensors, AI-driven analytics will facilitate early detection of structural issues, leading to timely interventions. This shift is expected to improve bridge safety and longevity while optimizing maintenance. Emerging technologies, including IoT, drones, robotics, and AI, are set to revolutionize SHM systems. Advances in sensor technology, particularly with nanotechnology, will improve SHM system precision and durability, steering bridge maintenance towards more effective and future-focused practices.

On the note of nanotechnology then this technology is starting to influence structural health monitoring in bridges, by providing advanced tools and materials for enhanced maintenance and safety. Han et al. (2023) discuss the use of nanosensors, which are emerging as promising tools for assessing the structural integrity of bridges whereas Zheng et al. (2019) talks about nanocomposites for structural health monitoring.

7 CONCLUSION

This paper has detailed the ongoing implementation of a Structural Health Monitoring System (SHMS) on the Bogibeel Bridge, marking a pivotal shift in bridge maintenance and safety methodologies. The SHMS, with its extensive network of approximately 920 sensors, is poised to transition bridge maintenance from traditional reactive methods to a more proactive, data-driven approach. Once operational, this system is expected to significantly enhance the safety and efficiency of the bridge, setting a precedent for future infrastructure projects.

The anticipated outcomes of this SHMS implementation include improved early detection of structural issues and a more efficient maintenance response. This proactive strategy is projected to extend the bridge's service life, ensure safety, and optimize maintenance costs. However, it's crucial to recognize the current challenges, such as the complexities involved in data validation and interpretation in the initial phases of the system's operation.

Future research opportunities plentiful in the realm of SHMS. The integration of emerging technologies like artificial intelligence and the Internet of Things could potentially enhance the predictive accuracy of SHMS. Furthermore, expanding the system to encompass environmental impact assessments might provide a more comprehensive approach to infrastructure maintenance.

In sum, the ongoing installation of the SHMS on the Bogibeel Bridge represents a significant stride towards adopting modern engineering solutions for improving the durability and reliability of crucial infrastructure. As the field of structural health monitoring advances, it is expected to revolutionize maintenance strategies for large-scale structures globally, potentially marking a new era of infrastructure management.

Digital health monitoring of the Great Belt Suspension Bridge

T. Friis, S.S. Christensen, S.T. Nielsen, M. Lollesgaard & T.B. Bangsgaard
Rambøll Danmark A/S, Denmark

M.D. Havelykke
Sund & Bælt Holding A/S, Denmark

ABSTRACT: This contribution demonstrates how operation and maintenance of one of the largest suspension bridges worldwide have significantly benefitted from a structural health monitoring (SHM) setup with +400 sensors developed in a unique collaboration between consultants at Ramboll, contractors and the owners from Sund & Bælt. The Great Belt Fixed Link in Denmark opened in 1998 and consists of an 18 km road and railway link composed of a tunnel, a continuous multi-span beam-type bridge, and a suspension road bridge with a main span of 1624m, the current 6th longest worldwide. The aim of the tailormade SHM setup is to provide knowledge of structural performance, deterioration and remaining lifetime to the asset managers that can accordingly plan maintenance and actions for mitigation of undesirable structural performance to ensure economical and sustainable asset management and safe operation. The paper provides an overview of the SHM system followed by case studies showing SHM outputs and how these are used in the operation and maintenance. Specifically, it is presented how the SHM provides insight into the vibration phenomena and fatigue lifetime of the hangers, insight into fatigue lifetime of the main girder including influences of operational and environmental parameters, and insight into wear and lifetime of the bearings. It is revealed how this valuable information are used in decision making of the operation and maintenance of the suspension bridge. Lastly, further improvements of the monitoring system and subsequent analyses are discussed with respect to the further value it brings for the asset managers.

1 INTRODUCTION

The Great Belt Fixed Link in Denmark opened in 1998 and connects the islands of Zealand and Funen. It consists of an 18 km road and railway link composed of a tunnel, a continuous multi-span beam-type bridge (the West Bridge), and a suspension road bridge (the East Bridge) with a main span of 1624m, the current 6th longest worldwide (3rd longest outside of China). The Great Belt Suspension Bridge is a landmark engineering marvel. The Great Belt Suspension Bridge is not only a symbol of Denmark's technological advancements, but also a vital link for the country's infrastructure.

The combination of aging infrastructure, advances in technology and concerns of safety and sustainability have all contributed to the growing popularity of Structural Health Monitoring (SHM) in the past decades. The advances in technology have made it easier and more cost-effective to implement SHM systems and the increasing emphasis on safety and sustainability has also contributed to the popularity by creating the need for more knowledge of the structural condition to ensure the correct level of safety and by addressing the importance of longevity to fulfil sustainability goals (Straarup et al. 2022). Thus, an SHM system is an essential tool in management, maintenance and operation of large infrastructure, where these systems are designed to provide real-time information about the structural condition and

DOI: 10.1201/9781003483755-378

behavior of a bridge, allowing asset managers to detect and address potential problems before they become comprehensive.

The SHM system on the Great Belt Bridge is designed to continuously monitor the condition and behavior of the bridge and its mechanical equipment, e.g., tuned mass dampers and hydraulic buffers, and detect any changes that could indicate potential structural or mechanical problems and supply information for both the present and future maintenance decision-making process. The system consists of a network of sensors and monitoring equipment that is distributed throughout the bridge, see Figure 1. The SHM system on the Great Belt Bridge is considered to be one of the most advanced in the world, and it has played a key role in ensuring the safety and longevity of this important infrastructure in a cost-effective manner (Lollesgaard & Brøndum 2018, Myrtue et al. 2021).

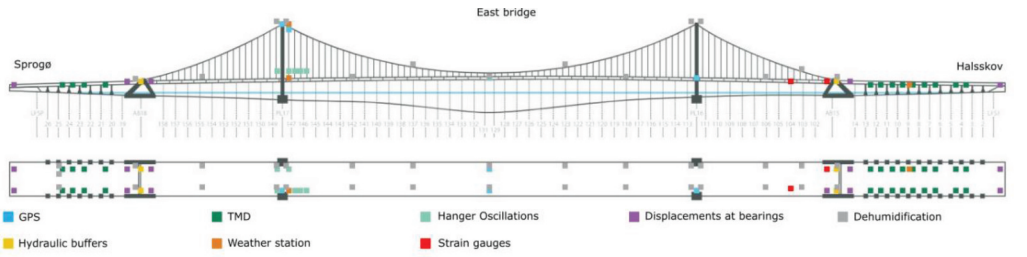

Figure 1. Sensor positions on the Great Belt Suspension Bridge.

In this paper, the current SHM system of the Great Belt Bridge is shortly described followed by a description of the analysis outcome of the measurements and the related benefits for operation and maintenance for a selection of the measurement systems. The focus is on the monitoring of the hangers, bearings and main girder. Towards the end the paper, a discussion of further improvements of the SHM system and the related benefits is provided along with a discussion of the present transformation towards digital enabled asset management.

2 STRUCTURAL HEALTH MONITORING SYSTEM

The entire SHM system is named Konmos, which stands for Structural Monitoring, Great Belt (**kon**struktions**mo**nitering, **S**torebælt in Danish). The system includes approximately 650 sensors distributed on the West Bridge and East Bridge with associated data storage and data access (user interface) on Azure Cloud. The structural monitoring of the suspension bridge consists partly of measurement systems that were installed during the construction of the bridge, and partly of systems that have been installed as the need arose. The Konmos system itself was established in 2015 with its own user interface and data storage for sensors on the West Bridge. Existing sensor systems on the East Bridge were connected to Konmos in 2018-2019.

The user interface is an intuitive tool that makes it easy for anyone who needs information from construction monitoring to quickly access an overview of measurement data from a wide range of different sensors. The user interface provides flexible options for presenting measurement data, making it easy to get an overview and create figures for reports and email correspondence. For further description of the SHM system see (Lollesgaard & Brøndum 2018, Myrtue et al. 2021).

2.1 *Bearing monitoring*

The bearing displacements are monitored on both the West Bridge and the East Bridge and have been in place since the construction of the link. The bearing measurements on the suspension bridge measure horizontal displacements in the direction of the bridge at 12 bearings.

The sensors are placed on each side at the ends of the suspended span and on each side at the ends of the two approach spans, see Figure 1. Specifically, the displacement sensors measure all relative movements with submillimeter resolution between the bridge deck and the support with a sampling frequency of 10 hz, and a photo of a bearing with the measuring equipment can be seen in Figure 2.

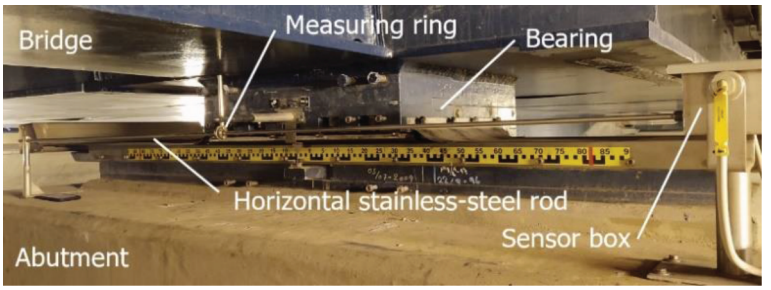

Figure 2. Photo of abearing with the sensor for monitoring bearing displacements on the East bridge.

2.2 *Strain monitoring of the main girder*

The system is established in the late part of 2019 and consists of a temperature sensor and 29 strain gauge sensors, which respectively measure temperature in the steel deck and strains in the steel in relation to fatigue of welds on troughs in the upper side of the bridge deck in sections 101 and 104, see Figure 3. Here it can be seen that the sensors in section 101 are located approx. 10 m from the anchor block under the westbound lanes. The sensors in section 104, on the other hand, are located approx. 120-160 m from the anchor block under the eastbound lanes.

Strains are measured in section 101 close to the expansion joints, as it is assessed as one of the more severely affected locations in terms of fatigue, since the expansion joint is expected to give rise to an additional impact from the passing vehicles compared to the other sections of the bridge. The impact results from the lack of evenness at the transition between the expansion joint and the adjacent road surface. Section 104 is thought to be more representative of the rest of the bridge deck in the suspension section. The focus is also on measuring strains under

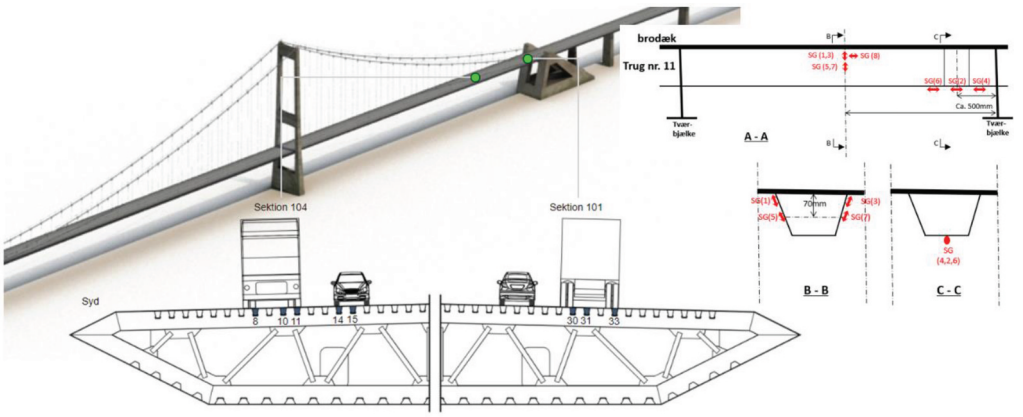

Figure 3. Figures from the Konmos user interface showing the locations of the strain gauges. Section A-A is a longitudinal section in the girder.

slow-moving lane, as the response from traffic is, as expected, greatest here. Moreover, the measurement setup is measuring continuously with as sampling frequency of 600 Hz to capture the fluctuation of stress in the steel caused by relatively fast-moving local traffic load.

2.3 *Hanger monitoring*

Selected hangers are permanently monitored with accelerometers to continuously monitor the vibrations of the cables that have been found to oscillate with large amplitudes from time to time (Gjelstrup 2011). The present monitoring setup consists of accelerometer measurements in 2 horizontal directions on 7 hangers around the western pylon. All 4 hangers in position 2 from the pylon, as well as hangers in positions 1, 3, and 4 Southeast of the pylon, are monitored. The accelerometers are mounted 4.5 m above the bridge deck and sample with a frequency of 25 Hz.

Sensors in the hanger monitoring system have been replaced during the 2023 and additional sensors are added. The new setup cover 10 hangers and on one hanger, the setup is expanded to include 2 dual-axis accelerometers, 2 triaxial accelerometers, and 5 dual-axis inclinometers.

3 ANALYSIS OF MEASUREMENTS AND BENEFITS FOR OPERATION AND MAINTAINANCE

In the present section, the analysis outcome of the measurements and the related benefits for operation and maintenance are presented for a selection of the measurement systems. The focus is on the monitoring of the hangers, bearings and main girder.

3.1 *Bearing monitoring*

The continuous monitoring of the longitudinal displacements at the bearings are analyzed in several different ways from more simple verification of maximum displacements not exceeding the physical limits to more advanced estimation of bearing lifetime. The outcome of the analyses has the following benefits for operation and maintenance:

- Surveillance of larger, slow temperature related displacement with alarm system for detection of critical displacement in respect to physical limits of the bearings, expansion joints and supports incl. assessment of the presence of warping effects. Potential problems are detected before they become adverse and preventive measures can be planned well in advance.
- Estimates of bearing lifetime can potentially be used to ensure timely planning of maintenance and full utilization of bearings before replacement.
- Analysis of governing parameters of the bearing displacement was used to optimize pressure settings of hydraulic buffers which damp longitudinal displacements of the bridge deck. This led to decrease in longitudinal displacements of the suspended bridge deck. The optimization approx. doubled the expected lifetime of the bearings under the main span.

Studies of the measured displacements have shown that the wear of the bearings is caused by accumulation of smaller and faster displacements over time caused by traffic and wind load rather than larger and slower displacements caused by temperature changes. This is in line with the general knowledge of the employed bearings, where the lifetime is given by the accumulated displacement over time but also from the velocity of the displacements. On that basis, estimates of lifetime are obtained based on measured displacements and estimated velocities to get an equivalent accumulated displacement that is comparable to the capacity stated by the manufacturer.

A study of the accumulation of equivalent displacement showed a necessity to reduce the smaller and faster displacements of the main girder. The settings of the hydraulic buffers in the ends of the main span of the suspension bridge were then optimized to reduce the

longitudinal displacements even further, which has been shown to significantly reduce wear and approximately double the expected lifetime of the bearings. The study also revealed the importance of the bearings being able to withstand small and fast displacements, which was important information for the consideration of bearing types and material during bearing replacement. The chosen material can better absorb the small and fast displacements that these bearings have been found to be affected by, which in turn lead to even less maintenance in the future.

Figure 4 shows equivalent accumulated displacement over time from one of the bearings in the main span from June 2021 before optimization of the damping (blue) and June 2022 and after the optimization (orange). A significant difference in the accumulation is seen between these two periods, which leads to the significantly increased lifetime. Moreover, the lines are shown to have sudden changes in inclination, which is found to be a result of the difference in the amount of heavy traffic passing during the weekdays and during the weekend.

3.2 *Strain monitoring of the main girder*

It is known from older bridges with orthotropic steel girders that issues with fatigue cracks of welded connections occur within the lifetime of the bridge. On that basis, it is quite important for operation and maintenance to know when it is expected that the fatigue cracks can occur and where. Thus, the current setup is used to continually estimate the fatigue lifetime of selected welded connections, which is essential input for the planning of current and future actions with respect to inspection and maintenance of several kilometers of welds, and for a potential planning of mitigating actions that will prevent comprehensive problems in the future.

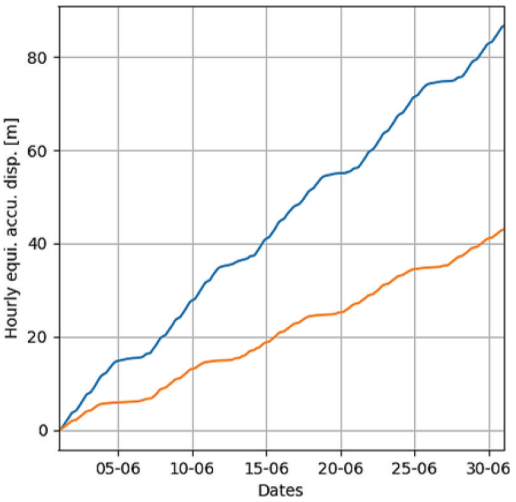

Figure 4. Equivalent accumulated displacement from June 2021 in blue (before optimization of the damping) and June 2022 in orange (after optimization of the damping). The measurements are from a bearing supporting the main span (AB18 NW).

The fatigue lifetimes of selected welded connections are currently estimated based on more than 3 years of continuous measurements of strain. The measured strains are transferred into stresses, and from the time series of stress, rainflow counting is conducted based on ASTM E1049-85 to get stress ranges and counts. The stress ranges and counts are turned into values of damage using the S-N curves of the standard DS/EN 1993-1-9 2007 and the Palmgren-Minor rule. For the final estimate of fatigue lifetime, the estimated damages are scaled based on traffic counts of heavy traffic and a prognosis of traffic development over the Great Belt Bridge in the future.

The estimated remaining fatigue lifetime of the selected welded connections is ranging from approximately 50 years (characteristically) in the heaviest loaded location under the slow-moving lane to a theoretical infinity of least loaded location under the fast-moving lane. This knowledge is essential input for the planning and prioritizing of current and future actions with respect to inspection and maintenance. Additionally, this knowledge and a continues monitoring is also essential input for potential planning of mitigating actions in the future that will prevent comprehensive problems that might arise as the bridge ages beyond the lifetime of the heaviest loaded welds, and thereby extending its lifespan and minimizing the costs over time.

The strain gauge monitoring has also provided increased insight into the relation between the asphalt and the lifespan of the bridge deck, where temperature and the condition in terms of thickness and unevenness of the pavement have shown to have a significant impact. The temperature decreases the stiffness of the asphalt causing larger stress changes in critical locations. In Figure 5, a plot is seen of the damage on a weld between trough and top plate for one year computed from the measurements on an hourly basis over hourly mean road temperature and hourly traffic count of trucks and busses. From these results it is clear that the hours with higher amount of fatigue damage only occur at higher road temperatures and with many heavy traffic passages.

The knowledge of how much the road temperature affects the lifespan of the weld in the main girder is beneficial input to the operation and maintenance since it shows the importance of choosing and maintaining an asphalt pavement with the right properties (thickness and stiffness) to prevent fatigue cracks and not just for the sake of the comfort of the passing traffic. Even for design of new bridges, it shows the importance of these considerations of the asphalt pavement to ensure the longevity of the welds of the girder and prevent expensive maintenance work when the bridge becomes older. Additionally, the asphalt pavement in slow-moving lane with passage of trucks has been renewed during 2022 to ensure the longevity of the Great Belt Suspension bridge and the comfort of the passing traffic. Preliminary studies of the strain gauge measurements have shown that the renewal of the asphalt might have a significant positive effect on the lifetime of the welds in the top part of the main girder.

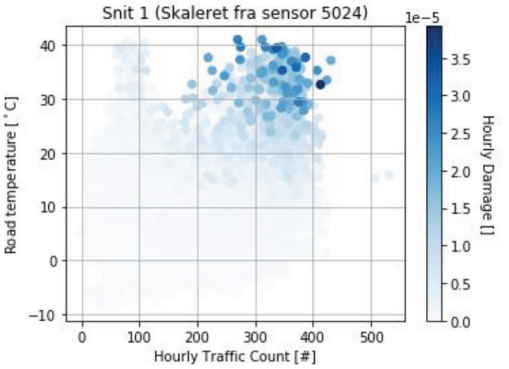

Figure 5. Hourly damage over hourly mean road temperature and hourly traffic count of trucks and busses for a weld between trough and top plate. The measurement period is from February 2021 to February 2022.

3.3 *Hanger monitoring*

As previously described, selected hangers are permanently monitored, and the measurements are analyzed with focus on the following benefits/input for operation and maintenance:

- Surveillance and knowledge of oscillation levels and phenomena which is also employed for planning, design, and evaluation of potential mitigation actions.

- Estimation of fatigue lifetime for timely planning of potential replacement and assessment of the need for mitigation actions that can extend the lifetime.
- Surveillance of estimated hanger forces as continuous monitoring of the load distribution, where changes in the load distribution potentially can indicate damages. Thus, potential damages can be detected immediately, and appropriate measures can be carried out in timely and cost-effective manner. This is elaborated in the current section.
- Surveillance of estimated hanger damping to continuously evaluate performance of external dampers. Dampers with poor performance can be replaced to ensure longevity of the hangers.

The continuous monitoring of the oscillations for more than 3 years has given insight into the oscillation levels and frequency of the occurrence of the higher vibration levels. Maximum vibration levels are found with amplitudes in the range of 1.5-2.0 m at the center of the hangers.

The oscillations of the cables cause bending stresses and fretting wear at the ends where the curvature is largest, which potentially can result in fatigue of the cables. Thus, one of the main reasons for monitoring the hangers is to estimate the fatigue damage from these oscillations.

The estimation of the fatigue damage and lifetime is carried out in several steps. At first, the subject of virtual sensing is employed to estimate virtual measurements of displacements and stresses at the critical positions. Secondly from the time series of stress, rainflow counting is conducted based on ASTM E1049-85 to get stress ranges and counts. Then stress ranges and counts are turned into values of fatigue damage using an appropriate S-N curve and the Palmgren-Minor rule.

At this point in time, the estimates of fatigue lifetime have been found to be towards a disappointing low level. The current calculations, however, have also been assessed to be quite conservative with an overestimation of the stresses. On that basis, two actions have been set in motion: i) The measurement setup has been expanded during 2023 to cover more hangers but also to have more sensors on one hanger. The latter is planned to give a better insight into the structural characteristics of the hangers and reduce the aforementioned conservatism. ii) Additional dampers have been designed for some of the hangers and are currently being produced. Vibration dampers were already installed in 2007 on the two longest hangers on each side of the pylons (i.e., 8 damped hangers at each of the two pylons). The additional dampers are planned to cover hangers in position 3 and 4 from the pylons.

In one case, the external damper (local viscous) of a hanger was found completely defect during maintenance, which led to a continuous estimation of modal damping from the measured accelerations using Operational Modal Analysis in order to monitor the performance of the external dampers. For the specific hanger, it even led to an evaluation of the damper concept by estimating the modal damping before and after replacement of the damper cylinder, see Figure 6. It was found that the dampers in one position did not supply a sufficient level of damping due to the damper not having a large enough movement range and not providing the optimal force level. New dampers are planned for the one position to ensure longevity of the hangers.

The monitoring of the hangers has already given much value for operation and maintenance. Vibration levels are known, and potential future problems are illuminated and analyzed, and actions have been set in motion in a timely and cost-effective manner to ensure safe operation now and in the future. By already carrying out preventive action in the early ages of the bridge, the lifetime is potentially expanded past the intended lifetime during design.

4 DISCUSSION AND DIGITAL ENABLED ASSET MANAGEMENT

A good yield with significant operation and maintenance cost benefits is already achieved from monitoring, as described for a selection of the measurement systems in the previous section. Nonetheless, there is still a greater yield to be gained if the monitoring hardware, the subsequent analyses and its implementation in the operation and maintenance procedures are

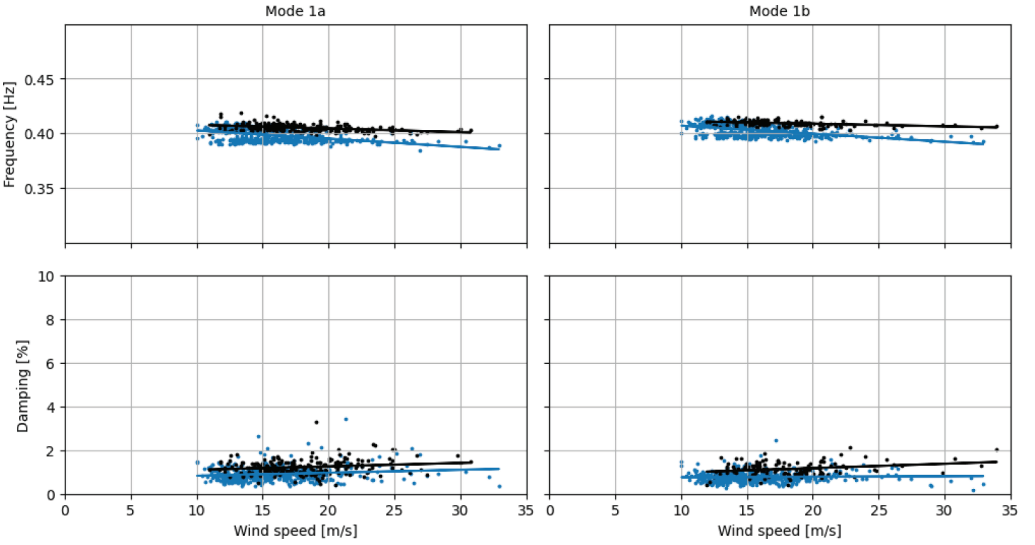

Figure 6. Lowest natural frequency and damping as a function of the 10-minute mean wind speed for a hanger in position 1 from a pylon. Blue represent data from before the defect damper cylinders on the hanger were replaced, and black represent data from after the damper cylinders were replaced. Mode 1a and 1b are the two closely-spaced fundamental modes of the hanger.

expanded and developed further, so that the maintenance moves further towards being condition-based or predictive, as it can help to provide or increase the following benefits even further:

- Lower maintenance costs - optimization of inspection intervals and reduction of manual inspection, timely planning and full utilization of elements before replacement.
- Extend lifespan - some elements have a predetermined design life, which may prove to be longer under actual conditions. Factors that reduce lifespan can be identified and rectified, so that construction parts last longer.
- Increase safety - when actual conditions are known and monitored, uncertainties are reduced and reliability increases. In other words, the deterioration of structural components over time can be detected or even predicted to avoid possible accidents and collapses.
- Increased sustainability - the monitoring provides more knowledge about the condition of the structure, whereby climate-damaging maintenance, renovations, and partial replacements are prevented with countermeasures in due time or not carried out until necessary.
- Minimize downtime - when the condition of the structural components can be predicted, maintenance and repairs can be planned well in advance and arranged so that traffic is disturbed as little as possible.
- Improve the customer/user experience - structural-related conditions that may worsen the customer/user experience can be reduced and rectified.
- Knowledge sharing and collaboration with universities and other bridge owners - increased yield through research and knowledge sharing.

Digital enabled asset management is the process of using digital technologies to optimize the management of physical assets throughout their lifecycle, from design and procurement through to operation, maintenance, and decommissioning. This approach involves the use of digital tools such as sensors, data analytics, algorithms and machine learning to collect and analyze data on asset performance, condition and usage, and to use this information to make more informed decisions about how to manage and maintain assets. By leveraging digital technologies, asset managers can gain real-time insights into asset health, anticipate and prevent failures, and optimize maintenance schedules, leading to reduced downtime, increased asset

longevity, and lower overall costs. Digital-enabled asset management also enables better collaboration between stakeholders in the asset management ecosystem, such as owners, operators, maintenance teams, and suppliers, by providing a shared digital platform for data collection, analysis, and decision-making. Overall, digital enabled asset management offers significant benefits for organizations across a wide range of industries, helping them to improve asset performance, reduce costs, and increase overall efficiency and effectiveness (Straarup et al. 2022).

The maintenance and operation of the Great Belt bridge has taken the first steps towards an implementation of digital enabled asset management as is evident from the present paper. The transformation is, however, not straightforward and will naturally face challenges and difficulties, and take time. Changing set ways of conducting operation and maintenance is not done overnight and will most probably be conducted in both small and large steps. In order to have predictive maintenance and optimized inspection, the knowledge obtained from the monitoring has to be transferred into practical ways of inspection and maintenance. The latter is a challenge often underestimated, which will inevitably demand willingness to change to be successful.

Florida Department of Transportation Skyway Bridge Project Manager, Tampa FL, USA

ABSTRACT: The Sunshine Skyway Bridge, inaugurated in 1987, was born out of necessity following a tragic vessel collision that destroyed the southbound main span, killing 35 people. Conceived by the accomplished French engineer, Jean M. Mueller, this iconic bridge boasts a 366 m cable-stayed main span, complemented by a 1,219 m main unit featuring 11 spans employing a combination of cable-stayed box girder and balanced cantilever post-tensioned concrete box girder components for the back spans. Acknowledging the significant milestone of the bridge reaching its 37th year,, the Florida Department of Transportation is actively engaged in intensive efforts to extend the service life of the bridge. This paper delineates the innovative *Data-Driven Preventive Maintenance and Service Life Extension* approach currently being applied to the Sunshine Skyway Bridge. Spearheaded by TYLin, the approach integrates structural monitoring employing nearly 100 sensors, encompassing conventional structural health monitoring (SHM) sensors combined with custom-built sensors designed to cater specifically to the distinctive monitoring requirements of this structure. Concurrently, a finite element model is under development to precisely represent the as-built structure. This model will be fine-tuned with sensor data, culminating in the creation of a comprehensive digital twin of the bridge, which is poised to enhance comprehension of the bridge's behavior and furnish crucial data for gauging the remaining service life of critical components such as stay cables and stay cable dampers. In tandem with monitoring and modeling, the data procured from sensors undergoes advanced post-processing techniques using "Big Data" analytics. Currently, this data is used to train a *machine learning model*, enabling real-time prediction of structural parameters. This capability will facilitate the instantaneous identification of any parameter deviating from the normal range, thereby enhancing the bridge's overall safety and performance.

1 INTRODUCTION

The Bob Graham Sunshine Skyway Bridge, a renowned and vital structure recognized as the State of Florida's "flagship bridge" stands as an symbol of resilience and innovation. Completed in 1987, its inception followed the tragic failure of the original Skyway Bridge's South Bound Main Span due to a vessel impact, resulting in a catastrophic event that claimed 35 lives. This poignant history underscores the critical importance of the current bridge as a vital link, spanning 6.66 km across Tampa Bay and connecting the communities of Pinellas and Manatee Counties. The bridge boasts a cable-stayed main span and high-level approach spans constructed

DOI: 10.1201/9781003483755-379

with precast segmental concrete superstructure and substructure. Additionally, the trestle spans feature AASHTO concrete beams and a conventional concrete pile/bent design. A distinctive feature of the bridge is the inclusion of forty-two total continuous stay cables, with twenty-one gracefully running through each of the two towers along the center line, providing indispensable support to the entire structure. In light of the Sunshine Skyway Bridge's extremely aggressive environmental conditions, corrosion has emerged as the primary challenge. This persistent threat manifested in significant issues with the post-tensioning (PT) system during the early 2000s, necessitating substantial cost to rectify the deficiencies. In light of the bridge reaching its 37th year, the Florida Department of Transportation (FDOT) remains steadfast in their ambitious endeavor to to extend the bridge's operational lifespan to an impressive 100 years.

Recognizing this ambitious objective, FDOT has astutely acknowledged that traditional, reactive maintenance approaches are insufficient for such a challenging task, and in collaboration with engineering consultant T.Y. Lin International (TYLin), has adopted innovative methodologies and cutting-edge practices, with a particular focus on Data-Driven Preventive Maintenance. The utilization of data-driven preventive maintenance not only enhances the bridge's current structural health but also positions it to successfully navigate the challenges of the future. As the bridge continues to gradually age, these initiatives underscore a commitment to safety, longevity, and the seamless functionality of this iconic structure for generations to come.

Figure 1. The Sunshine Skyway Bridge.

2 STRUCTURAL MONITORING

The structural monitoring system in this bridge encompasses a diverse array of structural sensors, incorporating accelerometers, displacement sensors, strain gauges, GPS units, weather stations, acoustic sensors, water sensors, and thermocouples. This comprehensive suite comprises nearly 100 sensors, with an ongoing commitment to expanding this network by installing additional sensors annually, see Figure 2. These augmentations are thoughtfully tailored to meet the evolving monitoring requirements of the bridge, ensuring a dynamic and responsive approach to safeguarding its structural integrity.

2.1 *Accelerometers*

The accelerometers are tactically placed at three general locations, the top of the tower, the stay cables, and the interior of the superstructure.

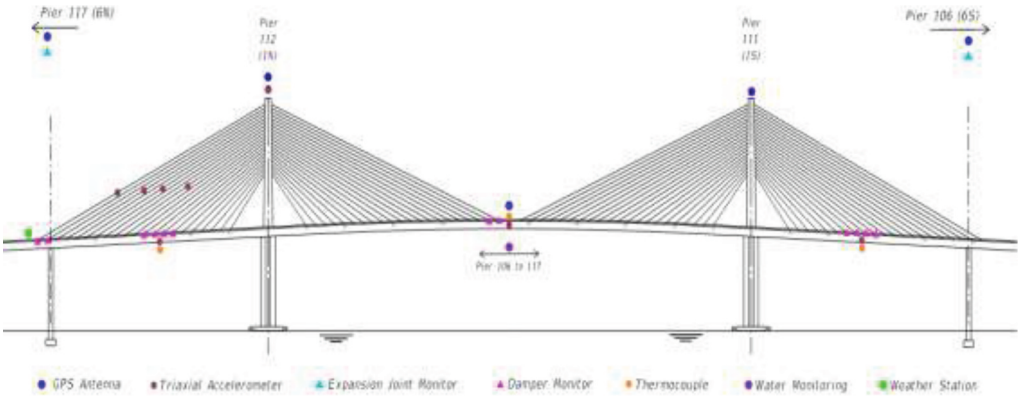

Figure 2. Location of structural monitoring sensors.

2.2 *Stay cable and tower accelerometers*

Presently four stay cables are instrumented with triaxial MEMS accelerometers. These accelerometers are installed on the top side of the cable and located about 15.2 m above deck level. They have a 100Hz sampling rate and a 16-bit resolution at +/- 2g scale. The cable accelerometers are wired to a data logger housed in a cabinet located in the median of the bridge.

Consistency in monitoring technology is maintained using the same triaxial MEMS accelerometers as were installed on the stay cables and at the summit of the north tower in 2016.

2.3 *Deck accelerometers*

Deck accelerometers have been tactically placed at critical points including the center of the main span and the center of the two back spans. Installed between 2021 and 2023, the specifications are: Triaxial MEMS accelerometers with 16-bit resolution, and a 50Hz sampling rate. These accelerometer units are portable, and real-time communication is obtained through an embedded 5G cellular modem. The raw accelerometer data is compressed using an algorithm that allows compression rates of 30x.

Additionally, these accelerometer units are equipped with a triaxial gyroscope, enabling the measurement of angular velocities along three axes. This gyroscopic data is particularly crucial for monitoring torsional vibration modes.

2.4 *Expansion joint monitoring*

The expansion joint monitoring sensor provides real-time measurements of joint movement with a high resolution of 0.1mm. The system, equipped with redundant sensors, can capture absolute values, not just differentials from reboot time. It features acoustic monitoring for continuous noise level surveillance in the joints. Another highly innovative aspect of these sensors is the incorporation of on-demand video, enabling visual confirmation of alarms and time-lapse capabilities for the joint system as shown in Figure 3. The system operates on a cellular basis through an embedded 5G cellular modem.

Furthermore, the system integrates thermocouples to monitor internal temperature, advantageously placed at the top slab, web, and bottom slab of the box girder. These temperature sensors are positioned at the midspan of both the main span and the back spans.

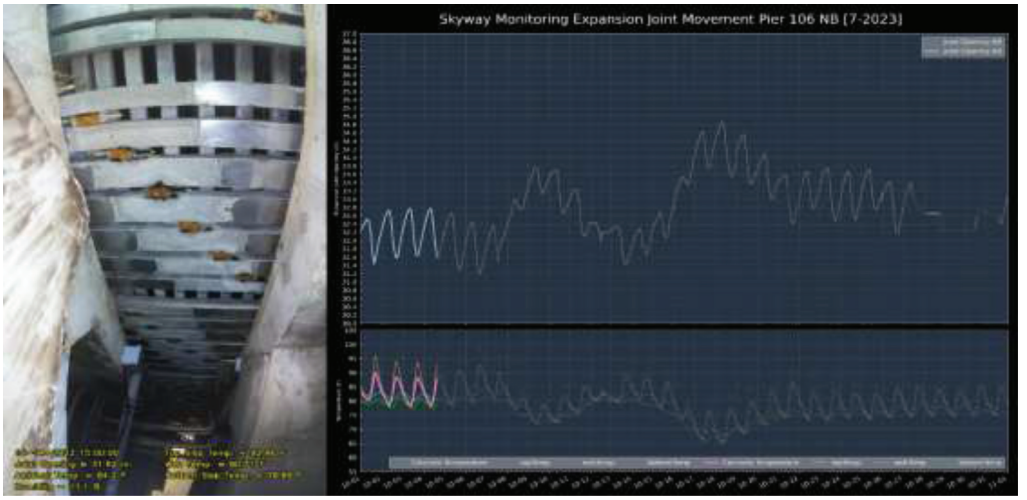

Figure 3. Example of joint timelapse video and movement and temperature plots.

The joints, situated at the ends of the 1,219-m main span unit, are 61-cm, 20-ton, modular joints replacements for the original joints, which were replaced via emergency contract in 2004 due to premature damage. The current joints have been in service for 19 years.

2.5 *Cable damper monitoring*

The stay cable dampers consist of two damper sets at each end of each cable, each set consisting of three damper shocks situated within the interior of the superstructure. These dampers are connected to the stay cables through two struts, linking to the cables approximately 1.5 m from the top of the median slab.

At present, monitoring systems are integrated into 12 stay cables, specifically targeting the cable dampers. They operate in real-time, capturing the movement of the dampers with an impressive 0.1 mm resolution. The sensors operate at a sampling rate of 5 Hz and offer a maximum amplitude range of 5 cm, providing detailed insights into the dynamic behavior of the cable dampers.

2.6 *Water presence monitoring*

Water presence near PT tendons has persistently posed challenges in this bridge, prompting the incorporation of a water monitoring system. To address the expansive coverage needed, wireless IoT water presence sensors were deployed. These sensors operate on a plug-and-play basis, facilitating placement at any location with power access, instantly initiating the reporting of water presence conditions to a gateway unit. Designed with measures to prevent electrical currents from accelerating corrosion on bridge components, the 20 installed sensors are purposefully placed in areas prone to water intrusion. The system's flexibility allows for seamless integration of additional wireless sensors as needed.

2.7 *Future sensors*

2.7.1 *Midspan deflection*

We are currently developing a real-time deflection monitoring system for the bridge's main span, designed to meet specific criteria: suitability for long spans, high resolution (up to 0.1mm), high accuracy (+/- 2 mm), real-time readings at a 2 Hz sample frequency, and no

long-term drift in deflection readings. Notably, this system does not require a clear view of the sky, allowing it to be entirely housed within the bridge. Additionally, its accuracy remains unaffected by structural vibrations, severe weather conditions, or space weather phenomena like solar storms.

This system empowers us to track changes in the main span deflection resulting from daily temperature variations and live loads. The high resolution and sampling frequency enable monitoring of low-frequency oscillations as well. By focusing on mid-span deflection with these specifications, we can promptly identify unexpected structural changes, offering valuable insights into potential issues with stay cables or live load overloads.

2.7.2 *Stay anchor strain gauges*

As part of a pilot program, we will monitor strains and stresses at the stay cable anchor block spacers. While these sensors won't provide stay cable tensions directly, they offer a precise method to track changes in stay cable tensions since installation. This monitoring system represents the optimal approach for promptly detecting any sudden changes in stay cable tension, particularly in response to strand or cable failures.

3 DATA EVALUATION

3.1 *Data collection and presentation*

Data from various sensors is transferred through either a fiber optic network or a 5G cellular network, reaching a Microsoft Azure cloud server. Next, decimated data is presented on a web interface. Simultaneously, raw data files are automatically uploaded to TYLin servers for additional post-processing. All systems are equipped with programmed sensor alarm trigger levels, ensuring that SMS text messages are promptly sent when alarms are triggered.

3.2 *Postprocessing*

The gathered data undergoes evaluation, and a comprehensive report is furnished to the FDOT on a monthly basis or following significant events, such as severe weather occurrences.

The raw data acquired from accelerometers is presented as acceleration time history, denoting changes in the acceleration of the member over time. While this data alone may not yield extensive insights into structural behavior, additional processing unlocks valuable structural parameters.

Initiating the data processing, the first step involves normalizing raw acceleration magnitudes. This normalization is imperative due to variations in acceleration axes over time, induced by minor shifts in accelerometer orientation caused by the thermal movement of the structure. To achieve normalization, the mean of a 500-point moving average is subtracted from each data point, resulting in an acceleration time history centered over the 0g axis.

The normalized acceleration data is further transformed into a frequency domain plot using the Fast Fourier Transform algorithm applied to a 10-second time slice. The frequency domain plots illustrate all frequencies present in the data slice, facilitating the identification of the most predominant frequency. These dominant frequencies are tabulated for each slice, and the collective frequency distributions for a given time are depicted in a histogram for each member and evaluated time period.

Crucial to structural assessment is determining the extent of cable, tower, or deck movement during wind-induced oscillations. However, this calculation is complex, and the derived value is considered an estimate. The peak to peak displacement (amplitude x 2) is computed by applying sinusoidal motion equations, establishing a relationship between frequency, acceleration, and amplitude using Equation 1 below.

$$D = \frac{G * A}{2 * \pi^2 * F^2} \tag{1}$$

where: D= Displacement (m), A= Max acceleration (g), F= Oscillation frequency (Hz), G= 9.8066 m/s^2

To apply the equations accurately and obtain precise estimates, it is crucial to isolate low-frequency oscillations and eliminate high-frequency vibrations from the data. This is achieved through the application of a low-pass filter, effectively removing frequencies higher than 2 Hz from the signal. Subsequently, the displacement equation is applied to the filtered signal. The low-pass filter is implemented by excluding frequencies above 2 Hz from the frequency domain, followed by signal reconstruction through the inverse FFT algorithm in the time domain.

The scale of postprocessed raw data in this evaluation is substantial, with each channel generating approximately 17 million data points daily. Given the immense size of the datasets, conventional data processing applications proved inadequate for handling this volume, necessitating the utilization of "Big Data" procedures implemented in the versatile computer programming language, Python.

In light of the complexity of the post-processing algorithms and to enhance confidence in the results, a decision was made to validate these scripts using computer-generated signals with predetermined parameters. The signals (acceleration vs. time) underwent processing using the same scripts employed for raw data, and the output was meticulously compared with known signal parameters. This iterative verification process continued until the analysis output was consistently aligned with the known parameters.

As shown in Figure 4, the output data is presented comprehensively in a summary plot, showcasing acceleration, frequency, amplitude, wind speeds, and directions (arrows). Following this summary plot, additional plots depict histograms of frequency distribution and 10-second snapshots illustrating the 10 maximum amplitudes and accelerations. These snapshots serve as visual verification of the data presented in the summary plots, enhancing the interpretability and reliability of the results.

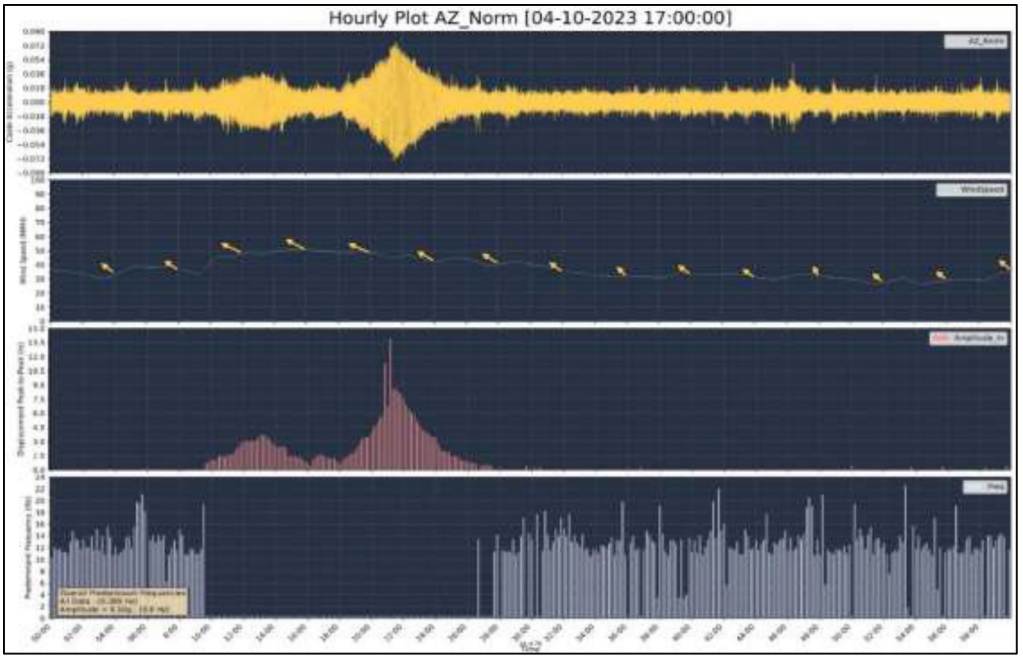

Figure 4. Example of deck accelerometer post-process data during a high oscillation event.

4 DATA-DRIVEN PREVENTIVE MAINTENANCE

Bridges are vital components of transportation networks, necessitating robust maintenance strategies to ensure their longevity and structural integrity. Traditional maintenance approaches often rely on reactive responses to issues, leading to increased costs and potential disruptions. The emergence of data-driven preventive maintenance presents a revolutionary approach, where the power of data analytics is harnessed to predict, prevent, and address maintenance needs proactively. Data-driven preventive maintenance revolves around the continuous collection, analysis, and interpretation of various data sources related to bridge health. This includes structural data, environmental conditions, traffic patterns, and historical performance records.

The objective of data-driven preventive maintenance is to proactively identify potential issues before they escalate, enabling timely interventions that mitigate risks and extend the service life of the bridge. To achieve this objective, a series of impactful measures have been implemented, including:

4.1 *Stay cable service life evaluation (fretting analysis)*

The Skyway Bridge employs a unique saddle system for attaching cable-stays to the towerhead. In this system, the strand bundle constituting each cable is guided through a steel cable saddle, rather than being terminated with an anchorage in the towerhead. The saddle configuration of the strand bundle introduces radial forces resulting from the curvature of the cable bundle as it passes through the tower resulting in fretting stress.

The assessment of stay cable service life, specifically focusing on fretting analysis, involves utilizing collected cable acceleration data to measure oscillation cycles. A complex analysis to determine fretting stress on the cables was conducted in 2019 but there wasn't sufficient data to conclude the study. This measured data provides a more accurate input for cable fretting evaluation, surpassing the previous estimation derived from wind studies. Additionally, the data gathered from damper monitoring and cable accelerometers contributes to obtaining an improved estimate for the cable damping ratio, a pivotal input in the fretting analysis. The integration of these data sources enhances the precision and reliability of the evaluation process, leading to more informed insights into the service life of stay cables.

4.2 *Cable damper service life and replacement evaluations*

Cable damper monitoring provides an estimation of structural damping for the cables, specifically obtaining the 1st Mode Damping on all cables. Employing the free-vibration method, we systematically excite the cables, recording decay traces of their motions. The estimation of structural damping incorporates corrections for ambient aerodynamic damping, ensuring a comprehensive analysis.

Next, we calculate the Scruton Number (Sc) for each cable and mode. This dimensionless parameter in structural dynamics serves to quantify damping efficiency by comparing the viscous damping in the system to the critical viscous damping. A higher Scruton Number indicates more effective damping relative to the critical value. This characterization proves essential for understanding the structure's response to dynamic loading, particularly in vibration analysis.

Efficient damping is paramount for controlling vibrations and mitigating resonance-related issues in bridges. Damper monitoring helps determine actual operation parameters in the field (amplitude and frequency of oscillations), these parameters will be used in the lab for testing of the dampers and to determine the remaining service life and replacement.

4.3 *Water intrusion detection and repairs*

TYLin has designed and placed moisture detection sensors in various areas within the box girders. If water is detected, the system triggers a real-time alert, notifying FDOT instantly via text and

providing an accompanying image of the identified moisture. This timely notification prompts the owner to take immediate action, initiating a thorough inspection and assessment to pinpoint and address the source of the detected moisture. Leaks typically occur through cracks, joints, sealant failures, or other openings. Identifying these entry points is crucial for effective remediation. This may involve repairing or replacing damaged sealants, addressing joint deficiencies, and ensuring that expansion joints are functioning properly. Concrete repair consists of patching or replacing concrete elements and applying waterproofing materials to prevent further moisture penetration. By following these steps and tailoring the approach to the specific conditions of the segmental components of the Skyway Bridge, we reduce the need for frequent and expensive physical inspections. This enables us to assess the efficacy of past water intrusion repairs, systematically address leaks, uphold structural integrity, and ultimately improve overall performance and durability.

4.4 *Expansion joint monitoring*

TYLin has engineered comprehensive expansion joint monitoring systems for the main modular joints on each side of the main span unit of the Skyway Bridge. Due to the complexity of the joints, relying solely on expansion-contraction measurements may not be sufficient to identify broken components within them. The presence of damaged components poses a heightened risk to both the segmental boxes and, more significantly, the entire modular joints. This situation can potentially result in significant expenditures, as exemplified by the emergency replacement in 2004. To enhance our monitoring capabilities, alongside the expansion joint movement monitors, we have seamlessly integrated acoustic monitoring devices on the modular joints. This additional layer of monitoring enables the prompt identification of any broken components within the modular joint system through the analysis of sound. We received a recent alert signaling a loud noise emanating from the south expansion joint. Subsequent inspection revealed that failing modular joint bearings were the root cause, resulting in the system producing high-decibel sounds. In response, FDOT has promptly scheduled a repair for the joints, which will involve the replacement of the bearings within the joint to ensure proper and effective functionality.

4.5 *Finite element model (digital twin)*

In the maintenance of complex bridges, the development and implementation of a finite element model (FEM) is an indispensable tool for structural assessment and bridge preservation. The FEM, currently in progress, serves as an accurate representation of the as-built structure. By assimilating data collected from an extensive network of sensors strategically placed throughout the bridge, the FEM becomes a dynamic and evolving *digital twin* of the bridge capturing the intricate nuances of structural behavior.

The digital twin, born from the refined FEM, serves as a virtual counterpart to the physical bridge. This virtual representation not only mirrors the current state of the structure but also facilitates real-time monitoring and analysis of its dynamic responses. The digital twin becomes a powerful tool for comprehending the bridge's behavior under diverse conditions, allowing for predictive insights into potential stress points, vulnerabilities, and the overall health of critical components.

The digital twin will be essential for proactive maintenance and precise assessment of structural integrity. This approach enables a deeper understanding of the bridge's response to external forces, aids in predicting potential wear and tear, and provides invaluable data for gauging the remaining service life of critical components like stay cables and stay cable dampers, ensuring optimal performance, longevity, and safety of the structure.

5 CONCLUSION

In conclusion, the integrated structural monitoring system and data-driven preventive maintenance approach underscore a comprehensive and forward-thinking approach to bridge management for the Sunshine Skyway Bridge. The dedication to harnessing data as a valuable

resource reflects the management's commitment to ensuring optimal performance, longevity, and safety of this iconic structure.

The deployment of custom-built modular sensors emerges as a pivotal tool for precise and nuanced data collection, enabling a deeper understanding of the bridge's dynamic behavior. This tailored approach to sensor technology positions the monitoring system as a cutting-edge solution for gathering critical insights into structural health.

A key takeaway is the recognition of data's intrinsic value in reaching strategic decisions for bridge management. Leveraging this valuable resource allows for proactive measures that not only address current challenges but also contribute to extending the remaining service life of the bridge. This calculated utilization of data positions the Sunshine Skyway Bridge as a benchmark for the effective and sustainable management of complex bridge structures.

In essence, the continuous improvements in the monitoring system, alongside the commitment to data-driven strategies, position the Sunshine Skyway Bridge as a model of excellence in the realm of bridge management. This achievement is manifest evidence that the accumulation of mere data is not just information, but a powerful tool that can enhance the longevity, safety, and optimal performance of complex bridge structures.

Sustaining structural bearings – assessment of renovation design on Storebælt West Bridge

A. Smyth, D. Lang, J. Fogh-Svensson & N. Grønkjær Rasmussen
Rambøll Danmark A/S

M. Duus Havelykke & F. Raun Gottfredsen
A/S Storebælt

ABSTRACT: The Great Belt Fixed link is an 18 km combined road and rail link composed of a tunnel, suspension bridge and a 6.6 km long continuous multi-span concrete box-girder bridge, the Storebælt West Bridge. The Great Belt Link is the only railway connecting the Danish main islands of Zealand and Funen, which later connects to Jutland, forming a vital piece of infrastructure between Sweden and central Europe.

A total of 276 structural bearings support the two box-girders of the Great Belt West Bridge, one each for road and rail. In a collaboration between consultants from Rambøll and the owners Sund & Bælt, a bearing renovation/replacement program has been initiated to ensure the overall health of the structure, as the service life of the bearings is significantly lower than the 200 expected years of lifetime for the concrete structures.

Due to the scale of the structure and the quantity of bearings, a strategic digital-enabled maintenance program integrates a thorough inspection regime with permanent structural health monitoring providing the basis for detailed condition assessment of the bearings. Through these activities, the basis of a holistic maintenance program for renovation/replacement of the bearings is established, being carefully developed to minimize traffic disruption.

The challenge of undertaking precise renovation work in harsh sea conditions encompasses several disciplines: innovative design of temporary structures, mechanical and electrical design, and hydraulic bridge lifting, while incorporating effective IKT and risk management. A detailed concept development for the bearing renovation/replacement work is supported by 3D finite element models of temporary/permanent structures, as a vital means to examine key details and the effects of renovation work. This is further addressed by a planned test lifting and bearing replacement to assess the developed strategies and concepts before full scale implementation.

1 INTRODUCTION

1.1 *Background*

The two 6.6km bridges are each comprised of 6 box girders approximately 1.1km each in length, supported by a total of 276 bearings, allowing expansion and contraction of the girders due to thermal effects by approximately +/-170mm over the course of a year. The structural bearings must also support significant dynamic loads applied by vehicles and trains, as well as strong winds. This is to ensure that forces are not significantly transferred to the slender piers supporting the structure.

DOI: 10.1201/9781003483755-380

1.2 *Structural bearing function*

The pot bearings each support loads up to 48 Meganewton in the vertical direction, while allowing the superstructure to rotate through deformation of a rubber pad contained within the steel pot base plate. Under these significant loads, the pad acts like a liquid with a resilient plastic seal around the pad designed to prevent the pressurized rubber escaping.

To allow horizontal movement, the top plate is designed to slide against the PTFE material in the piston – the surface of the PTFE containing recesses, which retain special grease used to maintain an ultra-low friction coefficient throughout the lifetime.

The side restraints prevent significant transverse movement occurring, restraining against various loads such as high winds and even ship impact, while still allowing low friction sliding between the top plate and piston through composite sliding interfaces.

The top plate and base plates are bolted to corresponding anchor plates, which are embedded within the concrete structures.

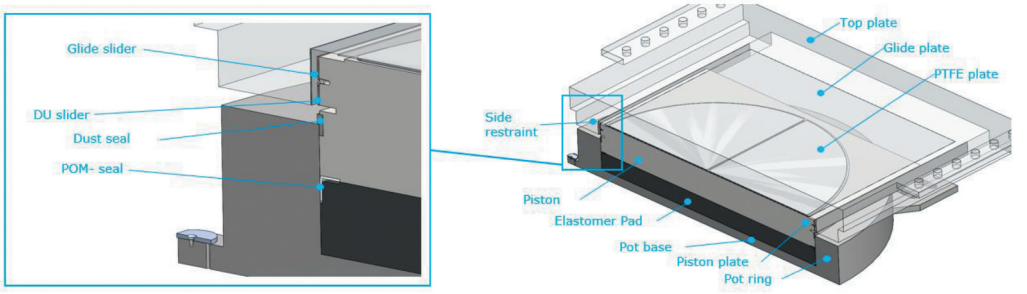

Figure 1. A model of one of the typical pot bearing designs used on the structure recreated in 3D CAD.

2 BEARING CONDITION MONITORING

2.1 *Overview*

Storebælt have in place a robust, digitally-enabled strategic inspection plan, which utilizes a live measuring system, *Konmos,* supplemented by regular physical inspections of the bearings, with additional focused measurements within key areas.

2.2 *Konmos monitoring of bearings*

The movement monitoring system installed on the bridge in 2017, provides live data and analysis of horizontal, vertical and rotational movements of the superstructure at many bearing locations, typically those at the expansion joints that experience the largest movements, as well as temperature and wind sensors throughout the bridges. This is a powerful tool to verify that the structure and bearings are performing as expected, and providing any warning to problems before they develop. For example, a clear correlation between bridge temperature and expansion of the bridge can be seen and continuously monitored. It can also be used to assess the condition of components that might not be possible through a physical inspection, such as checking the rotation of the elastomer pads, which cannot be visually inspected. It provides interesting information on the nature of the bridge movements, indicating how the faster movements of the rail bridge can contribute to higher wear rates of sliding components.

Figure 2. One of the bearings with the horizontal translation monitoring equipment installed. In addition, several other movement sensors are installed including inclinometers to measure bearing rotation.

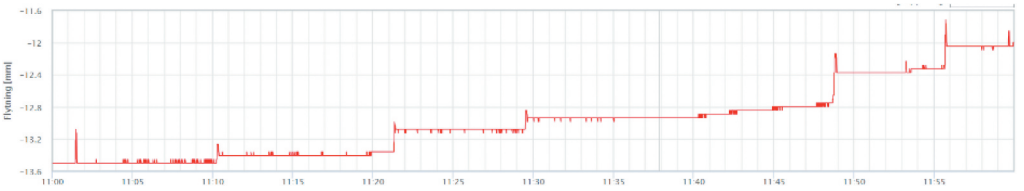

Figure 3. Example of 10hz data reading of longitudinal translation of one bearing close to the expansion joints, supporting the rail bridge. The sharp movements can be attributed to a train passing, which releases frictional forces, enabling the bearing to translate due to thermal expansion.

2.3 *Structured physical inspection*

The Konmos monitoring data supplements physical inspections, which are strategically planned with routine yearly inspections of each bearing, as well as targeted detailed measurements of key wearing components taken at set intervals. Two important checks encompass measuring remaining thickness of the PTFE sliders and measuring any damages to the sliding plates, to ensure there is minimal resistance to the bearing sliding. The damages to the sliding plates can be brought on by corrosion to the steel. An important element to the inspection is to understand when maintenance or remedial steps are to be taken to combat corrosion induced damages. Applying a numerical value to this during inspection, stored digitally and updated annually, enables us to build up data on wear patterns, which can inform future maintenance.

Figure 4. (Left) Example of the well-maintained paint system with protective covers designed to prevent corrosion within the bearing. (Right) Weathering to paint within the bearing can occur, with potential future damages to critical sliding components identified.

2.4 *Condition reporting*

The condition reporting of the bearings is made annually, with an assessment made of the remaining lifetime of each bearing. This is carried out by comparing measurements from previous years in order to establish a rate of wear. Typically, it is found there is accelerated wear on the sliding PTFE plates and an increase in corrosion to bearings near the end of the bridge, closer to land. This increased deterioration due to corrosion is attributed to their proximity to seawater, making them more vulnerable to the effects of salt and water spray. In contrast, bearings on the longer, central piers exhibited less wear. The hypothesis is that these slimmer piers flex more under the frictional bearing loads, with the soil beneath the piers undergoing some rotation of the superstructure. In this case, the piers themselves could be moving slightly instead of the bearings, helping to explain the reduced wear rates on some of these bearings.

The lifetime analysis of the bearings indicates that over 100 bearings may require replacement within the next 20 years, and as such a renovation works plan was undertaken.

3 RENOVATION PLANNING

3.1 *Renovation scope*

Having identified that over 100 of the bearings could require renovation, the challenge is how to carry this out. Structural bearings are assembled by specialists in a controlled environment. Renovation of the bearings is possible, but to carry out any meaningful works to sufficient quality on the piers themselves is near impossible. It was deduced that the bearings should be taken off site and either replaced with new ones or renovated.

Both methods can result in the same quality, also allowing for an improvement in performance and wear lifetime by upgrading the material of wear-prone components to more modern standards.

In order to undertake this renovation, some significant challenges must be overcome.

- Lifting the bridge
- Access to the work area
- Removing and replacing the bearings
- Sustainable renovation
- Renovation quality and efficiency

3.2 *Lifting the bridge*

3.2.1 *Hydraulic jack arrangement*

It is necessary when replacing structural bearings to first transfer the load of the structure off the bearings, and this is accomplished by a carefully controlled load transfer onto hydraulically activated jacks. The lifting itself is, likely a maximum 10mm vertically is to be carried out within a few hours overnight with reduced traffic on the bridge. After this, the jacks are mechanically locked which increases their vertical capacity and enables normal traffic to run over the bridge during the work. With the bearings removed, the hydraulic jacking arrangement is designed to mimic the characteristics of the structural bearings, thereby maintaining the dynamic stability of the bridge. These jacks are designed to accommodate movements within the structure while simultaneously restricting transverse motion. This capability is crucial for countering lateral forces such as high winds, braking forces, uneven vertical loads, and even potential ship collisions, ensuring the bridge's safety and structural integrity in this temporary phase. The original designers took this process into account, ensuring that there was adequate space to install these. This is often not the case with many older structures, which can result in a complex and expensive process to lift the structure, due to the lack of design provisions for hydraulic jacks in the original design.

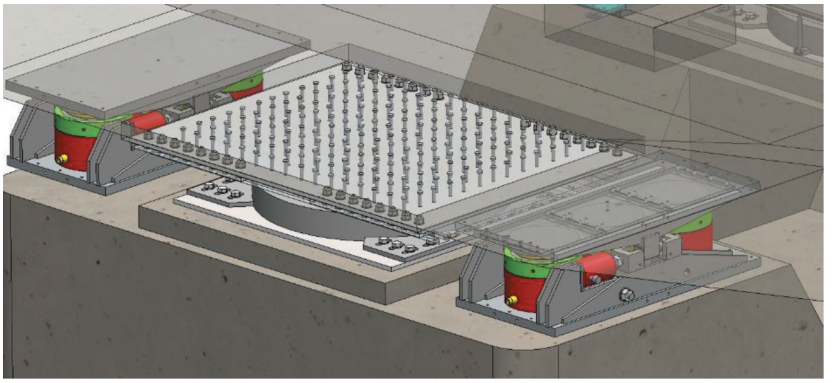

Figure 5. A 3D-CAD arrangement of 6 x 900-ton hydraulic jacks required to support the load bridge deck and act as a temporary bearing during replacement work for a typical pier. Built-in horizontal restraints around the jacking assembly restrain the horizontal bridge loads, with horizontally orientated jacks also allowing the structure to be re-aligned transversely during bearing replacement.

3.2.2 *Finite element analysis*

A global FE-model of the bridge has been developed to help assess the different possibilities regarding the jacking order. The FE-model was used to assess whether the girders could be lifted on one or both sides.

The bearing replacement process involves transferring the load of the superstructure onto hydraulic jacks. Rambøll's finite element analysis revealed that the superstructure, especially the slender railway bridge, subject to significant dynamic loads, needs to be uniformly and smoothly lifted to avoid stress concentration on any one side. This analysis was crucial in rapidly evaluating the different pier geometries.

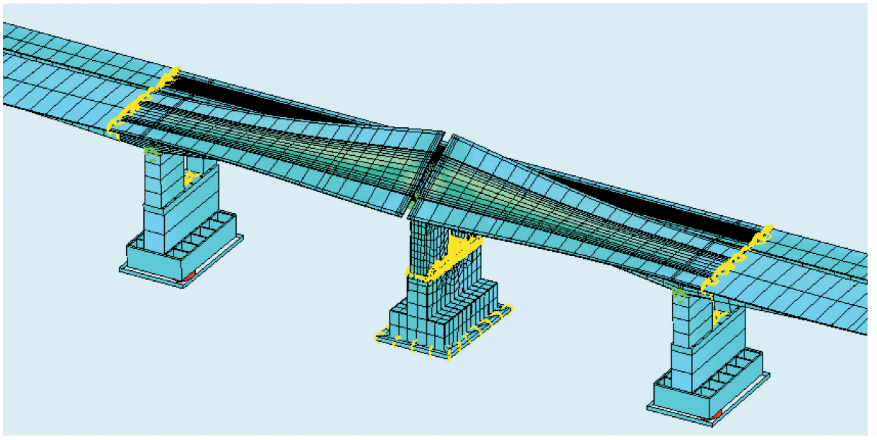

Figure 6. Example of twisting deflection that could occur due to uneven lifting of the bridge deck and understanding their interplay, ensuring a safe and efficient lifting process.

3.3 *Access*

The design of the work platform for the bearing replacement project required balancing numerous considerations. It needed to be easy to install and move, while providing a secure environment for workers and materials under challenging environmental conditions.

The design had to accommodate different methods of bearing removal and replacement. 3D modeling of the process revealed that dividing the bearing into parts for removal was

impractical; instead, each bearing, weighing up to 7,800 kg, had to be removed and installed as a single unit.

This required the creation of specialized, robust mechanical systems for safe handling.

The work platform is designed as a lattice girder, on which a work area is established around both piles with the help of beams and fiberglass sheets, as well as enabling the transport of the bearings across the bridge. The platform is cantilevered to the south in relation to the pier on the road bridge. The cantilever enables the platform to be lifted into place on the pier top from a barge, using two cranes on the road bridge. Bearings and other equipment can be lifted onto the road bridge beyond the southern edge beam using a crane positioned in the emergency lane. Due to the size of the bearings, it is not possible to lift them up between the two bridge girders, which is why they must be lifted over the southern edge beam of the road bridge. The work platform is designed to be able to carry 2 bearings at a time, to speed up the work process.

Figure 7. Lifting capabilities from the roadside onto a cantilevered platform. The opposing side contains a rail bridge with very limited access.

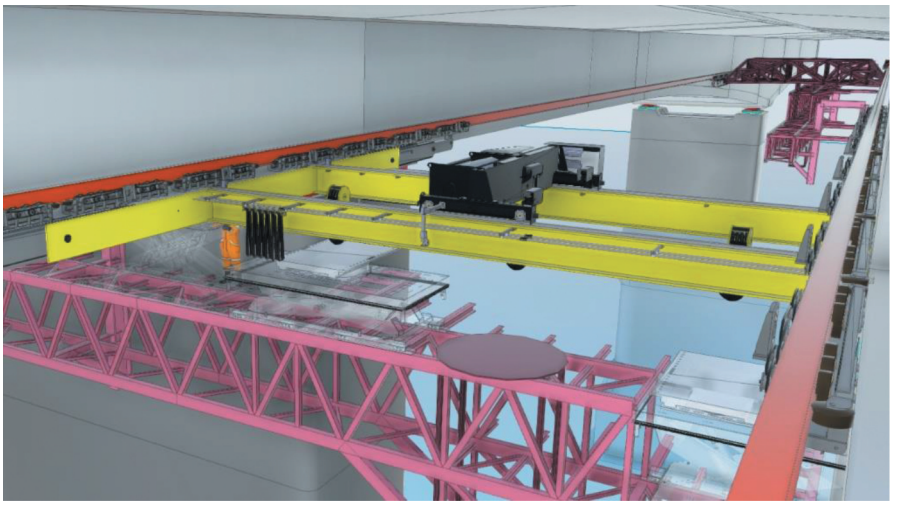

Figure 8. An innovative method was to utilize a current rail system that spans in between the 2 bridges, that can carry the platform and equipment as well as provide a lifting crane.

3.3.1 *Marine transport*

Another approach considered for the bearing replacement was using a specialist barge to move equipment between the bridge piers. A significant challenge in this method was the unpredictable weather. Rambøll conducted an extensive analysis of historical wave and wind data and, based on probability assessments, determined a feasible working window of six months.

The strategy involved employing a vehicular crane, positioned on a temporarily closed lane of the road bridge to lift the bearings from the road-side end of the platform and transfer them to and from the barge.

A lifetime cost analysis was conducted for both the platform and barge methods. One drawback identified in the bespoke mobile crane solution, was its high maintenance cost over its lifespan – a crucial factor to consider when determining the most cost-effective and sustainable approach.

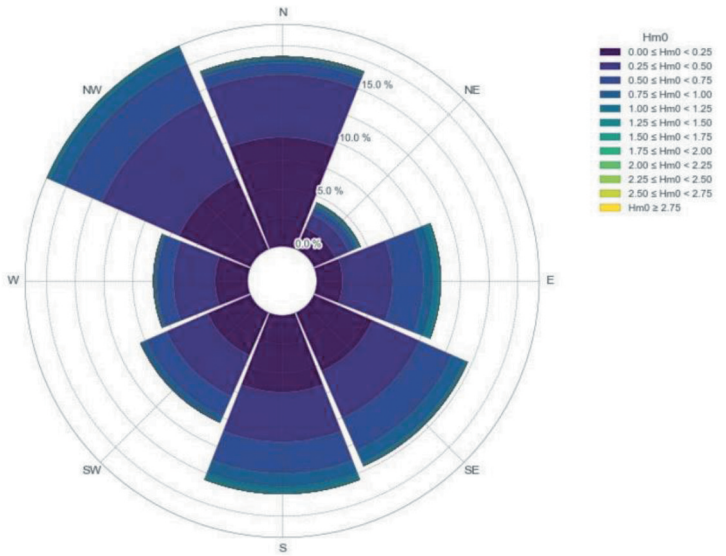

Figure 9. Wave level data for springtime, used along with wind data to verify when a barge transport can be used to move equipment.

3.4 *Renovate or replace?*

It was established that with suitable controls in place, a renovated bearing can attain the same lifetime expectation as a newly manufactured one. That is to say the mild steel, which comprises 98% of the weight, is renovated, while all other components are new.

The carbon emissions for the manufacture of the mild steel plates comprise over 95% of the overall emissions for manufacturing a bearing, including long distance shipping. For instance, manufacturing a single typical bearing, weighing around 7,800kg, is estimated to produce about approximately 37 tons of CO_2. To replace all 276 bearings with new bearings, 1000 tons of CO_2 could be produced – approximately equivalent to the annual emissions of 2,200 cars.

The decision comes down to time, financial and environmental costs. By establishing a work system in which one bearing is removed, immediately replaced, renovated and used at another location, it is possible to avoid any time wasted for renovations.

A financial and carbon emissions calculation is made comparing a program of mostly renovated bearings to that of bearings replaced with new.

A study of different levels of renovation for 84 bearings concluded that pursuing a strategy of mostly renovated bearings, as opposed to all new bearings, can yield a 60% decrease in carbon emissions overall. Crucially, the cost analysis demonstrated that this strategy also yielded an approximately 35% financial cost reduction.

4 CONCLUDING REMARKS

Sund & Belt's rigorous and ongoing maintenance program has been essential in maximizing the lifespan of the bridge bearings. Without this thorough upkeep, the bearings would have required replacement much earlier. A common characteristic of bearing replacement projects is that the cost of the bearing itself is relatively minor compared to the expenses involved in carrying out the actual work and replacement. Furthermore, the cost of carrying out a strategic maintenance program, is much smaller than any cost associated with early replacement or structural repair. Such a proactive approach in maintenance not only extends the life of critical infrastructure components like bearings, but also proves to be more cost-effective in the long term.

The study on how best to renovate the bearings is ongoing, and for a project of such scale as the Storebælt West bridges, advanced planning was important when considering the wide array of challenges associated with undertaking such significant renovations in a challenging environment.

ACKNOWLEDGEMENTS

This project's ongoing progress is by no means solely attributed to the authors of this paper. It is the result of collaborative, multidisciplinary contributions from a broad array of individuals. We extend our deepest gratitude to them for their significant contributions, whose expertise and effort has been invaluable.

Cause identification for uplifting behavior of truss bridges

K. Suzuki & Y. Nojima
University of Fukui, Fukui, Japan

K. Takeya, A. Akutsu, K.K. Vankayalapati, Y. Ito & E. Sasaki
Tokyo Institute of Technology, Tokyo, Japan

ABSTRACT: This research examines the vertical uplift behavior of a steel truss bridge and investigates the contributing factors. A thermal camera revealed that the temperatures of paint deteriorated areas were higher than those of paint remaining areas. A UAV and a still camera obtained the images of the upper and lower chord members to quantify the ratio of paint deteriorated area. Assumed member temperatures based on the degree of corrosion were input into the Finite Element Method (FEM) model, which confirmed up warping behavior consistent with experimental findings. Consequently, we concluded that paint condition differences influence member temperatures and vertical displacements.

1 INTRODUCTION

In the case of a steel truss bridge with deteriorated coating, it has been observed that the bridge exhibits static deformation, rising in the vertical direction as the temperature of its components increases. Depending on the level of this deformation, there is a potential impact on usability, which may cause discomfort to users of vehicles traveling at high speeds.

Murata et al. (1985) conducted measurements and simulations on a plate girder bridge with ballastless slab track on the Tohoku Shinkansen. They demonstrated that when the temperature difference between the upper and lower flanges of the main girder exceeds 10°C, the amount of vertical deformation of the girder reaches approximately 10 mm. Furthermore, they reported an increase in the vertical acceleration of the train body passing over the bridge corresponding to the amount of girder deformation. Kobayashi et al. (2006) monitored the deformation of bridge components due to temperature and temperature variations for over two years, focusing on a steel floor-beam box girder bridge. Daily temperature variations on sunny days were found to cause two-dimensional deformation, with the girder expanding vertically along with temperature rise. On days without sunlight, only one-dimensional deformation along the bridge axis was observed.

Nishikawa et al. (1992) reported that bending deformation due to temperature changes is not necessarily smaller than the influence of live loads. Hashimoto et al. (2015) investigated the temperature deformation behavior of a composite truss drawbridge with an SRC structure, elucidating the member stresses and vertical displacement behavior induced by temperature differences through both experimental measurements and finite element method (FEM) analysis. This suggests the existence of bending and vertical deformation behaviors, including the influence of sunlight.

The Road Bridge Design Specifications (Japan Road Association 2017) consider a relative temperature difference of 15 degrees between members or parts of members for steel structures, but specific details regarding the effects of temperature differences are not provided.

DOI: 10.1201/9781003483755-381

This study aims to elucidate the factors contributing to the uplifting behavior of a truss bridge, which manifests in vertical deformation. The analysis involves both actual measurements of the bridge's vertical behavior and simulations using the finite element method (FEM). The study comprehensively analyzes the temperature differences between bridge components using thermal cameras and thermocouples. Additionally, it verifies the coating condition of the upper and lower chord members on the truss using UAVs and still cameras, calculating the anticipated temperature differences between these members. The assumed temperature differences are then input into the finite element method to evaluate the bridge's response.

2 TARGET BRIDGE

The focus of this study is the bridge spanning the Kuzuryu River, referred to as the former Fuseda Bridge. Connecting Fukui City and Sakai City in Fukui Prefecture (Figure 1) in Japan, the bridge had a length of 559.6 meters. It was constructed in the year 1956 and remained in service for approximately 60 years until 2018. A new Fuseda Bridge has since been constructed approximately 200 meters upstream, taking over its role.

Table 1 presents various specifications of the bridge, and Photo 1 provides an external view. In this study, the upstream components are referred to as the south side, while the downstream components are designated as the north side. After the cessation of its use, in 2020, the truss bridge spans on the left bank, consisting of three simple curved-chord truss spans, had their deck removed. The specific span targeted in this study is the first span on the left bank, with a span length of 60.9 meters. The support system consists of four movable roller-type bearings on the bridge pier.

3 BRIDGE INSTRUMENTATION AND THE ACQUIRED DATA

3.1 *Bridge instrumentation*

The arrangement of each measurement device is illustrated in Figure 2, and followings explain the measurement detail.

[Contact Displacement Sensor**]** To measure the longitudinal displacement of the movable support, one displacement sensor was installed on the north side and another on the south side. The measurements were taken at intervals of 0.01 seconds.

Figure 1. Location of former Fuseda bridge.

Table 1. Bridge specifications of the former Fuseda Bridge.

Coordinates	36.146513N, 136.165087E
Constructed year	1956
Crosses	Kuzuryu river
Design	3-span simply supported lower truss bridge + 9-span RC Gelber girder bridge + 16-span RC simple T-girder bridge
Total length	559.6m

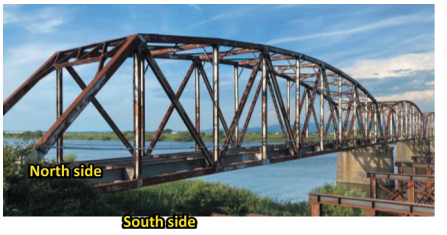

Photo 1. View of the former Fuseda bridge.

[Laser Displacement Sensor**]** For the purpose of measuring the vertical displacement of the bridge, laser displacement sensors were installed right beneath the panel point of the first vertical member and the sampling rate was 100Hz.

[Thermocouples, Thermal Camera**]** To measure the temperature of the structural components, thermocouples were installed at a total of seven locations on the upper chord, lower chord, and vertical members of the first panel. The thermal camera was positioned to cover the range shown in Figure 2. The sampling was done at 100Hz for thermocouples and at 30-second intervals for the thermal camera.

3.2 *Measurement results*

Figure 3 illustrates the temperature history of each structural component recorded from thermocouples during a 24-hour period from August 30th to 31st, 2022. Figure 4 presents the temperature and total solar radiation history recorded at the Fukui Regional Meteorological Observatory, located approximately 12.3 km away from the target bridge. The surface temperature of the main structure remained relatively constant at around 22.5°C during the early morning hours from 0 AM to 6 AM on the 30th. A slight decrease in component temperature was observed shortly after 6 AM, likely influenced by a decrease in ambient temperature. Subsequently, temperatures began to rise in conjunction with an increase in total solar radiation. The maximum total solar radiation was recorded at 11 AM, reaching a peak temperature of 29.6°C at 12 PM. In the afternoon, temperatures exhibited a declining trend, with a temporary increase around 4 PM.

The component temperatures peaked around 12 PM, with the south side of the lower chord exceeding 40°C. The lower chord experienced two peaks around 9 AM and 12 PM. The temporary decrease in structural temperature after 9 AM can be attributed to light rain during that period, causing a temporary drop in the structural temperature. It is noteworthy that the upper chord did not exhibit a peak around 9 AM. This discrepancy is attributed to the open U-shaped cross-section of the lower chord's underside compared to the closed cross-section of the upper chord, making the upper chord relatively less prone to temperature fluctuations.

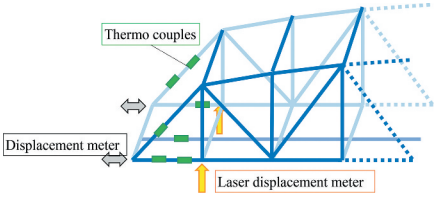

Figure 2. Bridge instrumentation.

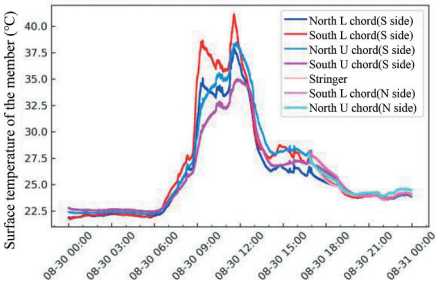

Figure 3. 24-hour history of member surface temperature.

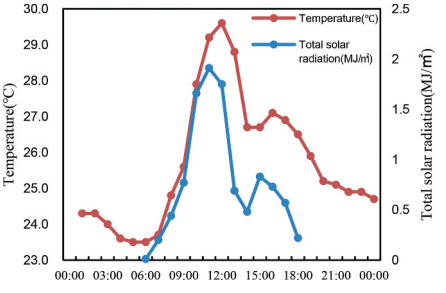

Figure 4. Temperature and total solar radiation (Fukui Local Meteorological Observatory).

Figure 5 illustrates a 24-hour history of the surface temperature, south-side support displacement, and vertical displacement of the south side lower chord and upper chord. The first vertical axis represents the surface temperature (°C), while the second vertical axis represents displacement

(mm). Horizontal displacements exceeding 7 mm were recorded in tandem with structural component temperature changes, indicating the functionality of the movable support's translational movement. Examining the vertical displacement reveals an upward movement with the increase in component temperature, resulting in a curvature of approximately 1 mm. Unfortunately, there is no record during the period between 1 PM and 2 PM due to equipment malfunction. Further discussion on the curvature phenomenon, including finite element analysis, will be undertaken.

The north side exhibited a similar trend, but due to recording malfunctions, the discussion will focus on the results from the south side.

Figure 6(b) displays the temperature distribution near the bridge pier of the first span captured by a thermal camera. Comparing this with the photograph of the corresponding location in Figure 6(a), it is evident that areas with well-preserved coatings have lower temperatures, while areas with deteriorated coatings and rust exhibit relatively higher temperatures. Similar trends are observed in Figures 6(c) and 6(d). This suggests a significant impact of rust rates on the surface temperature of the steel components.

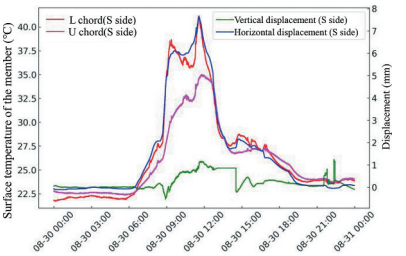

Figure 5. Truss member surface temperature and displacement history.

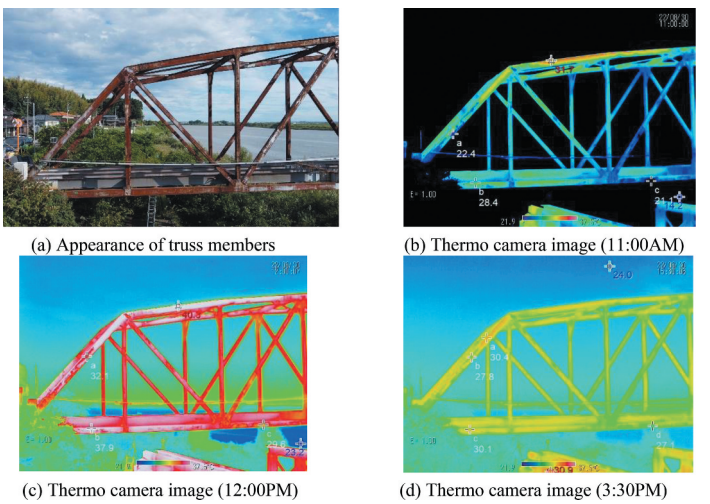

Figure 6. Comparison of thermo camera image and paint appearance.

3.3 *Estimation of rust rates for upper and lower chords*

The proportion of rusted area on the upper surface of the upper chord and lower chord materials was determined from captured images. A UAV was employed for the upper chord material, while a still camera was utilized for the lower chord material. As illustrated in Figure 7, the upper surface of the upper chord material exhibited a state where the coating had been lost, and it was covered with red rust.

Image processing was applied to calculate the surface rust rate (Figure 8). Initially, trimming was performed on the images to eliminate the background. Subsequently, using perspective transformation, the trapezoidal images were converted into rectangular images. Finally, binary processing of rust and coating was carried out, transforming the images into two colors: black (0) and white (1). Although the corrosion of steel progresses gradually, considering the dependence of member temperature difference on the occurrence of red rust based on thermal camera results, we decided to determine the rust rate through binary processing. The binary processing was performed using the OpenCV library in Python, with a threshold set at 120. As shown in Figure 9, the areas where red rust occurred and the areas where coating remained, as judged by the human eye, were generally distinguishable in black and white.

The rust rates for the upper chord and lower chord were calculated from the following equations:

$$\text{Rust Rate } (\%) = (\text{Sum of white regions})/(\text{Image area}) \times 100 \quad (1)$$

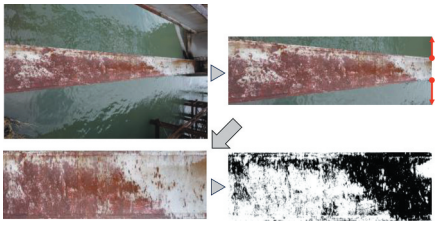
The averages for the first span were as follows: upper chord: 91.3%, lower chord: 33.2%.

4 SIMULATION OF THE INFLUENCE OF MEMBER TEMPERATURE DIFFERENCES ON STRUCTURAL BEHAVIOR USING FINITE ELEMENT ANALYSIS

4.1 *Analysis model*

To assess the influence of temperature differences in the upper and lower chord members on bridge response, a finite element method (FEM) model was constructed. The analysis model (Figure 10) consisted of approximately ten beam elements dividing the main members, using steel materials without material nonlinearity. Material properties are presented in Table 2. The model comprised 3071 linear elements and 3153 nodes, with simple support as the boundary condition. The model incorporated a camber to ensure the horizontal alignment of the lower chord under the condition of input gravity acceleration.

Figure 7. Appearance of the top chord taken by UAV.



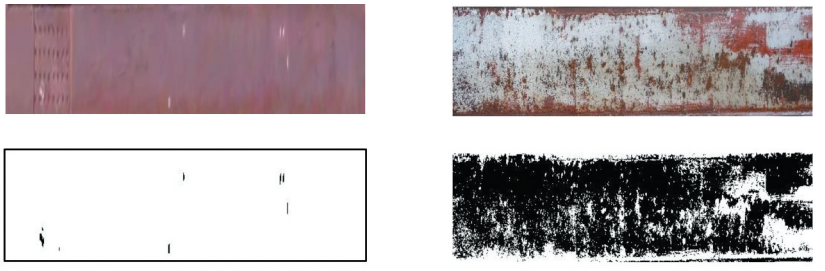


Figure 8. Image processing.

(a) Upper chord image binarization

(b) Lower chord image binarization

Figure 9. Binarization results.

4.2 *Input temperatures based on rust rates*

Assuming the highest temperatures of the members based on the temperatures obtained from thermal camera images, considering the rust rates, was performed to evaluate the impact. The applied formula (2) is presented below. The temperature difference between the measured surface temperature using thermocouples on 2022/08/30 0:00 and this calculated temperature was used as the input temperature for the FEM model.

$$\text{Assumed Temperature} = \text{Min} + (\text{Max} - \text{Min}) \times \text{r} \tag{2}$$

Where, Max=Temperature of rusted area; Min=Temperature of painted area; r=Rust rate.

Three models (A to C) were prepared based on rust rates, and structural responses were examined. Table 3 presents the rust rates and input temperatures. Model A represents the actual rust rate situation, where the temperature difference between the upper and lower chords is 3.7° C. Models B and C have smaller temperature differences between the upper and lower chords. Model B exhibits a condition where rust progresses at similar levels for both upper and lower chords, while Model C shows a state where both upper and lower chords have remaining coatings at similar levels. It should be noted that the input temperatures for vertical members and diagonal members in each model were set as the average values of the upper and lower chords. The upper lateral member had the same input temperature as the upper chord, while the stringer and floor beam had the same input temperature as the lower chord.

4.3 *Analysis results*

After inputting gravity acceleration, member temperatures were applied. Figure 11 illustrates the vertical displacements after temperature input for each Panel point of the upper and lower chords, as per Figure 10. Panel point numbers are as indicated in Figure 10, where Panel point 0 is on the abutment and Panel point 10 is on the first pier.

Table 2. Material specifications.

Density (kg/m^3)	7,850
Young's modulus (MPa)	205,000
Poisson's ration	0.3
Linear expansion coefficient (/°C)	1.17×10^{-5}

Table 3. Rust rate and input temperature of each model.

		A	B	C
Upper chord	Rust ratio (%)	91.3	91.3	33.2
	Input temperature (°C)	18.7	18.7	14.2
Lower chord	Rust ratio (%)	33.2	91.3	33.2
	Input temperature (°C)	15.0	19.5	14.5

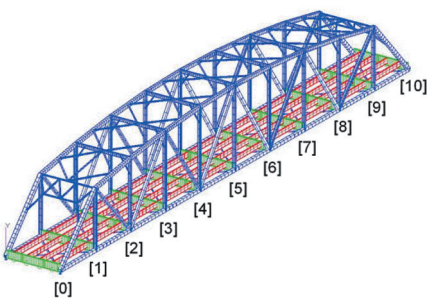

Figure 10. FE model.

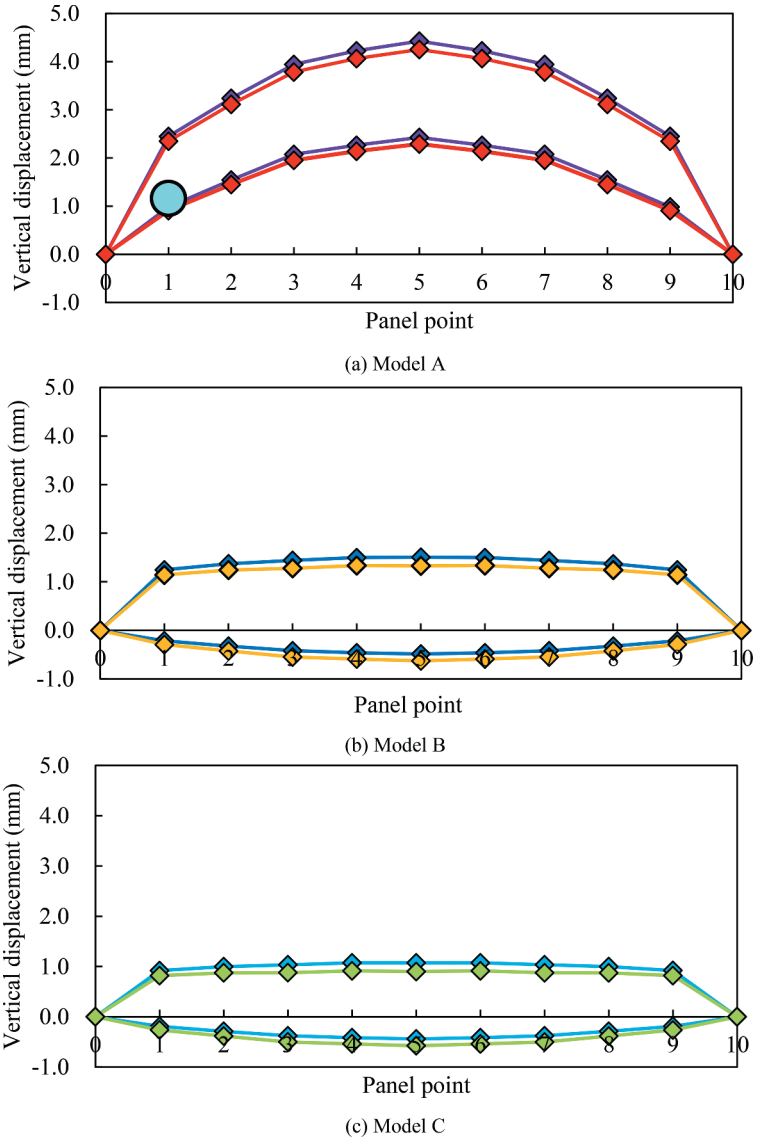

Figure 11. Vertical displacement at each panel point of the lower chord.

Firstly, Model A exhibits an upward deflection response, with the analysis result at Panel point 1 closely matching the measured value. When the temperature of the upper chord is higher than that of the lower chord, as in Model A, an upward deflection response can occur. Secondly, for Model B, there is almost no vertical displacement motion. The slight downward displacement of the lower chord is thought to be due to the elongation of diagonal and vertical members. Similarly, for Model C, there was almost no vertical displacement motion. Regarding this phenomenon, it is considered that the upper chord with a higher rust rate, as shown in Figure 12, is more easily warmed, causing greater elongation than the lower chord. This condition leads to an overall negative bending of the truss bridge, resulting in an upward behavior in the vertical direction. Conversely, if the temperature of the lower chord members is relatively higher than that of the upper chord members, the occurrence of downward deflection behavior is anticipated.

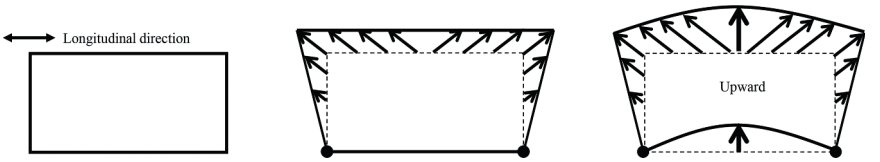

Figure 12. Assumed upward behavior due to temperature difference between upper and lower chord.

5 CONCLUSIONS

In this study, the deformation behavior of a truss bridge was analyzed from both measured results and Finite Element Method (FEM) simulations. The aim was to elucidate the factors contributing to the upward behavior of the bridge. The obtained insights are summarized as follows:

(1) Rusty areas tend to have higher temperatures, while painted areas exhibit lower temperatures. Additionally, the rust rate of steel members significantly influences the surface temperature of the members.
(2) Deterioration in the coating of the upper and lower chord members of the truss bridge leads to differences in the coating conditions, causing temperature differences in the members. These temperature differences, in turn, induce vertical movements in the bridge.

ACKNOWLEDGMENTS

We would like to express our sincere gratitude to the Fukui Prefecture Mikuni Public Works Office for granting permission for measurements, providing drawings, and offering substantial support and understanding. Special thanks to Mr. Takamura and Mr. Tagawa from the same office for their invaluable assistance.

ABSTRACT: Large-scale replacement projects for the restoration of old or heavily deteriorated expressway bridges, have recently become a major topic in Japan's bridge maintenance. In most situations, it is difficult to prepare ground-level construction yards for the demolition of existing viaduct bridges built in already urbanized areas. The degree of difficulty becomes even more severe when the replacement takes place directly above an intersection with heavy traffic. This paper will introduce an aerial-demolition method for an existing PC bridge that allows continuous uninterrupted vehicular traffic and pedestrian access on the ground even while the demolition is taking place. The feature of this demolition method is to complete all the demolition processes that take place above an intersection, such as cutting the bridge into small pieces, lifting them, and conveying them in the air, by using movable workstations, cranes hanging at or placed on the temporary girder laid over the bridge to be demolished.

1 INTRODUCTION

Hanshin expressway (HEX) is an urban expressway in the Osaka and Kobe area which is one of the most populated urban regions in Japan. Metropolitan areas in Japan had to build the expressways to pass through the large volume of car traffic demand. To build expressways in already urbanized and limited road width area, it was often necessary to adopt the bridge or viaduct structure. Kire-Uriwari bridge is one of the bridges in HEX which is 3-span prestressed concrete (PC) ramen box girder bridge (154 m) constructed by cantilever method in 1980 (Figure 1). The bridge is located directly above an intersection with heavy traffic, and the central hinge area drooped approximately 24 cm five years after its opening. For this reason, the bridge was pushed up and reinforced from the bottom side with outer cables in 2003. However, to achieve longer durability, a decision was made to replace the bridge in 2015, and the replacement work began in June 2022.

In this construction, an aerial-demolition method where most work processes are completed in air was adopted, so as not to obstruct traffic on the local roads directly below the construction site.

This paper describes the outline of the Kire-Uriwari bridge restoration construction and the progress of the demolition work of the existing PC bridge, together with the issues specific to this construction and the response to the issues.

Although there are multiple cases of demolition of existing PC bridges (Singh, S. et al. 2008, Kramer, W. et al. 2018, Daescu, C.A. et al. 2023), there are no other cases like this construction

DOI: 10.1201/9781003483755-382

where an aerial-demolition was carried out in an urban area so as not to obstruct the traffic on local roads directly below the construction site. This construction has novelty in terms of aerial completion type existing PC bridge with various constructional ingenuities. The knowledge gained from this is meaningful for the smooth progress of similar constructions in the future.

Figure 1. Kire-Uriwari bridge (before demolition, April 2022).

2 BUSINESS OUTLINE

2.1 *Examination for replacement method*

Regarding the replacement method of the existing bridge (Figure 2), the following methods were studied; Proposal 1: a method of temporary providing a detour route for both the in-bound and out-bound lines and then replacing the bridge, Proposal 2: a method of dividing the in-bound and out-bound lines of the existing bridge and then replacing the bridge while using either line, and Proposal 3: closing the expressway main roads and replacing the in-bound and out-bound lines by a single-operation. As a result of comparing them from the viewpoints of the effects on the surrounding areas, effects on traffic on the expressway and local roads and construction period, while taking in the opinions of experts, etc. We have determined to carry out the construction by adopting the method of Proposal 3 after taking countermeasure against the effects on the traffic.

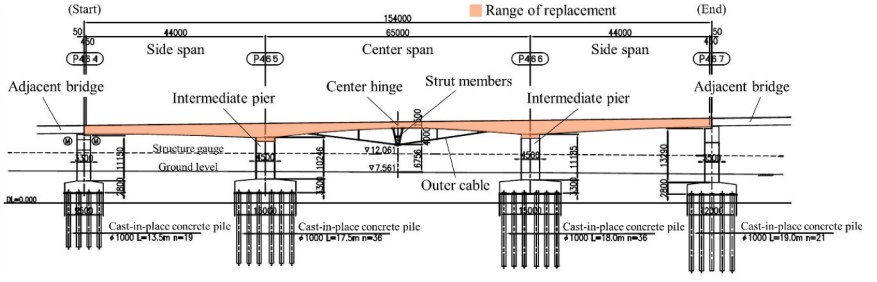

Figure 2. Kire-Uriwari bridge (side view).

2.2 *Construction procedure*

Figure 3 shows the construction procedure. For removal of existing bridge, first, erect a temporary girder with the total length of 165 m over the existing bridge ([1]). Next, install four movable workstations and two transport carts that can be moved in the bridge axis direction to the temporary girder. Then, cut out the bridge girder portion into blocks inside the movable workstations and carry them to the adjacent bridge by the transport carts ([2]). While conducting this process, remove the outer cables and the strut members under the

center hinge, then separately remove the upper portions of the two intermediate piers after removing the girder portion.

For erection of a new bridge, construct by a single-operation erection using multiple-axis carts ([3]: bridge pier portions), launching erection ([4]: side span portions), and lift-up erection ([5]: center span portions).

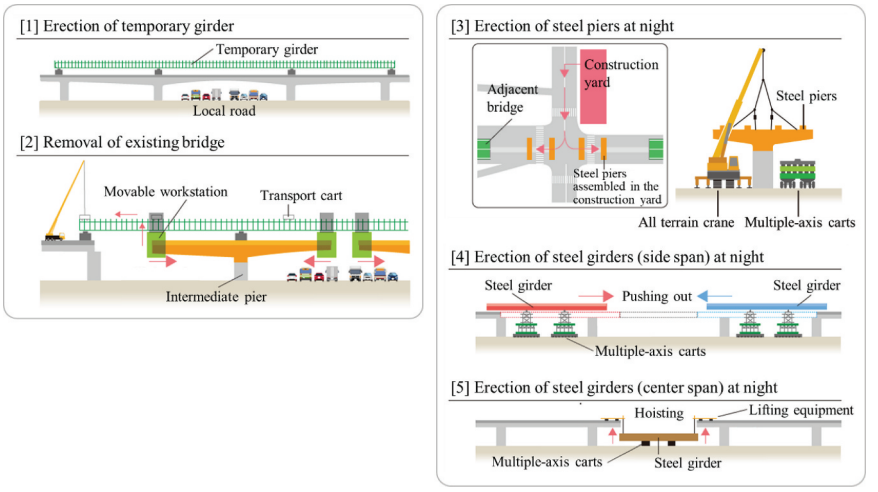

Figure 3. Construction procedure (left: demolition of existing bridge, right: erection of new bridge).

2.3 *Construction process*

Table 1 shows the overall process of this construction. We are planning to complete the removal of the existing bridge by approximately two years and the erection of the new bridge by approximately one year.

3 MAJOR ISSUES IN THE CONSTRUCTION

3.1 *Thorough implementation of countermeasures against effects on traffic*

Since this construction is carried out by closing the expressway main roads, we will not impose traffic restrictions by occupying any lane during daytime on local roads, so as not to put further load on the traffic on the local roads directly below the construction site. Work that unavoidably requires restriction will be carried out at night, while striving to minimize the range of restrictions.

3.2 *Work in limited construction space*

Work which takes place on the existing bridge, such as an erection of each member needs to be conducted within the limited width on the expressway. Even though the construction space

is extremely limited, falling objects are prohibited since the construction takes place directly above the intersection in use.

3.3 *Consideration of the proof strength of the existing bridge*

Regarding proof strength of the existing bridges (including the adjacent bridges in the area affected by the construction), safety must be absolutely ensured at all removal steps, including in the event of an earthquake. In addition, since the center hinge area is dropped, measurement control and fulfillment of safety equipment is necessary in preparation of unexpected circumstances.

3.4 *Consideration of the surrounding environment*

Residences and commercial facilities are close to this construction site, and it is especially necessary to pay attention to the work noise. The distance from the existing bridge to the nearest facility (apartment building) is approximately 15 m.

3.5 *Ensuring the processes*

Since we are aiming to complete this construction before EXPO 2025 Osaka, Kansai is held, it is necessary to steadily advance the construction while ensuring safety.

4 CONSTRUCTION PROGRESS AND RESPONSE TO THE ISSUES

4.1 *Removal of the pavement and median strips*

Since a large amount of equipment for demolition such as the temporary girder are going to be placed on the existing bridge, to reduce dead loads as much as possible, a secure construction yard was ensured, and pavement and median strips were removed in the first place. Low noise cutting machine (diamond wire saw) was adopted for the removal of the median strips.

4.2 *Construction of temporary girder*

The temporary girder is an important member for installing various equipment for removal such as movable workstations and transport carts and it is a steel girder with a total length of 165 m and a total weight of 1,286 tons composed of four box girders. For the assembly of the temporary girder, the members divided into 15 blocks were constructed by a vent method from above the center hinge portion toward the outer bridge axial direction using two 120-ton crawler cranes. Considering the proof strength of the existing bridge, the crane was controlled so that the loads are applied only on the main girder web. Especially around the adjacent bridge where it is necessary to consider the proof strength (P467), erection was progressed by dispersing the loads by adopting multiple-axis carts (Figure 4).

Temporary girder was supported by the four vents above the piers separately constructed at the pier positions (Figure 5). The gravity position of the temporary girder became higher by

Figure 4. Temporary girder erection status (left: the first block, right: the last two blocks on the end).

installing a work area (4 m high) between the bridge surface and the temporary girder for cutting and removal of the existing bridge. Therefore, to secure the overall seismic performance including the temporary girder, we corresponded to the issue by combining steel bars for PC and seismic rubber bearings.

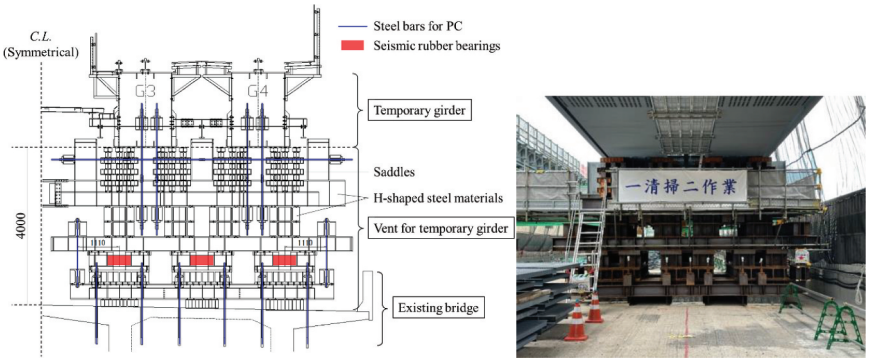

Figure 5. Temporary girder and vent above piers (cross-sectional view).

4.3 *Installation of suspension cranes*

After the construction of the temporary girder, crane equipment referred to as a suspension crane was installed by hanging it from the temporary girder side rails (Figure 6). Two suspension cranes were installed at each of the four movable workstations to achieve smooth process by simultaneous construction on both the in-bound and out-bound lines.

Figure 6. Suspension crane installation status.

4.4 *Construction of movable workstations and transport carts*

Movable workstations and transport carts were assembled on an adjacent bridge and installed on the rail on the upper surface of the temporary girder by a crane. To prevent unnecessarily extruding from the existing bridge, a laser barrier was provided and a notification system for

Figure 7. Mobile work vehicle construction status (left: upper member, right: lower member).

the crane operators were provided (Figure 7, left). Since it is necessary to install the lower portions of the movable workstations from the local road, they were constructed by using multi-axis carriers at night by imposing traffic restrictions (Figure7, right). Figure 8 shows the situation after installation of the equipment for removal.

Figure 8. Situation after installation of removal equipment on temporary girder.

4.5 *Removal of the existing bridge*

Cutting work of the existing bridge by wire saws began in January 2023. The bridge is cut at 1.75 m intervals in the bridge axis direction and each cross section is further divided into 16 pieces (8 pieces each for in-bound and out-bound lines, Figure 9). The bridge was divided into 84 pieces in the axial direction and there were up to approximately 1,300 blocks removed in total.

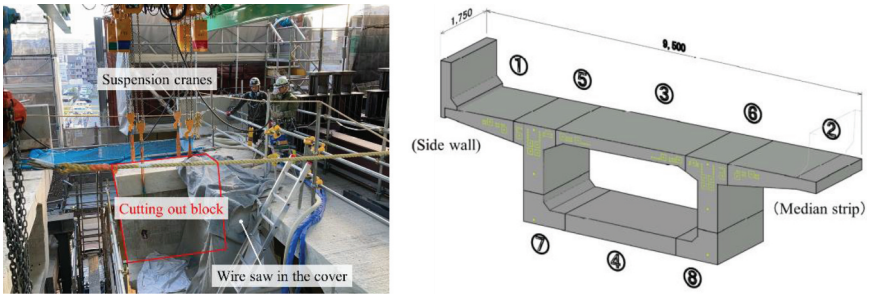

Figure 9. Removal of existing bridge (left: removal status, right: one cross-section removal order).

Figure 10 shows the construction procedure in the bridge axial direction. The removal is carried out by the reverse procedure of the cantilever erection method, however since the side span of this bridge has been partly (end portion) constructed by the vent method and the girder length is approximately 12 m longer than the center span (1/2). Then, the side span end

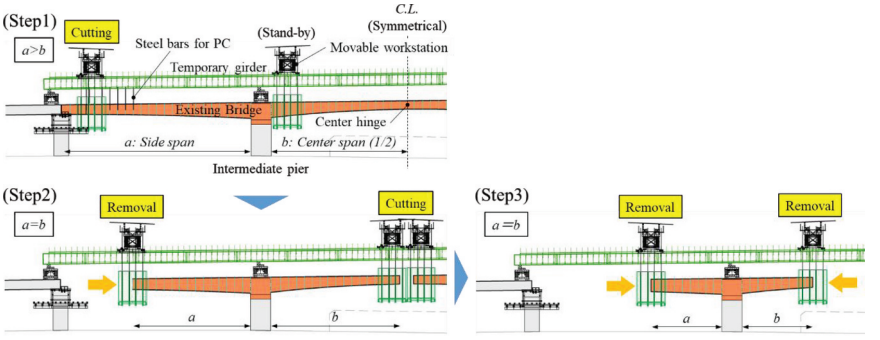

Figure 10. Removal order in the bridge axial direction (side view).

portion was cut and removed from the temporary girder while temporarily slinging the side span edge portion from the temporary girder with steel bars for PC until the overhanging lengths with the intermediate piers at the center become equal on both sides (Step 1). Then, the center hinge portion was cut at the point where the overhanging lengths on both sides were balanced (Step 2). Then, removal was advanced toward the intermediate pier by the two movable workstations simultaneously (Step 3).

4.6 *Box girder uplift countermeasure*

Steel bars for PC inside the existing bridge were cut by core drilling (φ54 mm) from the upper surface of the slab and measures to reduce the excessive stress to a safe level were studied in advance (Figure11). The fixation positions of the steel bars for PC in the bridge axial direction were confirmed, the targets for cutting were preset for each of the six cross-sections for which the up-lift measures are to be implemented and cutting was carefully progressed.

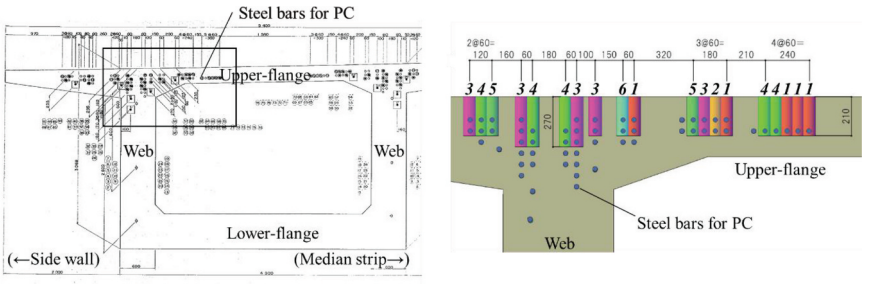

Figure 11. Box girder cross-sectional view (left: position of the steel bars for PC shown in the completion drawing, right: steel bars for PC applicable to tension reduction and core drilling sequence).

4.7 *Retracting and removing the temporary girder*

The demolition of the PC box girder was successfully completed in approximately 5 months of construction period. Temporary girder which has finished its duty was provided with a launching nose, retracted by an endless roller installed on the vent above piers and retraction equipment on the front (hydraulic jacks) to the adjacent bridge by a single-operation, and demolished. For the first time in 43 years, there was no structure on the intersection (Figure 12).

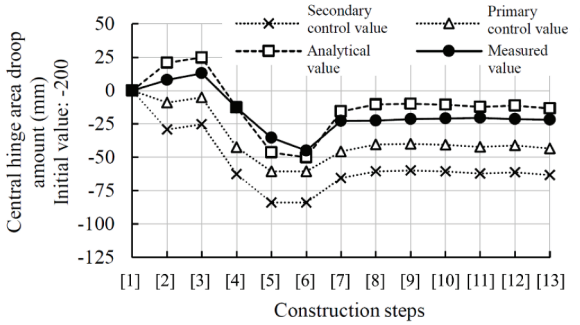

Figure 12. Temporary girder retraction status (after completion of the existing bridge girder removal).

5 EFFORTS TO SAFELY PROCEED WITH THE CONSTRUCTION

5.1 *Constant observation of the center hinge portion displacement*

Figure 13 shows the transition of center hinge area droop amount from the start of construction to the completion of the temporary girder (comparison of the analytical values and measured values). After starting the construction work, in the pavement removal ([2]) and median

strip removal ([3]) steps which are carried out in the first place, dead loads were reduced, and the droop amount was reduced in both steps. On the other hand, in the subsequent outer cable tension release ([4]) and temporary girder erection ([5] to [6]) steps where loads concentrate on the center of span, the droop amount increases. Regarding the subsequent steps, the result of the analysis showed that since the loads ap-plied to the center of the span were switched to be applied to the vent above piers, the fluctuation in the droop amount was stabilized ([7] to [13]). On the other hand, although the behavior was not as sensitive as the analytical values, the measured values showed the same tendency.

6 CONCLUSION

In this construction, an aerial-demolition method for completing most work processes in air was adopted so as not to obstruct traffic on the local roads directly below the construction site was adopted for demolition of the existing PC bridge. Due to the condition of the site where it is above an intersection in an urban area, the difficulty is very high. However, construction progress was achieved by additionally implementing various ingenuities against the difficult issues.

A large-scale restoration construction is for a society in which people can live safely into the future. However, due to its large scale, the effects during construction also tend to be large. For the growth of sustainable urban cities and regions, the technology to reduce these effects is assumed to be of great value.

Due to the aging of road structures, there is a possibility for construction works in which removal of bridges, etc. needs to be carried out safely without causing effects on areas directly below the construction sites to occur in the future. We hope that the ingenuities and results of this construction will be helpful.

Risk assessment of the K-bridge over the Danube

B. Kövesdi, D. Kollár & L. Dunai
Department of Structural Engineering, Faculty of Civil Engineering, Budapest University of Technology and Economics, Budapest, Hungary

Z. Hodik
Budapest Közút Co., Budapest, Hungary

ABSTRACT: The K-bridge spans over the Danube between Buda and the Hajógyári Island in Budapest, Hungary. The originally railway, recently mixed road and pedestrian bridge have a more than 70-year-old steel truss main girder with a span of 98.04 m and a steel-concrete deck system. It plays an important role in Budapest city life and is heavily used during the Sziget festival, one of the biggest festivals in Europe. In 2022, during the regular bridge inspection, heavy corrosion and material loss were found by the experts in the bridge deck system and on the steel cantilever beams under the pedestrian walkways. The Budapest University of Technology and Economics (BME), Department of Structural Engineering together with design and maintenance experts investigated the condition of the structure and made a probabilistic analysis to verify the resistance of the corroded structure and made the risk assessment before the organization of the Sziget festival. The main aim of the analysis was the assessment of the load-bearing capacity of the corroded structure and determination of its risk against possible failure, based on the survey results of the current corrosion condition. Detailed inspection, on-site geometrical and corrosion measurements and partial loading tests were executed on the structure, which results served as input data of the probabilistic analysis. Advanced numerical models are developed to accurately calculate the load-bearing capacity of the heavily damaged structural details of the bridge by using stochastic analysis combining geometrical and material nonlinear analysis using imperfections (GMNIA). Based on the investigations, the necessary short-term and long-term maintenance tasks could be identified to be carried out on the bridge to ensure safe operation of the structure during the Sziget festival and to prolong the service lifetime of the bridge.

1 THE ANALYSED STRUCTURE

The structure under investigation is a steel girder bridge with a truss main girder system. The bridge is located on the northern side of Budapest and spans over the Danube connecting the Buda-side and the Hajógyári Island. The span of the bridge is 98.04 m. The main girder was originally designed and developed as a military bridge with a one-and-half "K" shape, as shown in Figure 1. The connections of the truss girder are all bolted connections using pretensioned bolts. The bridge was built from modular system, typified structural elements. The longitudinal axis of the bridge is straight. The distance between the two truss girders is 4.42 m. The structure carries a unified railway track, with one track width, and a 2.8 m wide carriageway between the truss girders. The total width of the bridge is 8.72 m, and its structural height is 12 m. The main girders are stiffened with lower and upper wind bracings. The material of the bridge is a mixture of normal-strength steel and cast iron, with a min. yield strength equivalent to S235 steel grade.

The deck system consists of steel I-section cross-girders located 3 m apart and I-section longitudinal girders carrying a reinforced concrete slab. Railway traffic was originally carried over the longitudinal girders by timber sleepers. Later, secondary steel cross-girders were

DOI: 10.1201/9781003483755-383

placed between the cross-girders, and the deck system between the main girders was filled with concrete. According to the plans originally made in 1955, the bridge was designed for a static load of 2 pieces of 411 series locomotives and a railway carriage weight of 40 kN/m according to the Hungarian 1951 Railway Bridge Standard.

The structure plays an important role in the Budapest city life. It serves as the main entrance of the worldwide known "Sziget festival", which is organized on a yearly basis in Budapest, as one of the largest and most popular festival in Europe with an average of 450.000 – 500.000 visitors. Therefore, the condition of the bridge, its maintenance and safe operation has special focus among the bridges of Budapest. The present paper shows results of the latest bridge inspection followed by advanced numerical calculation proving the safe operation of the structure.

Figure 1. The K-bridge of Budapest: a) from air [1a] b) main entrance of the Sziget festival [1b – Photo: Tamás Vasvári/Index] c) side view [1a].

2 RESULTS OF THE ON-SITE BRIDGE INSPECTION

In 2022, a wide range inspection was carried out to check the structural health of the bridge. During the inspection it was observed that bridge bearings did not work properly, the cylinders fallen apart, the location of the cylinders was irregular and disorganized. Furthermore, it was detected, that the bridge deck system was in a highly corroded state. According to the measurements carried out during the 2020 main inspection, the average material loss was about 10% in some places. Based on the 2022 expert report, the condition of the connection plates within the joints is critical at many places, the material loss due to corrosion reached 25%, which highlighted the need for a careful corrosion measurement and advanced static check of the deck system considering the actual conditions of the structure.

At first, an extensive literature review was made on the possibilities of the corrosion measurement techniques and its modelling options in advanced numerical models. Based on the international literature visual examination is the most often used form of corrosion inspection. However, it only detects surface corrosion. On the other hand, various non-destructive physical probing methods have been developed and implemented to describe and assess material loss and corrosion levels such as: ultrasonic thickness measurement method [2], gamma radiation

[3], X-ray-based technologies [3,4], holographic interferometry [4], white light interferometry [5], thermography [6], scanning electron microscope stereo photogrammetry [7], optical three-dimensional scanning [8,9], and atomic force microscopy [10]. Several research results indicate a correlation between the mechanical properties of structural steel and corrosion-induced damage rate. It is attributed to local defects (notches) on corroded surfaces, leading to the initiation of fractures at lower stress levels. Characteristics of stress-strain curves heavily depend on corrosion damage, location, size and depth of dislocations [11]. According to Kim et al. [8], tensile tests indicate that yield strength and ultimate strength of structural steels remain relatively unaffected by corrosion when considering reductions in geometric dimensions. Conversely, the ultimate strain exhibits a nearly linear decline with the increase of corrosion damage. In addition, several research [8,12] pointed out the disappearance of yielding plateau, or reduction in its length, in the case of severe degradation due to extensive corrosion damage. Therefore, various corrosion models exist for the assessment of mechanical characteristics in corroded steel elements. Based on literature review, within the numerical calculations the effective plate thickness is determined and considered in static calculations as function of the average material loss. Furthermore, in the numerical calculations the largest localised section reduction (local corrosion) is also considered. Both are taken based on on-site measurement results.

In case of this bridge visual inspection, mechanical measurements combined with ultrasonic thickness measurements are applied. The condition of the main girders apart the support regions were evaluated to be good. The recommended value for material loss due to corrosion is 5% in average (maximum 10% at several locations) to be considered in the static calculations. No harmful deformation or local damages are visible on the main girders. A typical detail of the main girder is shown in Figure 2a).

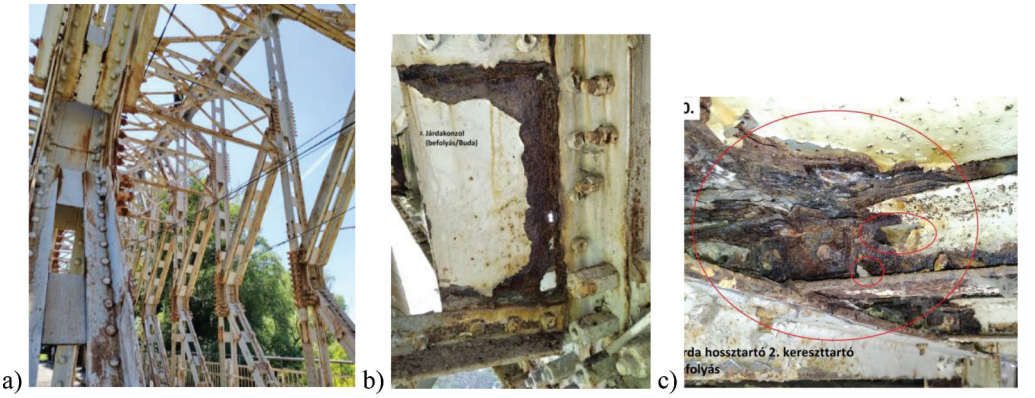

Figure 2. Corrosion damages of the bridge: a) main girder, b) most corroded cross-girder, c) longitudinal girder under the pavement.

The bridge deck system is in significantly worse condition than the parts above the deck system. During the on-site inspection, where significant corrosion damage was observed, the corroded part was excavated so that the extent of the section loss could be determined. The connection plate of the sidewalk cantilever connecting to the bridge is typically heavily corroded. In general, the amount of section reduction to be considered in the calculation is 20-30%. The exception is the cross-girder #2, which is in the worst condition (Figure 2b), whose upper part has ~80 %, the lower part ~90% cross-section reduction. The longitudinal girders are supported on the upper chord member of the sidewalk cantilevers, which corrosion loss is typically around 10-20%. At several places, in the cross-section of the supports, the reduction reaches 90%, an example is shown in Figure 2c). At the connection of the longitudinal steel girders and the cross-girders, an average section loss of 5% could be observed at the lower connection plate. There was an average of ~10% reduction in the web plates of the

longitudinal girders, while on average of 20% on the flanges. During the static check of the bridge, the main girders, the deck system including cross-girders, longitudinal girders, reinforced concrete slab and cantilevers under the sidewalks were carefully analysed. Their resistances were checked, and the utilization ratios were calculated separately. In the current paper, only the investigation of the mostly corroded part of the structure, the cantilever under the sidewalk is discussed.

3 NUMERICAL MODEL OF THE CROSS-GIRDER CANTILEVERS

Beside the global model of the bridge, for the analysis of the cross-girder cantilevers a separate numerical model, as shown in Figure 3, has been developed in the general finite element software, Ansys 19.0 [13]. The model is a full shell model, containing all the details of the sidewalk system between 5 cross-girders. Two cross-girders are analysed with the same numerical model: (i) average cross-girders having uniform material loss – the middle cross-girder is analysed, (ii) cross-girder #2 – having the most intensive local corrosion damages – the second cross-girder of the model is analysed.

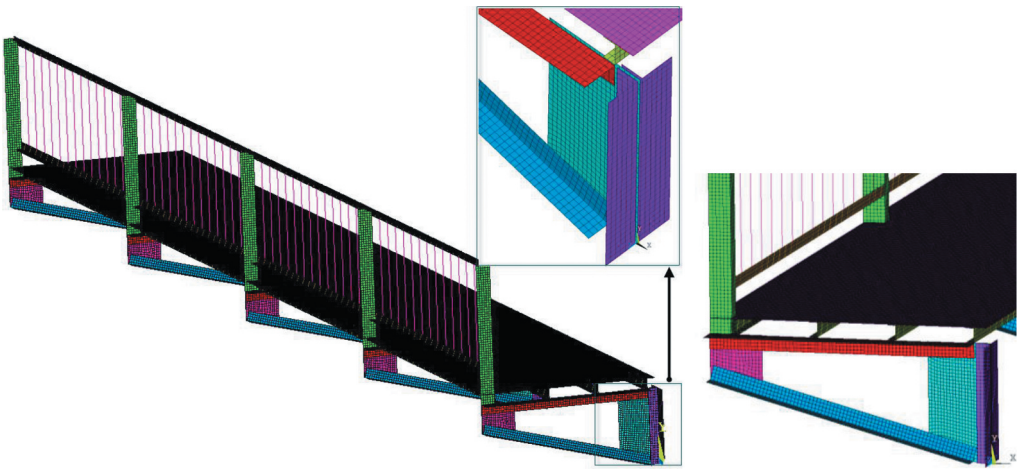

Figure 3. Numerical model of the cross-girder cantilever.

All structural elements and plates are modelled in their middle lines, so gaps are formed between the modelled plates (as shown in Figure 3 enlarged), through which the different plates were connected at the bolt locations using rigid bodies. Such a dense finite element mesh is applied that at least 4 rigid bodies were placed at the location of each bolt to avoid local stress concentration and local failure modes. Thus, the numerical model is suitable for checking the load carrying capacity of individual structural elements. However, the calculation does not directly include the static check of bolted connections. At the same time, it takes into account the structural behaviour characteristics resulting from the eccentric connections of the individual structural elements.

In the numerical model, a uniformly distributed load of 5 kN/m^2 is applied, multiplied by a dynamic amplification factor of μ=1.4 based on the Hungarian design code [14]. The resistance was first determined using the original intact cross-sections without corrosion loss, and then it was determined considering the resistance reduction effect of corrosion. In the numerical model, two different corrosion models were used: (i) general, uniform section loss covering the entire structure – 20% on all elements of the cross-girder cantilever, and (ii) local corrosion, which takes into account the local, significantly advanced corrosion rate of the connection plate as shown in Figure 2b). So, three different calculations are executed,

and their results are compared. The first two calculations are deterministic calculations applying geometrical and material nonlinear analysis using imperfections (GMNIA) to determine the characteristic and design value of the resistance. To investigate the resistance reduction effect of the local corrosion – due to its large variation and significant uncertainties in their degradation rate – stochastic analysis is applied, in which numerous GMNI analyses are executed by using different input data, where corrosion is considered as a probabilistic variable.

Figure 4a) shows the connection that is critical in terms of local corrosion. There is a significant amount of corrosion loss in a well-defined region close to the bolted connection of the connection plate (marked by red in Figure 4a). At several places the plate is completely punctured (zones marked by yellow in Figure 4a). This was taken into account in the numerical model by defining a corrosion matrix in this highly corroded zone in addition to the general section loss of 20%, in which the joint plate was divided into 30 parts along its height and a different section loss rate was determined for each matrix element and applied to the numerical model by using random distribution. Considering the high degree of corrosion damage of the section, the random distribution function was set so that the remaining section in each matrix element should be between 1-40% of the original 10 mm plate. A total of 20 corrosion loss models with different geometries were generated within the stochastic calculation, in which the average residual section measured over the entire connection plate height is ~20% of the original section (equivalent to an average section loss of ~80%). The geometry of the connection plate used in the stochastic analysis is shown in Figures 4b) and 4c), where different colours represent the different plate thicknesses. Since 100% corrosion loss can be observed in several places on the connection plate, the elements of the numerical model in the zones marked in yellow in Figure 4a) were eliminated and assumed that there are no load-bearing steel sections within these regions.

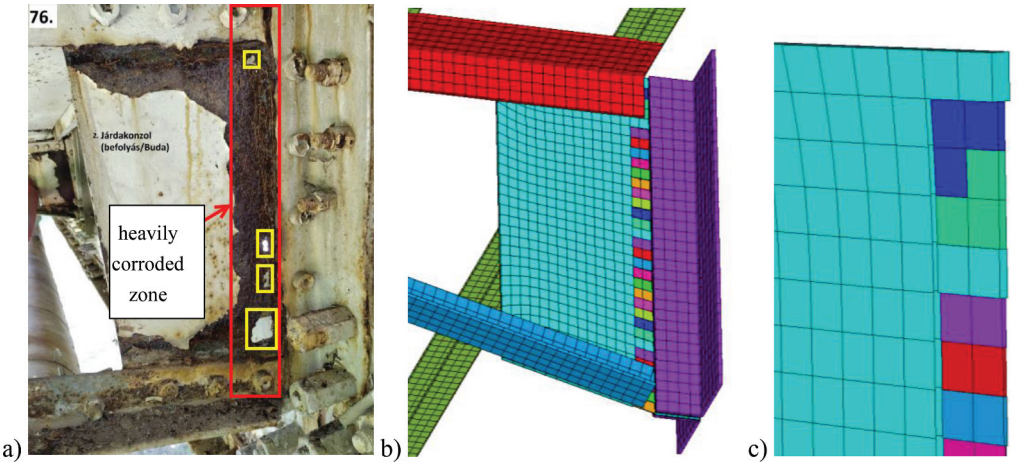

Figure 4. Modelling of local corrosion a) corroded connection plate, b) numerical model representing different thicknesses by different colours, c) connection plate model of the heavily corroded region.

Two different imperfections are applied in the nonlinear calculations: (i) global imperfection representing flexural torsional buckling of the lower chord member in combination of plate buckling and (ii) plate buckling-type imperfection of the connection plate, as shown in Figure 5.

The plate buckling-type imperfection was scaled to $b/200$, where b is the connection plate depth; the global imperfection is scaled to $L/200$ (where L is the member length of the lower chord) based on the design recommendations of EN 1993-1-5 [15] and EN 1993-1-1 [16].

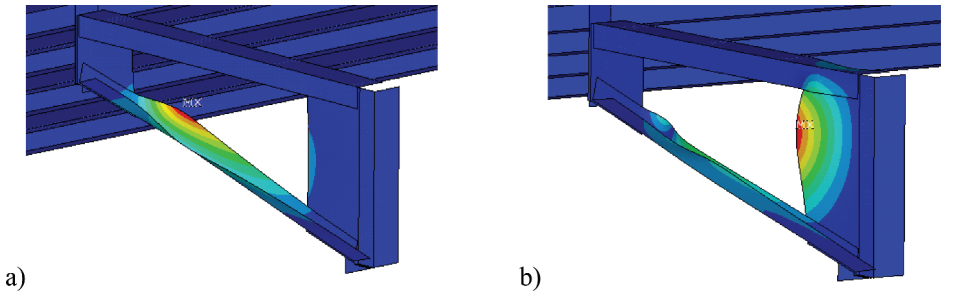

Figure 5. Applied equivalent geometric imperfections: a) flexural torsional buckling-type imperfection, b) plate buckling-type imperfection.

Within the deterministic and stochastic analysis nonlinear material model is used. The applied material model is linear elastic – hardening plastic with isotropic hardening rule using von Mises yield criterion. The material was assumed to behave as linear elastic and to obey Hooke's law with a Young's modulus of E = 210000 MPa up to the yield strength, which is set to 235 MPa. After this point the material was assumed to follow linear hardening with a reduced hardening modulus of E/10000 according to EN 1993-1-5 Annex C [15].

4 RESULTS OF THE NUMERICAL MODEL

4.1 *Results of general cross-girders*

At first, the load carrying capacity of the sidewalk structure is determined using the advanced numerical model. The observed failure mode is presented in Figure 6, which is buckling of the lower chord member. Based on the GMNI analysis, the load-displacement curve of the structure is determined as shown in Figure 7. The graph shows the results of (i) the intact structure and (ii) cross-girder having average of 20% corrosion loss. The horizontal axis shows the vertical displacement of the cantilever, and the vertical axis shows the load scaling factor utilized for the design load level. The horizontal lines present the characteristic and design load levels of the corroded cross-girder determined based on the proposed evaluation process of the nonlinear analysis according to prEN1993-1-14 [17] and using the global safety factor given by the Hungarian design code [14]. The point of the first yielding limit state is also marked, which check is also mandatory for bridges in Hungary. Based on the numerical calculations, the adequacy of the general cross-girder is proven. The load carrying capacity of the sidewalk could be verified according to the Hungarian design code with the maximum utilization ratio of 92%.

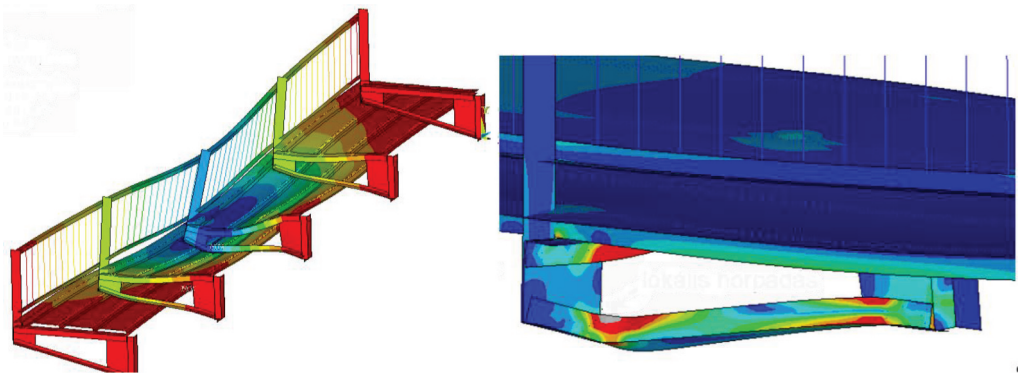

Figure 6. Obtained failure mode by the advanced numerical model – general cross-girders.

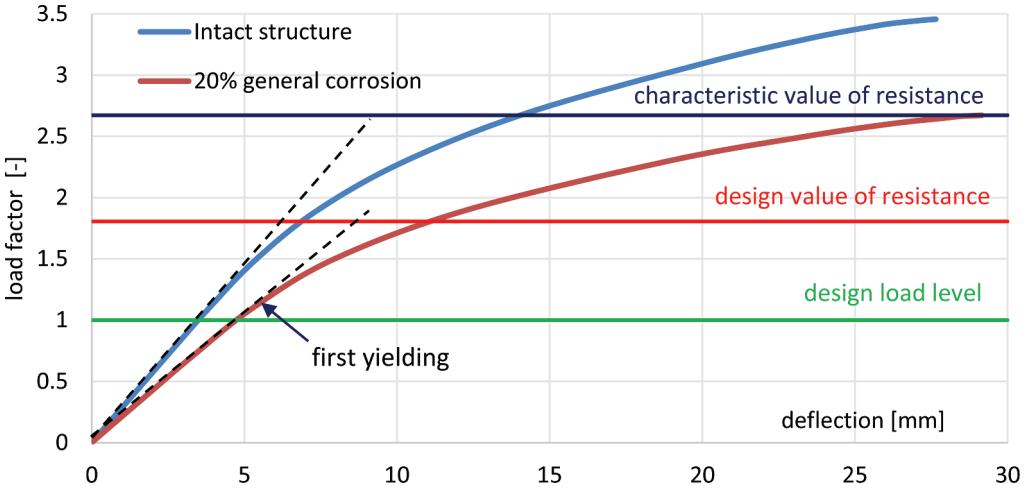

Figure 7. Obtained load-displacement curves, characteristic and design resistances and design load level.

4.2 *Result of cross-girder #2*

The failure mode of the numerical model considering both global and local corrosion damages, is shown in Figure 8. Based on the results, it can be seen that the failure mode changes, local buckling of the lower chord members starts, but the final failure occurs within the connection plate in the zone of the local corrosion in form of plastic failure.

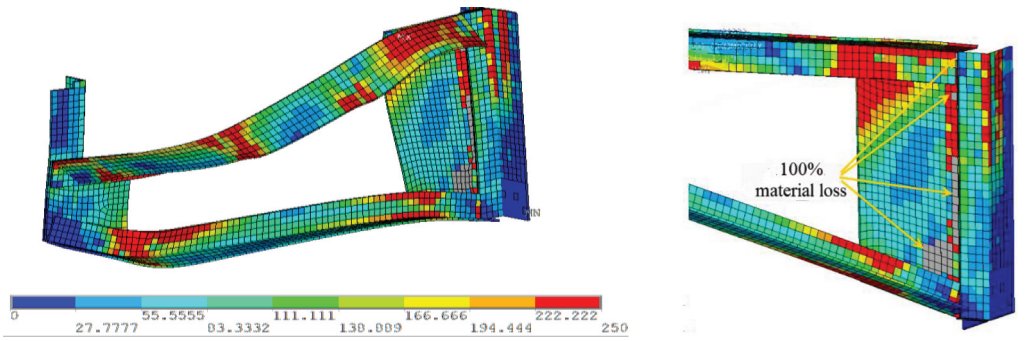

Figure 8. Obtained failure mode by the advanced numerical model – cross-girder #2.

Multiple GMNI analyses are performed on the numerical model using various input data determined on probabilistic basis. The load carrying capacity of the structure is determined for each corrosion situation. The ratio of the load factor corresponding to the design load level and the average remaining cross-section is shown in Figure 9. It can be seen that the load factor corresponding to the safety level required by the e-UT regulations (marked by red line) in the case of an average residual cross-section of ~20% can still be verified (80% average section loss) with a maximum of 99% utilization ratio, which result corresponds to the corrosion state observed in June 2022.

4.3 *Result of the proof loading test*

Due to the significant material loss of the cantilever connection plate and the variability experienced in them, the company Provix Híd Ltd. made the proof loading test of the

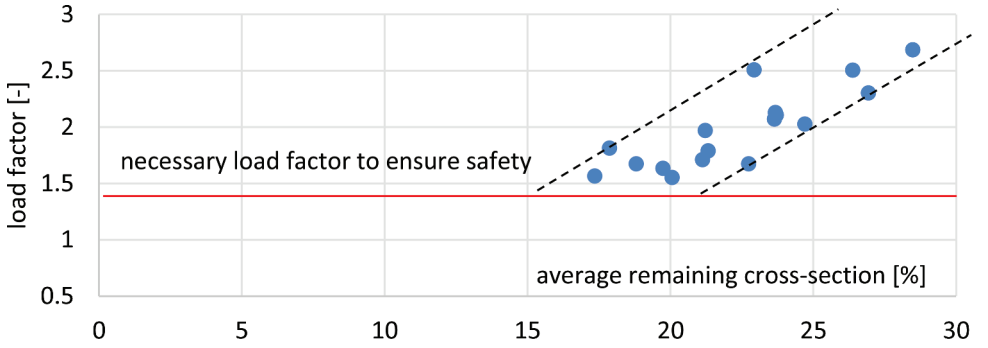

Figure 9. Obtained load-displacement curves, characteristic and design resistances and design load level.

sidewalk's structure. During the test load, wooden plates were put on the pavement, on which a load of ~21 kN (~5 kN/m^2) was applied and moved along the entire length of the bridge. Thus, all cross-girders and longitudinal stringers are loaded by the proof load. The only exception is cross-girder #2, on which the test load is reduced to 11.5 kN (~2.75 kN/m^2 load intensity, which corresponds to more than 2 times of the pedestrian load corresponding to the exceptionally dense traffic situation according to the recommendations of the JRC Scientific and Technical Reports [18]). After the test load was applied, the structure is visually inspected, and it is determined that the structure withstand the test load without any damages.

5 CONCLUSIONS

The BME Department of Structural Engineering carried out the expertizing task of the K-bridge to assess the load carrying capacity and structural health condition. The level of reliability of the structure is checked taking into account the current corrosion damages based on on-site measurements. It has been assessed whether the corroded structure meets the requirements according to the current Hungarian design code and it has been also decided if the bridge could be kept in operation and open for the daily traffic. The results of the 2022 proof load test and the probabilistic numerical analysis using the on-site corrosion measurement results confirmed the adequacy even of the cross-girder cantilevers which were in the worst condition, however, with large utilization ratio (99%). Based on the on-site measurements and the above introduced advanced analysis, the structural health of the bridge and conditions of further operation could be evaluated. Based on the advanced calculations, finally the bridge condition was also assessed by a group of Hungarian bridge design and maintenance experts. They concluded that within the main girder, the bridge deck system is adequate in terms of load carrying capacity despite the significant corrosion damages. They called the attention, however, if no intervention would be carried out in the near future (within 1 year time), as corrosion develops, this compliance can only be verified for short term. As corrosion propagates, the structural safety (especially for cross-girder #2) may be reduced. Therefore, strengthening of the mostly corroded connection plate is suggested as soon as possible.

ACKNOWLEDGEMENT

The authors would like to express special thanks to the members of the group of experts (Adrián Horváth, Gyula Kolozsi, Zoltán Müller and Zsolt Nagy) for their cooperation within the expertizing tasks and evaluation of on-site measurements and risk analysis results. The presented research program is also supported by the Grant MTA-BME Lendület LP2021-06/2021 "Theory of new generation steel bridges" program of the Hungarian Academy of

Sciences, the support is gratefully acknowledged. The authors dedicate the paper to the memory of their colleague, Zoltán Müller, who tragically died in 2023, with whom this was their last joint bridge inspection work.

Development of the maintenance strategy for Västerbron

J. Sandberg
AtkinsRealis, UK

L. Steen
Systra, Sweden

J. Hedenström
Stockholms Stad, Sweden

ABSTRACT: The Västerbron link in Stockholm, comprises Riddarfjärdsbron to the north and Pålsundsbron to the south, is a strategic link between northern and southern Stockholm and was the first crossing constructed outside the city centre. Opened in 1935, this structure pioneered early welding technology. The bridge is now an important landmark within Stockholms City. Due to the age of the structure and reported concerns regarding the adequacy of the material used in its construction, extensive works were carried out to assess the current structural condition of the main bridges and develop a maintenance strategy to ensure the safe operation of the structure over the next 40 to 80 years. This paper sets out the technical work carried out to assess the current condition of the structure to ensure its adequacy, focussing on managing the stability of this very slender steel structure.

1 INTRODUCTION

With maintenance of existing infrastructure becoming increasingly important for many road authorities with ageing infrastructure, developing practical maintenance strategies for older structure is required. In steel structures built before 1960s, material properties are often variable due to limited control in fabrication processes which means that these steel structures can contain materials that do not meet modern brittle fracture requirements. A practical approach towards managing this is therefore required. One such structure is the Västerbron link, a main road located to the west of Stockholm City Centre. It was constructed during the early 1930s with construction completion in 1935. The link comprises three parts, including Riddarfjärdsbron to the north; the central portion, over Långholmen comprising an embankment supported by stone retaining walls which then connects onto Pålsundsbron to the south. The focus of this paper is on the two main bridges outlining how variable steel fracture properties were considered for the assessment.

2 BACKGROUND

Riddarfjärdsbron has a total length of 601.5m and a width of 26m between parapets. The deck is supported on two arches with clear spans of 168m and 204m. The arches comprise steel box cross sections supported on multiple pin bearings (allowing moment resistance) and mass concrete blocks founded on rock. The bridge deck comprises a multibeam deck with a non-composite concrete slab supported on slender steel tubular pin ended piers at each edge of the deck. The arches and main transverse beams are formed through built up sections that are riveted using

DOI: 10.1201/9781003483755-384

construction techniques common to this era of early steel structures. The longitudinal beams generally comprise welded sections. Additionally, many stiffeners and ancillary steelwork were welded. Pålsundsbron has a total length 272m. Whilst there are similarities to Riddarfjärdsbron in construction, far more welding was carried out to build up all structural elements including the arch, which has a clear span of 56m. There is also very little bracing below the steel deck level for this structure, see Figure 1 for a 3D model of Västerbron.

The original bridge was built through a German/Swedish consortium. The slender design of the bridge was a significant departure from earlier bridge forms typical around Stockholm, which were far more massive. The slender superstructure supported on long spanning arches was a huge architectural leap and paved the way for slender structures to be adopted around the country. As well as the aesthetic innovations at the time, significant technological innovations were also adopted. In particular, Pålsundsbron was the first bridge in Sweden where welding was implemented to such extents as described by *Ulvsgärd (2021)*. The innovative architectural style, the use of innovative technology at the time of construction together with its importance within the landscape of Stockholm has therefore led to the link being classified as blue (the highest level of importance for cultural and historic value) in accordance with Stadsmuseets classification system.

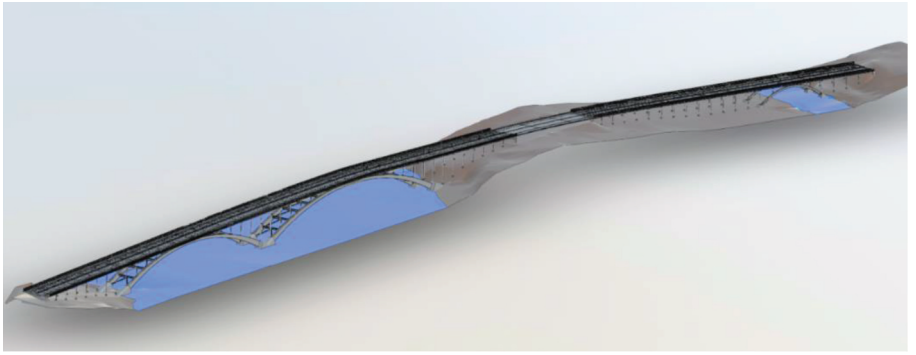

Figure 1. Revit model showing Västerbron.

Whilst construction records indicate that rigid quality control systems were implemented during fabrication, NDT techniques now commonly used in the construction of steel bridges to detect microcracking within welded structures were not available and likely unknown at the time. In addition to this, standard detailing that we today associate with welded steel structures had not yet been developed which means that much of the detailing comprises a mix of details normally associated with riveted structures and experimental new weld details, many of which would be avoided today as they are known to introduce stress concentrations into the steelwork. This particularly includes details such as fully welded stiffeners, with no allowance for cope holes. When Västerbron was constructed, there were limited requirements regarding steel ductility and steel material properties were often variable. It wasn't until the 1960s that this was recognised as a significant issue in steel structures and therefore better controls were brought in to avoid this.

Poor brittle fracture properties can cause premature failure of an element before it reaches its yield stress under an impact load scenario and has the potential to affect the long term performance of the bridge. Initial investigations and testing were carried out in 2016 and 2021 as part of the development of Tillståndsbedömning Västerbron developed by *Ramboll (2021)* which identified potential concerns with the material properties used in the original construction of the bridges comprising the Västerbron link. This report recommended that additional work be carried out to ensure the structures long term integrity. NDT testing has also been carried out on the welding, identifying the presence of cracking within the welds. The aim of this paper is therefore to discuss the management approach for these bridges based on the abovementioned data to ensure that this historically important link can be maintained for

future generations. The approach incorporates the testing, current standards and guidance documents and an understanding of the structural analysis to outline key risk factors in the structure in its current condition.

3 APPROACH

The approach taken comprised a step by step process whereby various considerations were made. Whilst the full study is not yet complete, these are planned to be carried out over the next few years. Prior to this study, a full assessment was done on the structure, whereby the overall assessment rating was derived based on the TRV assessment standards *TDOK 2013:0267 version 5 (2018)*. The assessment found that the structure was adequate for BK1 loading, which ensures adequacy under normal vehicle traffic typical to an inner city bridge, though it does not have sufficient capacity for heavy vehicles, including 74 tonne vehicle. It should however be noted that to ensure transverse stability it was assumed this was provided by the slab working compositely with the steel beams through friction as what we now consider standard composite connections not yet commonly used. As a full composite connection was not achieved, beam resistances where the top flange was in direct contact with the slab were based on the steel only resistance of the beam rather than including a contribution from the concrete. Whilst this is considered to be an acceptable (though conservative) approach for assessment, it is only likely to be accurate once the friction connection is lost and the beam slips relative to the concrete. This is therefore an important assumption to be aware of when trying to understand the measured stress ranges recorded in the structure and how it compares with the predicted stress ranges based on the model behaviour and has an impact on the results discussed below.

The investigation into the adequacy of the structure under brittle fracture was undertaken in three separate stages as follows:

- Stage 1 - Loading calculation, results extraction, stress calculation and preliminary sensitivity study of results;
- Stage 2 - Fracture Mechanics calculation;
- Stage 3 – Structural analysis to investigate sensitivity of the loss of structural element.

The intention of the above approach is to provide a simplified method of assessing the overall risk to the structure based around limited material testing, calculations predicting likely cracking of the structure and an understanding of the structures' behaviour. It is noted that this is likely to be a common consideration with early steel structures as it is unrealistic to conduct wholesale testing on every structural element on a bridge structure without attracting significant cost.

Stage - 1 Preliminary investigation

The numerical assessment of the structure was used to identify the most highly stressed elements. Elements with significant tension were considered at higher risk as cracking is more likely to develop here. Also, elements subject to variable stress ranges from traffic and other variable actions were also considered as cracks forming in these elements are likely to propagate. This influences the structures sensitivity to brittle fracture. Additionally, while brittle fracture is a separate mechanism to fatigue, there are links in the behaviour and therefore sensitive fatigue details will also be prone to brittle fracture, particularly where the material properties show poor brittle fracture behaviour. The steel samples were tested in accordance with *"Brottseghet och kemisk analys av konstruktionsstål"* (Trafikverket) which applies to structures with steel built before 1970. Tests were carried out at -30°C as per ASTM E 1820 and a loading rate to be appropriate for the traffic loading applicable for the structure. Test results were then evaluated based on the recommendations set out in TRVINFRA-00228, where fracture toughness was reviewed against predicted stress ranges from the structural analysis model. TRVINFRA-00228 indicates that J values should meet the minimum limits according to Level 1. If these minimum limits are not met, Level 2 verifications are required. TVINFRA-00228 tables are reproduced in Table 1 and 2.

Table 1. Table 5-3 in TRVINFRA-00228 – Level 1 requirements.

f_{yk} (MPa)	f_{yd} (MPa)	J (kN/m)	Conditions
220	167	30	Accepted without special conditions
260	197	40	
290	220	50	

Table 2. Table 5-3 in TRVINFRA-00228 – Level 2 requirements.

J (kN/m)	Max allowable σ_{nom} (Mpa)
20 < J < 30	σ < 100 + 6,7 (J - 20)
30 < J < 40	σ < 167 + 3 (J - 30)
20 < J < 30	σ < 197 + 2,3 (J - 40)

Where Level 2 limits are applicable, the maximum stress limits shown in Table 2 are verified against SLS stresses in the assessment standards. Provided these limits are met, the structure is considered adequate. The test samples were evaluated against these requirements. Table 2 shows the fracture toughness results that were carried out in 2016 for both Pålsundet and Riddarfjärden. Results marked with LV are from Pålsundet, whilst those indicated by 1-12 are for Riddarfjärden.

Table 3. Summary of sample results 2016 (Ramboll (2021)).

Test	1	2	3	4	5	6	7	8	9	10	11	12	LV1	LV2	LV3	LV4	LV5	LV6
Jq/kN/m	37	183	11	34	48	35	51	25	33	10	32	38	445	451	508	161	35	36

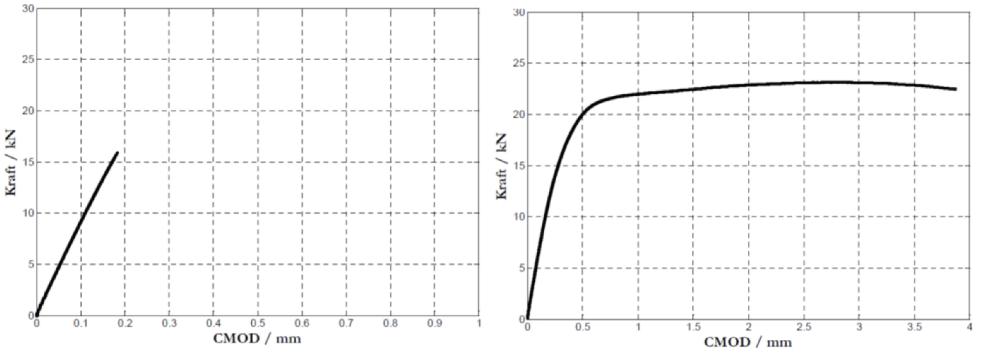

Figure 2. Good and poor brittle fracture behaviour with test on the left indicating poor behaviour and test to the right good behaviour (Ramboll (2021)).

A large variability in fracture toughness occurs for both bridges indicating variable material properties. Figure 2 shows examples of good and poor brittle fracture behaviour from the bridge samples. Particularly concerning were the low results at Riddarfjärdsbron. These indicate potential for very brittle failure. The transverse members at Riddarfjärden (ST 52) should have a minimum J value (load per crack tip opening displacement) of 50 for Level 1 requirements, and the longitudinal beams (ST 44) a minimum J value of 43.3. Level 1 properties are desirable, many tests did not meet the minimum of the Level 2 requirements. The two lowest values for Pålsundsbron are 35kN/m and 36kN/m meet the level 2 limits, indicating that these can be managed. Work carried out by Ramboll in 2021 included further material testing for Riddarfjärdsbron. This was due to the lower fracture toughness results obtained for this structure. Ramboll noted the testing from 2016 used a very high load rate of around 160 MPa/s which was deemed conservative as measured stresses in the deck varied between 5 - 15 MPa/s. Measured stresses elsewhere in the structure had lower stress ranges due to higher proportions

of permanent loading (ie the arches). The new tests used a rate of 30 MPa/s as this was deemed more realistic.

A similar variability in material properties was identified in these revised tests. However, there a marginal improvement at the lower end is seen, though the level 2 limit from TRVINFRA-00228 are still not met. Testing seemed to indicate the material with higher allowable yield strength displayed greater propensity towards brittle failure. The number of samples tested is very small and therefore cannot be confirmed. The samples from Pålsundsbron indicate less propensity towards brittle material, though noting again the small sample size. Though the results show significant variability for toughness, surprisingly the fracture appearances didn't reflect the big numerical differences, noting the appearance of cracks can be very difficult to control in brittle materials.

Table 4. Summary of sample results (Ramboll (2021)).

Designation	T1	T2	T3	T4	T5	T6	L1	L2	L3	L4	L5	L6
JQ/kNm^-1	16.5	17.8	424.3	720.2	586.1	16.3	35.5	42.7	57.7	39	66.3	38.6
Ds/dr/Mpa/s	30.2	30.6	31.3	30.9	30.7	30.3	31.5	29.9	30.9	31.6	31.3	32.1

Three main reasons for the large variation in CTOD test results are identified:

1. The -30ºC test temperature is likely around the ductile to brittle transition, and therefore relatively small temperature differences can have a large influence on the measured toughness. Some steels of this vintage will have low toughness levels.
2. For steel manufacturing at the time, there were often significant differences in steel properties dependent on which part of the ingot the section of plate/beam originated from. The basic chemical composition in the ingot will be similar, but porosity, segregation and oxide entrainment can cause some variations which affect toughness.
3. The effects of steel toughness were not well understood at that time and the steel specification most probably did not include a minimum requirement for toughness. This could potentially result in large variations in toughness, even for the same steel strength grade.

As the samples did not meet the simple requirements for material toughness, this then lead to the next stage in the approach, whereby detailed fracture mechanics calculations were carried out.

Stage 2- Fracture mechanics calculation

The stresses obtained from stage 1 were used to assess the fracture mechanics behaviour to determine the likelihood of cracking, the critical dimensions (mainly critical crack depth) and the number of cycles to failure assuming an initial detectable crack depth of 4mm. This was assumed as it is the smallest practical size of crack detectable using standard NDT testing on in-situ steel structures. Where transverse stiffeners are welded to the flanges, residual stresses tend to be locked into the steel elements. The presence of residual stresses impacts on crack size development and number of cycles to failure. Residual stresses were considered in the calculations where applicable. BS 7910 was used for the fracture mechanics calculations as there were no known Swedish standards that cover detailed fracture mechanics calculations. Calculations were then based on the at the most stressed location of the elements identified to be at greatest risk of cracking as identified in stage 1. Where toughness tests had not been carried out for a particular member, ie bracing members, material properties for other elements specifying the same steel grade were adopted. This approach was deemed valid as additional testing was considered unlikely to provide any significant benefit due to the variability in test results already identified.

A fracture mechanics approach was used to determine critical crack sizes and rates of crack growth for the main structural members, based on the stresses estimated by structural modelling and the J values from the tests. No further adjustments were made for temperature

impact. K_I (crack tip stress intensity) is a parameter that defines the likelihood of brittle fracture, which predicts the stress state local to the crack tip and depends on the component geometry, the size and location of the crack, and the magnitude and distribution of the applied stresses. The likelihood of plastic collapse is determined by the 'reference stress' σ_{ref}, essentially a 'far field' stress, or limit load. The longitudinal and transverse beams on Pålsundet are generally welded, and include welded stiffeners along the length of the beam. The process of heat application during welding locks stresses into the cross section making it more prone to cracking. The stress calculations therefore assumed a crack formation likely to occur in areas of adjacent to the stiffeners as we considered these to be at greatest risk of crack propagation that would then lead to potential critical cracking in the beam. Whilst the beams also have longitudinal welds connecting the web with the flanges, these welds are considered less critical.

The supporting deck beams at Riddarfjärden are made up of a combination of welded and riveted sections. Both internal and external longitudinal beams and intermediate transverse beams are made up of welded sections with welded transverse stiffeners. The main transverse beams however are built up using several sections, where the flanges are riveted to the webs through angle connectors and additional plates which are riveted to the bottom flange to provide additional flange thickness. Stiffeners are still welded to the angle sections and webs and therefore, critical details were considered around the riveted holes and the transversely welded connections. Closed form solutions for stress intensity and reference stress for a wide variety of cracked component geometries can be found in published literature. For this project, the solutions in BS 7910 were used. In the absence of accurate non-destructive testing (NDT) crack measurements for the bridges, an initial crack size was assumed. This was based on the smallest crack detectable by standard surface NDT methods such as magnetic particle inspection (MPI) or dye penetrant testing (DP). Tables T.4 and T.5 BS 7910 recommend a crack length of 20 mm and a through-wall depth from the surface of 4 mm. The calculations assume that the cracks will grow in proportion, with a constant ratio of length to depth of 5:1. The cracks are assumed to be located on the top surface of the tension flange of the beams. A semi-elliptical surface crack geometry was assumed; this is judged to be both credible and conservative. As this was a sensitivity study rather than an assessment of actual cracks, the choice of crack geometry was made by judgement of the most likely crack location (the tension flange of members in bending) and form (detectable by surface inspection techniques such as MPI or DP). The stress concentrating effect of rivet holes was not considered as a solid model finite element analysis (FEA) would be required to determine the resultant stress distribution, which was not considered for this study. For welded attachments such as web/flange stiffeners where the weld direction is perpendicular to the tensile stress orientation, a residual secondary tensile stress equal to the material yield stress was added to the assessment, which is conservative. The material fracture toughness K_{mat} was derived from the test results as follows:

$$K_{mat} = \sqrt{\left(J_q \times E'\right)} \tag{1}$$

Plane strain conditions were assumed throughout. The approach adopted is considered standard withing the industry for assessing cracks. A typical FAD (failure assessment diagram), for the Pålsundet transverse diaphragm, is shown in Figure 3. This member contains welded web/flange stiffeners. If it is conservatively assumed that these are located close to the most highly stressed areas, it is standard practise to also assume that tensile welding residual stresses equal to the material yield stress are present. This has a significant effect on the critical crack depth, in this case reducing it from 31 mm to 8.3 mm. It increases the fracture ratio for the assumed 4 mm deep initial crack from ~0.2 to >0.6, but does not affect the plastic collapse ratio, as secondary stresses do not contribute to the reference stress. For all beams assessed, the critical crack size is based on the 'worst case' stress combination.

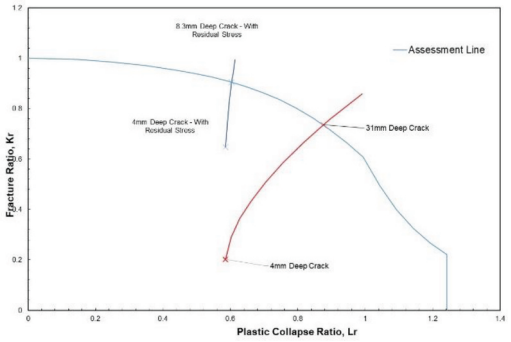

Figure 3. Failure assessment diagram.

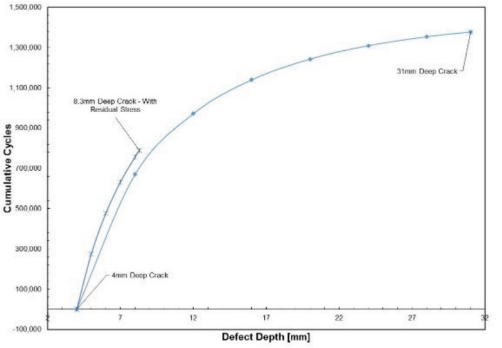

Figure 4. Fatigue crack growth.

Fatigue crack growth rates were estimated using the Paris law with coefficients from BS 7910. The only significant cyclic load, in terms of stress magnitude and frequency, is the traffic load; other stresses were below the fatigue crack growth threshold. Fatigue crack growth from the initial 20 mm x 4 mm assumed defect to a critical defect depth (i.e. failure) is shown for the Pålsundet transverse diaphragm in Figure. The assumption of weld residual stresses has a significant effect on the number of cycles to failure, reducing it by around 50%. The crack growth rate is non-linear, as is proportional to the cube of the crack stress intensity. The results from the analysis showed reasonable margins of safety between the smallest detectable crack size and critical crack sizes, with relatively long predicted fatigue lives. For example, if surface NDT on the areas assessed is carried out to an acceptable standard in the near future and no defects are found, it can be stated with reasonable confidence that the largest defect likely to be present (and not detected by NDT) will be of the order of 20 mm long by 4 mm deep. Provided that critical areas are monitored, it is feasible to expect that cracking can be observed prior to the crack size becoming critical. The fatigue calculations suggest that defects of this size will not reach a critical size until many thousands of traffic cycles have passed which again indicates a reasonable probability of effective monitoring being able to identify a critical crack.The information from this analysis was then carried into the next stage 3.

Stage 3- Loss of part of or full element

In parallel to assessing fracture mechanics and the impact of cracking in the steel leading to local failure of an element, a sensitivity study was carried out on the structure to evaluate the impact of a crack leading to the failure of either a part of or the full element under consideration. This study included the removal of the critical elements including flanges, webs and the entire beam. The impact on the damaged element and the surrounding structural elements was investigated to assess whether a local failure leads to progressive collapse of the rest of the structure. The study was carried out considering the accidental removal of different parts of the structure (for example partial flange loss or partial web loss) or the full element to model the ineffective behaviour of that part/full of the element. The utilisation of the affected and surrounding elements was then determined using the accidental design situation as outlined in SS EN 1990 and compared with the utilisation of the elements without damage under the ultimate limit state (This was based on the original assessment results). The loss of part or full element was considered independently. For example, when loss of part of an element was considered for one element, the adjacent elements were kept as undamaged (acting in full capacity). This was done on the basis that probabilities would suggest that it is unlikely that several adjacent elements will be subject to the same defects simultaneously. Plastic load distribution was not considered at this stage of the analysis as this added an additional level of complexity to the

analysis that was not desired at this stage. The purpose of this study was to establish whether the structure had enough residual capacity within the system to avoid collapse. The typical approach when considering an accidental scenario is to allow for significant damage to the structure. However, the overall collapse of the structure should be prevented. This was also the approach taken in for this study.

Where built up cross sections were relevant, such as for the Riddarfjärden cross beams, it would be unlikely that all parts of a built-up member would have the same defect in each of the different layers of the built-up section. Therefore, the impact of failure of a single plate within this system was considered. The study identified that the main transverse beams were of greatest risk to the structure and if these were to fail, this would lead to overall structural collapse. Loss of parts of the remaining structural elements would lead to significant damage to the structure, but the structure would remain standing. A further comparison was then carried out considering strain measurements that were obtained by Ramboll during the condition study carried out in 2020. As part of this work, stress ranges in the bridge deck were monitored under traffic loading for approximately 6 months (2021 Ramboll). These findings are shown in Table 3. Where stress ranges are below the cut off limit (as defined in SS 1993-1-9), damage to the structure is unlikely to occur and cracks are unlikely to propagate. Table 5 indicates that measured stress ranges are mostly below this limit, though isolated instances exceed this. However, whilst theoretical calculations indicate that stress ranges in the arch are relatively small, stress ranges in the deck element are in the region of 60 MPa in some instances. It is believed that the reason for this discrepancy is due to the real versus assumed connection to the slab. As discussed above, there is no composite connection to the slab through shear studs or other means instead the connection maintained through friction. Whilst this is a recognised mechanism, it is difficult to quantify by calculation, particularly where there is a risk that that friction connection is lost. Therefore, the assessment derived a stress range based on the slab as a non-contributing component. This was considered in the risk analysis as it reduces the overall risk due to the lower measured stress ranges.

Table 5. Measured stress ranges.

	Typical stress variation (MPa)	Maximum stress variation (MPa)	Relevant fatigue detail category	Stress range cut off limit (MPa)
Riddarfjärden arch	1-4	16	71	21.3
Riddarfjärden deck	1-6	24	40, 71, 80	12.0, 21.3, 24.0
Pålsundet arch	1-4	16	63	18.9
Pålsundet deck	1-6	18	40	12.0

4 FINDINGS

Whilst the study has not been finalised, the process adopted has worked through different key stages and risk analysis. So far, the study has shown that whilst there is still a potential risk to the structure due to the variability of the material properties, this risk can be managed based around an approach where theoretical stress ranges and measured stress ranges are considered. Critical members can be monitored and the intention is to carry out a full visual inspection and targeted NDT inspection of critical details when the structure is next repainted. Whilst this approach has not completely eliminated the risks to the structure, it has identified how these risks can be managed with limited intervention. The precise nature of these interventions are yet to be determined, though they will be significantly less than the initial conservative interventions of remedial works being required to all members not meeting the limitations set out in TRVINFRA-00228.

5 CONCLUSION

This paper sets out the approach taken to understanding the impact of the variability in steel material properties encountered during the material testing on the Västerbron steelwork. Through a series of initial sensitivity calculations, detailed fracture mechanics calculations based on simplified assumptions and global analysis of the structure considering the loss of structural elements an understanding of the risks to the structure has been developed. This knowledge is now being used to determine the long term management strategy for the bridge and most importantly ensuring that the structure can be safely managed into the future. It is envisaged that a similar approach may be relevant to other structures with steel from before 1970, where material properties were not adequately controlled during construction and which may display similar concerns.

Enhancing Dybbølsbro Bridge – Refurbishment and expansion without new substructure

L. Thormann, C. Pedersen & J. Fogh Svensson
Ramboll Denmark A/S, Copenhagen, Denmark

ABSTRACT: The refurbishment and expansion of the Dybbølsbro Bridge in Copenhagen presents a unique engineering challenge. This contribution details the process of suspending a new 2000 m^2 bridge between two existing bridges, all while maintaining traffic on the existing bridges, and executing work over twelve operational railway tracks. The innovative expansion uses a deck superstructure that requires no additional substructure. Achieved by strengthening and utilizing existing bridges, the new bridge consists of 55 independent steel elements. By reusing the existing bridges for the new superstructure and avoiding construction of a new substructure, we minimized the material consumption, consequently reducing the project's environmental footprint and reduced the disturbance of the rail traffic, all contributing to a more sustainable project. The expansion of the bridge epitomizes the future of sustainable urban infrastructure, demonstrating that conscientious planning and innovative design can bring ambitious infrastructure projects to fruition, enhancing city landscapes and serving communities better.

1 INTRODUCTION

Dybbølsbro, a pivotal structure in Copenhagen's urban landscape, has undergone a significant transformation. Originally erected around 1900 as a steel truss bridge, initially served as a vital connection over the Copenhagen Freight Yard to Kalvebod Brygge. The bridge was replaced by pedestrian and cycle path bridge in the mid 1980's. In mid-1990's a parallel road bridge was erected creating a ~10 m wide gap between the two 190 m long bridges. Both existing bridges were push launched and constructed as post tensioned 5 span concrete bridges.

This paper presents an in-depth exploration of the recent expansion of Dybbølsbro, a project that seamlessly integrates contemporary engineering excellence with the bridge's storied past. The expansion initiative is a testament to Copenhagen's commitment to sustainable urban development and the enhancement of public infrastructure. The undertaking addressed the need for increased capacity and improved safety for pedestrians and cyclists.

The Dybbølsbro expansion project, characterized by its innovative approach represents a paradigm shift in urban bridge expansion. Challenges, such as the integration of new structures with the existing framework and minimizing disruption to the city life, were met with advanced engineering solutions. The project's approach to utilizing the existing concrete structures, coupled with the implementation of state-of-the-art digital tools, sets a new benchmark in bridge engineering and urban infrastructure development.

As urban spaces evolve, the demand for infrastructure that can adapt and accommodate growing needs becomes more important. The Dybbølsbro project emerges as a beacon of such adaptability, showcasing how existing structures can be repurposed to serve new requirements.

By examining the Dybbølsbro expansion project, this paper aims to provide valuable insights into the complexities and opportunities of modernizing existing infrastructure.

DOI: 10.1201/9781003483755-385

2 PROJECT OVERVIEW AND TECHNICAL APPROACH

The bridges are situated in a high-traffic zone, accommodating a steady stream of pedestrians, cyclists, and vehicles. They span across all railway tracks that feed into Copenhagen's central station. It was crucial that throughout the construction process, these varied modes of transport could continue to operate, ensuring minimal disruption during construction.

2.1 *Existing conditions*

Dybbølsbro, comprised of continuous spans in post-tensioned concrete box girders, approx. 40 m in span and totaling approx. 190 meters in length, rests on pile foundations embedded in old seabed. The existing bridges, launched from the eastern end, had surplus load-bearing capacities due to their robust prestressing and erection scheme. This structural reserve played a crucial role in the expansion project, allowing for the resistance of additional loading.

The two existing bridges have a gap of approx. 10.2 m between the edge beams, 14.4 m between the faces of the box girders and approx. 19 m between c/c of substructure which is also sketched in Figure 1.

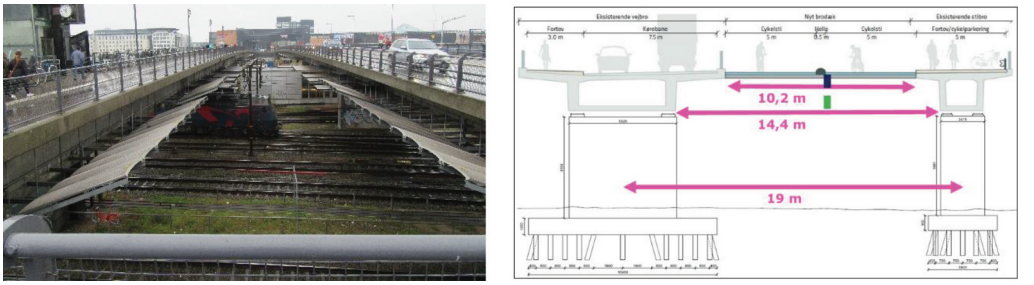

Figure 1. Photo of existing bridges and underpassing railway tracks (left) and main dimensions between bridges (right).

2.2 *External project interfaces and neighboring projects*

The bridges are located at an area giving a lot of different external interfaces which include:

- Underpassing railway track leading into Copenhagen central station
- Catenary system for railway tracks
- A train station having access from the pedestrian bridge
- High number of cyclists and pedestrians crossing the bridge
- A nearby area for long distance busses which had most busses cross the road bridge
- Road traffic on the bridge
- Neighboring projects including plans for erecting twin high-rise student accommodation houses and a large warehouse.

All these interfaces had to be considered and handled during design and under construction. Several of these interfaces heavily influenced the final design of the bridge, in particular the underpassing railway.

2.3 *Considered concepts*

Suspending a new steel bridge between the existing concrete structures required a comprehensive understanding of the existing bridges' load-bearing capabilities and the intricacies involved in integrating a new structure.

Critical to the project was the analysis of static systems and the effective distribution of loads in relation to the existing load carrying capacities. The existing bridges, being post-tensioned continuous spans on pile foundations, offered a robust platform for expansion. Leveraging the existing concrete structures was a cornerstone of this project. The existing bridges were originally designed with surplus load-bearing capacities since both bridges were

push-launched during construction. The design philosophy focused on utilizing these reserves to support the additional weight of the new bridge.

The strategy for integrating a new steel bridge involved suspending it between the existing structures. This approach was chosen for its minimal impact on the existing bridges. The suspension system was to be engineered to ensure stability and safety, with careful attention to the load distribution to avoid overloading any part of the existing structures.

The bridge widening concept needed to consider all the external boundaries and limitations while still resulting in an effective expansion of the available bridge deck area. Initially four different alternatives were considered. These four include:

- New steel deck suspended between wings on existing bridge decks (top left in Figure 2)
- New steel deck suspended between boxes, i.e. 14.4 m spans (top right in Figure 2)
- Beams between existing columns, deck spanning longitudinally between beams, i.e. 14.4 m or 19 m spans to avoid eccentric load on substructure (bottom left in Figure 2)
- New independent parallel bridge (bottom right in Figure 2)

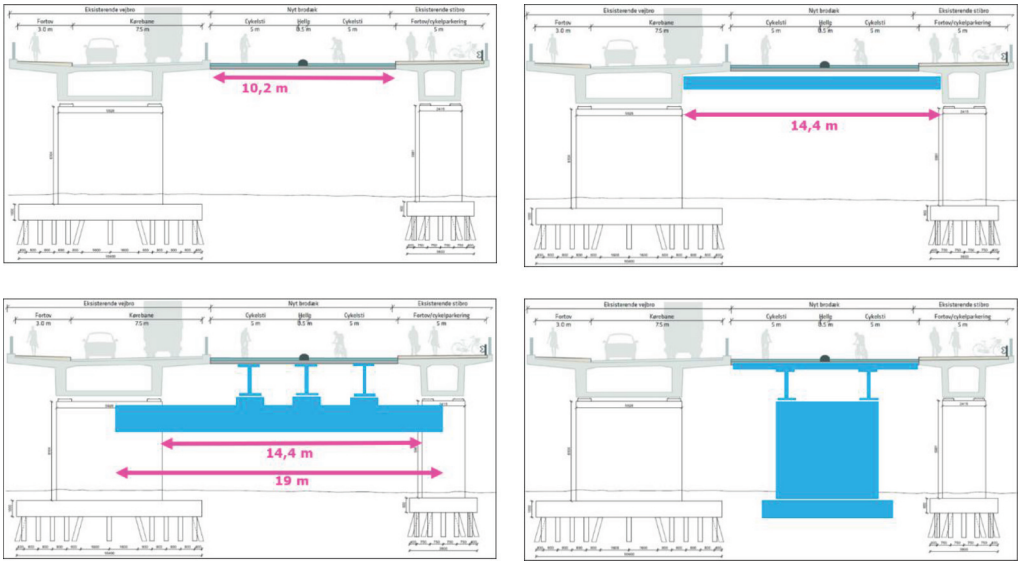

Figure 2. The four concepts initially considered.

All four alternatives had their pros and cons. Alternative 1 with deck suspended between wings on existing bridges was chosen due to the advantages of low self-weight, span width of new structure minimized and simple installation of bridge elements. This alternative further had the disadvantage of high loading on bridge wings and high eccentric loading of existing box girders and substructures. These negative effects were reduced through clever detailing of the permanent supports for the steel deck and implementation of structural parts to reduce the eccentric loading on the substructure. This is further described in the following sections.

2.4 *Design philosophy and structural system integration of implemented concept*

The core challenge of the implemented alternative was to increase the bridge area by 70% without constructing new supports. The design philosophy revolved around leveraging the existing structures' strengths, particularly their load-bearing reserves. The chosen approach was to suspend a new steel bridge between the existing concrete bridges, a method that presented both structural and construction advantages. This approach required detailed planning and precision to ensure compatibility with the existing structures.

Analyzing the static systems and load distribution capabilities of the existing structures was essential. The expansion involved the careful calculation of loads and the distribution of

additional weight between the existing structures. The static system for the new steel bridge was designed to minimize eccentric loading on the existing bridges. The engineering team explored multiple alternatives, eventually selecting a system that optimally distributed the loads while ensuring structural integrity and safety.

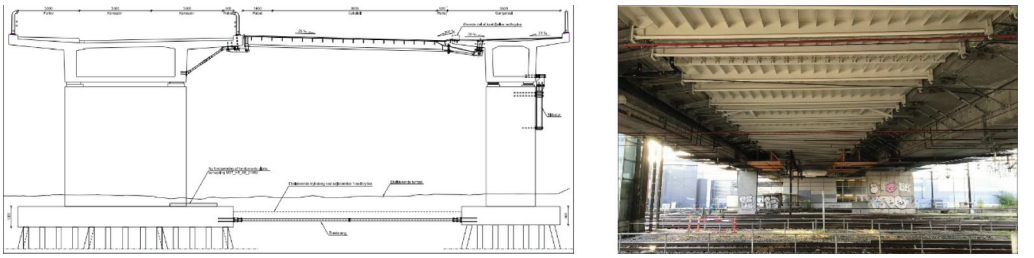

Figure 3. Cross section (left) and photo (right) of bridge after installation of suspended steel deck.

Identification of weaknesses of the existing bridges were essential. Some weaknesses required strengthening of the bridges while others were not possible to strengthen, thus required alternative ways of resisting external forces.

The most significant change due to a weakness was the change in the overall statical system of the three combined bridges. Suspending a deck between the existing bridges results in torsion in the superstructure leading to transverse bending in the substructure. This was, in particular, critical for the pedestrian bridge. The transverse bending was instead resisted by horizontally paired forces where the new steel deck was used as a compression member while new tension members connected the pile caps of the existing concrete bridges.

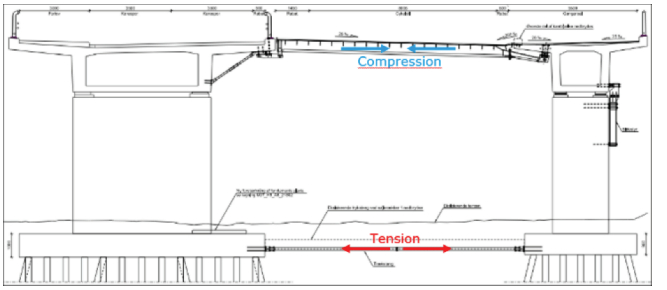

Figure 4. Compression and tension members between existing bridges resists the transverse bending introduced by the eccentric loading created by the suspended steel deck.

3 TECHNICAL CHALLENGES AND SOLUTIONS

The project encountered several technical challenges, notably the need to work above active railway tracks and maintain uninterrupted traffic flow. The solutions included construction of the bridge in elements that could be installed during track possessions of typically 2-3 tracks during nighttime, which allowed for efficient and safe work without significant disruption of the traffic above and below the bridge. This section elaborates on some of the challenges handled in order to meet the requirements to maintain road, pedestrian and cycle traffic and train operation during construction.

3.1 *Safety measures over operational railway tracks*

Twelve railway tracks pass under the bridge. All tracks have very high traffic intensities. Major closures over longer periods were not an option. Track possessions of typically 2-3 tracks during a night were allowed. This called for phased construction by constructing the bridge of

individual elements. Carrying out the full construction of the bridge necessitated approx. 60 instances of track possessions distributed over the approx. 9 months construction period.

Working above active railway tracks presented safety challenges. The steel elements were attached to the bottom of the existing superstructure wings. It was therefore of high importance that unhindered access to the bottom face of the bridges was given. The access was provided by temporary platforms attached to the webs of the box girders. These were installed in segments during nightly track possessions. The platforms included shielding towards the underpassing railway tracks making it possible to work without any disturbance from the railway traffic.

Figure 5. Access platforms below the bridge superstructures.

3.2 *Effects on existing bridges*

Suspending the steel deck directly between the two inner edge beams would introduce torsion into the bridge decks and result in transverse bending in the substructures. This was not a problem for the road bridge but turned out to be critical for the pedestrian bridge. The issue on the pedestrian bridge was solved by connecting the deck closer to the webs of the superstructure as shown in Figure 6.

To ensure sufficient bearing capacity of the wing on the road bridge superstructure, compression struts were introduced as shown in Figure 6. These ensured that the allowable vehicle loading on the bridge could remain the same after the widening. Combined, the 2 solutions are a clear example on how different solutions can be required to meet the different requirements from the existing structures.

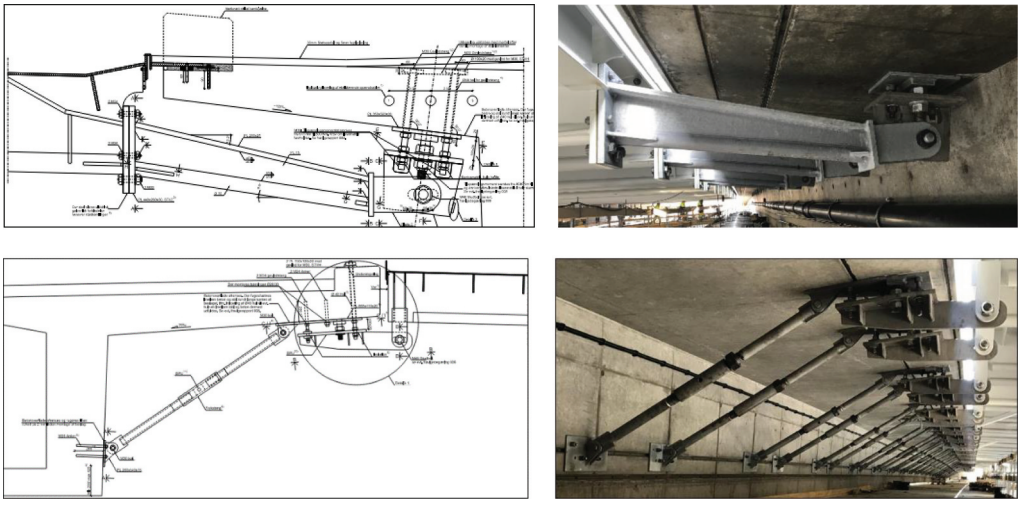

Figure 6. Upper left and right: Suspension of steel deck on pedestrian bridge. Lower left and right: Compression struts below wing on road bridge.

3.3 *Element installation and assembly*

Typically, three elements were installed during a night. Effective installation was required especially for elements above railway tracks since reopening of the railway traffic after a nightly track possession was mandatory. Lifting brackets were developed serving a dual purpose meaning they could be used for lifting the elements into position while also acting as temporary supports for the elements until the permanent supports were installed. After the elements had been placed on the temporary supports it was possible to move the elements into their final position before installation of permanent supports.

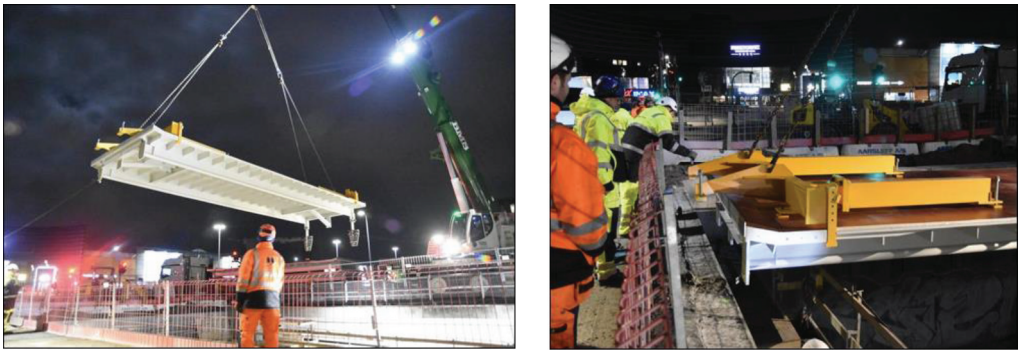

Figure 7. Lifting brackets also serve the purpose as temporary element support.

The steel elements required joining to guarantee the durability of the surfacing and the cyclists' comfort. The temporary platforms below the existing bridges gave access to the existing bridges' wings and approximately 20% of the area of the steel elements. However, as there was no access to the remaining roughly 80% of the steel elements' underside, a bolted connection assembled from above was designed. This connection's primary function was to assure that neighboring elements would deflect simultaneously. The plate in the bolt connection had oversized holes to take up any tolerances during installation. The bolt connection is shown in Figure 8.

Figure 8. Connecting the steel elements from above on the central part of the spans.

3.4 *Permanent supports for steel elements*

The two existing concrete bridges were in theory parallel and shared the same longitudinal profile. However, there were small deviations due to construction tolerances etc. which meant the need for tolerances for installation of the new steel elements. The majority of the tolerances were handled in the permanent support brackets. These were designed to take up tolerances of ±30 mm in transverse and longitudinal directions of the bridge and ±20 mm vertically. The ability to take up tolerances meant that installation of the new steel deck could be carried out without any requirements for demolition and adaption of old/new structure.

Figure 9. Permanent support brackets with capacity for taking up tolerances. Bracket on pedestrian bridge (left) and road bridge (right).

In conclusion, the technical approach to the Dybbølsbro expansion project exemplifies engineering ingenuity. The careful integration of a new steel structure with the existing bridges and the solution-oriented approach to challenges contributed to the project's success.

4 SUSTAINABILITY AND ENVIRONMENTAL CONSIDERATIONS

The expansion of Dybbølsbro not only focused on engineering innovation but also heavily emphasized sustainability. This approach reflects Copenhagen's broader commitment to sustainable urban development.

One of the project's primary sustainability strategies was the reuse of the existing bridge structures. This approach significantly reduced the material consumption typically associated with bridge expansion projects. By leveraging the existing concrete bridges' load-bearing reserves, the need for new substructures was eliminated, thereby minimizing the use of new raw materials and reducing the project's carbon footprint.

Widening the bridge deck without construction of a new substructure is also sustainable in the sense that it significantly reduced the disturbance of the underpassing railway tracks and reduced the economic range for the project.

The project's sustainability considerations extended beyond the construction phase. The new bridge was designed with sustainability in mind, ensuring that future maintenance would be efficient and environmentally friendly. Future surface treatment of the steel deck bottom face towards the railway tracks will have a major impact on the underpassing railway. Therefore, the steel elements were given the best possible surface treatment which included a duplex painting system C5VH. This included spray metallization and paint.

In conclusion, the Dybbølsbro expansion project stands as an example of sustainable engineering, balancing the demands of modern infrastructure development with environmental stewardship.

5 DIGITAL TOOLS AND TECHNOLOGY

The Dybbølsbro expansion project represents a forward-thinking approach to bridge engineering, leveraging advanced digital tools and technologies, all playing an important role in ensuring the project's precision, efficiency and success.

Scanning for Precise Expansion One of the technological highlights was the use of 3D Light Detection and Ranging (LiDAR) scanning. This tool provided three-dimensional data of the existing bridge structures, crucial for the design and integration of the new steel bridge. The LiDAR scans offered detailed insights into the geometry of the existing structures, enabling engineers to make informed decisions about the design and placement of the new components. The information made sure that tolerances required in the project in order for the new deck to be installed on the existing bridges could be determined. This ensured that installation of the elements and permanent supports could be carried out without any major challenges.

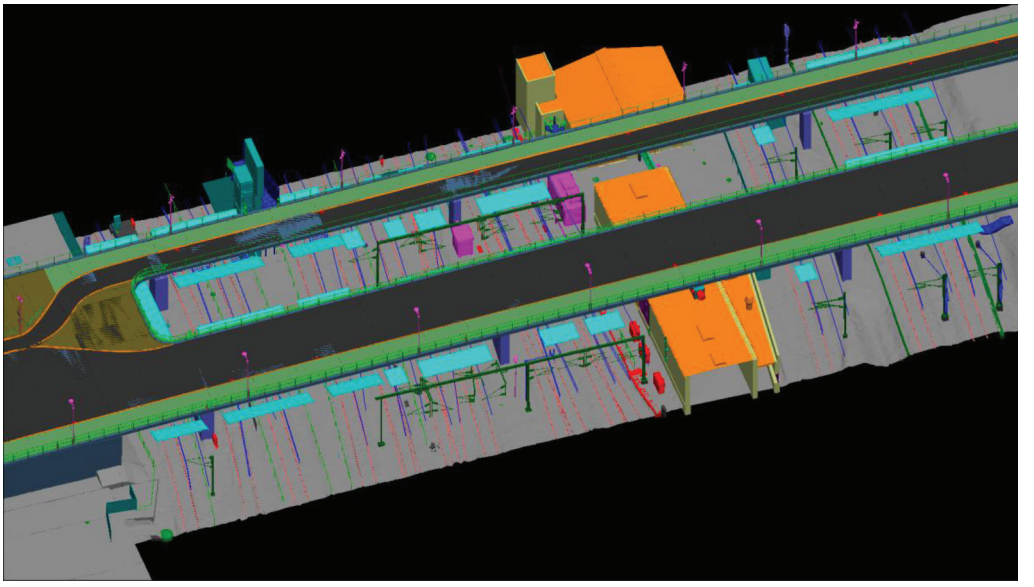

Figure 10. 3D-model created from 3D-LiDAR scanning of project area before installation of the new steel deck. Approximately half of the bridge length is shown.

6 RESULTS AND CONCLUSION

The Dybbølsbro expansion serves as a model for urban infrastructure projects worldwide. It demonstrates how engineering ingenuity, combined with a focus on sustainability and community needs, can lead to significant urban improvements. The project's ability to balance existing structure preservation with modern infrastructure needs is particularly noteworthy.

The project successfully expanded the bridge without constructing a new substructure, an innovative feat that required meticulous planning and execution. A notable accomplishment of the expansion is the creation of Denmark's widest bicycle track. The expanded bicycle track offers ample space for cyclists and pedestrians, significantly improving safety and encouraging more people to opt for cycling over motorized transport.

The expansion project placed a strong emphasis on sustainability, evident in the reuse of existing structures. This approach not only reduced the environmental impact but also preserved the existing structures at Dybbølsbro.

ABSTRACT: Quality resilience assessment for transportation systems relies on realistic representations of the network and traffic demand, and credible network traffic modeling. This paper presents a framework that incorporates time-dependent functionality analysis of disrupted networks and dynamic traffic simulations. Focusing on bridge disruptions, two distinct types of events are considered, earthquake and civil protest. The mesoscopic traffic flow model and the dynamic traffic assignment approach (as opposed to the static assignment approach) are utilized to realistically represent traffic dynamics. The presented results show that the dynamic traffic simulations provide traffic measures at a fine-grained spatiotemporal level which are valuable for post-event performance assessment. Traffic congestion effects are identified in earthquake-disrupted networks. Despite the limited disruption scope, protests on bridges can have significant impact on local travel cost. These findings promote using dynamic traffic modeling for transportation network analysis, highlighting the usefulness of more reliable and granular metrics for decision-making.

1 INTRODUCTION

In the context of community and transportation system resilience assessment, bridges manifest their significance due to their vital role in network connectivity. The efforts required for quality resilience quantification include but are not limited to reliable modeling for hazard and damage analysis, realistic representation of the network and traffic demand, credible traffic simulation as well as calculation of informative performance metrics. The Resilience and Disaster Recovery (RDR) Tool Suite is a state-of-the-art tool for transportation planning decision-making offered to U.S. transportation agencies (U.S. Department of Transportation, 2023). The RDR Tool Suite supports the consideration of hazard-related disruptions and various recovery patterns while at the core it utilizes the user equilibrium-based static traffic modeling. However, it has been recognized that such static traffic assignment approach fails to reflect the time-varying network traffic condition and thus may yield unreliable and even misleading traffic measures (Chiu et al., 2011). While dynamic traffic simulations have reached popularity in system performance assessment under post-disaster emergency evacuation scenarios (Pel et al., 2012), the potential and value to incorporate them into the long-term resilience planning remain to be explored. Moreover, bridges are subject to threats from both human-made and natural hazard events. Depending on the nature and intensity of the events, the number of bridges out of service and the type of actions required to reopen them change.

DOI: 10.1201/9781003483755-386

A comprehensive community resilience assessment should consider the various potential disruptions for which different performance quantification methods and metrics may be used to support decision-making (Rokneddin et al., 2013; Blagojević et al., 2022). In this context, the impact of human-made bridge disruptions (such as protest and terrorism) is less studied compared to that of natural hazard-caused bridge disruptions (such as flooding and earthquake). Indeed, a recent report commissioned by the U.S. Congress recommends that a resilience assessment and a resilience-based cost-benefit analysis should be performed to prioritize investments accessing federal funds (Schofer et al., 2021).

To address the above issues, this study first formally presents a framework that integrates the functionality analysis of disrupted networks and the dynamic traffic modeling. In particular, a case study for a real-world large transportation network is provided, where the bridge-related disruptions from earthquake events and protest events are considered separately. The strengths of dynamic traffic simulations are highlighted by various traffic measures.

2 METHODOLOGY

This study proposes a probabilistic framework for transportation resilience assessment that incorporates the time-dependent functionality analysis of disrupted transportation networks and the analysis of traffic dynamics. As shown in Figure 1, three modules — the Hazard (or Disruptive Event) Simulation module, the Damage and Functionality Assessment module, and the Recovery Analysis module — determine the disrupted state and functionality of the transportation network at any investigated time (t). Taking as input the time-dependent transportation network, the traffic analysis consists of two other modules: the Traffic Demand module, and the Dynamic Traffic Simulation module. Uncertainties are considered in all five modules and propagated throughout the framework. More details on the approaches and tools used by all modules are provided in the subsections that follow.

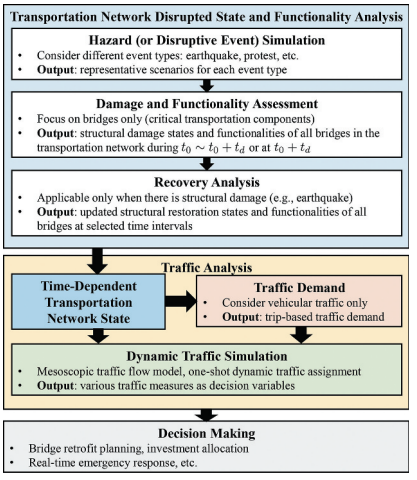

Figure 1. Framework for transportation resilience assessment and resilience-based decision making.

2.1 *Hazard simulation*

Table 1 compares the characteristics of the two distinct types of events with a focus on bridge disruptions in the transportation network. Despite the seemingly lesser extent, human-made events like protests are more frequent and can cause severe traffic disruptions. Therefore, for a comprehensive assessment of the system and community resilience, both types of events should be considered.

Focusing on bridges only, this study considers two types of disruptive events: earthquakes and civil protests. In the Hazard Simulation module, a portfolio of representative and realistic scenarios should be created for each considered event type. For this purpose, the well-established earthquake hazard model available in Hazus can be utilized (FEMA, 2022). In contrast, there is a lack of hazard models for human-made events. Concerning the disruptive effect on traffic, a protest event can be captured by several key descriptors, including the location, start time (t_0), duration (t_d), etc. Hence, a set of protest scenarios can be generated with combinations of well-defined descriptor values, for which local expertise shall be consulted.

Table 1. Different characteristic of disruptive events (earthquake and protest as illustrative examples).

Event type	Frequency	Structural damage	Functional loss	Spatial extent	Temporal extent
Earthquake	Relatively rare	Yes	Yes	Relatively large (multiple bridges)	Instantaneous ($t_d \approx 0$) but entails recovery process (Δt)
Protest	Relatively frequent	No	Yes	Relatively small (very few bridges)	Lasting (t_d) but with immediate recovery ($\Delta t \approx 0$)

2.2 *Bridge damage and functionality assessment*

The second module performs damage and functionality assessment for bridges during and after the event. Damage assessment is done from the structural perspective and is based on physical damages, such as cracking of columns. On the other hand, the functionality assessment is done from an operational perspective and is based on the functional loss, such as closure or reduced traffic flow capacity of the bridge. As shown in Table 1, earthquake events can cause structural damage to bridges with subsequent functional loss, whereas protests can shut down traffic on bridges even if there is no structural damage. This study adopts fragility curves available in Hazus for seismic damage assessment of bridges (FEMA, 2022). Figure 2a shows example fragility curves for a class of highway bridges. For an earthquake scenario, the damage state (DS) probabilities for each bridge in the transportation network can be obtained. For the other components in the transportation system (e.g. roadways and tunnels), a similar analysis can be performed.

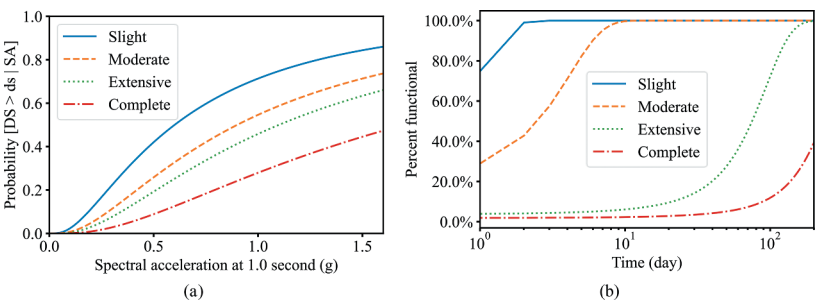

Figure 2. (a) Fragility curves for highway bridges (reproduced from Hazus); (b) Restoration curves for highway bridges (reproduced from Hazus).

The functionality assessment for seismically damaged bridges are also performed utilizing Hazus. The functionality result given by Hazus, expressed as the percentage of the full functionality, is the expected functionality ($\bar{Q}(t)$) which can be computed by:

$$\bar{Q}(t) = \sum_{i=1}^{5} P(DS_i) \cdot Q_{DS_i}(t) \tag{1}$$

where i indicates one of the five possible initial damage states, i.e. no damage, slight damage, moderate damage, extensive damage, and complete damage;$P(DS_i)$ is the probability of the bridge being in the initial damage state i; and $Q_{DS_i}(t)$ is the time-varying functionality percentage corresponding to the initial damage state i (see Figure 2b). Hazus adopts deterministic functionality recovery models, but more sophisticated, probabilistic models can be easily integrated in this framework (Decò et al., 2013).

This expected functionality can be used to compute the reduced traffic flow capacity which can then be input for the disrupted transportation network analysis. More details on the damage and functionality analysis in Hazus can be found here (Rojahn et al., 1985). For protest events, damage assessment is not needed with the assumption that no structural damage is involved. Based on the fact that protests typically result in complete bridge closure, it is assumed that the bridge is non-functional (i.e. traffic flow capacity becomes zero) during the protest event.

2.3 *Bridge recovery analysis*

Recovery analysis, sitting in the core of resilience assessment, quantifies the restoration performance of the system and community following disruptive events. Depending on the nature and intensities of the events, the restoration activities required to reopen bridges vary. For post-earthquake recovery analysis of bridges, restoration curves are used herein. As shown in Figure 2b, each restoration curve describes the functionality change of the bridge as a function of time ($t \geq t_0 + t_d$), given an initial damage state after the earthquake (FEMA, 2022). Despite the continuous form of the restoration curves, in practice recovery analysis is often performed at selected time intervals where Δt can be 1 day, 3 days, etc. As for protest events, given that no physical damage is caused, it is assumed that the bridge will regain its full functionality immediately after the protest is dismissed (i.e. $\Delta t = 0$).

With the abovementioned three modules, the time-dependent physical state and functionality of the transportation network (i.e. supply) can be determined. While the study of any disruptive event can be generally divided into 3 stages, i.e. pre-event ($t < t_0$), during event ($t_0 \leq t < t_0 + t_d$), and post-event ($t \geq t_0 + t_d$), the evolution of the network functionality can be relevant only in some of these phases, depending on the type of extreme event considered. For earthquake events that are instantaneous but often cause physical damages, it is more meaningful to discuss the time-dependency of the network during the post-earthquake recovery stage. As for protests that usually last for hours but exhibit immediate recovery, the time dependency is more relevant during the event.

2.4 *Traffic demand*

Another input required for traffic simulation is the traffic demand, which is defined as trips and conventionally represented by Origin (O) - Destination (D) matrices for certain time periods. The normal (before event) traffic demand is traditionally generated based on household travel surveys and is generally available from transportation authorities. The during-event and post-event traffic demand, however, can be drastically different due to the disrupted physical network and the purposes of trips (such as emergency evacuation) (Pel et al., 2012). This study aims to investigate the effect of bridge-related disruptions on the performance of transportation systems in support of long-term resilience planning decisions. Therefore, the emergency evacuation traffic analysis is beyond the scope of this work. Specifically, the normal traffic demand corresponding to the morning rush hours is used herein. Despite the disrupted networks, this traffic demand is assumed to remain unchanged and is used for post-earthquake traffic analysis at the selected time intervals. This approach does not aim at capturing the actual traffic flows during the emergency response. Instead, this approach allows to determine the network performance "normalized" to standard traffic demands. For protest events, the same normal traffic demand is also used for the disrupted network.

2.5 *Traffic simulation*

The Traffic Simulation module performs network system analysis considering the interdependence of component functionality (bridges, roadways) and overall system functionality. For this

purpose, microscopic simulation software such as the Simulation of Urban Mobility (SUMO) can be used while other options are also available (Alvarez Lopez et al., 2018). In particular, a spatial-queue-based mesoscopic traffic flow model is recommended over a microscopic traffic flow model because of its efficiency for large network analysis and relatively detailed outputs. To more realistically model the time-varying traffic flow dynamics, the one-shot (non-iterative) dynamic traffic assignment approach is recommended. Compared to the static traffic assignment, dynamic network analysis not only determines the travel time and cost measures more credibly, but also provides fine-grained insights into the spatiotemporal change of traffic that are useful for decision making (Chiu et al., 2011).

3 CASE STUDY

The transportation network in the San Francisco (SFO) Bay Area is selected for the case study, where both the earthquake and protest disruptions are investigated. Figure 3 shows the SFO network which has a total length of 564,340 lane-km (Ambühl et al., 2023). The Santa Clara county is chosen as the study region for earthquake analysis and it covers mostly the bottom part of the network. In addition, this case study focuses on the highway transportation system and thus only highway bridge damage is considered in the analysis. The locations of the 962 highway bridges within the Santa Clara county are also shown in Figure 3.

Using SUMO for traffic simulations, this study considers only vehicular traffic while other transport modes (e.g. transit, pedestrians) are ignored. The trip-based traffic demand is defined for the entire SFO network using available data (Ambühl et al., 2023). For earthquake hazard events, the traffic simulation starts with a post-earthquake disrupted network (at $t = t_0 + t_d + \Delta t$) due to bridge damages before loading any vehicle onto the network. For protest events, the traffic simulation starts with an undisrupted network (at $t < t_0$) and bridge disruptions are applied beginning from t_0 while there is already traffic on the network. Note that the Traffic Control Interface (TraCI) provided by SUMO is used to achieve the real-time disruptions on a running traffic simulation. All traffic analyses are performed for the extended morning rush hours (6:00 AM–10:00 AM). Periodic rerouting is used to simulate vehicles adapting to jams or other changes in the network. Specifically, every 6 minutes, 50% of the vehicles will update their shortest-path routes. Moreover, 325 induction loop detectors (sensors) are simulated within the network. The simulation time step length is 1 second while the results are aggregated every 5 minutes. Results and discussions for the respective events are provided in the sub-sections below.

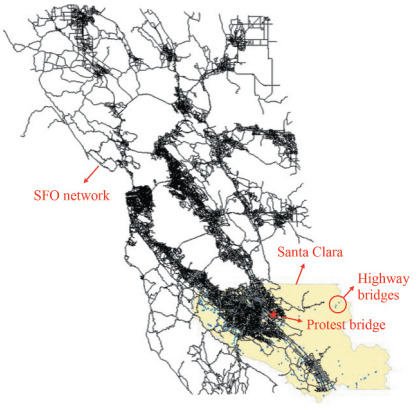

Figure 3. The SFO transportation network in relation to the Santa Clara county.

3.1 *Earthquake event*

For illustration purpose, one earthquake scenario (return period = 100 years, magnitude = 7.0) is analyzed for the highway transportation system in Santa Clara. The functionality

distribution of all highway bridges at selected time intervals is presented in Figure 4a. As expected, Day 1 bears the worst situation with the lowest median functionality (92.20%) and the largest dispersion (8.32%). The functionality of damaged bridges is gradually restored over time, as observed from the increasing median and decreasing dispersion. Although the functionality results by Hazus are in continuous form, for simplicity, this study adopts a binary classification for bridge service status. A bridge is classified as out-of-service (i.e. closed) if its expected functionality is smaller than 75% or as in-service (i.e. open) otherwise:

$$S(t) = \begin{cases} 0 & if\ \overline{Q}(t) < 75\% \\ 1 & if\ \overline{Q}(t) \geq 75\% \end{cases} \tag{2}$$

where $S(t)$ denotes the in-/out-of-service bridge status actually used in the network. As a result, there are 39, 23, 15, 12, 11, and 1 bridge needing to be closed at the six time intervals respectively, which is depicted by different colors in Figure 4b. The post-earthquake disrupted networks are created by making the corresponding edges inaccessible. Traffic analyses are performed for Δt = 1, 3, 7, 14 days only, since the network states at Day 30 and Day 90 are only one bridge different from that at Day 14 and pre-earthquake respectively.

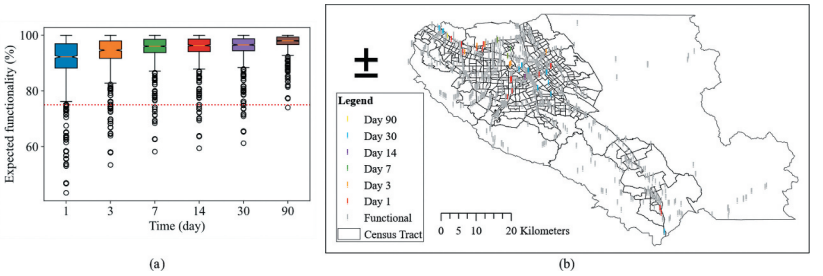

Figure 4. Bridge functionality in the network: (a) boxplots at selected time intervals; (b) map of closed bridges.

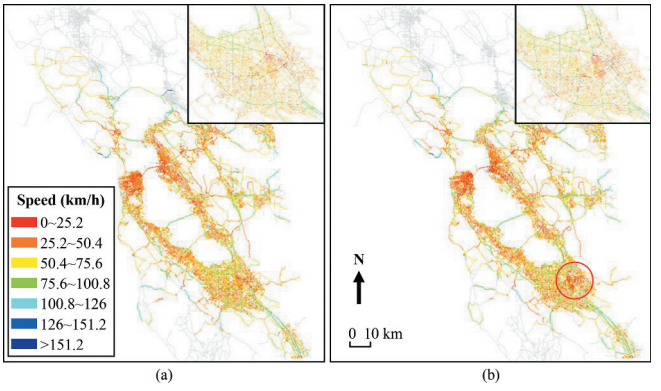

Figure 5. Snapshots of network speeds at 8:00 AM: (a) non-disrupted network; (b) disrupted network (1 day after earthquake).

The trip duration is an important traffic measure for evaluating the performance of the transportation system. With the same traffic demand, the durations of all trips within the morning rush hours are obtained for the abovementioned different network states. It is found that the disruptions due to closed bridges slightly increase the trip durations systemwide. For example, the first quantile, median, and the third quantile of trip durations for pre-event are 10.3 minutes, 18.8 minutes, and 35.9 minutes, whereas those for Day 1 are 10.4 minutes, 19.3 minutes, and 36.9 minutes. As the bridges are recovered, the performance of the network

improves with trip durations at Day 14 almost reaching the pre-event level. The disruption impact on trip duration appears small (even at Day 1), which can be attributed to several factors. For instance, the disruptions of the physical SFO network are limited to the small portion within Santa Clara (see Figure 3), so the disruption impact may be diluted by the overall traffic on the entire network.

One exclusive benefit of the dynamic traffic simulation is that it offers insights into the spatio-temporal evolution of the traffic on the network. Figure 5a, b present the snapshots of the network speeds at 8:00 AM (2 hours after the traffic analysis starts) with zoomed-in portions at the top right corners. Compared to the non-disrupted network, the disrupted network clearly indicates new congestion near where the highways bridges are closed (see the red circle in Figure 5b). Such traffic congestion effects, captured by dynamic traffic simulations at a fine-grained temporal level, are valuable for evaluating the bridge disruption impact with greater granularity.

3.2 *Protest event*

For simplicity, only one hypothetical protest scenario is considered herein. The protest is assumed to happen during 8:00 AM–9:00 AM on the bridge (37°19′55.5″N, 121°51′53.3″W) which has the highest daily traffic (238,000 vehicles/day) among all 962 considered highway bridges (FEMA, 2022). The corresponding two edges (in opposing directions) are part of the Sinclair Freeway associated with the Interstate 280 (I-280) near downtown San Jose (see Figure 3). TraCI is used to achieve the real-time interactions with the simulation – closing edges at 8:00 AM and reopening them at 9:00 AM.

Figure 6a shows the disruptive impact of the protest on trip duration, where the trips are selected such that the departure time is during 8:00 AM–9:00 AM and the departure or arrival edge is close to the disrupted edges. Although only one bridge is involved, it is shown that the disruption leads to noticeable increase in travel cost with the median trip duration escalating from 26 to 32 minutes. Given the special attributes of protest events (i.e. local disruption, short duration, immediate recovery), sensor-measured speed — available by dynamic traffic simulation as well as with traffic sensors in reality — may be useful for evaluating the recovery ability of the system and the community. Figure 6b shows the speed time histories at five simulated sensors that are closely related to the inaccessible edges. As expected, following the start of the event, the speeds drop to zero at all five sensors because vehicles are routed away from using the associated edges. Note that sensors 1 and 4 are located further to the closed edges than the other sensors, which explains the time lag of speed drop. Traffic flow is restored immediately after the disruption ends, as observed from Figure 6b. It is worth mentioning that such real-time traffic measures offered by dynamic traffic simulation can be useful for emergency response, such as for emergency vehicle routing.

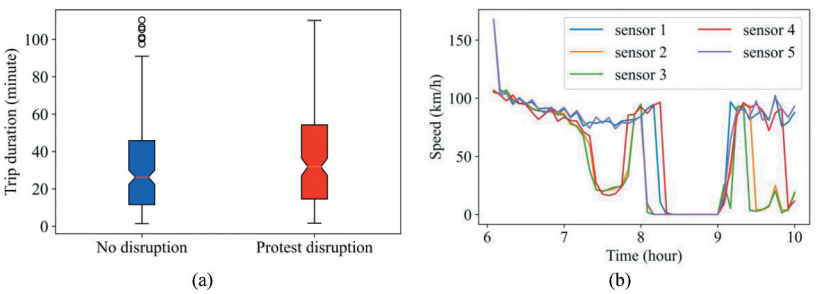

Figure 6. Protest disruption impact: (a) comparison of trip durations; (b) speed time histories (5-minute aggregate).

4 CONCLUSIONS

This paper presented a framework for transportation system resilience assessment that integrates functionality analysis of disrupted networks and dynamic traffic analysis. Two distinct types of

events — earthquake and protest representative of natural hazard events and human-made events respectively — were investigated. The dynamic traffic simulation can provide more insights into the system performance with greater granularity than static simulation, as shown in the case study. For example, the spatiotemporal speed patterns within the network were used to identify disruption-introduced bottlenecks and congestion. Bridge disruption caused by protests (or other events alike) can have important influence on the local traffic, as shown by the noticeable increase of trip durations. Despite the short duration and immediate recovery, such disruptions should not be ignored, because they can have significant impact on emergency response.

Future work can include exploring the applicability of the framework to other types of events, such as floods and fires. Furthermore, the results should benefit from using more representative scenarios, as well as exploring the traffic stochasticity by using different random seeds in traffic simulation.

ABSTRACT: Environmental and resource constraints are crucial for adapting Critical Transport Infrastructures (CTIs) to the ever-changing environment. Inadequate resources coupled with the implementation of non-resilient and unsustainable mitigation measures pose a considerable risk, potentially steering CTIs towards maladaptation. This paper investigates the interplay of CTIs' resilience and adaptive capacity under multiple hazards. In line with this, the resilience level of a bridge case study is estimated with the use of resilience indices. Beyond resilience assessment, the research scrutinizes the efficacy of potential mitigation measures designed to facilitate the adaptive transition of these critical assets. In a proactive approach to mitigate maladaptation risks, the chosen measures undergo a thorough evaluation using sustainability indices. This evaluation considers a comprehensive spectrum of criteria, encompassing societal, environmental, and economic factors. By blending resilience and adaptive capacity analyses with sustainability assessments, this paper aims to provide a holistic framework for fortifying CTIs against the uncertainties of a dynamic environment. Through a careful examination of both the challenges and opportunities, it strives to guide the implementation of resilient and sustainable strategies, ensuring the continuity and efficiency of critical transport infrastructures in the changing world.

1 INTRODUCTION

The urgent need for Critical Transport Infrastructures (CTIs) adaptation to the new demands and the extreme load conditions is guided by environmental and resource constraints (OECD, 2020). In 2022, the United Nations Office for Disaster Risk Reduction announce the six interconnected principles for resilient infrastructures in alignment with the objectives of the Sustainable Development Goals (SDGs) for achieving systemic infrastructure resilience. The principles ensure that infrastructures' management is based on 1) continuous learning, 2) proactively protection, 3) environmental integration; 4) shared responsibility; 5) protection by design and 6) adaptive transformation (UNDRR 2023).

Following a strategy for the adaptive transformation of CTIs, the exploit of lessons learnt, and the benefits of emerging technologies ensure for the proper allocation of resources and minimization of losses (Buurman & Babovic 2016); (Connelly et al. 2017); (Miao & Ghosn 2016); (Ghasemi & Nowak 2017); (OECD, 2020); (Bueb et al. 2021); (IPCC, 2022); (UNDRR, 2023).

DOI: 10.1201/9781003483755-387

As information technologies emerge, big data are generated and need to be man– collected, transmitted, and processed to support decision-making. New generation sensors have been used broadly to enhance reliability (Achillopoulou et al. 2020); (OECD, 2020); (Makhoul et al. 2023a).

The probability of exceeding acceptable limits depends on many parameters and the ageing period (Cerar et al. 2017). The reliability of information lead to different strategies of maintaining the asset and taking measures. This paper develops a methodology to assess the adaptive capacity of an asset taking into account engineering, economic and social parameters.

2 ADAPTIVE TRANSITION

The adaptive transition of CTIs into more resilient and sustainable systems depends on their adaptive capacity (Werners et al. 2021); (UNDRR 2023). The adaptive capacity expresses the ability of infrastructures to efficiently adjust and cope with the progressively changed environment, as well as the shifts in the supply and demand (Adey et al. 2003). As such, monitoring the capacity of CTIs throughout their lifecycles, adaptive transformation can be achieved (ADB, 2021); (Mehryar et al. 2022); (UNDRR 2023).

2.1 *Adaptive pathways*

The strategic deployment and implementation of dynamic and flexible Adaptive Pathways (APs) is needed to manage efficiently the long-term impacts of climate change and financial instability. Within this context APs, represent a sequence of decision points, related to events, mitigation measures and risk levels through time to achieve specific objectives and goals (Bueb et al. 2021); (Werners et al. 2021); (IPCC, 2022); (Makhoul et al. 2023b). Therefore, APs can be beneficial for CTIs' adaptive transition by avoiding maladaptation (Bueb et al. 2021); (Werners et al. 2021); (IPCC, 2022); (Makhoul et al. 2023b).

2.2 *Data-driven resilience*

The resilience level associated with a pathway exhibits a robust correlation with several parameters encompassing the sequence of events, hazards, mitigation actions, financial and environmental constraints, infrastructure's structural integrity and functionality levels as well as risk levels (Bueb et al. 2021); (IPCC, 2022); (Makhoul et al. 2023b). Hence, the pathway's resilience level is data-based and fluctuates among the different actions' resilience levels.

Data-driven resilience quantification is highly contingent upon the risk level (Achillopoulou et al. 2020); (Afrin et al. 2023). Data, and actions associated with increased risk levels can result to maladaptive APs (Werners et al. 2021); (IPCC, 2022); (Makhoul et al. 2023b). The lower the risk level is, the more reliable the resilience level of AP can be. As such, to avoid CTIs' devaluation, the following AP should be represented by a series of actions characterized by increased reliability and resilience levels over time (Bueb et al. 2021); (IPCC, 2022).

2.3 *Reliability of data*

The holistic impact of uncertainties on CTIs is crucial for their efficient management and associates with the reliability of data (Frangopol et al. 2019); (Diamantidis et al. 2019); (Achillopoulou et al. 2020). Poor reliability can result to non-resilient and -sustainable actions leading to maladaptation of CTIs (Bueb et al. 2021); (Werners et al. 2021); (IPCC, 2022); (Makhoul et al. 2023b).

The uncertainties of CTIs decision-making policies throughout their life cycles may pertain to factors such as climate change effect, economic instability, probability of failure and/or asset disruption, mitigation measures effectiveness as well as the accuracy of models, analyses, codes, metrics and monitoring data (Frangopol et al. 2019); (Achillopoulou et al. 2020); (Makhoul 2022); (Afrin et al. 2023). Their quantification makes aware stakeholders of the risk level and can be achieved by statistical and probabilistic models; scenario analysis, pathways deployment and expert judgment when the data is limited (Diamantidis et al. 2019);

(Achillopoulou et al. 2020); (Pasman & Rogers 2020); (Malekloo et al. 2022). Model updating can also be employed to reduce further the uncertainties levels by aligning computational models with the most realistic data and predictions (Achillopoulou et al. 2020); (Malekloo et al. 2022); (Makhoul et al. 2023 a and b).

2.4 *Sustainability*

Sustainable solutions to the decision-making process of CTIs can be well informed by enhanced reliability levels as they derive from accurate data and predictions (Achillopoulou et al. 2020); (Makhoul et al. 2023b). On the contrary, sustainability is not always expressed by actions with high resilience levels (IPCC, 2022); (Makhoul et al. 2023b). Environmental compatibility, adequate structural integrity levels and prevention of CTIs' disruptions along with optimum use of resources are crucial to ensure sustainability in resilience solutions (UNDRR, 2022 and 2023); (Makhoul et al. 2023b). In line with this, to obtain long-term socio-economic and environmental benefits that enhance the adaptive capacity of CTIs, sustainability constraints need to be established (European Commission 2022); (UNDRR, 2022 and 2023); (Global Infrastructure Hub 2023); (Lei et al. 2023); (Makhoul et al. 2023b).

3 METHODOLOGY

In this research, the quantification of resilience, sustainability and adaptation levels of CTIs, such as highway bridges, is founded on the research by Stamataki et al. (2023) and integrates the APs framework introduced by Makhoul et al. (2023b). The sequential phases of the methodology, which is used for the evaluation of the mitigation measures through the assets' life cycle to assess the pathway with the optimal resilience level, the lowest resources cost, and the supreme socio-economic and environmental benefits, are illustrated in Figure 1.

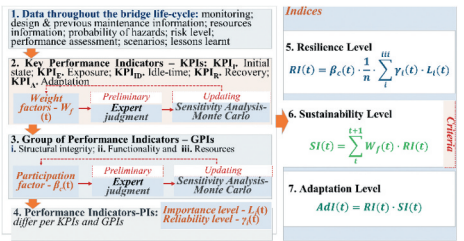

Figure 1. Adaptation space assessment methodology.

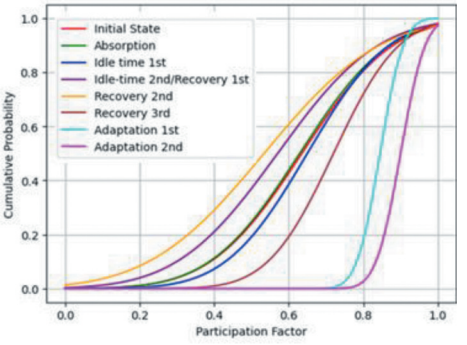

Figure 2. Probability of participation factor values over time.

3.1 *Data*

The methodology is data-driven, multi-criteria and comprises with seven phases commencing with the data acquisition. Data are not limited only to the maintenance information and design, but also to the lessons learnt throughout the life-cycle.

3.2 *Key performance indicators*

Key Performance Indicators (KPIs) that express the ageing periods of the asset's life cycle are employed to further organize and correlate the data. In general, there are five KPIs, though their number can differ from asset to asset. For example, the number of KPIs associated with

idle-time (KPI_{ID}) and recovery period (KPI_R) initiation is related to the number of mitigation measures implemented in the case-study. To assess the contribution of the asset's ageing periods, Weight factors (*Wf*) are applied to each KPI. The preliminary *Wf* are established through experts' judgment, and their values are subsequently updated after the completion of the recovery periods. In cases where the asset demonstrates adequate levels of resilience and sustainability, reflecting an enhanced adaptive capacity, the *Wf* are recalculated based on a Sensitivity Analysis (*SensAn*).

3.3 *Resilience components*

Comprehensive research has been carried out concerning the resilience of CTIs, emphasizing their functionality and the interplay with structural integrity, as well as the resource requirements for their maintenance (Capacci et al. 2022). These three indicators are interdependent as inadequate levels of performance condition can trigger asset disruptions, whereas a lack of resources can progressively lead to safety and functionality problems. In line with this, the components of resilience considered in the adopted methodology are three and are related to i) the structural integrity, ii) the functionality and iii) the resources of the asset.

The components are expressed by Group of Performance Indicators (GPIs) that are considered complementary and are factored per KPI with the use of participation factors (β_c). The preliminary estimation of the participation factor for the resources component derives from a Life Cycle Cost (LCC) analysis as Stamataki et al. (2023) have already presented. A *SenAn* follows to determine the $\beta_c(t)$ per KPI based on the resilience thresholds as Stamataki & Achillopoulou (2023) have proposed. The criticality of the components on the overall resilience level arises from the type of distribution function of the factors. Throughout the life-cycle of the asset, the participation factors are also calibrated with a more sophisticated Monte Carlo Analysis (Figure 2).

3.4 *Parameters*

A set of Performance Indicators (PIs) is employed to associate the available data with the parameters that express each one of the GPIs. The total number of PIs (n) per component differ, whereas different PIs can be activated throughout the ageing periods of the asset. For example, the parameter of continuous monitoring is activated at the KPI corresponding to its initiation, while in cases of periodic monitoring, the parameter is deactivated. The assessment of each PI accounts for two variables i) the importance level and ii) the reliability factor as described in subsections 3.4.1 and 3.4.2 respectively.

The PIs pertaining to structural integrity are articulated with data such as a) the geometry and the type of the asset, b) material properties, c) damage index, d) structural health monitoring data, e) performance assessment, f) hazard occurrence, g) structural mitigation measures, g) mitigation impact and h) environmental limitations. Analogously, the PIs for functionality encompass a) design traffic capacity, b) traffic load changes, c) disruption, d) functionality monitoring data, e) functionality mitigation measures, f) hazard occurrence and extreme events, g) mitigation impact and h) environmental limitations. Finally, the resources component employs PIs such as monetary resources for a) maintenance and b) replacement, c) need for expertise staff, d) human resources, e) need for investment, f) financial limitations and g) bridge financial impact.

3.5 *Importance level*

The importance level (L_i) of each PI corresponds to the influence of the parameter in the resilience quantification. In total, the methodology comprehends four importance levels: 1-low, 2-moderate, 3-high and 4-very high. TheL_i may vary or remain consistent depending on the parameter and the ageing stage of the asset's life cycle. For example, factors such as failure of support or tendon loss are characterized by a consistently "4-very high" importance level per KPI due to their impact on the asset's safety and functionality levels.

3.6 *Reliability factor*

The methodology takes account of two different reliability levels with the use of reliability factors (γ_i). The first level pertains to reliable PIs with values equal or higher than 92.5%

($\gamma_i \geq 92.5\%$), while the second takes values below 92.5% ($\gamma_i < 92.5\%$), signifying non-reliable PIs. The factor is associated with the distribution function each PI follows, or the risk level and the probability of occurrence related to the PI ($\gamma_{i,PI}$), such as in cases of hazards, increase traffic demands and requirements for capital infusion. The γ_i is further updated based on the performance assessment of the asset in various scenarios ($\gamma_{i,p}$). The overall factor is anticipated to decrease over the exposure periods, while the implementation of mitigation measures and monitoring systems is expected to augment it.

3.7 *Resilience Index*

The overall resilience level of the asset is based upon the calculated resilience indices per KPI, *RI*(t), as presented by the equation in phase 5 of Figure 1. It derives from an overall average of risk, hazards, monitoring, components (structural, functionality, resources, operation) also taking into consideration the reliability level. The index ranges from 1 to 4, with lower values denoting a lower level of resilience. The critical level is at the middle of the scale corresponding that any further decrease of the RI can be related with safety, functionality and/or resources.

3.8 *Sustainability level*

Increased resilience levels did not always ensure high levels of sustainability. In the past decades, sustainable planning and management were not of high concern. Sustainability was promoted in 1987 WCED Commission's Report. The sustainability level is defined by Sustainability Indices, *SI*(t) as indicated by the equation in phase 6 of Figure 1. The estimation of the *SI*(t) takes advantage of the calculated *RI*(t) and the weighted KPIs. For a certain KPI the SI is calculated as the relative sum of the SI between two successive ageing periods.In this study, all pillars of sustainability are considered by including: 1) the environment through climate change, 2) the society through the population and traffic increase, and 3) the economy through the resources allocated to the infrastructure project.

3.9 *Criteria*

To ensure that the indirectly expressed sustainability level of the asset is well informed by the weighed RI, proper criteria and a classification scale ranging from 1 to 4 are selected. A rating of 1 denotes a non-sustainable level, 2 indicates the necessity for sustainability improvement, while 3 and 4 signify levels ranging from acceptable to sustainable sustainability. The selected criteria are related with the three pillars of sustainability i) society, ii) economy and iii) environment and take account the impact of the CTI throughout its life cycle.

3.10 *Adaptation Index*

The Adaptation Index (AdI) serves as a metric for assessing the adaptation level, and thus adaptive capacity of asset over its life cycle, in addition to evaluating the efficacy of different mitigation measures and policies. As the adaptive capacity should encompass both resilience and sustainability considerations the AdI is considered as their intersection and is determined based on the computed *RI*(t) and *SI*(t), as presented i by the equation in phase 7 of Figure 1.

4 CASE-STUDY

The bridge case study of this research the Hollandse Brug, the oldest prestressed RC highway bridge in the Flevopolder region of the Netherlands. The bridge plays a crucial role in connecting Almere, Amsterdam, and Schiphol Airport. Since its construction in 1969, many operational challenges led to the implementation of various mitigation measures throughout time. In 2007, as part of a refurbishment effort, a system of sensors was installed on the deck of the bridge for the continuous monitoring of strains, deflections, and temperatures (Achillopoulou et al. 2022); (Stamataki & Achillopoulou 2023); (Makhoul et al. 2023b). A Finite Element Analysis was performed to further investigate the performance and flexibility of the bridge under multi-hazards especially with climate change.

4.1 *Scenarios*

The hazard scenarios are based on the region's risk and account for a) traffic load changes and b) seismic events. According to NCEI (2023), in the next 50 years, the temperature increase in the region is expected to be slightly lower than the worldwide average, but still significant. Further to this, an augmented increase in the bridge's traffic volume, 247% greater than 1990, is predicted to take place by 2030 (IPCC, 2023). The earthquake occurrence in the Netherlands is classified as medium, meaning that in the next 50 years there is a 10% probability of such an event. In total four different hypothetical scenarios are considered as Table 1 presents. At the first stage of all the scenarios, the bridge is subjected to an initial temperature difference (ΔT) of 10◦C to consider the temperature increase due to global warming. The next stages of the scenarios include the occurrence of hazards related to traffic load changes (normal or increased) and seis-mic events (design or extreme). The final stage (4th) for all the scenarios, i.e., after the seismic event, restores the bridge to the initial considered traffic conditions (normal or increased).

Table 1. Multi-hazard scenarios.

Stage	1st	2nd		3rd		4th	
Hazzard	ΔT 10°C	Traffic		Seismic event		Traffic	
Scenario		*n*	*i*	*d*	*e*	*n*	*i*

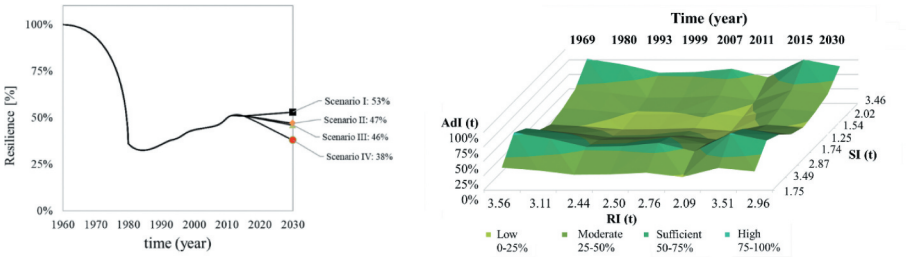
* Symnols *n* and *i* are used for normal and increased traffic load and *d* and *e* for design and extreme seismic events.

4.2 *Simulation*

The bridge is 355m long with seven simply supported spans, featuring a 38m wide deck following its expansion in 2007. The structure comprises nine prefabricated prestressed girders and four cast in situ and post-tensioned transverse beams evenly distributed across the spans. The deck is supported by piers connected by elastomeric bearings, which offer both vertical stiffness and flexibility for anticipated horizontal deformations.

The model of the bridge was created with SOFiSTiK software. The dimensions estimated from existing drawings, and any missing data, such as transverse beam geometry, reinforcement arrangements, and prestressed tendons, were determined based on load combination results. The RC elements (slab, beams, piers) were simulated using 3D finite elements. Three axial and torsional springs were used for simulating the bearings.



5 RESULTS

The results of the four scenarios examined are shown in Table 2 in terms of the percentage of the structural elements, parameters or functionality been affected. The first scenario indicates that the damages in the girders, transverse beam or the bearings provoke a disruption of traffic with closing a part of the bridge for mitigation measures. The crack width seem to be unaffected by the increase of temperature and the designed traffic load. The second scenario indicates that even there are not extensive failures the risk of damage is increased since the percentage of elements passing the controls are decreased and approximately 10% of them are not sufficient to bear the loads. This automatically would cause a disruption on the bridge functionality by closing more lanes (based on the map of damages). Scenario III induces greater damages and risk of failure to the structural elements. From the analysis results, 83% of the structural elements are passing the acceptable thresholds, whereas 58% of the bearing

do pass too. Lastly, Scenario IV prompts the severe damaged to be happened resulting in full closure of the bridge for mitigation measures and avoidance of losses.

Table 2. Multi-hazard scenarios' results.

Elements/ parameter	Scenario I			Scenario II			Scenario III			Scenario IV		
	failed %	damaged %	pass %	failed %	damaged %	pass %	failed %	damaged %	pass %	failed %	damaged %	pass %
Girders	2	3	95	5	5	90	3	14	83	3	22	75
Crack width	0	2	98	0	10	90	0	17	83	3	22	75

(a) (b)

Figure 3. (a) Resilience indices (b) Adaptation space over time versus Resilience and Sustainability indices.

From the artificial data derived from the Finite Element Analysis, there is not significant decrease in the reliability of tendons to bear loads, therefore those elements didn't seem to have altered their importance level in the capacity of the asset. The rest of the structural elements sifted their importance due to the uncertainty and the risk for further damage.

The different scenarios seem to have an influence for the future resilience of the asset as shown in Figure 3a. It seems that only the first scenario manages to provide a resilience index just above 50% of the initial resilience. Damages on all the other scenarios range from 47-38% resilience levels. Specially for the extreme scenario IV, the resilience levels seem to have decreased to the level of the 1980s when the bridge could not further withstand the demands.

Although the resilience indices are changing, it seems that their influence to the sustainability, according to the current methodology is not significant. Figure 3b presents a 3D surface diagram providing a representation of the RI and SI changes over time. Versus the adaptation level of the asset. The adaptation level is expressed as a percentage of the relative AdI to the maximum potential AdI derived from the novel methodology considering the maximum RI and SI values.

It is remarkable that the highest SI value (3.49) is observed at the completion of the initial state period, while the RI experiences a slight decrease of 13% (from 3.56 to 3.11) indicating the start of the exposure period. At this stage, the adaptation level stands at a moderate level of 39%. The subsequent mitigation periods from 1993 to 2011 exhibit varying levels of low to moderate adaptation, ranging from 20% to 44%. The lowest AdI value of 20% corresponds to 2007 when traffic restrictions were imposed on the bridge.

To better understand the adaptation over the periods, the investment, operational but also the value of the asset is plotted in Table 3 over time. The value of the asset in monetary terms is calculated by considering the Effective Annual Interest Rate over the periods which is considered as 5% throughout the years, based on the Netherland data. The adaptation of the asset was in

low levels in the 2000s when a big investment was needed to transform the asset again to ma bridge meeting the needs. This automatically increased the value of the asset, especially with increasing the demand for use by widening the deck and adding lanes ever since. Ever since the installation of SHM systems in 2007, the investment needed added tremendous value to the asset and made it more flexible to adaptation for the future, needing lower investment capital and steady operational cost.

Table 3. Asset's costs over time in Euro.

period name	Initial state	Exposure	Idle time 1st	Idle time 2nd	Recovery 2nd	Idle time 3rd	Recovery 3rd	Adaptation
period (years)	1969-1979	1980-1992	1993-1998	1999-2006	2007-2010	2011-2014	2015-2022	2023-2030
Age (years)	10	23	29	37	41	45	53	61
Asset value	2.63E+07	7.10E+07	6.54E+07	6.65E+07	1.12E+09	1.43E+09	3.47E+09	3.53E+09
Total Capital Investment per Period (TCIP)	6.22E+07	5.00E+07	1.65E+08	1.95E+08	2.01E+08	3.25E+08	9.00E+07	8.50E+07
Total cost per period (TCP)	6.59E+04	1.78E+05	1.63E+05	1.66E+05	2.81E+06	3.58E+06	8.68E+06	8.84E+06

6 CONCLUSIONS

The proposed methodology intricately captures the essence of adaptation capacity. Lower levels of adaptive space signal a pressing need for increased investment, while moderate to high levels signify a tangible enhancement of the asset's intrinsic value. In the face of unforeseen events and circumstances, the adaptation space remains at a moderate level.

As outlined by the methodology, the forecast for future adaptive space is notably high, indicating the bridge's robust capability to withstand hazards. This resilience is underpinned by the implementation of strategies grounded in a wealth of engineering expertise and historical data, ensuring a well-informed and proactive approach to fortifying the bridge against potential challenges and maladaptation strategies.

Machine learning improving seismic infrastructure recovery time estimation

N. Makhoul
École Spéciale des Travaux Publics, ESTP, Paris, France

B. Derras
University of Tlemcen and University of Saida, Tlemcen, Algeria

ABSTRACT: To maintain infrastructure functionalities and ensure the rapid recovery of their functionalities, during powerful earthquakes, an assessment of infrastructure's seismic resilience is essential. One of the crucial elements of an investigation of seismic resilience is recovery time (RT). It is essential to make sure that the RT is anticipated in advance. This RT relies on various factors (Derras & Makhoul 2022). Unfortunately, the full set of factors that likely impacted RT are not always available. For this reason, we adopt in this study, an approach that is based on the simulation of the missing factors from those already available (Derras & Makhoul, 2023). To prove this, several machine learning algorithms have been adopted. This reveals that the "Boosted Trees Regression" algorithm is the best. Sensitivity analysis revealed that "system type" is the most important factor, followed by cumulative absolute velocity (CAV). The model thus developed is validated by dividing the data set into three "training-validation-test" subsets. The methodology, used in this study, allows us to prevent overfitting problems and to obtain an optimal aleatory variability of DT represented here by RSME (sigma). The best present model (Boosted Tree algorithm) allows us to reduce this variability at a rate equal to 51 %. It can offer specialists an approximate value of recovery time, an important piece of information when assessing seismic resilience.

1 INTRODUCTION

The recovery time is the time needed for infrastructure such as roads, bridges, buildings, and utilities to be repaired and functional after a disastrous event (Cao et al. 2022). The prediction of the recovery time is based on various factors, for example in the case of an earthquake, it includes the earthquake severity, the infrastructure condition, and the resources available for the recovery work. The motives in predicting the infrastructure recovery time after an earthquake are: i) To allocate resources, ii) to effectively plan the response and recovery efforts, iii) to prioritize repair for quick restoration, iv) to identify potential challenges in the recovery procedure which grant proactive planning, and contingency plans to address these issues.

Methods to predict the recovery time of infrastructure after an earthquake event include (Cremen et al. 2020): 1) Statistical models which investigate data from past earthquakes and the related infrastructure recovery time aiming to identify patterns and trends for predictions of future recovery times. 2) Expert judgment which uses the expert experience and knowledge to offer informed estimations of the infrastructure recovery time. 3) Machine learning algorithms analyze a wide range of data (i.e., the earthquake severity, the infrastructure condition, and the resources available for the recovery effort ((Derras & Makhoul 2022), (Durante & Rathje 2021)), and train a model on data from past earthquakes, to make predictions about the recovery time for future earthquakes.

DOI: 10.1201/9781003483755-388

Statistical models might present some disadvantages to predicting the infrastructure recovery time after an earthquake such as limited data, reliance on assumptions, and limited flexibility, which can limit the accuracy of the predictions by the model (Derras & Makhoul, 2023).

Potential shortcomings are also available while using expert judgment such as limited knowledge, objectivity, and scalability, time-consuming in the case of evaluation of large numbers of infrastructure systems, and dependence on a single source.

To overcome those limitations, in this study, machine learning algorithms are suggested as a powerful tool in the prediction of the infrastructure recovery time after an earthquake event. Numerous advantages are available while using ML algorithms. Those are the ability a) to handle large amounts of data, b) to make accurate predictions when trained on sufficient data, c) to continuously improve whilst it is trained on newly available data, helping thus improve over time the accuracy of the predictions, d) to automate prediction procedure, thus, saving time and reducing the potential for human error.

Machine learning was used, for example, to assess earthquake-induced damage grade and rehabilitation intervention in residential buildings (Sajan et al. 2023); to predict earthquakes in four different seismic zones (Japan, Turkey, Greece, and Indian Subcontinent) (Hoque et al. 2020); natural hazards (Dubrow 2021).

To estimate the post-earthquake downtime, the following steps are suggested and detailed in this study that allows: 1) Determine the scope of the analysis such as the infrastructure systems and the time frame to estimate the downtime. 2) Collect the data on the location and magnitude of earthquakes, the types, and conditions of the infrastructure (i.e., material, design, construction, past damage, repairs, etc.). 3) Analyze the seismic impact (e.g., infrastructure damage) on the systems or infrastructure using the gathered data. 4) Estimate the downtime, which can be assessed based on the infrastructure damage, by calculating the time needed for replacement or repair and accounting for the time needed to implement contingency plans or bring back the full infrastructure functionality. 5) Validate your results to ensure the accuracy and reliability of the downtime estimates by comparing them to real-world data or by using different methods. This will confirm the analysis' validity and identify possible areas for improvement.

2 DATA

2.1 *Initial dataset and evaluation model*

The dataset from 32 worldwide earthquakes based on (Kammouh et al. 2018) is in this article. Those earthquakes occurring between 1960 and 2014, with a magnitude between 6 and 9 are distributed as follows: 28% in the USA, 31% in Japan, 18% in South America, 12% in Southern and Eastern Asia, 6% in Oceania, 3% in Africa. The lifelines that are affected by those earthquakes are the water, telecom, power, and gas. Their downtime (DT) after earthquake events is collected. This empirical dataset was completed using AI methods. In this article, the downtime DT expressed in number of days is the same as the recovery time RT, i.e., T_{AB} the time needed for the lifeline to recover (Cimellaro et al. 2006) and (Bruneau et al. 2003). The evaluation model starts with the initial simplistic dataset, and it grows with sophistication with the additional input factors.

2.2 *Additional factors to improve data quality*

To improve the model performance, estimation factors can be added as inputs to the ML model. It is done by offering additional information from which the model can learn. The process is called feature engineering. It is an iterative process and tests different features, where the most informative ones are designated for the final model. Then, the model can be re-trained using the new data.

The model's performance can be evaluated using the square correlation coefficient R and Root Mean Square Error (RMSE). In case the new features improve the performance, then they are beneficial and kept in the final model.

The initial dataset (Figure 1) considered the factors system, magnitude, and PGA. Then we add and test the following factors: Joyner-Boore distance (RJB), cumulative absolute velocity (CAV), EMS-98 (European Macro-seismic Scale), and country global recovery time from the GEM platform. We use the neural networks technique as a reference model (B. Derras et al. 2012). Other variables need to be considered as well (Derras & Makhoul 2022), such as the region's wealth, manpower, season of the earthquake occurrence, the localization within a country, etc.

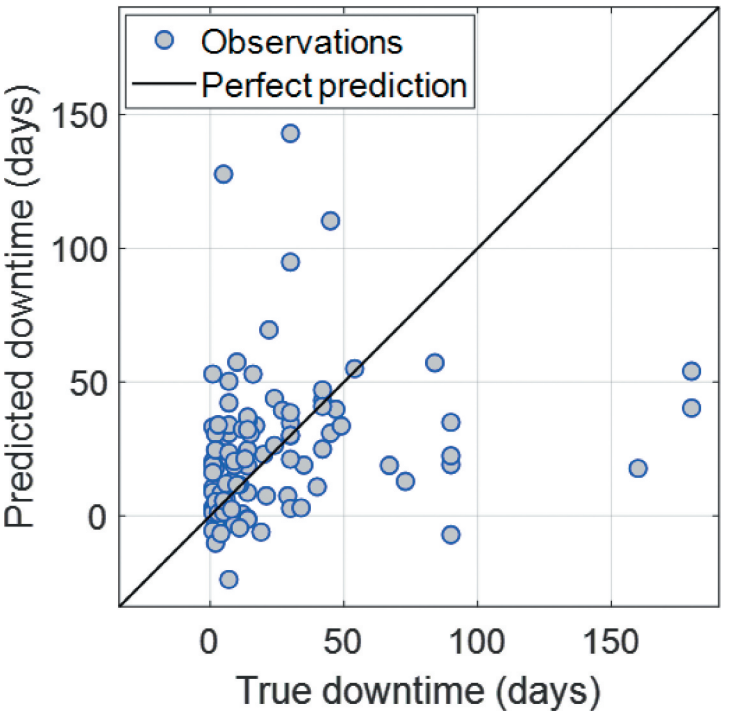

Figure 1. Predicted downtime and initial downtime evaluated with the model using the initial dataset.

2.2.1 *Joyner-Boore distance (RJB)*

After an earthquake occurrence, the relationship between the downtime and the distance of Joyner-Boore is mostly inversely proportional. The greater the Joyner-Boore distance, the less intense the ground motion is, and the less severe the damage to the structure or building. Thus, the farther the structures or buildings are from the earthquake's epicenter, the shorter the downtime after the event is, and vice versa.

Figure 2 shows the typology of the machine learning model that predicts the Joyner-Boore distance from the magnitude and the logarithm of the peak ground acceleration (PGA). The standard deviation (RMSE) of aleatory variability associated with this model is equal to 0.37.

Figure 3 shows the example of the median predicted by the model represented in Figure 2. It shows the PGA versus the RJB for a given magnitude.

2.2.2 *Cumulative absolute velocity (CAV)*

Cumulative Absolute Velocity (CAV) is a metric that is used to account for frequency, amplitude, and time). In seismic engineering, it is used for measuring the total amount of ground shaking occurring during an earthquake. CAV is a sound indicator of the potential damage of earthquakes, thus used herein. Generally, the higher the CAV value, the more significant the damage, then the more repairs it needs and the longer the downtime is.

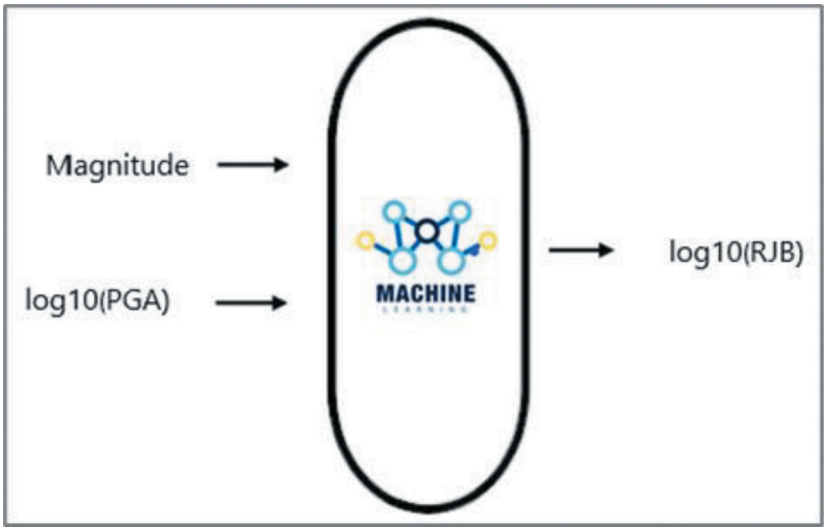

Figure 2. The Input and Output factors of the Machine Learning model for RJB.

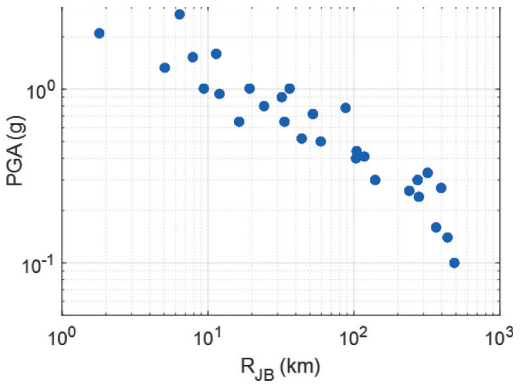

Figure 3. The PGA function of the RJB for the dataset.

2.2.3 *EMS-98 (European macro-seismic scale)*
The European Macro-Seismic Scale (EMS-98) measures the intensity of ground shaking during earthquakes. It is used to evaluate seismic intensity in European countries and ranges from 1 to 10 (1 is the lowest level of intensity). Thus, the EMS-98 and ground-motion parameters (i.e., peak ground acceleration (PGA, CAV)) are correlated. Still, no direct relation between EMS-98 and post-earthquake downtime is available EMS-98, can be linked to the potential damage of an earthquake through the ground intensities measured such as the (Zanini et al., 2019) expression:

$$ESM_98 = 2.03 + 2.28 * log10(PGA);\ \%\ PGA\ in\ gal \tag{1}$$

A theoretical assumption of the relationship can be suggested between the EMS-98 and downtime after an earthquake: the higher EMS-98 value generally corresponds to greater damage, thus, more repairs and longer downtime.

2.2.4 *The level of global recovery*
The recovery and reconstruction potential map is thoroughly aligned with the disaster resilience notion. To enhance the seismic resilience of a country needs to increase its capacity to

anticipate threats, decrease its overall vulnerability, and permit the community recovery after the seismic event. The measurement of recovery and reconstruction potential needed to capture the inherent conditions includes the built environment density, levels of education, and political participation.

2.3 *Anomalies data detected*

They detect the anomalies in the selected data. The box plot of the data distribution was done. Figure 4 shows the box plot of data distribution. It shows the downtime versus all symbolic features. The left plot shows the dataset before the anomalies' analysis. The right plot represents a clean dataset (after the outlier is eliminated).

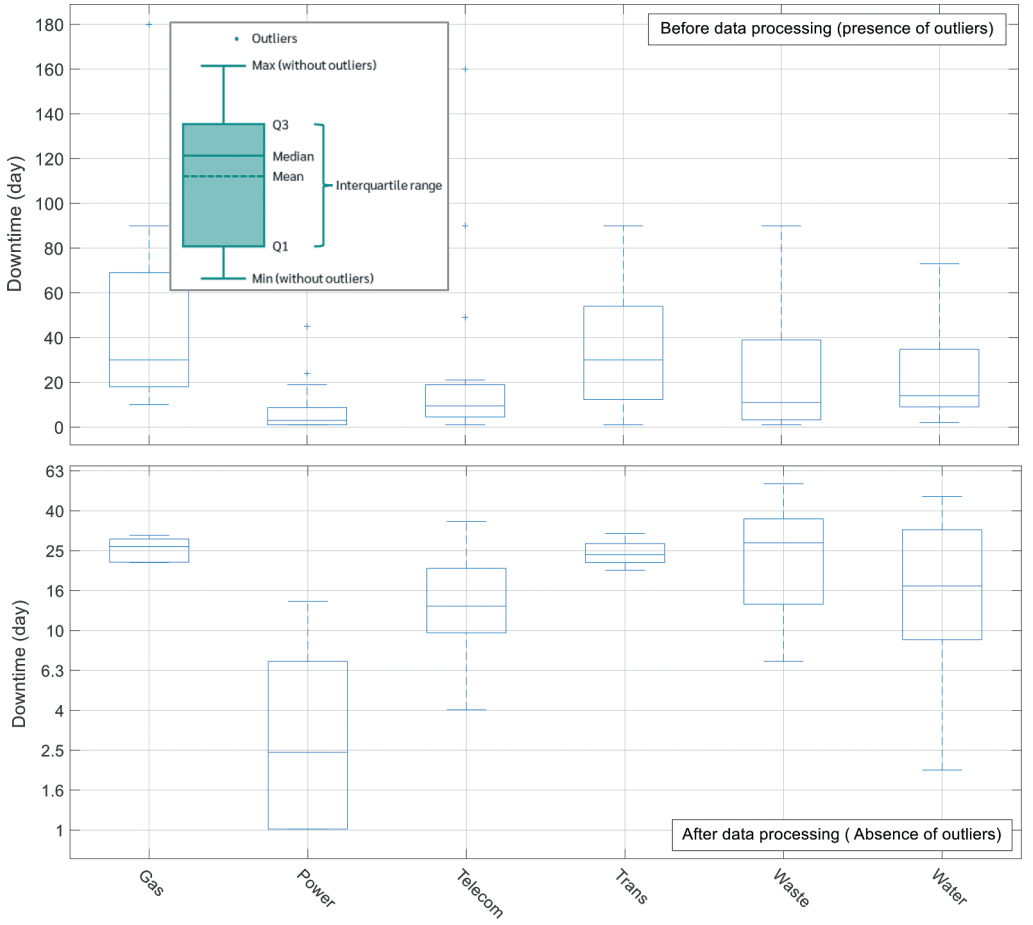

Figure 4. The box plot of data distribution. The figure presents the statistical distribution of data, before data processing (top plot) and after data processing (bottom plot). A short definition (such as median, interquartile range "IQR" and the position of outliers) is given also on the box top-left.

3 METHODOLOGY USING MACHINE LEARNING ALGORITHMS

To predict accurately the downtime T_{AB} is essential for the resilience evaluation of a system, i.e., the considered lifelines, that have been disturbed by an external force, and which are: power, water, gas, and telecom. T_{AB} is meticulously connected to the

functionality Q, which is reliant on several social, and economic metrics, structural typologies, and parameters and intensity measures of the earthquake. A correlation between these factors and the T_{AB} can be established using a supervised machine-learning model ((Derras et al. 2012), (Derras & Makhoul 2022), (Derras & Makhoul, 2023)). It is done using the factors for inputs and then training the model to obtain the output predictions for T_{AB}. Nevertheless, it is essential among others to account for all factors that influence T_{AB} when building the model.

The Machine Learning (ML) concept, first introduced by Arthur Samuel, is a subset of the broader field of Artificial Intelligence (AI). It allows algorithms to learn and improve their performance without any explicit programming.

One category of particular interest in ML is supervised learning. It trains the model to map inputs to outputs built on examples of input-output pairs. Various supervised ML algorithms are commonly used in earthquake engineering, to extend classical regression techniques and eliminate the necessity for pre-defined functional forms. The following section compares some of the most broadly used ML algorithms.

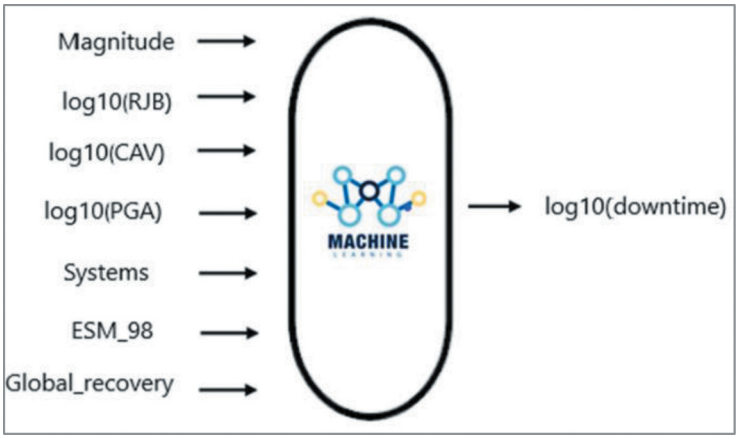

Figure 5. Input and output factors for the final Machine Learning model.

4 COMPARISON BETWEEN SEVERAL MACHINE LEARNING APPROACHES

To evaluate the performance of various machine learning algorithms, some metrics are frequently used such as the Root Mean Squared Error (RMSE) and the correlation coefficient. Those metrics can be used to compare the different machine learning algorithms' performance. In this article, we use the following machine learning algorithms for comparisons: Linear Regression, Decision Tree (DT), Support Vector Machines (SVM), Boosted Tree, Gaussian-Process Regression, and Neural Network. The details of those algorithms are presented in detail in (Derras & Makhoul, 2023). The higher correlation coefficient and the lower RMSE designate a better model fit to the data and a better algorithm performance.

The statistics parameters, such as means, standard deviations, and correlations, are sensitive to outliers. Since we do not know the origin of outliers, we suppose that they are due to incorrectly entered or measured data, consequently, we drop the outliers.

Figure 4 which represents the box plot, allows the detection of any outlier point (anomaly analysis). Overall, an observation point is considered an outlier when is outside of the box either Q1-1.5×IQR or Q3+1.5×IQR.

Table 1 shows the hyperparameter values obtained through six machine-learning models. These values are given for the validation and test phase. It shows that the Boosted Tree is the more adequate model for this case.

Table 1. The hyperparameter values obtained for the machine-learning models.

	Validation		Test	
Default hyperparameters	RMSE	R^2	RMSE	R^2
Linear Regression	0.36	0.33	0.2	0.78
Decision Tree	0.37	0.26	0.21	0.74
SVM	0.35	0.38	0.22	0.74
Boosted tree	0.32	0.43	0.075	0.97
Gaussian-process regression	0.33	0.47	0.16	0.86
Neural Network	0.44	-0.02	0.075	0.97

4.1 *Boosted tree ensemble*

The Boosted Regression Trees (BRT) combine two techniques, the decision tree algorithms and the boosting methods (Sajan et al. 2023).

BRT is an ensemble meta-algorithm for ML to reduce errors in predictive data analysis (Sajan et al. 2023) and (Dubrow 2021), with the aim to form one strong classifier ((Hoque et al. 2020), (BCCVL 2021)). It is very used when a large number of variables for the number of observations is available.

4.2 *Hyperparameter optimization*

The hyperparameter optimization for boosted trees comprises tuning parameters such as the learning rate, the number of learners, and the minimum number of leaves to ameliorate the performance of the model. It is done by Bayesian optimization techniques to guide the search for the optimal set of hyperparameters through the probabilistic model. The following values were obtained for our model while keeping 20 % of the data for the validation phase to avoid overfitting problems: Minimum leaf size equals 1, Learning rate equals 0.1, and Number of learners equals 1000.

5 RESULTS

The results are presented briefly in Section 5.1 for the predictor importance, Section 5.2 for median trends, Section 5.3 for the residual analysis of the validation phase, and Section 5.4 for the final improved estimation using machine-learning techniques.

5.1 *Predictor importance*

The Predictor importance (PI) demonstrates the importance of the predictors in the prediction-making process. For the Machine Learning of the DT model for the lifelines recovery proposed herein, and based on (Derras & Makhoul, 2023), it was obtained that the systems (i.e., lifelines) are the most vital predictors (around 60%), then the CAV (15%), with the least importance given to the EMS_{98} with 0% relative value.

5.2 *Residuals' analysis of the validation phase*

For the residual analysis (equation 2), the box plot is used to show the interquartile range and lower/upper fence. Figure 6 shows the residuals analysis is an important step before validating any model, mainly the ML models. Since these last are based on the data. If the outcome of this analysis shows that not is any bias and the Q1 and Q3 are inferior to 3×RMSE it can be said that our model, statically speaking, is strong; which is the case for the Boosted tree model used here.

$$\text{Residuals_downtime} = \log_{10}(\text{Observed_downtime}) - \log_{10}(\text{predict_downtime}) \qquad (2)$$

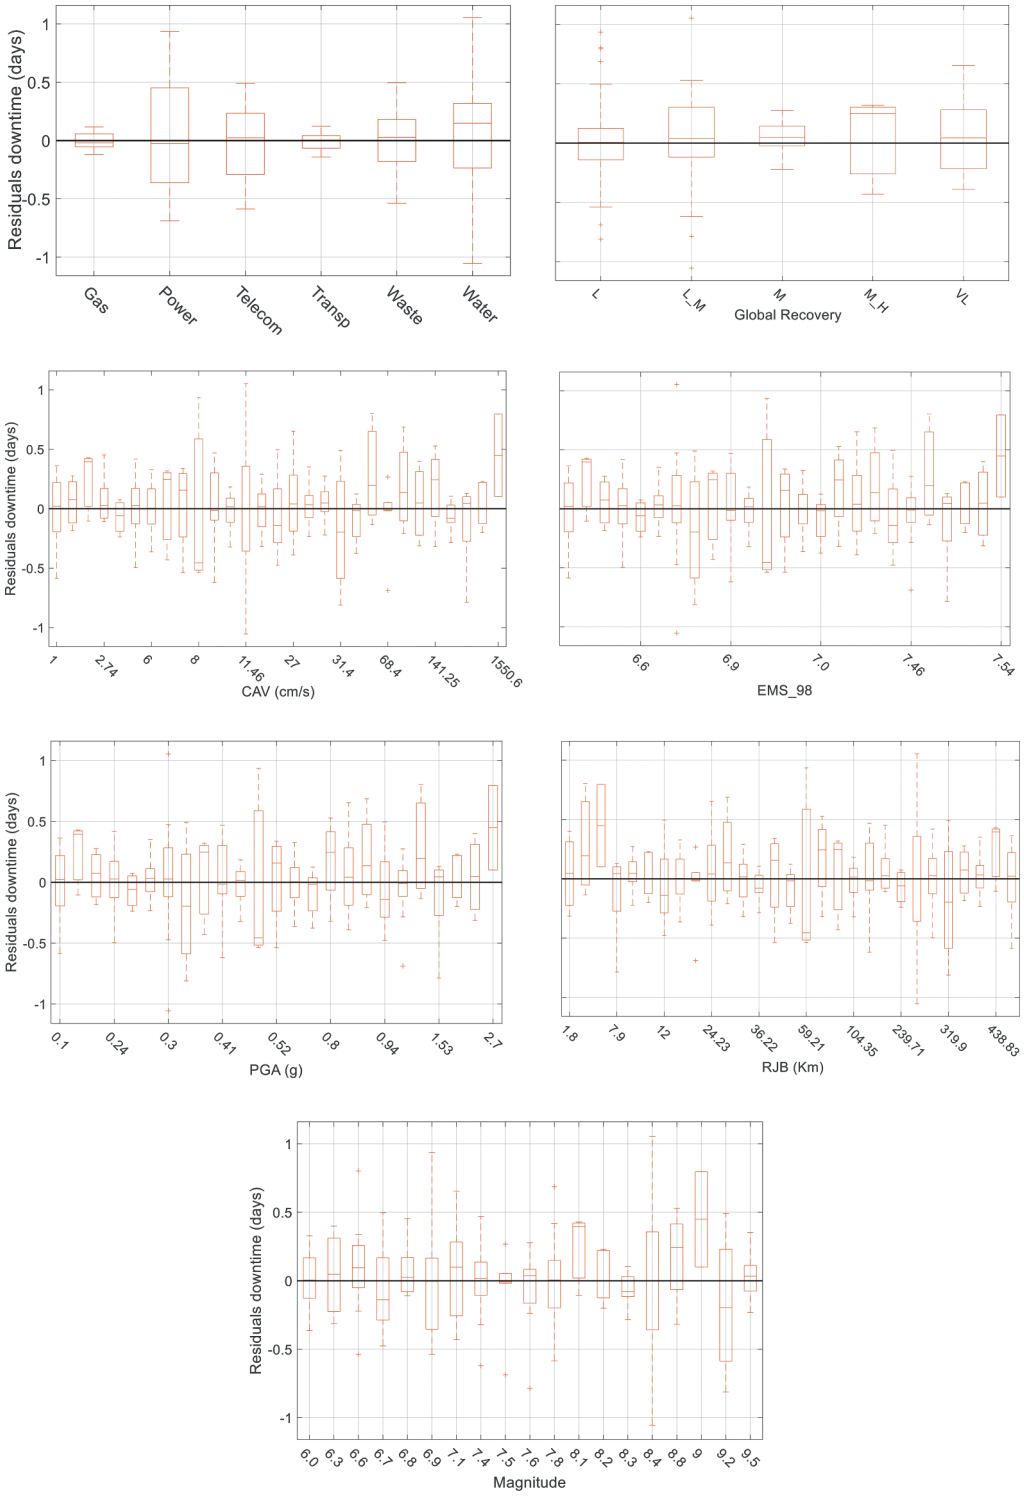

Figure 6. The residues' values (observed downtime minus predicted downtime) vs features (which represent inputs of machine learning algorithm: Figure 5). All residues (equation 2) have been obtained with the Boosted tree algorithm.

5.3 *Median trend*

To check the median trend again here we use the box plot concept. Figure 6 shows the comparison between data (observation) and prediction for all datasets. Through Figure 7, we notice that prediction values of downtime converge towards observation data. We can see that the statistical parameters: Q1, Q3, and IQR (yellow color) are lower than those of true data (blue color). In addition, medians (horizontal lines) getting closer.

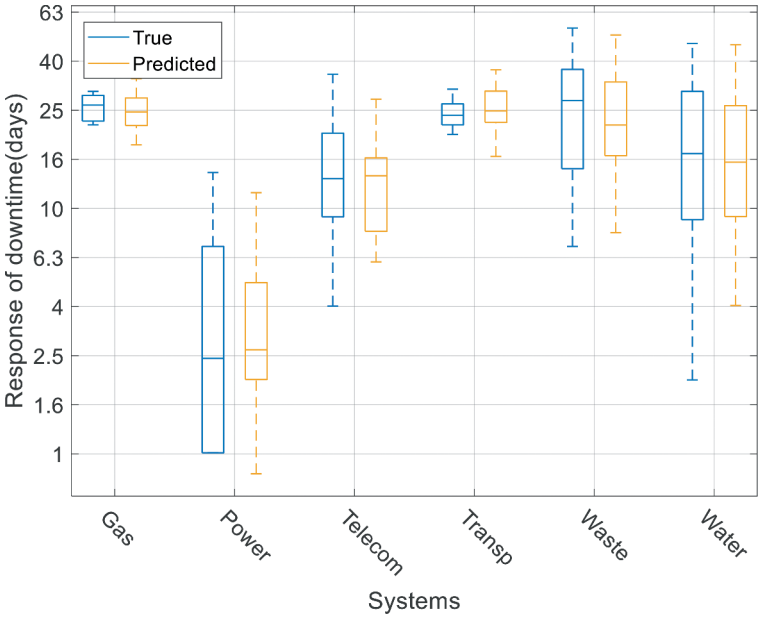

Figure 7. Comparison between data (observation) and prediction for all datasets.

5.4 *Improve estimation by using a machine-learning technique*

To demonstrate the improvements made by the machine-learning technique to the DT estimation model, Table 1 reports the values of the simple metrics RSME and R^2. It is done for the original model data (Kammouh et al. 2018) and the improved model data ((Kammouh et al. 2018) plus the boosted data for this study. It shows a significant improvement of 51% using RMSE and 757% when for R^2.

Table 2. Values of the simple metrics RSME and R^2.

Metrics (validation phase)	*Initial model*	*improved model*	*improvement (%)*
RMSE in log10	0.59	0.29	51
R^2 in log10	0.07	0.53	757

6 CONCLUSIONS

The recovery time (RT) or its complement the downtime (DT) are essential components of the infrastructure earthquake resilience analysis. Therefore, it is essential to keep the functionality of critical infrastructure and recover them quickly during strong earthquakes, which is reflected by a shorter recovery time.

A machine-learning empirical model is developed, in this article, for assessing the predicted DT using a dataset of earthquake damage to the gas, power, water, and telecommunications lifelines.

The ML models herein utilized the most renowned machine learning algorithms. The ML model was progressively improved by accounting for additional factors (i.e., RJB, CAV, etc.). The results are offered using the predictor importance, the median trend, and the residuals' analysis of the validation phase. It was concluded that 1) the selected factors can improve the DT model and 2) the lifeline systems are the most significant predictors followed by the CAV. Comparing several ML-model, it was found that the Boosted Tree algorithm is the best one for this issue. This model allows us to reduce the aleatory variability of 51 %.

This study is further developed for additional data and the full assessment is considered (Derras & Makhoul 2024).

Information entropy-driven recovery strategies for systems' resilience

A. Tzioutziou & Y. Xenidis
Department of Civil Engineering, Aristotle University of Thessaloniki, Greece

ABSTRACT: A resilient system is able to overcome an adversity as a consequence of the anticipation of the disruption, the resistance to the damage, and mainly the recovery of its original functions. Especially in the context of technical systems, the recovery process relies on diverse estimations about performance levels and functional states. Therefore, the purpose of this research is to theoretically explore and practically employ a measure of information entropy, as an optimization variable for the process of recovery. Two novel entropy-driven recovery approaches are developed, modeled, and comparatively evaluated with a performance-based approach under different conditions of disturbance via agent-based simulations. The results suggest that the recoveries using the information entropy are more effective in both the performance maintenance and the time to recovery of the examined system, compared to the traditional recovery approach. The findings provide a conceptual and practical background to further utilize the information entropy for the design of recovery strategies and the engineering of systems' resilience.

1 INTRODUCTION

Resilience is broadly conceived as an emergent property, which enables the system to withstand and recover from a disturbance. Regardless of the application context, the established analytical description of recovery process features the definition of the system's original state, the damage state and the state after the recovery (Ahmadi et al. 2021, Hosseini et al. 2016). According to the literature, the concept of entropy is appropriate to describe the diverse system's states, especially when they dynamically evolve (Cabral et al. 2013, Fistola et al. 2020, Marťinez-Berumen et al. 2014, Purvis et al. 2019). Given its universal applicability, the information entropy is the most suitable entropy measure for such a generic application (Han et al. 2020, Purvis et al. 2017).

To this aim, the agent-based modeling approach effectively allows the observation of emergent behaviors, like resilience, in general types of complex systems (Tolk 2019). The agent-based model permits disaggregation of the examined system to the basic elements and their functions, which inherently determine its entropy (Batty 2010). Therefore, the agent-based simulation is considered an effective approach to estimate the system's entropy levels, as confirmed by several similar applications (Rahman et al. 2020, Wilson 2010). The purpose of this research is to theoretically investigate and practically deploy the measure of information entropy as a target criterion for the recovery process, by utilizing an agent-based approach. The results of the experimental entropy-driven recoveries' simulations are evaluated in comparison with a traditional performance-based recovery approach, in order to determine their effectiveness in the enhancement of resilience.

The paper is organized as follows. Section 2 presents the methodological steps for the development of the examined model, the recovery strategies and the analyses scenarios. Then, Section 3 comprises the results of the simulations and the respective analyses, while Section 4 concludes this work.

DOI: 10.1201/9781003483755-389

2 METHODOLOGY

The methodological approach for the evaluation of the impacts of the proposed entropy-driven recoveries on system's resilience relies on agent-based modeling, which is appropriate to effectively capture the effects of systems' emergence (Railsback & Grimm 2012) and particularly resilience (ten Broeke et al. 2016). This generic agent-based model is developed in order to examine diverse features of a complex technical system on the face of a set of specifically designed disruptions (Tzioutziou & Xenidis 2023).

This research methodology consists of two (2) sequential and discrete phases. It starts with the development of models with the corresponding recovery strategies and then continues with the development and the analysis of the different scenarios and their respective outcomes. The following sections present all the details about the aforementioned phases.

2.1 *Model development*

The purpose of the developed agent-based model is to simulate in a very simplistic manner, the structure and the function of a complex engineered system, such as an urban transportation network. As presented in Figure 1, the model includes two discrete but interdependent subsystems in the form of networks of undirected links between nodes in fixed locations.

In detail, Subsystem 1 consists of five (5) fully interconnected nodes (white-colored circles), whereas Subsystem 2 consists of four (4) nodes (black-colored squares) that are only connected with their closest neighbors with the respective intra-system links. The two subnetworks are partially interconnected via three trans-system links, which are illustrated in Figure 1 with thick black lines.

The system's sole function is to sustain and overcome a disturbance, while it is constantly monitoring its performance status. Hence, it is possible to explore the restorative capacity and to evaluate the overall resilience of the system. The system's performance estimation follows a simple approach, which has been originally introduced by Baggio & Hillis (2018) and further developed to meet the specific experiments' requirements. According to this approach, the nodes' connectedness is a measure of performance, estimated separately for each one of them by the number of its links. A simple directed intra-system link between two agents would get the value of 1, however, given that all the links are undirected, each link gets the value of 2. For the trans-system links, the performance estimation is more elaborate, to reflect their special role in the system. The estimation includes the summation of all the individual directed performances of the corresponding end nodes divided by the number of the trans-system links. The integrated performance value of the entire system is the sum of all the individual performances, which is finally transformed into percentage in order to easily capture the changes in the respective states.

Since the system's connectedness determines its performance, both the disturbance and the recovery of the system's functions are also associated with this aspect. In fact, the examined

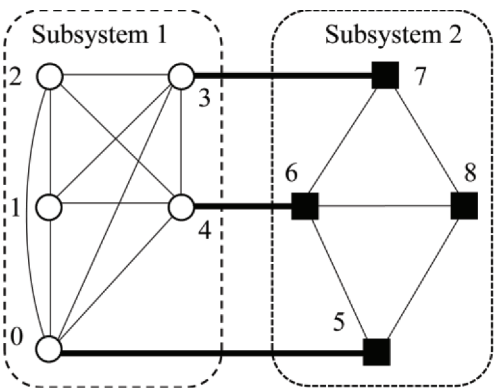

Figure 1. Structure of the developed model.

disruptions are designed as losses of specific links, while the recovery processes aim to restore the lost connectivity by establishing new links.

The agent-based model introduces the parameter of time in the form of procedural steps or ticks, which are useful for a variety of timeframes. The system's evolving performance states on the occurrence of the disruptive event are observed with reference to the tick axis, a fact that supports the estimation of the respective resilience metrics.

2.2 *Recovery strategies development*

The first recovery strategy is a simple approach, which serves as a reference basis for the evaluation of the advanced entropy-driven approaches. This recovery strategy is based on the performance of the examined system and particularly on the connectedness among the nodes within the subnetworks. As presented in the flowchart of Figure 2, the recovery process involves only few steps. At the beginning of the simulation, each subsystem's agent counts the number of its links with other neighboring agents and records its own original links. As the simulation continues, the agents constantly check the number of their own links and compare it with the respective original links. If these variables are equal for each one of the network's nodes, there are no missing links, the relative nodes are fully connected and the process ends at this point. On the other hand, if the original links of an agent are more than its current links, the algorithm identifies the loss and initiates the following restoration processes. The node with the missing links needs to identify another node that reports a loss and create a new link with it. It must be noted that in this approach the recovery relies entirely on the lost links reported by the agents, regardless of the disruption type. The performance-based recovery process runs firstly in Subsystem 1 and then in Subsystem 2 but effectively, it is executed in the same procedural step.

Although both the proposed entropy-driven approaches comprise more complex procedures, their basic recovery process is demonstrated in the flowchart of Figure 3. This recovery approach features two (2) sequential phases, first the identification of the agents that need restoration and second the main restoration that re-establishes the lost connections.

Particularly, the identification phase starts with the estimation of the information entropy for each one of the nodes of the examined subsystem. In this procedure each agent calculates the Shannon entropy for its own state of connectedness, by assessing the number of its current links over its original links according to Equation 1.

$$H = -\sum_{i=1}^{n} p_i \log p_i \tag{1}$$

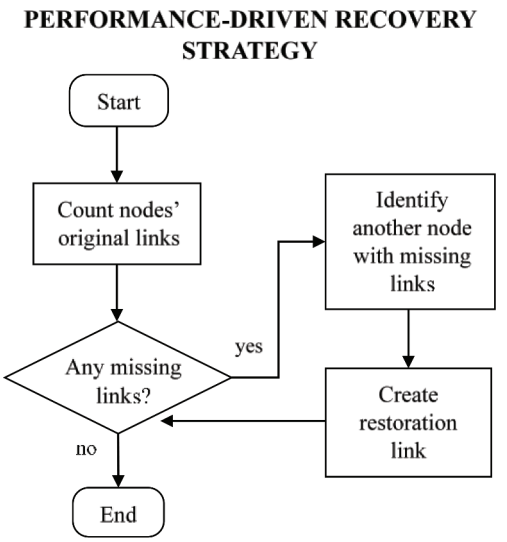

Figure 2. Flowchart of the performance-driven recovery strategy.

where p represents the node's connectedness state and is expressed as a quotient of the number of the node's current links divided by the number of its recorded original links.

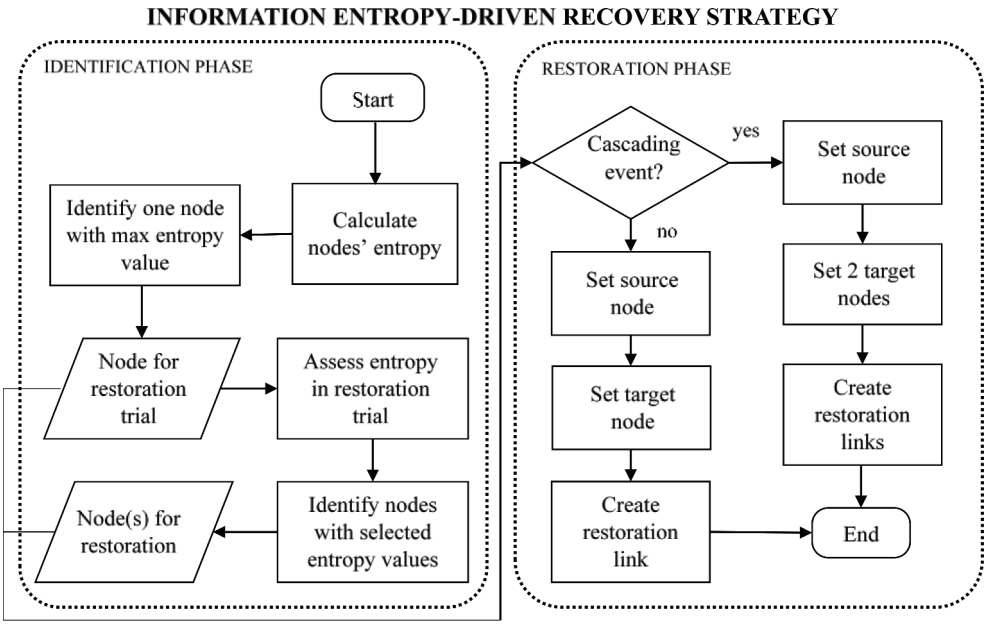

Figure 3. Flowchart of the entropy-driven recovery strategies.

Evidently, according to Equation 1, if the current links are equal to the original links, the agent is fully connected and the entropy value is zero (0), highlighting the complete and certain information about this connectivity state. Otherwise, if a link is missing, the respective agent's reported entropy value is greater than zero, reflecting the loss of information and the uncertainty about this connection. The algorithm needs to find at least one node with the maximum entropy value among all the other agents, in order to determine the most disturbed node.

The subsystem's agents execute the process of restoration trial in order to identify and finally record all the remaining disturbed agents in the examined subsystem. The specific node that was previously identified as the most affected by the disruptive event is already recorded and thus, it serves as the recovery target. One by one all the remaining agents, create a probationary link with the most disturbed agent, estimate the entropy of their connectivity status according to Equation 1 and then they report their updated information entropy levels, respectively. Through this procedure, the agents provide a measurable value that describes their state of connectedness. In particular, if the number of current links including the probationary link between two nodes exceed the number of the original links of this connection, the respective entropy value yields a negative number. Similarly, if the current connectedness state is identical to the original state, the respective entropy value is zero (0) and if the connectedness is not yet restored, the relevant information entropy value is a positive value. On this basis, it possible to discern the current connectedness states and accordingly, set the restoration target and select the appropriate nodes for restoration. These nodes pertain to the outcomes of the identification phase and constitute the fundamental inputs for the next phase.

At the beginning of the main restoration phase, the algorithm recognizes the ongoing disruption type, namely the simple and the cascading event and initiates the corresponding process for a single or double restoration links, respectively. In both the recovery strategies, the most disturbed node of the previous phase is set as the source or start, while the one (1) or two (2) affected nodes are the targets or ends of the respective restoration links. The

information entropy-based recoveries include procedures, which allow monitoring the states of connectedness and identifying the disruptive event, but also require more automation from the component agents. It must be noted that this recovery process is executed practically in parallel by the two subsystems. It starts with the identification phase in Subsystem 1 followed by Subsystem 2 and it moves on to the restoration of Subsystem 1 and then 2.

Although the majority of the procedures are identical between the two (2) proposed entropy-driven recoveries, the restoration target is their key difference. Recovery Strategy 2 aims for the re-establishment of the lost links and the recovery of the original connectedness and functionality state of the entire system. For this purpose, the restoration targets are the nodes that yield the highest entropy values during the restoration trial. On the contrary, Recovery Strategy 3 on the face of the disturbance aims to reach a better and more stable state of functionality for the system, by introducing new connections between the agents. In this case, the nodes with the lowest entropy values are set as the respective restoration targets. Table 1 presents the differences between Recovery Strategies 2 and 3 in terms of their discrete aims and computational approaches.

Table 1. Differences between the Recovery Strategies 2 and 3.

Information Entropy-Driven Recovery	Aim of recovery	Rule for arget nodes selection	Target nodes' entropy value
Strategy 2	Original state	Maximum Information Entropy	$H(x) \geq 0$
Strategy 3	New and more stable state	Minimum Information Entropy	$H(x) < 0$

2.3 *Analysis scenarios development*

Two (2) discrete disturbance scenarios are developed to investigate the effectiveness of each one of the three recovery strategies. Firstly, the simple disruptive event, which causes the least damage to the system with the loss of an individual intra-system link in each one of the two examined subnetworks. Secondly, the cascading disruptive event describes a more complex and severe damage, comprising the simultaneous collapse of two (2) links that connect to the same agent in Subsystem 1 and Subsystem 2, respectively. Table 2 presents the characteristics of the two examined disruptive scenarios of increasing magnitude and complexity.

Table 2. The disruptive scenarios and their damages to the subsystem and to the entire system, respectively.

Disruptive Event	Disturbance in each subsystem	Disturbance in entire system
Simple	1 link, 2 nodes	2 links, 4 nodes
Cascading	2 links, 3 nodes	4 links, 6 nodes

Each one of the recovery models is examined under both the disruptive events, leading to six (6) analysis scenarios. In each analysis scenario, a randomly located disruption, according to the relevant disruptive event scenario, occurs in the system, which directly responds by recognizing the affected elements and then starts the respective recovery strategy. For accuracy purposes, each analysis scenario is executed for 20 repetitive simulations by the NetLogo's BehaviourSpace tool (Wilensky 1999).

The simulation's outputs of the developed agent-based model include the system's performance level and the number of ticks to recovery. Based on these outcomes, a metric based on Bruneau's resilience loss is calculated for each simulation run of every analysis scenario, in order to compare directly the different recoveries impacts on the system's resilience (Bruneau

et al. 2003). The metric represents the percentage difference between the maximum performance and the observed performance levels, which is reduced as a result of the disturbance, as described by Equation 2:

$$R = \frac{Q_{max} - Q(t)}{Q_{max}} \tag{2}$$

where Q represents the performance of the system.

Further comparative analyses for all the relevant outcomes feature differential comparisons and sensitivity analyses, the latter of which is highly recommended for the evaluation of agent-based simulations (Railsback & Grimm 2012). Particularly, the sensitivity analysis estimates the differences between the performance-driven recovery that serves as the base case and the two (2) information entropy-driven recoveries. All the aforementioned analyses are implemented in Microsoft Excel 2013.

3 EFFECTIVENESS OF RECOVERY STRATEGIES

The increased effectiveness of the entropy-driven recovery strategies over the traditional performance-based approach is evident from the first findings on the performance levels and the ticks to recovery. The histograms of Figure 4 present the respective average outcomes of each examined strategy under the two disruptive scenarios. Based on the evidence of graph in Figure 4a, the entropy-based Strategies 2 and 3 maintain higher performance levels during both types of disturbance, compared to Strategy 1. Regarding the time to recovery, Figure 4b demonstrates that Strategy 1 leads to significantly longer recoveries, whereas Strategies 2 and 3 provide consistently the fastest recoveries, regardless of the disruptive event.

Despite the relatively small differences between these first findings, it is clear that the improvement in the duration of the recovery is more significant than the observed changes in the performance maintenance. In order to combine these results and to assess the effectiveness of the examined recovery strategies, the graph of Figure 5 presents the outcomes of the examined resilience metric.

The simulations' average resilience metrics confirm the trends identified in the previous performance-related results and support the argument that both the entropy-based recoveries are more beneficial for the system's resilience under any disturbance. Additionally, it is clear that the recovery strategies' capacity to preserve the systems functionality is affected by the type of the disruption. Particularly in the cascading event, the different entropy-driven approach of Strategies 2 and 3 is reflected in their impacts on the system's performance.

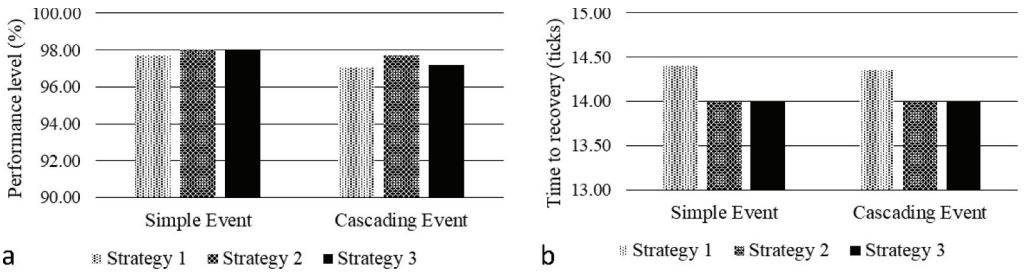

Figure 4. Simulations' average results for a) performance levels and b) ticks to recovery of each strategy, respectively, under the different disruption scenarios.

The sensitivity analysis provides a closer look to the changes among the respective observations between the basic performance-driven approach and the proposed entropy-driven recoveries in terms of performance maintenance, recovery time and resilience metric. Table 3

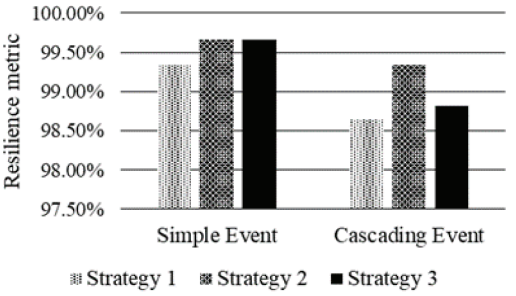

Figure 5. Simulations' average results for the examined resilience metric.

exhibits the results of the comparative sensitivity analyses, the simulations' outputs and their corresponding variances, as well as the percentage differences for both the simple and the cascading event, respectively.

Table 3. Data table of simulations' average results, variances, and differences in performance levels, time to recovery and resilience metric, under the different disruptive scenarios.

Simple event	Recovery strategies			cascading event	Recovery strategies		
	1	2	3		1	2	3
Performance				Performance			
Level (%)	97.71	98.03	98.04	Level (%)	97.02	97.71	97.19
Variance	0.227	3E-04	6E-04	Variance	0.442	0.001	0.482
Difference (%)		0.33	0.33	Difference (%)		0.71	0.18
Time to recovery (ticks)	14.40	14.00	14.00	Time to recovery (ticks)	14.35	14.00	14.00
Variance	3.621	0.000	0.000	Variance	3.713	0.000	0.000
Difference (%)		-2.78	-2.78	Difference (%)		-2.44	-2.44
Resilience				Resilience			
metric (%)	99.34	99.67	99.67	metric (%)	98.64	99.33	98.81
Variance	2E-05	3E-08	5E-08	Variance	4E-05	7E-08	5E-05
Difference (%)		0.33	0.33	Difference (%)		0.71	0.18

Based on the evidence of Table 3, the more severe and complex event leads to lower values of performance maintenance, in contrast to the respective results of the simple event scenario. The performance levels during the simple disruption suggest that Strategies 2 and 3 are more effective and significantly consistent in the system's performance maintenance, compared to Recovery Strategy 1. In fact, both the entropy-based approaches increase the performance level by 0.33%, however their fundamental operational difference is not obvious in these results. Concerning the results of the cascading event, the performance outputs lead to a different evaluation of the examined recoveries. Strategy 2 provides the highest performance value with the most consistent manner, while Strategy 3 only slightly surpasses the performance of Strategy, with similar levels of inconsistency. During the cascading disturbance, Strategy 2 yields an increase in the system's performance by 0.71%, whereas Strategy 3 leads to an insignificant increase of 0.18%, compared to the base case Recovery Strategy 1. It is interesting to note that during the most severe event, Strategy 2 is more effective in the performance maintenance, as opposed to Strategy 3 that seems to be negatively affected by the cascading event.

Regarding the time to recovery, the results of Table 3 demonstrate that both the entropy-driven strategies respond fast and absolutely consistently, regardless of the conditions of the disruption. The time to recovery of Strategy 1 also seems unaffected by the disturbance type, in both terms of value and variance. It must be noted that the reductions in the ticks to recovery by 2.78% for the simple and by 2.44% for the cascading event, are the most significant

differences, highlighting the impacts of the operational dimension of the examined recovery strategies.

Finally, the outcomes of the relevant resilience metric are highly correlated with the respective performance results, a fact complying with the selection of a performance-based metric. The resilience metrics provide quite high and consistent values, i.e., at an average of 99.56% in the simple event and at 98.98% in the cascading event, respectively. This evidence suggests that the system with its diverse recovery processes is greatly resilient to the designed disturbances. Following the trend of the respective performance results at the first rows of Table 3, the resilience metric yields identical percentage changes between the examined recoveries. Considering that the duration of the recovery process is reflected in the recorded sequence of performance values, this metric can integrate the aspect of duration. Nevertheless, the observed operational advantage of the reduced recovery times in the entropy-driven strategies is not reflected in the relative results of the examined resilience metric. This fact implies that the specific resilience metric is not appropriate to capture this operational feature of recovery and its impact to the system's resilience.

4 CONCLUSIONS

This research explored the potential impact of a novel recovery approach, which is based on the information entropy, on systems' resilience under different conditions of disturbance. Apart from the classic performance-based recovery strategy, this work featured the development of two computationally different recovery strategies. The outcomes of the relevant simulations highlight that the entropy-driven strategies increase the system's performance maintenance and reduce effectively the time to recovery, compared to the classic performance-based recovery.

Particularly, the recovery that focuses on the agents with the maximum information entropy value is the most effective strategy in the performance maintenance of the examined system, especially during the cascading event. Simultaneously, the recovery strategy of the entropy minimization fails to provide similarly increased performance levels in the most severe disruption, probably as a result of the different operational approach. Moreover, the performance-based resilience metric seems inappropriate to capture all the potential of the entropy-driven recoveries. The research findings support the exploration of the information entropy as an optimization variable for the recovery process and reveal new pathways towards the engineering of systems' resilience.

Physics-based earthquake-tsunami fragility surfaces for risk and resilience analysis

Mojtaba Harati & John W. van de Lindt
Center for Risk-Based Community Resilience Planning, Colorado State University

ABSTRACT: Community resilience models employ fragility functions to link hazard outcomes to infrastructure damage assessments. These predictions inform recovery analyses that consider cascading effects across economic, social, and household sectors. Current performance-based frameworks for tsunami engineering use distinct fragility curves for tsunami and earthquake effects but have not combined them due to data constraints. This study introduces a computational methodology for creating 3D earthquake-tsunami fragility surfaces for reinforced concrete frame buildings in coastal areas. The approach involves a two-stage analysis: earthquake followed by tsunami. Uncertainty is addressed through millions of nonlinear simulations that consider a number of structural, seismic, and tsunami-related variables. A proposed multi-distributed framework significantly enhances computational efficiency, facilitating more robust community resilience studies. The resulting 3D fragility surfaces account for isolated and combined earthquake-tsunami risks, offering a comprehensive tool for risk and resilience assessment.

Keywords: Community resilience, fragility functions, computational methodology, two-stage analysis, risk assessment

1 INTRODUCTION

Frameworks for resilience and performance-based design (PBD) have been proposed for various single- and multi-hazard events, inspired by the success of PBD in earthquake engineering and seismic provisions (Günay and Mosalam, 2013). These frameworks have expanded to cover different natural hazards, including coastal (González-Dueñas and Padgett, 2021), hurricane-related (Barbato et al., 2013), wind engineering (Spence and Arunachalam, 2022), and tsunami engineering (Attary et al., 2021, 2017), among others. They separate the risk into key components, namely hazard analysis, structural system characterization, structural analysis, damage analysis, and risk assessment. For community-scale modeling, fragility functions—which integrate structural system characterization and analysis—are essential for predicting damage across diverse building types.

Earthquake fragility curves are well-documented in the literature (Akhoondi and Behnamfar, 2021; Bandyopadhyay et al., 1990; Chen et al., 2022; Kazantzi et al., 2008; Li et al., 2014; Xu et al., 2018). There is also a growing body of research on tsunami fragility curves for building structures, encompassing both empirical and physics-based fragility functions. Most empirical-based tsunami fragility curves are correlated with tsunami inundation depth because it it can be observed and correlated to damage levels (Petrone et al., 2017). Some studies have explored the development of physics-based tsunami fragility curves, primarily using the Nonlinear Static Procedure (NSP) to account for the total equivalent tsunami force. These curves generally consider the tsunami effects separately from earthquake effects, and their combined impacts are often statistically combined in resilience-based frameworks. However, some studies have tried to incorporate the effects

DOI: 10.1201/9781003483755-390

of both earthquake and tsunami hazards simultaneously. For example, a few studies (e.g. Park et al. 2012; (Attary et al., 2021); Xu et al., 2021) have employed successive analyses to simultaneously account for both hazards, revealing that earthquake effects notably elevate collapse failure probabilities.

To account for uncertainties associated with this two-phase successive analysis, advanced computational methods are crucial. Multi-distributed parallel processing methods have been proposed to address the computational demands of various problems, including flood simulations, earthquake simulations, structural optimization, and structural reliability, to name a few (Ginting & Mundani, 2019; Wijerathne et al., 2013; París et al., 2013; Umesha et al., 2007; Hardyniec & Charney, 2015; Toma et al., 2016; Vicente da Silva et al., 2015; Yu et al., 2020).

This study, exemplified using a four-story reinforced concrete (RC) building as a representative case, introduces a versatile multi-distributed framework that overcomes computational challenges in creating 3D earthquake-tsunami fragility surfaces. It accommodates structural and hazard uncertainties and allows detailed structural models. The framework's adaptability extends to various scenarios, promising advancements in risk assessment and disaster preparedness. It is a valuable tool for researchers and practitioners dedicated to enhancing our understanding of structural vulnerabilities and strengthening our ability to protect and support communities in the face of diverse and evolving challenges.

2 PROBLEM STATEMENT

Earthquakes and tsunamis are intrinsically linked hazards that can result in cumulative damage. Despite originating from a common source, they impact structures independently and sequentially, each causing both structural and non-structural damage. While these hazards are statistically independent in terms of structural impact, accounting for reduced structural strength post-earthquake is essential when assessing sequential loading. Bayes' theorem provides a mathematical framework for this, updating the reliability assessment of a structure based on new information from subsequent hazards. In reliability analysis, the theorem serves to recalibrate beliefs or predictions concerning system or component reliability in light of new data can be expressed as

$$P(TS \mid EQ) = \frac{P(EQ \mid TS) \cdot P(TS)}{P(EQ)} \tag{1}$$

Equation (1) formalizes the conditional failure probability $P(TS|EQ)$, which is the focus of this paper. This term quantifies the likelihood of a structure collapsing during a tsunami, given prior damage from an earthquake. $P(TS)$ and $P(EQ)$ represent the individual failure probabilities due to tsunamis and earthquakes, respectively, and are established as 2D fragility functions in existing literature (Bandyopadhyay et al., 1990; Chen et al., 2022; Li et al., 2014; Alam et al., 2018; Attary et al., 2017; Petrone et al., 2017). The term $P(EQ|TS)$, though included in the equation, is not practically applicable as tsunamis do not naturally precede earthquakes. $P(TS|EQ)$ can be interpreted as the fragility function for tsunamis when considering antecedent earthquake damage.

In deriving P(TS|EQ) using Bayes' equation, the term $P(EQ|TS)$ is theoretically required, which complicates the analysis due to its impracticality in real-world scenarios. To circumvent this, the current research introduces a novel two-phase sequential analysis approach, allowing for the determination of earthquake-tsunami fragility functions without depending on $P(EQ|TS)$. This innovative methodology effectively navigates the intricate interplay between earthquake and tsunami hazards, thereby contributing a pragmatic tool for structural reliability analysis.

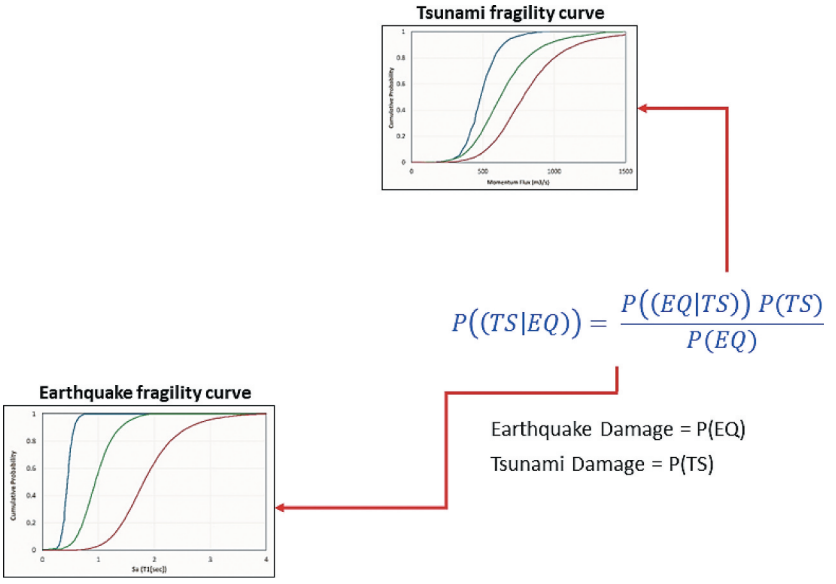

Figure 1. Conceptual demonstration of the problem.

3 METHODOLOGICAL APPROACH

This study leverages the computational power of clusters and supercomputers, comprised of numerous machines, each housing ten to thousands of CPUs or GPUs. In this case, a cluster boasting 1160 CPUs, distributed across 29 distinct computers, each equipped with 40 CPUs, serves as the primary computing infrastructure (Figure 2). The study's multi-distributed framework capitalizes on parallel programming, harnessing the capabilities of the Message Passing Interface (MPI) for efficient processing. In this MPI framework, a send and receive protocol is employed to dispatch all tasks (N jobs) from the manager node to the available worker nodes. These worker nodes can either reside within a single cluster or supercomputer

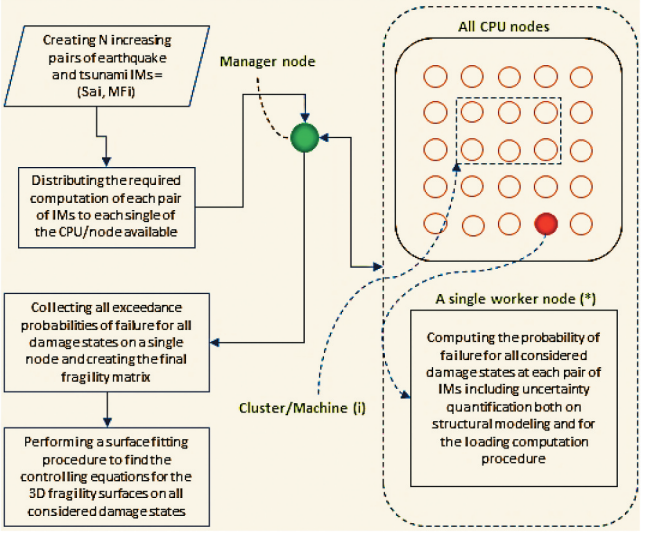

Figure 2. Multi-distributed framework designed to solve the 3D fragility surface problem.

or can be extended by incorporating nodes from external clusters. Each worker node and its CPUs independently carry out the required computations, with the results relayed back to the manager node, where they are consolidated into a single file.

Within this computational framework, the input matrix is structured with the first two columns dedicated to the earthquake and tsunami Intensity Measures (IM), creating N pairs of joint-IM values. The IM values exhibit an increasing trend in both directions, necessitating a proper definition of discretization on each axis. For example, to attain 900 joint IM points, 30 points along each IM axis are designated, ensuring 30 distinct values of tsunami IM for each earthquake IM value. Each row of the input matrix contains two IM values: the Spectral Acceleration (Sa) and the Momentum Flux (MF). Through MPI programming, N sequential algorithms are replicated with N paired input values (Sai, MFi), which are subsequently dispatched to the manager node for distribution among the worker cores/CPUs. For more information on this method, readers are referred to the study by Harati and van de Lindt (2023a).

4 TWO-PHASE SUCCESSIVE ANALYSIS

The foundation of this study rests on the concept of the "successive analysis procedure," a pivotal technique essential for crafting earthquake-tsunami fragility surfaces, shown in Figure 3. This procedure involves two distinct phases of analysis, carefully designed to encapsulate the cascading effects of both earthquake and tsunami loadings on a given structure.

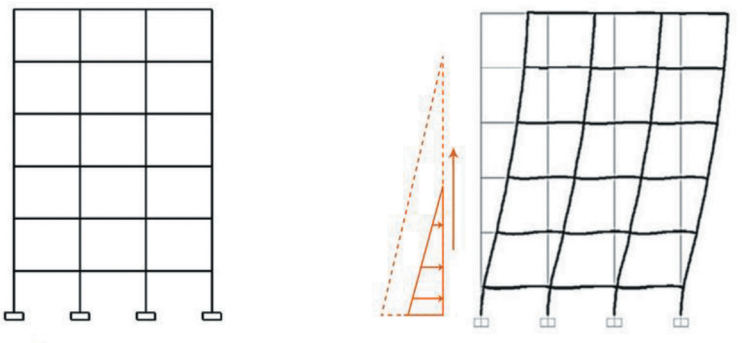

Figure 3. Proposed two-phase successive analysis procedure.

In the initial phase, the structural response to earthquake ground motion is simulated through the Multiple Strip Analysis (MSA), adhering to Baker's recommendations (Baker, 2015). The seismic intensity is quantified by selecting the spectral acceleration (Sa) at the system's first-mode period. The Sa is then systematically increased through point scaling, generating multiple ground motion scenarios. Subsequent to these analyses, the peak inter-story drift ratio is evaluated as the engineering demand parameter (EDP), facilitating the delineation of slight, moderate, and complete damage states, in line with Hazus recommendations (2020). The second phase centers on the structural response under equivalent tsunami forces, necessitating a force-based nonlinear static procedure (NSP). Notably, this analysis phase is initiated following a free vibration analysis, encompassing the structural damage sustained during the earthquake phase. In the tsunami simulation, a variable-height load pattern is employed, which closely mirrors the hydrodynamic force of the tsunami wave. A key component in the analysis is the consideration of the momentum flux (*hu^2*) as the Intensity Measure (IM) for tsunami, a parameter strongly correlated with structural damage. Furthermore, the second phase introduces the shear capacity of the seaward columns as additional EDPs, factoring the shear capacity of the columns in conjunction with the inter-story drift. This multifaceted approach for modeling the structural response provides a comprehensive understanding of the effects of earthquake and tsunami loadings on the structure (Attary et al., 2021).

The structural modeling utilized for this study revolves around a four-story reinforced concrete (RC) building, representative of a typical RC moment-resisting frame (MRF) structure found in Los Angeles, California. This structure was designed with a focus on capacity-based design, adhering to seismic codes and provisions such as the International Building Code, ASCE 7-02, and ACI 318 (Haselton et al., 2011). The seismic characteristics and detailing of the members are based on the spectrum acceleration coordinates of SS = 1.5 g and S1 = 0.6 g, suited for a site with a soil class D. The structural model, implemented using the OpenSeesPy software, incorporates both stiffness and strength aspects. The gravity load destabilization effects are effectively accounted for by introducing leaning columns linked to the structure using truss-based link elements. Moreover, the shear panel at the joints is modeled with Joint2D elements, and a nonlinear rotational spring model, specifically the modified Ibarra-Medina-Krawinkler (IMK) deterioration model (Lignos and Krawinkler, 2011), controls the degrading behavior of elements concerning strength and stiffness. In addition, the shear behavior of the beam-column joints is controlled through a nonlinear uniaxial material model. To complete the structural simulation, the Rayleigh damping method with a random damping ratio is introduced to account for viscous damping (Attary et al., 2021).

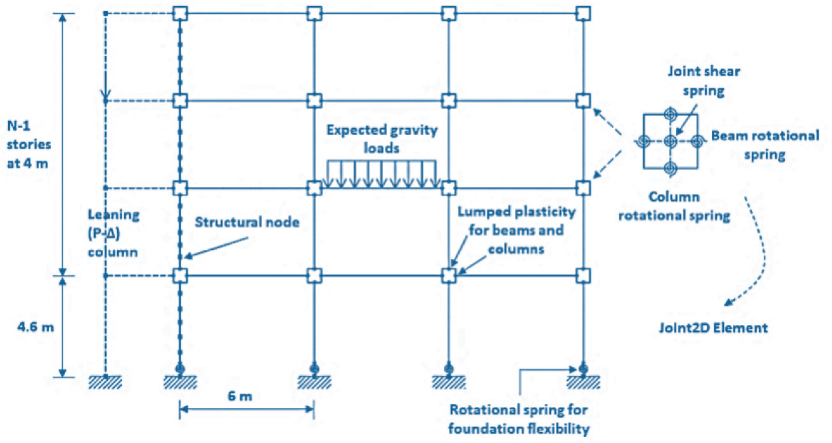

Figure 4. Macro modeling of the structural system in OpenSeesPy (Haselton et al., 2011).

In addressing the complexities of this multi-hazard analysis, the study embraces the importance of uncertainty modeling, as brought in Table 1. The uncertainties associated with ground motions (GMs) required for the Multiple Strip Analysis (MSA) are quantified using a suite of far-field GMs, following FEMA P-695 recommendations. For the input tsunami forces, uncertainties are incorporated by modeling the *Co* and *Cd* factors (refer to: Harati and van de Lindt (2023a)) as random variables with uniform distributions. Additionally, numerous parameters in the structural analysis are modeled as random variables, contributing to a comprehensive representation of the structural system's uncertainties (Harati and van de Lindt (2023a)). This multifaceted approach, anchored by the successive analysis procedure, serves as a powerful tool for comprehensively evaluating structural vulnerabilities and responses in the face of earthquake and tsunami events.

Table 1. The characteristics of the random variables used to model the structural system as well as the tsunami lateral loading (Harati and van de Lindt, 2024).

Random Variable	Distribution type	Mean	COV
C_o	Uniform (0.35-1)	-	-
C_d	Uniform (1.25-2)	-	-

Column footing rotational stiffness	Log-normal	1.0 × (computed)	0.3
Joint shear strength	Log-normal	1.40	0.1

5 RESULTS

The study offers a detailed analysis of the fragility matrix for a 4-story ductile RC frame, using a 30x30 matrix and joint intensity measures: Sa for earthquakes and MF for tsunamis. Based on the recommendation of Harati and van de Lindt (2023a), 400 data points for joint IMs are sufficient for generating accurate earthquake-tsunami fragility surfaces. Figure 5 shows discrete data points indicating the complete collapse of the 4-story RC frame. Notably, the term $P(TS|EQ)$ is computed using our method, avoiding the impractical term $P(EQ|TS)$.

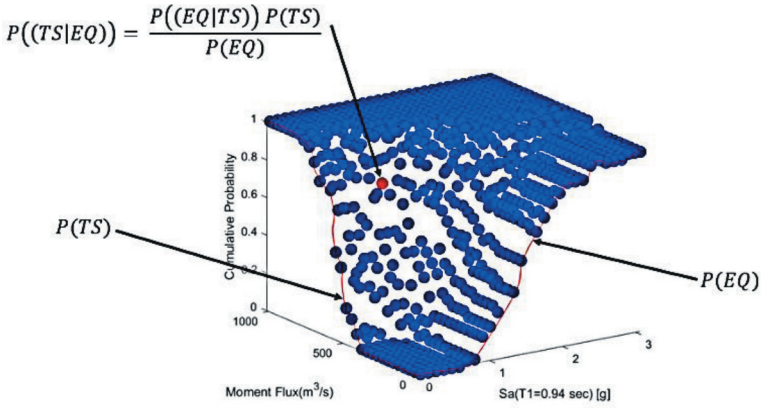

Figure 5. Graphical output of the fragility matrix computed by the proposed multi-distributed methodology.

Figure 6(a) shows the earthquake-tsunami fragility surface for a representative building, where the x and y-axes denote earthquake and tsunami intensity measures (IM), respectively, and the z-axis indicates the exceedance probability of building collapse. Governed by Equation (2), the surface originates from the mathematical model $h(E, C1, C2, \alpha, n, Sa,\ MF)$, as proposed by Kern et al. (2004). This model has five unknown parameters for estimating the joint failure probability $P(Sa,\ MF)$:

$$P(Sa,\ MF) = \frac{E.\left(\frac{Sa}{C1} + \frac{MF}{C2} + \alpha.\left(\frac{Sa}{C1}\right).\left(\frac{MF}{C2}\right)\right)^n}{\left(\left(\frac{Sa}{C1} + \frac{MF}{C2} + \alpha.\left(\frac{Sa}{C1}\right).\left(\frac{MF}{C2}\right)\right)^n + 1\right)} \tag{2}$$

The unknown parameters can be obtained using a surface-fitting optimization procedure suggested by Kern et al. (2004). According to Equations (1) and (2), the relationships below are valid:

$$P(TS \mid EQ) = P(Sa,\ MF) \tag{3}$$

From Equation (5), the impractical term in Equation (1), $P(EQ/TS)$, can be represented through parameters in Equation (2). Thus, the desired term in Equation (1), $P(TS/EQ)$, can be approximated as follows:

$$P(EQ \mid TS) = h(E, C1, C2, \alpha, n, Sa,\ MF).\left(\frac{P(EQ)}{P(TS)}\right) \tag{4}$$

$$P(EQ \mid TS) = f(E, C1, C2, \alpha, n, Sa,\ MF) \tag{5}$$

$$P(TS \mid EQ) = f(E, C1, C2, \alpha, n, Sa,\ MF)\left(\frac{P(TS)}{P(EQ)}\right) \tag{6}$$

Figure 6 (b) illustrates earthquake-tsunami fragility surfaces for the 4-story ductile RC system, covering all assessed damage states, including slight, moderate, and complete damage. Along each edge of these fragility surfaces, there are three sets of 2D fragility curves. For instance, within the Sa and z-axis plane, one can observe the 2D fragility curves for earthquake-only hazards ($P(EQ)$), reflecting various damage states. Similarly, on the opposing side of the fragility surfaces along the MF axis, 2D fragility curves for tsunami-only hazards ($P(TS)$) across different damage states can be observed.

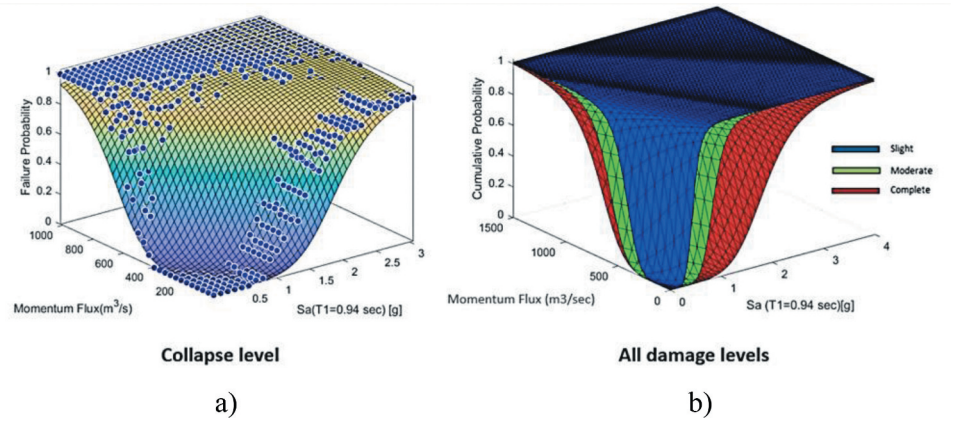

Figure 6. Surface fitting over the raw data of fragility matrix datapoints and the final surfaces for different damage states: a) discrete data points for the collapse damage state versus the final surface fitted to them, and b) fragility surfaces in different damage states.

In Figure 7, the performance of the framework and the corresponding computational time are depicted as the number of requested cores/CPUs increases along the x-axis. This analysis encompasses two scenarios, one with N equal to 225 and the other with N equal to 400. For clarity, when the CPU count is set to 120, parallel processing occurs with 120 CPUs exclusively. Notably, a significant reduction in computational time is observed once the CPU count exceeds 80, irrespective of the case. Figure 10 serves as a reference point, with one CPU symbolizing the computational capability of a single machine or a basic personal computer running these analyses sequentially. The data presented in Figure 7 reveals that a single machine requires 203 days to complete the computational analysis for cases with N=400 and 101 days for cases with N=225.

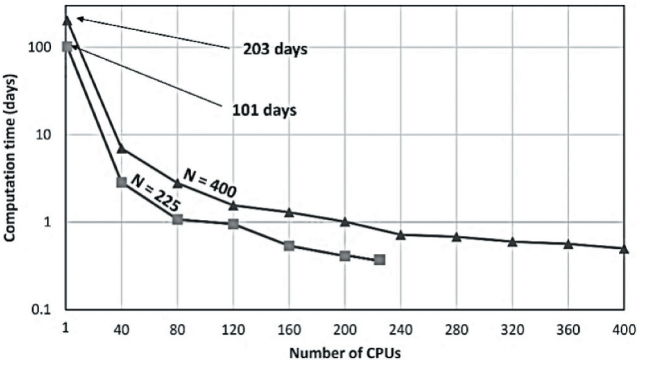

Figure 7. The computation time required for the generation of 3D fragility surfaces with N values equal to 225 and 400 shown for a single machine versus multi-distributed systems with increasing numbers of CPUs.

6 CONCLUSIONS

This study presents a novel framework for multi-distributed parallel processing, tailored for the generation of three-dimensional fragility surfaces relevant to earthquake and tsunami hazards. The framework rigorously accounts for uncertainties in structural modeling and hazard-induced loadings. A case study employing a Reinforced Concrete (RC) moment frame validates the framework's efficiency, illustrating that a configuration of 400 cores processing 400 data points delivers robust results. This computational approach substantially reduces both time and computational overhead, offering a scalable solution for generating fragility surfaces adaptable to diverse structural archetypes within a community. The produced surfaces quantify risk associated with individual earthquake and tsunami scenarios, as well as their concurrent impacts. The study also highlights the imperative of incorporating earthquake-induced modifications in tsunami fragility assessments, particularly following high-magnitude seismic events. These insights can contribute significantly to the body of knowledge in risk and resilience engineering by enabling efficient analyses.

Bridge maintenance methodology accounting for climate change dependent parameters

S.A. Keo & N. Makhoul
Associate Professor, ESTP – Grande école d'ingénieurs de la construction, Dijon, France

ABSTRACT: The article demonstrates the climate change impact on the corrosion damage of an inspected bridge abutment (6 meters by 1.5 meters) through the maps of corrosion alarm probabilities obtained from a Bayesian network (BN) predictive model. The methodology for establishing corrosion alarm mapping of the first layer reinforcements consists of three steps: building the database, learning the BN structure and parameters from the non-destructive inspection data (NDT data), and using the BN for creating the corrosion alarm map. The studied BN model has four 4 variables: corrosion potential, corrosion rate, electrical resistivity of concrete cover, and corrosion alarm (related to corrosion rate). The available corrosion potential values (NDT data) of the inspected bridge abutment are used as the new information for updating the BN model to obtain the probability corrosion alarm map. Two scenarios are proposed in the study: decrease of 50 mV in all points, and decrease of 50 mV in the middle part, and of 100 mV in the edges. The results open a perspective to implement the real environmental exposition classes of the structures in the BN model to obtain a resilient maintenance (for corrosion of reinforcements) strategy.

1 INTRODUCTION

The Bridges are one of the most critical transportation infrastructures. However, most of bridges were built mainly in the last decades. Therefore, they are aging, and their reinforced concrete structural elements are suffering from reinforcements corrosion (AFGC, 2004). To face this issue, many monitoring techniques and maintenance strategies have been developed by various scientific and expert communities. Different maintenance methodologies were proposed, combined with on-site inspection and different non-destructive techniques (NDT) have been used to obtain relevant durability indicators for the concrete structures (Gomez et al., 2018). However, constraints (economic and feasibility) on the on-site measurements lead to partial information for the inspected structures. To resolve this issue (lack of information), Bayesian networks (BN) have been used in many methodologies (Tran et al., 2015). A recent BN based methodology has been proposed for creating 2D maps of corrosion alarm probabilities related to corrosion levels of the reinforcements (Keo et al., 2022, 2023a, 2023b). It is a predictive model (i.e., specifically before the propagation of the corrosion) accounting for various indicators such as electrical resistivity of concrete cover, corrosion rate, polarization resistance, capacitance, thickness of concrete cover, and half-cell potential. The methodology is divided into three stages: creating data base, learning stage, and utility stage. The learning stage led the predictive model to a final BN structure called physically optimal with three indicators: the corrosion potential, the corrosion rate, and the electrical resistivity.

However, the methodology didn't account for climate change. Climate change can affect the structure degradation with the increase of CO_2 concentration, temperature, and changes in relative humidity (Iamsumang et al., 2018). It can also increase uncertainty on model parameters. To enhance the resilience of bridges to climate change, this paper demonstrates

DOI: 10.1201/9781003483755-391

the climate change impact on the corrosion damage of the inspected structures through the maps of corrosion alarm probabilities obtained by the proposed BN based methodology. Moreover, variation of the corrosion potential values (one of the durability indicators) will be linked with two suggested climate change scenarios.

2 MATERIAL AND METHOD

2.1 *Methodology and Bayesian network used in the present study*

The methodology based on a Bayesian network (BN) developed in the previous study (Keo et al., 2022, 2023a, 2023b), for creating corrosion alarm maps of reinforcements for inspected real structures, is used in the present study. The methodology consists of three principal phases: database construction based on NDT inspection data, structure and parameter learning, and utility of BN for corrosion alarm mapping. The procedure of the methodology is illustrated in Figure 1 (Keo et al., 2023). The database of all parameters (thickness of concrete cover, capacitance, corrosion potential, electrical resistivity of concrete cover, corrosion rate, corrosion level, and corrosion alarm) was used for the Bayesian network. The structure and parameter learning were then carried out in the second step to obtain the optimal BN structure, and conditional probability function (CPF) of each variable of the BN. Finally, the corrosion alarm map (probabilities of corrosion alarm of all the points on the surface of the inspected element) is obtained after updating the BN with available NDT data (as new information of the BN) for the inspected structural element.

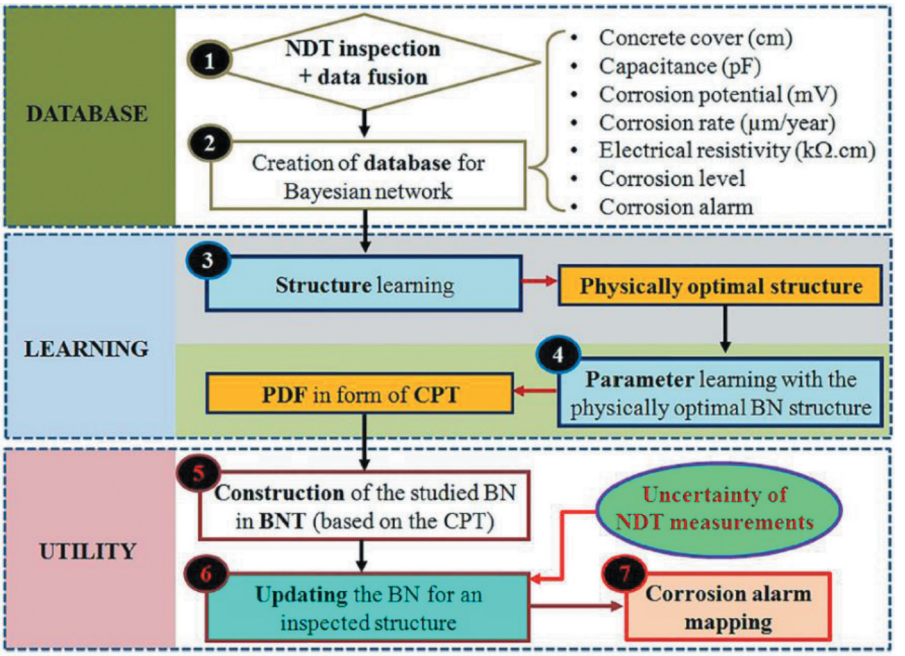

Figure 1. Methodology for corrosion alarm mapping with uncertainty of measurements (Keo et al., 2023).

The structure of the studied BN is the optimal structure with 4 variables, as shown in Figure 2 below.

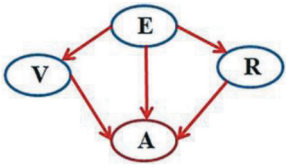

Figure 2. Physically optimal structure with 4 variables studied in (Keo et al., 2023).

Where, E, V, R, and A nodes represent the corrosion potential, the corrosion rate, the electrical resistivity of the concrete cover, and the corrosion alarm (related to corrosion rate) parameters, respectively.

2.2 *Suggested scenarios for demonstrating the climate change effect on the corrosion alarm*

To demonstrate the effect of the climate change on the probabilities of corrosion alarm obtained from the NDT data based predictive BN model, the schema below (Figure 3) is suggested.

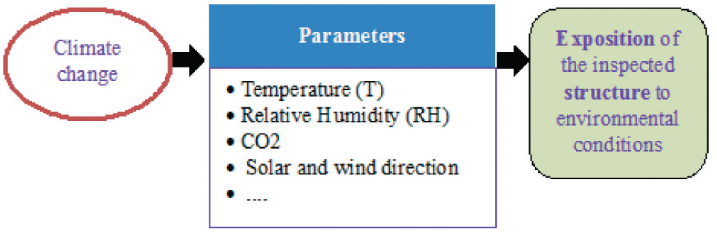

Figure 3. Exposition of inspected structure impacted by climate change effect.

Important parameters which depend on the climate change include atmosphere temperature (T), relative humidity (RH), CO_2 rate, solar and wind direction (Iamsumang et al., 2018). These parameters depend on where the studied structural elements are situated. Thus, accounting the effect of the climate change on the structures could be simplified by considering the class (or degree) of exposition of the structures. In other words, how the structures are exposed to environmental conditions, which is related to the climate change, will affect the corrosion rate of the reinforcements inside the structures.

In the present study, the NDT data of an inspected bridge abutment is used as the new information for updating the BN model to obtain the probability corrosion alarm map. The studied bridge abutment is shown in Figure 4 below.

Figure 4. Inspected bridge abutment for the present study (in DIAMOND project in the previous study).

The bridge abutment was inspected in an area of 6 meters by 1.5 meters (red frame in Figure 4). With the dimension, and its geometry configuration, the inspected area can have different parts which are differently affected by climate change dependent parameters (contact with rain, solar radiation, and so on). The degree of climate change impact on the different parts of the studied area can be differentiated by shelter period.

In the first stage of the present study, the parts in yellow frames (in Figure 4) are considered to be more unfavourable to the climate change effect than the middle part of the abutment area. Thus, the variation of the values of the durability indicators (NDT data), which are related to the corrosion rate, in these parts might be higher than that in the middle part. The available NDT data of the studied bridge abutment is the values of the corrosion potential. For these reasons, two scenarios are proposed to observe the corrosion alarm maps of the inspected abutment based on the BN model and the observed corrosion potential: decrease of corrosion potential (more unfavourable to corrosion due to the age of the structure) in the whole inspected area without considering the effect of climate change (decrease of 50 mV), and the decrease of the corrosion potential accounting the effect of climate change. The variation of the corrosion potential in the second scenario is illustrated in Figure 5.

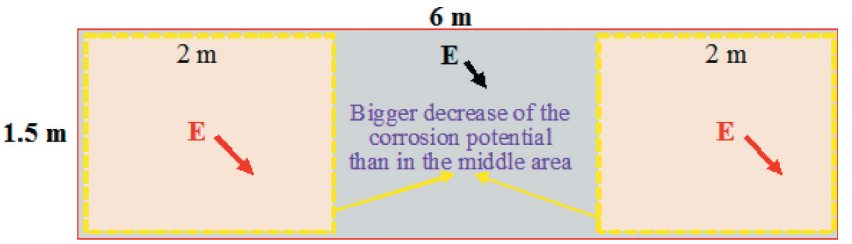

Figure 5. Decrease of the values of corrosion potential on the inspected area of the bridge abutment accounting the climate change condition.

As shown in Figure 5, the middle part of the abutment (2 meters by 1.5 meters) has a smaller decrease of the corrosion potential values. In the middle part of the inspected abutment face, the values of the corrosion potential are supposed to be decrease of 50 mV, whereas that in the other parts (which are more exposed to the climate change dependent parameters especially contact with the rain and solar radiation) is 100 mV. It is worthwhile to note that, in the first stage of our study, decreased values of the corrosion potential are supposed to be uniform in each part of the observed abutment area. The values of 50 mV, and 100 mV are not the exact values; so as to allow to observe different corrosion alarm maps affected by the climate change dependent parameters.

3 RESULTS AND DISCUSSIONS

3.1 *Corrosion alarm map of the inspected abutment with available NDT data*

The available values of the corrosion potential in the whole inspected area of the abutment (44 detected points in total) are used to update the BN model. The corrosion alarm map in this case of inference is obtained, as shown in Figure 6.

The map in Figure 6 shows the higher probabilities (between 80 % and 100 %) of corrosion alarm in the upper part of the inspected abutment. The lower parts, especially the edges (left and right parts) have many points with the probabilities lower than 50 % representing no-alarm state. It is reminded that the uncertainty of measurement was also considered in the BN model in the last stage of the methodology (Keo et al., 2023).

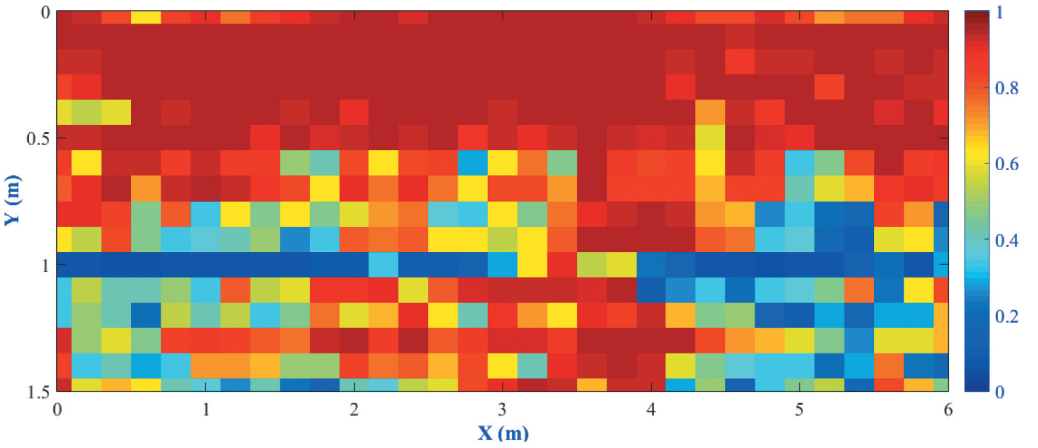

Figure 6. Corrosion alarm probability map of the inspected abutment area with the available values of corrosion potential.

3.2 *Corrosion alarm maps with the decrease of the corrosion potential values*

In order to observe the effects of the environmental condition exposition of the structures on the corrosion alarm, corrosion alarm maps obtained from updating the BN with the new values of the corrosion potential varying accordingly to both suggested scenarios are obtained in Figure 7.

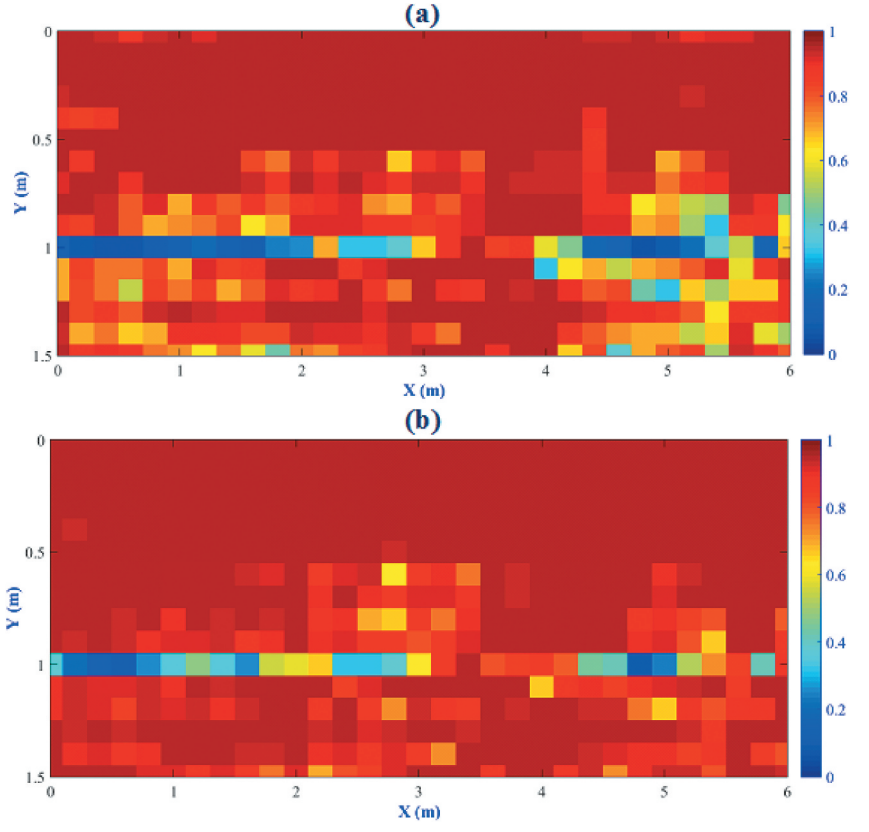

Figure 7. Corrosion alarm probability maps of the inspected abutment area with the decrease of the corrosion potential values, (a) without climate change effect scenario, (b) with climate change effect scenario.

Figure 7a illustrates more points with high probabilities of corrosion alarm (higher than 80 %) compared to Figure 6. This is conformed with the hypothesis of the decrease of the corrosion potential values (representing the degradation of the abutment with its age). It confirms that the BN model can be used as a bridge maintenance strategy with the case of inference (observed node of the proposed BN structure) with the available corrosion potential values in the future inspection campaigns. Figure 7b shows even more points with high probabilities of corrosion alarm (higher than 80 %, and even higher than 90 %) compared to Figure 7a. It explains the necessity of accounting the exposing environmental conditions into the BN predictive model to void the under-estimation of the degradation (related to corrosion of the first layer reinforcements) of an inspected structure. This effect will become more critical for the bigger inspected area.

Thus, complementary to the durability indicators (NDT data), the exposition classes of the structures to environmental conditions should be implemented in the BN model in order to assure a resilient maintenance strategy. It is worthwhile to remind that the exposition classes, which depend on the geographical locations, are related to climate change dependent parameters (Iamsumang et al., 2018) affecting the life of structures.

4 CONCLUSIONS AND PERSPECTIVES

A methodology based on a Bayesian network (BN) for creating corrosion alarm maps of reinforcements is used in the paper. NDT data of an inspected bridge abutment is used as the new information for updating the BN model to obtain the probability corrosion alarm map. Two scenarios are proposed to observe the corrosion alarm maps of the inspected abutment: decrease of corrosion potential (more unfavourable to corrosion due to the age of the structure) in the whole inspected area without considering the effect of climate change (decrease of 50 mV in all points), and the decrease of the corrosion potential accounting the effect of climate change (decrease of 50 mV in the middle part, and of 100 mV in the edges).

The results confirm the hypothesis of the decrease of the corrosion potential values (representing the degradation of the abutment with its age), as well as the possibility to use the BN model as a bridge maintenance strategy with the available corrosion potential values collected in other future inspection campaigns. On the other hand, it is necessary to account the exposition environmental conditions in the predictive model.

The results from the present paper opens an important perspective to implement the real exposition classes of the structures to environmental conditions in the BN model in order to obtain a resilient maintenance strategy related to the corrosion of reinforcements. Accurate relation of the variation of the NDT data and climate change dependent parameters will lead to enhancing the BN predictive model as an effective maintenance method.

ACKNOWLEDGEMENT

The authors would like to express their gratitude to LERM laboratory for the inspections and the information of the experimental campaigns, and to all the partners in FUI program for the DIAMOND project (DIAgnostic corrosion and MONitoring for the Durability of reinforced concrete and steel structures) for the financial support. Moreover, thanks to all the partners for the creation of the corrosion predictive model in the previous work, especially LMDC Toulouse laboratory (Laboratoire Matériaux et Durabilité des Constructions), allowing to reach the present work.

Enhancing urban resilience and sustainability under wind disasters with carbon emission as an indicator

Ting-Yau Wang
Research Assistant, Department of Civil Engineering, National Taiwan University, Taipei, Taiwan

Chi-Ying Lin
Assistant Professor, Department of Civil Engineering, National Yang Ming Chiao Tung University, Hsinchu, Taiwan

ABSTRACT: Communities and systems are inevitably vulnerable to disasters, particularly typhoons. Thus, to adapt to the destruction caused by natural hazards and to achieve a low-carbon community, this study compares critical infrastructure systems with their remaining functionality under various carbon-reduction measures and initiatives aimed at enhancing urban stability in the aftermath of a typhoon event. Hence, this research focuses on reducing carbon emissions and bolstering urban resilience in the context of Kaohsiung, Taiwan, a city that is increasingly susceptible to major typhoons. This study concentrates on four strategies: (i) augmenting network redundancy, (ii) establishing backup solutions or temporary facilities at critical nodes, (iii) strengthening facilities against wind forces, and (iv) substituting damaged infrastructures with low-carbon materials or construction methods. Comparing the results of these strategies through carbon emission during restoration and the average performance of the systems in the short term, this study provides decision-makers a reference for improving community resilience and reducing carbon emissions simultaneously.

1 INTRODUCTION

In recent years, the escalating impact of natural disasters has not only caused substantial economic losses but also posed severe threats to the lives of countless individuals. The concept of "resilience" has emerged as a critical discourse, aiming to mitigate the damages inflicted by disasters and facilitate swift recovery in their after-math (Timmermann, 1981). The discussion on resilience often concerns Critical infrastructure systems (CISs), which significantly influence the life quality of res-idents. However, the vulnerability of CISs to the impacts of natural hazards has be-come strikingly clear. Compounded by interdependencies among these systems, the impairment of one not only diminishes its functionality but also cascades disruptions to interconnected CISs, resulting in wide-spread damage (Guidotti et al., 2016).

In response to the UN's Zero Carbon Cities competition, which advocates for a transformation towards net-zero sustainability, cities worldwide are compelled to reevaluate both the supply-side issues (power supplies and transportation) and demand-side issues (reducing usage through improved urban design and policies). Thus, striking a delicate balance between maintaining a high quality of life and implementing low-carbon maintenance strategies becomes crucial (Shi et al., 2022). This balance is especially challenging in scenarios such as high energy consumption in transportation due to re-mote settlement areas or the inefficient utilization of energy services.

This study delves into the intersection of carbon reduction and the enhancement of urban resilience, with a focus on Kaohsiung serving as a case study. Tai-wan, experiencing an

DOI: 10.1201/9781003483755-392

average of 4.6 typhoons annually, faces heightened vulnerability to the impacts of these storms. The city of Kaohsiung, located in the southern region of Taiwan, is particularly susceptible to the destructive forces of powerful typhoons, resulting in significant economic losses. This scenario underscores the urgent need for flexible urban disaster mitigation strategies. Climate change exacerbates risks, including heavy rainfall, urban flooding, and the urban heat island effect. This intensifies the urgency to reduce car-bon emissions and transition towards low-carbon urban development, aligning with global sustainability objectives. The current research concentrates on the interdependent transportation and power systems and critical components often incapacitated during typhoons. The study conducts a comprehensive assessment by drawing inspiration from the investigation of four strategies, including (i) preparing backup solutions like backup power and temporary replacements, (ii) adopting low-carbon materials, for example, fiber-glass reinforced plastic (FRP), (iii) improving structural safety design to enhance wind resistance, and (iv) increasing network redundancy by increasing grid complexity.

The urgency of this research lies in providing practical insights for evaluating different strategies' resiliency and environmental sustainability. Through considerations of short-term post-disaster recovery, this study aims to guide the formulation of pre-disaster management and post-disaster response approaches that ensure the continued functionality of urban systems in the face of climate-induced disasters and contribute to the overarching goal of mitigating carbon emissions.

2 SYSTEM RESILIENCE

2.1 *Kaohsiung's CIS modeling*

In this study, emphasis is placed on the topological characteristics of the road network in the traffic system, where assessing the system's ability to handle disasters relies on the integrity of the network of connectivity and the determination of the shortest traffic paths (Zhang et al., 2017).

The damage to the capacity of the road network considered in this study encompasses three types: the first is the collapse of bridges; the second is the decrease in road capacity due to reduced vehicle speed caused by high wind speeds; and the third is road blockage caused by fallen roadside elements such as signages and streetlights due to the wind. All three scenarios pose challenges during typhoons and result in disruptions to traffic.

Besides, this study builds the power system model comprising Kaohsiung's power generators, substations, and transmission systems with their power capacities. Power transmission is one-way linear, and damage to any power tower or power station along the way will cause the end user to be unable to use power (Cai et al., 2019). Thus, to detect the physical damage caused by wind attacks, the parameters of physical damage and repair time for high-voltage towers and stations are also listed in Table 1.

The fast recovery usually depends on how long the maintenance unit arrives at the road obstruction. Meanwhile, shorter path selection can reduce the energy consumption in the transportation of construction vehicles and facilities. In order to identify the residual performance of the infrastructures, this study assesses the impact of different wind speeds on traffic flow. Simultaneously, the corresponding time required for maintenance and road cleaning is linearly allocated based on historical records, as shown in Table 1.

The road network and power grid distribution in Kaohsiung City are shown in Figure 1 and Figure 2. The current study is based on these interdependent systems to conduct research on community resilience under typhoon disasters.

2.2 *System interdependencies*

Many researchers are studying on the dependent systems, such as Hasan (2015) and Reed (2015). The experts collected others' opinions; in addition, for different aspects, multiple

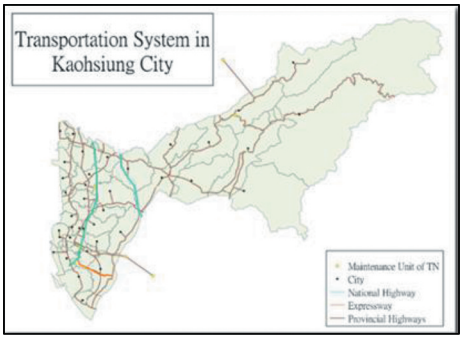

Figure 1. The road network in Kaohsiung City.

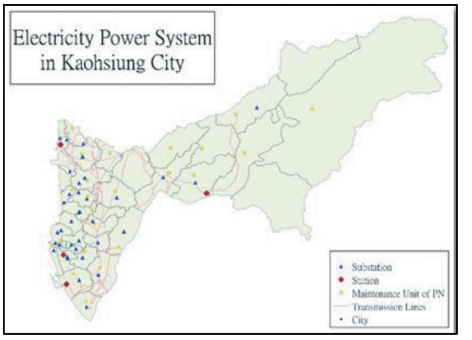

Figure 2. The power network in Kaohsiung City.

systems are combined, and the dependencies between infrastructures are evaluated through a large number of simulations.

For the interdependencies between transportation and power systems, we consider the impact of three aspects:

(1) Functional-dependent—traffic signals and monitors work because of sufficient power supply.
(2) Spatial overlapping—the transmission lines have geographical intersections with road systems, which may affect the traffic volume after a disaster.
(3) Obstructed path—the repair time relies on the shortest paths from maintenance units to the damaged facilities, which are determined by the functionality of road networks.

Table 1. The parameters of facilities. *

Node	Damage level	Fragility (lognormal distribution)	Repair (linear model)
Station	Moderate	Median: 89.0 m/s	Mean:19 h
Transmission	Extensive	Median: 34.2 m/s	Mean: 48 h
	Destruction	Median: 84.4 m/s	Mean: 30 d
Bridge	Half blocked	Median: 41.4 m/s	Mean: 6 h
	Fully blocked	Median: 50.6 m/s	Mean: 48 h
Accessories	Fallen	Median: 34.2 m/s	Mean: 2 h

*Data sourced from Gu et al. (2020); Testa et al. (2015); Bie et al. (2017); Salman et al. (2015)

2.3 *Typhoon hazards*

Typhoons wield substantial energy, making their impact on large structures in Taiwan a significant concern, resulting in annual economic losses amounting to billions of New Taiwan dollars (Yin, 2009). Understanding and assessing typhoon-related disasters is imperative for Taiwanese meteorological research. This involves tracking the historical trajectory of the typhoon eye and gauging the extent of its wind impact, aiding in the identification of affected areas. By analyzing wind fields and overlaying wind radii, government and emergency management agencies can formulate effective strategies for typhoon preparedness and disaster mitigation, considering the distribution of infrastructure in various regions.

The typhoon simulation involves Monte Carlo methods encompassing typhoon generation, path, wind field, and boundary layer flow models. To assess the impact of typhoon models on transmission lines and roads accurately, this study establishes a detailed typhoon model based on landing location, central pressure difference, maximum wind speed, and the radius of maximum wind speed. Using historical records from the Joint Typhoon Warning Center at 6-hour intervals, this study extracts parameters suitable for infrastructure vulnerability analysis with

the maximum wind speed radius. Thus, the wind speed at the facility will be determined by the following formula:

$$v(\mathrm{t}) = \begin{cases} v_{max} \times [D/R_{mw}]^{\eta}, if\ D \leq R_{mw} \\ v_{max} \times [R_{mw}/D]^{\eta}, if\ D > R_{mw} \end{cases} \quad (1)$$

where v represents wind velocity, R_{mw} is the radius of the maximum wind speed, D is the distance between the node and typhoon eye, and η equals 0.5 in Taiwan.

The study employs circular symmetric wind field models, utilizing an exponential-type wind field represented by Rankine vortices (Wang et al., 2022). The model considers factors like the distance between the node and the typhoon eye to determine the local maximum wind speed. However, it acknowledges limitations, such as relying on discrete observation points and analyzing only continuous and non-quadrant wind radii of the typhoon eye, potentially deviating from the actual typhoon path.

2.4 *Carbon emissions during restoration*

Maintenance operations play a crucial role in sustaining infrastructures, and meanwhile, it is essential to scrutinize the associated carbon emissions. This section explores the carbon footprint generated during restoration, focusing on human activities, construction machinery operation, and transportation distance based on previous studies (Chen et al., 2023; Wei et al., 2017; Yang, 2010):

(1) Human activities—the carbon emissions generated by on-site living and commuting of engineering personnel contribute significantly to daily carbon emissions during maintenance. Individuals involved in the maintenance process emit approximately 0.047 metric tons of CO2 per day.
(2) Operation of construction machinery—it constitutes a substantial portion of carbon emissions during restoration efforts. On average, the emissions are estimated at 0.128 kg of CO_2 per square meter of restoration.
(3) Transportation distance—the path to the repair site plays a pivotal role in maintenance, and the associated carbon emissions are contingent on the distance traveled. For every kilometer covered, maintenance activities contribute 0.106 kg of CO_2. This metric encompasses emissions from the entire transportation process, from fuel combustion to logistical considerations.
(4) Material used for facility repair—after a typhoon event, infrastructures experience damages and require replacement materials. The restoration process produces the corresponding greenhouse gas based on types of materials (as shown in Table 2) and types of facility damages (as shown in Table 3).

Table 2. Carbon emissions for different materials in Taiwan (from Taiwan Ministry of Environment).

Materials	Unit	Carbon emission*
Steel bars for reinforced concrete	kg	0.834
Pre-mixed concrete	m^3	338
Diesel (road transport and machines)	L	3.34
Asphalt concrete	t	9.56

* The unit of carbon emission is kg-CO_2e.

Table 3. Carbon emissions for construction of different facility rehabilitations.

Facility	Restoration	Carbon emission*
Transmission tower	Cable installment	352.65
	Tower reconstruction	15646
Substation and plants	Machine repairment	14
road pavement	Obstacles removing	0.3
	Repaving asphalt road	1.6

* The unit of carbon emission is t-CO_2e.

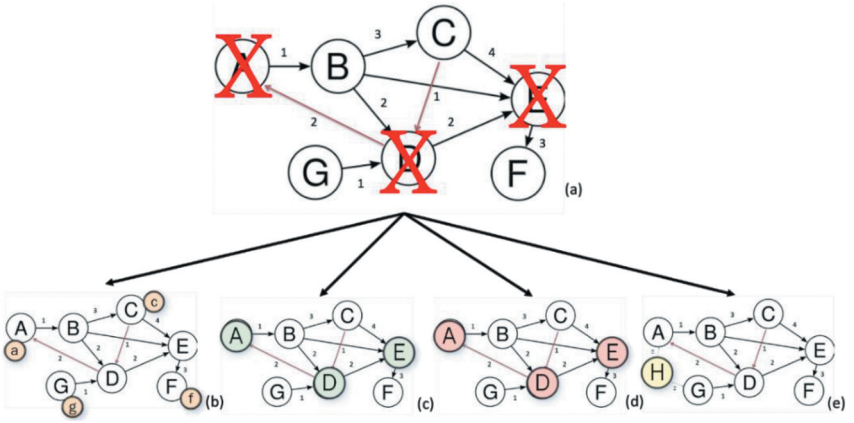

Figure 3. Illustration of the carbon reduction measures and resilience enhancement strategies: (a) schematic diagram of network damage in disasters; (b) backup solutions; (c) low carbon alternatives in materials or construction; (d) wind resistance enhancement; (e) network redundancy.

3.1 *Prepare backup solutions*

In the realm of infrastructure systems, ensuring stability and rapid recovery from disruptions is paramount. This study places a strong emphasis on deploying robust backup solutions to enhance the resilience of critical infrastructure, exemplified by innovative measures such as the "Composite Lightweight Bridge for Emergency Disaster Relief." (Yeh et al., 2020) This groundbreaking bridge technology is designed for swift reconstruction, reconnecting vital transportation routes within a remarkable 8-hour timeframe, thereby significantly reducing downtime and enhancing overall system stability.

Additionally, the integration of backup generators stands as a cornerstone in fortifying infrastructure against potential disruptions (Xiaoguang et al., 2017). These generators play a pivotal role in maintaining an uninterrupted power supply, even in the face of equipment damage. According to data from Taipower, at Taiwan's power stations, the operating level of the units has not yet reached the maximum supply, and 15% to 20% of the units in the plant are in standby and dormant status. When other units encounter problems or the power supply is insufficient, they can be woken up within a day for operation without the cost of additional equipment installation. In an era where continuous power is fundamental for various critical functions, these backup generators serve as a linchpin, mitigating the impact of destruction and ensuring sustained operations.

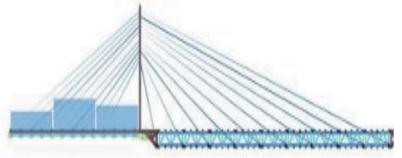

Figure 4. Temporary rescue bridge. (Yeh et al., 2020).

Table 4. The parameters for modeling the probability distribution of repair time for the temporary facilities under consideration.

Facility	Carbon emission	Repair time	Source
Backup power	0.17	Mean: 6 h, cov: 2 h	Wei (2017)
Temporary tower	139.54	Mean: 16 d, cov: 1 d	Yeh (2020)
Emergency bridge	0.63	Mean: 8 h, cov: 2 h	Xiaoguang (2017)

* The unit of carbon emission is t-CO_2e.

This study extends its focus beyond conventional recovery approaches. It delves into fast replacements, featuring emergency bridges, temporary towers, and the activation of dormant machines in power stations. These rapid replacement strategies are detailed in Table 4, providing insights into construction times and associated carbon emissions.

3.2 *Switch to low-carbon alternatives*

In pursuing fortifying infrastructure systems with a focus on sustainability, this study adopts a two-fold approach: the incorporation of recycled asphalt concrete pavement for road repairs and the transition from traditional steel to FRP materials in transmission towers.

Research by Yang (2010) underscores the environmental benefits of utilizing recycled asphalt concrete pavement in road surface repairs. The application of this sustainable alternative not only reduces carbon emissions by approximately 18%, considering material production and transportation, but also offers a shorter environmental impact post-disaster, aligning with the imperative of a smaller post-disaster environmental impact.

Simultaneously, due to increased global discussions on sustainable building materials and addressing rising steel prices, scholars such as Kumar (2020) advocate for the integration of FRP materials. The utilization of FRP instead of secondary steel has been shown to reduce a structure's embodied carbon by 60-85% and have faster construction timelines decreasing about 10-20%. Although the cost of FRP materials is roughly 30% lower than steel, careful consideration of trade-offs is imperative due to increased failure probability. It's noteworthy that fragility parameters for the initial steel tower indicate a mean of 45.94 m/s with a coefficient of variation (cov) of 8.1, while the FRP tower has a mean of 42.94 m/s with a cov of 8.8. (Bilionis et al., 2022).

3.3 *Increase wind resistance*

While the augmentation of wind resistance stands as a strenuous strategy against disasters, it necessitates a careful examination of the associated trade-offs. The proposed methodology involves fortifying infrastructure elements to withstand the impacts of adverse weather conditions, particularly focusing on high wind events. However, the infrastructure stability reinforcement requires targeted reinforcement based on its damage situation, which takes a long time and requires different materials. Though incurring higher initial costs, this preemptive approach acts as a preventive measure to mitigate the destructive consequences of disasters, especially in regions prone to high winds.

This study improves wind resistance capabilities by one level, aligning with existing regulations specifying accessories with a 7 Beaufort wind force scale. The reinforcement process necessitates an additional 0.5 days of construction time, with the reinforcing materials accounting for 2% of the overall material (attachment part). Consequently, carbon emissions increase due to the reinforcing materials and extended construction time, resulting in an approximate 1-3% rise in carbon footprint. However, this reinforcing strategy raises pertinent questions about the potential trade-offs. There's an inherent tension between resilience and durability under reinforcing facilities. In some cases, structures face potential challenges such as the difficulty of integrating old and new structures, or some facilities have reached their usage limits as the cost of repair has exceeded the cost of reconstruction. The damaged infrastructures, with its reduced lifespan, can be partially restored through reinforcement, but these reinforcements take longer and cost more than original repairs. Nevertheless, the advantage of the fortified infrastructure can maintain regular operations without succumbing to power shortages or traffic disruptions, ensuring uninterrupted functionality without disturbing residents.

3.4 *Increase network redundancy*

This study aimed at fortifying the resilience of infrastructure systems, such as developing a more decentralized power grid. Enhancing network complexity with microgrids contributes to increased stability, adaptability, and overall robustness. By intricately interconnecting various components, this approach seeks to mitigate vulnerabilities, improve response mechanisms, and enhance the overall sustainability of the power grid. While power generation capacity exists,

challenges in effective delivery persist. To mitigate these challenges, this strategy adopts a decentralized approach, particularly in densely populated urban areas, to reduce the risk of centralized power grids and to enhance the stability of the power supply.

The strategy expands power transmission lines from substations to surrounding cities, specifically targeting substations with surplus energy, surpassing the residents' consumption needs. The selection criteria for substations are based on their excess power generation capacity. Besides, to improve power distribution efficiency by identifying districts facing energy shortages, we consider the energy consumption of businesses, factories, and residential areas in the designated zones. To reduce the power outage risk, we established a linkage between the selected substations and high-power consumption areas or areas with only a single power supply source to build a more resilient power system. The study proposes the establishment of transmission towers at 300-meter intervals along the shortest paths, a strategic move aimed at optimizing power distribution efficiency. However, this expansion is not without its environmental considerations. This study examines the carbon footprint associated with this measure. The carbon emissions per unit distance of the transmission line are calculated at 287 t-CO_2e./km, with each tower's construction contributing 1,410 t-CO_2e (Wei et al., 2017).

4 RESULTS AND DISCUSSION

The study conducted 1000 Monte Carlo simulations to assess the impact of historical typhoons on Kaohsiung, Taiwan. The focus was on evaluating the performance of the transportation and power systems during the post-typhoon repair period, along with the associated environmental effects, by adopting Cimellaro's (2016) resilience index:

$$Res = \frac{1}{T_{LC}} \int_0^{T_{LC}} \mathrm{Q}(t)dt \tag{2}$$

where Res is the Resilience index, T_{LC} is the target time or the time when the system is fully repaired, and Q is the functionality of the system, such as traffic flow and power capacity. The calculation of the resilience index depends on the recovery curves, as shown in Figure 5.

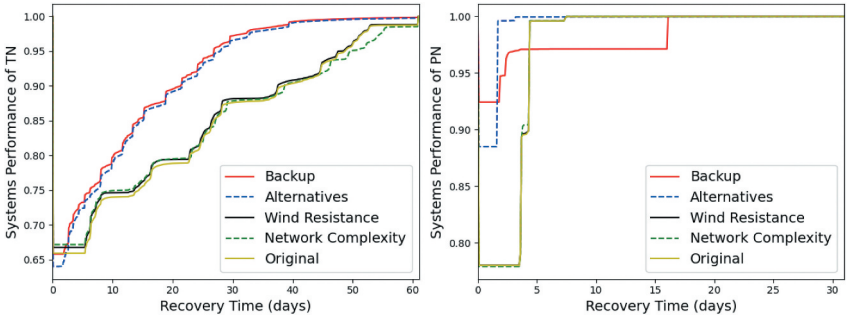

Figure 5. The recovery curves of transportation and power system after typhoon disasters.

During the recovery phase, it is noteworthy that some strategies shorten the repair time, primarily due to the lower construction timelines and faster functionality recovery. Compared to the network without resilience enhancement, which needs 4 days in PN and 38 days in TN to repair, backup solutions and low-carbon alternatives both shorten the repair time by 3 days in PN and 17 days in TN, respectively. The observed reduction in repair times underscores the efficacy of these resilience strategies. In contrast, the repair time of wind resistance and that of network complexity solutions are longer than the original network by 2 days in PN and 1 day in TN, respectively. But they resulted in increased resilience with higher robustness.

The examination of the original network reveals a moderate level of resilience, with an average resilience index of 0.786 in the transportation system and 0.914 in the power system. According to the results, the implementation of a backup solution significantly elevates the resilience index, emphasizing its effectiveness in enhancing urban resilience and ensuring a sustained quality of life for residents. Notably, the strategy demonstrates lower carbon emissions, mainly composed of human activities, for transportation system restoration, which is attributed to the reusable emergency bridges and original standby generators minimizing material pollution. Furthermore, the adoption of low-carbon alternatives contributes positively to urban resilience. Despite its elastic modulus of one-tenth that of steel, resulting in reduced robustness, its higher durability compensates for this limitation. The construction of FRP towers requires professional teams, but the advantages include lower labor requirements and a simplified installation process, reducing repair time similar to preparing backup solutions.

Enhancing the wind resistance of facilities proves to be a successful strategy, resulting in increase-ed robustness for CISs. The resilience index surpasses that of the original network, accompanied by lower carbon emissions due to reduced facility damage.

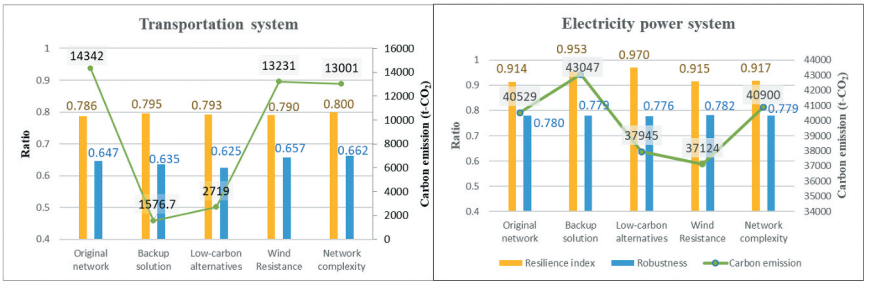

Figure 6. The indexes for typhoon disaster recovery of transportation and power system.

5 SUMMARY AND CONCLUSIONS

Recently, natural disasters have become increasingly unavoidable, inflicting inevitable damage upon urban environments. As a case study, this study focuses on the city of Kaohsiung in Taiwan, a locale frequently subjected to typhoon impacts. The research analyzes the enhancement of community resilience and its implications under the strategies of preparing backup solutions, switching to low-carbon alternatives, enhancing wind resistance, and increasing network complexity. By scrutinizing traffic flow and electrical currents, the study examines variations in system performance. These performance changes are observable through the proportional shifts in consumption patterns among end-users, namely, the residents. Furthermore, the research takes into account the carbon dioxide emissions generated during maintenance processes, material degradation, human activities, and transportation. Utilizing greenhouse gas emissions as a criterion enables the evaluation of impacts on the urban environment and provides insights for designing future zero-carbon cities.

Our investigation into strategies for enhancing urban resilience within CISs yields valuable insights. The original network exhibits a commendable level of resilience, yet implementing targeted strategies unveils opportunities for improvement.

The backup solution stands out for its remarkable impact, significantly elevating the resilience index. Its effectiveness in minimizing carbon emissions during transportation system restoration, particularly through the reusable nature of emergency bridges, underscores its practicality and sustainability. Similarly, the integration of low-carbon alternatives proves beneficial, contributing positively to urban resilience. Strengthening the wind resistance of facilities emerges as a successful strategy, elevating the overall robustness of CISs. This not only improves resilience but also translates to lower carbon emissions owing to reduced damage to critical facilities. However, the introduction of network complexity extends repair time and increases carbon emissions due to a higher probability of facility destruction, indicating the need for a balanced approach.

In conclusion, this study provides a comprehensive evaluation of diverse strategies, offering urban planners and policymakers valuable insights into crafting resilient and sustainable urban infrastructure. As cities continue to face diverse challenges, the pursuit of a resilient urban future remains a critical imperative. This research contributes to a comprehensive understanding of resilient infrastructure systems by addressing recovery speed and the environmental impact. The deployment of backup solutions, low-carbon replacement strategies, and network strengthening not only reduces recovery time but also minimizes the overall influence of disruptive events, underscoring the importance of strategic preparedness in safeguarding our critical infrastructure.

Identification of a suitable case study for the development of accessibility based vulnerability score for bridge maintenance decision making

M. Lydon, A. Vega, E. Fitzpatrick, R. Higgins & A. Fenerich
University of Galway

ABSTRACT: Prioritising bridge maintenance interventions is a complex task that involves consideration of various factors, such as the bridge's lifespan, characteristics, operating conditions, environmental impact, and the consequences of infrastructure unavailability for local communities. In this paper, network vulnerability analysis is used to enable local authorities to identify and evaluate changes of access levels across a disrupted network, thereby providing insight on the impacts to a broader range of socio-economic aspects and to society. The paper provides an overview of the road network in Ireland and identifies a suitable case study area to development of accessibility based vulnerability score for bridge maintenance decision making. A version of the Hansen's gravity-based accessibility model where the indirect effects of bridge failure are accounted for by incorporating information on travel times and traffic flows between spatial units and essential services, as well as data on population, education, and employment opportunities in and around potentially affected areas is proposed.

1 INTRODUCTION

Climate-related disasters have cost the world more than £450 billion over the last three years [1]. Transport infrastructure is directly impacted by climate change with extreme weather conditions accounting for up to 35% of delays/service interruptions in road and rail infrastructure [2]. This daily cost due to extreme weather was estimated at £280m across England in 2010 by the DoT and in some cases up to £276.5m for a single event. One such event was the 2009 extreme flood event which resulted in the partial or total collapse of 29 bridges in Cumbria [3], [4]. The probability of repeated events in the future is extremely high given that 40% of UK bridges are considered historic assets (that is,. beyond their design life) and the majority of our bridges possess similar attributes, in terms of age, construction type and condition, as those identified in the Cumbria failures. Pregnolato highlighted the true vulnerability of UK bridges is unknown due to the lack of high-quality bridge data, which is ultimately jeopardising bridge safety [5]. This risk is now increasing as climate models suggest up to 24% increase in heavy precipitation intensity by 2100. The absence of a national bridge database that is interoperable with climate models, environmental and population data results in a lack of understanding of fragilities within transport networks. This is particularly problematic at locations where an individual bridge provides the only means of utilities, passengers and freight crossing an obstacle and failure leads to catastrophic consequences, such as the Malahide viaduct collapse in 2009. Bridge collapses, such as the tragic incident of the Morandi Bridge in Genova, Italy in 2018 that claimed 43 lives [2], have brought attention to critical problems in bridge safety. Subsequent studies have revealed concerns about the structural integrity of flyover bridges throughout Europe. For instance, a French study found that out of 12,000 state-maintained bridges in the country, one-third were in need of repair, and 840 were at risk of collapse [3].

DOI: 10.1201/9781003483755-393

With substantial maintenance backlogs worldwide and limited budgets, it is crucial to prioritise bridge repairs based on a risk consequence scoring. Existing bridge management systems have significant limitations. They often operate in isolation from other asset management tools and lack interoperability with geographical, societal, and climate-related data sets.

Bridge criticality operates on the basis of assessment and prioritisation of bridge maintenance taking into account their significance within the road network. This evaluation considers factors such as access to critical services and risks and designate resources to increase resilience and prevent bridge failure. Current criticality is mostly limited to a technical perspective which disregards users and their opinions and requirements [6], [7], [8].

Degraded network performance from bridge failure can have significant social and economic impacts. Investments in transport infrastructure can have positive cascading effects across communities enabling efficient movement of people or goods, supporting access to education and essential resources. This paper highlights the need to connect bridge condition data with national and regional road network information using network vulnerability analysis. While the main driver of vulnerability analysis has been the need to consider the performance and impacts of degraded networks in terms of the probability that a network will deliver a required standard of performance, the wider social and economic consequences of network failure or degradation is of great importance to modern society.

This research is focused on the national and regional road networks in Ireland and the selection of suitable region to develop a vulnerability score for utilization as a bridge investment metric. Bridge failure or closures caused by extreme weather or condition deterioration can disproportionally impact rural communities.

2 REVIEW OF THE CURRENT LITERATURE

Many countries across the world introduced methods to provide a ranked list of bridges requiring the most urgent attention. Each of the methods, both within the research field and in practice, all take in-to account different factors that they believe have the highest impact on the need for maintenance. Various studies such as Echaveguren et al [9], Dromey et al [10] and Contreras Nieto et al [11] have developed priority indexes based on the factors that have been determined to have an impact on maintenance needs. The first of these focuses on short-term maintenance planning by considering factors that have an influence of maintenance needs. In this case, the priority index considered bridge condition index, hydraulic vulnerability, seismic risk and strategic importance. This index was then used to calculate bridge maintenance cost therefore a limitation of the proposed method is that it relies heavily on a unit price database for maintenance activities which is not readily available. Similarly, Contreras-Nieto et al [11] presented a prioritisation framework by using bridge ratings and average daily traffic. The weights were determined based on importance of bridge ratings when investigating four key criteria (safety, resilience, serviceability and comfort) by using the Analytic Hierarchy Process (AHP). A case study which compared water crossing and non-water crossing bridges was used to show the method was robust and reliable. In a slightly different approach, Dromey et al [12] focuses on a prioritisation calculation which separates the bridges into two categories, critical-condition and non-critical. Each of these two calculations consider different factors which the authors used to reflect the different motivations used when determining maintenance projects in practice. This study concluded with outlining that critical condition bridges most influential factor was the overall structure condition, on the other hand non-critical condition bridges ranked hydraulic vulnerability as most important. These studies clearly indicate that the importance of including multiple potential influential characteristics in a prioritisation calculation. While these approaches look at what bridges to maintain, it is important to consider how decisions made about what structures to maintain or replace on the future condition of the entire network and the impact this will have on the communities who use the bridge to access critical services.

Network vulnerability analysis has emerged as a significant area for transportation planning research in the last decade [13].It deals with the socio-economic impacts and transport systems performance of failed or degraded transport networks, which is of great importance

to local communities and society in general [14]. Both the concepts of vulnerability and resilience have been widely investigated in recent years, with increasing applications in transport economics, urban and regional studies, and, more generally, in the social sciences [15]. While there is still no consensus on the definitions of vulnerability and resilience, the literature has attempted to conceptually differentiate between the two terms referring to vulnerability analysis as the propagation of shocks in a network, while resilience analysis is more aligned with the idea of the speed at which a network returns to its equilibrium after a shock [16].

In this paper, a case study is identified to determine if network vulnerability analysis can to enable local authorities to identify and evaluate changes of access levels across a disrupted network, thereby providing insight on the impacts to a broader range of socio-economic aspects and to the society. Previous studies have highlighted the challenge to assess the vulnerability of transport infrastructure to bridge failure at different locations, to better understand the wider impacts on the communities in and around the disruption [17]. One way to do this is through an accessibility-based vulnerability approach (see Shi et al [18]for a review of recent studies) to evaluate changes of access levels across a disrupted network, thereby providing insight on the impacts to a broader range of socio-economic aspects for society.

This research proposes to use an adapted version of the Hansen's gravity-based accessibility model where the indirect effects of bridge failure are accounted for by incorporating information on the following: travel times and traffic flows between spatial units and essential services, as well as data on population, education and employment opportunities in and around potentially affected areas. The relevant data sources and details of the case study area are presented in this paper. The gravity-based accessibility model that is proposed uses the shortest travel time between zones as the impedance function, which is an inverse relationship, as one of the most disruptive consequences of bridge failure is longer travel times as result of traffic diversions. Similar to Papilloud and Keiler [19], this paper proposes to weight the Hansen index by the number of employment and education opportunities that can accessed when transversing the bridge, including essential services such as health facilities.

3 CASE STUDY IDENTIFCATON

3.1 *The Irish road network*

The road network in Ireland is has the 5th highest density across Europe, with 20.9 kms per 1000 inhabitants it is significantly above the EU average of 9.6km. One of the contributing factors is Ireland's low level of population density on rural areas, as a result many sections of the regional and rural road networks are subject to low traffic loading but provide the only means of access for communities. Private car is the dominate choice of travel in Ireland which places significant importance on the road network [20]. The network is made up of close to 100k kms of road with over 90k intersections between road and river networks. Motorways typically connect major cities and facilitate fast travel. The motorway network has expanded substantially over the past 30 years in Ireland, expanding from 12.5km in 1986 to 916.4km in 2016. National roads connect important cities and towns and support long distance travel and the movement of goods. The National Road network in Ireland accounts for over 5,400 kms of the overall road network in Ireland. Regional roads link smaller towns and villages to the National Road network, while Local roads connect local routes within towns, villages, and rural areas. Local roads also facilitate local transportation and accessibility to services. The Regional and Local Road networks in Ireland account for over 93,500 kms of the overall road network in Ireland [21].

The network facilitates the movement of people and goods across the nation and serves as a connector for cities, towns and regions. Some road connectors within a network play a vital role in allowing access to airports and ports which are key industries for trade and mobility. These connectors are travelled on daily by a large number of users and are a crucial part of a successful road network. However, there are other connector or link roads in the network that may be the only means of access to rural areas and therefore execute a 'lifeline' function for users. 'Lifeline'

links typically have limited alternative travel options and, in their absence, the negative impact on users would be considerable, as there would be a need for long diversions (Martinez-Pastor, Dunny and Gillard, 2019).

3.2 *Bridge management in Ireland*

EIRSPAN is the BMS used in Ireland. It was established in 2001 after many years with little to no investment in Ireland's transportation infrastructure. EIRSPAN applies to bridges with a span of greater than or equal to two meters and retaining walls with retained height of greater than one and a half meters [22]. The BMS was heavily influenced by aspects from systems used around the world with significant input from the Danish DANBRO system. Prior to EIRSPAN there was no definitive inventory and no standard methods for bridge management. Out of the estimated 20,000 bridges in Ireland, roughly 16,000 are masonry arches with a portion of these bridges being over 200 years old. EIRSPAN captures data for all bridges within the strategic road network and bridges captured within the system are well maintained.

All other bridges within the road network in Ireland are managed by respective local authorities in each county. Within this research a review of the current process across multiple authorities identified a range of methods used for bridge management. The bridge stock ranges from 2k to 4k and is generally managed by small teams of engineers, using excel, access databases and increasingly the Bridge Asset Management System. In 2015, the bridge asset management project (BAMP) was introduced in Ireland by the Department of Transport, Tourism and Sport. This provided a bridge asset management android application to be used by local authorities for brides and other structure assets within the local and regional road network. This application allows for the collection of relevant information through a Bridge Inventory Survey (BIS), an initial inspection referred to as a Maintenance Inspection (MI) and a detailed inspection by means of an Engineering Inspection (EI). The BIS contains data associated with the structure covering location, type, material, size etc. Basic condition data is input into the MI by ranking six elements (three structural and three non-structural) which then grants a bridge a red, amber or green (RAG system) rating. The EI is used for more detailed inspections where fourteen elements (eight structural and six non-structural) are ranked 1-5 (Dept. of Transport Tourism and Sport, 2019). The investment decision making is based on bridge condition, budget, human resourse. Community impact is considered in the process however there is a need for a formal data driven approach to identifying community impact. This research aims to address this challenge. County Galway is located on the west coast of Ireland and has the second highest proportion of road network managed by a local authority. It also contains a high volume of lifeline roads in the Connemara area as high-lighted in Figure 1. This are has been selected as pilot region to develop a community impact metric for bridge criticality ranking.

Figure 1. Lifeline roads.

4 DATA COLLECTION FOR THE CASE STUDY AREA

Geographic Information Systems (GIS) is a powerful tool used for management and analysis of spatial data and is utilized in the existing BMAP. This enables each bridge location to be examined by its proximity to certain infrastructure, Figure 2 (a) presents a map of all bridges in the Connemara region. Figure 2 (b) presented a map of local amenities including primary schools, post-primary schools, healthcare centres, libraries, piers and harbours, etc. to identify the proximity to communities. This can lead to a basic analysis on criticality as failure of a bridge located in a built-up area would have greater impact to travel than a bridge on a local road.

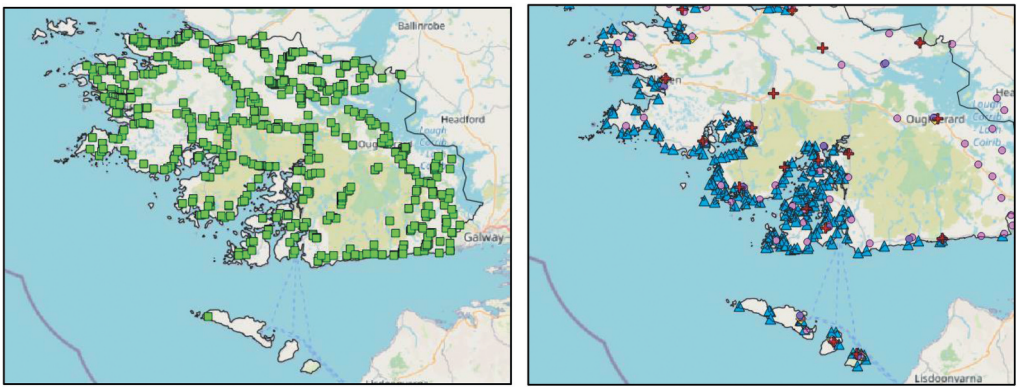

Figure 2. (a) All bridges in Connemara highlighted in green. (b) Local amenities in Connemara.

Within this regions areas of high vulnerability are causeway connections. As highlighted in Figure 3, this area is fully reliant on one bridge for access to all critical services such as healthcare and the community amenities such as shops and business are serviced by the bridge. This area has been selected as a pilot region, it is acknowledged that community vulnerability is easily identifiable. The research aims to accurately quantify this risk to enable future mitigation planning. Bridge failure in this would lead to loss of access for the entire community. Resulting in significant impact in emergencies as access to emergency services would be extremely limited. Additional bridges selected for this study are within inland routes in Connemara whereby loss of service would require lengthy delays. Recent examples of bridge failure in this area include the Leenane bridge failure which resulted in diversions of up to 80kms [23].

Other factors which were consider in the selection of the case study bridges was proximity predicted flood zones, Figure 4 presents the bridges map overlayed with flood prediction zones. This informed the selection of a masonry arch bridge in the village of Clifden, Co. Galway. From the mapping carried out to date, it is evident that GIS is a useful tool for bridge criticality analysis. As the project progresses, GIS will be used to complete bridge and river vulnerability analysis. Further analysis will be carried out on the existing data and travel times and diversions will be assessed. Population data will also be examined to pinpoint the areas with larger communities and identify their access routes. It is hoped that all these factors will lead this approach to criticality and shape the criticality metrics best suited to rural transport networks.

5 CONCLUSIONS AND FUTURE WORK

This outlined the proposed methodology for the development of an accessibility based vulnerability index for rural communities. A case study area has been selected and presented along with initial analysis of bridge condition data. GIS has been proposed as a suitable platform to develop the research and an adapted version of the Hansen's gravity-based accessibility model will be implemented. Where the indirect effects of bridge failure are accounted for by incorporating information on the following: travel times and traffic flows between spatial units and

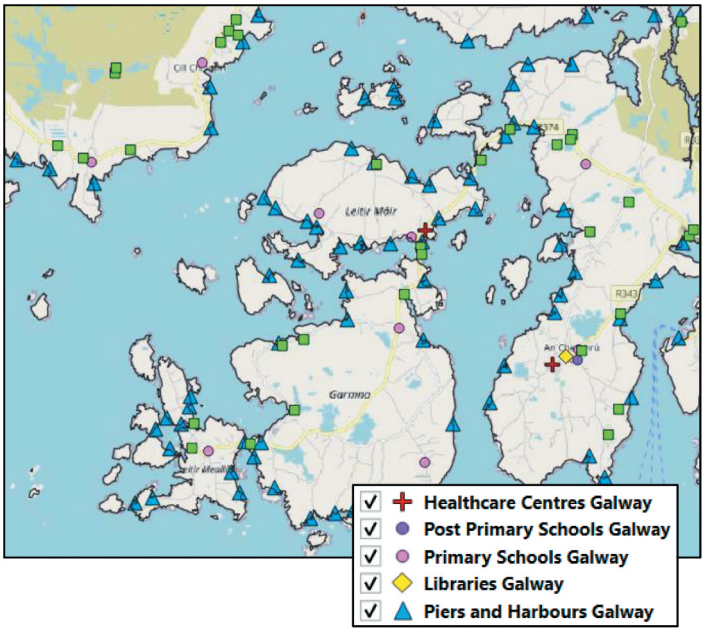

Figure 3. Bridge and amenities in the Lettermore Area.

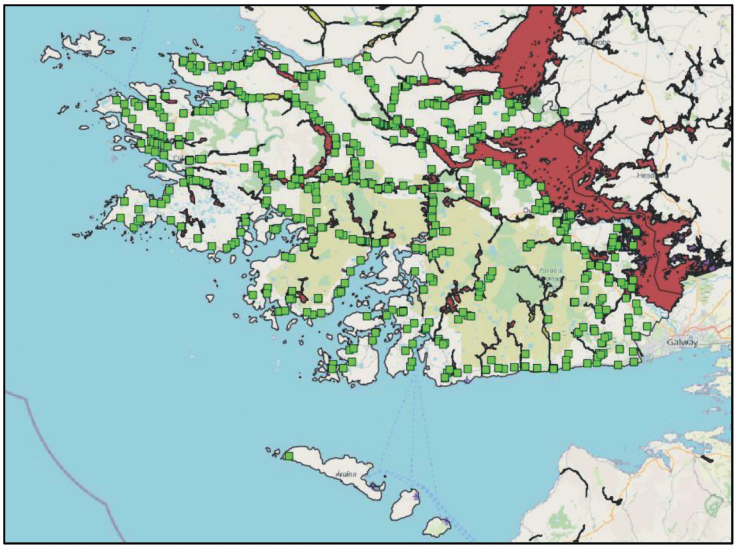

Figure 4. Current, mid-range and high-end flood extents in Connemara.

essential services, as well as data on population, education and employment opportunities in and around potentially affected areas. This will enable the development of investment metrics for decision support in bridge maintenance on the rural road network in Ireland.

A plan for assessing the damage to highway bridges after an earthquake

J.S. O'Connor
Consultant, Florida, USA

S. Alampalli
Stantec, New York, USA

ABSTRACT: A post-earthquake response plan and bridge inspection guidelines were developed under a research project funded by the New York State Department of Transportation. The Earthquake Response Plan consists of four levels of response, delineated by ranges of earthquake magnitude. A phased approach was used, first mobilizing maintenance workers familiar with the road network to provide a quick initial assessment. This was followed by detailed bridge inspections performed by certified bridge inspectors and, if necessary, by engineers with specialized skills. Key advantage of the proposed response plan is that it was developed to mesh well with the sponsoring agency's existing staffing and organizational structure. The project report contains a process flowchart, clear lines of responsibility, prioritization methods, reporting forms, list of necessary resources, sample photos of possible earthquake damages, strategies for post-earthquake repairs, and staff training exercises. This paper briefly describes the earthquake response plan.

1 INTRODUCTION

Bridges are often considered the most critical link in a highway network. While safety is the primary objective of any post-earthquake bridge inspection program, the need for continued mobility is also important because the highway network is needed to provide emergency services, ensure security, provide access for relief and reconstruction, and to facilitate the revitalization of the economy after a devastating event.

The absolute size or strength of an earthquake is referred to as its magnitude. Generally, a higher magnitude means greater shaking, shaking for a longer time, and over a larger area. It is a measure of the energy released by the earthquake but is not a measure of damage. Bridge damage depends on the magnitude but also upon other factors such as distance to the epicenter, the type of soil through which the seismic waves pass, as well as features of the bridge itself. While various strategies exist to estimate damage resulting from an earthquake, individual visual inspections of structures are usually needed. Figure 1 shows the earthquake damage that caused rocks to fall from the mountain that was looming over this truss bridge in Peru, causing impact damage to the bottom chord, a primary structural member. In addition to the obvious deformation, cracked welds were discovered. This figure illustrates damage that would be difficult to anticipate or detect without a visual inspection.

DOI: 10.1201/9781003483755-394

Preparedness is the first step toward the mitigation of losses. The Earthquake Response Plan (ERP) proposed by the authors provides a framework so that, in the event of an earthquake, managers will be ready to respond quickly and confidently when they deploy damage assessment teams. Resources can be deployed efficiently, attending to the most critical structures first. Clearly documented instructions and guidance can be provided to staff, so they are prepared to conduct damage assessments of bridges and recommend appropriate action. In particular, it will help ensure the safety of staff and the traveling public, establish when a callout is needed, how a response is to be conducted, establish clear lines of responsibility, describe appropriate phases and levels of response, what first responders and bridge inspectors should look for, how to report their findings, what training and resources are needed, how to determine appropriate follow-up action (such as closure, restriction of traffic, issuance of structural critical findings, and recommendations for repairs or retrofits), and where to get additional information.

The post-earthquake response plan and bridge inspection guidelines were developed under a research project funded by the New York State Department of Transportation (O'Connor and Alampalli, 2012). It was adopted by the agency later (EI 20-021, 2020). This paper presents the proposed ERP that consists of four response levels, delineated by ranges of earthquake magnitude. The tiered approach is intended to direct an appropriate level of resource toward the response. If the earthquake has a magnitude (M_w) less than a threshold value of 3.5, a response is not mandatory; the area engineer who is responsible will use his/her prerogative to inspect bridges on a case-by-case basis. For stronger earthquakes, damage assessments are required within a certain radius of the epicenter. For the highest response level, the Department's Incident Command System (ICS) is activated to manage the response and all structures within a specified radius are inspected.

2 BRIDGE PERFORMANCE DURING EARTHQUAKES

AASHTO's bridge design specification is accepted in the U.S. as the consensus standard for the design of new bridges. However, it was not until the mid-1970's that the design specifications began to include detailed provisions for seismic design. Since the average "year built" for highway bridges in the U.S. is 1969 (Shemaka, 2009), roughly half of the country's existing

bridges were built without the benefit of modern earthquake engineering principles. Thus, how well they would withstand an earthquake is uncertain.

The performance of a bridge under earthquake excitation depends on characteristics of the event itself (hazard factors), the structure's location (site factors), and factors related to its design and condition (response factors). The hazard is defined by its magnitude, a measure of the energy released, its epicenter, and the direction and type of ground waves. Site conditions, particularly the type of rock or soil supporting the structure, play an important role is a structure's response. Response factors include the structure type, material, and condition. Additional response factors include the details of the connections, and reinforcement, as well as the foundation fixity.

Since many in-service bridges were designed without the benefit of modern seismic design standards, some do not have the features needed to resist the seismically induced forces and displacements and may be vulnerable to damage. In addition, the physical condition may have changed since the date a bridge was built. For instance, there may be section loss due to rust, or weakness from fatigue or impacts that can reduce a structure's capacity to carry seismic loads. Structural modifications made over the years for different reasons may improve performance or may have the unintended consequence of negatively affecting seismic performance. When a region is rarely subjected to earthquakes, it also means that the robustness of the system is unproven under this scenario. Engineers must rely on condition inspections, vulnerability assessments, probabilistic scenarios, and detailed analyses of particular bridges to make an educated guess about the fragility of the highway system. More details on behavior of specific type of bridges under earthquakes can be found in the report (O'Connor and Alampalli 2012).

3 RESPONSE PLAN OVERVIEW

Transportation managers in the U.S. use USGS's Earthquake Notification System (ENS) to receive information about earthquakes via email and text messaging. Information is available at https://sslearthquake.usgs.gov/ens/

The Earthquake Response Plan described here is activated upon receipt of an ENS alert. Detailed information about an event, such as magnitude and location, is usually available within 30 minutes, but if a strong earthquake is felt, the DOT should respond immediately. The particular response will be dependent on the reported magnitude and the coordinates of the epicenter. An initial damage assessment phase, carried out by residency maintenance staff under the direction of the responsible regional engineer, will be accomplished by driving priority routes immediately and continuing until all state routes have been checked. The objective is to determine the extent of damage and to close unsafe bridges. This phase is referred to as the Preliminary Bridge Damage Assessment (PBDA). If the epicenter is in one residency and its impact is felt in an adjacent residency, both RE's will be expected to respond as if their entire residency is in the affected area.

After the PBDA, the Regional Structures Engineer (RSE) will oversee a second phase of deployment that consists of professional engineers (PE) performing detailed bridge inspections. These Special Post-Earthquake Bridge Inspection (SPEBI) teams will normally be deployed within 8 hours of the event and continue in subsequent weeks until a comprehensive picture of the damage is obtained. Special access equipment, maintenance, and protection of traffic (MPT) support may be needed for these teams. The RSE and the bridge inspectors will prioritize the SPEBI's using findings of the PBDA's, the criticality of bridges in the area, their vulnerability to seismic damage due to structural features, site conditions, and other factors. Geographic Information Systems (GIS) maps, seismic vulnerability ratings, and predefined inspection priority lists, will facilitate the efficient management of these inspections. Additional inspection teams will be brought in from consulting firms, other DOT regions, and the state Office of Structures, as necessary.

The bridge inspector will decide what follow-up action is required. Action might consist of flagging (reporting) a deficient condition, closing (or reopening) a bridge, restricting traffic, writing a repair request, suggesting more substantial remedial work, or requesting further investigation. Four response levels and the associated radius of concern (R) are listed in Table 1.

Response Level I can also be referred to as a Discretionary Response Level with Level IV as a High-Level Response. The listed radius gives an indication of the area around the epicenter that should be investigated. However, if initial reports show that damage is more

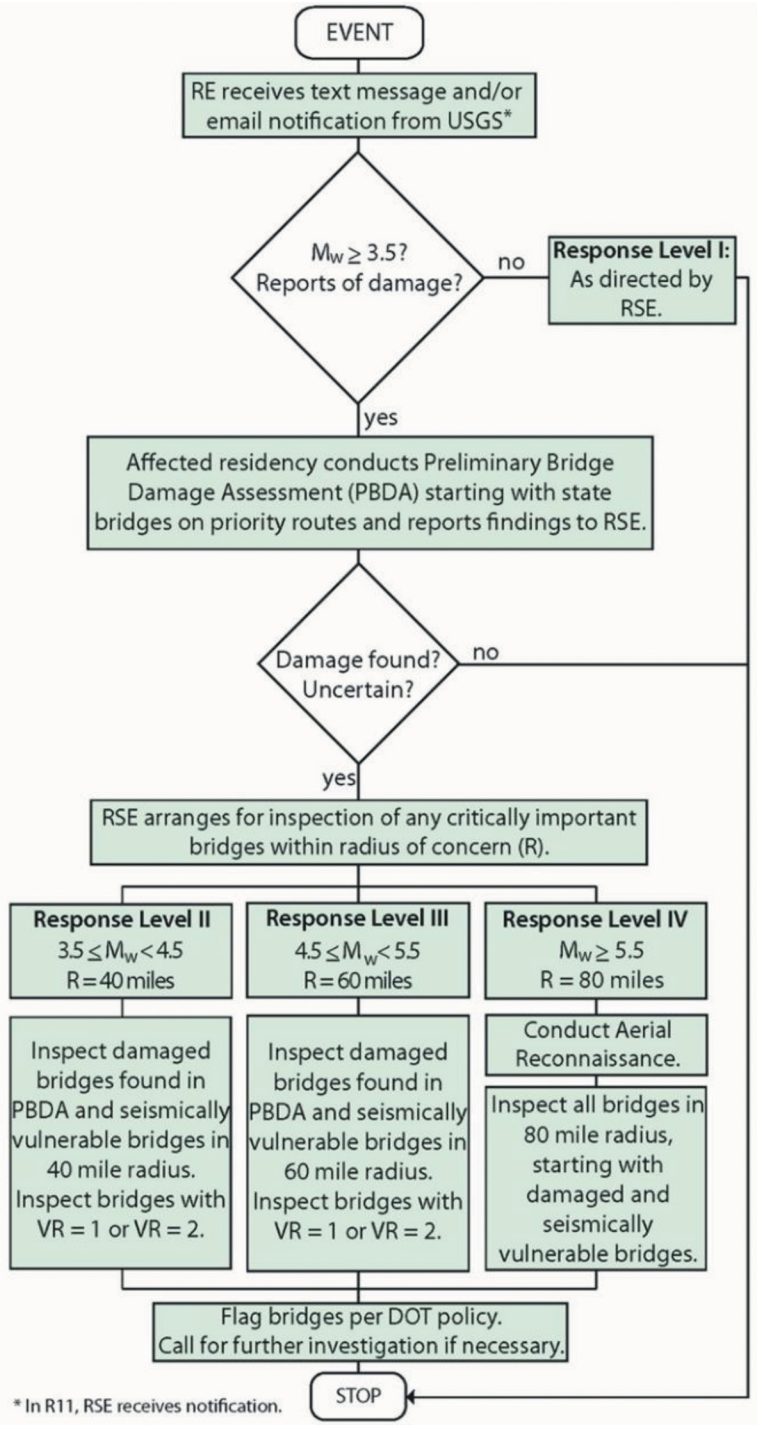

Figure 2. Process flow chart for the ERP.

Table 1. Post-Earthquake response levels.

Response Level	Earthquake Magnitude*	Radius of Concern	Description of Response
I	$M_w < 3.5$	-	A broad-based response is not planned or required. If there are reports of damage, RE is to notify the RSE. On a case-by-case basis, the RSE will determine if a **Special Post-Earthquake Bridge Inspection (SPEBI)** needs to be done. RSE uses discretion to inspect especially vulnerable or critical bridges close to the epicenter.
II	$3.5 \leq M_w < 4.5$	40 mi	RE will immediately initiate **Preliminary Bridge Damage Assessments (PBDA)**. All state routes within the residency will be driven according to priority and all bridges investigated. Reports of damage or questionable conditions will be called in immediately. Summary reports are to be sent to the RSE at the end of each day. If no damage is discovered during PBDA, the post-earthquake response can be terminated. As soon as possible, RSE will arrange for a **SPEBI** using a RSE-generated prioritized list of seismically vulnerable Bridges. SPEBI will be done on bridges within the radius of concern: • deemed *critically important* by the RSE • where damage was reported in the PBDA • where evaluation by a more trained or experienced person is needed • with a seismic vulnerability rating (VR) of 1or 2. • considered vulnerable or especially important
III	$4.5 \leq M_w < 5.5$	60 mi	If there are reports of bridge damage outside of the default radius of concern, the RSE will increase the radius and adjust the inspection program accordingly. Use the same criteria as Response Level II, but with a larger radius.
IV	$M_w \geq 5.5$	80 mi	NYS's Incident Command System (ICS) will be activated for this High-Level Response to ensure coordination of effort among DOT Regions, Main Office and other agencies. RE will conduct **PBDA** on routes immediately and RSE will arrange for **SPEBI** of all bridges that are within the radius of concern as soon as possible.

widespread than anticipated, the RSE has the discretion to expand the radius of concern or elevate the investigation to a higher response level. Figure 2 is a process flowchart of the entire ERP. Table 2 shows a comparison of the different types of bridge damage assessments, with the most immediate type of assessment on the left, and the more time/labor intensive ones on the right. Obviously, the greater the earthquake, the more resources will be needed to obtain a good understanding of the problem in a reasonable timeframe.

4 PRELIMINARY BRIDGE DAMAGE ASSESSMENTS

The RE in the affected area is responsible for initiating the PBDA program in the event of an earthquake, managing and supporting staff in its execution, working closely with the RSE to implement closures or take other action, and communicating with other DOT managers. Specific steps related to the RE's execution of the PBDA program are:

1. Provide earthquake awareness training to residency staff, at least annually.
2. Ensure that resources needed for earthquake response are ready for deployment at any time.
3. Personally subscribe to ENS and assign this responsibility to next in command.

Table 2. Types of Post-Earthquake bridge damage assessment.

Type	Aerial Reconnaissance (Response Level IV)	Preliminary Bridge Damage Assessment (PBD-A)	Special Post-Earthquake Bridge Inspection (SPEBI)	Further Investigation
Objective	'Global' perspective	Route reconnaissance	Detailed Post-Earthquake Bridge Inspection	Special study to address a particular concern
Scope	All bridges in affected area	All bridges in affected area, starting with priority routes.	Site-specific. Table 2 shows bridges to inspect for a given magnitude.	Site-specific, as needed
Inspection Method	Helicopter or small fixed wing aircraft	Drive-through with quick stop at each bridge	Bridge inspection vans, MPT & special access equipment if needed	Any special equipment that is needed
Personnel	1 or 2 DOT managers	Residency staff	Bridge Inspection Teams with supplemental TL's, if needed	Specialists e.g. Structural, Geotechnical, Metallurgical
Timeframe	Immediate (within 24 hours)	Immediate (within hours)	Start a.s.a.p. (usually within 8 hours) and continue as necessary	Subsequent to a SPEBI
Outcome	• Determine the extent of damage • Identify impassible routes & traffic bottlenecks • Locate bridges that have major damage or are obviously unsafe • Suggest priority for ground assessments	• Determine the extent of damage • Identify impassible routes & traffic bottlenecks • Close collapsed or dangerous bridges • Recommend SPEBI bridge inspection for damaged or suspect bridges.	• Flag if necessary • Close collapsed or dangerous bridges • Recommendations for restriction, repair, or further investigation. • Reopen bridges deemed safe that were closed as a precautionary measure during PBDA survey	• Flag as necessary • Detailed analysis • Provide specific recommendations on necessary restrictions and/or repair • Approximate cost estimate for remedial work
Deliverable	Reconnaissance report with photos and/or video	PBDA Form (one line per bridge)	• SPEBI Report • Daily Summary Report (DSR)	Special engineering report

4. Maintain a map and/or list of priority routes in the residency.
5. Maintain a map and/or list of all bridges in the residency, with an identification of bridges considered most critical.
6. Immediately commence PBDA on all routes in the residency whenever:
   a. The epicenter of the earthquake is within the radius of concern of any part of the residency. (The radius of concern varies according to the earthquake magnitude.)
   b. There are reports of earthquake damage to bridges, buildings, or slopes, within the residency.
7. Deploy two-person PBDA teams.

8. RE responds to questions from field teams and provides any necessary support.
9. Collect and review daily reports from field teams. Summarize findings and send a daily report to RSE with digital photos of any damage. Provide the data electronically (i.e. in a spreadsheet), if possible.
10. Verbally report any significant bridge damage to the RSE immediately.
11. Immediately close and barricade any bridges that appear to be unsafe.
12. If there is any uncertainty about a bridge's condition, request that the RSE conduct a bridge inspection (SPEBI).
13. After SPEBI's are completed, close or reopen bridges as requested by the RSE.
14. Arrange for immediate repair of damage that does not require any analysis (e.g., damaged approach). Document all activity with photographs and inform RSE.

5 SPECIAL POST-EARTHQUAKE BRIDGE DAMAGE ASSESSMENTS

The RSE in the affected area is responsible for accomplishing detailed inspections in an expeditious manner, with an effort that is commensurate with the severity of the event. The RSE will also direct follow-up action, such as conducting detailed investigation, structural or geotechnical analysis, designing repair or retrofit schemes, or initiating long-term replacement or rehabilitation. Program steps include:

1. Annually provide earthquake awareness training to bridge inspectors and other staff who might be called into service after an earthquake.
2. Ensure that resources needed for an earthquake response are ready for deployment at any time.
3. Personally subscribe to ENS.
4. Communicate with regional GIS and emergency response staff and share data that is required to maintain a current:
   a. Map and list of priority routes in the region that can be used as lifeline routes.
   b. Map and list of all bridges in the region, with an identification of bridges considered most critical, those that are flagged, and if possible, those considered seismically vulnerable.
   c. Lists with emergency contact numbers for bridge inspectors and office staff who may need to be involved in post-earthquake response.
5. Notify local County Highway Superintendents, authorities, and other bridge owners whenever any significant earthquake occurs and advise of appropriate action.
6. Refer to ERP, determine which response level and radius of concern is appropriate and communicate to others. Organize bridge inspection teams and commence SPEBI's, preferably within 8 hours.
7. Generate a prioritized list of bridges to inspect and print GIS maps with these bridges located on it. Provide to bridge inspection teams.
8. Inspectors are to submit Daily Summary Reports (DSR) at the end of each day when SPEBI's were done. Collect and review daily reports from field teams. Summarize findings and send a report to RD and Director - Office of Structures, the Incident Commander and ICS as appropriate.
9. Review SPEBI reports. Determine if any bridges should be closed or restricted (weight restricted, reduced number of lanes, or open to just emergency vehicles). Give authorization to reopen bridges that were closed as a precaution during the PBDA phase if it is appropriate to do so. Track resolution of any structural flags.
10. Prepare plans for repair, retrofit or replacement as appropriate and work with Structures Asset Management Team to program remedial work.
11. Defer any communication with the media to the Regional Director's designee.

As part of the implementation of this plan, anyone who will be expected to respond to an earthquake should either attend a one-day workshop on post-earthquake damage assessments or take a computer-based training (CBT) course to familiarize them with the same material. Annually afterwards, they should take a one-hour CBT presentation to refresh their memory.

The purpose of the training is twofold: to reinforce the required post-earthquake inspection procedures, and to familiarize them with basic earthquake principles and types of bridge damage that could occur. The training courses should include photographs of possible earthquake damage. Scenario exercises are also useful for ensuring that key players fully understand their responsibilities. More details on the ERP, follow-up actions, and other information can be found in the report (O'Connor and Alampalli 2012).

6 CONCLUSIONS

The above is a brief explanation of a earthquake response plan that can be valuable even where earthquakes are not a day-to-day concern. This paper presented the details of the emergency response plan, Key advantage of the proposed response plan is that it was developed to mesh well with the sponsoring agency's existing staffing and organizational structure. The project report contains a process flowchart, clear lines of responsibility, prioritization methods, reporting forms, list of necessary resources, sample photos of possible earthquake damages, strategies for post-earthquake repairs, and staff training exercises. Further details and technical guidance are available from the authors.

Rapid response for ensuring safety following bridge hits

Maqbool A. Mohammed
Stantec, New York, USA

ABSTRACT: Collision damage is the second leading cause of bridge failures in the United States. Data from NHTSA shows a gradual increase in bridge hits over the last few years, which has helped identify the leading causes of bridge strikes. The costs to repair the bridges are also rising due to an overall spike in bridge strikes. Substantial effort has been invested in technology to curb accidents by projecting deterrent messages, sending personalized alerts, and using innovative software. More often, a bridge strike results in a complete or partial closure of the roadway carrying the bridge or under the bridge. A rapid response is paramount in these situations to avoid immediate closure. This paper focuses on bridge impact case studies and the basis of establishing rapid response procedures.

1 INTRODUCTION

Bridges are a vital component of transportation networks, serving as the vital arteries that enable the movement of goods and connect previously isolated regions. Robust bridges and roads help economies with trade, investment, and growth. However, when a bridge fails, it can have a significant impact on the economy and public.

Collision damage is the second leading cause of bridge failures in the United States after hydraulic failures (Cao, R. 2019). Data from the National Highway Traffic Safety Administration (NHTSA) shows a gradual increase in bridge hits over the last few years, with New York state collecting and mapping such data since 1993 (Rey, M. & Munson, E. 2022). This has helped identify the leading causes of bridge strikes, including low clearance and the use of non-commercial GPS systems. Appropriate reporting procedures have increased awareness of this pressing issue.

The costs to repair bridges are also rising due to an overall spike in bridge strikes, with owners having to front the repair costs leading to high-priced insurance claims. Substantial effort has been invested in technology to curb accidents by projecting deterrent messages, sending personalized alerts, and using innovative software.

Most studies on bridge strikes have focused on causes and post-incident remediation methods. More often, a bridge strike results in a complete or partial closure of the roadway carrying the bridge or under the bridge. A rapid response is paramount in these situations to avoid immediate closure. There are very few established procedures for a rapid response that discuss communication and notification protocols, available resources including personnel and repair materials, repair procedures, and challenges. This paper focuses on bridge impact case studies and the basis of establishing rapid response procedures. A robust response procedure will ensure public safety, communicate in a timely manner, restore essential services, and protect the environment and property. The role of bridge owners and other stakeholders to improve response will also be discussed.

DOI: 10.1201/9781003483755-395

2 BRIDGE IMPACTS

Collisions with bridges can be caused by a variety of factors. Common causes of bridge strikes include low clearance, inadequate signage, driver negligence or behavior, use of non-commercial GPS systems, and changes in traffic flow or lack of alternative routes. It is important to take steps to prevent bridge strikes and minimize their impact when they do occur.

The National Highway Traffic Safety Administration (NHTSA) provides data on motor vehicle crashes in United States. According to NHTSA, collision between a motor vehicle and a fixed object were the second most common type of crash, accounting for over 29% of deaths in 2021 with 2% of deaths attributed to collision with a bridge.

Table 1. Recorded number of collisions with a fixed object (bridge) in the United States.

Year	2017	2018	2019	2020	2021
Bridge Collisions	15,000	13,000	11,000	14,630	13,092

Source: NHTSA Traffic Safety Facts Annual Report Tables. 2023-2017.

New York state has been collecting and mapping the data for vehicle collisions with bridges since 1993. Figure 1 below shows number of vehicle collisions with New York bridges each year from 2011 to 2021.

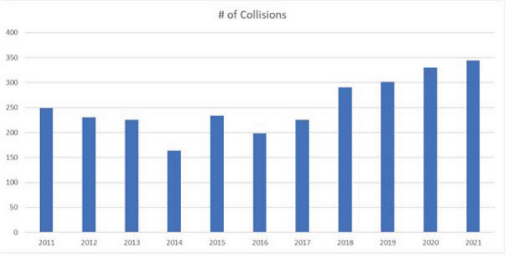

Figure 1. Number of vehicle collisions with New York bridges each year (Rey, M. & Munson, E. 2022).

Bridge strikes can have significant impacts on the economy and public. Disruption of traffic flow impedes emergency response, daily commuting, and freight movement. The resulting consequences of bridge impacts include serious injuries and even fatalities, chemical spills, traffic jams, taxpayer money spent on repairs, and increased insurance costs. These impacts can be costly and time-consuming to address and can have long-lasting effects on the community. It is important to take steps to prevent bridge strikes and minimize their impact when they do occur.

Depending on the severity of the impact, bridge damage may include scratches, scrapes, spalls, delamination, cracking, distortion, loose connections, partial failure, or complete failure. In addition to the bridge strikes causing significant damage to the bridge structure, leading to costly repairs and potential safety hazards, they can also result in socio-economic impacts.

3 RAPID RESPONSE PLAN

Bridge owners typically follow a set of routine actions when made aware of a bridge hit, such as closing roads, inspecting the bridge, and erecting temporary shoring. The general timeline for a bridge impact response is as follows:

1. A phone call is directed to the city maintenance/owner.
2. City maintenance/owners dispatch engineers (on staff engineer or consultant) immediately.

3. Depending on the location, an inspector reaches the site (usually within 1-2 hours).
4. The inspector performs initial visual inspections.
5. Depending on the severity and location of the impact, access equipment and traffic control are arranged (within a few hours).
6. Based on the severity of the damage, the inspector may recommend temporary supports to prevent local failure.
7. For any potential failures, the bridge may be recommended for partial or complete closure.
8. Temporary support is designed, assembled, and erected (usually within 24 hours to allow traffic).
9. Permanent repairs are usually completed within a few days (depending on the severity of the damage).

Bridge owners have created their own unique policies and procedures for responding to situations. The written procedures can range from a single page outlining the necessary actions to much more detailed procedures, including stand-alone documents. According to the 2020 FHWA Case Study of State Practices on Responses to Bridge Impacts (FHWA. 2020), the Iowa DOT is the only agency with a standalone document for responding to over-height collisions with bridges, titled the Emergency Response Manual for Over Height Collisions to Bridges. MnDOT's Bridge and Structures Incident Response Plan outlines the response, defines responsibilities, and includes a flow chart, as depicted in Figure 2.

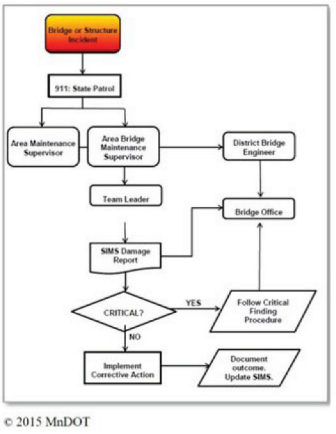

Figure 2. MnDOT response flowchart (MnDOT. 2019).

Notification and communication protocols are critical in an emergency to ensure public safety, protect property, facilitate response efforts, and instill public confidence. The emergency response plan should specify which personnel will communicate with each other and how communication will occur during an emergency. This includes bridge owners, responsible parties for response, and inspectors and engineers addressing the issue. The communication protocols should also address information media to motorists affected by the bridge impact. In addition to the requirements for bridge owners, there are certain internal protocols needed for inspectors responding to the site and the engineers addressing the repairs. In summary, notification and communication protocols in an emergency are crucial for effective emergency management. They help ensure public safety, protect property, and facilitate response efforts.

Field personnel responding to bridge impacts should be equipped with the necessary knowledge and tools to ensure a swift and effective response. They should be aware of the bridge records and the tools and equipment required to address the issue at hand. In addition, they should have access to vehicles and phones to reach the site quickly and communicate with other personnel. It is important to note that certain locations or

equipment may require special permits or training, which should be obtained beforehand to avoid any delays in the response time. Furthermore, it is essential to consider the availability of staff on nights and weekends, as this can impact the response time. If staff availability is limited, it may be necessary to have a contingency plan in place to ensure that the response is not delayed.

In addition to field personnel, engineers in the office should also be available to work on repairs on an emergency basis. They should have access to all bridge records to come up with an effective repair plan. Access to design or analysis software is also necessary to ensure that the repair plan is feasible and effective. Communication with ground staff can help in creating an effective repair solution. By collaborating with the field personnel, the engineers can gain a better understanding of the situation on the ground and develop a repair plan that is tailored to the specific needs of the situation. It is also prudent to involve the contractor in the repair process to ensure that the design solution can be implemented within the short duration. By working closely with the contractor, the engineers can ensure that the repair plan is feasible, and that the contractor has the necessary resources to implement the plan effectively. In summary, engineers in the office play a critical role in the emergency response process. They should have access to all bridge records and design or analysis software to develop an effective repair plan. Communication with ground staff and collaboration with the contractor can help ensure that the repair plan is feasible and effective.

4 REPAIR PROCEDURES AND CHALLENGES

Common repair procedures for bridges include grinding damaged areas on steel members at gouges and scrapes, drilling out cracks in metal, repairing or replacing diaphragms, heat strengthening, repairing or replacing steel members using steel plates or angles, patching concrete areas, repairing steel bars or cables, and installing external carrier beams or post-tensioning cables/bars.

Case Study: A crack was discovered in the steel fascia beam after an impact on a Friday afternoon on a bridge over a connector highway with heavy traffic, including a connection to a major airport (actual location is not mentioned to maintain anonymity). The owner was promptly notified, and traffic was immediately shifted to other lanes away from the fascia beam. In the office, a load rating was performed to determine the safe load carrying capacity, and it was determined that the fascia beam needed to be temporarily supported using a shoring. However, material availability for shoring was a challenge on a weekend as the designated contractor for the emergency repairs did not have the right size shoring members. Working with contractors, structural designers were able to come up with alternate details that could safely support the beam. The placement of shoring over the major 3-lane highway, including an on-ramp, presented another challenge. Traffic engineers were onboarded to come up with a detour and lane shift within the constricted space to erect the shoring. Within a matter of a few hours and in the midst of heavy rush hour traffic, the beam was shored (see Figure 3). Another structural team in the office started working on the permanent repairs. Over the weekend, final repairs were designed, approved, and the contractor was able to source the material. A simple solution to drill a hole at the crack end and strengthen the beam with angles and plates was adopted, considering the time and location of the impact. The contractor was able to complete repairs in a day. Unfortunately, the same bridge was impacted again in less than a year. The severity of the impact (see Figure 4) presented another challenge to come up with an alternate repair, as the beam could not be repaired in traditional ways. Code compliance may also be a challenge, especially when working on older bridges. Finally, the design team adopted a solution to support the fascia beam using a carrier beam on top of the sidewalk. The owner, designer, and contractor worked together to come up with a solution in a short time frame, using the available materials and without affecting public safety. Ultimately, the bridge was replaced with a new structure that has higher clearance as part of a major project.

Figure 3. Temporary shoring.

Figure 4. Impacted fascia beam.

5 CONCLUSIONS

The aim of any Rapid Response Plan for Bridge Collisions is to ensure public safety, preserve life, and minimize injury. In the event of a bridge collision, it is crucial to communicate with the public in a timely manner to provide information about the incident and any necessary detours or closures. The restoration of essential services is also a key priority, as it helps to minimize the impact of the incident on the community. Finally, it is important to protect the environment and property by taking appropriate measures to prevent further damage.

To achieve these goals, a Rapid Response Plan should include clear procedures for notifying emergency services, assessing the damage, and coordinating the response effort. The plan should also outline the roles and responsibilities of different personnel involved in the response effort, including bridge owners, engineers, contractors, and emergency services. In addition, the plan should include procedures for communicating with the public, including the use of social media, news releases, and other communication channels. The plan should also address the restoration of essential services, and the protection of the environment and property.

By having a well-designed Rapid Response Plan in place, bridge owners and authorities can ensure that they are prepared to respond quickly and effectively to any bridge collision, minimizing the impact on the community and ensuring public safety.

Critical role of the bridges ensuring emergency services and disaster recovery in Turkey

N. Memişoğlu Apaydin & R.B. Sikar
Istanbul University-Cerrahpaşa, Istanbul, Turkey

ABSTRACT: After a major earthquake or flood, the importance of functional bridges cannot be overstated. Bridges' significance becomes unmistakable during times of crisis, particularly in the aftermath of natural disasters such as earthquakes and floods. In the destroy of a functional bridge, search and rescue efforts can be interrupted and the affected people number may increase and face isolation and delayed assistance. In recent years, Turkey has witnessed several devastating earthquakes and floods that have severely impacted its infrastructure, including bridges.

This article explores the critical role bridges play in ensuring emergency services and disaster recovery in Turkey, shedding light on the rapid measures taken to address damaged bridges in the wake of recent earthquakes and floods.

1 INTRODUCTION

Bridges are of great importance in major disasters such as earthquakes and floods. Inspecting bridges after a disaster is a critical step for emergency rescue operations as well as long-term recovery processes (Wang et al., 2023). These inspections provide important information regarding the safety, durability, and usability of bridges. Engineers determine the damage caused by the impact of the disaster and estimate how long it takes to repair bridges, helping the community return to normal life.

Pre-disaster precautions also play an important role. Bridge engineers make design to increase the resistant of bridges against earthquakes, floods, and other natural disasters. Strengthening bridges using latest engineering codes and technologies aims to minimize the effects of disasters.

However, damage to bridges may occur due to reasons such as lack of maintenance, poor design, or natural disasters being more severe than expected. In this case, rapid inspection, and rapid repair of bridges after the disaster is of great importance. This process is critical not only for ensuring transportation mobility but also for accessing emergency teams to disaster area and work effectively.

Immediately after the disaster, it is important to repair bridges to increase the resilience of the road network and accelerate the return of society to normal life. In the study published in 2020, the importance of repairing bridges to maximize the durability of the road network was emphasized (Merschman et al., 2020). Following a disaster, factors such as infrastructure damage, changes in traffic patterns, and emergency traffic control can combine to cause traffic congestion to worsen. In this process, it is of great importance to make bridges available for the delivery of emergency supplies and the organization of logistics operations (Chang et al., 2000). This ensures effective emergency response and minimizes the effects of the disaster.

Many methods have been developed as post-earthquake inspection methods. One of the oldest methods for restoring bridges after earthquakes was published in 1990. The proposed inspection method effectively evaluates the seismic sensitivity of existing highway bridges

DOI: 10.1201/9781003483755-396

without the need for complex calculations, based on the sensitivity to extreme deformation and infrastructure failure (KAWASHIMA & UNJOH, 1990). By 2009 The California Department of Transportation (Caltrans) had created and implemented a customized version of ShakeCast, a post-earthquake analysis tool designed to quickly assess potential structural damage (Loren et al., 2000). In addition, the methodology proposed by Norimitsu Koike, and Issam E. Harik can effectively evaluate bridge safety and functionality after a major seismic event, shorten inspection time, and reduce overall damage (Koike & Harik, 2012).

Many methods have been developed as inspection methods in cases of flood, as well as after earthquakes. The 2011 Missouri River flood caused significant damage to many structural systems in western Iowa. It affected bridge foundations, asphalt and unpaved roads, culverts, and embankment slopes. This flooding led to the closure of multiple intersections and 10 miles of road closures in western Iowa. The report published in 2013 is an example of field assessments and measurements made after the flood (Flooding, W. I. M. R. 2023). In the report prepared by the Illinois Transportation Center in 2022, it was stated that post-flood control methods and many cases were revealed (Tom et al., 2022). Recently, with the advancement of communication technologies, the communication of objects with each other has begun to be used in post-event inspection as well as in every field. One of the most current methods for post-event investigation is the IoT-based bridge collapse and flood detection system. It improves bridge condition assessment, maintenance planning, and emergency planning by automatically detecting cracks and alerting authorities (Aher et al., 2023).

In this study, the post-event inspection and evaluation studies are explained after the flood and the earthquake in Turkiye.

2 DESTRUCTIVE EARTHQUAKES AND FLOODS IN TURKIYE

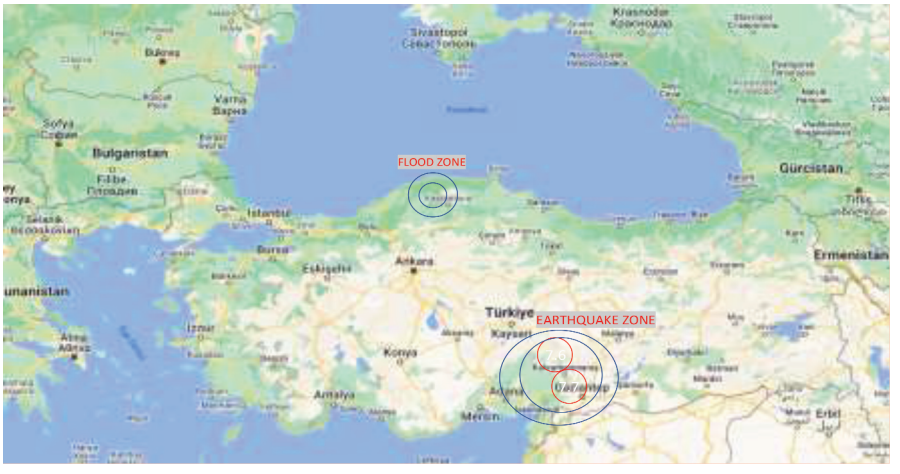

Figure 1. Disaster Zones in Turkiye.

Turkiye has a geography that is frequently exposed to natural disasters due to location. The disasters experienced in the last two years have once again demonstrated the country's efforts to cope with difficult situation. In particular, the Western Black Sea Flood Disaster on August 6, 2021, and the Kahramanmaraş-centered earthquakes on February 6, 2023, have shown how Turkiye struggled with serious disasters.

Along with these, similar disasters that have occurred in other parts of country last two years have also tested the resilience. The Elazığ-Malatya Earthquake on January 24, 2020, the Izmir Earthquake on October 30, 2020, the Ağrı Earthquake on February 23, 2020, and the

Eastern Black Sea Flood Disasters in July-August 2020 reflect Turkiye's determined struggle against natural disasters.

These disasters not only caused loss of life and property but also seriously affected the country's infrastructure. However, government and related instutuions responded fast initiated search, and rescue efforts, and took action to quick repair the damaged infrastructure. This process has once again demonstrated how important a coordinated effort is at both local and national levels.

These experiences enable stronger preparations and the development of disaster management strategies. In addition, the lesson learned from these disasters that rapid reactions and quick repair provide post-disaster emergency requirement and decraese the loses.

3 BEHAVIORS OF THE ROAD TRANSPORTATION NETWORK DURING 6 FEBRUARY 2023 EARTHQUAKE

The Eastern Anatolian Fault System is one of the most active fault systems in Turkiye and determines the boundary between the Anatolian and Arabian Plates. It has been the source of several significant earthquakes throughout history. Remarkable events occurred in two consecutive earthquakes with which the system interacted. In the first earthquake, approximately 290 km of surface ruptures on the fault line caused significant cracks and displacements in the region. The severity of these cracks showed itself with horizontal fault displacements of up to 6.5 m.

In the second earthquake, it was observed that an area of approximately 130 km along the fault line was affected. This event once again caused serious horizontal fault displacements in the region and had significant impacts on the surrounding areas. According to AFAD's 2023 report, these events highlight the complexity of earthquake activity in the region and the potential danger of the Eastern Anatolian Fault System (AFAD 2023).

Fault ruptures, ground shaking, liquefaction, and co-seismic landslides have caused various levels of damage to transportation networks. Especially with the effect of fault ruptures, serious deformations have occurred in many roads and bridges, and faults have even cut some roads and bridges and affected transportation lines. Due to the damage to the transportation infrastructures, search and rescue works delayed a few days in the region.

Highways and railways were damaged due to the ruptures in the fault line, and cracks and deformations occurred on the road surfaces. In addition, the durability of some bridges has decreased, and this has created concern for the safety of transportation. Airports and seaports also felt the effects of this natural disaster, with cracks in the runways and deformations in the take-off and landing lines.

Damages to transportation infrastructures especially to roads between provinces in the region caused difficulties in the coordination of emergency services. Quick repair teams made an intense effort to repair the damaged roads and to open the vehicle traffic. At the same time, the need for a coordinated logistics effort has emerged to ensure the safe delivery of vehicles carrying emergency aid and supplies to damaged areas.

According to KGM (General Directorate of Highways) data, a large area in the earthquake zone covers a surface area of approximately 109,000 square kilometers and there is a total of 9,176 kilometers of asphalt roads in this area (KGM 2023). A significant part of the total highway network throughout Turkiye is spread over this earthquake zone, with a share of 15 percent. This includes 12 percent of the state highway network and 14 percent of the provincial road network. These roads constitute an important part of the transportation infrastructure in the provinces affected by the earthquake.

In addition, according to SBB's (Presidency of the Republic of Turkiye, Strategy and Budget Directorate) 2023 report, 15 percent of the total vehicle-kilometer, 15 percent of the passenger-kilometer, and 20 percent of the ton-kilometer occur in this earthquake zone (SBB 2023). These statistics show that these regions account for a significant share of not only road traffic but also transportation volume.

3.1 *Case study: Restoring the bridges on the 6 February 2023 earthquake*

It has been observed that the level of damage to the transportation infrastructure plays a critical role, especially in the timing of vital search and rescue operations carried out in the first 72 hours of the earthquake and other disaster response services after this period.

Vital rescue operations during earthquakes often aim to save people trapped in collapsed buildings, and these operations usually occur intensively within the first 72 hours. However, damage to transportation infrastructure at the early step may make it difficult for rescue teams to reach the area quickly. Damage to roads, bridges, or tunnels may prevent access to critical locations, reducing the effectiveness of rescue operations.

At the time period following the earthquake, similar difficulties may arise for other disaster services. In the days and weeks following the initial response phase, it is of great importance to quickly restore transportation infrastructure for operations such as health services, aid distribution, and shelter provision. Measures such as repairing damaged roads, strengthening bridges, and reopening railway lines can speed up the post-disaster recovery process and contribute to more effective delivery of relief services.

There are a total of 243 bridges in the road network in the region. Nearly twenty of these bridges encountered different levels of damage on the roads under the responsibility of the General Directorate of Highways (KGM) (SBB 2023). Most road bridges and tunnels in the earthquake zone are located close to fault lines; in some bridges, fault lines pass between the columns of these structures. This situation has increased the potential for earthquake effects to directly affect these structures.

Interestingly, the bridges did not collapse even though they were subjected to acceleration values of 1.5-2 times their design acceleration. Instead, they were usually limited to moderate to minor damage and remained functional. This draws attention to the durability and safe design of bridges from an engineering perspective. The bridges were able to cope with the high accelerations they were subjected to during the earthquake and remained without collapsing.

Bridges often suffered non-structural damage such as expansion joints, shear keys, and deformation of bridge bearings. These damages were observed in the bridge piers and superstructure and mostly occurred in non-structural details such as expansion joints and earthquake wedges, which are special design elements. These elements generally showed a certain level of resilience despite the high energy generated during the earthquake.

Structural damage to the piers and bridge superstructure was largely repairable. Evaluations showed that these types of damage did not compromise the basic structural integrity of the bridge and did not make it unsafe for vehicles to use the bridge. This shows that the bridges are built with significant durability and design purpose.

Structural damage to some bridges, although not critical, required detailed inspection of the bridges. Experts at the General Directorate of Highways (KGM) examined these bridges in more detail and identified cases where the damage did not adversely affect traffic flow or traffic safety. Depending on the location of the damage, traffic continued to flow using at least one lane on the bridges, and temporary traffic arrangements were made. This process shows that bridges can be repaired quickly and remain functional.

Due to earthquakes, only two bridges collapsed due to the secondary effects of ground motion. One of these bridges was the Hitit-Demirköprü on the Antakya-Reyhanlı-Cilvegözü (D420) state road. Hitit-Demirköprü consisted of two twin bridges side by side, 61.8 meters long. However, due to soil liquefaction, which was the secondary effect of the earthquake, one of the bridges lost its load-bearing feature because of the rotation of its side piers and became completely unusable.

General Directorate of Highways (KGM) teams carried out temporary repairs on the collapsed bridge to maintain traffic flow and provide mobility. The collapsed side abutment of the less damaged one among the twin bridges was filled, and by using an asphalt mixture, the superstructure was brought to the traffic crossing level and access was provided over a single bridge. By means of rapid and effective repairments, the main artery was kept open to traffic in the first 24 hours after the earthquake (Figure 2).

Figure 2. Demirköprü: side abutment was repaired by filling the upper part.

The other collapsed bridge was the 52.50-meter-long Bulam II Bridge on the Adıyaman-Yeşilyurt-Malatya State Road. The rock mass that broke away during the earthquake fell from the slope and broke the precast beam of the bridge. This incident negatively affected transportation as there was no alternative route for vehicles to be directed in the region. However, the General Directorate of Highways (KGM) teams quickly stepped in and produced temporary solutions to keep traffic open.

Within the scope of the temporary repair works carried out by KGM teams, the 3-span simple girder beam on the damaged bridge was removed and replaced with stone filling. In this way, it was aimed to maintain the function of the bridge and ensure traffic passage. These temporary productions represented a rapid and effective intervention to ensure the continuity of traffic. Figure 3 shows the details of the temporary production made with stone filling.

Figure 3. Repair of Bulam II bridge with stone filling.

A common type of damage to bridges was damage to non-structural element such as expansion joints that prevented traffic from passing. Although such damage was expected, it had to be repaired quickly due to its impact on traffic. After the earthquake, rapid scanning was carried out on all bridges, the damaged parts of small-sized expansion joints were cleaned, and the remaining gaps were filled with asphalt to ensure safe traffic passage. In expansion joints with larger capacity, the road was kept open to traffic with temporary rapid repairs. The work on the TAG (Tarsus-Adana-Gaziantep) highway is one of the best examples of this rapid response.

The TAG highway played an important role as one of the most important transportation routes in the earthquake region. After the earthquake, all search and rescue teams and emergency services transportation usedthis highway. Bridges and viaducts located on the fault line showed perfect performance despite near fault effect. Along with repairable damage to some bridge components, damage to expansion joints on long-span viaducts was initially severe enough to prevent traffic flow.

As seen in Figure 4, the General Directorate of Highways (KGM) responded very quickly, repairing the damage to the expansion joints of the viaducts on this route within 24 to 36 hours using temporary repair methods and reopening the highway to traffic. This is a successful example of effective deployment of emergency response capabilities and planning. While this rapid response ensured uninterrupted transportation, it also laid the foundation for planning and implementing long-term improvement works.

Figure 4. Expansion joint repair on TAG Highway.

4 EFFECTS OF THE 11 AUGUST 2021 FLOOD ON THE TRANSPORTATION NETWORK

The disaster, described as the most devastating flood in the history of Turkiye, affected 3 provinces in the Western Black Sea Region and a total of 12,000 km^2 (Kelesoglu et al., 2023). Extraordinary rains in Kastamonu, Bartın, and Sinop provinces caused various damages to the transportation infrastructure and led to a major disaster. These damages increased the loss of both life and property and made post-disaster first aid and search and rescue efforts difficult.

The flood that occurred in the Western Black Sea Region affected an area of 240 km, especially in coastal areas, and caused various levels of damage (Kelesoglu et al., 2023).This situation remarkably complicated the provision of transportation and emergency aid in the disaster area. The map in Figure 5 shows the highway network of provinces such as Kastamonu, Sinop, and Bartın, which were affected and damaged by the flood.

To provide rapid transportation and first aid in the disaster area, intense efforts were made to open the roads to traffic and keep the main arteries open by establishing portable bridges. This formed an important part of the emergency response and allowed rapid aid to be delivered to survivors.

4.1 *Case study: Bridge damages on 11 August 2021 flood in the Western Black Sea region*

Many bridges were damaged in different lengths and widths due to the impact of streams flowing through different neighborhoods and even different blocks. Although most of these

Figure 5. The road network of the flood-affected area.

bridges are located on main arteries, they were built between 1955 and 1975.Some bridges were constructed according to the H15-S12 load class between 1955 and 1965. Bridges built in the 1965-1975 period were designed for 100-year floods, considering the H20-S16 load class (AASHTO 2002) (Kelesoglu et al., 2023).

They have different lengths which are 26 meters, 39 meters, 52 meters, and 65 meters. Among the general characteristics of reinforced concrete slab bridges, they have shallow foundations. These bridges were built quickly to connect city road.s

In response to the escalating flood disasters attributed to global warming and other factors, legislative changes have been implemented, particularly in regions prone to flooding. Hydraulic criteria in bridge design over main arteries had been considered a 100-year flood by the General Directorate of Highways. However, due to increased flood events in recent years, the criteria were revised five years ago to incorporate a 500-year flood depth.

The bridges affected by the August 11, 2021, flood in the Western Black Sea Region were predominantly designed approximately 40 years ago under the previous legislation. This resulted in insufficient hydraulic sections, leading to severe damage. Notably, there are 115 bridges connecting main arteries, towns, and neighborhoods in the region, totaling approximately 4600 meters. Among them, 27 bridges fall under the responsibility of the State Highways Administration, with a total length of 1100 meters. Six of these bridges suffered complete damage, and twelve experienced partial damage (KGM 2021a).

Damages occurring on bridges can be summarized in two basic categories; bridges that were destroyed and collapsed due to floods, and partially damaged bridges that can be opened to traffic in a short time with quickrepairs.

Transportation was provided with panel bridges instead of collapsed bridges. Due to the limited number of panel bridges, panel bridges were established considering the importance of the road. In places where the stream widths were suitable, diversion work was carried out, the direction of the water was changed, and the water was derived until the new bridge was manufactured.

When we look at the bridges that were damaged due to floods but can be opened to traffic with urgent repairs; The repair of the 42 m long Valay bridge on the Cide-Kastamonu road can be cited as an example of the repairs made on this type of bridges.

In this region, damage occurred to the approach embankments of dozens of bridges due to floods. The approach embankments damaged by the flood were quickly repaired and the bridges were opened to traffic. Figure 7 shows the damage and repair of the approach embankment on the Valay 1 bridge.

A quick intervention was made to the partially damaged bridges and traffic was reopened. Most of the damage in these cases resulted from erosion of the approach embankment, often

Figure 6. Kumluca Bridge and the panel bridge installed in its place.

Figure 7. Valay Bridge-flood damage and appearance after repair.

caused by flood debris. Large trees and logs carried by the flood posed a significant threat, causing lateral impact on bridge piers and blocking waterways, causing additional horizontal pressure.

Damages resulting from flooding demonstrate the need for ongoing adjustments to infrastructure standards and the importance of considering dynamic environmental factors in the resulting design and maintenance. Case studies reveal the vulnerabilities of old bridge structures in the face of evolving climate challenges.

5 CONCLUSIONS

The recent earthquake and flood disasters in Turkiye, especially the major earthquake on February 6, 2023, and the Western Black Sea flood disaster on August 11, 2021, caused significant damage to transportation infrastructure.

It was observed that the level of damage to the transportation infrastructure had an impact on vital search and rescue services, especially in the first 72 hours of the earthquake, and disaster services in later steps. Due to the successive earthquakes, 15 percent of the existing highway network in provinces was affected. Damage generally prevented traffic on bridges because of non-structural elements such as expansion joint. The rapid repair of damages in expansion joints provided to the rapid normalization at transportation.

The Western Black Sea flood disaster on August 11, 2021, which took place in Turkiye, also caused various damages to the transportation infrastructure. This disaster caused many bridges to be damaged in different lengths and widths due to streams flowing through the neighborhoods.

Both disasters caused structural and non-structural damage to bridges. However, with a rapid and effective intervention, the damage to the transportation infrastructure was repaired in a short time. The rapid repair response to transportation infrastructure after the disasters played a key role in effectively directing emergency aid and services. All these processes, combined with the contribution of the local people and the personnel affected by the disaster, enabled a historic mission to be accomplished in a short time.

ABSTRACT: Using real-time crack width calculation with Canny edge detection, errors may occur in the crack itself due to factors such as the direction, continuity, and shape of the crack. On the other hand, according to the tests, human factors such as the observer's distance from the crack, the observing angle, and the observer's movement speed also influence the measured crack width. Therefore, this paper will conduct further experiments on human factors through collecting crack width data using Augmented Reality (AR) headsets. If these human factors can be systematically addressed, more accurate data can be obtained, making it easier for observers to use the system and reducing the impact of terrain constraints. Focusing on the error caused by distance and angle, there is a positive correlation between the error and both factors. Additionally, when further investigating the distance, there is an exponential relationship between the pixel unit of the crack and the distance. Various factors contribute to errors in outdoor crack measurements, such as lighting conditions, observation angles, and distance limitations. To initially exclude these factors, this paper focuses on indoor experiments, with the expectation that the findings could be applied to future outdoor observations.

Keywords: Augmented Reality, Pixel Unit Conversion, Edge Extraction, Concrete Crack Width, Canny Algorithm

1 INTRODUCTION

Recently, researchers have proposed various conceptual frameworks that can integrate image-based defect detection techniques with inspections. Researchers and industry experts are exploring the possibility of providing human inspectors with a tool for real-time image processing and decision assistance in their work environment. Previous research has suggested using AR headsets equipped with image-based flaw detection methods as the interface for image processing and visual inspection [1]. AR headsets can run applications that detect and characterize cracks, allowing inspectors to conduct hands-free visual inspections and simultaneously gather valuable data through computer-environment interaction [2]. Past studies explored the use of AR technology for object-recognition [3]–[9]. AR headsets are also used for real-time crack quantifications [10], [11].

The AR crack characterization tool functions as a decision-assisting tool during real-world human inspections of concrete structures. It presents crack dimensions to inspectors and facilitates crack evaluation based on the criteria outlined in relevant specifications. To perform real-time measurements of crack width on an AR head-mounted device, there are the

DOI: 10.1201/9781003483755-397

following steps: (1) the transformation of pixel information to AR platform; (2) edge extraction utilizing the Canny algorithm; (3) crack measurement at the pixel level adopting the horizontal approach; (4) CCD and camera angle measurement using AR orientation capabilities and applying this information for perspective correction; (5) Engineering scale dimensions computation using the results of (3)–(4). A scaler equation for perspective correction streamlines the algorithm toward real-time implementation [10], [11]. This approach can be applied in most situations, but there are limitations under certain conditions. The limitations mentioned in [10], such as concrete with curved surfaces, multiple crack constraints, and direct sunlight, are constraints imposed by the physical characteristics of cracks and the surrounding environment. However, after conducting more in-depth tests, it was found that human factors could also cause significant errors. The impact of these human factors begins from step (3); therefore, this paper primarily focuses on the influence of distance and examines its errors at each step.

2 METHODOLOGY

In the analysis of indoor single crack tests and outdoor multiple crack tests, several key conclusions were reached. First, the orientation of the crack significantly impacts measurement accuracy, with vertical cracks exhibiting smaller errors. Second, the algorithm used for width calculation introduces notable errors when detecting multiple cracks. Additionally, the method faces challenges in cases where crack shapes vary. Consequently, subsequent experiments focus on cracks meeting specific criteria: vertical orientation, consistent width, and singularity.

While Canny edge detection and the horizontal approach for crack measurement at the pixel level are generally applicable, certain limitations arise under specific conditions. Factors such as concrete with curved surfaces, constraints related to multiple cracks, and exposure to strong sunlight are dictated by the physical characteristics of cracks and the environment. However, after conducting more comprehensive tests, we discovered that human factors also contribute to errors. The influence of these human factors becomes evident starting from crack width measurement at pixel level. Therefore, the experiments will initially observe the relationship between crack width and distance, and angle and subsequently delve into the relationship between width and distance in pixel units.

3 INDOOR EXPERIMENT AND ANALYSIS

3.1 *Design of the experiment*

Figure 1a demonstrates how the observer conducts the experiment, what the observer sees can be projected to the computer. Figure 1b shows the interface of the AR crack detection. When a crack is identified, the application utilizes two parallel blue lines to enclose the region and highlights the detected crack with a red line segment. The four numerical values within the interface represent the average width (mm), maximum width (mm), evaluated length (%), and distance to crack (m). This study primarily focuses on investigating the relationship between distance and the predicted width. Hence, only the first and fourth values are recorded in the experiments.

3.2 *Distance effect*

Based on tests of both indoor and outdoor cracks, we have found that the distance between the observer and the crack can lead to errors in the measured crack width under the same conditions. So, we experimented on an actual crack in the wall, focusing on the vertical part of the crack. Figure 2 demonstrates the experiment of investigating the distance effect and the X,Y, Z-coordinate. According to the distances measured by HoloLens 2, the observer moved from

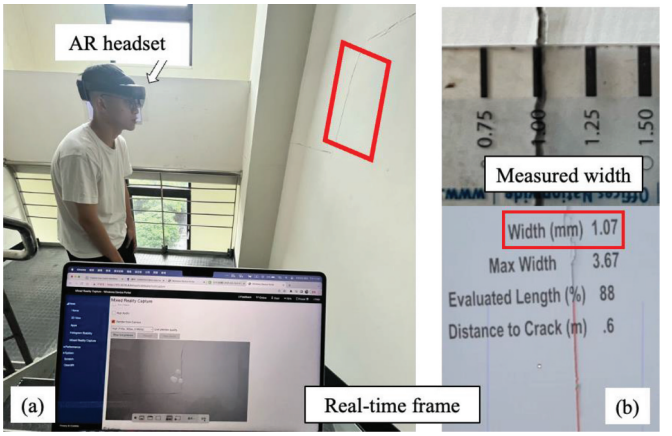

Figure 1. (a) Observer using HoloLens 2 to collect data indoors; (b) Measured width in gauge card and the app.

a distance of 80 cm to 40 cm for each one-centimeter movement, repeated points were recorded, and there was no backward movement. Figure 3 shows the detected width increases linearly with the distance increase. There is a jump at 70 cm, and the data stabilizes between 50-70 cm.

3.3 *Angle effect*

To confirm the hypothesis that the detected crack width is linear with distance, the same experiment was conducted at different angles, including 0, 30, and 45 degrees. Figure 4 demonstrates the experiment of investigating the angle effect and the X,Y,Z-coordinate. Figure 5

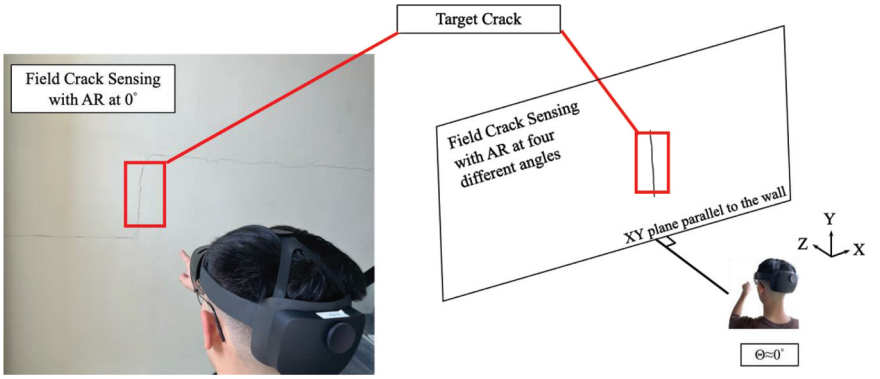

Figure 2. Experiment of investigating distance effect.

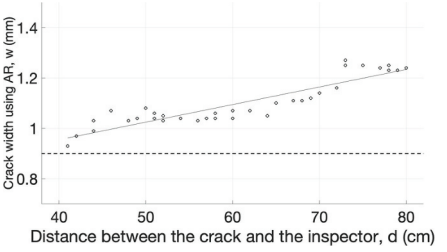

Figure 3. Collected data from the distance experiment.

indicates there is a similar linear relationship in each group, and as the angle increases, the data becomes more scattered. It can be assumed that these errors are caused by angle distortion correction and are expected to be validated in future studies. In addition, when experimenting at angles beyond 45 degrees, the application almost cannot detect the crack. Therefore, the discussion is limited to a maximum angle of 45 degrees.

3.4 *Pixel unit and distance*

If overcoming distance errors within the application could reduce unnecessary error sources in outdoor experiments, minimizing cumulative errors. Therefore, a further experiment was con-

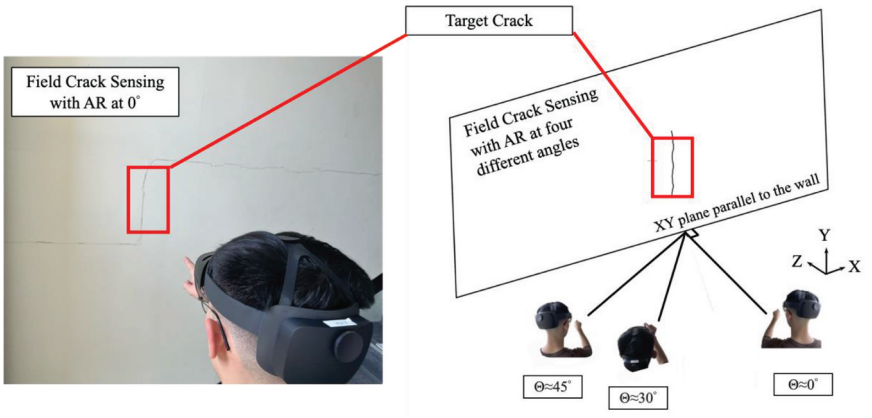

Figure 4. Experiment of investigating angle effect.

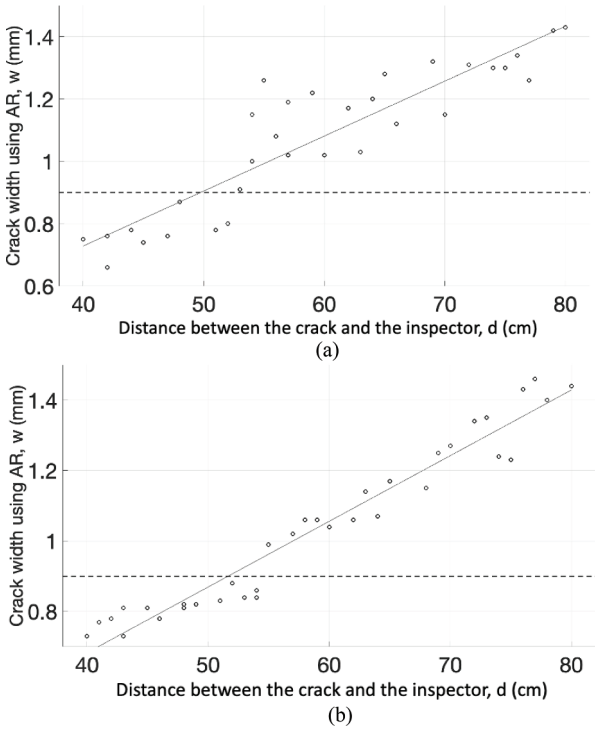

Figure 5. Collected data from the angle experiment. (a) 30 degree; (b) 45 degree.

ducted to explore the impact of distance. According to [10], to obtain the width in engineering units, first need to calculate the pixel unit, then apply perspective distortion correction, and then convert it to engineering units. So here first explore the relationship between pixel units and distance. Similar to the previous experiment, but with modifications to the program to display the values as the pixel count of the crack width. Data was obtained for cracks with widths of 1.3 mm and 2.7 mm, observed perpendicular to the wall surface.

Figure 6. shows the theoretical resolution of the PhotoCapturing mode of HoloLens2 and the theoretical number of pixels depending on distance when the crack width is 1 mm. The data of these two groups are shown in Figure 7, although the experimental values also exhibit an exponential relationship, there is still a discrepancy compared to the theoretical values. It is speculated that the error may be caused by edge detection, where the algorithm automatically cuts off the crack edges during edge extraction, causing the pixel quantity to deviate from a perfect regression relationship with distance.

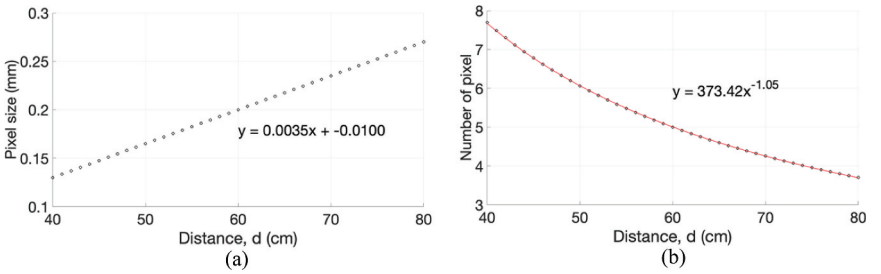

Figure 6. Theoretical performance of HoloLens 2 PhotoCapture mode (a) Resolution; (b) Number of pixels when crack width = 1 mm.

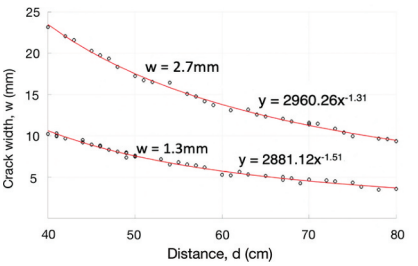

Figure 7. Collected pixel unit data from the distance experiment.

4 OUTDOOR INVESTIGATION

Figure 8 shows that in the outdoor experiment, three tests were conducted on three sections of a damaged wall specimen outside The National Center for Research on Earthquake Engineering (NCREE) building. The first section had cracks of equal width, the second section had a wider crack, and the third section had the widest and most irregularly shaped crack. From the results, it is evident that the errors are larger compared to indoor conditions. To accurately assess outdoor post-disaster cracks, addressing challenges related to multiple cracks and irregularly shaped cracks may be a primary concern.

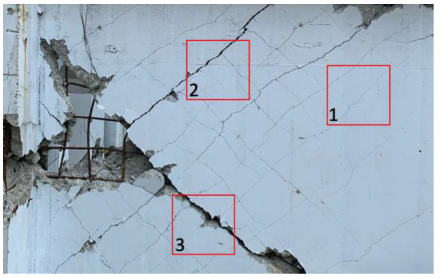

Figure 8. Outdoor experiment concrete.

5 CONCLUSIONS

The original application can be real-time crack width detection and demonstrates good accuracy in most conditions. This paper proposes some limitations, including those at the crack end and observer end, and further discussion is conducted on the observer-related factors. Based on repeated testing, it is found that distance and angle are two key factors influencing accuracy. In terms of distance, there is a positive linear relationship between the distance from the observer to the crack and the measured crack width. As the distance increases, the error also increases. Regarding angles, the application can detect angles up to a maximum of 45 degrees. As the angle increases beyond this threshold, the error also increases, and the linear relationship between distance and width still exists at each angle. To obtain the width of the crack in engineering units in the process, it requires crack measurement at the pixel level, followed by perspective distortion correction, and a conversion algorithm to get the result. Therefore, this paper focuses on the direction perpendicular to the crack, making the impact of pitch, yaw, and roll all equal to zero, eliminating the potential errors introduced by distortion correction. In the last experiment, the number of pixel units representing crack width shows an exponential relationship with distance. It is considered that this relationship is reasonable because, in previous experiments, the size(mm) of each pixel at different distances showed a linear relationship. However, the regression equation in the experiment did not perfectly match the theoretical values. So the error in this case may arise from edge detection, where the algorithm automatically cuts the crack edges, resulting in a non-perfect regression relationship between pixel quantity and distance. Outdoor cracks are often irregular and densely distributed. Overcoming the observational limitations of angle and distance, accurately evaluating post-disaster cracks outdoors may be primarily concerned with addressing challenges associated with multiple and irregularly shaped cracks. Future research should focus on optimizing the AR software using the data obtained in the experiments to automatically remove the effect of the crack edge cut-offs. Additionally, the application of AR headsets for outdoor use can be explored, where environmental factors such as lighting and weather conditions introduce additional complexities. Developing adaptive algorithms that can adjust to varying outdoor conditions will significantly improve the accuracy and reliability of crack measurements in real-world scenarios. Another key area for improvement is the integration of advanced machine learning techniques. By incorporating AI-driven edge detection and image processing, the system can better handle the diverse shapes and orientations of cracks, especially in outdoor environments. This integration could lead to more precise measurements and a reduction in the error margin caused by human and environmental factors.

Condition assessment and repair protocols for dynamically impacted bridge girders

W. Zatar
Marshall University, 1 John Marshall Dr, Huntington, USA

ABSTRACT: The most frequent causes of bridge failures in the United States are floods, collisions, overloads, and scour. Damage may occur when an over-height or oversized truck dynamically strikes a highway bridge superstructure. Over-height trucks have hit one in every five overpasses in the United States, and one-sixth of these bridges have received considerable damage and required repair. The collision could produce significant local plastic deformations of steel girders. Localized concrete spalling and tendons and steel reinforcement damage are encountered for struck prestressed concrete girders. An extensive list of highway bridges impacted by over-height, overweight, or oversized vehicles in West Virginia was developed. The authors documented the West Virginia Department of Transportation (WVDOT) process for recording damage and for deciding to repair the affected members after evaluating their remaining load-carrying capacity. Recommendations to determine the remaining capacities of damaged girders are made through either performing finite element analyses or conducting proof load testing. Repair recommendations using fiber-reinforced polymer composites are adopted for impacted prestressed concrete girders, and protocols for multiple heat-straightening repairs of damaged steel girders are implemented.

1 INTRODUCTION

Damage to highway steel or prestressed bridge girders may occur when an over-height truck dynamically impacts a bridge. The collision could result in significant plastic deformations and strains in localized areas of the steel girders. Studies in Maryland have shown that an over-height truck has struck approximately one in every five overpasses. The impacted bridges are most likely located on interstate highways. One-sixth of these bridges have received considerable damages and required repair.

Heat- -straightening to repair damaged steel members dates back to the 1930s with low-grade steel. For many years, heat-straightening of damaged steel bridge girders has been more of an art than a science. Several safety concerns have historically limited their validity as a repair technique. When applied appropriately, heat-straightening and mechanical techniques, including pressing or jacking, offer an economical and viable alternative to replacing damaged steel girders.

The Principal Investigator has completed WVDOH Research Project RP202 (Zatar and Leftwich 2009). The SPR project was entitled: "Effect of Repeated Heat-Straightening on Behavior of Impacted Highway Bridge Steel Girders." The primary objectives of RP202 were to: a) Conduct a state-of-the-art literature review on the technique, advantages, and shortcomings of heat-straightening; b) Address the fundamental principles for heat-straightening and illustrate how these principles are implemented in practice; c) Review literature on what damage is heat-straightenable; d) Summarize significant technical challenges during a heat-straightening repair; e) Investigate how to use the heating patterns to repair several damage types; f) Study how to avoid potentially damaging mistakes during a heat-straightening repair project; g) Address the number of cycles a bridge girder can be heat-straightened; and h)

DOI: 10.1201/9781003483755-398

Prepare a final report that addresses all the listed tasks. Tasks of RP202 were completed, and the Final Report was submitted in 2011. The report provides the WVDOH engineers and staff with sufficient details about current practices followed by other State DOTs. RP202 Report showed that heat-straightening provisions vary among State DOTs. These variations were exhibited through comparing the provisions/specifications of Connecticut, California, Georgia, Iowa, Kansas, Michigan, Minnesota, New York, Texas, Virginia, and Washington. Analyzing the survey data led to concluding that: (a) The heat-straightening repair technique has not gained a full acceptance by all State DOTs yet, and (b) Only a few contractors are qualified to complete a repair project successfully.

The Federal Highway Administration (FHWA) identified four fundamental heat-straightening patterns in 2023: (a) Vee heat, (b) Strip heat, (c) Line heat, and (d) Spot heat. The Vee heat effectively bends a damaged member about its strong axis. The strip heat is effective in shortening a damaged member. The line heat effectively turns a damaged member about its minor axis. The spot heat is effective in causing local bulging in a damaged member.

Typically, heat-straightening patterns used to repair damaged steel bridge girders are combinations of the four fundamental heat-straightening patterns. Selection of the heat-straightening patterns and combinations for a particular repair project shall be based on the structural damage caused by the collision and the need to keep portions of the bridge open to traffic while conducting repairs. The importance of identifying the maximum heating temperature, cooling temperature before successive heats, and maximum torch diameter while completing a heat-straightening project have been documented.

2 LIST OF STRUCTURES STRUCK BY OVER-HEIGHT VEHICLES

2.1 *List of structures struck by over-height vehicles in west virginia*

According to WVDOH, there are approximately 6,958 bridges in West Virginia. Of these bridges, 33 percent are more than 100 feet in length. Many overpass highway bridges within the state have been struck by over-height vehicles, as shown in Table 1. Some bridge members have been hit multiple times, and damaged steel girders were heat-straightened, replaced, or repaired/retrofitted. Below are details of the bridges that have been impacted more than once and heat-straightened at least once.

Table 1. List of structures struck by over-height vehicles in west virginia.

2.2 *Current WVDOH process for recording data in bridge inspection reports of struck and misaligned members*

According to WVDOH, inspection reports are categorized into different types, such as periodic, in-depth, inventory, interim-condition, and damage/special inspection reports. The damage inspection report is an essential source of information for engineers to decide whether to repair or replace damaged members. It is required by WVDOH when over-height vehicles hit a bridge. In this task, we provide detailed information on the current process for recording

data in the damage inspection report. The report comprises five significant sections: purpose, procedure, findings, drawings, and photographs.

2.3 *Current WVDOH process for evaluating load-carrying capacity of damaged members*

The current WVDOH process for determining whether or not a damaged member should be repaired, replaced, or do nothing is described in this section. This process is used to establish a bridge repair report. This report includes the following sections: 1) Purpose; 2) Descriptions of the existing conditions of the bridge; 3) Repair options; 4) Structural Analysis; 5) Verification of the repair options proposed in Section 4; 6) Recommendation: A recommendation will be provided to WVDOT about the decision made in section 5.

3 PROCEDURES, GUIDELINES, AND SPECIFICATIONS FOR APPROVAL AND IMPLEMENTATION

3.1 *Proposed method to determine moment capacity of damaged beams*

As previously mentioned, WVDOH currently uses the strength-reduction method to determine the remaining load-carrying capacity of damaged members. This method is dependent upon the effective-section-modulus-reduction graphs. These graphs were established by Avent and Mukai (1998) for two specific sizes of beams with depth-to-width (H/b) ratios of 1.24 (W 10×39 beam) and 2.66 (W 24×76 beam). W-beams commonly used for many WV highway/overpass bridges have higher H/b ratios than Avent and Mukai's beams (e.g., W 33×130 beams in Dallas Pike bridge and W 30×132 beams in US 52 bridge have H/b = 2.87; W 36×150 beams in Rockport bridge have H/b = 2.99). Therefore, it is necessary to establish practical graphs that can be applied to beams with varying H/b ratios.

The research team proposes proof load tests for W 10×39 and W 24×76 beams subjected to three-point bending (Figure 1) with a loading span of 9.84 ft. (3 m). These beams are selected because they can easily be handled in laboratory space and loaded to failure using regular actuators. If necessary, large beams can be experimentally tested using higher-capacity actuators. Finite element (FE) analysis can be used to evaluate the effect of various H/b ratios, and experimental data will validate FE results. The primary test variable includes the rotation angle (q), as shown in Figure 2. Tensile coupon tests conforming to ASTM E8 (Standard Test Methods for Tension Testing of Metallic Materials) will be used to determine the tensile properties of W-beams.

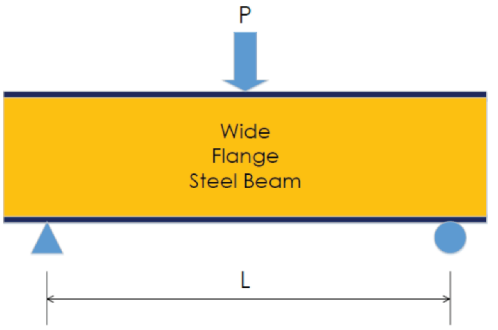

Figure 1. Proof load tests of W-beams subjected to three-point bending.

Load-carrying capacities of W-beams can be calculated based on moment/stress diagrams in Figure 3. The ratio of the ultimate moment of the deformed section to that of the undeformed can then be calculated. Figure 4 shows idealized relationships between the distorted moment and undeformed moment ratio and the rotation angle (q). This figure can be

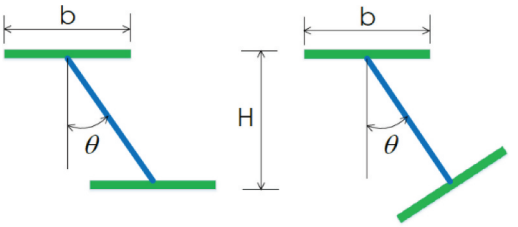

Figure 2. Idealized geometry of deformed beams.

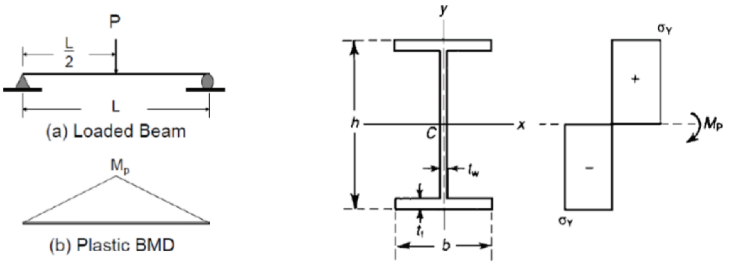

Figure 3. Analysis of W-beams and idealized reduction in moment capacity of damaged beams.

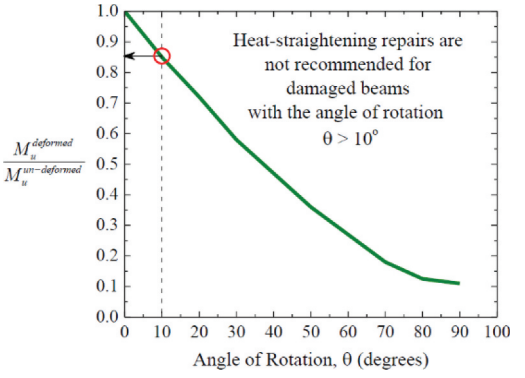

Figure 4. Idealized reduction in moment capacity of damaged beams.

used as a reference chart to determine the moment capacity of damaged beams. By consulting WVDOH experts, it is essential to note that heat-straightening repairs are not recommended for damaged beams with an angle of rotation larger than 10 degrees. For damaged beams with q>10°, further research must be conducted to decide whether heat-straightening repairs are safe and economical.

3.2 *Repair recommendations using fiber-reinforced polymer composites*

Applying high-strength carbon fiber reinforced polymer (CFRP) composite laminates proves to be an efficient and effective method for retrofitting bridge elements. This approach enhances the strength and stiffness of the components, ultimately extending the service life of the bridge. The detailed evaluation includes: 1) Determine truck type; 2) Finite element analysis; 3) Moment curvature analysis.

Moment-curvature analyses determined the number of CFRP laminates required to reinforce the beams (Figure 5). This analysis was essential in determining the appropriate amount of material needed, as FRP rupture influenced the retrofitted section's ultimate strength (Choo et al., 2007).

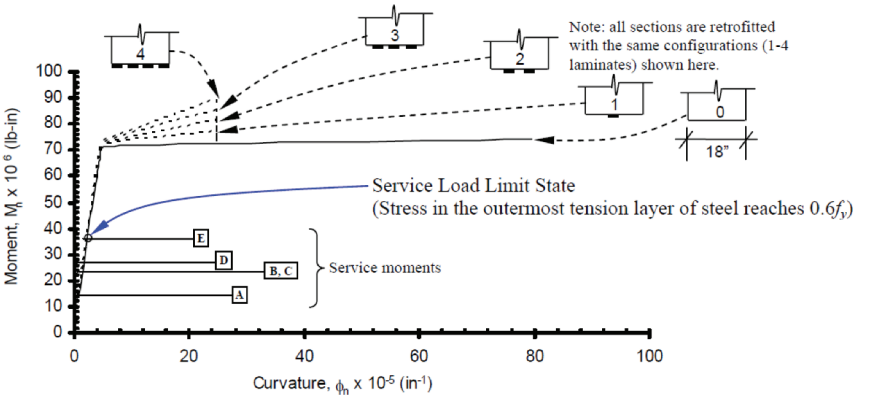

Figure 5. Comparison of service moment.

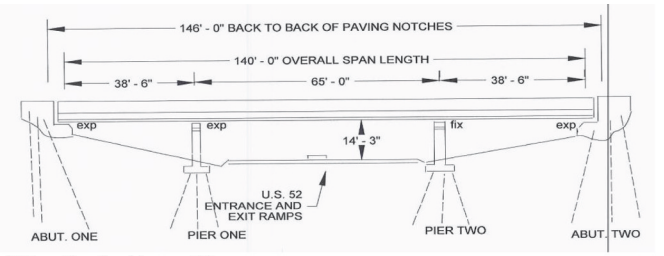
4 EXAMPLES OF DAMAGED AND REPAIRED BRIDGES

4.1 *Kenna Overpass Bridge over Interstate 77 North*

This bridge is located 5.00 miles South of County Route 21 in Jackson County, WVDOH District 3, West Virginia, as shown in Figure 6. On September 9, 2010, a truck hauling a tank struck beam #5 in span #2 and bent this member. Beam #5 was bowed 5" and turned 5" out of plumb. Civil Construction heat-straightened this beam in 2012; however, the bottom flange is still bowed out 1".

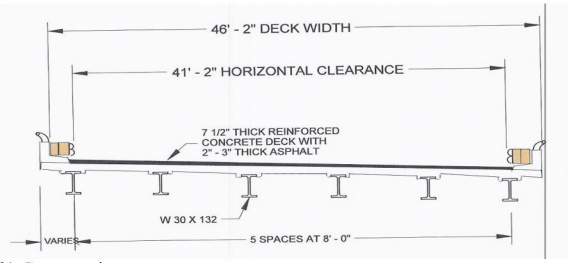
a) Elevation view (looking west)

b) Beam #5 (before heat straightening)



c) Beam #5 (after heat straightening)

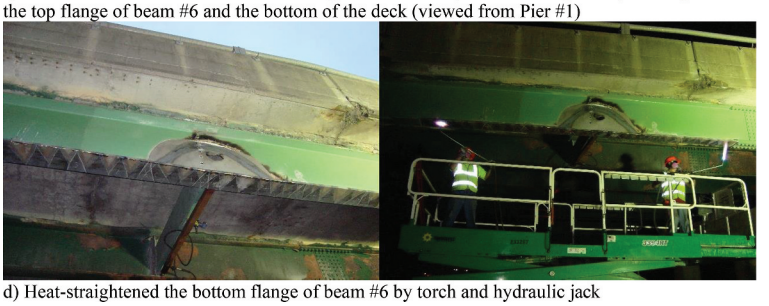
Figure 6. Details of Kenna Overpass Bridge.



Damage inspection was conducted on November 28-29, 2011, to inspect the span #2-floor system for cracks or problems that may have occurred because of an accident that occurred on November 21, 2011 (the structure was struck by an over-height load truck traveling east on WV 34 under the structure). The inspection consisted of visually observing the span #2-floor system from the ground, an extension ladder, and the top of a tool truck. The following inspection results were found: 1) Fresh yellow paint and bare shiny metal indicate that the contact point was at the west edge of the bottom flange of stringer #6; 2) The resulting impact caused a 1 1/2" outward bowing of the beam and moved the beam 1 3/8" out of plumb.

4.2 *US 52 Overpass Eastbound Bridge*

This bridge is located 1.73 miles West of West Virginia 152 (Cabell County, District 2), as shown in Figure 7. A damage inspection was conducted on June 3, 2013, to document vehicular impact damage to beams #5 & 6 at span #2. The inspection visually observed beams #5 &



a) Elevation (looking north)

b) Cross section

c) Plastic deformation in the lower flange of beam #6 (viewed from pier #1) and separation between the top flange of beam #6 and the bottom of the deck (viewed from Pier #1)

d) Heat-straightened the bottom flange of beam #6 by torch and hydraulic jack

Figure 7. Details of US 52 Overpass Eastbound Bridge.

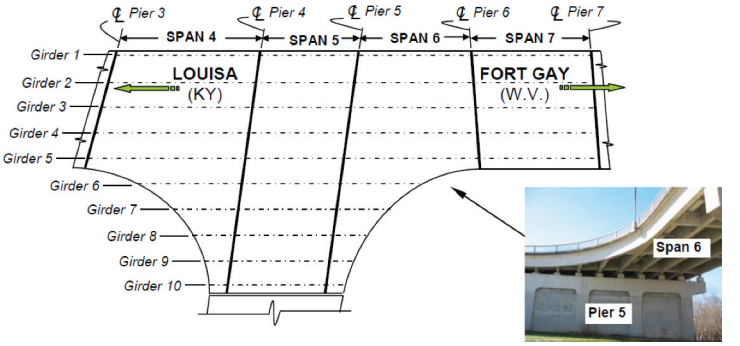


Figure 8. The continuous reinforced concrete middle spans of the Louisa-Fort Gay Bridge.

Figure 9. Reinforced concrete beams retrofitted with CFRP laminates.

6 from arm's length. Extension ladders and a bucket truck were used to access these beams. This structure tested positive for lead-based primer and had no fracture-critical members. The inspection results showed that beam #5 is in fair condition. Scraping is present on the bottom flange of beam #5 from vehicular impact damage. No other deficiencies were found on beam #5. Beam #6 is in poor condition. Beam #6 has severe impact damage. The diaphragm connection in row #1 to beam #6 has torn away from the web connection angle. The web splice plates, at splice #1 on beam #6, are cracked at the top of the plates. Plastic deformation is present throughout beam #6. There is a 2" to 3" separation between the top flange and the bottom of the deck on the interior side of beam #6.

4.3 *The Louisa-Fort Gay Bridge*

The Louisa-Fort Gay Bridge, constructed in 1979, is in Lawrence County, Kentucky. This bridge comprises a 12-span continuous structure featuring composite concrete deck-steel girder spans and reinforced concrete middle spans (Figure 8). The reinforced concrete central spans serve as an intersection, facilitating traffic flow from three directions.

Routine inspection identified cracks in the reinforced concrete girder in Spans 4, 6, and 7 of the Louisa-Fort Gay Bridge. These cracks originated at the bottom web of a standard reinforced concrete girder at the bridge. The primary cause of these cracks was attributed to elevated flexural stresses that emerged in the positive bending region of the girders.

The bridge underwent repair by applying CFRP laminates, involving the following phases: 1) Applying the mixed epoxy onto the concrete using a trowel or spatula to achieve a specified thickness.; 2) Applying the mixed epoxy onto CFRP laminates; 3) Placing CFRP laminates to the affected concrete surfaces; 4) Pressing the CFRP laminates using a hard roller

until adhesive is forced out on both sides; and 5) Removing excess adhesive. The completed retrofitting work for Span 6 is depicted in Figure 9.

5 CONCLUSIONS

An extensive list of struck highway bridges in West Virginia has been developed. Detailed conditions of each struck bridge and times of damage/heat-straightening are documented. The current WVDOH process for recording data in damage inspection reports of crashed and misaligned members is reported. The procedure for registering damage is systematically recorded, and the decision on whether to repair the affected members is determined through an assessment of their remaining load-carrying capacity. Recommendations for gauging damaged girders' remaining capacities involve conducting finite element analyses or implementing proof load testing. Additionally, protocols for implementing multiple heat-straightening repairs are applied to address damage in impacted steel girders. Repair recommendations incorporating fiber-reinforced polymer composites are adopted in the case of impacted prestressed concrete girders.

Data-derived train classification and monitoring of masonry bridge

J. Cheng, A. Chen & M.J. DeJong
University of California, Berkeley, Berkeley, USA

S. Cocking
University of Cambridge, Cambridge, UK

ABSTRACT: CFM-5 bridge in Barkston Ash, UK presents an asset monitoring and maintenance challenge. Since its construction in 1868, the masonry arch bridge has suffered damage and undergone a variety of repairs. The uncertainty of the repairs' effectiveness motivates the need for automated monitoring. As such, Fiber Bragg Grating fiber optic sensors have been installed along the underside of the masonry arch and dynamic strain data have been collected during train passages over the last 2 years. Each FBG measures average strain over its gauge length, and 2 lines of 10 grating rosettes were installed along the arch soffit. These provide distributed strain data over the extent of the arch, yielding more global information compared to typical point sensors. In this context, this paper presents a framework for post-processing and interpreting the monitoring data from bridge CFM-5. The objectives are to investigate long-term and future structural performance. To achieve this, data must first be normalized against train type; using features extracted from the dynamic response to a train passing overhead, the train type is classified via XGBoost, a framework for gradient-boosted decision trees. Then, the dynamic responses are analyzed to evaluate the sensitivity to different train types by observing peak dynamic strains and their correlation with temperature.

1 INTRODUCTION

Maintenance and management of infrastructure assets continues to be a challenge for asset managers. Masonry arch bridges play a significant role in the infrastructure of transportation networks across Europe, making up roughly 40-50% of rail and road bridge spans in the UK (Augusthus-Nelson et al. 2016). The number of masonry railway and road bridges across Europe is estimated to be around 300,000 (Brencich & Morbiducci 2007).

These structures are aging, with many experiencing 100 or more years of continuous operation. Inevitably, interventions are needed to repair damage suffered during operation. However, these repairs can unfavorably alter the stiffness profile of a bridge, resulting in further damage.

The complexities associated with managing masonry arch bridges motivate the need for comprehensive monitoring solutions. Automated data capture and analysis can significantly reduce the time, effort, and cost required to monitor and assess such bridges. Many sensing technologies have been applied to bridge monitoring. Deformations and changes to bridge geometry can be detected by LiDAR (Ye et al. 2018). Computer vision algorithms can be used to automatically detect cracks in images of masonry structures (Chaiyasarn et al. 2018). Dynamic deformations can be monitored with digital image correlation (DIC) techniques (Acikgoz et al. 2018).

Fiber Bragg grating (FBG) fiber optic sensors offer dynamic strain sensing for long term monitoring of structural degradation and have been installed at multiple masonry railway bridges throughout the UK (Alexakis et al. 2018). From these FBG deployments, preliminary analysis of changes in dynamic strain have been conducted, and monitoring of force flow through the masonry rail bridges has been carried out. In addition, statistical shape analysis (SSA) has been applied to FBG data to track changes in dynamic strain profiles over time (Alexakis et al. 2018).

DOI: 10.1201/9781003483755-399

These studies either only analyze behavior with regard to a single train type or rely on operator-provided train classification. In addition, some train classes are not easily distinguishable from one another through manual interpretation of the strain record. Thus, an automated train classification workflow is necessary to streamline the monitoring process when labelled events are not available to evaluate the effect of different train classes on bridge degradation.

Following recent research regarding the use of FBG sensing on masonry arch bridges, this paper examines the use of gradient-boosted decision trees for automated train classification. Long-term analysis of bridge responses against train class and temperature are also presented in this paper.

1.1 *Bridge CFM-5*

The bridge evaluated in this paper is the Barkston Road Bridge, designated as CFM-5 by the asset owner, Network Rail. Built in 1868, bridge CFM-5 is a single arch masonry bridge, carrying a variety of passenger and freight rail traffic over a local road at a skew angle of 26°. CFM-5 supports two trackways, a northern track for eastbound trains and a southern track for westbound trains.

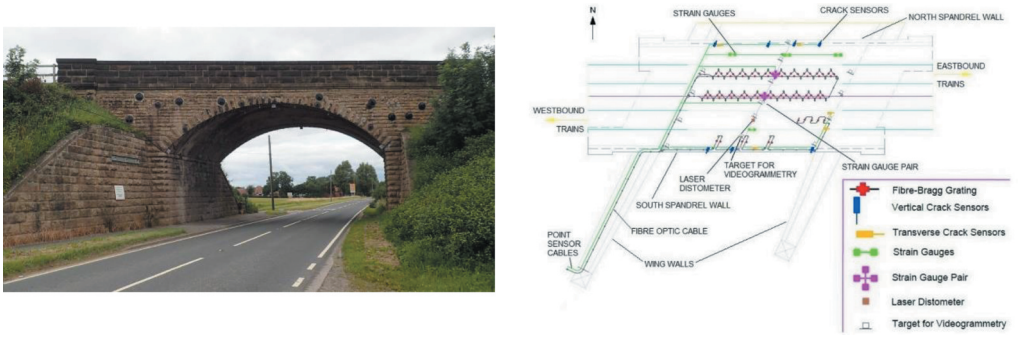

Figure 1. Elevation view of the CFM-5 bridge and its sensor installation plan.

The bridge has suffered various damage throughout its operation. The main signs of damage include separation cracks between the brick arch barrel and the stone spandrel walls and a longitudinal crack in the south-east of the arch barrel. To remedy these damages, various interventions have been implemented at bridge CFM-5, including transverse tie rods, soil anchors, and grout crack stitching. However, the effectiveness of these interventions is uncertain, motivating the need for remote monitoring technologies at bridge CFM-5.

1.2 *Monitoring installation*

Multiple sensing technologies were installed at bridge CFM-5, including FBGs, videogrammetry targets, strain gauges, and laser distometers. This paper focuses on the data obtained from the FBG sensors and ambient temperature sensors.

The FBGs are arranged in two configurations: in pairs to measure in-plane and out-of-plane strains across cracks, or in one of 20 triangular strain rosettes. One line of 10 FBG strain rosettes is installed in the arch soffit beneath the centerline of the northern track, and another line of 10 rosettes is located under the centerline of the entire bridge.

Because trains always travel in opposite directions on opposite tracks, rotational symmetry of the loading and thus response of the bridge has been assumed. Analysis of the strain readings support these assumptions so far (Cocking et al. 2019).

The installation is programmed to automatically record and upload strain readings for each train passing; data are logged during commute times to obtain records with relatively consistent passenger loading (Cocking et al. 2019). The Micron Optics FBG interrogator logs data at a sampling frequency of 250 Hz.

2 TRAIN CLASSIFICATION

2.1 *Traditional approach: Timetable dataset*

The reference dataset used for this classification problem is curated by scraping publicly available records of train departures and arrivals between August 2018 and January 2022, at stations adjacent to CFM-5, into a timetable. This timetable also includes both the direction of travel of the trains across the bridge and the train class. Then, the timestamp and direction of travel of each FBG record is compared with the timetable to match the record with a timetable entry.

Three direction checks are conducted to ascertain the direction of travel, for each FBG record. The first direction check compares the maximum peaks of two FBGs at the arch midspan, one under each track, as the FBG under the northern track will record a higher peak dynamic strain than the FBG under the bridge centerline when a train is passing over the northern track and vice versa. For the remaining two direction checks, the position of maximum dynamic peak of the FBG records on the eastern side of the bridge are compared to those on the western side of the bridge. That is, if a train is travelling eastward on the northern track, a peak is expected first on the western FBG before the eastern FBG. One of these checks is performed per FBG array. If all three direction checks agree, then the direction of the train is denoted accordingly.

Table 1. 2020-2021 dataset train types, carriage numbers, and total counts after cleaning.

Train Type	Number of Carriages	Count
Voyager 220	4	81
Voyager 220+220	8	131
Voyager 220+221	9	200
Voyager 221	5	165
Class 185	3	310
Class 185+185	6	834
Class 43	9	280
Northern 2 Car	2	511
Northern 3 Car	3	1244
Northern 4 Car	4	20
Nova 1	5	940
Nova 3	6	154
Total:		4870

Of about 7,100 FBG records collected between July 2020 and October 2021, about 5,300 are matched to the timetable in this way. Any records containing missing data are removed, as these correspond to instances when the analyzer was unable to automatically connect to the sensors upon booting. This leaves about 4,900 matched records.

In total there are 12 different train types, operated by 4 different train operating companies. A breakdown of the different train types observed in the 2020-2021 data is shown in Table 1.

2.2 *Proposed approach: Extracted features*

The approach proposed relies on the classification of trains based on extracted features from an FBG located near the midspan of the northern track. A truncated version of the timeseries data from this FBG are stored for analysis, as the original file contains buffer data at the start and end of the train event. In the unloaded bridge state, these buffer data mostly contain noise, whereas the portion of the record that contains relevant strain information as the train passes over is of more interest. This portion of the record that contains the train passing over the bridge is noted as the importance region.

The importance region is determined as follows. First, the mean of the last 1000 measurements of the record, called the tail, is calculated. The entire record is then vertically shifted to the mean of the tail, to remove any offset in absolute strain. Then, the standard deviation of the tail is calculated. Any portion of the record that exceeds 10 times the standard deviation of the tail is classified as the importance region. Records without an importance region are discarded, as these correspond to measurements that have been incorrectly triggered, resulting in a record with only noise. There are about 300 such records.

To focus on the shape of each signal and to reduce the variation in signal due to differences in train weight and speed, each record from this FBG is then normalized by its maximum recorded value. Finally, the signal is passed through a Savitzky-Golay filter, followed by a low-pass filter, to smooth out the measurements and remove any high frequency noise.

As seen in Table 1, some train classes have unique carriage numbers, resulting in signals with a unique number of peaks. However, simple peak counting is not sufficient for classification, as there remain other train types with equal carriage counts. Thus, features aim to characterize the peaks of the signal not just by counts, but also by peak heights and widths.

As shown in Table 2, Some of these features are calculated using a ring-up-ring-down scheme. That is, a threshold is set for the signal, and in this case, it is 0.05. The area where the signal surpasses this threshold before descending past it again denotes a ring up zone. Each ring up zone contains a peak, and the width of each ring up zone is also recorded.

Table 2. Features extracted from strain timeseries.

Feature	Description
len_ratio	Ratio of truncated length to untruncated length
peak_count	Sum of the numbers of peaks and valleys in timeseries
peak_spacing	peak_count divided by length of truncated timeseries
peak_freq	Highest-density frequency in PS of timeseries after filtering
avg_freq	Average frequency in PS after filtering
pass_count	Number of times signal exceeds threshold
height_avg	Average value of peaks within each ring up zone
height_std	Standard deviation of peaks within each ring up zone
widths_avg	Average length of the ring up zones
widths_std	Standard deviation of the widths of the ring up zones
width_max	Maximum width of the ring up zones

Lastly, other features are derived from the power spectrum (PS) of the signal, with the power spectrum being calculated via the SciPy Python library. Further details regarding these features are summarized in Table 2.

2.3 *Proposed classification model*

Gradient boosted decision trees are used for classification, namely XGBoost. Gradient boosting iteratively combines weak learners, into a single strong learner. In this case, the features are provided to the model, and through gradient boosting an ensemble of decision trees are combined to produce a stronger predictive model.

The objective function to be optimized at step t is defined as

$$obj(\theta) = \sum_{i=1}^{n} l(y_i, \hat{y}_i^{(t)}) + \sum_{i=1}^{t} w(f_i) \tag{1}$$

where $l\left(y_i, \hat{y}_i^{(t)}\right)$ is the multi-class softmax loss function and $w(f_i)$ is the complexity of the i-th tree. The complexity of a tree is defined by

$$w(f) = \gamma T + \frac{1}{2}\lambda \sum_{i=1}^{t} s_i \tag{2}$$

where s is the vector of weights assigned to each tree leaf and T is the number of leaves. The regularization parameters γ and λ are set to 0.2 and 0.01 respectively.

Taking the second order Taylor expansion of the loss function, the objective function for additive training can be re-expressed as

$$obj^{(t)}(\theta) = -\frac{1}{2}\sum\nolimits_{j=1}^{n} \frac{G_j^2}{H_j + \lambda} + \gamma T \tag{3}$$

where G_i and H_i are defined as

$$G_j = \sum\nolimits_{i \in I_j} \partial_{\hat{y}_i^{(t-1)}} l\left(y_i, \hat{y}_i^{(t-1)}\right) \tag{4}$$

$$H_j = \sum\nolimits_{i \in I_j} \partial^2_{\hat{y}_i^{(t-1)}} l\left(y_i, \hat{y}_i^{(t-1)}\right) \tag{5}$$

I_j is the set of indices of the input that are assigned to the j-th leaf (Chen & Guestrin 2016).

2.4 *Experimental method*

To replicate the performance of the model during online implementation, 4370 records between July 2020 and September 2nd, 2021 were used for training, and 500 records between September 2nd and October 19th 2021 were used for testing.

3 RESULTS

3.1 *Model performance*

Using the framework described in Section 2, a test accuracy of 96.8% is achieved. Class-wise precision, recall, and F_1 scores are displayed in Table 3. The F_1 score is defined as the harmonic mean of precision and recall and can be calculated as

$$F_1 = \frac{2}{recall^{-1} + precision^{-1}} \tag{6}$$

As seen in Table 3 and Figure 3, most train classes are classified with few or no mistakes, including rarer classes like the Northern 4 car. Additional performance may be achieved by fine-tuning filter parameters, model parameters, or extraction of further characteristic features.

Table 3. Test precision, recall, and F_1 score by class.

Train Type	Precision	Recall	F_1 Score
Voyager 220	0.667	1.00	0.800
Voyager 220+220	1.00	1.00	1.00
Voyager 220+221	0.962	1.00	0.980
Voyager 221	1.00	1.00	1.00
Class 185	0.903	0.800	0.848
Class 185+185	1.00	0.966	0.982
Class 43	1.00	0.964	0.982
Northern 2 Car	1.00	1.00	1.00
Northern 3 Car	0.925	0.976	0.950
Northern 4 Car	1.00	0.875	0.933
Nova 1	1.00	0.990	0.995
Nova 3	1.00	1.00	1.00

Figure 2 shows the gain, or average improvement in accuracy, of each feature after training. As expected, XGBoost uses features related to the number of peaks in the signal for much of the classification, as this relates to the number of carriages of each train.

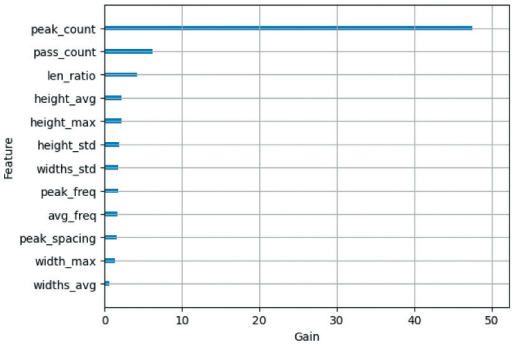

Figure 2. Feature importances.

This is supported by Figure 3, which displays information regarding the misclassification of trains. There are a significant proportion of Class 185 trains misclassified as Northern 3 car trains. This is likely due to actual and misclassified train types having the same number of carriages, as seen in Table 2. While peak counting and other features may be sufficient to distinguish between other train types, more complex classification models or features may be needed to fully separate signals of these similar train types.

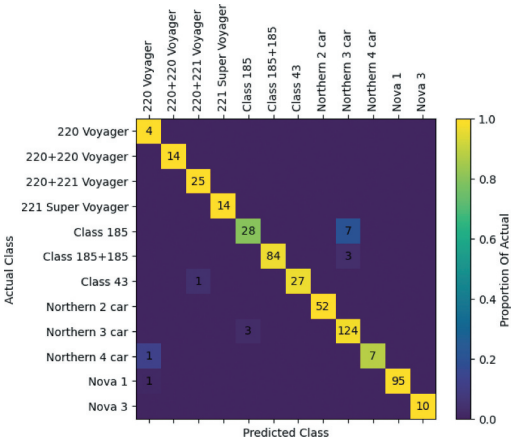

Figure 3. Confusion plot of XGBoost classifier on test set. Counts displayed in squares.

3.2 *Temperature-strain correlation*

With a robust classification framework, further analysis conditioned on train type can be conducted. A further 930 train events, which were collected from January 2023 through August 2023, have been labelled using the framework presented in Section 2. As seen in Figure 4, the train type compositions of both datasets are similar, and there is very little increase in the frequencies of relatively poorly classified train types (i.e., Class 185 and Northern 4 car trains).

Due to the relative abundance of Class 185+185 trains throughout the survey period, this class of train was selected for long-term temperature analysis. The following analysis and

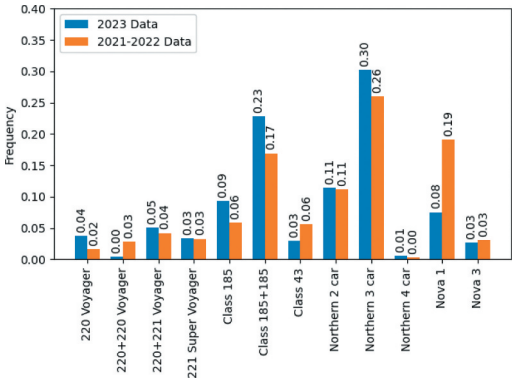

Figure 4. Frequency of predicted train classes.

results consider XGBoost labelled data from both the 2020-2021 and 2023 monitoring periods.

FBGs N_MID, C_MID, LCRACK_MID, and LCRACK_TIP were selected for observation. FBGs N_MID and C_MID are located near the middle of the span under the northern track and bridge centerline respectively. This northern portion of the bridge is relatively undamaged and exhibits the most linear behavior. LCRACK_MID and LCRACK_TIP span across a longitudinal crack in the southeast corner of the arch soffit, with LCRACK_MID positioned at the middle and LCRACK_TIP at the tip of the crack. If the crack progresses, it is expected that LCRACK_TIP, will show increased movement as the crack length grows. Opening displacements at LCRACK_MID may well also increase.

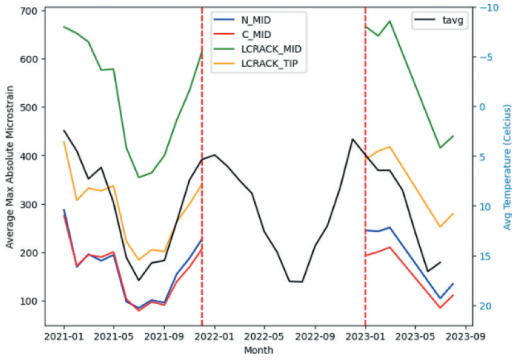

Figure 5. Monthly average maximum strain readings and monthly average temperature for Class 185 +185 trains travelling eastward.

It is known that maximum dynamic strain is well-correlated with temperature (Alexakis et al. 2021). Figure 5, which plots the average maximum dynamic strain reading across each month, for the four FBGs, along with monthly average temperature of a nearby weather station in Bradford, UK, clearly confirms this correlation. This value is calculated by averaging the monthly low and high temperatures.

To observe long-term differences more clearly, without the overlying effect of temperature, months with similar average temperatures were analyzed to compare the maximum dynamic strains of each Class 185+185 train event. Three spring months and three summer months with average temperatures around 6.4°C and 15.5°C respectively were selected for this purpose.

Figure 6 presents violin plots of the maximum dynamic strain measurements for Class 185 +185 trains. The thick dashed lines denote the distributions' median values, and the thin dashed

lines denote distributions' first and third quartile values. The median maximum dynamic strains for February 2023 and March 2023 are similar while the measurements for April 2021 are notably lower. This could be an indication of damage progression from 2021 to 2023, or possibly a sign of remaining temperature variation which the use of monthly average temperatures cannot remove. More complex normalization of the measurements against temperature will be explored in future work. Violin plots for summer months of similar monthly average temperatures yield similar results in the evolution of average maximum dynamic strain over time. Again, there is no clear ordering of the average maximum dynamic strains with respect to temperature. Generally, the average strains in 2023 are larger than those in 2021, but the extent to which the 0.2°C difference in average monthly temperature and operational damage contribute to this difference is unclear, and this will be explored further in future work, potentially by observing changes in correlation between temperature and maximum dynamic strain over time.

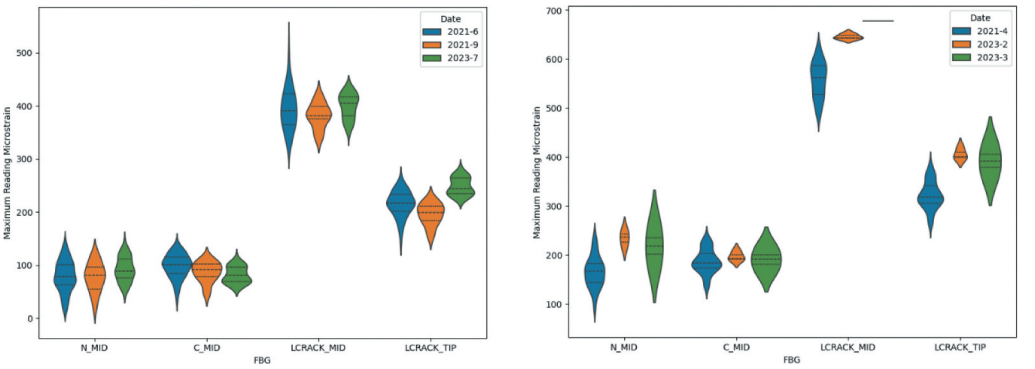

Figure 6. Maximum dynamic strain measurements for Class 185+185 trains, grouped by similar monthly average temperatures in (left) spring and (right) summer.

4 CONCLUSIONS

In this study, a comprehensive framework for post-processing and interpreting FBG monitoring data from the CFM-5 masonry arch bridge is presented. The primary focus is on automated train classification using gradient-boosted decision trees, specifically XGBoost, in order to study the bridge response normalized for different train types. The classification model exhibits a high test accuracy of 96.8%, demonstrating its efficacy across diverse train types, including rarer train classes. Further refinement of feature extraction could potentially enhance its performance.

Additionally, the study explores the correlation between temperature and strain, a critical factor in understanding long-term bridge performance. The observed correlation between maximum dynamic strain readings and temperature variations underscores the importance of considering environmental factors when assessing structural health.

The results highlight the significance of automated monitoring solutions, such as FBG sensors coupled with advanced classification models, for evaluating the health of aging infrastructure such as masonry arch bridges. Beyond streamlining the monitoring process, the proposed framework offers valuable insights into the structural response under varying operational and environmental conditions.

ACKNOWLEDGEMENTS

Deep reinforcement learning-driven life-cycle management of bridge and pavement systems

A. Bhattacharya, M. Saifullah & K.G. Papakonstantinou
Department of Civil & Environmental Engineering, The Pennsylvania State University, University Park, PA, USA

ABSTRACT: Optimal management of bridge systems and related transportation infrastructure poses multi-faceted challenges, requiring adept inspection and maintenance policies at both system and individual asset levels, to minimize life-cycle costs while considering various operational, risk, and performance constraints. This demanding type of optimization problems entails, among others, high-dimensional aspects, describing multi-component systems, long-planning horizons, diverse probabilistic and deterministic operational objectives and constraints, and inherent uncertainties associated with inspections and stochastic models. Effective coordination among individual component assets considering various inter-dependencies is also essential to enable a true system-based optimal solution. In this work, this optimization problem is formulated within the framework of Partially Observable Markov Decision Processes (POMDPs) and constrained Multi-Agent Deep Reinforcement Learning (MARL). POMDPs offer a principled mathematical approach for sequential decision-making under uncertainty, incorporating Bayesian inference to address the observation/monitoring data uncertainty, and can be suitably scaled to high-dimensional state and action spaces associated with multi-component systems, exploiting the rich representational capacities of deep learning and decentralized control settings of MARL. In this work, the recently developed DDMAC deep reinforcement learning (DRL) algorithm (Deep Decentralized Multi-Agent Actor-Critic) has been successfully deployed based on the Centralized Training and Decentralized Execution (CTDE) formulation. The efficacy and implementation aspects of the developed framework are originally studied in this work based on two existing real-world transportation networks in Virginia and Pennsylvania, USA, following all regulations imposed by the relevant agencies, as well as their overall practices, in an effort to investigate the use of the suggested framework in practical, actual settings. In both cases, DRL results significantly surpass the ones related to current state-of-practice and state-of-the-art policies, providing further support and insights toward the use of DRL-driven policies for infrastructure management.

1 INTRODUCTION

This work presents a multi-agent deep reinforcement learning framework tailored for the inspection and maintenance (I&M) planning of extensive transportation and bridge networks. This framework is methodically applied to two existing networks in Pennsylvania and Virginia, in the U.S., serving as practical, indicative, real-world case studies.

Significant computational challenges are encountered in managing multi-component infrastructure systems. These challenges include, but are not limited to, the heterogeneity of different asset classes, the extensive number of components, the presence of noisy data, limited availability of resources, and diverse performance-based constraints. The existing optimization methodologies for I&M planning range from threshold-based strategies with risk-based principles to decision tree analysis and renewal theory (Luque & Straub, 2019; Frangopol, et al., 1997). Despite their merits, many of these solutions suffer from optimality-, scalability-, and uncertainty-

DOI: 10.1201/9781003483755-400

induced complexities and are often not easily extendable to environments with constraints. Stochastic optimal control approaches based on Partially Observable Markov Decision Processes (POMDPs), e.g., in (Madanat, 1993; Papakonstantinou & Shinozuka, 2014) can support dynamic policies and noisy real-time observations in the decision-making framework, but are often hard to scale to large systems with multiple components.

To address these limitations, we combine the principles of POMDPs with the advanced capabilities of multi-agent Deep Reinforcement Learning (DRL), as explained in (Andriotis & Papakonstantinou, 2019; Andriotis & Papakonstantinou, 2021) for the Deep Centralized Multi-agent Actor-Critic (DCMAC) technique and its subsequent variant, the Deep Decentralized Multi-agent Actor-Critic (DDMAC). These techniques are designed to manage the complexities of decentralized execution and to efficiently navigate the vast parameter spaces, typical in large-scale infrastructure systems. Lately, as a further development, DDMAC is also shown under the paradigm of Centralized Training and Decentralized Execution (CTDE) (Lyu, et al., 2021) in (Saifullah, et al., 2024), with decentralization at both the action and information levels. This approach reduces the scalability involved complexities even further, by providing only local observations to the actors.

In this paper, the DDMAC-CTDE framework is uniquely applied to analyze two separate, existing, real-world transportation networks in Pennsylvania and Virginia, USA, and the resulting policies are compared against the respective current state-of-practice/state-of-the-art. Both networks under consideration consist of a set of stochastically deteriorating bridge assets necessitating maintenance, considering various deterministic and stochastic resource and condition constraints and targets, aligning closely with the actual methodologies and practices utilized by the respective transportation agencies. The Virginia network also considers multiple asset classes, i.e., pavement and bridge components, utilizing probabilistic deterioration models for the different classes of assets (Saifullah, et al., 2024), and has also been mentioned in (Saifullah, et al., 2022). In each case, results are compared with optimized Condition Based Maintenance policies (CBM) and compatible variants of current I&M policies implemented by the Pennsylvania and Virginia Department of Transportations (PennDOT and VDOT), respectively, with DDMAC-CTDE significantly outperforming both the CBM and the current state-of-practice approaches.

2 BACKGROUND

2.1 *Partially observable markov decision processes*

The POMDP framework is defined by the 7 elements tuple consisting of S,A, $\mathbf{P}$, Ω, $\mathbf{O}$, $\mathbf{C}$, and γ, where S, A, and Ω are sets of states, actions, and observations, respectively, $\mathbf{P}$ is the model of state transitions, $\mathbf{O}$ is the observation model, $\mathbf{C}$ is the cost function, and γ is a discount factor. In POMDPs the agent starts at a state s_t at a time step t, takes an action a_t, receives a cost c_t transitions to the next state s_{t+1} based on the transition model $p(s_{t+1}|s_t, a_t)$, and receives an observation, $o_{t+1} \in \Omega$ based on the observation model, $p(o_{t+1}|s_{t+1}, a_t)$. Due to partial observability, the agent can only form a belief $\mathbf{b}_t$ about its condition state, where $\mathbf{b}_t$ is a probability distribution over S. The goal for the agent is to choose actions at each time step that minimize its expected future discounted cumulative cost (Papakonstantinou & Shinozuka, 2014a; Papakonstantinou & Shinozuka, 2014b). Despite existing mathematical convergence guarantees, the traditional point-based POMDP solvers do not scale adequately for large systems with multiple components. However, neural network-based deep reinforcement learning methods can alleviate this curse of dimensionality.

2.2 *Deep reinforcement learning and DDMAC-CTDE*

Within the context of infrastructure management, DDMAC, as developed in (Andriotis & Papakonstantinou, 2021), provides an algorithm for system-level I&M optimal planning well-suited for large multi-component systems. The framework also considers the presence of constraints through state augmentation and Lagrange multipliers. DDMAC uses a sparse parametrization of the actor-network without parameter sharing between agents (i.e., each

component has its own actor network). For even larger systems, the DDMAC-CTDE formulation (Saifullah, et al., 2024) can be used, allowing for even sparser actor parametrizations. The policy, π, and its gradient are then given as (Saifullah, et al., 2024):

$$\pi(\mathbf{a}_t|\mathbf{s}_t) = \prod_{i=1}^{n} \pi_i\left(a_t^{(i)}|s_t^{(i)}\right) \tag{1}$$

$$\mathbf{g}_{\theta^\pi} = \mathrm{E}_{\mathbf{s}_t\sim\mathbf{p},\mathbf{a}_t\sim\mu}\left[w_t\left(\sum_{i=1}^{n}\nabla_{\theta^\pi}\log\pi_i\left(a_t^{(i)}\,|\,s_t^{(i)},\theta^\pi\right)\right)A^\pi(\mathbf{s}_t,\mathbf{a}_t)\right] \tag{2}$$

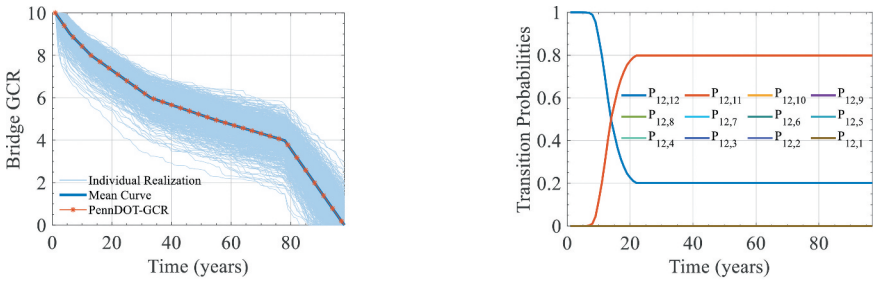

Figure 1. (a) Fitted gamma model for GCR. (b) Transition probabilities for multi-span bridges belonging to PennDOT Family 1, with starting state 12.

3 ENVIRONMENT DESCRIPTION

3.1 *Condition states and transitions*

In the case of the Pennsylvania network, the POMDP environment is derived based on PennDOT's Bridge Asset Management System (BAMS) (PennDOT, 2022; PennDOT, 2021), focusing only on bridge decks here as the primary deteriorating constituent of bridge assets. The network considered for this study consists of 30 Family 1 multi-span bridge decks in District 8, with General Condition Rating (GCR) as the indicator of bridge deck conditions, ranging from 0 to 9.99. A probabilistic non-stationary GCR model is developed based on the deterministic deterioration model, as employed by PennDOT, as detailed in (Papakonstantinou, et al., 2024, under prep.). A non-stationary gamma process is utilized, with its mean being in time equal to the PennDOT model GCR values, and a suitable model variance. Figure 1a shows some representative simulation results for multi-span bridges belonging to PennDOT Family 1. The solid line represents the mean GCR and the red curve is the GCR model used by PennDOT.

To calculate the transition probabilities, the continuous GCR values are discretized into 15 states, with state 15 being GCR ≥9.5, state 14 being GCR ∈ (9.5, 9.0], and so on until state 1, which is a compound state for all the GCR values < 3.0, to accommodate PennDOT's prescribed maintenance recommendations. Fifty million Monte Carlo sequences from the developed gamma process are simulated to obtain the transition probabilities for a given bridge family and span type, appropriately smoothed over a time window of 5 years. Figure 1(b) indicatively shows some computed transition probabilities for the Family 1 multi-span bridges.

In the case of the Virginia network, the Hampton Roads network is considered. It comprises 85 pavement (including interstate, primary, and secondary highways) and 11 bridge components, with 6 Critical Condition Index (CCI) states and 5 International Roughness Index (IRI) states used as condition indicators for pavements, and 7 GCR-based bridge states (Saifullah, et al., 2022). A non-stationary CCI model is devised based on VDOT's model (Katicha, et al., 2016). More details on the condition state transition probabilities can be found in (Saifullah, et al., 2024).

3.2 *Maintenance and inspections*

In the Pennsylvania network, bridge deck maintenance follows PennDOT's BAMS specifications, involving five specific maintenance actions: *Do-Nothing*, *General Preservation, Epoxy Overlay, Structural Overlay*, and *Deck Replacement*, along with their respective costs (PennDOT, 2022). All considered actions generally impact both the bridge deck condition state and deterioration rate. Detailed descriptions of these actions are provided in (Papakonstantinou, et al., 2024, under prep.). In this work, a high-fidelity inspection with 90% accuracy is assumed, performed every two years, to adhere to PennDOT's bridge assessment policies.

For the Virginia network, based on (VDOT, 2016), four different maintenance actions are considered for pavements, i.e., *Do-Nothing*, *Minor Repair*, *Major Repair*, and *Reconstruction*. Minor Repair (crack filling, moderate patching, etc.) can improve the CCI and IRI condition states but does not affect their rate of deterioration. Major Repair can improve condition states and also reduce their deterioration rate by 5 years. Reconstruction resets the pavement to an intact condition. A detailed description of maintenance actions and their costs can be found in (VDOT, 2016). Similarly, four maintenance actions are also considered for bridge decks. These actions, the related transition probabilities, action durations and costs are described in detail in (Saifullah, et al., 2024). Towards generality, inspection actions are also optimized in this case and three inspection options are considered, characterized as uninformative, low-fidelity, and high-fidelity inspection techniques, respectively. The observation probabilities for the corresponding inspections can also be seen in (Saifullah, et al., 2024).

3.3 *Costs, risks, and constraints*

For the Pennsylvania bridge network, the total cost is composed of the costs associated with maintenance actions and risk. The risk cost depends on the current condition rating along with the risk score (*RS*) associated with a bridge, as reported in BAMS. The risk score describes the importance of a bridge, which is a function of deck area, annual average daily traffic, truck traffic percent, detour length, scour rating, fracture criticality, and history of flooding (PennDOT, 2022). The risk score-based cost, $c_{RS}(t)$ at time t is quantified here as:

$$c_{RS}(t) = \sum_{i=1}^{N} \left(10 - GCR(t)_i\right) RS_i \tag{3}$$

where $GCR(t)_i$ is the GCR rating at time step t for the i^{th} bridge, and N is the total number of bridges considered. Inspections are not controlled in this case but are pre-assigned every two years. Their costs are thus not considered in the total cost to be optimized. Therefore, the total cost at time t can be estimated as:

$$c(s_t, a_t) = \underbrace{c_M(s_t, a_t)}_{\text{maintenance cost}} + \underbrace{c_{RS}(s_t)}_{\text{risk score cost}} \tag{4}$$

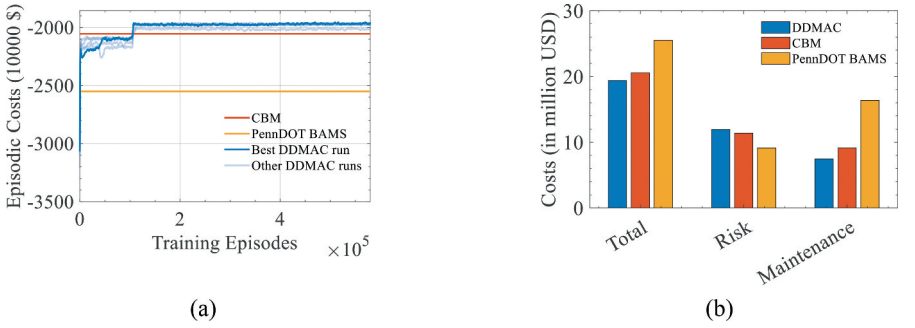

Table 1. Comparison of different solution schemes in terms of average (+/- 95% confidence bounds) total cost and performance for the Pennsylvania network.

Objective & Constraints	DDMAC-CTDE	CBM policy	BAMS policy
Total costs (million USD)	19.3779 (± 0.0211)	20.5435 (**+6.02%**) (± 0.0215)	25.5061 (**+32%**) (± 0.0116)
Poor Interstate (cap 5%)	0.5329 (± 0.0790)	0.0245 (± 0.0162)	0.00 (± 0.00)
Poor NHS (cap 7%)	3.7489 (± 0.1356)	6.4255 (± 0.1923)	0.3237 (± 0.0648)
Poor total (cap 10%)	8.3886 (± 0.2325)	4.6769 (± 0.1296)	12.3157 (± 0.1293)

Table 2. Comparison of different solution schemes in terms of average (+/- 95% confidence bounds) total cost and performance for the Virginia network.

Objective & Constraints	DDMAC-CTDE	CBM policy	VDOT policy
Total costs (billion USD)	6.55 (±0.003)	7.03 (**+7.3%**) (±0.004)	8.35 (**+27%**) (±0.008)
CCI<60 and IRI>2.2m/km for I-Hwy (%, cap 5%)	1.34 (±0.02)	1.61 (±0.02)	3.39 (±0.07)
CCI<35 of I-Hwy (%, cap 2%)	1.50 (±0.02)	0.68 (±0.01)	3.80 (±0.07)
CCI<60 for I and P-Hwy (%, cap 18%)	17.65 (±0.04)	12.67 (±0.02)	5.80 (±0.04)
IRI>2.2 m/km for I and P-Hwy (%, cap 15%)	15.40 (±0.04)	11.49 (±0.04)	15.65 (±0.07)
CCI<60 for S-Hwy (%, cap 35%)	33.00 (±0.08)	28.18 (±0.04)	37.86 (±0.13)
Bridges with GCR ≤4 (%, cap 10%)	8.33 (±0.05)	8.79 (±0.06)	15.85 (±0.15)

The Pennsylvania network in this study consists of 30 multi-span District 8 bridges belonging to Family 1, including 3 Interstate NHS and 3 Non-Interstate NHS bridges. The constraints under consideration include a hard budget limit of 5.30 million, renewed every 5 years, and 3 performance targets: (1) for Interstate bridges the average deck area in poor condition (GCR ≤ 5.0) should be less than 5% over the decision horizon; (2) for NHS bridges this target is 7%; and (3) across the entire network the average proportion of bridges in poor condition state should not exceed 10%. These constraints are integrated into the DRL framework as outlined in (Andriotis & Papakonstantinou, 2021; Saifullah, et al., 2024).

(a) (b)

Figure 2. (a) Total life cycle costs comparison of DDMAC-CTDE solution with CBM and PennDOT policy baselines. (b) Comparison of the total cost and its constituents with CBM and PennDOT policy baselines.

For the Virginia network, the total cost includes inspection, maintenance, traffic delay, terminal costs, and bridge failure risks. Budget constraints with a 5-yearly budget of 1.3 billion USD, and six performance targets are used, with the latter sought to be satisfied in an average sense over the decision horizon, based on FHWA and VDOT guidelines (Saifullah, et al., 2024).

4 RESULTS

The networks have been trained using the DDMAC-CTDE architecture, with their existing conditions as the initial condition states, an episodic length of 20 years, and considering

a discount factor of $\gamma = 0.97$. 5 maintenance actions per component are considered for the Pennsylvania network, totaling ~10^{21} available actions for the entire network, and 10 inspection and maintenance actions per component are considered for the Virginia network, with 10^{96} total available actions for the system. The 5-yearly budgets used for both the Pennsylvania and the Virginia networks follow the guidelines by the respective agencies.

To compare the DDMAC-CTDE solutions, two types of baselines are evaluated, i.e., (i) a condition-based maintenance (CBM) policy, and (ii) policies following PennDOT/BAMS and VDOT practices. The CBM policy is heuristically optimized, to identify the relevant thresholds, based on the conditions of each component type. The details of CBM, BAMS, and VDOT policies can be found in (Papakonstantinou, et al., 2024, under prep.; Saifullah, et al., 2024).

Figure 2(a) demonstrates DDMAC-CTDE performance over CBM and BAMS during its training on the Pennsylvania network, with weights initialization in this case based on an unlimited budget earlier trained case. Figure 2(b) showcases relevant histograms of total, maintenance, and risk costs from 5,000 Monte Carlo policy realizations. DDMAC-CTDE policy is 6.02% and 31.64% less expensive in total cost, in relation to the CBM and BAMS policies, respectively, and it spends 120% less than BAMS and 23% less than CBM on maintenance. Table 1 presents further details on the average performance of the Pennsylvania network over 5,000 Monte Carlo simulations, showcasing the total cost and the three constraints related to poor bridge conditions percentages, together with their recommended targets. Table 2 similarly compares six performance constraints and their targets for various pavement types and bridges in the Virginia network, where I-, P-, and S-Hwy represent interstate, primary, and secondary highway components, respectively. Both Tables provide the estimated values along with their 95% confidence bounds.

To better understand the converged DDMAC-CTDE policies, Figures 3 and 4 illustrate instances of the Pennsylvania and Virginia networks, respectively. In Figure 3, the maintenance policies for five randomly selected bridges in PA are shown over time, together with the

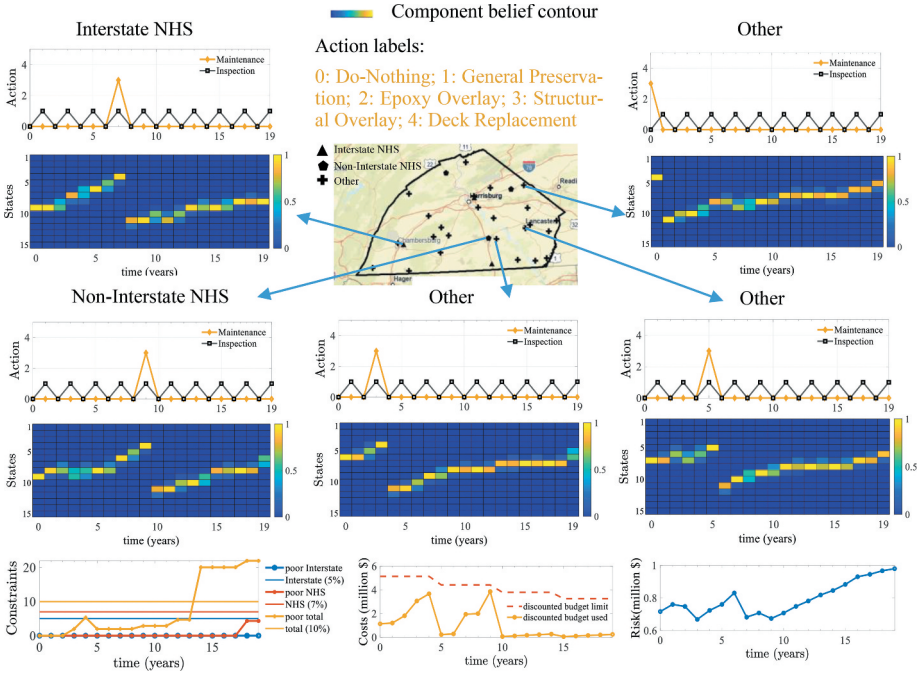

Figure 3. Indicative realization of the learned DDMAC-CTDE policy for the PA transportation network. Due to safety considerations by PennDOT, the true identities of the individual bridges are withheld. The visualization here serves solely as an illustrative depiction of the network under consideration and does not correspond to the actual bridges analyzed in this study.

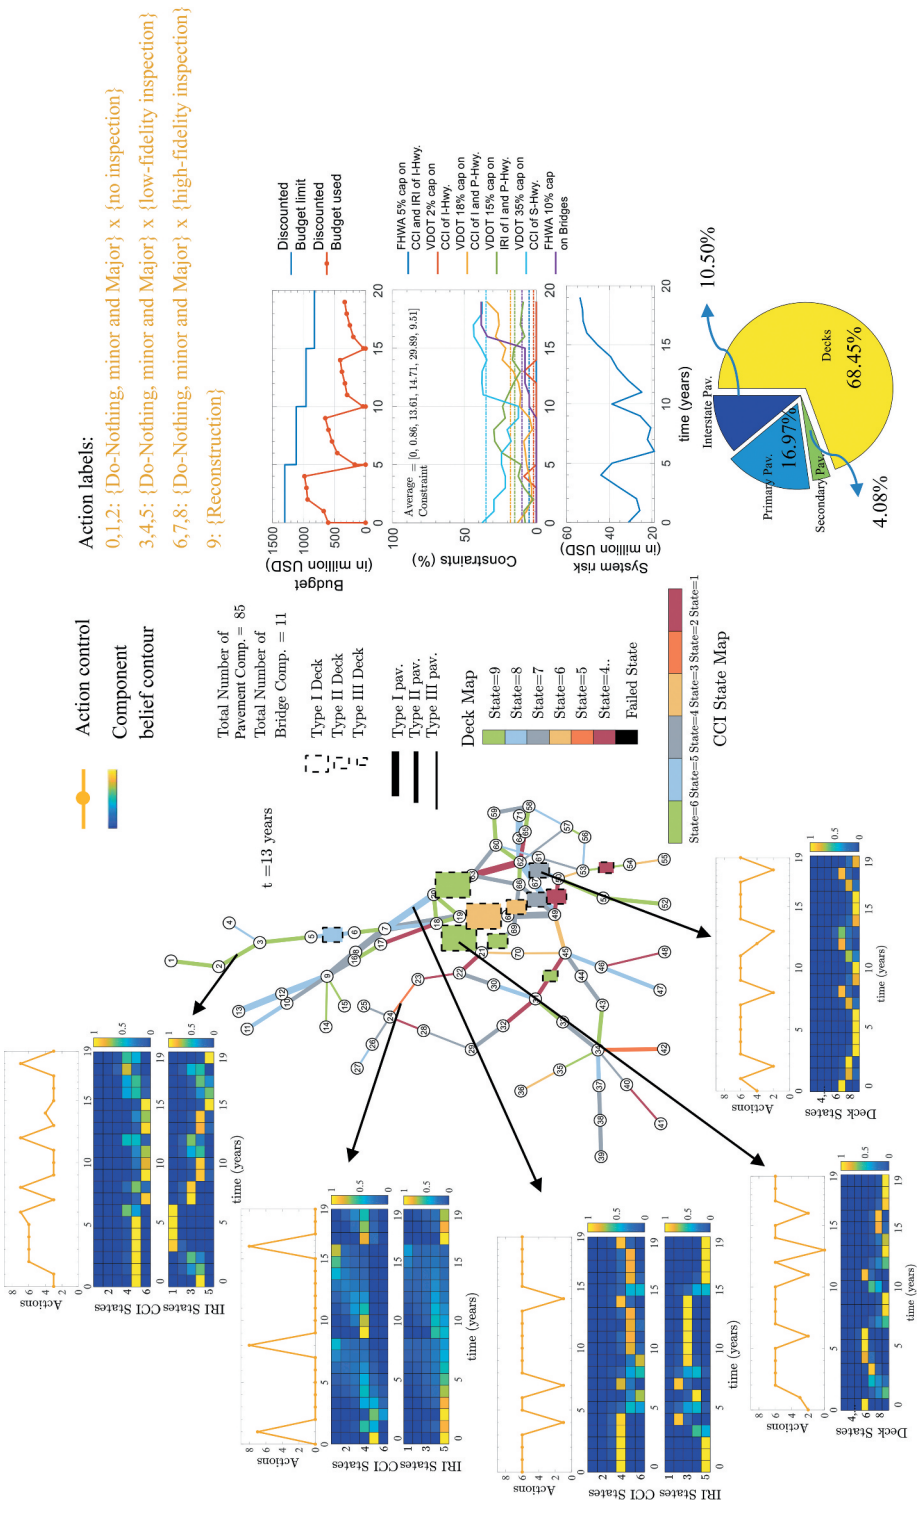

Figure 4. Illustrative realization of the learned DDMAC-CTDE policy for the Hampton Roads network.

action effects on the belief states. Figure 3 also depicts variations in considered performance constraints, their targets, the total system risk cost, and the utilized budget, with the total available budget discounted for each five-year cycle. The figure indicates that performance constraints are well-respected, on average over the decision period, and the budget remains within limits throughout the entire horizon.

Similarly, Figure 4 represents a policy instance for the Virginia network, where there are 10 available control actions. The time variations of budget utilization, system risk, and six performance constraints are also shown. The budget is always under its limit in this case as well, and discounted for each five-year cycle. A pie chart representing the I&M cost distributions for different asset types is additionally shown, with most funds spent on bridges in this case, having also a failure risk associated with them. Among the pavements, primary highway pavements utilize the most funds, as they represent the most components in this network.

5 CONCLUSIONS

Deep Decentralized Multi-Agent Actor Critic with Centralized Training and Decentralized Execution (DDMAC-CTDE) solutions are evaluated in this work, for managing bridge and bridge-pavement systems, related to two real-world networks in Pennsylvania and Virginia, USA. Comparisons with the corresponding agency policies, i.e., PennDOT (BAMS) and VDOT, respectively, and with optimized Condition-Based Maintenance (CBM) policies are performed as well. The DDMAC-CTDE solution is shown to surpass the State DOT-based baselines by 32% (for BAMS) and 27% (for VDOT) in terms of the total overall cost. CBM policies for the two networks are also surpassed by 6.02% and 7.3%, respectively, while generally meeting all the specified performance targets. Overall, this work and results indicate the applicability and effectiveness of our DRL framework for asset management of real-world networks, characterized in their full complexity, and can set solid foundations for further developments and implementations in the field, related to bridge networks and beyond.

ACKNOWLEDGEMENTS

Analyzing uncertainty in strain estimation framework for bridge condition assessment

S. Sadeghi Eshkevari, I. Dabbaghchian, G. Marasco & S. Pakzad
Lehigh University, Bethlehem, PA, USA

D. Sen
Southern Illinois University, Carbondale, IL, USA

ABSTRACT: Fatigue assessment of bridge infrastructure entails in-situ instrumentation of structural components. Consequently, the quality of collected data can be compromised considerably owing to various noise sources. Previously, the authors proposed a novel Artificial Neural Network (ANN) architecture for strain signal estimation from field acceleration measurements. This study aims to examine the impact of acquired acceleration data quality on strain signal estimation using the proposed ANN. Data collected from a real-scale case study is utilized to analyze noise levels in the input acceleration signal, measured strain signal, and subsequently the predicted strain signal to show if and how the quality of data has been affected by the ANN model. This is an effort to further understand the so-called black box neural networks specifically in the context of uncertainty propagation. Understanding the impact of data quality on the ANN's performance is crucial for enhancing the accuracy and trustworthiness of structural health monitoring in real-world applications.

1 INTRODUCTION

Measurement quality specifically in a field data collection case holds considerable importance. The quality of the collected data highly depends on the instrumentation precision, the environmental effects, and the susceptibility of the sensors. When proposing a data-driven methodology, the data quality can considerably affect the performance. Also, the framework might be able to overcome some of the uncertainties because of its designed architecture and the appointed input bundle. For this purpose, this chapter studies the data quality of the measurements for a previously proposed strain estimation framework on the Gene Hartzell Memorial bridge in eastern Pennsylvania, USA. Subsequently, the framework's capacity for maintaining the data quality is evaluated.

Previously, an artificial neural network-based strain estimation framework has been proposed and investigated to circumvent labor-intensive and costly strain sensor network deployment on a bridge by utilizing acceleration measurements on the bridge (Sadeghi Eshkevari, 2024). The proposed framework includes a novel powerful tool for sequences, Transformers, along with Convolutional Neural Networks (CNN) for the prediction of continuous strain signals using acceleration measurements from field data acquired from bridges. The schematic of this framework is shown in Figure 1. Although, to effectively address challenges stemming from various sources of noise in field measurements, it is crucial that the proposed framework captures the nonlinear spatio-temporal relationship between strain and acceleration.

Transformers, initially developed for natural language processing, demonstrate promising performance by utilizing self-attention layers to enhance the correlation between input and output sequences (Vaswani, 2017). Additionally, CNN-based networks (O'Shea, 2015) facilitate knowledge transfer and scalability (Chattopadhyay, 2012). The suggested network design merges CNN and Transformer blocks to attain excellent performance while minimizing

DOI: 10.1201/9781003483755-401

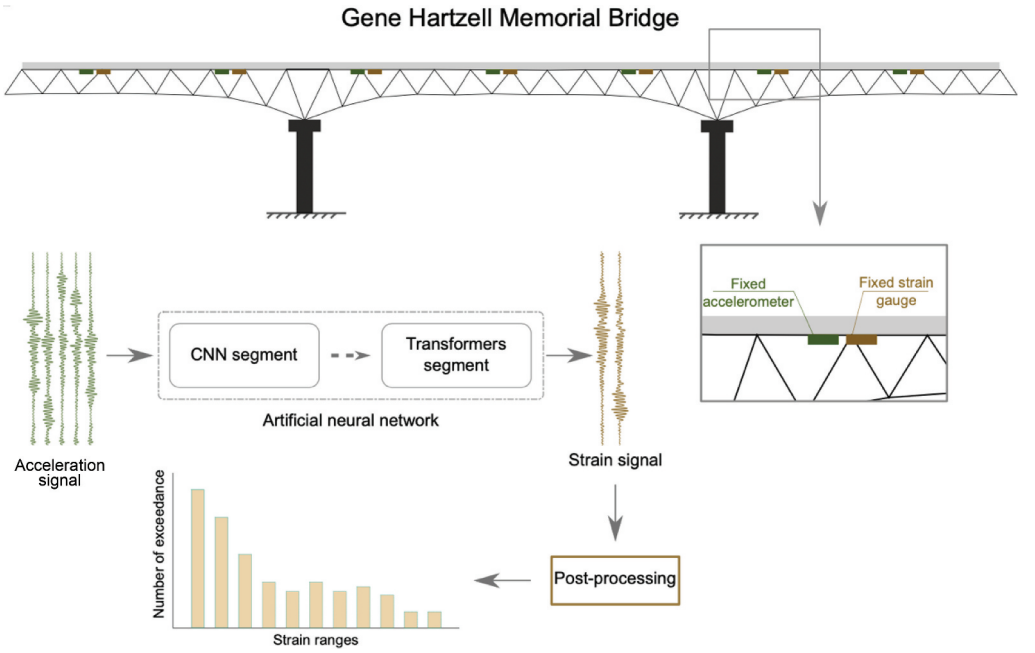

Figure 1. Strain estimation framework schematic.

computational expenses. It operates on an input array containing acceleration signals collected from multiple points along a bridge span. These signals undergo processing via an embedding layer and a positional embedding layer to preserve both dimensionality and order information. Subsequently, the matrix traverses through three CNN blocks featuring skip connections, followed by a final CNN layer before entering two Attention blocks. Ultimately, the network yields two variants of the strain signal for one location to preserve both high-frequency and low-frequency strain response content.

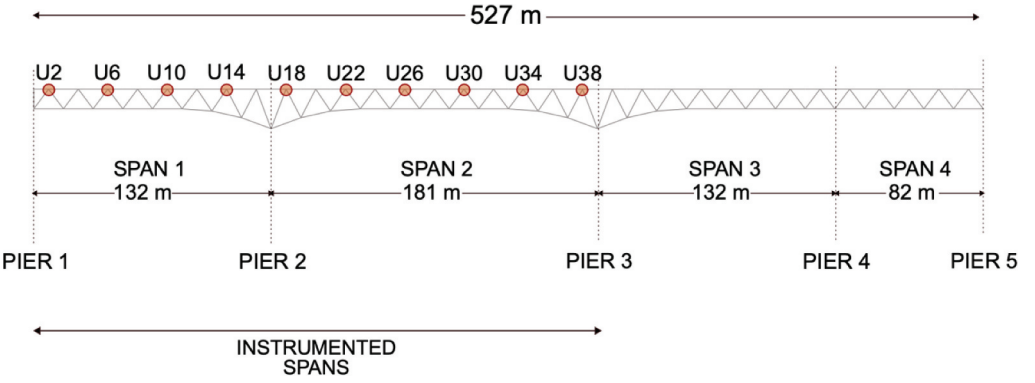

Figure 2. Instrumentation plan for Gene Hartzell Memorial bridge. Bridge side view and locations of the sensors (circles) along spans 1 and 2 of the bridge.

The case study used for instrumentation, training of the framework, and finally the evaluation is the Gene Hartzell Memorial Bridge in Easton, Pennsylvania. This bridge, completed in 2002, is a steel truss bridge with a reinforced concrete deck. It spans the Lehigh River, the Lehigh canal, and a double set of Norfolk Southern railroad networks, serving as a crucial

segment of the Pennsylvania State Route 33 (SR 33) that runs north-south. The southern two spans of this bridge were instrumented as shown in Figure 2.

The data collected from a real structure is typically noisy and needs to go through data pre-processing to be prepared for conducting further analyses. In this work, the pre-processing includes three steps: (a) applying low-pass and high-pass filters to eliminate noise and detrend the data, (b) down-sampling, and (c) segmentation of the time signals. These steps are implemented to both acceleration and strain measurements. To perform frequency filtering, the fast Fourier transform (FFT) is employed, followed by its inverse transform acting as the filter. Two distinct high-pass cut-off frequencies, 0.1 Hz and 1 Hz, are utilized. These settings enable the capture of vehicle-induced peaks responsible for high-range fatigue cycles and high-frequency dynamic strain signals associated with low-range stress cycles. These two versions of strain signals are named α for pseudo-static and β for dynamic signals. Subsequently, the collected ≈8 hour one-day data is segmented to smaller sections with length of 25 seconds (500 samples per signal) with strides of 20 to produce a larger dataset with the available data.

In this paper, the proposed framework and the case study are investigated further to explore the quality of measurements both for the acceleration as input to the methodology and strain as the output for the training phase, the quality of predicted strain signals type α and β and the comparability of the uncertainties among measured and predicted signals.

2 DATA QUALITY INVESTIGATION

To evaluate the confidence and quality of data for the field measurements and the proposed framework, investigation of the time signals does not suffice. The time signals carry the transient effect of the vehicles and therefore statistics of the time signals along the dataset (i.e. along hours of the instrumented day) is difficult to study. Although, since both types of these response measurements, acceleration, and strain signals, are a product of the loading scenario and structural dynamics of the instrumented bridge, the frequency content of the signals along the dataset offers a consistent representation along with quantification on the dispersion. For this, the following sections study the frequency content and its statistics along the dataset (as schematically shown in Figure 3) on the measured data (acceleration and strain), predicted data (strain signal type α and β), and a comparison of the measured and predicted.

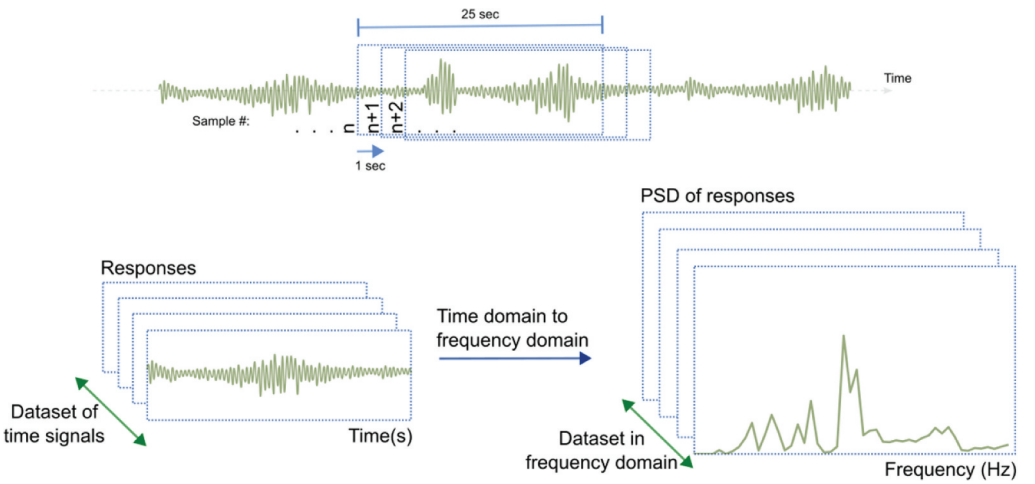

Figure 3. Schematic of the data quality measure.

3 MEASUREMENT QUALITY

First, the power spectral density (PSD) of the measured acceleration and strain signals are shown. The PSD is found for trimmed signals of 500 data points long (≈25 sec). The statistics for a random and evenly distributed subset of the full dataset (1460 signals) are calculated and the average values along with the 95% confidence interval (CI) are found as follows. The PSD for strain measurements both in the form of α and β which are the output to the ANN framework are shown in Figure 4. It can be observed that as discussed previously, signal α mostly represents the low-frequency content while signal β preserves high-frequency content that is also visible in PSD of acceleration measurements.

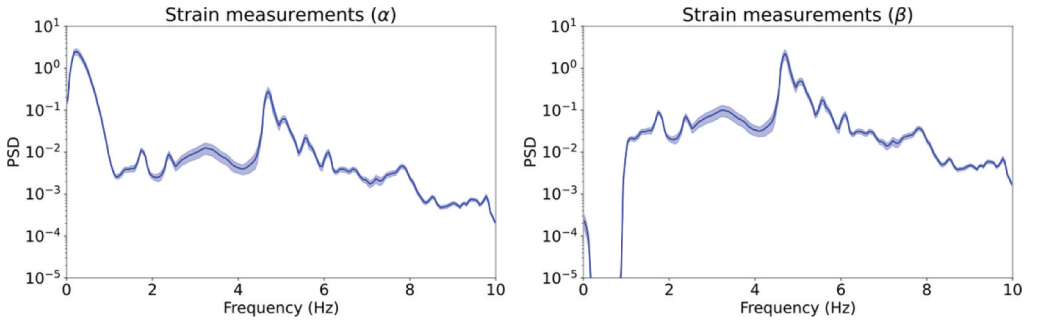

Figure 4. Average PSD (log) of strain measurements along with 95% confidence interval.

3.1 *Uncertainty along measured locations*

PSD of acceleration signals which are input to ANN is shown in Figure 5 along a bridge span. The locations are addressed according to Figure 2. The highlighted area also shows 95% confidence interval of the PSD on each location. It can be observed

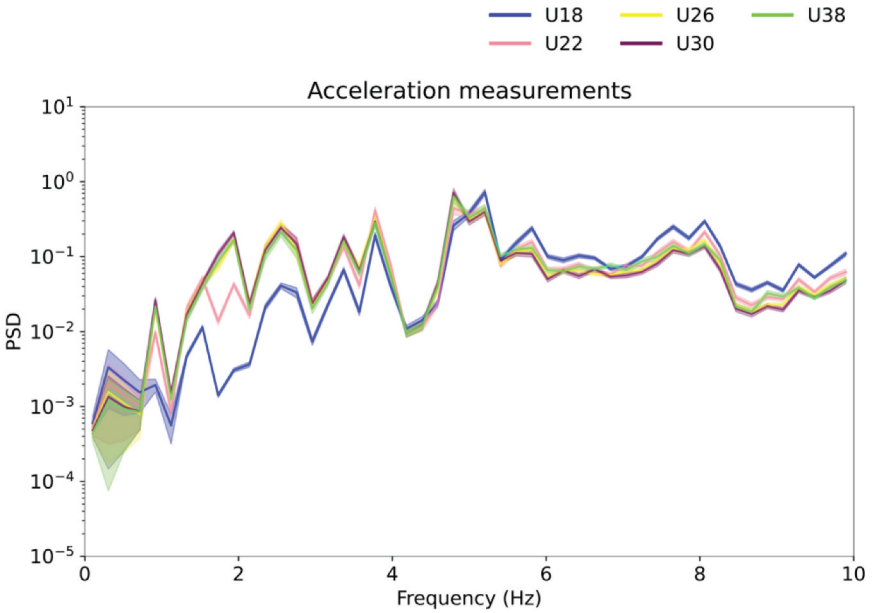

Figure 5. Average PSD (log) of acceleration measurements along 95% confidence interval for five input locations.

that different locations participate in different frequency contents and to varied degrees due to their modal participation. Low frequency content shows high versatility in the acceleration measurements. Although, in terms of CI the rest of the content indicate high certainty and low variation along each of the measured signals.

Figure 6 shows the combined statistics over all locations without the logarithmic scale. In this case, major frequency content around 5 Hz shows the most variability.

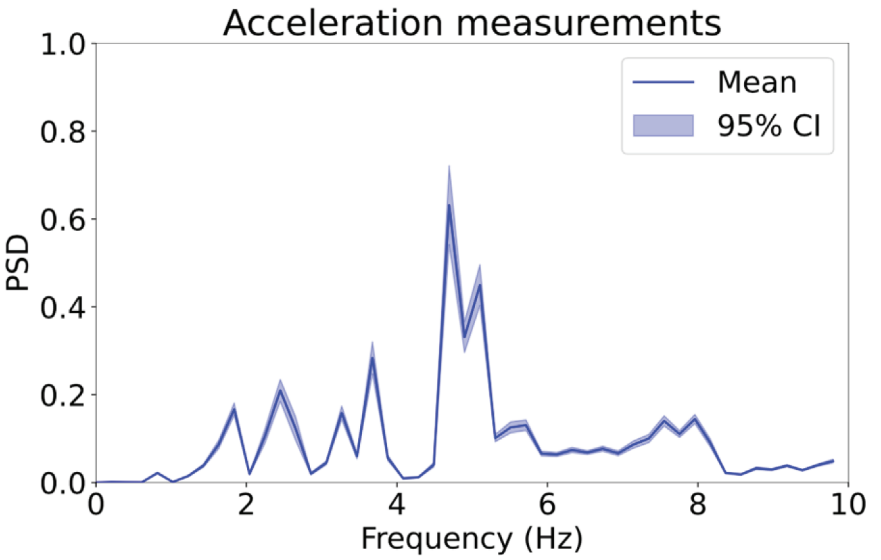

Figure 6. Average PSD of acceleration measurements along with 95% confidence interval.

3.2 *Uncertainty along time of the day*

In this section, the uncertainty along time of the day for acceleration data from one location (U18) is shown along a day of measurement (Oct. 13, 2021). The signal throughout the day is divided into 50 groups with 80% of overlap to find temporal statistics in one day of data collection. Figure 7 shows this variation along the indicator of groups along time within a day. The vertical axis shows the average PSD and the heat map represented via the change of colors shows the standard deviation of the PSD. It can be observed that later in the day of data collection (around 12:00) the peak frequency content is excited more. Simultaneously around these peak hours, the standard deviation indicates to be highest for major frequency contents of between 4 Hz and 6 Hz.

4 PREDICTION QUALITY

Following statistics of the measured signals, the prediction of strain signals are presented in a similar scale as Figure 4. Here the ANN-based framework is used to estimate the strain signals merely based on acceleration inputs. Initially, the average PSD plots for the randomly chosen dataset (similar as before) of predicted signals α and β is shown in Figure 8 along with 95% confidence interval of them. It can be observed that the major frequency contents are predicted with high confidence.

5 COMPARISON OF QUALITIES

To better evaluate and compare the statistics between measurements and predictions, the average PSD of each strain signal type (α and β) is shown in Figure 9. We can observe the measurement

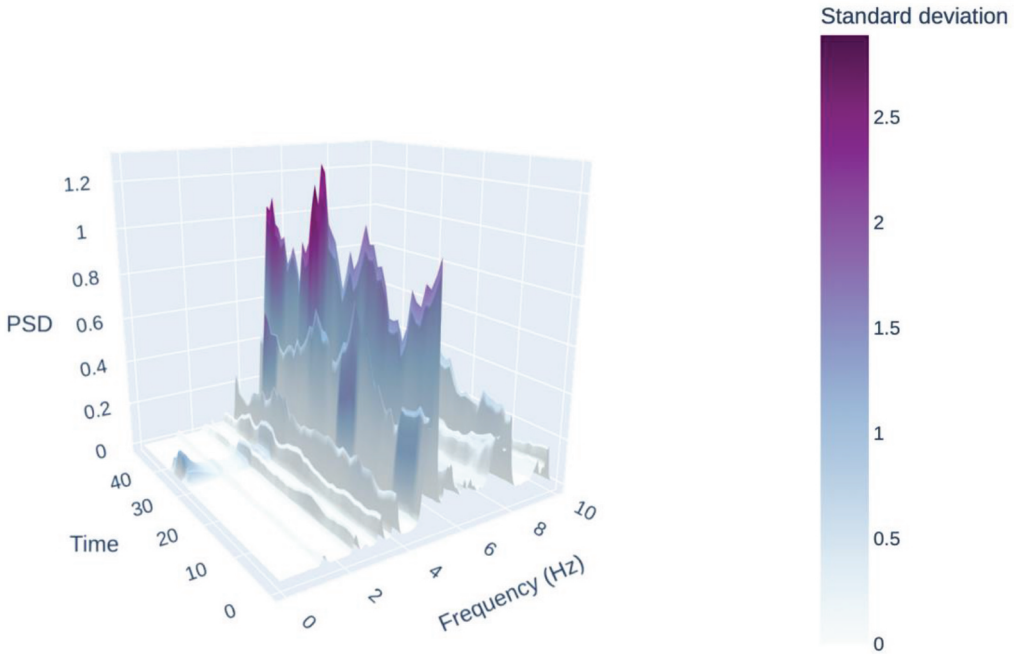

Figure 7. PSD variation along one data collection day for U18.

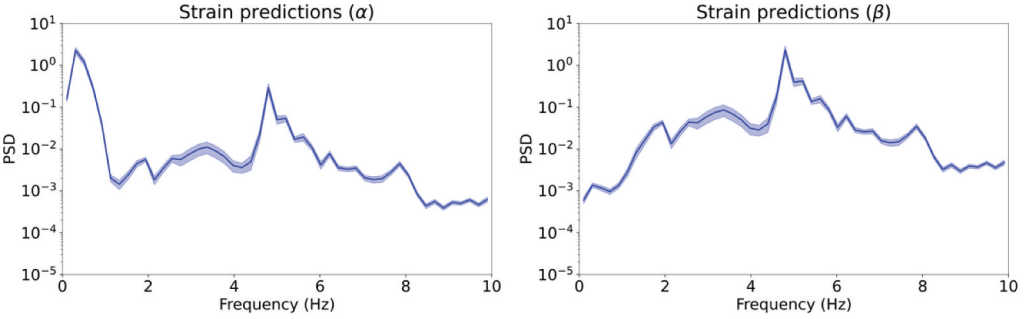

Figure 8. Average PSD (log) of strain predictions along with 95% confidence interval for signals α and β.

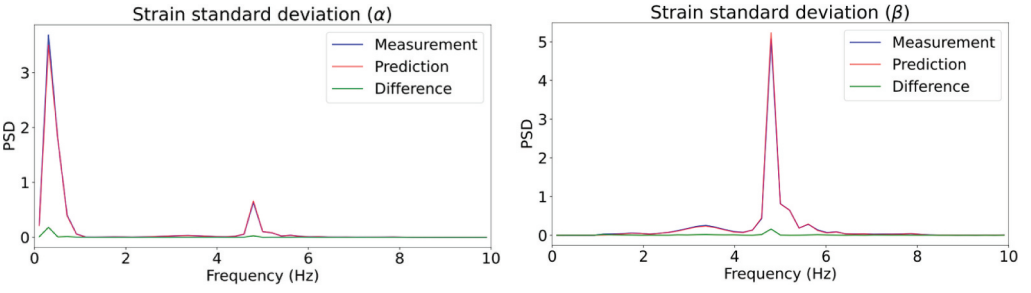

Figure 9. Standard deviation of PSDs of strain measurements vs. predictions. vs. absolute difference for signals α and β.

has a higher standard deviation when compared to the prediction of signal α. However, for signal β the opposite is evident where prediction slightly shows a higher standard deviation than the measured strain signal. Both observations can be expected when evaluating a data-driven methodology. Quality improvement compared to measurement is achieved since multiple locations are measured and provided for a framework for the strain estimation of a single location and the spatially comprehensive information can limit the variability. Therefore, the measurement is on average enhanced through the prediction process when predicting signal α. However, for signal β, the data-driven framework yields less confidence when compared to the measurement.

To spotlight the absolute differences of standard deviations for PSDs of measurement and prediction between signals α and β, Figure 10 is presented. Signal α shows slightly higher standard deviation difference at peak compared to signal β, although, the signal α improves the quality of PSD compared to measurement by the shown difference value. Also, the main structural frequency contents show the considerable difference between measurement and prediction while content at the rest of the frequencies show a higher match.

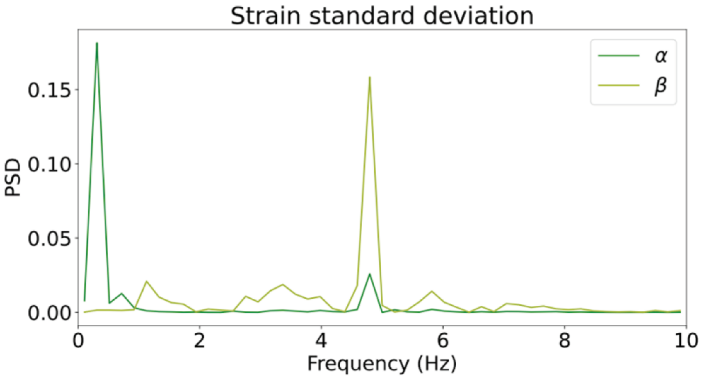

Figure 10. Absolute differences of measurement strain standard deviation and prediction.

Finally, the coefficient of variation for PSDs is compared in Figure 11 for signals α and β. It is evident that the CV shows consistency among measurements and predictions with prediction showing a slightly higher CV in the majority of frequencies. Moreover, the measurement strain signal shows large CV in the case of signal β because of the high pass filter of 1 Hz. The close match between CV of measurement and prediction shows that the ANN-based strain estimation framework does not manipulate or disrupt the signals in the process of signal reconstruction due to its data-driven nature.

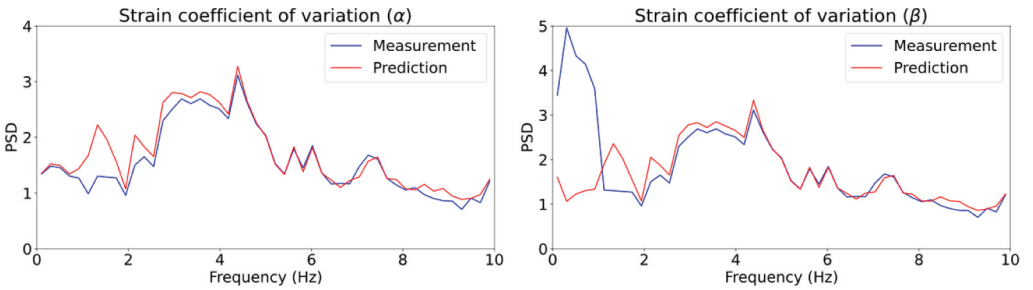

Figure 11. Comparison of PSDs coefficient of variations among strain predictions and measurements for signals α and β.

6 CONCLUSION

This paper conducts a comprehensive examination of the uncertainty inherent in the strain and acceleration data gathered from the Gene Hartzell Memorial Bridge. The primary aim is to assess how this uncertainty is influenced when employing a previously proposed ANN-based strain estimation framework. Initially, an analysis of the measurement data investigates uncertainty across various response locations and considers the time of day when the data was collected. Expanding on this uncertainty assessment, the study delves into the ANN-based strain estimation method and assesses prediction uncertainty measures. A comparative analysis between the uncertainty in strain measurements and the prediction uncertainty highlights that the proposed framework maintains the quality of the measurement data. As a data-driven framework translating acceleration measurements into strain signals, it ensures consistency while introducing no significant additional uncertainty to the strain signals.

ABSTRACT: A new paradigm for the automatic output-only modal identification of linear structures under ambient vibrations is presented, namely the intelligent automatic operational modal analysis (i-AOMA). It exploits the covariance-based stochastic subspace (SSI-cov) algorithm for the output-only identification of the modal parameters and its workflow consists of two main phases. Initially, quasi-random samples of the control parameters for the SSI-cov algorithm are generated. Once the SSI-cov algorithm is performed for each sample, the corresponding stabilization diagrams are processed in order to prepare a database for training the intelligent core of the i-AOMA method. This is a machine learning (ML) technique (namely a random forest algorithm) that predicts which combination of the control parameters for the SSI-cov algorithm is able to provide good modal estimates. Afterward, new quasi-random samples of the control parameters for the SSI-cov algorithm are generated repeatedly until a statistical convergence criterion is achieved. If the generic sample is classified as feasible by the intelligent core of the i-AOMA method, then the SSI-cov algorithm is performed. Hence, stable modal results are distilled from the stabilization diagrams and relevant statistics are also computed to evaluate the uncertainty level due to the variability of the control parameters. The proposed i-AOMA method is finally applied to estimate the modal features of a suspension bridge structure, the Hardanger Bridge in Norway, to demonstrate the feasibility of the proposed methodology.

1 INTRODUCTION

Aging infrastructure heritage is currently nearing the end of its intended lifespan, resulting in safety concerns (Aloisio, Pasca, Di Battista, Rosso, Cucuzza, Marano, & Alaggio 2022). Accordingly, research was focused on advancing structural health monitoring (SHM) methodologies (Farrar &Worden 2012, Marasco, Rosso, Aiello, Aloisio, Cirrincione, Chiaia, & Marano 2022). These endeavors aim to offer more effective and reliable tools for real-time structural health assessment. Indirect and non-destructive methods were particularly studied to leverage their advantages of less invasivity, rapidity, and efficiency. One widely embraced technique involves employing output-only vibration-based dynamic identification strategies denoting the operational modal analysis (OMA) field of study. These strategies delve into the dynamic modal properties of structures under operational and ambient vibration conditions, revealing crucial information, viz. mode shapes, natural frequencies, and damping ratios. In OMA, the stochastic subspace identification (SSI) method is a popular time-domain parametric strategy based on state-space identification, being the SSI-cov and SSI-data its main variants (Aloisio, Pasca, Di Battista, Rosso, Cucuzza, Marano, & Alaggio 2022, Pasca, Aloisio,

DOI: 10.1201/9781003483755-402

Rosso, & Sotiropoulos 2022, Rainieri & Fabbrocino 2014b, Reynders, Houbrechts, & De Roeck 2012). The bulk of current research efforts in SHM is directed toward developing automatic operational modal analysis (AOMA) methods, especially tailored for long-term dynamic monitoring procedures (Alaggio, Aloisio, Antonacci, & Cirella 2021). Typically, a standard workflow involving four primary steps is implemented in the scientific literature (Reynders, Houbrechts, & De Roeck 2012, Ubertini, Gentile, & Materazzi 2013). These steps encompass an initial phase of selecting SSI control input parameters, followed by computation and analysis of stabilization diagrams to identify stable poles and their modal parameters. Subsequent stability checks are performed, laying the groundwork for identifying stable poles' alignments along the order axis. Present approaches in the literature emphasize automation and innovative machine learning techniques, particularly clustering methods, for post-processing stabilization diagrams and collecting stable poles' alignments. In the current literature approaches, the automation and innovative machine learning-based (ML) part is mainly based on clustering techniques for post-processing stabilization diagrams and automatically collecting stable poles' alignments.

The selection of SSI control parameters during the initial phase is critical, as an improper choice may compromise the entire identification process of the modal properties. Despite numerous studies provide insights and suggestions for a proper SSI input parameters tuning (Rainieri & Fabbrocino 2014a, Zini, Betti, & Bartoli 2022), a fully and solid automated procedure for selecting SSI parameters has not been proposed to date. Therefore, this work illustrates a recent proposal able to fullfill the need of automatic dynamic identification, namely the intelligent Automatic Operational Modal Analysis (i-AOMA). This method aims to automate the selection of SSI-cov input parameters.
