Uehan (2023) analyzed recent advances in the study of dynamic effects on high-speed railway bridges. In this sense, the author evaluated the dynamic effects of wind action on the bridge structure as well as the support conditions of the superstructure and the behavior of the vehicle on the asset. Additionally, the effects of road irregularities were verified with a monitoring system on board the vehicle. The results obtained were used in computer simulations using the finite element method. The computational results obtained were compared with experimental responses of the asset; the displacements along the span showed an excellent correlation, demonstrating that recent advances in the study of dynamic effects are relevant to the topic.

The integration of the structural resilience concept into the digital twin of an infrastructure asset was proposed by Kaewunruen et al. (2022). The authors used an evolutionary concept between levels of detail of information about railway bridges located in the United Kingdom. The first level corresponds to drawing information (CAD), followed by two-dimensional and three-dimensional details until the integration between engineering and architecture (BIM). The last level of detail corresponds to the digital twin of the asset, which integrates numerical and analytical results, promoting a framework for determining the structure life-cycle and resilience.

Fernandes et. al. (2022) present relevant work related to the resilience of steel bridges. In this study, the authors evaluated the asset conditions of exposure, its failure modes, and the bridge degradation process. Therefore, the bridge performance was evaluated by considering various levels of maintenance, the repair and strengthening costs involved, as well as resilience to different scenarios linked to recovery time. The results obtained by the authors demonstrated that the 50% resilience was not affected by the rehabilitation time, considering a linear resilience function. On the other hand, log-normal resilience functions displayed a reduction of approximately 5% in the bridge resilience, considering repair times of 180 days and 270 days.

In this context, the present paper aims to determine and quantify the structural resilience of a reinforced concrete railway bridge employing computational modeling techniques. The proposed study opens new horizons for a quantitative assessment of the resilience of structural elements of railway bridges due to unusual degradation events, repair time, and efficient recovery.

1.2 *Asset description*

The asset studied in this paper was a six-pan reinforced concrete railway bridge with 180 meters in total length, built in the 80s and located in the northern region of Brazil (Figure 1). The bridge comprises two continuous sections: the first includes two 25-meter spans, and the second has four 25-meter spans. Each section ends with abutments. The bridge presents a hyperstatic configuration, with the superstructure consisting of two longitudinal beams with rectangular cross-sections, transverse beams, and a concrete deck with variable cross-sections. The superstructure is supported on the pile caps by neoprene bridge bearings. The infrastructure comprises pile caps and caissons supported by a rock layer.

The smallest section of the bridge, which is composed of a continuous section with two spans, had one of its piers subjected to an explosion during an act of vandalism that occurred on October 18, 2016. Therefore, due to this unforeseen event, this region was considered for the resilience study proposed in this paper. The damage effect on the asset was taken to the computational model produced in the CSiBridge 21 software by penalizing the stiffness of the affected elements (thickness of the shell elements and Young's modulus) as shown in Figure 2.

Specific details related to numerical modeling calibration, natural frequencies, and vibration modes can be checked in Gamino et. al. (2023). The geometric and mechanical properties used in the computational model of the railway bridge can be found in Table 1.

The stiffness values used in the foundation elements were determined from the soil-structure interaction (SSI) model by Morrison (1993) according to the local characteristics of the soil. Linear springs were applied to represent the lateral confinement effect of the soil. The existing neoprene bearing pads on the pile caps located in axes 4 and 5 (Figure 2) had Winkler spring stiffness using Guerreiro (1993) technique. Table 2 presents the spring stiffness values used in these regions.

Neoprene pads E4	7.8	- - -	8131	55.7

* x axis (longitudinal), y axis (transverse), z axis (vertical)

1.3 *Computational analysis*

Nonlinear time history analysis was used with 200-time steps and an increment of 0.1 s. The damping used in the asset (3.6% for all vibration modes) was obtained from a monitoring campaign carried out by a third-party company. The load conditions of the railway vehicle traveling over the asset at a speed of 60 km/h were used.

The computational model was initially calibrated based on experimental data (Gamino et al. 2023) and subsequently, the imposition of damage to the asset was carried out as shown in Figure 2 and Table 1. Shell finite elements were used throughout the model and an unstructured mesh (Figure 2). Finally, the FNA (Fast Nonlinear Analysis) technique implemented in the CSiBridge v. 21 program was used to obtain the time history traces.

2 DETERMINATION OF STRUCTURAL RESILIENCE

2.1 *Technique employed*

The technique for determining structural resilience in this paper was based on the formulation presented by Bocchini et al. (2014). In this context, resilience can be determined based on the loss of functionality $F(t)$ of the asset or its parts. Functionality can be related to displacements, speeds, accelerations, or even natural frequencies.

The residual functionality after the adverse event (earthquake, explosion, impacts, fires) determines the robustness $Ro(t)$ of the asset. Thus, the loss of functionality $F(t)_{loss}$ will be given by:

$$F(t)_{loss} = 1 - Ro(t) \tag{1}$$

Resilience depends on the asset's recovery time due to $F(t)_{loss}$. Thus, using t_0 for the start time of the rehabilitation of structural elements and t_f the end time, the angular coefficient of the asset recovery function can be defined with a linear approximation:

$$R(t) = \frac{F(t)_{loss}}{t_f - t_0} \tag{2}$$

where $R(t)$ is the rapidity with which the asset was recovered from the fortuitous event and the losses of identified functionalities.

Finally, the resilience triangle can be determined from the geometric figure generated vertically by $F(t)_{loss}$ and horizontally by $F(t)_{loss}/R(t)$.

$$Res(t) = 1 - 0.5\ F(t)_{loss}\ \frac{F(t)_{loss}}{R(t)} \tag{3}$$

where $Res(t)$ represents the resilience of the asset.

2.2 *Loss of functionality using computational modeling*

The assessed loss of functionality refers to the longitudinal velocities (direction "x") in the pile cap located on the damaged E4 axis following an explosion that occurred in 2016 (Figure 2). Two computational models were developed, one with the original undegraded configuration and the other with the degraded elements based on the photographic record obtained during the asset inspection. The dynamic analysis used is detailed in item 1.3 of this paper.

3 RESULTS

3.1 *Computational results*

Figure 3 shows the longitudinal velocities of the damaged and intact pile cap according to the description of the dynamic analysis carried out on the asset. Speed peaks for vehicle passage close to 5s of analysis can be seen.

Table 3 presents the speed peaks obtained in the computational models and the results of loss of functionality and robustness of the asset.

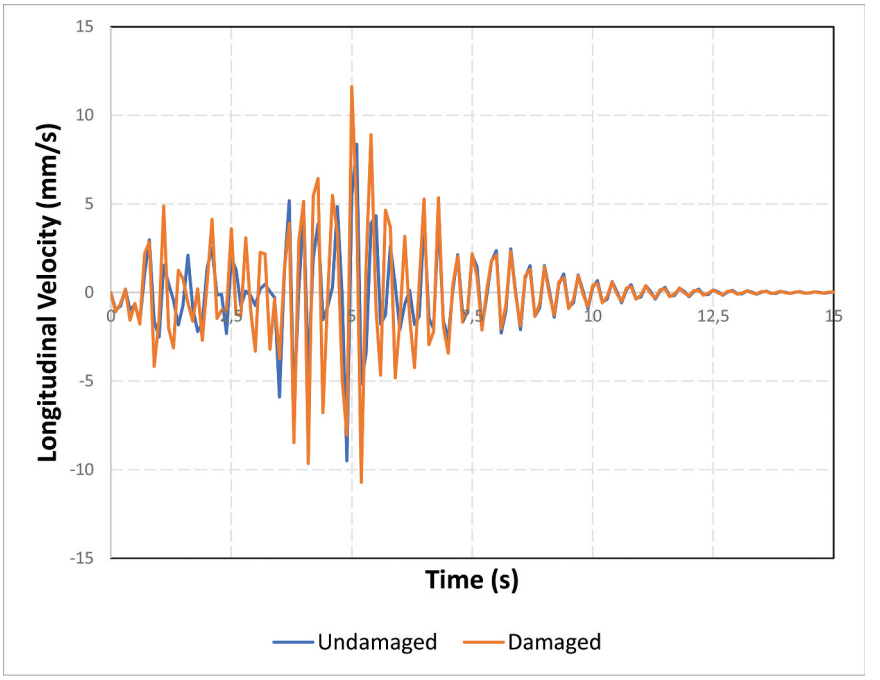

Figure 3. Variation over time of velocities in the studied pile cap.

Table 3. Loss of functionality and robustness.

Computational model	Vx_{peak} (mm/s)	$F(t)_{loss}$ (%)	Ro(t) (%)
Original asset	8.37	- - -	- - -
Damaged asset	11.62	39	61

From a documentary analysis of the asset, related to the identification of the recovery period, it was noticed that the time t_0 corresponded to the date of November 11, 2016, and the time t_f on May 17, 2017. Thus, based on the loss of functionality identified in Table 3 and the recovery time of the asset, we have the resilience triangle as illustrated in Figure 4.

Finally, the resilience of the railway bridge evaluated from Equation 3 was 64% as shown in Table 4. The results for the resilience variables were found based on reliable documents related to the rehabilitation of the asset for local conditions. The studied railway bridge is in an area of difficult access; there was a need to develop a specific reinforcement project in addition to mobilizing trained personnel to rehabilitate the asset.

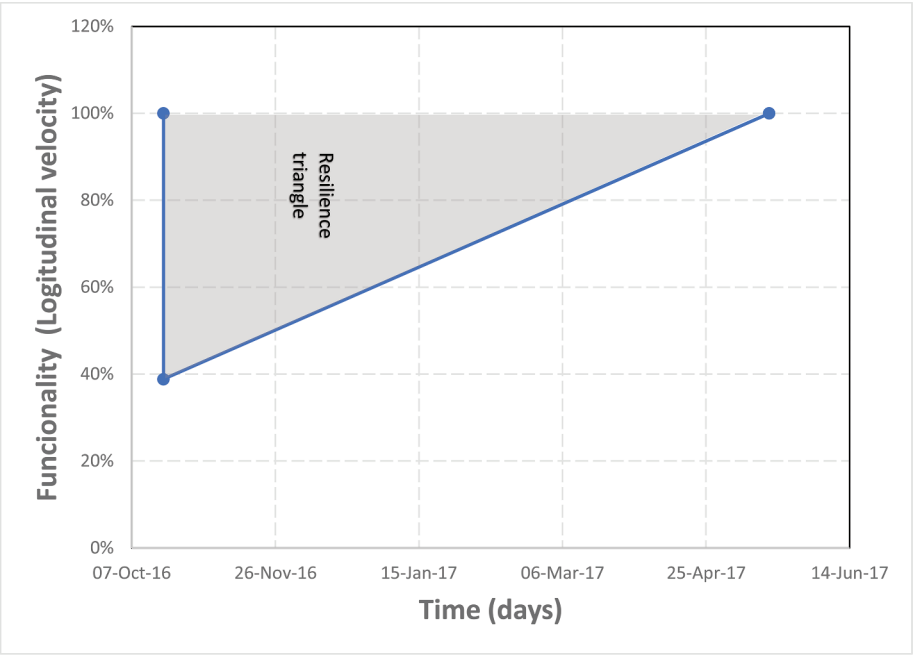
Table 4. Determination of structural resilience.

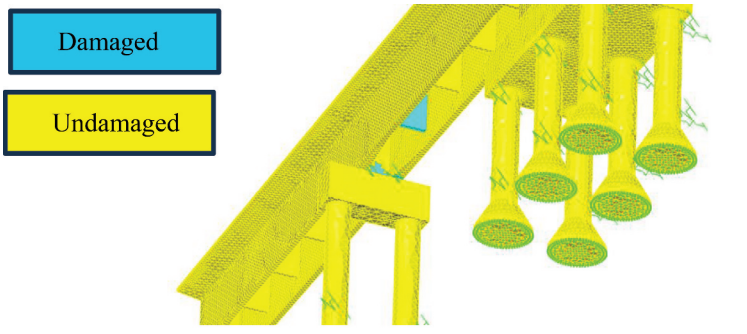
Resilience parameter	$t_f - t_0$ (days)	R(t) (%/day)	Res (%)
Value	187	0.208	64

Finally, the effect of asset recovery time was studied, considering official documents and the calibrated computational model developed. The restoration process was performed in three stages:

a. Stage 1: Pile caps recovery (140 days).
b. Stage 2: Recovery of floor beams (spans between girders, 28 days).
c. Stage 3: Recovery of girders (19 days).

Stage 3 was executed with the asset in its original configuration, before the damage event. Computational models were developed that simulated the recovery steps as shown in Figure 5.





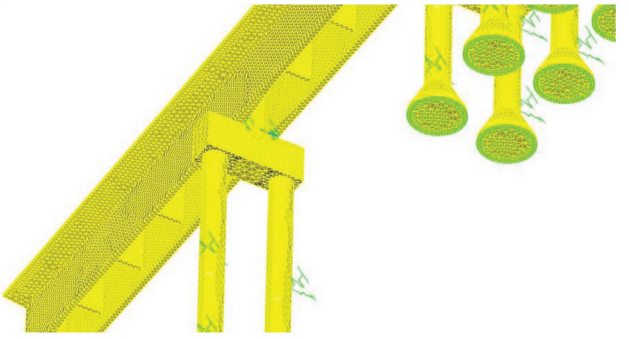


Figure 4. A resilience triangle was obtained for the damaged bridge pier.

a. Stage 1 (pile caps recovery).

b. Stage 2 (girders recovery).

Figure 5. Simulation of asset recovery in computational models.

Velocities peaks were taken from each recovery stage and resilience was calculated over time based on the performance of the asset obtained considering a linear recovery time and the real one obtained from official documents (Figure 6).

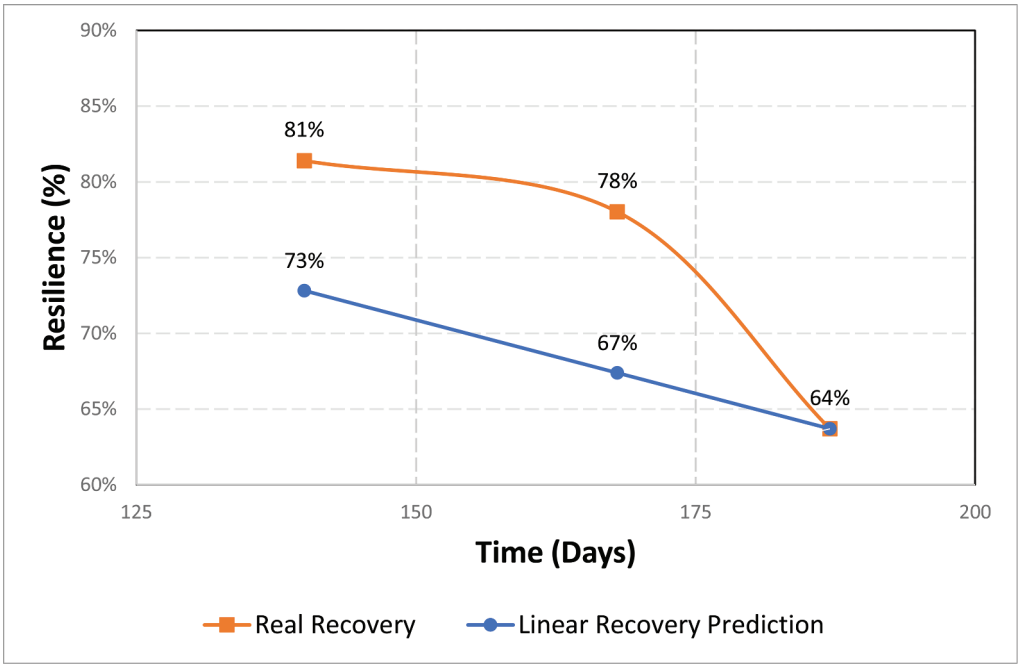

Figure 6. Effect of recovery time on structural resilience.

The results obtained demonstrate a non-linear relationship between resilience and asset recovery time. In the technical literature, probability functions simulate the uncertainties about these variables in the process of determining resilience. In the present work, it was found that linear variations in recovery times do not convey reliability to the resilience obtained.

4 CONCLUSIONS

Considering the results obtained in this paper from the proposed computational model, it is possible to identify the following conclusions:

- The proposed computational model, previously calibrated with experimental results previously obtained in an instrumentation and monitoring campaign (Gamino et. al. 2023), proved capable of predicting the loss of functionality of the asset in the event of an explosion.
- The resilience determined in this paper was directly impacted by the recovery time due to the adverse location of the railway bridge and all the work carried out in generating the reinforcement project and construction team.
- The loss of functionality can be explored in other results from dynamic analysis, such as displacements, accelerations, and natural frequencies; in this way, the minimum resilience of the asset can be determined.
- The recovery time of damaged elements directly affects the resilience of the asset according to a non-linear relationship between these variables.

- Considering the computationally determined loss of 39% for longitudinal velocities in the pile cap and a recovery time of 187 days, a structural resilience of 64% was obtained.
- The Winkler springs used in the soil-structure interaction modeling strategy were fundamental for calibrating the asset and obtaining structural resilience results.

Assessment of honeycomb cushion for enhancing bridge deck impact protection

H. Mraih, J. Hashemi, R. Kalfat, R. Al-Mahaidi & G. Lu
Swinburne University of Technology, Melbourne, Australia

ABSTRACT: This study examines the suitability of honeycomb panels as a viable protective cushioning system to mitigate the impact of over-height vehicle collisions on bridge girders. Two honeycomb specimens, composed of aluminium alloy 3003 and sharing cross-sections of 300 × 300 mm, with thickness variations of 300 and 150 mm were tested. These panels underwent static load testing to explore their capacity for energy absorption. The findings serve as a proof-of-concept, confirming the potential effectiveness of honeycomb panels as a promising choice for structural applications, particularly as sacrificial anti-impact cushions.

1 INTRODUCTION

The frequency of over-height vehicle collisions with bridge superstructures, specifically girders, poses a significant threat to the infrastructure networks and road users. It can lead to potentially catastrophic consequences that affect public safety and infrastructural integrity. Xu et al. (2012) stated that the percentage of overpasses in Beijing, China, that experienced collisions is around 50%, and the over-height vehicle collisions are approximately 20%. This impact event is also considered a fundamental problem in the USA. Hite (2007) states that the damage of over-height vehicle collisions to the interchange bridges in the USA is estimated to be 61%. Further, Nguyen (2018) claims that a report from the transportation department in the United Kingdom illustrates a significant increase in collisions involving over-height vehicles and bridge girders, rising from 729 incidents in 1990 to 1870 in 1994. This impact event can cause severe damage to the bridge girders (Figure 1-a) or a complete bridge collapse, as occurred to the footbridge on a motorway in Kent, UK (Figure 1-b).

Figure 1. Real-life over-height vehicle collisions with bridge girders: (a) Michigan, USA, 2023 (Pair, 2023); and (b) Kent, UK, 2016 (Nguyen, 2018).

DOI: 10.1201/9781003483755-75

Thus, different impact prevention strategies were defined to mitigate the collision effects on the bridge girders, such as rerouting, warning systems, clearance augmentation (e.g., steel pedestals) (Hite, 2007), and energy-absorber (Yang, 2006, Yang and Qiao, 2008, Yang and Qiao, 2010). While each mitigation strategy has limitations and advantages, energy-absorbing systems can be effectively designed with reduced cost, effort, and installation requirements. These systems need to be designed to absorb as much energy as possible and reduce the translated loads to the protected girder. The repairs may involve replacing the damaged cushion pieces, resulting in lower costs and effort.

In the existing literature, a limited number of studies were identified that explored the application of cushion materials in mitigating over-height vehicle collisions (Sharma, 2010, Xu et al., 2022, Yang and Qiao, 2010). Notably, honeycomb structures, characterised by their hexagonal cell arrangement, have demonstrated remarkable energy-absorbing capabilities. The manufacturing process of honeycomb structures involves bonding thin sheets of material, such as aluminium or composite materials, to create a rigid and lightweight core. When subjected to external forces, the honeycomb's cellular walls collapse in a controlled manner, deforming and absorbing energy through plastic deformation. This controlled deformation efficiently disperses impact energy throughout the structure, preventing concentrated damage and reducing the transmitted forces to the protected components.

Yang and Qiao (2010) adopted one type of honeycomb cushion with an energy-absorbing capacity of 147.2 kJ. Based on their analytical and experimental investigation, they confirmed that their innovative cushion system could be used to protect the girder from impact loads of 4.5 tons (the top part of the over-height vehicles that are involved in the impact event) travelling with 60 km/h (truck's velocity during impact) which was based on the assumption that there is a loss of the applied impact energy due to a bounce back of the impacting project. This paper presents an experimental and analytical assessment of one main component of a proposed hybrid cushion protective system. It is an initial step toward developing the next generation of impact-resistant cushions to protect bridge girders from collisions involving over-height vehicles.

2 EXPERIMENTAL PROGRAM

In this study, two honeycomb panels with hexagonal-shaped cells were tested under static loads. The honeycomb panels were made from aluminium alloy 3003 and manufactured by Foshan City Linwell Honeycomb Hardware Co. (2024). The detailed process of manufacturing honeycomb panels from aluminium involves a series of precise steps. The initial phase is the precision cutting of the solid aluminium alloy into plates. These plates are then stacked together using adhesive to form a consolidated block. The next step involves subjecting this block to hot pressing within a specialised machine. This process facilitates the fusion and melting of the adhesive, forming a solid composite structure. The block is carefully segmented into various heights, which are determined based on the thickness required for the honeycomb samples. The final stage of the manufacturing process is expanding the honeycomb structure. This expansion is a crucial step, and given the substantial thickness required for both the current study and practical applications, the manufacturer emphasises the challenge of achieving uniform expansion across the samples and their cells.

The two honeycomb specimens, with similar cross-sections of 300 $\times$ 300 mm, have respective heights of 150 mm and 300 mm, and both specimens share a foil thickness of 0.06 mm. The measured weights of the samples were 1.673 kg and 2.895 kg, resulting in densities of 124 kg/m^3 and 107 kg/m^3 for the small and large specimens, respectively. This density variance occurred due to the difficulties during the expanding phase for such a high panel's thickness.

The static test was performed using the Instron 5MN Four-column Static Testing Machine at the Smart Structures Laboratory at Swinburne University of Technology, Melbourne, Australia (Figure 2-a). Figure 2-b provides a view of the height of the two test samples. To ensure a stress distribution across the entire area of the samples, two steel plates measuring 400 $\times$ 400 $\times$ 40 mm were positioned on both the top and bottom of each sample, as depicted in Figure 2-c and d. The compression load was applied by moving the upper plate towards the lower one.

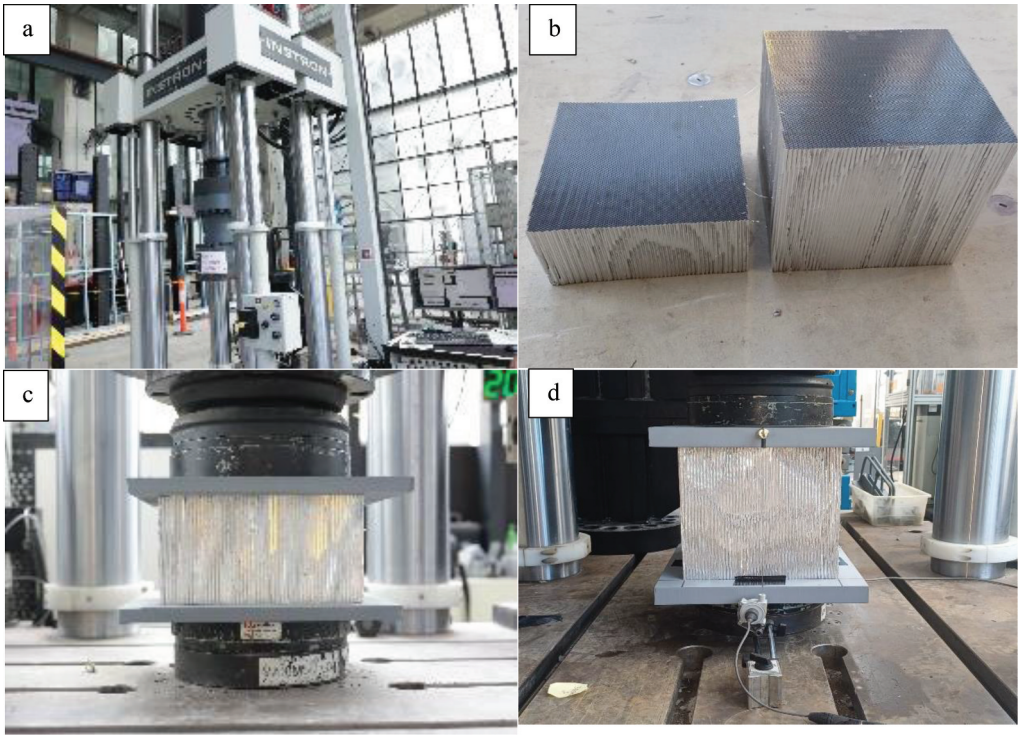

Figure 2. Static test apparatus and samples' placement: (a) Testing Machine – Instron 5MN; (b) Two tested samples; (c) Small specimen – 150 mm thick; and (d) Large specimen – 300 mm thick.

3 RESULTS AND DISCUSSION

This section covers the results of the static load testing of the cushions. Generally, and as defined in Ashby and Medalist (1983), the behavior of the honeycomb panel can be described in three regions: (i) the elastic zone, when all the panels resist the load without any permanent deformation; (ii) the plateau stress, where the layers of the honeycomb undergo deformation gradually; and (iii) the densification stage when the panel still deform but requires large corresponding loads. Figure 3-a, b, and c visually depict these three structural performance phases. In the first stage (Figure 3-a), the specimen is loaded, and the overall geometry of the panels was involved in withstanding the load until the first layer of the panel (close to the top steel plate was deformed). Then, Figure 3-b illustrates the middle of the consecutive deformation of the layers. Finally, when the total panel thickness was compressed, the specimen reached its densification stage (Figure 3-c).

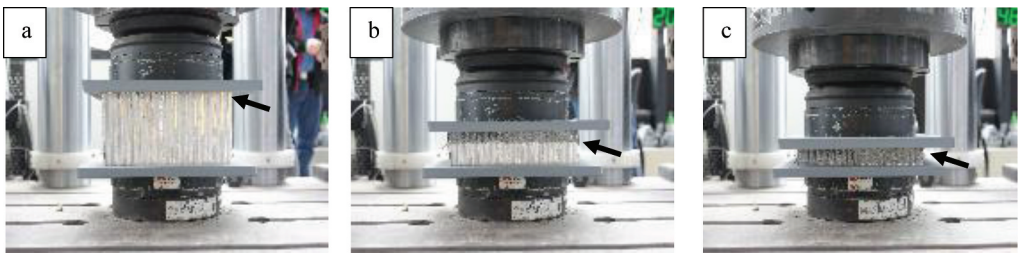

Figure 3. Loading stages on the honeycomb panel – 150 mm thick: (A) Starting of the plastic zone; (B) Within plateau loading stage; and (C) Starting to densification stage.

The pictures in Figure 3 above were captured using a Canon EOS R6 Mark II camera, which was automatically adjusted to capture one picture per second. The camera was synchronised with the testing machine, enabling the identification of images' locations on the load-displacement curve, as shown in Figure 4. It can be observed that the total panel resisted the compression load within the elastic zone (684 kN at 2.8mm). The sudden drop of force (103 kN at 3 mm) represents the failure of the first layer of the panel. Subsequently, the specimen's stiffness was re-exhibited until the failure of the subsequent layer. This phenomenon is evident as a load fluctuation along the displacement and test time. The fluctuation range is particularly noticeable in the early stages of the plateau force zone. With the consistent application of load and the continuous, consecutive failure of layers, the fluctuation range can be reduced until it becomes nearly a constant load. Finally, the final red dot depicts the starting point of the densification zone, in which the panel still undergoes displacement under high applied load, potentially translating the load to the protected members.

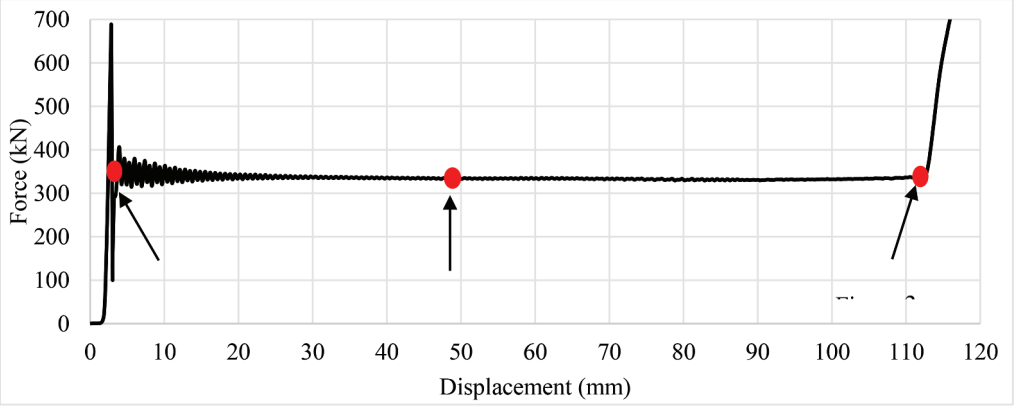

Figure 4. Load-Displacement curve of the honeycomb panel -150 mm.

The load-displacement curve of the two tested panels is presented in Figure 5; it is apparent that the density affects the energy-absorbing capacity of the overall system. However, due to the gradual deformation of the panel's layers along the thickness, the plateau stress continues for longer distance and duration, resulting in a total energy absorbing capacity of the large panel equal to 58.7 kJ compared to 38.3 kJ for the small panel.

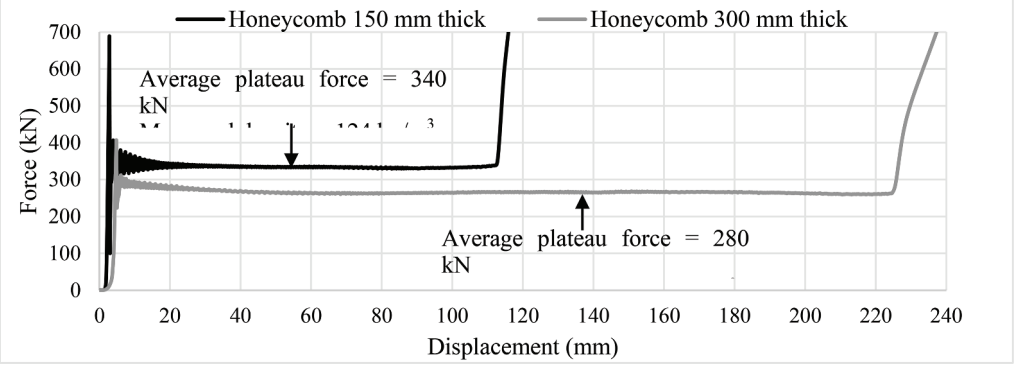

Figure 5. Load-displacement curve of the two tested panels.

4 ANALYTICAL ASSESSMENT OF HONEYCOMB PANELS

The energy absorbing capacity of the honeycomb sandwich panel was calculated using the procedure of Ashby and Medalist (1983) and Lu and Yu (2003). The relative density of the panel as it called cellular materials (ρ_c) can be obtained for general cellular materials. The relative density was experimentally demonstrated to be the significant factor that affects the mechanical properties of the cellular materials, including plateau stress, Young's Modulus, and densification strain, which governs the energy-absorbing capacity of these materials. The relationship model between the density and the mechanical properties of cellular materials was developed by Ashby and Medalist (1983), and it is known as the Gibson-Ashby Model. Like other cellular materials, honeycombs undergo three stress zones: elastic, plateau, and densification stress. The corresponding densification strain represents the point when the material absorbs energy, but transfers stress to the protected structure. Therefore, the energy-absorbing capacity of the panels was estimated by computing the area under these three regions of the stress-strain curve.

A regular honeycomb panel was used in this study, which has hexagonal cell shapes with equal side lengths and the angle of the cells ($\theta = 30^{o}$), the following equations (1- 4) were adopted to determine the relative density, plateau stress, and densification strain, which were used to estimate the energy-absorbing capacity of the panels.

$$\frac{\rho_c}{\rho_s} = \frac{2}{\sqrt{3}}\frac{t}{l} \tag{1}$$

$$\sigma_c = 5.6\ \sigma_s\left(\frac{t}{l}\right)^{\frac{5}{3}} \tag{2}$$

$$\varepsilon_D = \rho_c = 1 - \ 1.4\ \frac{\frac{t}{l}\left(\frac{h}{l}+2\right)}{2\cos\theta\left(\frac{h}{l}+\sin\theta\right)} \tag{3}$$

$$\mathrm{W}_\omega = \int_0^{\varepsilon} \sigma(\varepsilon)d\varepsilon \tag{4}$$

where ρ = density; E = modulus of elasticity; and σ = yield strength. Substrate "$_c$" is the corresponding property for the cellular structure. In contrast, the substrate "$_s$" refers to solid materials. ε_D = densification strain of the cellular product; t = foil's thickness; and h and l = the side lengths of the cell of the cellular structures in the in-plane direction; and W_ω = energy absorbing limit of the cellular material per unit volume.

In Table 1 below, a comparison is presented between the analytical approach to highlight the density and corresponding energy-absorbing capacity (EAC) in contrast to the experimental results of this study. Considering that the analytical approach is based on optimal panel properties, such as the exact hexagonal shape of the cells, foil thickness, and precise panel dimensions, a slight difference between the analytical and experimental results was observed.

For the large specimen, which has a measured density of 107 kg/m^3, close to the calculated analytical density of 103.4 kg/m^3, the experimental energy-absorbing capacity of the panel (58.7 kJ) is almost the same as the analytical value (60 kJ). However, the larger actual density of the small specimen resulted in a greater gap between the analytical and experimental values.

Table 1. Analytical and experimental comparison of two aluminium honeycomb panels.

Panel dimensions	Analytical approach		Experimental results	
mm	Density (kg/m^3)	EAC (kJ)	Density (kg/m^3)	EAC (kJ)
300 × 300 × 300	103.4	60.1	107	58.7
300 × 300 × 150	103.4	30.05	124	38.3

5 CUSHION APPLICATION IN PRACTICE

The results obtained in this study highlight the potential efficacy of employing honeycomb structures as a cushioning system to protect bridge girders from collisions with over-height vehicles. The energy-absorbing capacity of the honeycomb panels, as revealed in the small and large samples, is noteworthy. Specifically, a 150 mm thick panel demonstrated an energy absorption of 38.3 kJ, while a larger panel with a slightly reduced density exhibited 58.7 kJ.

It is essential to recognise that real-world collisions involving over-height vehicles can vary significantly in mass, ranging from a few kilograms to several tons. A parametric study by Yang and Qiao (2010) explored the impact mass of over-height materials from large trucks, ranging from 30.2 kg to 4.6 tons. Table 2 summarises the practicality of this study's panels regarding the actual cost, the total materials required, and associated prices for protecting a specific length of bridge girders. Additionally, the table presents the corresponding weights of the entire system, serving as a superimposed dead load on the structures. The cost for the required materials to protect 22 m of the susceptible bridge stands at 2000 US$, establishing the application of honeycomb structures as an attractive solution due to their efficiency, cost-effectiveness, and ease of installation.

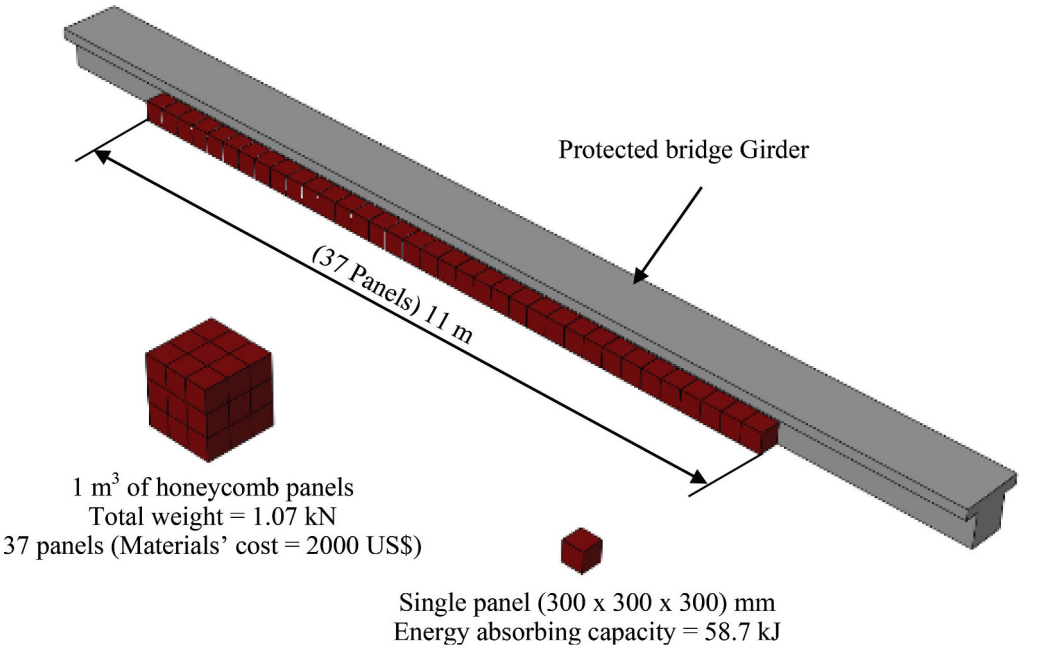
Table 2. Cushion-related features for practical applications.

Property	Large panel 300 ×300 × 300	Small panel 300 ×300 × 150
Density (kg/m3)	107	124
Energy absorbing capacity (kJ)	58.7	38.33
Cost of single panel (US$)	53	26.5
Mass of a single panel (kg)	2.895	1.673
Number of panels/cubic meter	37	74
Protected Bridge width (m)	11	22
Cost of the materials (US$)	1963	1963
Superimposed dead load (kN)	1.07	1.24

The large panel's practical properties, as detailed in Table 2, are illustrated in Figure 6 below. The bridge girder section in this figure represents the protected end girder of a susceptible low-clearance bridge. In practice, it is not necessary to incorporate all 11 meters (37 panels) on a single bridge. However, the total length was utilised for explanation purposes. It is essential to note that the total cost in the figure solely represents the cost of the materials, excluding considerations for transportation and installation phases. Additional materials, such as adhesive for bonding the panels to the girder, are also required to implement the protective system in practice.

To illustrate the practical application of honeycomb cushions, Figure 7 is presented, showcasing the efficiency of two different-sized honeycomb panels across various impact scenarios. It is worth mentioning that the analysis assumes that only the over-height portion of vehicles engaged in the collision with the bridge girders and the standard impact width is set at 2.5 m (width of the truck). The findings indicate that large panels can effectively protect a bridge girder against impacts up to 489.1 kg, sufficient to withstand the energy generated by a two-ton mass moving at 22 m/s (79.2 km/h). Meanwhile, the smaller cushion proves adequate for impacts up to 319.4 kJ, protecting girders from a 1.5-ton object travelling at 18 m/s (65 km/h).
where: Impact energy = $0.5mv^2$, energy absorbing capacity of large and small panels (489.1 and 319.4) kJ results from multiplying the capacity of the individual panel by the standard width of the truck (2.5 m) and divided by the width of the unique panel (0.3) m.

It is essential to highlight that the establishment of Figure 7 assumes that all the impact kinetic energy from over-height vehicles is transferred to the impacting cushion and requires absorption. However, a significant portion of energy may be dissipated due to the rebound of the impacting object (restitution coefficient's effects) and the loss of energy during indentation,



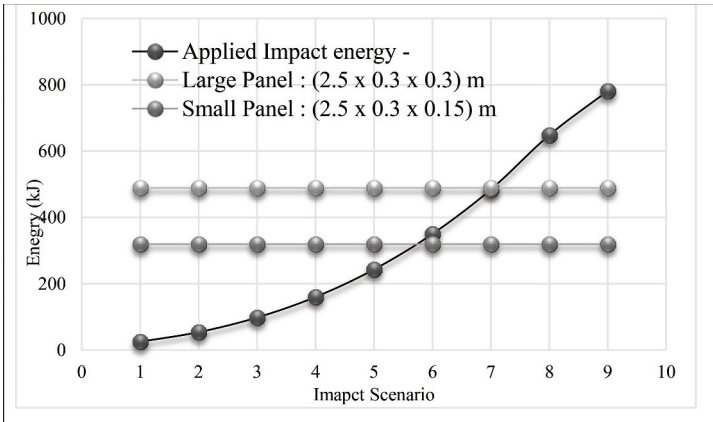


Figure 6. Illustration of the required materials, cost, and weight to protect 11 m length of bridge.

Impact scenario	Mass (kg)	Velocity (m/sec)
1	500	10
2	750	12
3	100	14
4	1250	16
5	1500	18
6	1750	20
7	2000	22
8	2250	24
9	2500	25

Figure 7. Energy absorbing capacity of two honeycomb panels against different impact scenarios.

as studied by Yang and Qiao (2010). Consequently, the cushion's effectiveness is evaluated against a conservative estimate of applied kinetic energy.

6 CONCLUSION

This study explores the potential use of aluminium honeycomb panels as sacrificial protection for bridge girders against impact from over-height vehicles. Two-panel sizes underwent quasi-static testing to determine their energy absorption capacity, which was then compared to analytical predictions. The alignment between observed and analytical results confirms the effectiveness of honeycomb cushions in mitigating impact loads on bridge girders. Panel density emerged as a critical factor affecting energy absorption. For example, a 300 × 300 × 150 mm

panel with a density of 124 kg/m^3 absorbed 38.3 kJ, while a larger 300 × 300 × 300 mm panel with a density of 107 kg/m^3 absorbed 58.7 kJ. Standardising panel density and refining manufacturing processes can enhance quality control in estimating energy absorption capacity for honeycomb cores with large thicknesses. This study represents a significant step in evaluating cushioning systems for practical use, contributing to the safety assessment of bridge infrastructure against over-height vehicle collisions. Its implications for transportation safety underscore its importance in advancing bridge safety measures.

Multi-hazard resilience-based bridge prioritization for aging bridge networks in a changing climate

L. Jafari & F. Biondini
Politecnico di Milano, Milan, Italy

ABSTRACT: Engineering structures and infrastructures are exposed to various hazards throughout their service life. When subjected to natural disasters, such as earthquake sequences and riverine floods, bridges emerge as highly vulnerable elements within transportation networks, which are important infrastructure facilities. The ongoing rise in greenhouse gas emissions, particularly carbon dioxide (CO_2), is widely regarded as the underlying cause of global warming and climate change that are posing a significant threat to various types of structures, including bridges. Studies have provided evidence that climate change is responsible for a rise in the frequency and magnitude of hydrological extremes. Intensified future design floods have been observed to lead to higher likelihood of increased scouring around river crossing bridge piers. Also, global warming and climate change accelerate aging and deterioration processes of materials and structural components. This paper presents a probabilistic resilience-based prioritization framework for aging bridges and bridge networks under multiple hazards, including seismic sequences, floods, and corrosion processes, in a changing climate. The proposed approach exploits multi-objective optimization to identify optimal solutions, determining the best retrofit methods, and prioritizing repair activities. The results of the application to a six-bridge transportation network address cost-effective enhancement of resilience by strategically managing rehabilitation activities.

1 INTRODUCTION

Over the lifespan of bridges within a transportation network, they may face not only a single hazard but a combination of hazards that can occur either sequentially or simultaneously (Argyroudis et al. 2020). Additionally, climate change poses significant impacts on both existing and future bridges' functionality, necessitating a comprehensive assessment of these effects in their lifetime. Fluctuations in precipitation intensity and quantity, coupled with temperature and humidity variations, stand out as the most evident indicators of climate change. As a bridge ages, its vulnerability due to corrosion becomes more distinct compared to its early years in service (Biondini & Frangopol 2016). These factors have the potential to amplify the vulnerability of structures when confronted with other hazards such as earthquakes and flooding (Milić & Marić 2023). The increase in the amount and intensity of precipitation leads to increase in higher level and frequency of floods and change in groundwater and geomechanical conditions. These outcomes lead to the activation of landslides, erosion, and soil liquefaction, which can also exacerbate the intensity of earthquakes and risk of scour (Harasti et al. 2021, Milić & Marić 2023). The altered precipitation patterns, additionally contribute to material degradation, a situation further compounded by the insufficient capacity of the drainage system. The increase in temperature and humidity can influence the structural dynamics, particularly in the case of steel bridges. Additionally, high temperatures may induce concrete cracking due to excessive stresses, potentially significantly reducing the lifespan of a structure, especially when exposed to aggressive environmental conditions (Nasr et al. 2020, Milić & Marić 2023, Nava et al. 2023). As stated, bridges may face various hazards, and it is imperative to mitigate consequences by deploying effective preventive and rehabilitation measures. The concept of resilience is extensively utilized to evaluate a system's capacity to mitigate

DOI: 10.1201/9781003483755-76

the impacts of hazards and recover, returning to its necessary functionality with both effectiveness and efficiency (Bruneau et al. 2003). Effectively managing rehabilitation interventions involves damage evaluation and condition assessment of structures. To ensure efficient decision-making, life-cycle resilience assessment and optimal resource allocation are crucial for bridges as vulnerable components of transportation networks. Resource allocation needs to take into account limitations related to the budget and availability of manpower and equipment for interventions. The adverse effects of climate change can be managed through adaptation measures and by implementing appropriate interventions to prevent or minimize the potential damage that such effects may cause (Figueiredo et al. 2023).

Numerous studies have suggested resilience-based approaches for prioritizing rehabilitation activities, whether post-event or pre-event, when exposed to single hazards (Capacci et al. 2022). Jafari et al. (2023a, b) developed a probabilistic framework that prioritizes both pre- and post-event interventions for bridge networks, accounting for aging and deterioration effects within mainshock-aftershock sequences. This probabilistic framework is extended in this paper to incorporate multiple hazards, specifically seismic sequences and floods as natural hazards, along with the environmental hazard of aging bridges affected by corrosion. The consideration of climate change effects on hazards and deterioration processes is also included. The proposed approach utilizes multi-objective optimization to identify optimal solutions, determining the best retrofit methods and prioritizing the initial time of repair activities. This aims to maximize aging bridge network resilience against prescribed multiple hazards while minimizing associated costs. Vulnerability assessment considers fragility curves, accounting for retrofitting, aging, deterioration, climate change and damage accumulation from previous hazards. The bridge network functionality is assessed using a traffic flow congestion metric, which considers travel time delays and distance increases during periods of reduced bridge traffic capacity caused by damage. The proposed approach is applied to a six-bridge transportation network including riverine bridges facing seismic scenarios and floods. The results address cost-effective enhancement of resilience by strategically managing rehabilitation activities. Considering that future climate change projections in bridge planning enables authorities to proactively prepare for a changing landscape, the implementation of the adaptation measures and rehabilitation strategies resulting from the proposed approach could be beneficial to reduce the potential impact of climate change on bridges, enhancing their resilience and functionality in the face of multiple hazards.

2 VULNERABILITY TO MULTIPLE HAZARDS

The vulnerability of a transportation bridge in the face of hazards is frequently assessed through fragility functions. These functions provide the likelihood of the bridge exceeding specified damage levels at given hazard intensity, such as peak ground acceleration (PGA) in earthquakes or parameters like water discharge or scour depth in floods (Nielson 2005, Argyroudis & Mitoulis 2021). There has been some research dedicated to creating fragility curves for multiple hazards irrespective of whether or not climate change is considered. Argyroudis and Mitoulis (2021) developed fragility surface for a typical river-crossing bridge exposed to flood and seismic hazard, considering the effect of scour, debris accumulation, and hydraulic forces along with seismic forces. Ghimire et al. (2022) developed fragility curves for earthquake and scouring scenarios, and their findings indicated that overlooking scouring conditions may lead to an underestimation of fragility across all damage states, highlighting the substantial impact of scouring if left unaccounted for. Mortagi and Gosh (2020) developed fragility curves for steel girder bridges exposed to earthquakes taking into consideration the effects of aging due to chloride-induced corrosion deterioration, and the impact of climate change on both the initiation time and rate of corrosion. Since the reference temperature T_0 and reference humidity RH_0 are taken as 20°C and 75%, respectively to predict initiation time and rate of corrosion, the study identified that the alterations in temperature T and relative humidity RH brought about by climate change are contributing factors to changes in the initiation time and rate of corrosion. The study also highlights that aging, along with the effects of climate change, exacerbates bridge vulnerability, emphasizing the critical importance of considering the influence of

initial temperature and relative humidity on seismic fragility estimates for aging highway bridges. Guo et al. (2019) introduced a scour-dependent empirical seismic fragility modeling approach, aiming to establish a fragility surface for earthquake and flood hazards. Their study underscores the significant influence of scour depth on the seismic performance of the investigated bridge system, especially regarding its contribution to severe damage. Different retrofit methods can be utilized to reduce the vulnerabilities of susceptible components in bridges, towards hazards. Various retrofit techniques for decreasing seismic vulnerability may involve seismic isolator bearings, seat extender, shear keys, different kinds of jacketing such as concrete, steel, fiber reinforced polymer (FRP), engineered cementitious composite (ECC), and fabric reinforced cementitious matrix (FRCM) jacketing. Riprap is one of the main approaches selected to minimize scour damage in the occurrence of flooding (Argyroudis et al. 2019). Additionally, the research illustrated that bridges equipped with seismic isolators exhibit lower vulnerability compared to non-isolated bridges when subjected to multiple hazards, including earthquakes and floods (Argyroudis & Mitoulis 2021, Billah & Iqbal 2022).

A fragility surface considering exposure to earthquake sequences and flood hazards as well as potential conditions of aging, climate change and retrofitting giving rise to as-built, retrofitted, state-dependent, and time-dependent fragility curves, can be formulated as follows (Argyroudis et al. 2019, Skokandić et al. 2022):

$$P[S_b \geq s_b|\hat{s}_b, r_b, i_b, t_b, Sc_b] = \Phi\left[\frac{\ln(i_b)-\ln(MF_a(s_b,t_b,T,RH)\cdot MF_{Sc}(s_b,Sc_b)\cdot MF(s_b,\hat{s}_b,r_b)\cdot MF_{Sc,r}(s_b,r_b,Sc_b)\cdot i_{b,m}(s_b))}{\zeta_{s,b}(s_b)}\right], \quad s_b > \hat{s}_b \tag{1}$$

where S_b is a variable denoting the damage state of the b-th bridge in the network, taking on values s_b = 0, 1, 2, 3, 4 corresponding to no damage, slight damage, moderate damage, extensive damage, and complete damage state, respectively; $\hat{s}_b$ represents the pre-existing damage state; r_b denotes the retrofit method, taking the value 1 for a non-retrofitted bridge, and values 2, 3, and so forth for various types of retrofit interventions; i_b signifies the seismic intensity at the b-th bridge site; Sc_b is scour depth at the b-th bridge site; $i_{b,m}$ (s_b) represents the median intensity measure leading to the exceedance of a given damage state s_b; $\zeta_{s,b}(s_b)$ is the standard deviation of the natural logarithm of the intensity measure leading to the exceedance of a given damage state s_b; t_b stands for bridge age; MF_a (s_b, t_b, T, RH) represents the modification factor for median values of fragility curves for damage state s_b, considering the bridge age t_b at the occurrence time of hazards integrating the consequences of anticipated shifts in temperature T and relative humidity RH, with MF_a (s_b, t_b, T, RH) ≤1. MF_{Sc} (s_b, Sc_b) functions as the factor that addresses the influence of scour depth on the vulnerability of bridges; MF (s_b, $\hat{s}_b$, r_b) denotes the modification factor for median values of fragility curves for damage state s_b, considering retrofit measure r_b and pre-existing damage state $\hat{s}_b$; $MF_{Sc,r}$ (s_b, r_b, Sc_b) is the modification factor utilized to incorporate the impact of riprapping or isolating on improving the fragility surface. Figure 1 shows typical trends of modification factors. Figure 2 shows typical fragility surface for combined earthquake and flood hazards considering the effect of deterioration and climate change (Figure 2a) and retrofits (Figure 2b). For $s_b = \hat{s}_b$, P [$S_b \geq s_b \mid \hat{s}_b$, r_b, i_b, t_b, Sc_b] = 1, and for s_b = 5, P [$S_b \geq s_b \mid \hat{s}_b$, r_b, i_b, t_b, Sc_b] = 0. Additional information can be found in Jafari et al (2023a, b).

The evaluation of the occurrence probability of damage state s_b on bridge b is therefore conducted using fragility curves in the following manner:

$$P[S_b = s_b|\hat{s}_b, r_b, i_b, t_b, Sc_b] = P[S_b \geq s_b|\hat{s}_b, r_b, i_b, t_b, Sc_b] - P[S_b \geq s_b + 1|\hat{s}_b, r_b, i_b, t_b, Sc_b], \quad s_b \geq \hat{s}_b \tag{2}$$

When $s_b < \hat{s}_b$, the probability of being in damage state s_b is null (P [$S_b = s_b \mid \hat{s}_b$, r_b, i_b, t_b, Sc_b] = 0). To quantify the damage level l_b for each bridge affected by earthquakes and flood, the average occurrence probabilities of different damage states can be utilized (Bocchini & Frangopol 2011):

$$l_b = E(S_b) = \sum_{s_b \geq \hat{s}_b}^{4} s_b \cdot P[S_b = s_b|\hat{s}_b, r_b, i_b, t_b, Sc_b] \tag{3}$$

The damage level l_b is limited to the interval [0, 5) ⊂ R. Bridges within a transportation network that are exposed to earthquakes and flood may experience varying levels of damage. The combination of these damage levels represents the overall damage state of the bridge network. In order to obtain a discrete number of damage combinations representative of bridge network damage state s, the damage levels l_b are rounded down to the nearest smaller integer, which takes the values 0, 1, 2, 3 and 4. More details can be found in Jafari et al. (2023a, b).

3 METHODOLOGY

A prioritized management plan for rehabilitation activities on aging bridges vulnerable to multiple hazards under climate change is established in order to maximizing network resilience R and simultaneously minimizing associated retrofit C_{Ret} and repair C_{Rep} costs. Resilience is characterized as the assessment of a network's reaction to hazards, encompassing qualities

such as robustness, rapidity of recovery process, resourcefulness, and redundancy in the face of potential threats. The resilience R can be quantitively defined by the integral mean of the functionality profile over a time horizon extending from the event occurrence time t_0 to a fixed horizon time $t_{\square}$. The functionality of the bridge network at each damage state s ($Q_i(s)$) is assessed using a metric defined by the increase in both total travel time $TTT(s)$ and total travel distances $TTD(s)$ resulting from the utilization of alternative routes when bridges are partially or fully closed. To assess resilience within the designated time frame, the network functionality is evaluated at each time step Δt_i of total number of steps N_t taking into account the damage status of bridges influenced by the impact of retrofit measures and the extent of repair. It is assumed that each bridge will recover from one damage state to the next within a given time interval. Damage state of bridges is evaluated by employing relevant fragility surfaces, as discussed previously. Three decision variables are considered for each bridge, including seismic retrofit r_b, flood retrofit $r_{b,Sc}$, and initiation time of repair activities $tInt_b$. Restrictions on the maximum number of repair activities occurring simultaneously $N^t{}_{SiAct}$ and the maximum duration of concurrent repair activities $N^T{}_{month}$ on various bridges are imposed due to resource limitations. The optimization problem is formulated as follows:

$$
\begin{aligned}
&\text{find}: \quad r_b,\, r_{b,Sc},\, tInt_b \\
&\text{so that}: \ \max R = \frac{1}{t_h - t_0} \sum_{i=0}^{N_t} Q_i(s) \cdot \Delta t_i;\ \min C = C_{\text{Ret}} + C_{\text{Rep}} \\
&\text{Constraints}: \\
&r_b \in \{1, 2, ..., N_{rb}\},\ r_{b,Sc} \in \left\{N_{rb}+1, N_{rb}+2, ..., N_{rb,Sc}\right\},\ tInt_b \in \{0 : \Delta t_i : t_h\} \quad \forall b = 1, 2, ..., N_b \\
&N^t_{SiAct} \le N^{\max}_{SiAct},\ N^T_{month} \le N^{\max}_{month}
\end{aligned}
\tag{4}
$$

This multi-objective constrained problem is solved using the NSGA-II meta-heuristic algorithm (Deb et al. 2002) with penalty functions. Decision-makers have the flexibility to choose optimal solutions from the Pareto-Front, which is derived by addressing the optimization problem, taking into account their specified resilience criteria, budget considerations, and available resources. Further details on how to exploit Pareto-Fronts can be found in Jafari et al. (2023a, b).

4 APPLICATION

The proposed approach is implemented on a hypothetical bridge network, shown in Figure 3a. It is assumed that B1 and B5 are multi-span continuous (MSC) concrete girder bridges, B2 is MSC steel girder bridge, B3 is multi-span simply supported (MSSS) steel girder bridge, and B4 and B6 are MSSS concrete girder bridges. The network is assumed to be situated in a seismic region with a considerable flood risk, expected to experience an increase in precipitation, attributed to climate change projections. A hazard scenario involving mainshock-aftershocks occurring at 0, 6, and 10 months, with magnitudes of 6.9, 7.5, and 6.0, respectively, is considered. The flood hazards are assumed to impact riverine bridges B1, B4, and B5 within the network. The seismic intensity i_b in PGA, obtained through attenuation law (Bindi et al. 2011), and flood hazard intensity in scour depth are illustrated in Figures 3b and 3c, respectively. At the occurrence of the mainshock, the six bridges are aged 50, 20, 40, 100, 70, and 80 years, respectively. The modification factor MF_a (s_b, t_b, T, RH) depicted in Figure 1b is applied to account for the average impact of variations in temperature (T) and relative humidity (RH) due to climate change on fragility curves of aged bridges. The effect of scouring is considered by applying modification factor MF_{Sc} (s_b, Sc_b) in Figure 1c. The possible seismic retrofits that can be applied on bridges are assumed to be steel jackets, elastomeric isolation bearings, restrainer cables, seat extenders, shear keys, concrete jacketing, ECC jacketing, CFRP jacketing and FRCM jacketing. The details for developing fragility curves of as-built and retrofitted bridges and required modification factor MF (s_b, $\hat{s}_b$, r_b) can be found in Jafari et al (2023a, b). The

flood retrofit methods include riprap and elastomeric isolation bearings and their associated modification factor $MF_{Sc,r}$ (s_b, r_b, Sc_b) are depicted in Figure 1d. The coordinates of nodes in the bridge network and the number of vehicles either originating from or being attracted to each node are listed in Table 1. Additional information regarding traffic characteristics, detours and traffic analysis of the bridge network, aimed at determining the network functionality under each damage state $Q(s)$, along with the necessary recovery time for each damage state of every bridge type, retrofit, and repair costs, can be found in Jafari et al. (2023a, b).

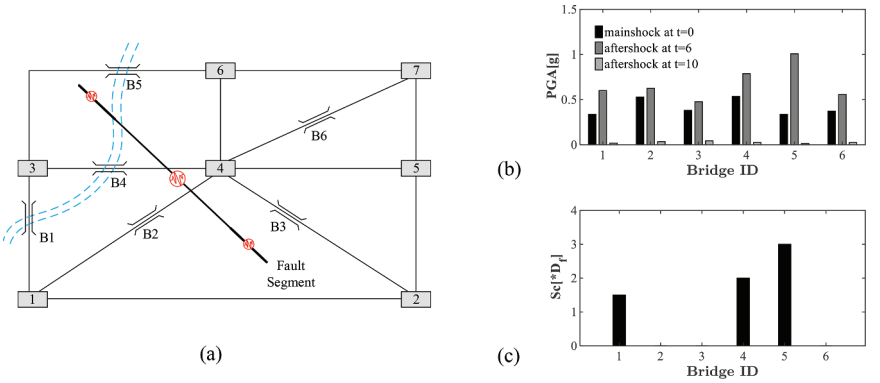

Figure 3. Six-bridge transportation network: (a) Bridge network layout; (b) Seismic demands at bridge sites associated with mainshock and aftershocks; (c) Scour depth (multiple of foundation depth D_f).

Table 1. Node characteristics of bridge network.

Node	1	2	3	4	5	6	7
X [km]	0	32	0	15	32	15	32
Y [km]	0	0	14	14	14	25	25
Originated vehicles [cars/h]	15400	16000	17000	28000	16500	19000	18500
Attracted vehicles [cars/h]	15400	16000	17000	28000	16500	19000	18500

The proposed methodology is applied to the network shown in Figure 3a and and resilience is computed over a 2-year horizon considering a time step of 0.2 month. Initial times of repair intervention are chosen from a 2-year horizon, allowing for a maximum of three simultaneous repair activities with a 12-month time interface on different bridges. Seismic retrofits r_b are chosen from {1,2, . . .,12}, representing no retrofit, steel jackets, elastomeric isolation bearings, restrainer cables, seat extenders, shear keys, restrainer cables & shear keys, seat extenders & shear keys, concrete jacketing, ECC jacketing, CFRP jacketing, and FRCM jacketing. Flood

Table 2. Details of selected pareto-front solutions.

#	Seismic retrofit/Flood retrofit interventions [ID]						Initial time of repair interventions [months]						Resilience [%]	Cost [M$]
	B1	B2	B3	B4	B5	B6	B1	B2	B3	B4	B5	B6

	13	3	1	13	13	3								

retrofits $r_{b,Sc}$ are selected from {1,3,13}, corresponding to no retrofit, elastomeric isolation bearings, and ripraps, respectively. The optimal Pareto-Front solutions is illustrated in Figure 4a. The details of selected solutions are presented in Table 2, featuring network functionality (Figure 4b) and bridge damage profiles (Figure 4c) with corresponding repair schedules (Figure 4d). These results provide key information for decision-makers.

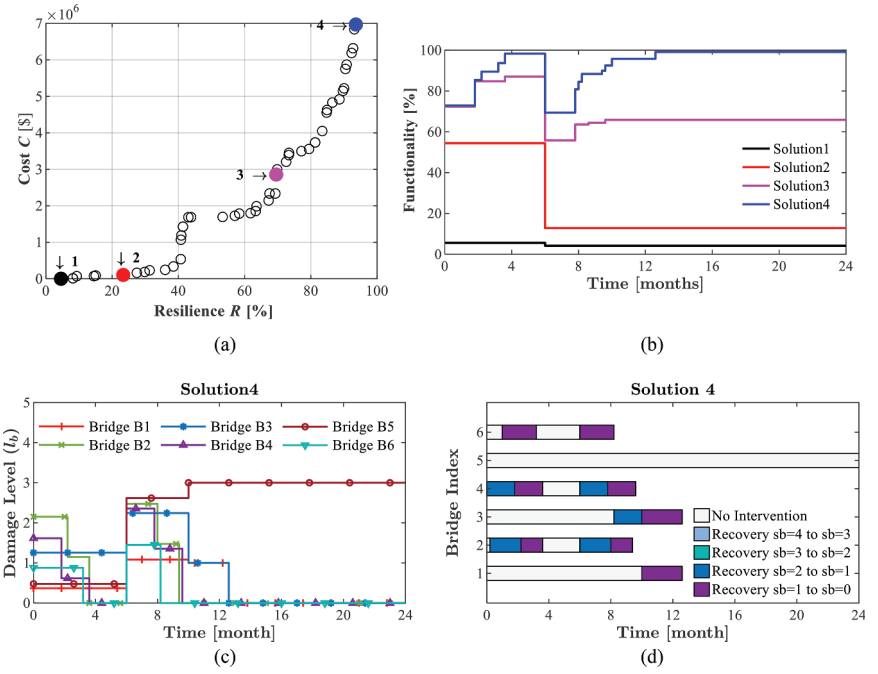

Figure 4. Solution of the optimization problem: (a) Pareto-Front with a selection of four optimal solutions; (b) Network functionality with recovery profiles of the four selected solutions; (c) Damage levels profile for solution #4; (d) Repair schedules associated with solution #4.

5 CONCLUSIONS

A framework for life-cycle management of aging bridge networks exposed to multiple hazards in a changing climate has been presented. The hazard scenario includes earthquake mainshock, aftershocks, floods, and deterioration processes influenced by climate change. Separate retrofit methods associated to each type of hazard implemented as pre-event activities are considered as decision variables to enhance the resilience of bridge network. Additionally, decision variables include the initial times of interventions on bridges, offering insights into effective post-event recovery. The prioritization of rehabilitation activities is determined by evaluating potential damages to each bridge, considering factors such as its location, exposure to hazards, importance, and its impact on traffic flow, along with considerations of time delay and distance increase. The vulnerability of bridges is estimated using fragility surfaces for multiple hazards. Resource limitations are addressed through constraints on the number of simultaneous rehabilitation activities and their duration on a limited number of bridges. The overarching goal is to maximize resilience while minimizing associated intervention costs. The results have been presented through Pareto- Fronts, providing decision-makers and managers with a range of solutions aligned with their budgetary constraints and resource availability, including labor and equipment. Future research can be dedicated on improving multiple hazards models and climate change projections, enhancing fragility surfaces, and developing comprehensive and realistic recovery models, to reach more effective management plan in the face of multiple hazards under a climate change.

ABSTRACT: Concrete-filled steel tubular (CFST) columns are increasingly used around the world due to their significant structural and economic advantages. Although considerable research and several experimental tests have been carried out on CFST col-umns, there are no mechanics-based probabilistic models of their axial capacity. The present paper proposes a mechanics-based probabilistic capacity model for the assessment of the ultimate axial capacity of CFST columns. The accuracy of the numerical predictions obtained with the proposed formulation is compared with that of existing capacity equations already in use within technical standards and available in the literature.

1 INTRODUCTION

Concrete-filled steel tubular (CFST) columns are largely employed around the world because they offer two significant advantages. The first one is the composite action of the steel tube and infilled concrete, which enhances the strength and ductility of the columns. The steel tube effectively confines the concrete core, thereby providing a highly ductile response under compression and increasing the overall energy dissipation capacity (Johansson, 2002). The second advantage is the use of the steel tube as a permanent formwork for concrete casting, which helps to reduce construction time and costs. In the last decades, multiple experimental findings (O'Shea and Bridge, 2000; Giakoumelis and Lam, 2004; Zeghiche and Chaoui, 2005; van de Lindt and Gupta, 2006) proved that the axial capacity of CFST columns N_u is generally higher than the sum of the axial capacities of their components, which are the steel tube and the concrete core. This mechanical behaviour is represented by the following inequality:

$$N_u - \left(f_c A_c + f_y A_s\right) > 0, \tag{1}$$

where f_c is the concrete compressive strength, f_y is the steel yielding strength, whereas A_c and A_s are the cross-sectional areas of concrete and steel, respectively. This behavior is attributable to the confinement effect provided by the steel tube on the concrete core. This confinement

DOI: 10.1201/9781003483755-77

effect, originally highlighted in (Gardner and Jacobson, 1967) determines an increment of the compressive strength of the concrete (Richart, Brandtzæg and Brown, 1928) that varies during the loading process of the CFST columns. The loading process of the CFST columns can be divided into three phases (Johansson and Gylltoft, 2001; Shanmugam and Lakshmi, 2001; Susantha, Ge and Usami, 2001; De Nardin, El Debs, and others, 2004; Sakino *et al.*, 2004).

According to the mechanical behaviour of CFST (Xue, Briseghella, and Chen, 2012), N_u can be estimated as the sum of the axial capacities of steel tube and confined concrete core using specific correction factors as follows:

$$N_u \simeq \left(f_{cc}A_c + \alpha_s f_y A_s\right), \tag{2}$$

where α_s is the factor that accounts for the reduction of the axial capacity due to the presence of the biaxial stress state inside the steel tube, and f_{cc} is the compressive strength of the confined concrete. Following a Mohr-Coulomb strength condition, the resistance of the confined concrete core can be obtained as follows:

$$f_{cc} = f_c + \alpha_c k_c \sigma_{c,r}, \tag{3}$$

in which α_c is a reduction factor related to the geometry of the concrete core, k_c is the confinement coefficient, and $\sigma_{c,r}$ is the radial compression stress.

In the literature, α_c is sometimes referred to as scale factor, and it is usually a function of the outer diameter of the CFST column D, as in (Morino, 2002) and (Hassanein *et al.*, 2018) where it is defined as

$$\alpha_c = \left(1.67D^{0.112}\right)^{-1}. \tag{4}$$

The values adopted for k_c vary within the different formulations available in the literature. While Richart et al. (Richart, Brandtzæg and Brown, 1929) suggested assuming a constant value in the range 4 − 4.1, Saatcioglu and Razvi (Saatcioglu and Razvi, 1992) showed that k_c can take values in the range 2.5 − 7, which decreases when the radial compression stress increases. Consequently, they proposed a formulation where k_c depends on $\sigma_{c,r}$ as follows:

$$k_c = 6.7(\sigma_{c,r})^{-0.17}. \tag{5}$$

The maximum confinement stress can be obtained from Barlow's formula (Timoshenko, 1983), assuming that the maximum tensile stress in the steel tube equals the steel yielding strength, and reads

$$\sigma_{c,r} = \frac{2t}{D} f_y, \tag{6}$$

where t is the thickness of the steel tube. By introducing the expressions for f_{cc} (Eq. 3) and $\sigma_{c,r}$ (Eq. 6) into Eq. (2), the axial capacity of CFST columns can be written as follows:

$$N_u \simeq \left\{1 + \left[\alpha_c k_c \left(\frac{2t}{D}\right)\frac{f_y}{f_c}\right]\right\} f_c A_c + \alpha_a f_y A_s. \tag{7}$$

In a more compact form, Eq. (7) can be rewritten as follows:

$$N_u \simeq f_c A_c (1 + \alpha_c k_c \psi + \alpha_a \xi), \tag{8}$$

where $\psi = (2t/D)\,/(f_y/f_c)$ and $\xi = f_y A_s / f_c A_c$. In technical standards and the literature, Eq. (7) is often presented as

$$N_u \simeq \alpha'_c f_c A_c + \alpha_a f_y A_s \tag{9}$$

assuming a constant value for α'_c. The values of α_s, α_c, k_c, and α'_c vary among the available formulations.

2 THEORETICAL BACKGROUND

Following (Gardoni, Der Kiureghian, and Mosalam, 2002), the proposed form of the axial capacity and reduction factors is written as follows:

$$T[C(\mathbf{x},\Theta)] = T\left[\hat{C}(\mathbf{x})\right] + \gamma(\mathbf{x},\theta) + \sigma\varepsilon, \tag{10}$$

where $T(\cdot)$ is a variance stabilizing transformation, $C(\mathbf{x},\Theta)$ is the dimensionless capacity, $\mathbf{x}$ are the measurable capacity variables, and $\Theta = \{\theta,\sigma\}$ are unknown model parameters. On the right side of Eq. (10), $\hat{C}(\mathbf{x})$ is a deterministic model based on mechanics rules (also borrowed directly from technical standards), $\gamma(\mathbf{x},\theta)$ is a correction term based on mechanics rules and evidence derived from the experimental data. The product $\sigma\varepsilon$ is the model error, with model standard deviation σ and normally distributed random variable ε. The model is based on three assumptions: additivity (i.e., the additivity of $\sigma\varepsilon$); homoskedasticity (i.e., the independence of σ from $\mathbf{x}$); normality (i.e., the normality of ε). Through a suitable choice of $T(\cdot)$, such assumptions can be approximately satisfied in the transformed space, within the range of the data used to calibrate the model. The correction term $\gamma(\mathbf{x},\theta)$ is selected as a linear combination of n dimensionless explanatory functions $h_i(\mathbf{x})$ and reads

$$\gamma(\mathbf{x},\theta) = \theta^{\mathrm{T}} \cdot \mathbf{h}(\mathbf{x}). \tag{11}$$

The set of explanatory functions $\mathbf{h}(\mathbf{x}) = \{h_1(\mathbf{x}),..,h_n(\mathbf{x})\}$ is constructed starting from physical variables not included in $\hat{C}(\mathbf{x})$ that may be relevant for the described physical phenomenon, but also from those included in $\hat{C}(\mathbf{x})$ and the effect of which should be recalibrated in light of the available experimental data. The parameters collected into Θ are calibrated using the Bayesian approach (Box and Tiao, 1992). It combines the prior knowledge on the parameters, which is contained in the prior distribution of Θ, $f'(\Theta)$, with the information provided by the data, which is contained in the likelihood function, $L(\Theta)$. The posterior distribution of the parameters $f''(\Theta)$ is defined as follows:

$$f''(\Theta) = kL(\Theta)f'(\Theta), \tag{12}$$

and it is obtained by dividing the product $L(\Theta)f'(\Theta)$ by the evidence k, which is the following normalizing constant:

$$k^{-1} = \left[\int_{\Omega_\Theta} \mathcal{L}(\Theta)f'(\Theta)\mathrm{d}\Theta\right], \tag{13}$$

where Ω_Θ is the parameters space.

The posterior distributions $f''(\Theta)$ obtained after the calibration can be used to find a point estimate for the model by ignoring the epistemic uncertainties in the model parameters. An alternative approach is used in the present study, which also accounts for the epistemic uncertainties in the model parameters. This alternative approach assumes Θ as random variables and find a predictive estimate of $C(\mathbf{x},\Theta)$ in agreement with (Gardoni, Der Kiureghian, and Mosalam, 2002) as follows:

$$\tilde{C}(\mathbf{x}) = \int_{\Omega_\Theta} C(\mathrm{x};\Theta)f''^{(\Theta)}\mathrm{d}\Theta. \tag{14}$$

Since an analytical solution for Eq. (16) is often missing, it is opportune to find a numerical approximation of the distribution of $\tilde{C}(\mathbf{x})$ by sampling from $f''(\Theta)$ and finding the corresponding realizations of $C(\mathbf{x};\Theta)$. In this way, it is possible to assume the sample mean of such realizations as predictive estimate and define the $\alpha\%$ confidence interval, where the lower and upper bounds are given by:

$$\{0.5(100-\alpha),\ [100-0.5(100-\alpha)]\}. \tag{15}$$

In this specific case, non-informative priors are chosen in the form of Gaussian distribution with zero means and large variance for all the parameters. In order to facilitate the use of the model and its possible implementation into technical standards, it should be parsimonious (i.e., with a correction term constructed using a limited number of explanatory functions n) and as accurate as possible (i.e., with a small value of standard deviation σ). However, a reduction of n usually entails a higher value of σ. Stepwise deletion allows finding a compromise between parsimony and accuracy. There are several procedures to apply stepwise deletion, and they mostly differ in the deletion criteria, such as the stepwise deletion based on p-values (Stone, 1996).

The stepwise deletion process used in this paper starts with a model that includes all the candidate explanatory functions, and at each step removes the explanatory function with the highest coefficient of variation (COV) of the corresponding θ_i, as proposed in (Gardoni, Der Kiureghian, and Mosalam, 2002). Once an explanatory function is removed, the model is re-calibrated and the deletion process repeated. The deletion process ends when either σ grows beyond an undesirable threshold, or the increment of σ is too large compared to the reduction of the model complexity.

3 THEORETICAL BACKGROUND

The model of the axial capacity of CFST columns follows the form presented in Eq. (10). The modeled non-dimensional capacity parameter is $C(\mathbf{x}, \Theta) = \tilde{N}_u(\mathbf{x}_u, \Theta_u)/N_c$, i.e., the ratio between the axial capacity of CFST columns $\tilde{N}_u(\mathbf{x}_u, \Theta_u)$ and the total compressive strength of the concrete core $N_c = f_c A_c$. For this model, the measurable capacity variables are $\mathbf{x}_u = \mathbf{s}$, and $\Theta_u = \{\theta_u, \sigma_u\}$ is the set of unknown model parameters. The variance stabilizing transformation used to approximately satisfy the additivity, normality, and homoskedasticity assumptions is the natural logarithm $T(\cdot) = \ln(\cdot)$ (Box and Tiao, 1992). The chosen deterministic model is the ratio between the plastic compression resistance $N_{pl} = f_c A_c + f_y A_s$ and N_c, i.e., $\hat{C}(\mathbf{x}) = N_{pl}/N_c = 1 + \xi$. Consequently, Eq. (10) is rewritten as

$$\ln\left[\frac{\tilde{N}_u(\mathbf{x}_u, \Theta_u)}{N_c}\right] = \ln(1+\xi) + \gamma_u(\mathbf{x}_u, \theta_u) + \sigma_u \varepsilon, \tag{16}$$

or, equivalently, as

$$\ln\left[\frac{\tilde{N}_u(\mathbf{x}_u, \Theta_u)}{N_{pl}}\right] = \gamma_u(\mathbf{x}_u, \theta_u) + \sigma_u \varepsilon \tag{17}$$

Through this formulation, the axial capacity of the CFST column is expressed as follows:

$$\tilde{N}_u(\mathbf{x}_u, \Theta_u) = N_{pl} \mathrm{e}^{[\gamma_u(\mathbf{x}_u, \theta_u) + \sigma_u \varepsilon]}, \tag{18}$$

and the exponential factor derived from the correction term assumes the meaning of Strength Index (SI), which is a dimensionless parameter that quantifies the strength improvement of CFST columns due to the confinement effect and defined as the ratio N_u/N_{pl} (Wang, Fan, and Lai, 2022). Given the normality assumption, a 67% confidence interval for $\ln\left[\tilde{N}_u(\mathbf{x}_u, \Theta_u)/N_c\right]$ can be found as follows:

$$\{\ln(1+\xi) + \gamma_u(\mathbf{x}_u, \theta_u) - \sigma_u, \ln(1+\xi) + \gamma_u(\mathbf{x}_u, \theta_u) + \sigma_u\}, \tag{19}$$

whereas the corresponding confidence interval for $\tilde{N}_u(\mathbf{x}_u, \Theta_u)$ is

$$\left\{N_{pl} e^{[\gamma_u(\mathbf{x}_u, \theta_u) - \sigma_u]}, N_{pl} e^{[\gamma_u(\mathbf{x}_u, \theta_u) + \sigma_u]}\right\}. \tag{20}$$

Table 1 shows the set of non-dimensional candidate explanatory functions $h_{ui}(\mathbf{x}_u)$ used in the initial step of the stepwise deletion process. The first explanatory function $h_{u1}(\mathbf{x}_u)$ takes into account a possible constant bias. The second and third explanatory functions, $h_{u2}(\mathbf{x}_u)$ and $h_{u3}(\mathbf{x}_u)$, are suggested by the formulation proposed by the Eurocode 4 (Eurocode 4, 2004) and are used to evaluate the possible effects of the relative slenderness λ_r defined as follows:

$$\lambda_r = \left(\frac{N_{pl}}{N_{cr}}\right)^{\frac{1}{2}}, \tag{21}$$

where

$$N_{cr} = \frac{\pi^2 EI_{eff}}{L^2} \tag{22}$$

is the elastic critical normal force for the relevant buckling mode, L is the length of the CFST column, and EI_{eff} is the characteristic value of the effective flexural stiffness of the cross-section given by

$$EI_{eff} = E_s I_s + 0.6 E_c I_c. \tag{23}$$

Herein, I_s and I_c are the second moments of area of the steel tube and concrete core, respectively. Moreover, E_s and E_c are the Young modulus of steel and concrete, respectively.

Table 1. Set of non-dimensional candidate explanatory functions $h_{ui}(\mathbf{x}_u)$ used in the initial step of the stepwise deletion process.

Explanatory functions		
$h_{u1}(\mathbf{x}_u) = 1$	$h_{u6}(\mathbf{x}_u) = \psi$	$h_{u10}(\mathbf{x}_u) = \xi$
$h_{u2}(\mathbf{x}_u) = \lambda_r$	$h_{u7}(\mathbf{x}_u) = \lambda_r \psi$	$h_{u11}\ (\mathbf{x}_u) = \lambda_r \xi$
$h_{u3}(\mathbf{x}_u) = \lambda^2{}_r$	$h_{u8}(\mathbf{x}_u) = \lambda_r^2 \psi$	$h_{u12}(\mathbf{x}_u) = \lambda_r^2 \xi$
$h_{u4}(\mathbf{x}_u) = \lambda$	$h_{u9}(\mathbf{x}_u) = \lambda \psi$	$h_{u13}(\mathbf{x}_u) = \lambda \xi$
$h_{u5}(\mathbf{x}_u) = \frac{t}{D}$	—	$h_{u14}(\mathbf{x}_u) = \frac{t}{D} \xi$

Similarly, $h_{u4}(\mathbf{x}_u)$ explores the possible contribution of the geometric slenderness ratio $\lambda = L/D$, whereas $h_{u5}(\mathbf{x}_u)$ reflects the contribution of the relative thickness of steel tube and concrete core. The explanatory functions $h_{u6}(\mathbf{x}_u)$-$h_{u9}(\mathbf{x}_u)$ and $h_{u10}(\mathbf{x}_u)$-$h_{u14}(\mathbf{x}_u)$ search for the interactions between the same effects relevant for the explanatory functions $h_{u1}(\mathbf{x}_u)$-$h_{u5}(\mathbf{x}_u)$ and the contributions due to the confinement effect and steel tube (i.e., ψ and ξ, respectively). The model $\tilde{N}_u(\mathbf{x}_u, \boldsymbol{\Theta}_u)$ is calibrated with records from the database analysed in (Thai *et al.*, 2019). The database contains tests conducted on both rectangular and circular CFST columns and includes data obtained from specimens with high-strength materials and slender sections. Some of the data are collected from tests where the normal force is applied in an eccentric position (i.e., tests where the members are subjected to combined axial compression and bending moment). Only data from tests without eccentricity of the applied axial loads and CFST columns with circular cross-section are herein used for the calibration of $\tilde{N}_u(\mathbf{x}_u, \boldsymbol{\Theta}_u)$, thereby resulting in a total of 815 records. Figure 1 presents the results of the stepwise deletion process for the axial capacity model. For each step, the figure shows the value for the posterior mean of σ_u, which is represented by a square, and the coefficients of variation of the θ_{ui}'s related to the h_{ui}'s included at that step, which are represented by dots. The dots with a cross denote the coefficients of variation of the terms that are dropped. The red line represents the value of σ_u at the first step, and it is used to facilitate the comparison with the values of σ_u in the following steps. The figure also explicitly shows the values of σ_u at some selected steps.

In the first step, the selection process removes h_{u4}, which is the term associated with the parameter that has the largest coefficient of variation, θ_{u4}, being $\mathrm{COV}_{\theta_{u4}} = 1.57$. One term is removed at each step up to Step 10, which leads to the elimination of θ_{u12} and a 5% cumulative increase in σ_u. The process stops at Step 11 because removing h_{u1}

would result in a cumulative increase in σ_u higher than 10%, which is deemed excessive, and because the additional step would entail an increase in σ_u equivalent to the cumulative increase of the first 10 steps. The 10% threshold is chosen to have a parsimonious model that could be adopted in technical standards. Moreover, the difference in accuracy between the reduced model and the full model (i.e., the model obtained without applying the stepwise deletion process) is limited. The reduced model resulting from the selection process has $\gamma_u(\mathbf{x}_u, \theta_u)$ in the following form:

$$\gamma_u(\mathbf{x}_u, \theta_u) = \theta_{u0} + \theta_{u2}\lambda_r + \left(\theta_{u10} + \theta_{u14}\frac{t}{D}\right)\xi \ . \tag{24}$$

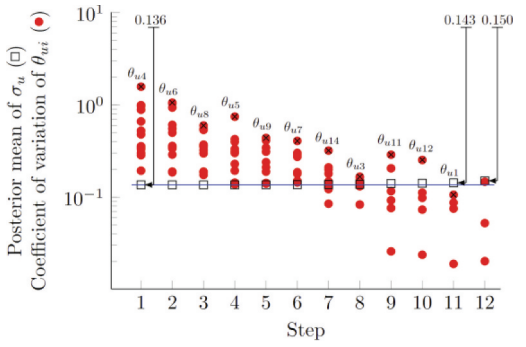

Figure 1. Stepwise deletion process for the axial capacity model.

This formulation suggests that there may be a systematic bias in the deterministic predictions obtained with N_{pl} because h_{u1} is retained in the model. It also shows that λ_r plays a significant role in reducing the axial capacity of CFST columns. The combined effect of h_{u10} and h_{u14} likely accounts for the confinement effect, which is proportional to the compressive strength of the steel column and depends on the t/D ratio. Table 4 gives the posterior statistics of the five model parameters. Figure 2 shows the predicted versus measured capacity for each test. The closer the data points are to the 1:1 lines (i.e., the continuous lines in the figure), the more accurate are the predictions. Figures 2(a) and 2(b) compare predictions made considering the plastic resistance to compression.

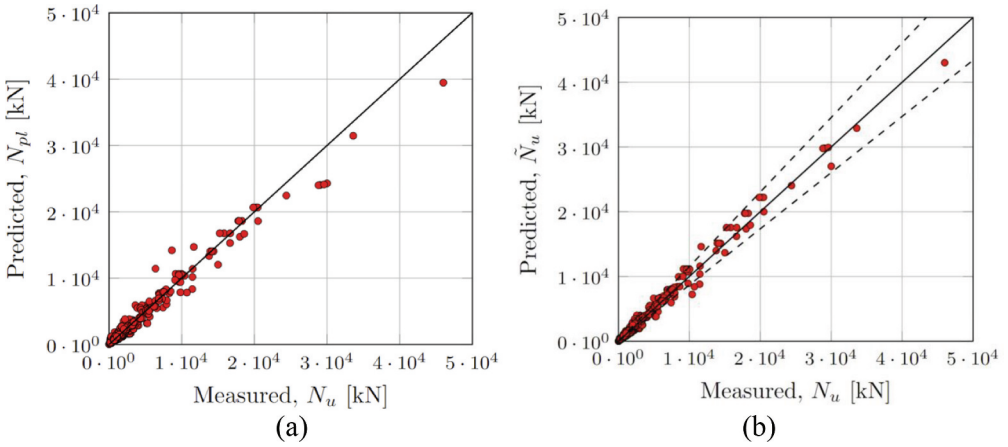

Figure 2. Predicted versus measured values of the axial capacity: (a) predictions with plastic resistance to compression; (b) predictions with proposed probabilistic model.

4 COMPARISON BETWEEN STANDARDS AND LITERATURE FORMULATIONS

Figure 3 presents a comparative assessment of the axial capacity of CFST columns in terms of the ratio between numerical predictions and corresponding experimental values $r_u = N_u pre/N_u exp$. The figure presents both predictions made with code-conforming formulations (ACI Committee 318, 1995; Eurocode 4, 2004; AISC Committee and others, 2010; GB 50923-2013, 2013) and with formulations from the literature (Goode and Narayanan, 1997; Giakoumelis and Lam, 2004; Ho and Le, 2021). A short presentation of these formulations is provided in Appendix. This assessment is intended to analyse the differences between the formulations and should not be considered as a competitive evaluation of their accuracy. This is because the existing formulations considered for the present comparative assessment might have been developed on a testing dataset instead of the complete dataset, or because the code-conforming formulations require design values and are not intended for mean values, or even because the considered formulations may not be valid for the intervals of the parameters in the considered dataset. Table 2 shows the statistics of the distributions of r_u obtained from the different formulations considered in the comparative assessment.

Table 2. Comparison between literature and technical standards, where S.D stands for Standard Deviation while M.S.E. for Mean Square Error.

Formulation	Mean	S.D.	M.S.E.
EC4	1.084	0.593	0.359
AISC	1.091	0.472	0.231
ACI	1.033	0.453	0.206
Goode et al. (1997)	0.627	0.284	0.219
Giakoumelis and Lam (2004)	1.293	0.546	0.384
Xue et al. (2013)	0.912	0.189	0.044
Ho and Le (2021)	1.188	0.230	0.056
Proposed	1.011	0.155	0.024

It can be observed from Figure 3 and Table 2 that all code-conforming formulations tend to underestimate the axial capacity of CFST columns. The formulations collected from the existing literature show a progressive increment of accuracy in time. Particularly, the formulation proposed by Ho and Le (Ho and Le, 2021) based on support vector machine and the one proposed

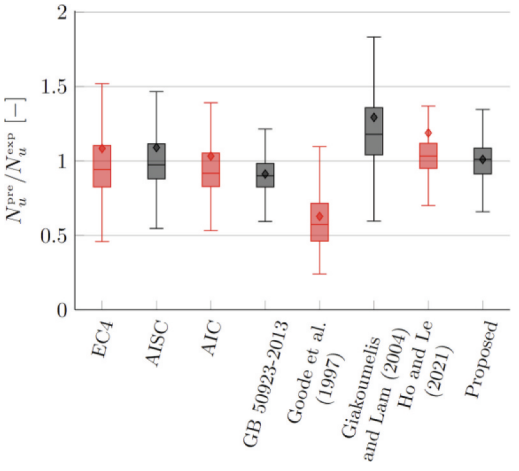

Figure 3. Comparison among predictions of the axial capacity of CFST columns in terms of box plot of the ratio between numerical predictions and corresponding experimental values $N_u pre/N_u exp$ (complete dataset of 815 samples).

in the present study show comparable levels of accuracy. The main difference with the earliest formulations (Goode and Narayanan, 1997; Giakoumelis and Lam, 2004) is the lack of the confinement effect, which is either not considered (in (Goode and Narayanan, 1997)) or overestimated (in (Giakoumelis and Lam, 2004)).

5 DERIVATION OF UNCERTAINTY FACTORS FOR DESIGN APPLICATION

The potential use of the proposed formulation for practical applications requires the definition of an uncertainty factor γ_{Nd} for the calculation of the design value of the axial capacity. Such uncertainty factor is needed to avoid the underestimation of the axial capacity due to the involved uncertainties, in such a way that the design can ensure a safety margin in compliance with code regulations. The code-format design axial capacity can be defined as follows:

$$N_{ud} = \frac{\eta}{\gamma_{Nd}} \tilde{N}_u(\mathbf{x}_{ud}, \Theta_u), \tag{25}$$

where η is a conversion factor that depends on the technical standard (Eurocode 4, 2004) and $\mathbf{x}_{ud}$ is the vector of the design values of the capacity variables. In a similar fashion, for CFST columns with axial load applied in eccentric position or with debonding, the code-format design axial capacity reads

$$N_{ud} = \frac{\eta}{\gamma_{Nd}} \tilde{k}_e(\mathbf{x}_{ed}, \Theta_e) \tilde{N}_u(\mathbf{x}_{ud}, \Theta_u), \tag{26}$$

and

$$N_{ud} = \frac{\eta}{\gamma_{Nd}} \tilde{k}_d(\mathbf{x}_{dd}, \Theta_d) \tilde{N}_u(\mathbf{x}_{ud}, \Theta_u), \tag{27}$$

respectively. The estimation of γ_{Nd} is performed by assuming that the design value is less than the corresponding experimental value with a probability equal to p as

$$P\left[N_{ud} < N_u^{exp}\right] = p. \tag{28}$$

The value of p depends on the reference technical standard. The estimation of γ_{Nd} is performed with $\eta = 1$ and characteristic values of compressive concrete strength and steel yielding stress equal to those in the experimental database used for the model calibration. The ratio of the number of samples for which $N_{ud} > N_u^{exp}$ and the total number of samples is used to estimate $P[N_{ud} < N_u^{exp}]$ and the corresponding value of γ_{Nd}. Table 3 compares the values of γ_{Nd} obtained for three different technical standards, namely Eurocodes, AASHSTO, and GB50923-2013.

The European building code sets p as $\Phi(\alpha_R \beta_{LS})$, where $\Phi(\cdot)$ is the standard Normal cumulative distribution function, α_R is the sensitivity factor for the capacity, and β_{LS} is the safety index relevant to the considered limit state. Assuming a 50-years reference period and an ultimate limit state, $\Phi(\alpha_R \beta_{LS})$=0.9988. For AASHSTO, the value of p is derived as $p = \Phi(3.5) = 0.9997$ because $\beta = 3.5$ is the target reliability index. Following the specifications of the GB50923-2013 technical standard, the value of p is derived assuming a ductile failure and the 2nd safety level, which lead to $p = \Phi(3.2) = 0.9993$. The calibration of γ_{Nd} is performed with all available data, including those with eccentric applied axial load and debonding. The accuracy in approaching the target values of p and, consequently, in defining an accurate value of γ_{Nd} is determined by both the number of available samples and the distribution of N_u^{exp}. Since 1006 tests are used, the probability values closer to the target values of p are $p^* = 1004/1006 = 0.9980$, $p^* = 1005/1006 = 0.9990$, and $p^* = 1006/1006 = 1.000$. The values of γ_{Nd} corresponding to the target values of p are obtained by linear interpolation. Table 3 shows the results of the calibration.

The higher values of γ_{Nd} derived for the AASHTO compared to those obtained for the Eurocode 4 and GB50923-2013 are due to both the higher target reliability index and the higher design values of the compressive concrete strength and steel yielding stress.

Table 3. Model uncertainty factors for γ_{Nd} for the proposed axial capacity derived according to the three different technical standards.

Technical Standard	Target p value	γ_{Nd} p=0.998	γ_{Nd} p=0.999	γ_{Nd} p=1.000	γ_{Nd} Interp.
EC4	0.9988	1.599	1.815	—	1.772
AASHTO	0.9997	—	2.276	3.128	2.872
GB50923-2013	0.9993	—	1.642	2.484	1.895

6 CONCLUSIONS

The beneficial interaction between steel tube and infilled concrete core has promoted the large diffusion of CFST columns in many projects over the years. To begin with, the concrete core prevents the inward local buckling of the steel tube. At the same time, the steel tube confines the concrete core. Such synergy results in high load-carrying capacity and enhanced ductility, that come together with economic and construction efficiency benefits due to the use of the steel tube as permanent formwork. Motivated by these attractive features, a large amount of experimental, analytical, and numerical studies about CFST columns under axial load have been performed in the last decades, but a probabilistic capacity model has not been proposed yet. Hence, the present study is meant at filling this gap and, to this end, proposed a comprehensive probabilistic model for the axial capacity of CFST columns. The probabilistic models for the axial capacity is derived by means of a Bayesian approach taking into rational account, both, model parsimony and model accuracy. The predictive performance of the proposed probabilistic capacity models are discussed within a comparative assessment that involves existing formulations collected from some available technical standards and previous researches. To foster the use of the proposed formulation for design purposes, the paper also provides uncertainty factors calibrated to meet the reliability levels required by three different technical standards.

ABSTRACT: Bridge condition assessment is vital for ensuring the safety and reliability of transportation infrastructure. Traditional inspection methods have limitations in terms of efficiency and coverage, motivating the exploration of innovative technologies. Our methodology introduces a robust image stitching approach, which enables the creation of full-scale views of target structures by seamlessly combining a vast number of single images from different vantage points. To facilitate efficient defect detection, segmentation techniques are used to automatically identify target structural surfaces and associated defects. This streamlined process significantly reduces the need for manual intervention, making the inspection more efficient and reliable. The advantages of the full-scale view-based approach lie in its ability to cover large bridge span with a single panoramic image, thus reducing the inspection time and enhancing safety by minimizing the need for inspectors to work in hazardous locations. The paper concludes by highlighting the significant impact of full-scale image-based assessment on bridge inspection, offering a cost-effective and reliable solution for infrastructure management. By leveraging advanced computer vision and deep learning techniques, the proposed approach represents a promising step towards ensuring the long-term integrity and safety of the transportation infrastructure.

1 INTRODUCTION

Bridges serve as essential components of transportation infrastructure, playing a crucial role in ensuring efficient connectivity and safe passage for vehicles and pedestrians(Lei et al., 2023). The assessment of bridge conditions is paramount to maintaining their structural integrity and, consequently, guaranteeing public safety (Lei et al., 2022, Dong et al., 2013). Traditional methods of bridge inspection often rely on visual assessments, which are not only time-consuming but also subject to human bias (Morgenthal et al., 2019). As the demand for more efficient and reliable inspection techniques grows, this study introduces a pioneering approach that combines full-scale view imaging and advanced computer vision methods for comprehensive bridge condition assessment.

The proposed methodology addresses the limitations of conventional inspection practices by leveraging a robust image stitching technique. This process seamlessly integrates numerous single images captured from diverse vantage points, creating expansive full-scale views of the target bridge structure. To enhance defect detection accuracy and streamline the inspection process, segmentation techniques are employed to automatically identify structural surfaces and associated anomalies (Gul et al., 2015). This innovative approach significantly reduces the reliance on manual intervention, thereby improving the efficiency and reliability of bridge assessments.

DOI: 10.1201/9781003483755-78

One of the key advantages of the full-scale view-based methodology is its ability to cover extensive bridge spans with a single panoramic image (Hu et al., 2023). This not only accelerates the inspection process but also enhances safety by minimizing the need for inspectors to work in hazardous locations. The amalgamation of advanced computer vision and deep learning techniques further contributes to the efficiency of defect identification and classification.

This paper aims to shed light on the transformative impact of full-scale image-based assessment on bridge inspections. By offering a cost-effective and reliable solution for infrastructure management, the proposed approach represents a significant advancement in ensuring the long-term integrity and safety of transportation infrastructure. Through the integration of cutting-edge technologies, this study contributes to the evolving landscape of bridge condition assessment, emphasizing the potential for improved accuracy, efficiency, and overall reliability in the evaluation of critical transportation assets.

2 OVERALL FRAMEWORK

The first step in our framework involves the application of a robust image stitching technique to seamlessly combine multiple images captured from diverse vantage points. This process aims to create comprehensive full-scale views of the target bridge structure. Advanced algorithms for image registration and feature matching will be employed to ensure the accurate alignment of images, resulting in a panoramic representation of the entire bridge span.

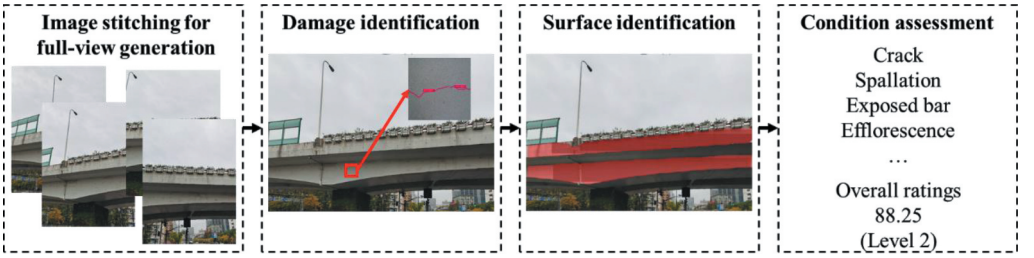

Figure 1. Full-view generation of bridge.

Following the generation of full-scale views, the next stage focuses on the automatic identification and segmentation of damaged areas on the bridge structure. Computer vision algorithms will be applied to analyze the visual data and detect anomalies or defects. These algorithms will be trained to recognize patterns associated with common types of structural damage, such as cracks, corrosion, or deformations. The output of this step is a segmented representation highlighting regions of potential damage.

To enhance the precision of defect detection and analysis, the framework includes a bridge surface segmentation process. This step involves the automatic identification and delineation of distinct structural surfaces within the bridge, such as decks, piers, and abutments. Accurate segmentation is crucial for isolating specific areas of interest, enabling focused assessments and reducing false positives in damage detection. Computer vision techniques, including semantic segmentation, will be employed to achieve reliable and detailed surface segmentation.

The final step of the framework involves a comprehensive structural assessment based on the segmented data. By integrating the information obtained from image stitching, damage segmentation, and bridge surface segmentation, the framework facilitates a holistic evaluation of the bridge's overall condition. Advanced algorithms, possibly incorporating machine learning models, will be employed to analyze the structural health and identify potential risks. The output will provide a detailed assessment report, highlighting the condition of different structural components and recommending necessary maintenance or repair actions.

By incorporating these four steps into our framework, we aim to establish a systematic and efficient approach to bridge condition assessment. The integration of image stitching, damage segmentation, bridge surface segmentation, and structural assessment leverages the capabilities

of computer vision methods to enhance the accuracy and reliability of the inspection process, ultimately contributing to the safety and longevity of critical transportation infrastructure.

3 IMAGE STITCHING METHOD

Image stitching is a computer vision technique used to combine multiple images into a larger, seamless panorama. This method is commonly employed to create panoramic photographs or to produce wide-angle views of scenes that cannot be captured in a single shot. The process involves aligning and blending overlapping images to create a cohesive and visually continuous result. Here is a step-by-step description of the image stitching method:

1) Image Acquisition: Capture a series of images of a scene, ensuring that each image overlaps with the adjacent ones. These images are usually taken from different viewpoints or angles.
2) Feature Extraction: Identify distinctive features in each image, such as corners, edges, or keypoints. These features serve as reference points for aligning and matching images.
3) Image Alignment: Align the images by matching the extracted features. This step involves adjusting the position, rotation, and scale of each image to ensure a precise overlap. Techniques like geometric transformation or homography are often used for this purpose.
4) Image Blending: Blend the aligned images seamlessly to create a smooth transition between them. This involves adjusting pixel intensities along the overlapping regions to avoid visible seams. Various blending algorithms, such as feathering or gradient-based blending, can be applied to achieve a natural and continuous appearance.
5) Panorama Composition: Combine the aligned and blended images into a single panoramic image. The resulting panorama provides a wide-angle view that encompasses the entire scene captured in the input images.
6) Color and Exposure Adjustment: Ensure consistent color and exposure across the panorama by applying adjustments to match the tones and lighting conditions of the original images. This step enhances the overall visual coherence of the stitched panorama.
7) Output: The final output is a seamless and visually cohesive panoramic image that represents a wider field of view than any of the individual input images. This stitched image provides a comprehensive representation of the captured scene.

4 DAMAGE SEGMENTATIONS

Damage segmentation with the YOLOv8 (You Only Look One-level) method involves employing a state-of-the-art object detection algorithm to identify and delineate areas of structural damage within images. YOLOv8 is part of the YOLO family of real-time object detection models, known for their speed and accuracy.

5 STRUCTURAL SURFACE SEGMENTATIONS

Structural surface segmentation with the YOLOv8 method involves leveraging the capabilities of the YOLOv8 object detection algorithm to automatically identify and delineate distinct structural surfaces within images of bridges. The final output includes visual representations of the original image with overlaid bounding boxes and segmentation maps, highlighting the identified structural surfaces. These visual outputs offer a clear and detailed overview of the different components, aiding in further analysis and assessment.

6 CONDITION ASSESSMENT

Condition assessment for bridges using full-view images involves a comprehensive analysis of the visual data captured through panoramic or full-scale images. Apply image stitching

Figure 2. Image capturing for the full-view stitching.

Figure 3. Full-view generation of bridge.

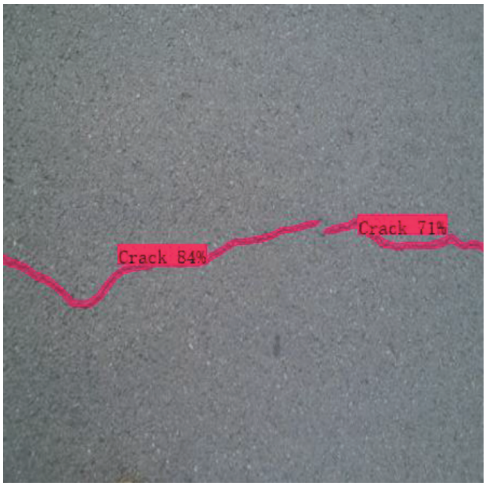

Figure 4. Damage segmentation.

Figure 5. Structural surface segmentations.

methods to seamlessly combine the individual images into a single, panoramic view. This creates a comprehensive representation of the entire bridge, allowing for a detailed inspection without the need for inspectors to physically traverse the structure. Perform quantitative analysis on the full-view images to assess parameters such as cracks, voids, spallation, etc. This involve comparing current conditions to baseline data or industry standards to determine the severity of identified issues.

Generate comprehensive reports and visualizations based on the analysis of the full-view images. This includes detailed maps of detected defects, the condition of structural components, and any recommended maintenance or repair actions. Visualization tools can assist in conveying complex information to stakeholders in an accessible manner. Integrate the findings from the full-view image assessment into broader infrastructure management systems. This allows for long-term tracking of the bridge's condition, facilitates maintenance planning, and supports decision-making for asset management.

7 CONCLUSIONS

In conclusion, the integration of full-view images and advanced computer vision methods for the condition assessment of bridges represents a significant leap forward in the field of infrastructure inspection. This study introduced a comprehensive framework that leverages panoramic images to provide a holistic view of bridge structures and employed sophisticated computer vision techniques, including image stitching, damage segmentation, and structural surface segmentation, to automate and enhance the assessment process.

Data-driven prediction models for extreme wave impacts on coastal bridges

Deming Zhu, Jiaxin Zhang & You Dong
Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong, China

ABSTRACT: Coastal bridges are susceptible to extreme waves during coastal natural hazards like tropical cyclones and tsunamis. The investigation of the structural performance of coastal bridges under extreme wave impacts plays a central role in the development of coastal communities. In recent years, deep neural networks based methods emerge and shown promising performance for these hydrodynamic problems. However, their interpretability and generalization remain a major challenge, especially for the complex uncertainties within the hydrodynamic process. In this study, the authors propose to combine the advantages of both experimental studies and deep neural networks for such investigations, so as to achieve reliability, network interpretability, and effectiveness simultaneously. Specifically, laboratory experiments are conducted to test the wave impacts on coastal bridges under various wave scenarios and hydrological environments. The measured wave profiles and wave loads are divided into a multivariate time series and used as the input of a Long-Short-Term-Memory (LSTM) model. Such a prediction method helps to reduce errors caused by experimental uncertainty by substituting every set of the collected data during the repeated experiments into the training set. In summary, the proposed scheme is effective and interpretable, and the comparisons with experimental results demonstrate its superior performance in predicting the structural performance of coastal bridges under wave impacts.

1 INTRODUCTION

Coastal bridges, serving as crucial elements within transportation systems in cities near shore, face significant safety risks due to the adverse natural environment. The rising sea levels and increasing intensity of hazards resulting from global climate change (e.g., tropical cyclones and tsunami-induced waves) have led to substantial damage to low-lying bridges in recent decades. A post-hazard survey reported that during Hurricane Ivan in 2004, 58 bridge spans became dislodged from their piers, and 66 spans experienced misalignment (Meng and Jin 2007). Afterward, Hurricane Katrina inflicted severe damage on the US 90 highway bridge over Biloxi Bay once again (Robertson et al. 2011). Among the critical failure modes observed in coastal bridges, the failure of deck unseating has been identified as a significant concern. Thus, this has motivated a number of studies to assess to magnitudes of wave loads and bridge failure mechanisms to improve the design and maintenance of coastal bridges.

The study of wave-bridge interactions faces a significant challenge concerning the limited availability of time series analysis of wave loads. While experimental tests and numerical simulations have been conducted to measure wave loads, most of these studies have primarily focused on capturing the maximum vertical and horizontal forces, neglecting the evolving process of external loads on the bridge surface (Jin and Meng 2011; Seiffert et al. 2016). Consequently, the structural performance of coastal bridges subjected to these extreme waves may lack accurate structural demand input, which merely compares the maximum load with the

DOI: 10.1201/9781003483755-79

static capacity of the bridge. This approach fails to fully predict the potential risks associated with periodic wave impacts during actual storm hazards, misleading maintenance and management strategies for high-risk bridges (Zhu et al. 2021b). To address this issue, this study measures the time histories of vertical and horizontal wave forces under different wave intensities. These measurements not only provide an intuitive reflection of the effects of different wave parameters but also serve as datasets for training prediction models.

Experimental methods are reliable for obtaining wave forces on coastal bridges but can be prohibitively expensive and challenging to conduct on a large scale (Xu et al. 2022). In an attempt to overcome these challenges, researchers and engineers have sought to develop full-scale numerical models to approximate wave forces under various hazard scenarios. However, the computational cost associated with creating a sufficiently large database often makes this approach impractical, particularly for reliability and life-cycle analyses that involve extensive computations (Jia et al. 2022; Xiao and Huang 2008). To address these limitations, machine learning (ML) methods have been employed to establish the relationship between input hazard intensities and output structural responses. For instance, Xu et al. (2022) found that ML models exhibited superior capabilities in estimating maximum wave forces, while more datasets were necessary to enhance model quality. Zhu et al. (2021a) utilized ML models to replace time-consuming simulations, facilitating risk assessment and the proposal of mitigation measures, and achieved satisfactory results. However, a common issue is that existing ML technologies primarily focus on peak values, while investigations into the effects of time series data are limited (Hu et al. 2023). Besides, numerical simulations remain the primary source of training data, limiting the wider applications of ML methods. To address this gap, the present study develops a Long Short-Term Memory (LSTM) network based on experimentally measured wave force time histories. Different hyperparameters are tuned and validated to enhance the accuracy of the model.

Overall, this study examines the effects of wave impacts on coastal bridge superstructures and develops data-driven ML techniques for predicting time series results. Laboratory experiments are conducted to investigate the time histories of wave forces. Based on the measured results, LSTM models are established to forecast wave impacts. The optimized LSTM model demonstrates favorable performance in forecasting wave forces under different wave scenarios. This model could provide more accurate load inputs for addressing the engineering challenge of coastal bridge interactions.

2 EXPERIMENT DESIGN FOR WAVE-BRIDGE INTERACTION

Laboratory tests are conducted in conjunction with activities at the Hydraulics Laboratory of the Hong Kong Polytechnic University, as shown in Figure 1(a). The 1:30 scale experiment is designed according to the open channel Froude similarity, which is suitable for phenomena where gravity and inertial forces are dominant, particularly for free surface flows (e.g., coastal structures and waves) (Yuan et al. 2022). The wave channel is 27 m in length, 1.5 m in width, and 1.5 m in depth. Solitary waves and regular waves are generated using a wave generator at one end of the channel. These two types of waves are used to study the extreme waves generated by the tsunami and tropical cyclone natural hazards, respectively. The storm-induced waves are highly periodic in nature, while tsunami waves are often caused by the displacement of a significant volume of water under the sea. For the regular waves, 5 different water depths D (0.48 m, 0.50 m, 0.52 m, 0.54 m, and 0.56 m) are selected. Four different wave heights H (0.10 m, 0.12 m, 0.14 m, 0.16 m) are paired with 6 different wave periods T (1.0 s, 1.2 s, 1.4 s, 1.6 s, 1.8 s, and 2.0 s) and tested under each water depth. With respect to the solitary waves, 6 different wave heights (0.10 m, 0.12 m, 0.14 m, 0.16 m, 0.18 m, and 0.20 m) are tested under the aforementioned 5 water depths. The selection of these wave parameters not only takes into account the performance of the wave generator but also satisfies the requirement that being converted to a prototype size can simulate the wave intensity in real disasters.

The dimensions of the investigated bridge specimen are plotted in Figure 1(b), which is a typical reinforcement concrete simply supported bridge in practical design (Robertson et al.

2007). The selected bridge span has a length of 15.85 m and a width of 10.8 m. The girder height is 1.37m and the deck thickness is 0.18 m. The overlength out of the two sides of the deck is taken as 0.5 m. To measure the external loads acting on the tested specimen, a three-axis force sensor is equipped. The sampling rate is set as 20 Hz. Each case is repeatedly tested 5 times to avoid experimental monitoring deviations. Figure 1(c) and 1(d) show two snapshots captured during the experiment, depicting specific moments in the specimen's behavior. Figure 1(c) corresponds to the moment just before the arrival of the wave, while Figure 1(d) captures the moment when the specimen is being subjected to wave impacts.

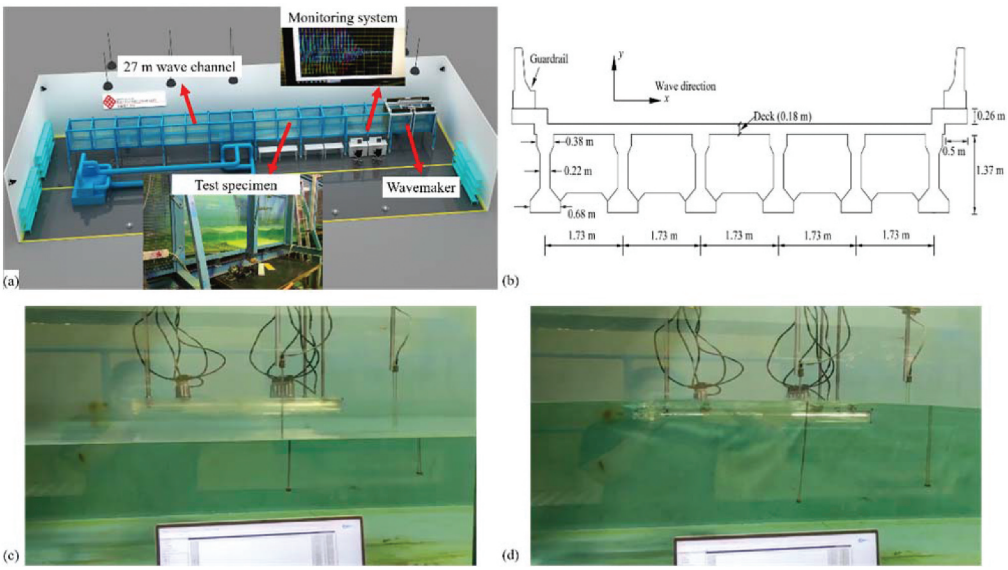

Figure 1. (a) Schematic diagram of the hydraulics laboratory and photos of experimental facilities; (b) dimensions of the investigated bridge superstructure model; (c) snapshots of the specimen before wave arrives; and (d) snapshots of the specimen under wave impacts.

3 LSTM PREDICTION METHOD FOR WAVE LOAD TIME HISTORIES

An LSTM network is employed in this study to predict wave force time series based on measured wave profiles. The LSTM network is an extension of the RNN architecture, incorporating four states within a single recurrent structure, which could overcome the limitations of conventional neural network architectures in handling input sequences that rely on the interdependence of information (Sherstinsky 2020; Zhang et al. 2021). These states enable the network to retain and manage input information over longer sequences. Each layer of the LSTM network consists of one recurrent structure, and the frequency of self-updates is determined by the input data dimensions and the number of cycles. This design allows the current LSTM layer to compute a single recurrent unit instead of multiple consecutive units, improving computational efficiency. In the trained LSTM cell, several components are involved in processing the input data. The input gate regulates the amount of current network input data that is stored in the unit at the current time step. The forget gate determines the extent of the transition from the previous state to the current state. Finally, the output gate controls the output of the current unit state. To assess the prediction performance of the LSTM models, two commonly used metrics are employed: mean squared error (MSE) and the R^2-score. MSE is a loss function that is typically minimized during network training. However, one limitation of MSE is that it does not account for the variability of the data since it assumes numerical values without normalization. To address this limitation, the R^2-score is utilized to evaluate the

predictive power of the model. The R^2-score measures the model's predictive performance compared to a trivial model that always forecasts the mean value of the observed data (where $R^2 = 0$). The R^2-score is widely used because it provides a normalized version of the R^2, making it a valuable metric for assessing the performance of the model. These two indicators are calculated as

$$MSE = \frac{1}{N}\sum (y - y')^2 \tag{1}$$

$$R^2 = 1 - \frac{\sum (y - y')^2}{\sum (y - \bar{y})^2} \tag{2}$$

where y = the measured data in the experiment; y' = the predicted value using LSTMs; and $\bar{y}$ = mean of the truth data.

4 WAVE-INDUCED LOADS ON THE BRIDGE SPECIMEN

To obtain more insight into wave force characteristics, time histories of vertical and horizontal wave forces are presented and discussed in this section. By collecting the measured results from the load cell, Figure 2(a) shows the time series results of the solitary wave case with D = 0.52 m and H = 0.18 m. Both the vertical wave force F_y and horizontal wave force F_x increase to a maximum value and then decrease as the propagation of the solitary wave. The maximum value of F_y is 101.36 N, and the maximum F_x is 44.78 N. The minimum forces occur at around 19 s, with F_y being -41.23 N and F_x being -14.56 N. Generally, the peak values of F_y and F_x in the positive directions (uplift and wave forward directions) are much larger than those in the negative directions. Figure 2(b) presents the time-dependent wave force acting on the specimen under a regular wave case with D = 0.52 m, H = 0.14 m, and T = 1.6 s. The wave forces also exhibit periodic fluctuations as the water surface rises and falls, but the differences in peak values between positive and negative directions are smaller compared to solitary waves. The maximum values of F_y and F_x are 43.24 N and 31.58 N, respectively, while the minimum values are -28.30 N and -12.63 N, respectively.

During the experimental tests, each wave case is repeated five times to mitigate monitoring deviations. Although the input parameters remain the same for repeated tests of the same wave case, there may still be slight variations in wave heights and waveforms during propagation, leading to deviations in the experimental measurements due to associated uncertainties. For example, in the repeated tests of a solitary wave case with D = 0.50 m and H = 0.20 m, the maximum vertical force ranges from 85.34 N to 89.17 N, and the horizontal force ranges from 50.03 N to 54.54 N. To address these deviations and uncertainties, the LSTM-based AI methods

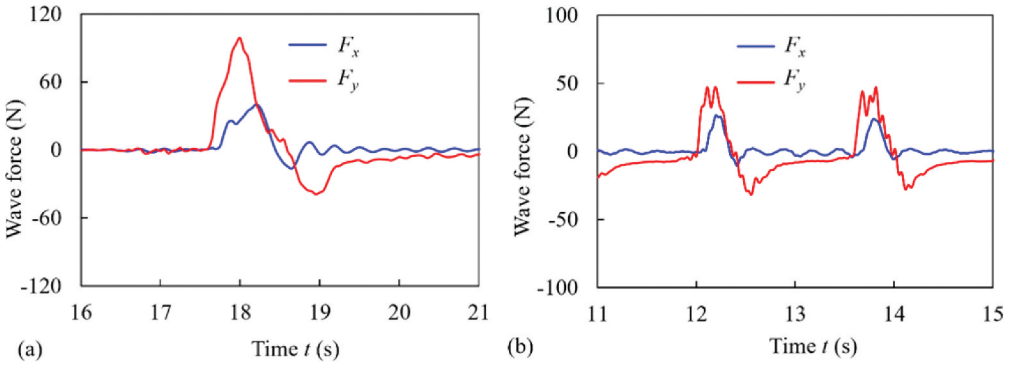

Figure 2. (a) Wave force time histories for the solitary wave case with D = 0.52 m and H = 0.18 m; and (b) wave force time histories for the regular wave case with D = 0.52 m, H = 0.14 m, and T = 1.6 s.

utilize all the test results in the training set. By directly relating the time histories of wave loads to the time-dependent water surface, the effects caused by changing wave profiles during wave propagation can be effectively mitigated. This approach overcomes the limitations of averaging the results after removing outliers, as is commonly done in experimental measurements, and provides a more comprehensive understanding of the wave load characteristics.

5 TRAINING OF THE LSTM MODEL

5.1 *Development of LSTM models*

In this study, the LSTM models are trained using experimental measured wave load time histories as the training database. The values of parameters water depth D, wave height H, and wave period T are chosen based on the experimental requirements to meet the wave-making conditions in the laboratory facilities. However, future studies may explore other value methods, such as stratified sampling and Latin Hypercube sampling techniques, to construct datasets with higher levels of independence. The changing wave profiles collected from the wave gauges are used as input to the LSTM models, while the wave force time series are used as the output. The training process utilizes 70% of the raw data as the training set, 15% as the test set, and the remaining 15% as the validation set. One potential advantage of this approach is that the LSTM prediction results can help reduce deviations caused by repeated tests since it incorporates all the available datasets.

After several trials, 128 hidden neurons are selected for the LSTM model. Each node in the fully connected layer is connected to all preceding nodes and plays a role in integrating the salient characteristics learned from earlier layers and capturing the hidden patterns in the time series. In this study, considering both computational efficiency and model accuracy, it is determined that 64 nodes in the fully connected layer are sufficient. The learning rate, a critical hyperparameter in supervised and deep learning, determines the speed at which the objective function converges to a local minimum. An optimal learning rate ensures that the objective function is resolved within a reasonable timeframe. Through rigorous experimentation, the optimal learning rate for this study is determined to be 0.005. The network training is conducted using TensorFlow, an open-source symbolic math library developed by the Google Brain team for machine learning applications. TensorFlow offers a flexible data flow architecture, enabling high-performance training of various neural network types on multiple platforms, including CPUs, GPUs, and TPUs. The simulations in this study are performed on a desktop computer equipped with 12th Intel Core i7-12700K CPUs and an NVIDIA GTX 1080Ti GPU card. The model training process takes approximately 10 hours to complete.

It is important to note that although the structure of the LSTM models is similar for both the solitary wave and regular wave cases, their hyperparameters, such as weights and biases,

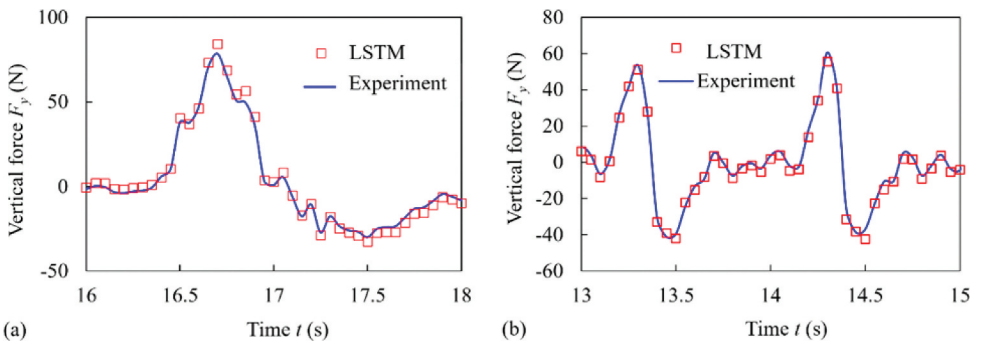

Figure 3. Comparisons between LSTM predicted wave force time histories with experimental measurements (a) solitary wave case with D = 0.50 m and H = 0.16 m; and (b) regular wave case with D = 0.50 m, H = 0.16 m, and T = 1.0 s.

are different due to the distinct characteristics of their input data. Figure 3 presents comparative results between the LSTM prediction of wave loads and the experimental measurements. It is worth mentioning that the cases shown in Figure 3 are all from the test set, not the training set. This means that the LSTM model has not been exposed to these specific cases during the training process. The high accuracy achieved in predicting these unseen cases demonstrates the model's generalization capability. The small loss value observed after 600 iterations and the good convergence observed in the comparisons further validate the prediction performance of the developed LSTM models. These results indicate that the LSTM models effectively capture the relationships between the wave profiles and wave forces, leading to accurate predictions of wave loads.

5.2 *Hyperparameter tuning*

In this section, the impact of hyperparameter configurations on the performance of the LSTM models is explored. Specifically, the effect of learning rate and dropout settings on the model's prediction results is investigated. Hyperparameter tuning is essential in optimizing machine learning models, and understanding the effect of individual hyperparameters on the model's performance is crucial for customizing the model for a specific task. In this study, the learning rate and dropout rate are considered as the hyperparameters of interest. The learning rate is varied from 10^{-4} to 10^{-2}, while the dropout values range from 0.2 to 0.7. Two performance indicators, mean squared error (MSE) and coefficient of determination (R^2), are used to assess the influence of hyperparameters on the model's prediction results. These metrics provide a reliable approach for evaluating the model's predictive capability compared to the actual observations.

For the LSTM model predicting solitary wave loads, Figure 4(a) and 4(b) depict the variation in predictive performance with different learning rates, while keeping the dropout values constant. The analysis reveals a quadratic relationship between the model's predictive ability and the learning rate, resulting in a single-peak curve in the model performance graph. The optimal

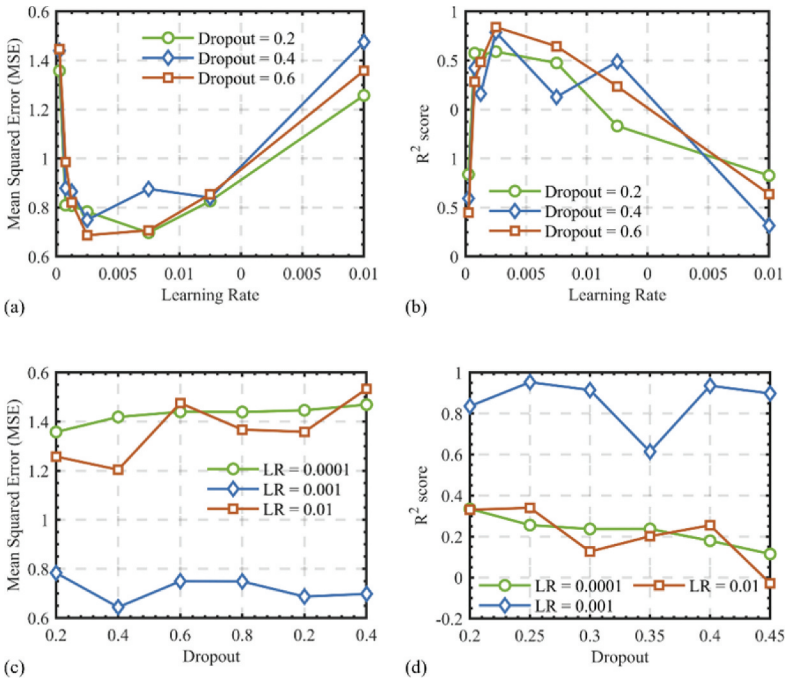

Figure 4. Comparisons between LSTM predicted wave force time histories with experimental measurements (a) solitary wave case with D = 0.50 m and H = 0.16 m; and (b) regular wave case with D = 0.50 m, H = 0.16 m, and T = 1.0 s.

learning rate is found to be approximately 0.001. These findings emphasize the importance of selecting an appropriate learning rate to optimize the model's prediction capability. On the other hand, Figure 4(c) and 4(d) illustrate the change in predictive performance with different dropout values, while keeping the learning rate constant. Interestingly, no clear trend is observed in the model performance curve, suggesting that the impact of dropout on the model's performance is relatively minor. However, it is worth noting that a dropout value of 0.5 typically yields the worst predictive performance, and it is advisable to avoid using it in practical applications. Furthermore, the analyses indicate that when the learning rate is low (around 0.001 to 0.003), the effect of dropout on the model's predictive accuracy is minimal. This finding is significant as it suggests that in certain scenarios, the specific value of the dropout rate may not be critical to the overall performance of the model when the learning rate is sufficiently low.

6 CONCLUSIONS

This study introduces a hydrodynamic experiment focused on studying the interaction between waves and bridges, as well as the development of LSTM-based data-driven techniques for forecasting wave forces in time series data. The experiment involves the use of a 1:30 scale bridge superstructure specimen subjected to wave tests in a wave channel. Various solitary wave and regular wave conditions are considered. During the experiment, measurements of wave profiles and wave-induced forces are recorded, forming the basis of the dataset used to train LSTM models. Through the tuning of different hyperparameters, high-performance LSTM prediction models are developed.

To optimize the forecasting performance for wave-induced forces, LSTM models with specific configurations are developed. These models consist of 128 hidden neurons, with each connected layer containing 64 nodes. They are trained using a learning rate of 0.001. Through the investigation of different hyperparameters, it is observed that when the learning rate is low, ranging from 0.001 to 0.003, the impact of dropout on the model's predictive accuracy is relatively minimal. The LSTM prediction models, based on experimental data, offer several advantages, including reduced deviation and improved efficiency. The LSTM models demonstrate satisfying performance, with R^2 scores close to 0.98 and low MSE values at the order of 10^{-1}. These well-trained models can accurately predict the time series of wave forces based on the wave profiles within seconds. The developed LSTM models provide effective prediction methods for wave load time histories, offering more accurate load inputs for engineering problems related to wave-bridge interactions.

Furthermore, it should be noted that these LSTM models can be enhanced by incorporating additional datasets from different test points, incorporating underlying mechanical mechanisms of wave-bridge interactions through physics-informed machine learning models, and conducting further examinations on bridge structures with varying dimensions.

ABSTRACT: Aging steel bridges constitute a significant portion of transportation infrastructure, requiring more efficient and intelligent maintenance to enhance their sustainability. This work presents a digital twin (DT) framework for the intelligent maintenance of aging steel bridges subject to time-dependent deterioration, by fully exploiting the prediction model and the data from monitoring and inspection. A tied-arch bridge, subjected to prominent corrosion fatigue (CF) in its hanger system, is selected as a case study. The DT framework comprises three modules: digital data perception, deterioration prognosis, and condition-based decision making. First, a finite element (FE) model of the bridge is developed as the mechanical backbone of the DT, based on the design document and updated with the latest inspection result. Then, the traffic data collected by the structural health monitoring (SHM) system are converted into fatigue stress spectra. Next, the stress spectra and site-specific environmental data are integrated to perform a hybrid deterioration prognosis using a time-variant probability-stress-life model. Finally, optimal maintenance actions are determined based on the prognosis results, by constructing a stochastic environment and adopting a customized deep learning-based solution algorithm. The research outcome demonstrates the value of incorporating SHM data in deterioration prognosis and maintenance planning, and provides a promising framework for the interoperable DT of aging structures at the mechanistic level. The result reveals the nonlinear evolution of C-F deterioration in steel bridge hangers, with increasing failure probability and dispersity. Consequently, different strategies are recommended by the proposed DT framework, such as regular repairs in the early life and frequent inspections and timely replacement in the late life. Furthermore, the present DT framework suggests that the appropriate use of SHM systems can effectively reduce the life-cycle costs and risks, with a value of information that exceeds the initial investment.

1 INTRODUCTION

1.1 *Background and motivation*

The need for condition-based maintenance (CBM) (Lai et al. 2023) of steel bridge hangers is underscored by their critical role in transferring vehicle loads from the deck system to the main structural member of bridges, such as the main arch or cable. These steel hangers are continuously subjected to vehicle-induced fatigue deterioration and environmental-assisted corrosion, leading to a synergistic corrosion fatigue (CF) coupled deterioration (Zhang & Yuan 2014). This degradation poses significant risks, as evidenced by the reduced service life of hangers in suspended arch bridges, often ranging from 10 to 15 years, and in extreme cases, even less than 10 years (Yao et al. 2021). This issue calls for an intelligent maintenance strategy tailored to the current deterioration state and future evolution of hangers, emphasizing the urgent need for proactive and informed maintenance approaches to ensure the longevity and safety of steel bridge hangers. As a result, it can be of the first priority to address two parallel research concerns: (i) obtaining current-to-future prognosis of CF deterioration in steel bridge hangers through integrating models and site-specific data, and (ii) stipulating an automatic and intelligent DIM policy based on the prognosis results.

1.2 *State-of-the-art overview*

Current standards, including JTG-D64 (MOT 2015), Eurocodes (CEN 2003), and AASHTO (AASHTO 2020), typically employ a fatigue load model (FLM) derived from national traffic statistics, which may not accurately reflect site-specific conditions. To address this, in-situ monitoring data, including weight-in-motion (WIM) data (MacLeod & Arjomandi 2023), has become increasingly integral in deterioration prognosis. For instance, studies by Deng et al. (2019), Li and Feng (2023), and Jiang et al. (2020) have utilized WIM data for fatigue stress and damage estimation in bridge hangers and stay cables, noting significant acceleration in fatigue deterioration above certain corrosion degrees, potentially leading to premature failure of critical components. This situation underscores the necessity of shifting from traditional corrective maintenance to more proactive CBM (Stenström et al. 2016), relying on sophisticated decision models for maintenance actions. Early decision models, typically based on decision trees (Rasouli & Timmermans 2014), segment structures based on components and damage, making decisions based on discriminative conditions at each node. However, these models lack dynamic adaptability. To overcome this, Bayesian networks (Heng et al. 2019) have been employed to balance risk and action costs, although they face limitations in scalability. An alternative, the Markov decision process (MDP) (Lei et al. 2023), and its adaptation, the partially observable MDP (POMDP) (Lai et al. 2023), offer more robust and flexible tools for managing stochastic deterioration in large-scale systems. POMDPs, in particular, have been applied across various infrastructure assets, demonstrating technical superiority in asset management. Based on the above theoretical progress, the innovative method of digital twins (Heng et al. 2023) is now gradually applied in the management of infrastructure assets, which is especially evidenced with a fast pace with the recent rapid advances in sensing, internet of things (IoT), computing, artificial intelligence (AI), numerical simulation, etc. Regarding the application of digital twins in bridge maintenance, the focus has been on two main aspects: geometric reconstruction and establishing physical-to-digital connections for real-time interaction. While computer vision technologies are successfully employed for creating geometric models of structures, efforts are ongoing to enhance the bidirectional link between physical assets and their virtual counterparts. Despite growing interest in using digital twins for bridge maintenance, much of the current research still remains conceptual. There is a pressing need for practical advancements in areas like physical-virtual communication and AI-assisted decision-making to fully realize the potential of digital twins in infrastructure maintenance.

1.3 *Research gaps and aim of the study*

This study identifies key research gaps in the field of bridge maintenance, particularly in applying digital twins and condition-based maintenance (CBM) strategies for aging bridges.

Despite the significant advances in understanding the deterioration mechanisms of bridge components and the integration of in-situ monitoring data for more accurate prognosis, there remain substantial gaps in practical application and scalability. Current models, while theoretically robust, often fall short in addressing real-world complexities, particularly in large-scale bridge networks. Moreover, the application of digital twins in bridge maintenance is still largely conceptual, with limited practical implementations. This study aims to bridge these gaps by developing an advanced, scalable model that integrates digital twins and CBM for effective bridge maintenance. The focus is on creating a practical framework that not only enhances the understanding of bridge deterioration processes but also provides actionable insights for maintenance and risk management. This study seeks to contribute to the body of knowledge by providing a comprehensive, real-world applicable model that combines the latest in sensor technology, data analytics, and AI algorithms, setting a practical instance in intelligent bridge maintenance and management.

2 METHODOLOGY

2.1 *Selection of the bridge for case studies*

The selected case study for this research is a concrete-filled steel tube (CFST) tied-arch bridge, as shown in Figure 1, an essential component located in the urban highway network of Chengdu, China. This bridge is uniquely characterized by its three tied-arches, each supporting the deck system with 21 steel hangers. These hangers are crucial for the bridge's structural integrity but are highly prone to corrosion fatigue, necessitating a shift towards condition-based inspection and maintenance strategies. The bridge's location further complicates maintenance efforts, with a busy railway running underneath, imposing strict limitations on the timing of maintenance activities. To address these challenges, a comprehensive Structural Health Monitoring (SHM) system has been installed. This system consists of a weight-in-motion (WIM) module to capture traffic loads and a vibrational measurement module, which tracks the acceleration and natural frequency of structural components, including the hangers. This setup not only aids in ongoing maintenance but also provides valuable data for this research.

Figure 1. The case-study bridge. (photo on courtesy of Dr Junlin Heng).

Traffic data over a year has been categorized into six types based on functionality and axle count, revealing that two-axle cars constitute a significant portion of the traffic, while heavy trucks, which have a more substantial impact on corrosion fatigue, account for a smaller fraction. Vehicle lane preferences have also been observed, with lighter passenger cars predominantly using the fast lane and heavier trucks favoring the middle and slow lanes. In addition to traffic load, the ambient conditions surrounding the bridge are monitored through a micro meteorological station. Key environmental factors, including temperature, humidity, and airborne salinity, indicate a subtropical climate conducive to steel corrosion. The presence of industrial activities in the

vicinity introduces moderate levels of sulphury dioxide, further influencing corrosion rates. Considering the susceptibility to anchor flooding, a conservative approach has been adopted in the study, using an adjusted average humidity value higher than the actual measurements to ensure a comprehensive assessment of the corrosion risks faced by the steel bridge hangers.

2.2 *General framework*

Figure 2 presents the general framework the digital twins for intelligent bridge maintenance, aimed at optimizing the trade-off between cost and risk in the maintenance of steel hangers on the case-study bridge. This comprehensive framework integrates four key modules: digitalization, prediction, prognosis, and AI-aided decision. The process initiates with the development of a numerical bridge model based on design documents, which is then fine-tuned using vibrational data collected from the monitoring system. This model underpins the hybrid simulations, where monitored traffic loads serve as inputs to a finite element (FE) model, enabling the assessment of fatigue stress spectra on the hangers. These spectra are projected into future states using a Bayesian dynamic linear model (BDLM) (Zhang et al. 2021), enhancing the accuracy of the deterioration prognosis. Following this, the framework engages in the prognosis quantifying uncertainties associated with the deterioration process of hangers through the application of partially observable Markov decision processes (POMDPs). This module assimilates both inspection results and maintenance action effects, offering a holistic view of the hanger condition over time. The final stage of the framework employs the asynchronous advantage actor-critic (A3C) algorithm (Shen et al. 2023), a deep reinforcement learning (DRL) strategy, to identify the most effective maintenance strategy within the POMDP environment. The framework does not merely replicate the physical bridge in a digital format but also facilitates a critical digital-to-physical interaction by advising on the optimal maintenance policy.

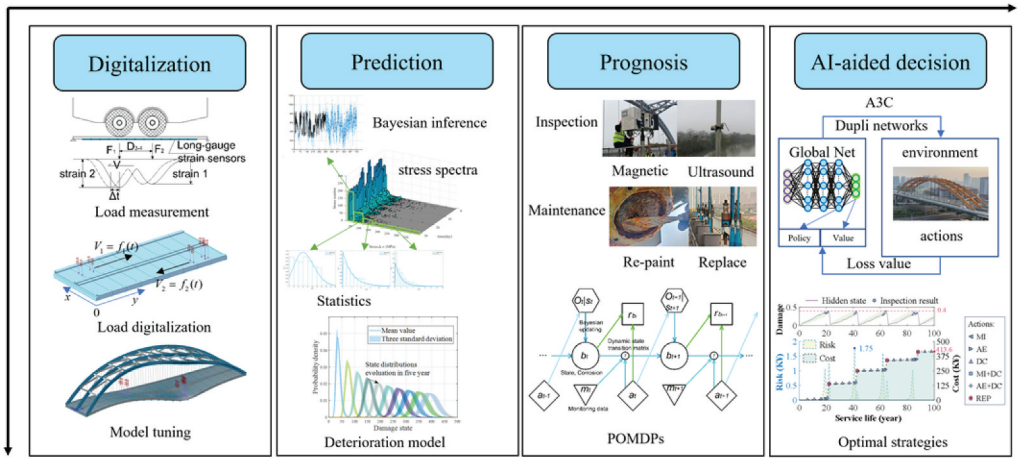

Figure 2. General framework of the digital twins for intelligent bridge maintenance.

3 RESULT AND DISCUSSION

3.1 *Digital twins of case-study bridge*

The implementation of digital twins for the case-study bridge marks a significant advancement in the domain of intelligent bridge maintenance. The first step of the digital twins focuses on analyzing and predicting the fatigue stress spectra of the steel hangers in the case-study bridge, which are critical to its structural integrity. Thus, a comprehensive and accurate virtual model of the bridge has been created, as shown in Figure 3. This model is based on detailed design

documents and is continuously refined using real-time data gathered from various sensors installed on the bridge. These sensor-monitored key parameters such as traffic loads, vibrational frequencies, and environmental conditions, providing an inclusive view of the operational state of the bridge.

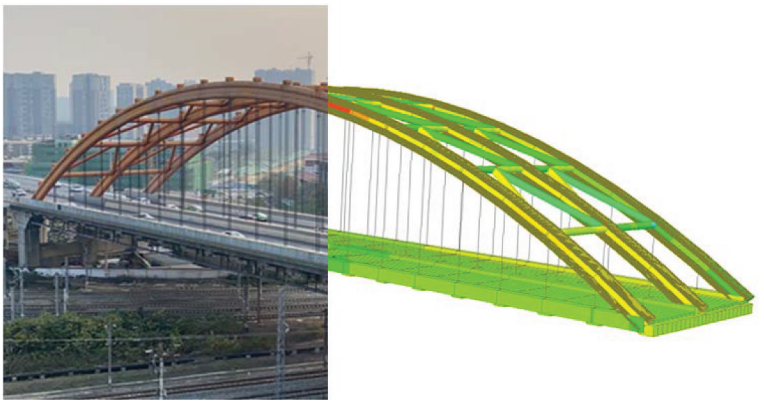

Figure 3. Virtual mirror of the case-study bridge by finite element modelling and tuning.

With this model, hybrid simulations are conducted to evaluate the fatigue stress spectra of the steel hangers. Figure 4 illustrates the fatigue stress spectra (during one month) predicted for the most critical hanger of the case-study bridge. These simulations use the monitored traffic load data as input for a (FE) model, allowing for a detailed assessment of the load effects on the hangers. The output of FE models can be then used to predict the future states of the stress spectra for the hangers, by utilizing advanced predictive techniques, i.e., the BDLM in the present work. To this end, the above digital twins not only help in identifying current stress levels but also in forecasting future deterioration trends.

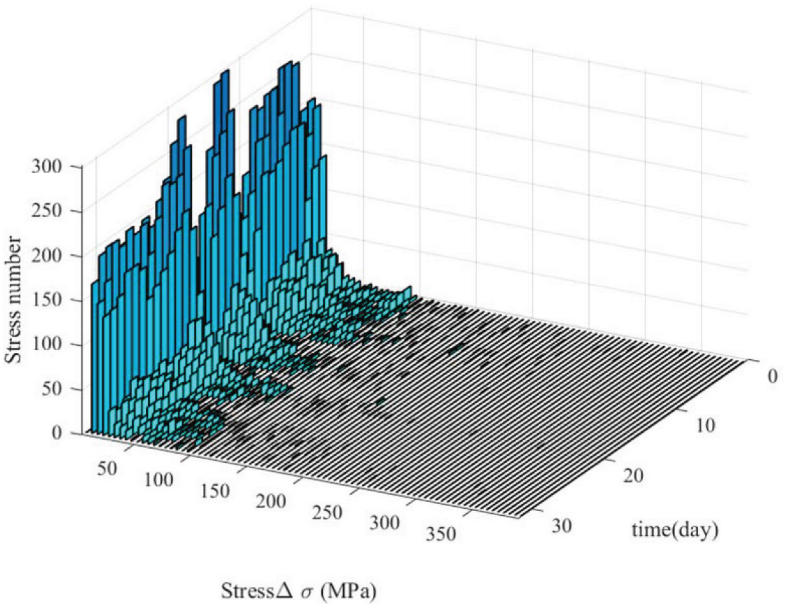

Figure 4. Fatigue stress spectra of the most critical hanger (for one month).

3.2 *Reliability evolution*

Based on the digital twins-based method stated above, the probabilistic prognosis can be carried out for various hangers in the case-study bridge, which effectively combines available data with the physical model to create a comprehensive understanding of the deterioration process over time. Figure 5 provides an insightful comparison of service reliability for hangers 9 and 11, incorporating scenarios in both corrosive and non-corrosive (in-air) environments. A failure limit, denoted as $\beta = 2$, is applied to determine the unreliability threshold.

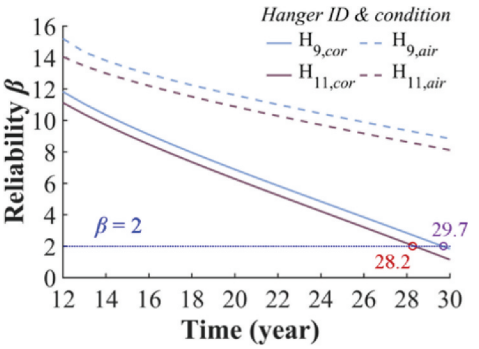

Figure 5. Reliability evolution of critical hangers (in-air versus corrosive).

In general, the nonlinear pattern in the C-F deterioration of steel bridge hangers is evidenced by the observed behavior under varying environmental conditions. The accelerated decline in reliability under corrosive conditions, as opposed to the more stable performance in non-corrosive environments, clearly demonstrates the increasing likelihood of failure and variability in deterioration over time. Initially, the reliability curves for both environments exhibit high values. However, under corrosive conditions, there is a noticeably accelerated decline in reliability compared to the non-corrosive environment. In the latter scenario, the curve remains well above the unreliability threshold, indicative of sustained robustness against deterioration. Conversely, in a corrosive environment, the reliability curve of hanger 11 approaches the limit after approximately 28.2 years, followed closely by hanger 9 at 29.7 years. These observations underscore the significant impact of environmental corrosivity on the fatigue deterioration of hangers, while also highlighting the variation in deterioration rates among hangers located in different parts of the bridge. The above variance emphasizes the need for a nuanced approach to maintenance actions, tailored to the specific conditions and deterioration rates of individual hangers.

3.3 *Optimal strategy*

As discussed above, the digital twin-based prognosis offers a detailed understanding of the current and future deterioration states of the hangers, thereby facilitating optimal maintenance strategies. The study evaluates four maintenance methods: acoustic emission (AE), magnetic inspection (MI), drainage and coating (DC), and replacement (REP), with a total of six envisioned actions due to possible combinations. The costs of these actions have been determined through industrial consultation and existing guidelines (MOT 2020), with an additional cost consideration for replacements due to the railway beneath the bridge. The results of MI and AE inspections are assumed to follow a normal distribution centered around their mean values, with standard deviations set at 0.1 and 0.025, respectively. The DC method is considered a partial repair, assumed to enhance corrosion resistance for an additional five years per effort. In contrast, the REP action is viewed as a full repair, resetting the hanger to its intact state. The study conducts a projective analysis into the future status evolution of the hangers in a stochastic space, assuming a 100-year design life for the bridge. Figure 6 illustrates the analysis result for the most critical hanger, considered critical, showing both the predicted hidden state and inspection results within a 2σ confidence interval.

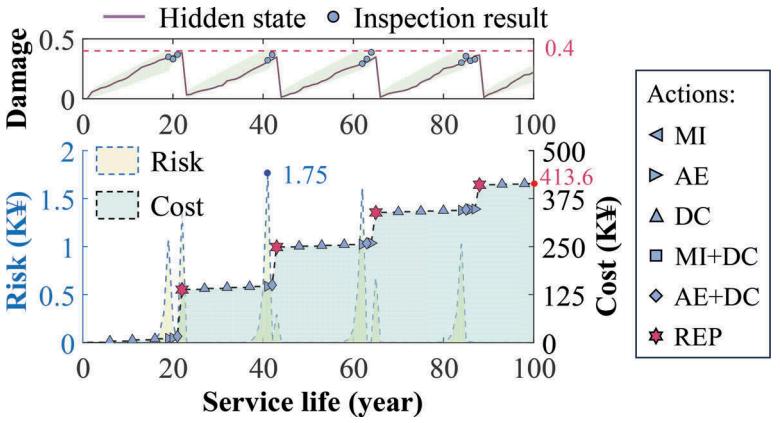

Figure 6. Life-cycle maintenance planning of the most critical hanger.

The digital twins approach proposes scheduling maintenance actions to minimize both cost and risk, as shown in the lower part of Figure 6. The optimal strategy suggests four REP actions approximately every 20 years throughout the design life of the bridge. Between REP actions, the digital twins approach recommends repeating the DC action every five years to reduce the deterioration rate of the hanger. This results in a linear increment in the damage factor, with intensive inspections scheduled before each REP action for well-informed decision-making. The total maintenance budget over the 100-year design life is estimated as 413,600 (in CNY). The proposed maintenance policy aims to maintain the damage factor generally below 0.4, which remarks a faulty warning that requires a mandatory shutdown and replacement. REP actions are advised when the damage factor approaches the limit of $D = 0.4$, maximizing the service life of the hanger within a safe margin. The risk is maintained at a moderate level throughout, peaking at 1,750 CNYs in year 40, coinciding with an inspection result indicating a critical state for the hanger, thereby justifying the need for a REP action.

4 CONCLUDING REMARKS

Based on the above study, the major findings can be drawn as below.

- A nonlinear pattern has been identified in the corrosion-fatigue deterioration of steel bridge hangers. This pattern is characterized by an increasing likelihood of failure and a growing variability in the deterioration process over time.
- According to the result of digital twins, the intelligent algorithm advocates regular repair work during the early stages of the lifecycle and more frequent inspections coupled with timely replacements as the hangers near the end of their service life.
- The result also underscores the importance of a tailored approach to bridge maintenance, one that adapts to the changing conditions of the bridge components over time and utilizes advanced monitoring techniques to inform maintenance decisions.
- The present work in generally, contribute to a comprehensive understanding of bridge maintenance, particularly emphasizing the role of advanced monitoring and predictive modeling in enhancing the safety, and cost-effectiveness of bridge management.
- For the future study, more in-depth cost-benefit analyses of SHM systems are suggested across different bridges. Besides, it is also worth exploring to integrate more sophisticated machine learning algorithms or deep learning techniques to improve the prediction accuracy and goodness of optimization.

ABSTRACT: Damage detection stands as a pivotal subject in bridge health monitoring. As the actual structures and their theoretical models inevitably have differences in structural parameters, it is practically challenging to detect damages in the absence of precise baseline information. In this regard, this paper introduces a baseline-free damage detection framework that combines measurements of moving loads with acceleration responses. Specifically, the moving loads are extracted using computer vision techniques while the acceleration is measured by distributed sensing. For each measured moving load, the same loading process is applied to the finite element models with different structural parameters and ambient noise. With simulated structural responses, an advanced 1d convolutional neural network is proposed for damage detection. Theoretical derivation reveals the proposed framework is applicable for damage detection without initial structural parameters. The proposed framework is validated to be effective on both damage localization and quantification.

1 INTRODUCTION

Damage detection (DD) is one of the most important concerns for structural health monitoring and has been a long endeavor in structural engineering for several decades (Doebling et al. 1996; Das et al. 2016; Li et al. 2023). Most of the previous efforts were on output-only approaches using measurements such as acceleration, strain, displacement, tilt, etc. The main barrier to output-only methodologies is that they highly rely on the baseline model quality, which was influenced by ambient environmental changes, such as traffic load, thermal effect and wind loading. Also, to mitigate the challenges posed by incomplete information, output-only methods typically necessitate the deployment of many sensors. Therefore, DD methods that introduce input information have also garnered widespread attention in recent years.

The approach based on Influence lines (ILs) is a representative method with both input and output information. An early study explored video recording and strain sensors to calculate strain influence lines (SILs) and then used them to detect damage in a bridge model (Zaurin & Catbas 2011). Displacement influence lines (DILs) were also validated applicable to damage localization and quantification on laboratory bridge models (He et al. 2018; Le et al. 2019). Since DILs have lower sensitivity to damage around the supports, rotational influence lines (RILs) were also considered promising for damage detection. Zhou et al. (2018) proposed a damage localization method by finding an abrupt change in RILs. Farhad et al. (2020) carried out experimental validations on a RILs based method in the laboratory and field. To combine the advantages of DILs and RILs, Breccolotti & Natalicchi (2022) proposed an

DOI: 10.1201/9781003483755-81

estimation method for flexural bending rigidity using the information from a FE model and validated it through numerical simulations.

Computer vision techniques have been used in recent years for measurements of vehicle trajectories and bridge displacements (Ge et al. 2020; Wang et al. 2023; Ge et al. 2024). With the combined information, DILs or RILs can be calculated in the field. For instance, Dong et al. (2019) implemented a field system for measuring the DIL of a small real truss bridge. Martini et al. (2022) identified the DIL of a steel beam for the purpose of finite element model updating. Even though the above vision systems are attractive to obtain ILs for real bridges, they are rarely applied to damage detection. Khuc & Catbas (2018) reported a successful experiment on the existence detection of damage. For damage localization, Ge et al. (2023) proposed a high-precision visual measurement system and successfully applied it to identify various damages. The two studies introduced a prototype for the input-output DD, however, these advancements primarily focus on static effects, and the exploration of input-output methodologies tailored for scenarios involving dynamic vehicle-induced responses remains an uncharted area of research.

Signal processing techniques, such as wavelet transform (WT) and Hilbert-Huang Transform (HHT), are widely used in DD research using vehicle-induced displacement or acceleration. Hester et al. (2012) suggested an improved WT using wavelet energy content at each bridge section and successfully detected damage in a bridge model with its acceleration response. Roveri & Carcaterra (2012) applied HHT to displacements to identify damage locations along beam structures. Nguyen et al. (2020) combined the WT with a deep learning network to detect multiple cracks in a beam. Basically, these approaches localize damage with some indicators (e.g., wavelet coefficient or Lipschitz exponent), but the physical correspondence between these indicators and the damage is not clear, resulting in natural limitations in damage quantification. Transfer learning, which is a branch of deep learning technologies, has also been applied recently in DD. For example, Teng et al. (2023) generated different digital models in simulation and trained a damage classification model with their response to random excitation force. Wang et al. (2021) created a free vibration dataset through finite element analysis and applied them to train a densely connected network to detect damages in a frame structure. Transfer learning approaches make baseline-free DD possible, but they are rarely seen in the existing DD related to vehicle-induced responses.

Regarding the limitations summarized from the existing DD approaches, this paper proposed a novel DD method using an input-output measurement system and transfer learning with vehicle-induced structural accelerations. This method does not require prior knowledge of structural initial parameters and can be used in both damage localization and quantification. In the following of this paper, the mapping relationship of the accelerations before and after damage is first introduced, followed by a demonstration of the proposed transfer learning framework. Then, Section 4 gives a numerical validation of the proposed approach. Section 5 presents conclusions.

2 MAPPING BETWEEN ACCELERATIONS BEFORE AND AFTER DAMAGE

To unveil the theoretical foundation behind using transfer learning for DD, this section derives the mapping relationship between the structural acceleration responses before and after damage.

Considering a linear discrete structure with n elements, if each node accounts for l degree of freedom (l=1∼6), then the structural governing equation can be expressed as:

$$M_{l(n+1)\times l(n+1)}\ddot{X}_{l(n+1)\times 1} + C_{l(n+1)\times l(n+1)}\dot{X}_{l(n+1)\times 1} + K_{l(n+1)\times l(n+1)}X_{l(n+1)\times 1} = P_{l(n+1)\times 1} \quad (1)$$

Where M is the mass matrix, K the stiffness matrix, P the vector of external force, and X the displacement vector for all nodes. The Rayleigh damping is adopted while it is assumed that the damping ratio ξ of the lower-order modes is identical. The damping matrix is given by

$$C = \alpha M + \beta K\left(\alpha = \frac{2\xi\omega_i\omega_j}{\omega_i + \omega_j}; \beta = \frac{2\xi}{\omega_i + \omega_j}\right) \quad (2)$$

ω_i and ω_j are the minimum and maximum frequencies analyzed. It is assumed that the damage state can be represented by stiffness reduction matrix D_K and mass reduction matrix D_M, both of which have dimensions of l(n+1)×l(n+1). Then, the stiffness and mass matrices after damage are

$$K_d = D_K K,\ M_d = D_M M \tag{3}$$

Substituting Equations (2) and (3) into Equation 1 yields the structural acceleration after damage:

$$\begin{aligned}\ddot{X}_d &= M^{-1}D_M^{-1}(RP - D_K KX - \alpha D_M M\dot{X} - \beta D_M K\dot{X}) \\ &= \left[M^{-1}D_M^{-1}RM, M^{-1}D_M^{-1}D_K M, E, M^{-1}D_M^{-1}D_K M\right]\left[M^{-1}P, -M^{-1}KX, -\alpha\dot{X}, \beta M^{-1}K\right] \\ &= \mathbf{T}\left[M^{-1}P, -M^{-1}KX, -\alpha\dot{X}, \beta M^{-1}K\right]^T\end{aligned} \tag{4}$$

In this equation, R is a $l(n+1)\times l(n+1)$ diagonal matrix representing the ratio coefficients of vehicle loads observed before and after damage, which is known in the input-output measurement system. E represents an equally sized identity matrix. For the undamaged state, the structural acceleration can be given by

$$\begin{aligned}\ddot{X}_d &= [E, E, E, E]\left[M^{-1}P, -M^{-1}KX, -\alpha\dot{X}, -\beta M^{-1}K\right] \\ &= \mathbf{T}_0\left[M^{-1}P, -M^{-1}KX, -\alpha\dot{X}, -\beta M^{-1}K\right]\end{aligned} \tag{5}$$

It can be seen from the above equation that the difference in acceleration of the structure at any time t, before and after damage, is determined by the difference in $\mathbf{T}$ and $\mathbf{T}_0$. $\mathbf{T}$ is named to as the damage mapping matrix. Furthermore, since the matrices K and M are basically assembled with the element stiffness K^e and M^e, respectively. If the stiffness and mass reduction coefficients of the element k are denoted as $d_{K,k}$ and $d_{M,k}$,K_d and M_d then can be expressed as

$$K_d = D_K K = \sum_{k=1}^{n} d_{K,k} G_k^T K_k^e G_k,\ M_d = D_M K = \sum_{k=1}^{n} d_{M,k} G_k^T K_k^e G_k \tag{6}$$

where $d_{M,k}, d_{K,k} \in (0, 1]$. It can be seen from Equations (4) and (6) that, $\mathbf{T}$ can be expressed by the following high-dimensional mapping

$$\mathbf{T} = F(d_{K,1}, d_{K,2}, \ldots d_{K,n}, d_{M,1}, d_{M,2}, \ldots d_{M,n}, M_1^e, M_2^e, \ldots, M_n^e, R) \tag{7}$$

It is important to emphasize that, since the element mass M^e is constant, this information is not required when comparing $\mathbf{T}$ and $\mathbf{T}_0$. Therefore, with R known, $\mathbf{T}$ is uniquely corresponding to the structural damage.

3 INPUT-OUTPUT TRANSFER LEARNING FRAMEWORK

3.1 *Overview*

The theoretical derivation demonstrates that when the spatiotemporal distribution of vehicle loads is measurable, the structural damage state can be uniquely determined by the acceleration response. Based on this core principle, Figure 1 illustrates the proposed transfer learning damage identification framework. Within this framework, the moving loads acting on the actual structure can be observed by vision-based load monitoring systems (Ge et al. 2020; Ge et al. 2023), while the structural effects are measured by synchronized accelerometers.

In this framework, the loads measured on the actual structure are applied to the finite element model with the same magnitude and location. The finite element model is parameter-variable, with changing parameters including the initial structural model parameters, damage parameters,

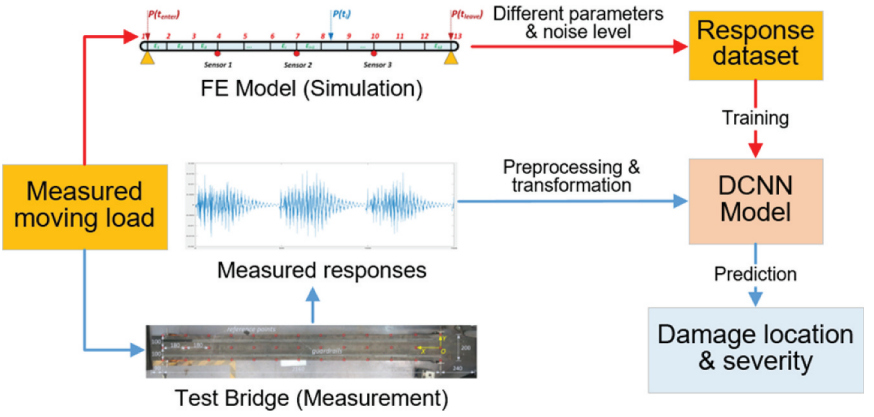

Figure 1. The transfer learning framework for damage detection.

and noise parameters. By continuously altering these three types of parameters, it is aimed to simulate structural effects under different parameter combinations as extensively as possible to create a simulated database. Both measured and simulated structural effects include acceleration signals before and after damage. Since the damage mapping matrix corresponds uniquely to the damage, theoretically, similar matrices **T** can be extracted from both simulated and measured signals for the same damage. Due to the high-dimensional and complex nature of the damage mapping matrix parameter space, it is advised to use deep learning methods for extraction in the proposed framework. Figure 1 displays the measured acceleration time history, which generally requires noise reduction and filtering processing before being input into the deep learning model.

3.2 *1D Efficient-V2 damage detection model*

To elaborate in greater details on the use of the damage identification framework, this section will introduce a deep convolutional neural network model and describe its application in time-domain signal damage identification. For the framework in Figure 1, the data input to deep learning models can be either time series or other forms post processing such as images. Since the input data is generally from simulation or ideally designed experiments, they are paired with a damage vector that reflects the states of all the elements. For example, in case a beam structure with n elements, the damage vector is defined as $\mathbf{d}=(d_1,d_2,, d_n)$, $(0 < d_i \leq 1)$. After the put data undergoes forward propagation through the network, a predicted damage vector $\mathbf{d}^{\mathbf{p}}$ of the same dimension is outputted. By using both $\mathbf{d}^{\mathbf{p}}$ and **d**, the loss function can be calculated, thereby ascertaining the accuracy of damage prediction.

This study proposes an adapted EfficientV2 network as the fundamental architecture of the deep learning model. The EfficientNetV2, introduced by Tan & Le (2021), was optimized using Neural Architecture Search (NAS) technique so that having a rational configuration of network depth, the number of channels, and network width. Considering data volume and training speed, this section focuses on modifying the smaller parameter version, EfficientNetV2-S, of which the structure is as presented in Table 1. More details of the listed modules can be found in the reference (Tan & Le 2021).

After undergoing a series of computations through Stages 0-7, the EfficientNetV2-S ultimately outputs a 1×1280 feature vector. In the original EfficientNetV2, the vector was used to calculate a one-hot encoded vector for image classification. However, the following modifications have been made in this study.

1) Labels: the labels of input data are revised into double-precision vectors from one-hot vectors.
2) Loss function: while cross-entropy is often used to evaluate the similarity between two vector distributions in image classification problems rather than regression problems, it is replaced with the Mean Squared Error function.
3) Activation function: the original Swish activation function is changed to the Tanh.

Table 1. Network structure of efficientNetV2-S.

Stages	Operations	Strides	Channels	Layers
0	Conv3×3	2	24	1
1	Fused-MBConv1, k3×3	1	24	2
2	Fused-MBConv1, k3×3	2	48	4
3	Fused-MBConv1, k3×3	2	64	4
4	MBCConv4, k3×3, SE0.25	2	128	6
5	MBCConv6, k3×3, SE0.25	1	160	9
6	MBCConv6, k3×3, SE0.25	2	256	15
7	Conv1×1 & Pooling & FC	-	1280	1

In this study, multi-point acceleration signals from bridge structures are used as input and the adapted EfficientNetV2-S is employed as the core of the DCNN model to localize and quantify the damage.

4 NUMERICAL VALIDATION

The steps using the proposed DD framework are:

1) Measure the real acceleration and moving loads. The simulation uses randomly generated load segments based on the traffic load models from (Ge et al. 2022), with acceleration responses computed by an initialized FE model.
2) Develop a simply supported model with variable structural parameters.
3) Apply real moving loads to the FE model to calculate accelerations. The model parameters, such as stiffness, mass, damage states, and noise levels, are varied to cover as many structural scenarios as possible. The "real" structure in the simulation is set as a FE model with random yet constant initial parameters to mimic the uncertainties in real-world.
4) Validate the predictive accuracy of actual structural damage using "measured" acceleration data, which are derived from finite element analysis of the "real" structure.

Figure 2 Presents a schematic diagram of the moving loads, FE model and the observation of acceleration involved in the simulation. The FE model is a 12-elements simply supported beam, with the following parameters: beam length of 2.16m, elastic modulus $2.06 \times 10^5 GPa$, moment of inertia $I = 3600mm^4$, and density $\rho = 7.8 \times 10^3 kg/m^3$. For the moving load, a 5-second segment is randomly generated with the distributions of headway, vehicle weight and speed obtained in (Ge et al. 2022). The load is simplified as a concentrated force moving uniformly from node 1 to node 13, with a load updating step of 0.01 seconds. Three measurement points are designed at the bottom of the beam to capture the structural acceleration under the load, calculated using *Newmark* β method with the computation step same as the load updating step. The figure illustrates the time history of the acceleration responses at the three measurement points under the 5-second moving load segment.

The numerical simulation considers only single damage scenarios. To acquire training data under various structural states, the initial FE model is repeatedly modified in the damage location, damage extent, and noise level. Specifically, the damage location is divided into 12 possible scenarios based on the element number. The damage extent involves reductions in element stiffness and mass, considering reductions at ratios of (10%, 20%, ... 50%) across 6 levels. Noise is added to the original signal at five levels: 2%, 4%, 6%, 8%, and 10%. The noise signal is calculated by

$$noise = \boldsymbol{e}_{N\times 1} \frac{N(0,1) \times noise\ level}{\sqrt{mean\ (signal^2)}} \tag{8}$$

where $\boldsymbol{e}_{N\times 1}$ represents a $N\times 1$ unit vector with the same size as the signal.

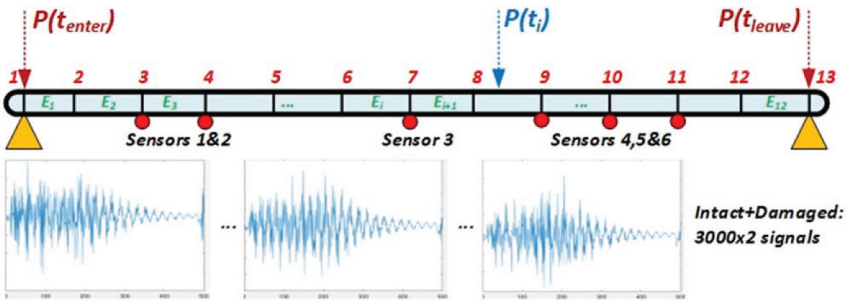

Figure 2. Diagram for the moving load, FE model and structural responses in simulation.

Further, to simulate the scenario of unknown initial structural parameters, the initial element stiffness is set as the product of the design value and a random coefficient within the range of 80%-120%. It is assumed that the mass of the elements remains unchanged, while the structural damping is determined based on the first three modal frequencies and their damping ratios. Assuming the first three modes have the same damping ratio $\xi = 0.03$, a total of 52,000 acceleration arrays with dimensions of 500×6 are obtained after 80 iterations varying the damage location, extent and noise levels. These arrays are concatenated with corresponding undamaged state signals to form 3000×2 arrays. These data are then input into different channels of the network, row by row, and divided into a training set and a test set in a 9:1 ratio for training the deep learning model.

The trained model was tested on a validation set containing 6, 500 signal arrays. These signals, derived from calculations under two different moving loads in both damaged and undamaged conditions, contain structural initial parameters and random noise that are completely distinct from the training data. This makes them ideal for validating the generalization capabilities of the proposed method. Figure 3 presents the accuracy of damage localization under various scenarios involving different damage positions and levels of damage extent. It can be observed that, even without a baseline model, the proposed method achieves an average accuracy of over 90% in locating damages at different positions, with a slight decrease in precision near the support location (element 11). When the stiffness reduction exceeds 20%, the accuracy of damage localization by the proposed method exceeds 98%. However, when the stiffness reduction is around 10%, the accuracy decreases to approximately 80%. This outcome is attributed to the lower signal-to-noise ratio in the structural response near the

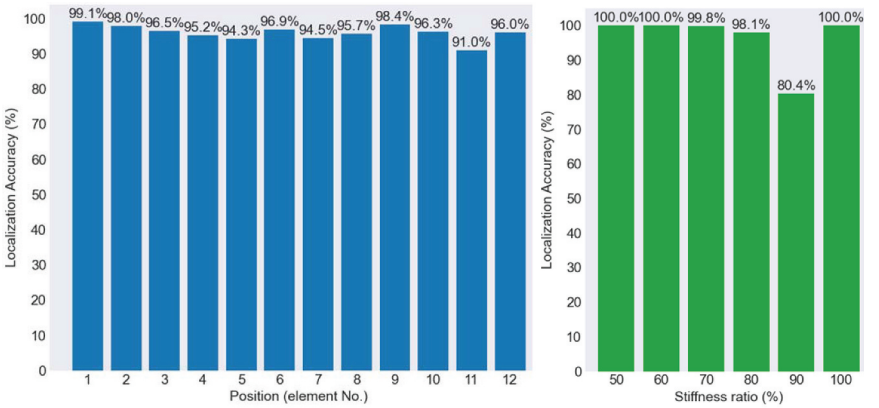

Figure 3. The accuracy of damage localization with respect to different positions and extents.

supports, where changes due to stiffness reduction might be more challenging to detect. Similarly, the smaller the damage, the more difficult it is to detect changes in structural response.

Furthermore, to validate the damage quantification capability of the proposed method, the relative error of predicted stiffness reduction for different damage scenarios is calculated on the validation set. The relative error is defined as

$$Er = \frac{\left|d_{i,pred} - d_{i,real}\right|}{d_{i,real}} \times 100\% \tag{9}$$

Figure 4 Presents the average relative error in predicted stiffness reduction for various positions and degrees of damage. The results demonstrate that the proposed method maintains a quantitative relative error of less than 10% for most damage scenarios. Similar to damage localization, a higher relative error is observed in elements 11 and 12, which are closer to the support positions. However, even with smaller degrees of stiffness reduction, the quantitative error in damage estimation remains at a relatively low level.

Figure 4. The absolute relative errors of damage quantification.

After the numerical validations and discussions presented above, it is reasonable to conclude that the proposed input-output framework can achieve both damage localization and quantification without the need for a baseline model. However, the applicability of this method still requires further experimental validation. In the model experiments, two points need to be noted. First, the consistency between the numerical model and the actual distribution of structural parameters should be considered. Although the method described in this paper can rely on numerical simulations to generate a large amount of training data, the distribution of this data should be similar to that of the actual structure. Therefore, in practical applications, a preliminary assessment and modification of the parameter space of the numerical model are necessary. Second, for actual structures, most cases of damage result in stiffness reductions of less than 10%, and the structural forms are more complex. The performance of the proposed framework for smaller damages and in more complex structures remains to be further explored.

5 CONCLUSIONS

In this paper, an input-output structural damage detection framework is proposed from a dynamic perspective. The framework constructs physical model information through the measured acceleration effects and moving loads on the bridge, and a digital model of the actual structure is created using FE modeling. The digital and physical models are connected by the measured moving loads. Under the action of these loads, the digital model generates a simulated acceleration effect database that encompasses various structural states. The

acceleration responses are comprehensively simulated for different damage locations, extents and noise levels, and are used to train an adapted one-dimensional EfficientNetV2 convolutional neural network model to detect damage in the physical model. Numerical experiments demonstrate that the framework preliminarily possesses the capability to locate and quantify structural damage using vehicle-induced acceleration signals.

Politecnico di Torino, Italy

ABSTRACT: In the evolving field of Structural Health Monitoring (SHM), the integration of diverse sensing techniques is pivotal for comprehensive structural analysis. This study introduces a novel data fusion methodology that synergizes the precision of strain gauges with the broad coverage of computer vision techniques. Aimed at advancing SHM practices, our approach facilitates a detailed understanding of structural behavior by concurrently analyzing strain fields and displacement signals captured through video streams. We employ Physics Informed Neural Networks (PINNs) to refine measurements and ensure physical plausibility in our data interpretation. Our methodology's effectiveness is validated through laboratory experiments on a simplified structural model, demonstrating enhanced accuracy and reliability in SHM. This paper highlights the potential of integrating traditional and contemporary sensing techniques in infrastructure monitoring, setting a new benchmark in the field.

1 INTRODUCTION

Structural Health Monitoring (SHM) is vital for ensuring the integrity and safety of key infrastructures. Conventionally, SHM has heavily relied on direct sensor installations like strain gauges (Mousa et al., 2021). These sensors are indispensable as they not only detect, localize, and quantify unusual structural behaviors but also project current and future structural predictions (Glisic, 2022). Nevertheless, their deployment poses logistical challenges and often require multiple sensors for single-point displacement estimation (Ma et al., 2023), prompting the need for alternative methods.

Shifting focus, non-contact methods like utilizing video streams offer a valuable alternative. These methods capture displacement fields, reflecting the overall stiffness of structures and providing an accurate assessment of structural conditions (Feng & Feng, 2018). Despite their precision, vision-based techniques are not without drawbacks, including high computational demands and sensitivity to lighting conditions (Ma et al., 2023). Alone, these methods may fall short of the accuracy and consistency achieved through sensor-based approaches.

To address these challenges, our study proposes a multi-modal sensor fusion strategy. Traditional fusions generally combine accelerometers with either strain sensors or vision cameras (Ma et al., 2023). Our approach goes further, merging strain gauge data with computer vision outputs. This fusion integrates the precision of strain measurements with the extensive spatial analysis offered by video-based techniques. The aim is to develop a robust analytical framework that correlates strain and visual data, thus enriching SHM with a more comprehensive understanding of structural behavior.

Further advancing our methodology, we introduce Physics-Informed Neural Networks (PINNs) (Raissi et al., 2019) into our vision-based SHM framework. PINNs represent

DOI: 10.1201/9781003483755-82

a significant evolution from traditional machine learning models, as they offer enhanced interpretability and conform more closely to physical principles (Faroughi et al., 2023). By incorporating physical laws into the neural network architecture, PINNs ensure that the model's predictions are not only accurate but also physically plausible. Their application in SHM is multifaceted: for instance, they have been effectively utilized in modeling stress and displacement under varying conditions, an aspect central to understanding structural behaviors (Henkes et al., 2022). Furthermore, PINNs show promise in accurately simulating the behavior of materials under different strain rates and temperatures, a factor crucial for assessing the long-term durability and resilience of infrastructure (Arora et al., 2022). Importantly, PINNs have the capability to refine wave velocity estimations from displacement data, enhancing the precision of structural imaging and enabling the early detection of potential structural failures (Rathod & Ramuhalli, 2022). Additionally, their adeptness in solving complex differential equations relevant to structural dynamics positions them as an invaluable tool in SHM, particularly for analyzing intricate structural responses under varied load conditions (Kollmannsberger et al., 2021).

Overall, this study presents a novel approach in SHM by leveraging the combined strengths of both strain gauges and computer vision, further augmented by the analytical prowess of PINNs. This unique combination not only promises to bolster the accuracy and reliability of structural assessments but also signifies a substantial advancement in the application of machine learning within the domain of infrastructure monitoring.

2 METHODOLOGY

2.1 *Theoretical foundation*

In SHM, leveraging the strengths of different sensors is key to achieving comprehensive monitoring. Strain sensors offer high-precision local measurements, crucial for detecting minute changes in structural integrity. In contrast, vision-based methods provide extensive spatial coverage, enabling the capture of broader deformation patterns. This fusion approach is vital for a holistic understanding of structural condition.

A core aspect of our methodology involves shape sensing, which reconstructs a structure's displacement field using discrete surface strain measurements (Gherlone et al., 2018). According to the Bernoulli-Euler theory of pure bending, there is a direct correlation between axial strain and the curvature of the beam (Ko et al., 2007). This relationship is mathematically expressed as $\kappa = d^2w/dx^2$, where κ represents the curvature, and $w(x)$ denotes the beam's deflection along its longitudinal axis. The axial strain (ϵ) at any point is linked to curvature by $\epsilon = -y\kappa$, with 'y' being the distance from the neutral axis.

Using this principle, curvature is deduced from localized strain measurements. Subsequent numerical integration allows us to calculate the beam's slope (dw/dx) and overall deflection ($w(x)$). The precision of these estimations hinges on the density of strain data points, the accuracy of the numerical integration method, well-defined boundary conditions, and an exact characterization of the beam's properties and loading.

Utilizing the strain data recorded by our sensors, we augment our analysis by contrasting these sensor-derived displacement values at specific sensory points against the displacement data acquired through vision-based displacement measurement techniques.

2.2 *Image based displacement measurement*

To facilitate vision-based displacement measurement, the Demons algorithm is employed. The Thirion's image matching algorithm (Thirion, 1998), known as the Demons algorithm, is a linear complexity technique for nonrigid image registration, crucial in applications requiring intense value preservation. The proposed algorithm consists of estimation of the demon forces for every demon (more precisely, the result of the application of a force during one iteration step, that is a deformation field), and update of the transformation based on the calculated forces (Sotiras et al., 2013).

The core of the Demons algorithm lies in its optical flow component, which calculates pixel displacements by comparing sequential images. This comparison relies on the assumption of constant brightness over time, enabling accurate estimation of pixel movement between images. Essentially, the algorithm computes the displacement needed at each pixel (treated as a "demon") to align the moving image with the reference image. This calculation involves analyzing intensity gradients and differences between pixels.

In implementing this method, our study involved converting each frame into grayscale to standardize intensity values, followed by applying normalization techniques to ensure uniformity across images, countering variations in illumination. This preprocessing set the stage for the effective application of the Demons algorithm.

For enhanced efficiency and accuracy, a pyramidal approach is employed. This involves performing multiple iterations at progressively coarser image resolutions, starting with a low-resolution overview and gradually refining the displacement field at finer scales. This multi-scale approach balances computational efficiency with detailed displacement estimation (Zitová & Flusser, 2003).

2.3 *Physics informed neural network*

Physics-Informed Neural Networks (PINNs) (Raissi et al., 2019) operate by incorporating physical laws into the neural network architecture and its loss function, and aim to approximate solutions that closely match both the training data and the underlying physical equations. Here, the SciANN (Haghighat & Juanes, 2021), a Keras/TensorFlow wrapper is employed to create the PINN model.

2.3.1 *Network architecture and data fitting*

The architecture of the PINN is based on a standard feed-forward neural network (Kollmannsberger et al., 2021). The network is designed to predict displacement and strain as a function of the position along the beam, taking into account the beam's length (L), applied load (P), and material properties such as the modulus of elasticity (E) and moment of inertia (I).

To train the network, a synthesized dataset is created using analytical solutions for displacement and strain under various loading conditions. The data is further augmented by adding Gaussian noise, to mimic the real scenario. The data-fitting loss, L_{data}, is formulated as the mean squared error between the network's predictions and the actual values from the dataset. It is expressed as:

$$L_{data} = \left(\frac{1}{N}\right) \sum_{1}^{N} \left(\hat{d}_{(x_i)} - d_{data(x_i)}\right)^2 + \left(\hat{\varepsilon}_{(x_i)} - \varepsilon_{data(x_i)}\right)^2$$

where N is the number of data points, $\hat{d}$ and $\hat{\varepsilon}$ are the network's predictions for displacement and strain, respectively, and subscript *data* refers to the corresponding true values.

2.3.2 *Incorporation of physical laws*

The distinct feature of a PINN is its ability to integrate physical laws into the learning process. This is achieved by adding terms to the loss function that represent the governing equations of the system being modeled.

For a cantilever beam under a point load P, the Euler-Bernoulli beam theory provides the necessary physical laws. The physics-based loss for deflection, $L_{deflection}$, ensures the network's compliance with the deflection equation of the beam. It is given by:

$$L_{deflection} = \left(\frac{1}{M}\right) \sum_{1}^{M} \left(\hat{d}_{(x_i)} - \frac{P x_i^2}{6EI}(3L - x_i)\right)^2$$

Strain in a beam is directly related to its curvature, and the curvature at any point along the beam is mathematically represented by the second derivative of displacement with respect to

the position. Similarly, the physics-based loss for strain, L_{strain}, enforces the correct strain profile as per the beam theory. It is calculated as:

$$L_{strain} = \left(\frac{1}{M}\right) \sum_{1}^{M} \left(\hat{\varepsilon}_{(x_i)} - \frac{d^2 \hat{d}}{dx^2}(x_i) \right)^2$$

where the term corresponding to the second derivative of the predicted displacement, indicates the curvature of the beam.

2.3.3 *Total loss function and training*

The overall loss function, L, for the PINN is a weighted sum of the data-fitting loss and the physics-based losses. It is defined as:

$$L_{total} = \alpha L_{data} + \beta L_{deflection} + \gamma L_{strain}$$

Here, α, β, and γ are coefficients that balance the importance of fitting the data and adhering to the physical laws.

2.4 *Data fusion*

The process begins with the calculation of the beam displacement field from the image sequence, designated as $v(z)$. This computation is conducted first through conventional image pre-processing, encompassing image cropping, selection of the Region of Interest, black weight artifact removal, and illumination correction. Following these initial steps, the punctual displacements are determined using the Demon algorithm, as previously stated. Then, the longitudinal strain field, termed $\varepsilon(z)$, is derived directly from the previously calculated displacement field, $v(z)$.

The refinement process involves enhancing the strain field, now referred to as $\varepsilon_{fix}(z)$, utilizing data from strain gauges. The displacement field, denoted as $v_{fix}(z)$, is then fine-tuned by numerically integrating this enhanced strain field, $\varepsilon_{fix}(z)$. An important assumption is the consideration of zero displacements at the beam ends. The interpolation of the displacement field employs smoothing splines. This stage is followed by a re-interpolation process, wherein an adjusted smoothing parameter is utilized to give precedence to data smoothness.

The computation of $\varepsilon(z)$ involves transforming the displacement data into strain data, guided by the principles of Hooke's and Navier's laws. The strain field, $\varepsilon_{fix}(z)$, is then calculated using a smoothing spline interpolation function. This function is designed to fit the data accurately and detect changes in slope, ensuring adherence to these changes. The computation of the refined displacement field is achieved through the double integration of linear functions. This process necessitates the imposition of boundary and continuity conditions.

2.5 *Experimental setup and testing procedure*

Our experimental investigation was conducted on a 6063 Aluminum beam, with dimensions of 50.80 mm width, 18.50 mm height, 1.60 mm thickness, and 2414.6 mm length. The beam was instrumented with six Type I strain gauges, arranged in a half-bridge configuration at intervals of L/4, L/2, and 3L/4 along the beam (Figure 1). This configuration, known for its high sensitivity and ability to compensate for temperature variations, ensured accurate strain measurement. Data from the strain gauges were captured using an NI cDAQ-9188 system, complemented by an optoNCDT 1420 laser sensor and an industrial-grade Ueye camera for deflection and motion tracking. To enhance image processing, the beam was marked with a colored speckle pattern, facilitating optical flow computations, and was positioned against a whiteboard for optimal contrast (Figure 2). The laser sensor acted as ground truth data for the investigations.

The experimental procedure involved a series of controlled static load tests with pinned ends to simulate hinge connections. The objective was to examine the beam's structural response to different load intensities, focusing on consistency and repeatability. Each test was conducted thrice to ensure the reliability of the data. The testing scenarios included 0.05, 0.2 and 0.5 kg load the beam's midpoint.

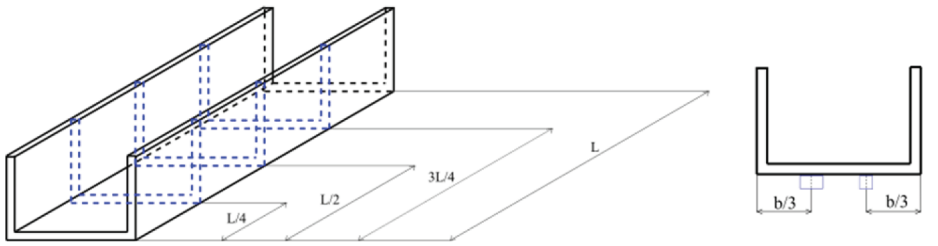

Figure 1. Beam section and strain gauge locations.

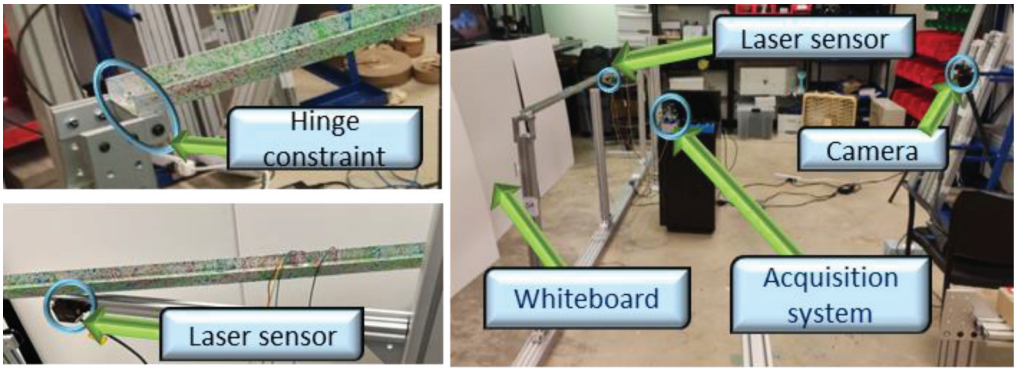

Figure 2. Experimental setup.

3 RESULTS AND DISCUSSION

This section presents the findings from our experimental tests, focusing on displacement and strain measurements under a 0.2 kg load at the centerline of the beam (Case 2), as these were typical for all conducted experienced. The results are illustrated in Figures 3 to 6.

Figure 3 displays the displacement curve obtained using the Image-based Measurement (IIm) method for Case 2. This graph results from iterative interpolation using smoothing splines, with the exclusion of residuals exceeding a set tolerance. The graph features an error measure focusing on data point fitting to the spline, along with a roughness measure:

$$p\sum_i w_i(y_i - s(z_i))^2 + (1-p)\int \lambda\left(\frac{d^2s}{dz^2}\right)^2 dz$$

Figure 4 illustrates the strain curve derived from both strain gauge readings and the analytical approach for Case 2. The stress-displacement relationship is characterized as

$$\frac{d^2v(z)}{dz^2} = -\frac{\varepsilon(z)}{Y}$$

by assuming zero second derivatives at the beam's extremes. This accounts for the beam's properties as slender, elastic, and isotropic, with shear effects neglected.

The results of the corrected strain field, integrating strain gauge measurements, are presented in Figure 5. The process involves iterative and weighted interpolation with smoothing splines, exclusion of data points that degrade the distribution, and enforcement of interpolation at strain gauge measurements. Correction is applied based on the boundary condition of zero strain at the clamp section.

The comparison of the neural network's performance with and without the inclusion of the physics-based loss function is depicted in Figure 6. It is evident that the incorporation of the physics-based loss function enhances the model's generalizability and alignment with the physical phenomena for both strain and deflection.

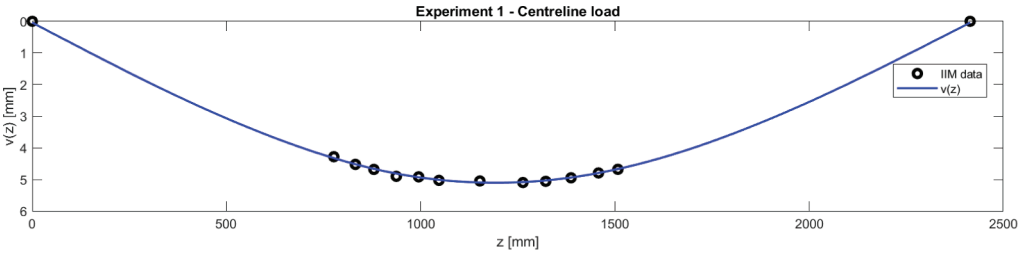

Figure 3. Image-based displacement measurement.

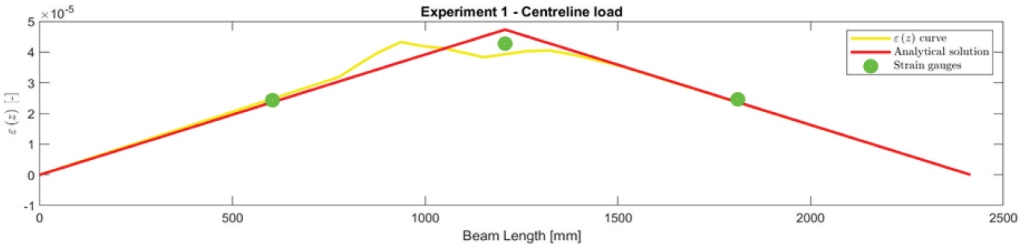

Figure 4. Strain analysis with strain gauges and analytical method.

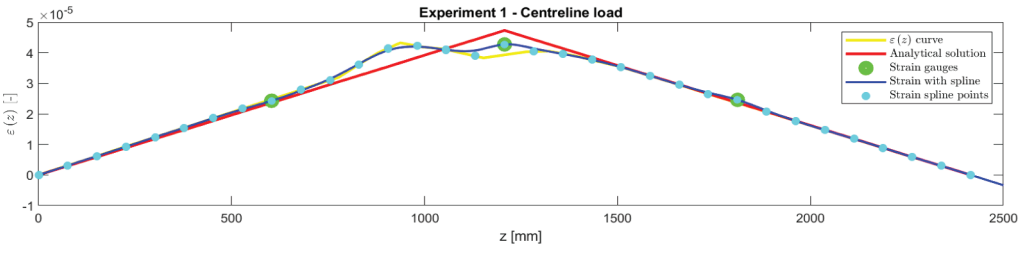

Figure 5. Corrected strain field with strain gauge measurements.

4 CONCLUSION

This study introduces an innovative approach that effectively combines strain gauge data and computer vision with an underlying physical formulation. Our method represents a significant advancement over traditional SHM techniques, particularly in its ability to accurately assess

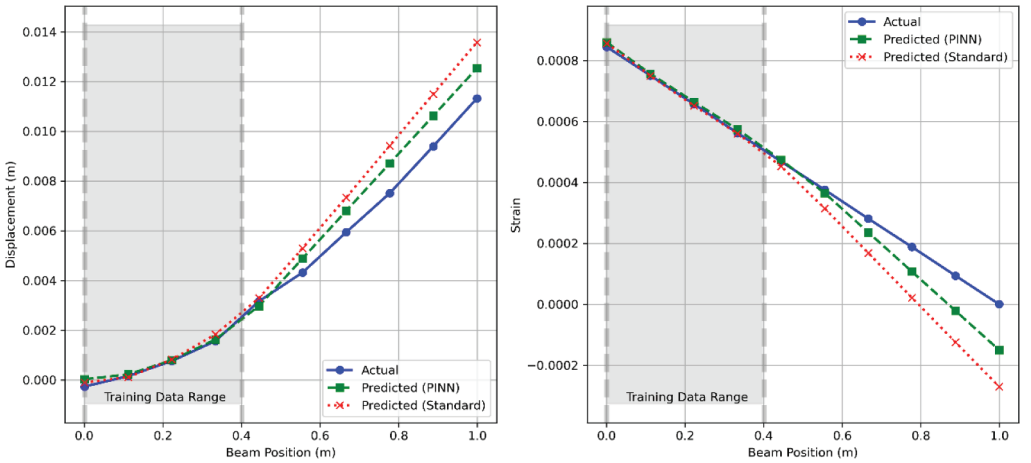

Figure 6. Neural network performance with and without physics-based loss function.

structural integrity. This is achieved by correlating displacement and strain data through corrected measurements. The incorporation of Physics-Informed Neural Networks (PINNs) substantially enhances the accuracy and physical plausibility of the predictions, ensuring close alignment with actual structural responses under various load conditions. While our approach is effective in standard configurations, future work could aim to further enhance and integrate the model's accuracy in more complex structural scenarios, particularly through the application of PINNs. Such advancements promise to broaden the applicability of this innovative approach in the field of SHM.

A smart robotic system for autonomous inspection of large-scale concrete girder

Yujie Cui, Yue Pan, Dalei Wang & Mazeyu Ji
Tongji University, Shanghai, China

Sugong Cao
Zhejiang Scientific Research Institute of Transport, Hangzhou, China

ABSTRACT: Inspecting concrete box girders is crucial for bridge maintenance. Challenges in accessibility and working conditions often hinder effective internal inspections, posing a serious threat to bridge operational safety. This paper proposes a solution using a lightweight and cost-effective robotic device for the automated collection of apparent internal defects in bridge box girders. Emphasizing the bridge environment and the lightweight nature of the device, we optimized mapping, path planning, and tracking schemes. Our robot, equipped with consumer-grade sensors, successfully mapped a hundred-meter-long box girder within a bridge at meter-level accuracy. Path planning covered the entire box girder, collecting defect information from the top and side walls.

1 INTRODUCTION

Concrete box girders in bridge engineering commonly exhibit defects like spalling, exposed reinforcement, and cracks over extended service periods. Manual visual inspections, the prevailing method for inspecting these girders, have inherent drawbacks such as subjectivity, inefficiency, and limited defect detection. The increasing labor costs and inspection volumes have spurred a shift toward automated methods for inspection support (Tung, 2002; M La, 2013; Lei, 2018).

Despite the growing trend towards automation, the distinct environment within concrete box girders complicates the direct application of automation solutions developed for bridge surfaces and exteriors. Weak GPS signals within the girders impede stable robot positioning using GPS, while alternative wireless positioning methods necessitate fixed base stations, adding both cost and inconvenience.

Simultaneous Localization and Mapping (SLAM) technology has witnessed significant development in scene perception over the past two decades, with researchers applying SLAM to bridge inspection (Jung, 2020; Phillips, 2019). However, existing SLAM methods encounter challenges in effectively addressing mapping and localization tasks within box girders. Visual SLAM struggles due to low light conditions and a lack of textured concrete surfaces on inner walls, while traditional laser SLAM faces difficulties in accurate mapping due to the absence of sufficient terrain features.

Another significant hurdle in the system pertains to path planning and coverage detection. While precise mapping simplifies path planning and coverage detection in box girders with simple terrain features, large concrete box girders in expansive bridge structures necessitate the introduction of multi-robot collaborative detection for enhanced efficiency.

Hence, considering the limitations of the box girder environment, this paper enhances existing methods and introduces a fully automated inspection framework specifically tailored for the interior of concrete box girders, as depicted in Figure 1. To address the dim and

DOI: 10.1201/9781003483755-83

feature-limited conditions within box girders, the paper optimizes the laser SLAM algorithm to construct a 2D grid map. Subsequently, the paper partitions the work area for multiple robots on the 2D grid map and employs an optimized Spanning Tree Coverage algorithm to generate efficient work trajectories. Finally, a tracked robot control scheme is proposed to guide the robot in achieving path navigation, image capture, and defect localization.

2 FRAMEWORKS

2.1 *Mapping*

SLAM, a method addressing the challenge of simultaneous robot position determination and map construction in environments lacking prior knowledge, proves particularly effective for mapping tasks within box girders. In this framework, information from various sensors, commonly LiDAR scan data and odometry information, is processed. These represent the point cloud from laser LiDAR environmental scans and the recorded positional data of the robot. Merging these data types enables real-time map generation and accurate estimation of the robot's current pose.

The paper utilizes the Cartographer algorithm, a sophisticated open-source 2D laser SLAM algorithm (Hess, 2016). Cartographer optimizes the robot's pose vector $(\xi_x, \xi_y, \xi_\theta)^T$ through both local and global optimization, where the first two parameters denote translation, and the third represents rotation. Global optimization, involving loop closure detection, eliminates cumulative errors. Local optimization optimizes a cost function by matching laser scan points with the map and updating submaps.

To achieve full automation, active SLAM is introduced, allowing the robot to autonomously explore unknown environments. The Frontier-based Exploration method (Yamauchi, 1997) selects boundaries in unexplored regions to acquire map and localization information simultaneously. This method guides the robot in selecting the next exploration target point with the highest information gain, balancing exploration performance and map information gain.

However, mapping issues arise due to the lack of sufficient environmental terrain features within the box girder, particularly in degraded scenes with long corridors and minimal terrain

features. Different frames scanning the scene exhibit extreme similarity, and odometry accumulates errors, leading to significant mapping inaccuracies.

In the foundational SLAM framework, Correlative Scan Matching (CSM) requires manual parameter tuning and does not consider the impact of degraded scenes and different environments. To address this, we design an environment-sensitive CSM method based on real-time results. This method dynamically adjusts motion weights, achieving autonomous adaptability to various environments (Shi.2023).

The Principal Component Analysis (PCA) method is employed to decentralize the normal vectors of all scanned points in the environment. The first and second eigenvectors, denoted as v_1 and v_2, are determined. The ratio $k = \frac{v_1}{v_2}$, $k \in (1, +\infty)$ is then mapped onto (0, 1) with $\beta = -\frac{1}{k} + 1$, yielding the degradation coefficient β. A value closer to 1 indicates a higher degree of environment degradation.

In SLAM algorithms, the probability distribution of the motion model is typically calculated and represented by a Gaussian distribution $\mathrm{x_i} \sim N(\mu, \sigma^2)$, where x_i represents the estimated robot poses, μ is the initial guess for the pose based on x_{i-1} and $\mathrm{u_i}$, and σ determines the weight of the initial pose. In a series of algorithms based on CSM, the motion score $\mathrm{S_{mot}}$ for each x_i is often calculated using the following formula. In this equation, the basic motion weight σ is replaced with the dynamic weight σ/β, allowing the adjustment of motion weight through the degeneration coefficient.

$$\Delta \mathrm{x_i} = (\Delta \mathrm{x}, \Delta \mathrm{y}, \Delta\theta)^{\mathrm{T}} = \mathrm{x_i} - (\mathrm{x_{i-1}} + \mathrm{u_i}) \tag{1}$$

$$p(x_i|x_{i-1}, u_i) \propto S_{\mathrm{mot}} = \exp\left(-\frac{\beta^2\left(\sqrt{\Delta x^2 + \Delta y^2} + |\Delta\theta|\right)^2}{\sigma^2}\right) \tag{2}$$

2.2 *Multi-robot path planning*

Upon achieving accurate mapping, to enhance the efficiency of detection in large box girder scenes, we can opt for the introduction of multiple robots collaboratively performing the inspection task. Thus, we need to devise path planning for the traversal of the scene by multiple robots, as illustrated in Figure 2. Firstly, this paper conducts down sampling of the grid map based on the robot's radius. Subsequently, the approximate rectangular box girder area is uniformly partitioned and assigned to each robot. After preprocessing the grid map, the paper employs the Spanning Tree Coverage (STC) algorithm to generate loop detection paths, ensuring each robot can access all locations on the map without redundancy. (Kapoutsis.2017)

The map is represented as a grid map, where the number of cells in the map signifies both the required spatial resolution and the transmission ability of the robot. Let's define a sequence set X with a neighboring connectivity length of m. The position of robot $\mathrm{x_i(t)} = (\mathrm{x_i}, \mathrm{y_i}) \in \mathrm{L}$ (where L is the traversable area), and the path length of $\mathrm{X_i}$ is denoted as $|\mathrm{X_i}|$.

The Spanning Tree Coverage (STC) algorithm is able to construct a minimum path covering all the manipulation area L starting from any obstacle-free cell. Each large unit is first split into four small units, which is done to make it easier to form a loop so that the robot can complete the traversal and return to the origin. The non-blocking region is then considered as a node, and neighboring nodes introduce an edge. Next, a minimum spanning tree is constructed using the STC algorithm. Finally, the path formed by each large unit is transformed into a connected loop formed by every group of four small units.

The original mCPP (Multi-robot Coverage Path Planning) problem can be simplified to generate paths L_i for each robot in the non-blocked area, satisfying the problem of minimizing the maximum path length $|L_i|$. This can be expressed mathematically as:

$$\begin{cases} \mathrm{L_i} \cap \mathrm{L_j} = \emptyset, \forall i, j \in 1, \ldots, \mathrm{n_r}, i \neq j \\ L_1 \cup L_2 \cup \cdots \cup L_{n_r} = \mathcal{L} \\ |L_1| \approx |L_2| \cdots \approx |L_{n_r}| \\ L_i \ \text{ is connected} \, \forall i \in 1, \ldots, n_r \\ X_i(t_0) \in L_i \end{cases} \tag{3}$$

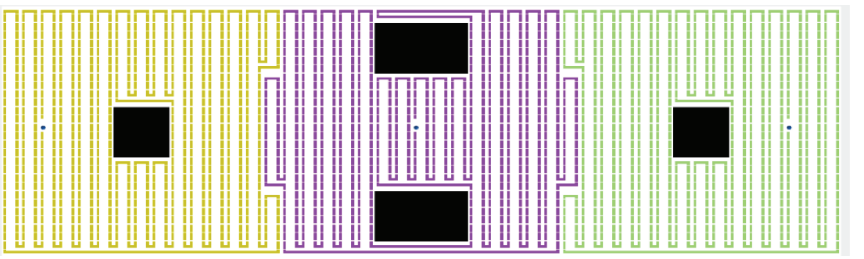

Figure 2. Illustration of multi-robot path planning: The diagram depicts the starting positions of three robots as indicated by blue dots, obstacles represented by black rectangles, and the paths planned by the three robots in yellow, purple, and green. The paths are evenly distributed.

2.3 *Tracking*

In the process of trajectory navigation, the control of tracked robots and the elimination of dynamic map errors during specific travel play crucial roles. The control scheme for tracked robots influences the trajectory strategy, particularly the transition strategy between different target points along the path. Additionally, the paths generated by the global planner need dynamic adjustments based on real-time discoveries of local changes during the trajectory process.

Opting for tracked robots to conduct exploration tasks within bridge box girders offers several advantages, including robust off-road capability, strong load-bearing capacity, and smooth traversal. Tracked robots can adapt to the terrain within box girders, carry additional sensors, and maintain stable operation.

A tracked robot, with one side of its track equivalently viewed as an infinite number of small wheels, ensures uniform rotational speed across these wheels. Therefore, the steering mechanism of a tracked robot aligns with that of a four-wheel-drive robot, involving sliding steering. (Martínez.2004)

In practical operations, precision in-place rotation and straight-line movement can be achieved using a tracked vehicle. Thus, controlling the tracked vehicle involves maintaining consistent wheel speeds, with opposite or identical directions. The magnitude of speed only affects the speed of rotation and forward movement, without introducing tracking errors.

After completing mapping and route planning within the box girder, deviations may occur due to errors in mapping, route planning, or changes in the internal environment during the trajectory process. Consequently, local path adjustments are essential, incorporating real-time navigation planning to achieve obstacle avoidance.

Upon determining the path, if it encounters obstacles, we establish start and target points before and after the obstacle. Utilizing the Time Elastic Band (TEB) algorithm (Rösmann,2012), we connect these points, allowing the path to deform. The deformation criterion involves treating all constraints as external forces acting like rubber bands, enabling the path to circumvent obstacles and avoid disruptions.

$$\mathrm{f(B)} = \sum\nolimits_{\mathrm{k}} \gamma_{\mathrm{k}} \mathrm{f_k(B)} \tag{4}$$

$$B^* = \text{argmin}_B f(B) \tag{5}$$

The objective function $f(B)$ represents a weighted sum of various components and is indicative of the optimization goals. Here, B^* denotes the optimized Time Elastic Band (TEB). The objective function is divided into two categories: penalties expressed through penalty functions, encompassing velocity and acceleration constraints, as well as trajectory-related objectives such as the shortest or fastest path, and objectives related to obstacle distances. The penalty functions employ a piecewise continuous and differentiable cost function to calculate penalties for violating constraints.

$$e_\Gamma(x, x_r, \in, S, n) \simeq \begin{cases} \left(\frac{x-(x_r-\in)}{S}\right)^n & if\ x > x_r - \in \\ 0 & otherwise \end{cases} \tag{6}$$

where x_r is the limit value, S denotes the scaling, n denotes the polynomial order, $\in$ denotes a small offset near the approximation, and $S, n, \in$ affects the accuracy of the approximation.

After the robot reaches each waypoint following the trajectory, it proceeds to perform data collection. The global path planning provides the coordinates of each waypoint, and if the trajectory is modified by TEB, the waypoint coordinates are adjusted accordingly. Once the coordinates of the waypoints are determined, the position of the imaging inside the box girder is derived by combining the gimbal angle at the time of shooting, the lens position, and the distance from the shooting plane to the lens. The gimbal angle is determined by sensors in the servo, while the shooting distance is measured by multiple parallel infrareds ranging sensors mounted on the lens.

3 APPLICATION

3.1 *Robot-design*

We have developed a robotic system for automated detection, as illustrated in Figure 3. The robot consists of three main components: the perception layer, the power layer, and the control layer. The perception layer is equipped with sensors to perceive the environment and collect data. Essential sensors include a laser rangefinder for laser SLAM mapping and a camera for capturing information on the interior walls of the concrete box girder. The power layer comprises essential motion components and energy storage elements, including batteries, motors, and wheels. The control layer is the core part, responsible for algorithm execution and driving various components. Considering the task difficulty and cost, microcontrollers such as STM32 and Raspberry Pi can be used.

In the experiments conducted on the Su-Tong Yangtze River Highway Bridge in Jiangsu Province, China, the perception layer utilized an industrial 4K camera from Hikvision with 32x optical zoom, mounted on a 2-DOF dual-servo gimbal for high-definition imaging of the box girder's interior walls. The perception layer also integrated a 2D laser rangefinder capable of scanning coverage with a minimum measurement distance of 0.05mm.

The power layer includes two batteries with a capacity of 9800mAh each, weighing 0.36kg each. The theoretical robot's rated power allows it to operate for 12 hours. The chassis has a carrying capacity of 3-4kg.

The control layer employs a 16GB Raspberry Pi as the main control board, orchestrating various components of the robot and storing the core algorithms used in this paper. Additionally, two STM32 microcontrollers are used to drive the chassis and the gimbal, respectively.

3.2 *Mapping*

In the testing phase, we conducted on-site mapping at the Su-Tong Yangtze River Highway Bridge in Jiangsu Province, China. The robot employed a 360° LiDAR with a scanning radius of 4 meters. The controller utilized a tracked two-wheel differential drive system with

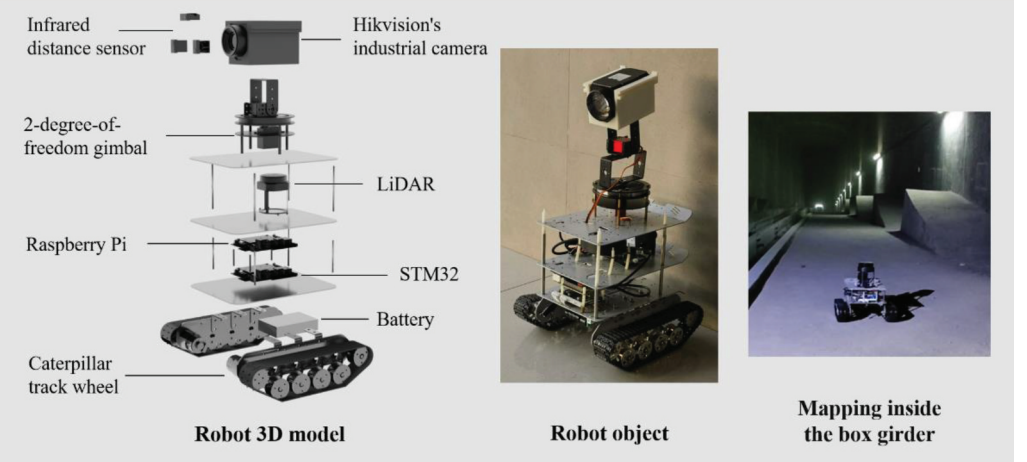

Figure 3. Three-dimensional exploded view of the robot's structure, a physical representation of the robot, and on-site mapping images of the robot within the box girder of the Su-tong Yangtze River Highway Bridge in Jiangsu Province, China. During the mapping process, the robot utilized only the functionality layer equipped with the LiDAR.

a maximum speed of 0.2 m/s. The mapping focused on the northern section of the first continuous rigid box girder in the navigation channel of the bridge, with a length of 139.6 meters, as illustrated in Figure 4.

During mapping, we collected datasets from all sensors and manually adjusted the relevant parameters of Correlative Scan Matching (CSM) within the SLAM framework. Multiple mapping iterations were conducted using the acquired data, as illustrated in Figure 5. In Figure 5 (a), we manually decreased the parameteσ, enhancing the confidence of the observation model primarily based on the laser radar, while lowering the confidence in the motion model. Conversely, in Figure 5 (b), we increased σ, resulting in higher confidence in the motion model and lower confidence in the observation model. It was observed that (a) performed poorly in similar segments of degraded environmental radar scans, while (b) exhibited deviations in describing features in rich environmental areas.

Our optimized algorithm, capable of adapting to the degree of environmental degradation, yielded the best mapping results in Figure 5 (c).

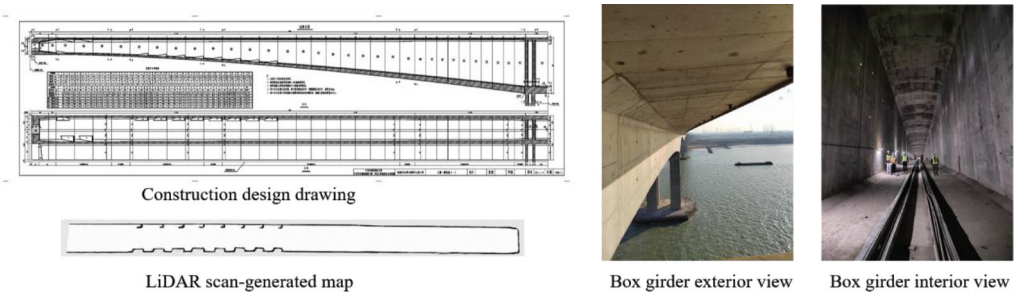

Figure 4. Construction design drawing, LiDAR scan-generated map, exterior view and interior view of the box girders in the navigable channel of the Su-Tong Yangtze River Highway Bridge. The construction design drawing includes side view and top view.

3.3 *Path-planning and tracking*

Once precise mapping results are obtained, path planning on the map becomes feasible. Considering the map's size and obstacles in the actual terrain, we selected an appropriate number

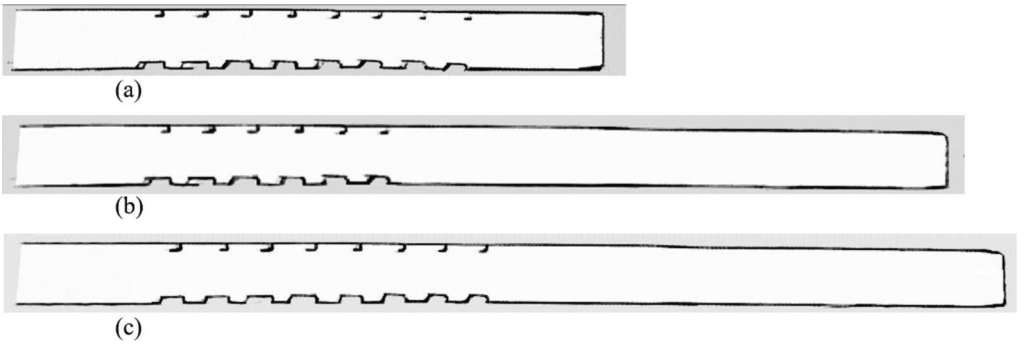

Figure 5. Mapping results under different parameters within the box girder of the Su-tong Yangtze River Highway Bridge in Jiangsu Province, China. (a) and (b) represent manually adjusted parameter results in Correlative Scan Matching (CSM). In (a), $\sigma = 0.1$ while in (b), $\sigma = 0.7$. (c) displays the mapping results of our algorithm, which can adapt to environmental features.

of robots and interval between working points to accomplish path planning, as depicted in Figure 6. It is evident that in multi-robot planning, effective terrain coverage is achieved with an even distribution of scanning workload for each robot. Additionally, Figure 6 showcases partial stitching results of scanned images along working points, utilizing a feature point matching algorithm to achieve seamless integration.

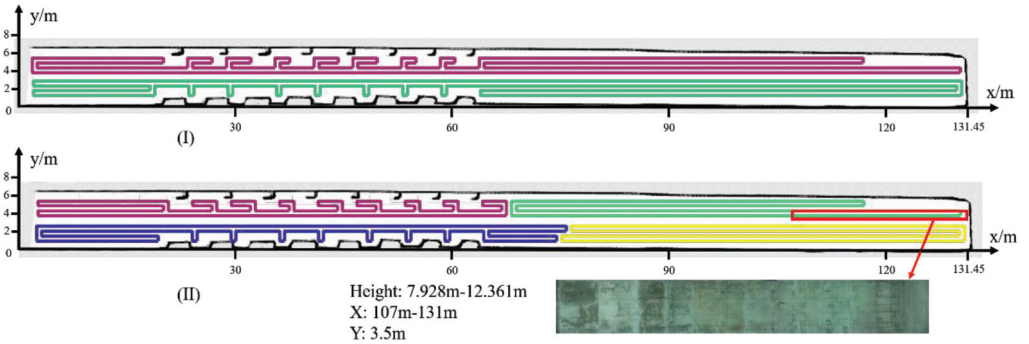

Figure 6. The path planning results for two robots and four robots, along with the stitched images from collecting data at selected working points.

3.4 *Detection*

During tracing, the robot captures images of the top and side walls at each working point, ensuring a capture range diameter approximately equal to the distance between working points for a comprehensive scan of the box girder. At a working point (x_0, y_0), the angles of the two gimbal servos θ_1, θ_2 and the distances d_1, d_2, d_3 from three infrared sensors (determining the distance from the lens to the capture plane) are synchronized and recorded with the captured images. This process facilitates determining the position of each image within the box girder, as illustrated in Figure 7.

The robot traverses the path during the data collection process of inspecting box girder's defects. To visually represent the location information of defects more intuitively, two surface images of beams obtained directly above two working points were selected, as shown in the right part of Figure 7. In the actual inspection procedure, when the machine learning algorithm identifies a relatively severe defect, the specific location of the defect within the beam can be pinpointed through the location information associated with the image. This assists human operators in detecting and repairing the defects.

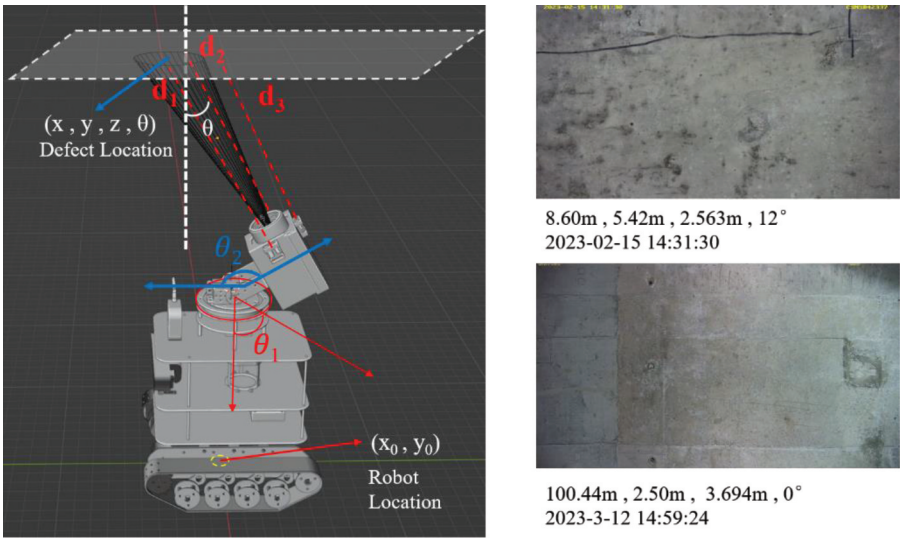

Figure 7. Schematic diagram illustrating the principle of concrete surface defects localization within the box girder. Two examples of defect location are also illustrated.

4 CONCLUSION

In this study, we developed a robotic autonomous inspection system tailored for the interior of large concrete box girders. The key contributions include the design of the robot body, synchronous mapping and localization (SLAM) within an unknown box girder environment, as well as a solution for path planning and tracking. Preliminary experimental validation was conducted on the Su-tong Yangtze River Highway Bridge. For mapping and localization, we employed the Frontier-based Exploration method for autonomous active SLAM and the Cartographer algorithm optimized for degraded scenes, resulting in higher precision in mapping and localization within the box girder. Multi-robot collaborative path planning was employed for increased efficiency. A robust track-based robot control strategy, using the TEB algorithm for dynamic obstacle avoidance and tracking, was implemented. The autonomous inspection system collected images of surface defects within the concrete box girder, obtaining accurate information for semantic segmentation and subsequent post-processing.

This comprehensive solution enables the fully automated collection of defect data, providing clear and intuitive records of the location and severity of box girder defects. This system greatly facilitates tasks such as box girder warning and maintenance.

In the future, we plan to deploy multiple robotic systems in actual box girder environments to more accurately reflect the advantages and limitations of the proposed methods. We will address any shortcomings through targeted improvements and enhancements.

LSTM-based structural pattern recognition for floating bridges

S. Ryu, S. Min, Y.J. Kang & S. Kim
Korea University, Seoul, Korea

ABSTRACT: This study introduces a deep learning approach to identify patterns in floating bridges, specifically employing the Long Short-Term Memory (LSTM) algorithm to analyze time-domain data. Wind, wave, and displacement that have been measured in the Bergsøysund bridge between the years 2014 and 2018 were used for the pattern recognition. For the feasibility study, the LSTM-based model was trained to recognize the complicated relation between the variables including the environmental conditions and induced response. After that, the response predicted by the trained model was directly compared to the measured one to evaluate the pattern model. According to this study, the proposed method can effectively recognize the structural pattern of a floating bridge from measured data. In addition, the pattern analysis-based structural health monitoring method can be used for early detection of the structural condition change of the floating bridge.

Keywords: Floating bridge, structural pattern recognition, deep learning, wave, wind

1 INTRODUCTION

Recently, several types of offshore structures have been actively developed for various purposes, such as sea crossing transportation and renewable energy facilities, as well as conventional offshore oil and gas facilities. (Min et al., 2023a) Among these, the floating bridge is one of the general structural systems in the world as a prospective sea crossing transportation system. The fundamental concept of floating bridges, believed to have first emerged around 2000 BC(Watanabe, 2003), has gained recognition in recent times as a vital component of infrastructure. Floating bridges offer significant advantages, particularly in reducing transportation time, thereby proving to be a crucial infrastructure solution in specific geographical and logistical contexts. In conventional infrastructure management, regular and systematic inspections are a generalized norm for identifying potential damages. These routine inspections are often complemented by detailed structural surveys and evaluations, especially when there is a need for an in-depth assessment of structural integrity and performance. In the case of large-scale infrastructures, real-time sensors are attached to the structures. These sensors facilitate the collection of response data crucial for both short-term and long-term Structural Health Monitoring (SHM). (Min et al., 2023b) Floating bridges, categorized as significant transportation infrastructures in marine environments, are similarly expected to benefit from a SHM system based on real-time data acquisition. An effective SHM system is critical in assessing structural health, thereby playing a key role in preventing structural deterioration and averting catastrophic events, such as collapses. (Min et al., 2023c)

However, in contrast to traditional bridges, floating bridges present a challenge in the realm of SHM. With only around 20 such structures installed worldwide (Kvåle et al., 2016), floating bridges are relatively scarce. This rarity limits the availability of measurement cases, posing significant challenges in acquiring comprehensive external and response data essential for SHM analysis. Consequently, there are relatively few studies investigating the feasibility and effectiveness of SHM systems in the context of floating bridges. In the specific instance of the Bergsøysund Bridge, a comprehensive sensor system has been implemented to monitor dynamic responses. Kvale et al.

DOI: 10.1201/9781003483755-84

(2023) provided data obtained from these sensors, which include metrics on acceleration, displacement, external sources, and sensor locations. (Kvåle et al., 2016) The current study leverages this rich dataset to evaluate the potential application of SHM analysis to floating bridges, utilizing the real-time data collected from the Bergsøysund Bridge.

2 PATTERN RECOGNITION-BASED IDENTIFICATION OF STRUCTURAL CONDITION

2.1 *Overview*

Structural responses are influenced by external sources as well as by the structural characteristics, which are defined by the geometry, material properties, and boundary conditions of the structure. This indicates that the responses of structures to external sources are inherently determined by these characteristics. Therefore, if we can successfully recognize and model the behavioral patterns of a structure, then it becomes feasible to estimate or predict structural responses in advance using a pattern model. (Min et al., 2023c, Lee et al., 2020) However, when working with actual measurement data, the challenge lies in the numerous of external sources affecting the structure. Accounting for all these sources may not be feasible. To overcome these limitations, our methodology focuses on recognizing structural patterns using previously measured structural responses and a limited range of measurable external sources.

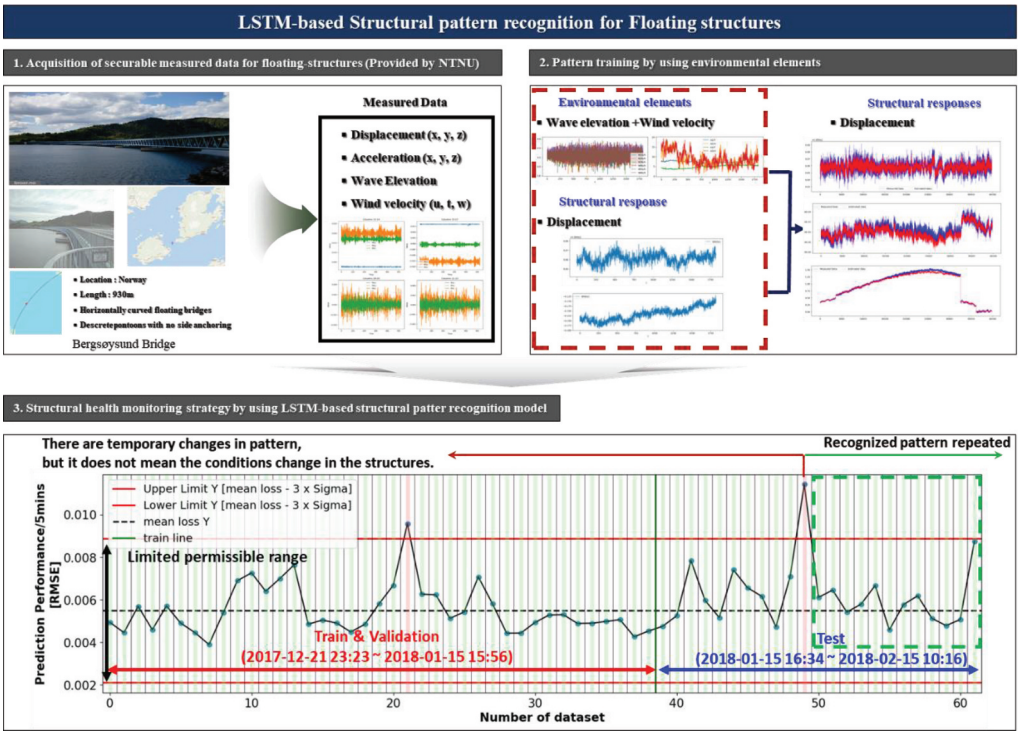

Figure 1. Overview of the proposed method for structural condition change recognition.

Figure 1 illustrates our methodological framework for detecting structural condition changes. We begin by analyzing a comprehensive dataset of the Bergsøysund Bridge's structural responses to identify behavior patterns. This analysis is conducted using the Long Short-Term Memory (LSTM) algorithm, well-suited for time-series data. The next step involves comparing the model's predicted responses with real data from structure-mounted sensors. If

the structure is stable and undamaged, the estimated data typically aligns closely with the actual measurements. However, significant differences between these datasets can indicate major changes in structural conditions or the presence of damage, aiding in continuous monitoring of the structure's integrity.

In this study, the three-sigma rule was utilized to define a threshold for the acceptable range of variance between the predicted and actual measured structural responses, serving as an indicator of changes in structural condition. The three-sigma rule, grounded in the principles of normal distribution, asserts that approximately 99.7% of data lies within ±3 standard deviations from the mean. To apply this rule, we initially calculated the prediction error for the structural response from the data trained. Subsequently, the mean and standard deviation of this prediction error were determined, setting the bounds for an acceptable range of difference in the test data. Finally, in this study, variation in structural conditions was detected and pattern analysis was performed based on the threshold calculated through three-sigma.

2.2 *Measured data details for patter recognition of floating bridges*

The Bergsøysund Bridge, a 930-meter-long horizontally curved pontoon bridge located in Norway, presents a unique structural design. Unlike most floating bridges, which are typically designed as continuous pontoon girder types with reduced flexibility due to side anchoring, Bergsøysund stands out as one of the few discretely pontoon bridges in the world. (Kvåle and Øiseth, 2017) As part of a project by the Norwegian Public Roads Administration (NPRA), Kvale et al. are making publicly available monitored dynamic response data of the Bergsøysund Bridge.(Kvåle et al., 2023) This dataset, stored in a hierarchical metadata structure, contains a variety of measurements such as acceleration, displacement, wave height, and wind speed.

These measurements were recorded from 2014 to 2018 at sampling rates of 2 Hz and 10 Hz. Once the threshold is exceeded, data measurement begins and lasts for 30 minutes. Therefore, we verified that data was missing for some periods where the threshold was not met. The available measurement data of Bergsøysund Bridge are shown in Figure 2. This study used the data on the period during which the GNSS Sensor was installed since we are focusing on the pattern recognition of structural responses such as displacement.

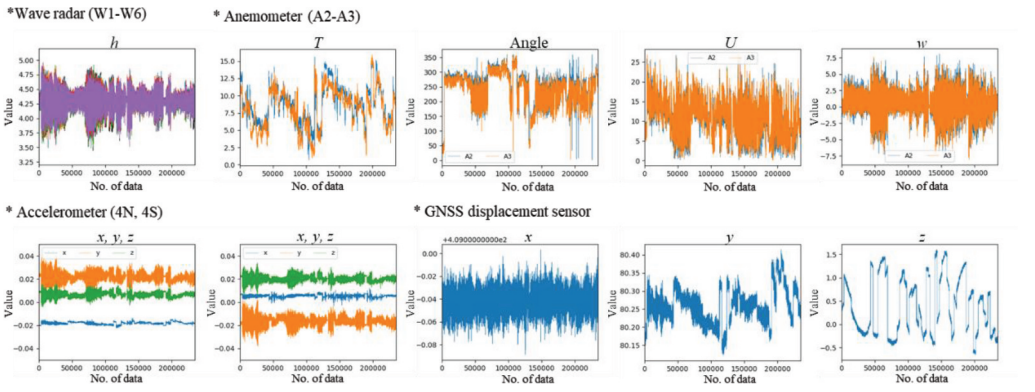

Figure 2. Available measurement data of bergsøysund bridge.

3 PATTERN RECOGNITION USING LSTM ALGORITHM

3.1 *LSTM architectures*

Many studies have been conducted on damage detection using various deep learning algorithms such as deep neural networks (DNNs), convolutional neural networks (CNNs), recurrent neural networks (RNNs), and long short-term memory (LSTM). (Carden and

Brownjohn, 2008, Gulgec et al., 2017, Moradi et al., 2023)Among these, LSTM algorithms are a special kind of Recurrent Neural Network (RNN) designed to address the vanishing gradient problem associated with standard RNNs. The core idea of LSTM is its ability to maintain long-term dependencies in sequential data, making it exceptionally well-suited for time series analysis, speech recognition, and similar tasks.

The dynamic response dataset from the Bergsøysund Bridge offers two sets of data sampled at 2 Hz and 10 Hz. In this study, the 2 Hz dataset was chosen, considering the balance between memory usage and computational speed. The focus of the study was on displacement as a primary structural response, hence data collected during the period the GNSS sensor was operational was utilized. The period from 2017-12-21 23:23 to 2018-01-15 15:56 was used as training and validation data for learning. Following this, the testing phase was divided into two distinct segments to assess the long-term effects. The first segment spanned from 2018-01-15 16:34 to 2018-01-16 03:54, and the second segment was conducted to 2018-02-15 10:16. From the available data - acceleration, wave height, wind speed, temperature and displacement - wind speed and wave height, temperature were selected as external sources, and displacement was selected as the structural response for the LSTM-based pattern recognition. The displacement measured via GNSS was the primary focus, so data from sensors near the center, where the GNSS was installed, was applied in this analysis. The LSTM architecture configuration used in this study is shown in Table 1 and the used data in study is shown in Figure 3.

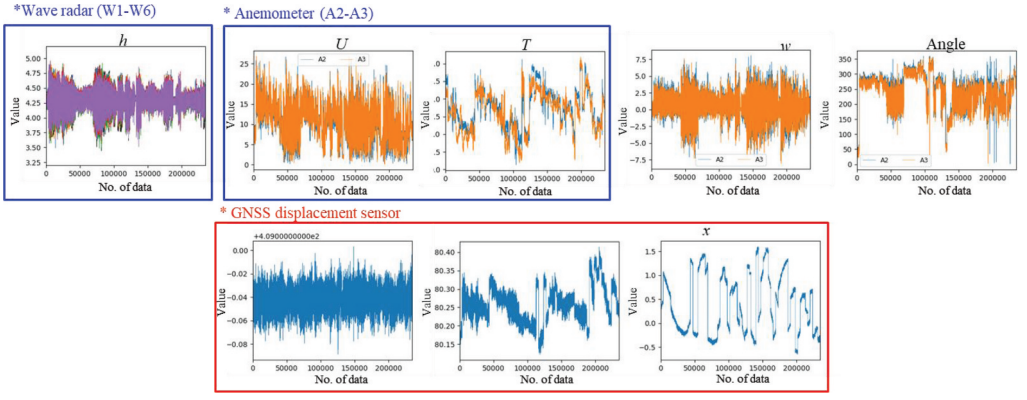

Figure 3. Used measurement data in SHM analysis.

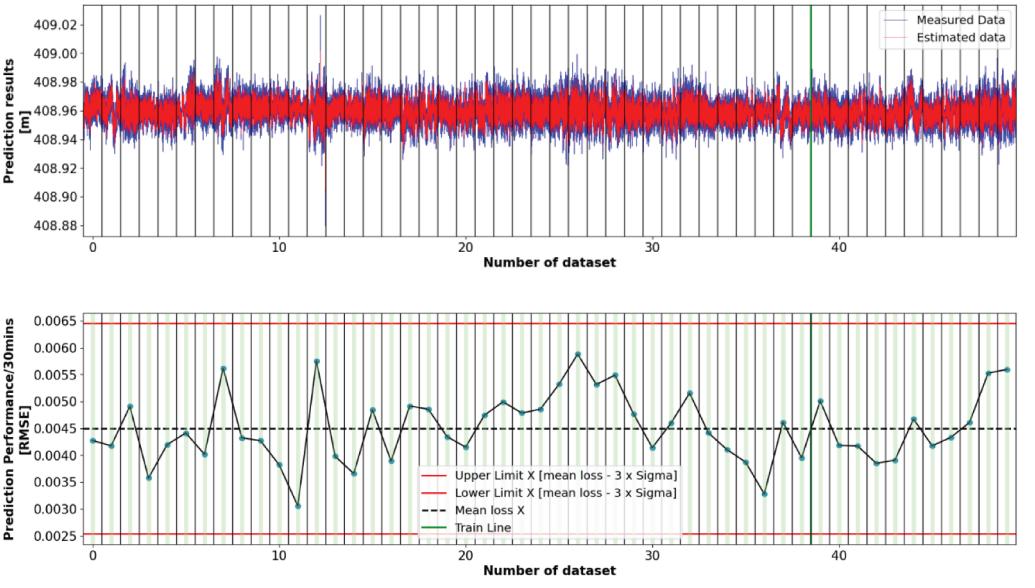
Table 1. LSTM model hyperparameters for structural pattern recognition.

Hyperparameter	LSTM (Limited external sources & structural response)
Input variables	Wind velocity, Wave elevation, Temperature, Displacement
Output variables	Displacement
Batch size	4,000
Number of hidden layers	1
Epoch	100
Number of units in hidden layer	200
Optimizer	Adam
Learning rate	0.001
Loss function	MSE
Activation function in hidden layer	ReLU
Weight initializer	glorot_uniform

3.2 *Pattern recognition using wave elevation, wind velocity and GNSS data*

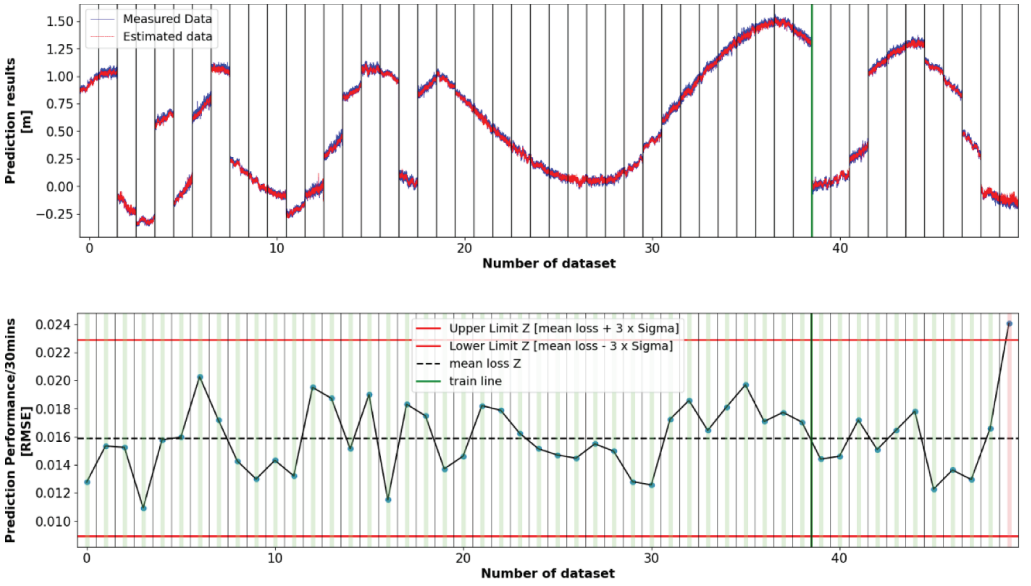


The methodology proposed in this study is predicated on the utilization of a deep learning algorithm that demonstrates robust predictive performance. Owing to its capacity to effectively capture the time-series characteristics of data, LSTM is particularly adept at processing sensor data that exhibits temporal features. To assess the predictive performance of the LSTM-based model employed in this study, regression performance metrics such as Mean Absolute Error (MAE) and Root Mean Squared Error (RMSE) were applied to the test data. As a result, confirmed through regression performance indicators in Table 2, The target main responses, longitudinal and lateral positions, and heave were confirmed to have high average performance with MAE of 0.0135 and RMSE of 0.0179.

Table 2. MAE, RMSE performance of LSTM-based model.

	MAE	RMSE
Position	m	m
Longitudinal	0.0034	0.0044
Lateral	0.0053	0.0067
Vertical (Heave)	0.0317	0.0427

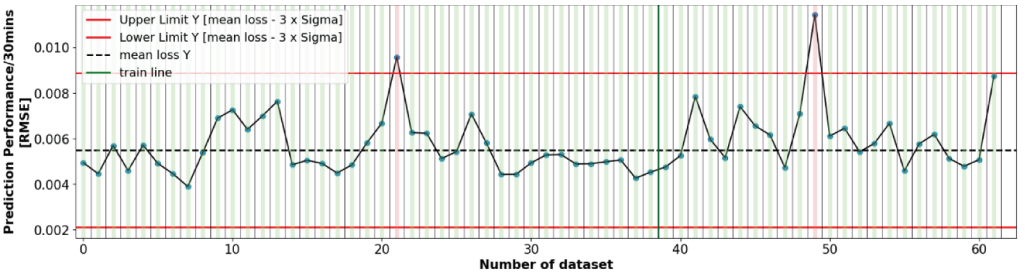
The results of prediction and pattern analysis are shown in Figure 4. Pattern analysis in this study was conducted using a recognized pattern through LSTM. To evaluate the performance, a graph was plotted with time on the x-axis and prediction performance on the y-axis. The y-value at any point on this graph represents the average difference between the predicted and directly measured data over a thirty-minute interval, serving as an indicator of pattern recognition performance. A red line on the graph delineates the calculated threshold through the three-sigma rule.



As you can see on the Figure 4, the pattern analysis results reveal that the majority of displacement values within the test section fall within the established limited permissible range. This observation leads to the inference that the structural condition of the bridge remained without variation throughout the test period, which spanned 2018-01-15 16:34 to 2018-01-16

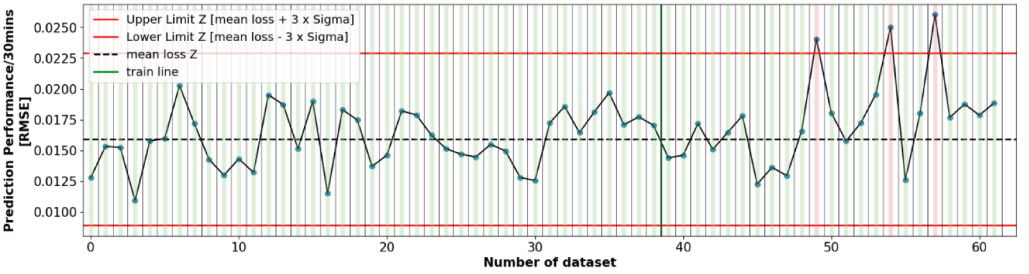
(a) Long-term estimated performance and pattern analysis (RMSE, Longitudinal position)

(b) Long-term estimated performance and pattern analysis (RMSE, Lateral position)



(c) Long-term estimated performance and pattern analysis (RMSE, Heave)

Figure 4. Long-term estimated performance by recognized pattern



03:54. In the case of lateral position and heave, some values did exceed this permissible range. However, these instances are considered to represent temporary fluctuations in the pattern rather than indicative of any significant changes in the structural conditions or damages to the bridge.

To verify that the deviations observed were merely temporary, this study extended the pattern analysis to a longer test period while applying the same recognized pattern. The pattern analysis results for lateral position and heave about prolonged test periods are shown in Figure 5. The prolonged analysis confirmed that the values eventually returned to within the

limited permissible range, conforming to the recognized pattern. This outcome suggests that the instances of values exceeding the permissible range were simply transient anomalies and did not signify any significant changes in the structural condition. On the other hand, a consistent pattern of values exceeding the limited permissible range, if observed repeatedly, could signify a change in the structural condition, potentially indicative of damage or the risk of catastrophic events such as a collapse.

(a) Long-term estimated pattern analysis (RMSE, Lateral position)

(b) Long-term estimated pattern analysis (RMSE, Heave)

Figure 5. Long-term estimated performance by recognized pattern.

This study suggests that the proposed methodology has the potential to effectively detect variations in structural conditions by directly comparing measured responses with those predicted from the recognized pattern. Although this data-driven approach may not precisely identify the specific causes of structural changes, it acts as a reliable tool for determining whether a structure is experiencing degradation or alterations in condition without extensive investigative procedures.

4 CONCLUSION

In this study, we trained and evaluated the LSTM models to predict structural responses using long-term measurement data from Bergsøysund Bridge to detect changes in the structural conditions. We confirmed that LSTM model effectively estimates structural response since the data shows time series characteristics. This model was employed to analyze the variations in the predictive performance and structural response patterns using actual data measured in Bergsøysund Bridge. In addition, a methodology was proposed to identify variations in the condition of the structure. The results of this study can be summarized as follows:

(1) The methodology adopted in this study relies on a model that demonstrates substantial learning and high predictive performance. The Long Short-Term Memory (LSTM) algorithm, known for its effectiveness with time-series data, was employed. The trained LSTM model exhibited impressive performance in estimating structural responses. The primary responses targeted, namely Longitudinal and lateral positions, and Heave showed high

average performance, with a Mean Absolute Error (MAE) of 0.0135 and a Root Mean Squared Error (RMSE) of 0.0179.

(2) The application of the LSTM model for pattern analysis facilitated the identification of the structural response pattern. Throughout the testing phase, it was observed that the majority of the predictive performance remained within the established threshold. This consistency implies that structural condition continues without notable variation. Although there were instances where some values exceeded the permissible range, these occurrences were interpreted as temporary fluctuations, not as indicators of a permanent change in the structural condition.

Pattern recognition was conducted using an LSTM model trained with data from a floating bridge, leading to the development of a methodology for verifying structural condition changes. This approach enables the assessment of structural conditions by directly comparing the measured responses with those predicted from the recognized pattern. However, it's important to note that the data used in this study did not encompass major structural changes such as damage or collapse, resulting in a largely consistent overall pattern. However, because the data used in this study did not include major condition changes in the structure, such as damage or collapse, the overall pattern was maintained. Therefore, research is needed to confirm changes in the pattern by simulating situations where damage occurs by adding noise to measured data.

CONFLICT OF INTEREST

The authors declare that the study was conducted in the absence of any commercial or financial relationships that could be construed as potential conflict of interest.

Vision-based structural displacement measurements using deep learning and super-resolution

Mubarak F. Abu Zouriq & Daniel G. Linzell

Roya Nasimi
Department of Engineering, California State University East Bay, Hayward, CA, USA

ABSTRACT: Vision-based displacements can be used to measure response of structures subjected to dynamic loading. The accuracy of these measurements can be dependent on a number of factors, with image resolution being one of the most critical factors. This study focuses on improving the accuracy of displacement measurements via tests of a dynamically loaded, reduced scale, cantilevered beam using a consumer-grade camera. The effectiveness with which a deep learning based Super-Resolution approach improved image quality was studied by training an Enhanced Super Resolution Generative Adversarial Network (ESRGAN). ESRGAN aims to construct artificial high-resolution frames by upscaling original frames to twice their dimensions with sharper details, leading to enhanced measurement accuracy. ESRGAN was selected for study because of its reported ability to generate detailed and realistic images. To examine SR model accuracy, displacement measurements from the original frames and from SR-extracted frames were compared to reference displacements measurements taken using a contact sensor. Results showed that root mean square errors (RMSEs) of the measured dynamic displacements were smaller when SR image enhancement was used.

1 INTRODUCTION

Structures can be subjected to various loads and environmental conditions, which may make it necessary to periodically monitor their health to maintain operational safety (Farrar & Worden, 2007; Feng et al., 2016). Increased need for safe, efficient, and economical monitoring solutions makes non-contact, computer-vision (CV) techniques a compelling option, particularly using low-cost cameras (Lydon et al., 2019).

Research examining image utilization to accurately measure structural displacements has encompassed three main areas: tracking movement of predefined templates (Xu et al., 2021; Du et al., 2022; Azimbeik et al., 2023); special feature point matching (Dong & Catbas, 2019; Franco et al., 2017; Brox & Malik, 2010); and optical flow techniques (Nie et al., 2022).

Employing low-cost cameras to extract dynamic displacements can potentially provide a simple, cost-effective data collection option (Wang et al., 2023). However, a perceived limitation is video quality as subtle deformation changes may not be adequately captured (Feng & Feng, 2016).

Super-Resolution (SR) can enhance images beyond original camera capabilities. the technique uses original images to generate artificial High Resolution (HR) images, which can be utilized to mitigate consumer-grade camera limitations (Yue et al., 2016). SR encompasses two prominent approaches, interpolation-based techniques and deep learning-based methods (Zhang & Yu, 2022). Interpolation-based SR embeds additional pixels in original Low-Resolution (LR) images to generate upscaled images by creating artificial pixels between original ones, with their values estimated using interpolation algorithms, such as bicubic or bilinear interpolation

DOI: 10.1201/9781003483755-85

(Gilman et al., 2008). Although interpolation-based methods provide a quick and computationally efficient SR approach, resulting images lack fine details or high-frequency components (Zhang & Yu, 2022). Deep learning-based SR leverages advanced neural network models, greatly enhancing image resolution. Deep learning models such as Convolutional Neural Networks (CNNs) and Generative Adversarial Networks (GANs) map between LR and HR pairs that can capture complex patterns and features when trained on extensive datasets, allowing the generation of upscaled, detail-rich HR images (Hoque et al., 2019).

The application of deep learning in SR has significantly advanced the accuracy and visual fidelity of upscaled images, finding widespread use in various domains. Many researchers have investigated the efficacy of SR models for crack detection, using techniques that include Attention-Dense Residual and Generative Adversarial Network (ADRAGAN) (Zhou et al., 2022), and Cycle Generative Adversarial Network (CycleGAN) (Zhang et al., 2020). The incorporation of these techniques substantially improved crack detection performance and growth tracking. Using SR methods with cameras to reduce structural displacement measurement error has seen more limited research activity. The effectiveness with which Super-Resolution Generative Adversarial Networks (SRGAN) improved displacement measurements using SR has shown considerable promise under static and dynamic loads (Sun et al., 2022), but the scope of dynamic evaluation needs more investigation as the performance of the SR under variable structure-to-camera distances, angle of the camera with respect to the structure, and the surrounding circumstances such as the lighting have not been investigated.

The study summarized herein provides some preliminary results related to the effectiveness of using deep learning-based Enhanced Super-Resolution Generative Adversarial Networks (ESRGAN) for image improvement when applied to the measurement of dynamic displacements. Outcomes of the study can serve as a foundation for subsequent research, potentially facilitating expansion of the ESRGAN deep learning technique into image based SHM and helping address increases demand for high-quality and accurate image-based monitoring that would effectively support more informed infrastructure management.

2 METHODOLOGY

This study utilized the multi-stage methodology presented in Figure 1 to extract improved, vision-based, vertical displacement measurements of a reduced scale, cantilevered beam. The primary concept revolves around generating HR images through transformation of captured LR counterparts and subsequently utilized these enhanced images to determine displacements. The subsequent sections summarize each stage provided in the figure.

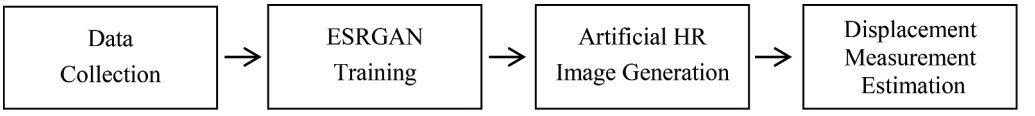

Figure 1. Proposed methodology.

2.1 *Data collection*

To create the ESRGAN model, the proposed methodology necessitated acquiring two types of image-based data. These were: 1) low-resolution video recordings of the cantilevered beam under dynamic excitation using an inexpensive, stationary camera; and 2) high-resolution images taken using a camera from a mobile device.

2.2 *ESRGAN training*

To train the ESRGAN model, an area that includes the region of interest (ROI) and its surroundings was cropped from the HR images to reduce computational needs. Corresponding LR images

were then developed by artificially degrading the HR dataset acquired using Python's OpenCV package via downscaling images to half their original size, imposing Gaussian white noise, and blurring the images by replacing each pixel value with the average value of its neighboring eight pixels. ESRGAN was developed and trained using Python by mapping features from degraded images to corresponding HR images.

2.3 *Artificial HR image generation*

The trained ESRGAN model was utilized to generate artificial HR images from extracted video frames that captured structural response. Before feeding the video frames to the ESRGAN model, a frame cropping operation was performed so that a smaller section of the frames containing the ROI could be analyzed.

2.4 *Displacement measurement estimation*

Displacements were extracted from the artificial HR images and the original LR frames by employing target-free feature tracking, which was selected due to its ability to extract feature motion at sub-pixel accuracy when coupled with an appropriate tracking algorithm. Necessary steps included lens distortion correction using intrinsic and extrinsic camera parameters, defining ROI for the target location on the structure, extracting the Speeded-Up Robust Features (SURF) from the ROI in the video frame prior to system excitation, and tracking movement of SURF features through the video frames with respect to a reference object appearing in the background using the Kanade-Lucas-Tomasi (KLT) algorithm. Average resulting motion of important features was then calculated in pixel coordinates and converted to displacements using a scale factor obtained via a dimensional relationship of a known object size to pixel sizes in the image.

3 EXPERIMENTAL SETUP

A simple, reduced scale, cantilevered beam was used as the test article. The beam, constructed of mild steel and 1100 mm long, 76 mm wide, and 6.5 mm thick, was made thicker in an arbitrarily selected ROI via the addition of wood blocks. Features within this ROI were enhanced using colored tape, which provided additional texture and contrast.

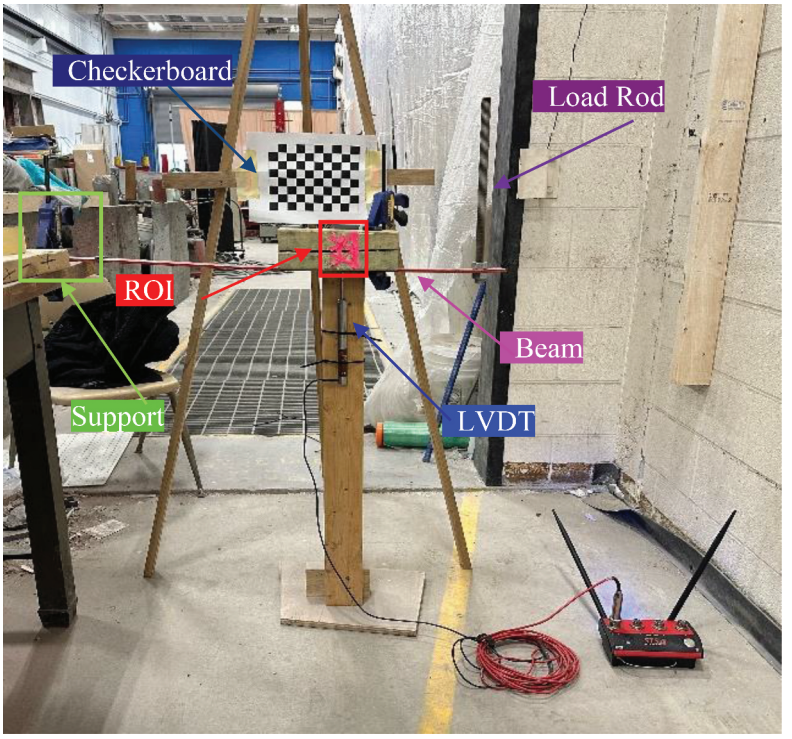
The beam was manually excited vertically using a steel rod affixed perpendicular to its longitudinal axis by pushing the rod downward and upward by hand. Reference vertical displacements were measured using a Linear Variable Differential Transformer (LVDT) at mid-length of the beam Image-based displacements were captured using a low-cost camera on a tripod 4.5 m away from the beam. A 20 mm checkerboard was used to find the corresponding scale factor and convert units of displacements from pixels to millimeters. An overview of the test is shown in Figure 2.

For ESRGAN model training, 250 HR images were collected at varying orientation and positions with respect to the beam using a high-resolution smartphone. As discussed previously, collected HR images were degraded by downscaling, imposing noise, and blurring to create corresponding LR images for ESRGAN training. Figure 3(a) shows a sample of an artificially degraded image and Figure 3(b) shows its corresponding, original, HR counterpart. Image pairs such as these were used to train the ESRGAN model.

4 RESULTS

After training the ESRGAN model using the image pairs, it was utilized to process the video frames and enhance the quality of the video data collected using the low-cost camera. A sample, cropped, LR frame, and its corresponding SR-generated image are shown in Figure 4.

The beam dynamic displacement time histories were calculated using both the original LR frames from the low-cost camera and enhanced SR artificial frames created using ESRGAN.



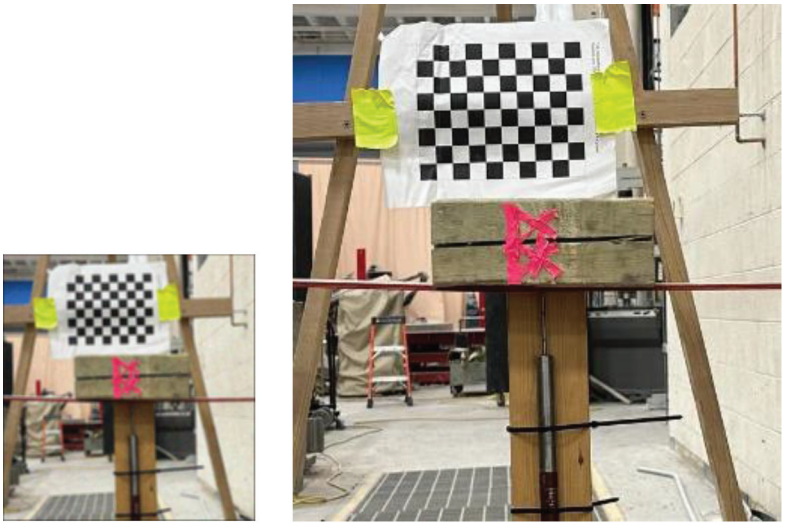


Figure 2. Experimental setup.

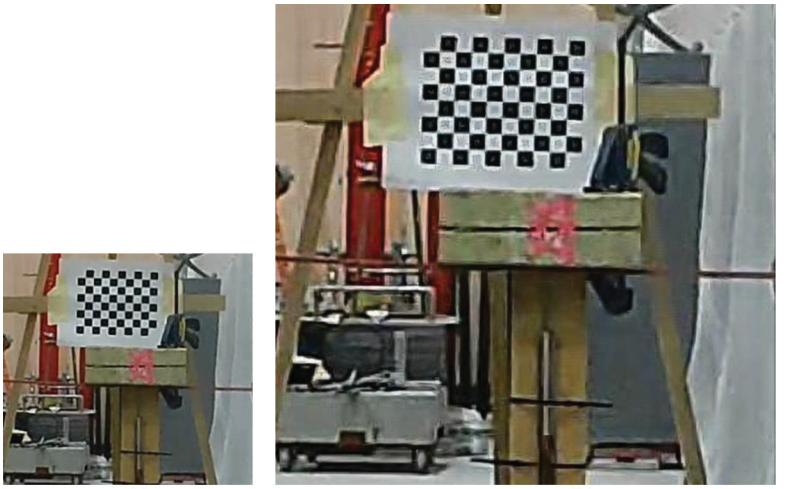

(a) (b)

Figure 3. Sample of HR-LR pairs; (a) LR image; (b) HR image.

Calculated displacements were compared to those measured using the LVDT. A sample time-history comparison is shown in Figure 5. Results indicate that extracted structural displacement accuracy was improved using the generated SR images, as it shows more pronounced alignment with LVDT measurements, when compared to response extracted using the original LR images.

Measurement accuracy was further examined using Root Mean Square Error (RMSE) values between the SR and LR displacement measurements and the reference LVDT values. The results showed that, for this test, using enhanced images for displacement measurement resulted in reducing the RMSE from 0.24 mm for LR measurements to 0.17 mm for SR measurements (a 29% reduction). This level of error reduction mimicked what was observed for all tests and can potentially highlight the efficacy of the proposed enhancement methodology for refining displacement measurement precision using low-cost cameras.

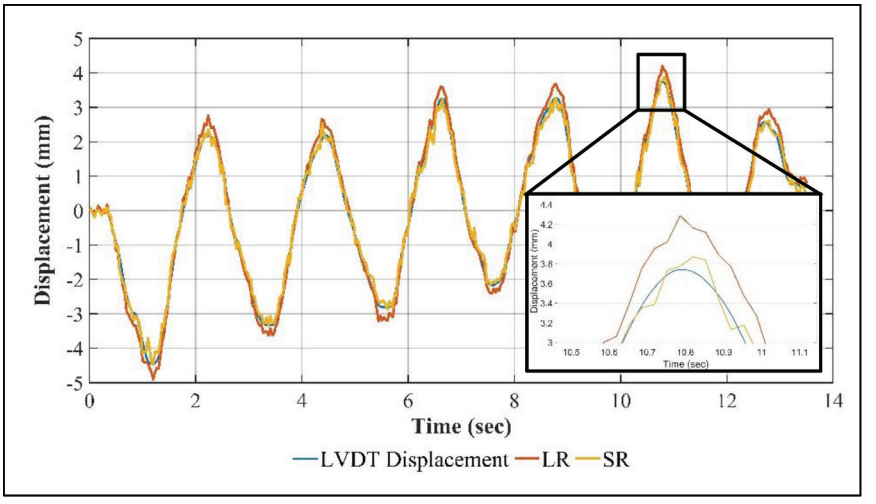

Figure 5. Vertical displacement measurements for the two types of frames.

5 CONCLUSIONS

This study investigated the efficacy of deep learning-based SR image enhancement for SHM dynamic displacement measurements captured using low-cost cameras. The ESRGAN model was selected and an architecture developed whose accuracy was examined using simple reduced scale cantilevered beam dynamic tests. The process used to develop and examine the

SR application involved acquisition of HR images using a high resolution mobile phone camera and videos using a low-cost camera, training the ESRGAN model using the high-quality images, and subsequently applying this trained model to enhance the frames from LR video that captured the beam movement. Vertical displacement time histories were extracted using the post-processed ESRGAN artificial high-resolution images and original LR images captured from the low-cost camera. Displacement measurements from both set of images were compared to one another and LVDT measurements.

Results indicate that using the artificial SR images leads to an accuracy improvement in vertical displacement extraction as a result of frames quality refinement. These results show that SR may be able to adequately improve low-cost camera resolution to the point where extracted displacements could be used within an SHM system.

Multimodal data collection using mobile robotics for rapid structural assessment

Furkan Luleci, Abdulrrahman AlGadi & F. Necati Catbas
Department of Civil, Environmental, and Construction Engineering, University of Central Florida, USA

ABSTRACT: This study focuses on assessing civil engineering systems lacking documentation, a common challenge in assessing old systems. Using tools like cameras and LiDARs to generate 3D models of the structure is a useful implementation; however, it becomes difficult when these systems are off-limits due to disaster-induced structural risks. Using mobile robots emerges as a promising solution to this limitation. Thus, this study employs a wheeled Unmanned Ground Vehicle (UGV) equipped with cameras, LiDARs, and other sensors (e.g., accelerometers) to collect multimodal data, including visual and monitoring. The study demonstrates using the UGV to collect data from a mechanical room of a building. The UGV navigates the room, collecting various data such as images, LiDAR scans, and vibration data while generating the interior mapping of the room in real-time. This study presents some of the collection results and highlights the significance of using mobile robotics for rapid assessments of civil systems.

1 INTRODUCTION

1.1 *Background*

The condition assessment techniques of existing civil engineering structures and infrastructure systems are vital as these systems age and undergo deterioration over time. Typically, these assessments involve traditional techniques like chain drag or hammer tapping to identify issues such as delamination and voids in concrete, often relying solely on visual inspections. However, these conventional methods are labor-intensive, time-consuming, and subjective. To address these challenges, Structural Health Monitoring (SHM) has been introduced and explored in research for its practical application (Aktan et al., 1996; Housner et al., 1997).

In essence, SHM is a methodology designed to monitor and assess the performance of civil structures by gathering and analyzing diverse data through various sensors. The goal of SHM is to track the responses of existing civil structures, enabling the determination of their condition through damage diagnosis and prognosis. This involves analyzing, visualizing, and interpreting sensor data collected from structures. The insights gained from SHM contribute to establishing a dependable foundation for decision-making regarding the operation and maintenance of civil structures (Aktan et al., 2000; Farrar & Worden, 2007).

SHM methods are typically categorized based on their application levels, either local or global (Dong & Catbas, 2021). Local-level SHM aims to diagnose specific defects, utilizing Non-Destructive Tools (NDT) such as ultrasound, ground penetration radar, and electromagnetic devices. On the other hand, global-level applications employ fixed setup systems like accelerometers, strain gauges, and potentiometers. Non-Contact Tools (NCT), including computer vision tools like various cameras and LiDAR, play a role in both local (e.g., crack or spalling detection) and global (e.g., displacement and acceleration monitoring) applications (Catbas et al., 2022; Catbas & Khuc, 2018; Dong & Catbas, 2019; Feng & Feng, 2018;

DOI: 10.1201/9781003483755-86

Gucunski et al., 2010; Gul & Catbas, 2008; Kaartinen et al., 2022; Luleci, Catbas, et al., 2022; Luleci & Catbas, 2023; Morozova et al., 2023).

A recent trend in the SHM field is the growing interest in robotic-based experiments (Charron et al., 2019; Van Nguyen et al., 2018; Zhu et al., 2012). Robotic applications can operate at both global and local levels. For instance, an Unmanned Ground Vehicle (UGV) equipped with vision sensors can gather acceleration (vibration) data for global-level modal analysis while simultaneously performing image-based defect detection at the local level. Accelerometers installed on the UGV enhance the spatial resolution of data collection, aiding in identifying local damage within the structure (McLaughlin et al., 2020; Mei et al., 2020; Tian et al., 2022). Similarly, an Unmanned Aerial Vehicle (UAV) can be utilized for image-based damage detection at the local level, and a group of UAVs can measure displacement or acceleration at the global level through vision sensors, presenting a new dimension to civil SHM with increased mobility and diverse sensor applications (Cha & Kang, 2018; Ribeiro et al., 2021).

1.2 *Challenge, objective, and scope*

One significant obstacle in the assessment of existing civil structures/infrastructure systems lies in the assessment of those lacking structural documentation, blueprints, or data. This challenge becomes more pronounced, particularly when conducting condition assessments of old systems.

Using cameras (e.g., regular digital camera, stereocamera, etc.) and 3D scanners (e.g., structured-light or time-of-flight 3D scanners, LiDARs - e.g., time-of-flight or phase LiDARs) come out as one of the most precise and reliable technologies to capture/scan and provide the 3D digital model of the existing civil structures (Hosamo & Hosamo, 2022; Kaile'a Moseley et al., 2021; Luleci et al., 2024; Luleci, Li, et al., 2022; Thelen et al., 2022; Xue et al., 2020). The 3D digital model can be in the form of a point cloud, mesh (textured point cloud), and numeric models generated from the point cloud (Catbas et al., 2024; Wang et al., 2023). This comes as very useful in assessing the existing civil systems with incomplete information, as it enables experts involved in the assessment process to have a complete understanding of the integrity of the structure/infrastructure system. However, one particular challenge related to gathering data for 3D model creation is that these systems may not be allowed for human occupancy nor near human presence due to disaster or other external stressors -caused structural, electrical, or mechanical risks. Therefore, the use of mobile robots, such as wheeled Unmanned Ground Vehicle (UGV), equipped with various sensors (LiDARs, cameras, and other types of sensors) is a very promising application for this challenge.

In light of the discussion given in the previous paragraph, the study herein aims to present a brief demonstration of using a UGV for rapid visual data acquisition from a research building structure located on the campus of the University of Central Florida (UCF). In doing so, different data modalities, including visual (LiDAR scans and camera captures) and monitoring data (vibration), are collected in a mechanical room of the research building. Some of the data gathered during the collection process are presented herein, and the subsequent studies will include full-scale 3D models along with further analysis of the mechanical room.

The study herein first introduces the UGV, presenting its configuration and sensors briefly. Then, the methodology of the study is presented, including the test location (the mechanical room of the research building), the data collection procedure via UGV, and some of its outputs. Subsequently, the conclusion of the study is given.

2 UNMANNED GROUND VEHICLE

The UGV, named Cypector (Cyber + Inspector), is a Husky model robot manufactured by Clearpath Robotics. Husky is a 4-wheeled UGV operating on a wheeled chassis. Including Husky, Cypector used in this study contains additional accessories, where some are installed on the plate, and some are under, as shown in Figure 1. The accessories are 2 VLP-16

LiDARs from Velodyne, an ADK Infrared Camera and 2 Blackfly S Cameras from FLIR, GPS-18x from Garmin, a ZED 2 Stereo Camera from Stereolab, an Omni 60 360 Camera from Occam, Wireless Router from Gigabit, and GPU-enabled Mini-ITX computer and IMU (Inertial Measurement Unit) from Microstrain, which are placed under the plate.

Robot Operating System (ROS) serves as a middleware framework in communicating with Cypector, offering a suite of open-source tools and libraries. ROS functions as a middleware layer, abstracting hardware intricacies and facilitating communication between software components and physical devices installed on the robot, like the accessories of Cypector. It achieves this communication by including device drivers that interface with various hardware components. For the User-Cypector connection, the User simply connects to the SSID (Service Set Identifier) broadcasted by Cypector's access point (router), which is linked to the robot's internal computer. After the connection, the User's computer is granted an IP address via static or DHCP ways. Users can now SSH into the Cypector's computer to control its operation.

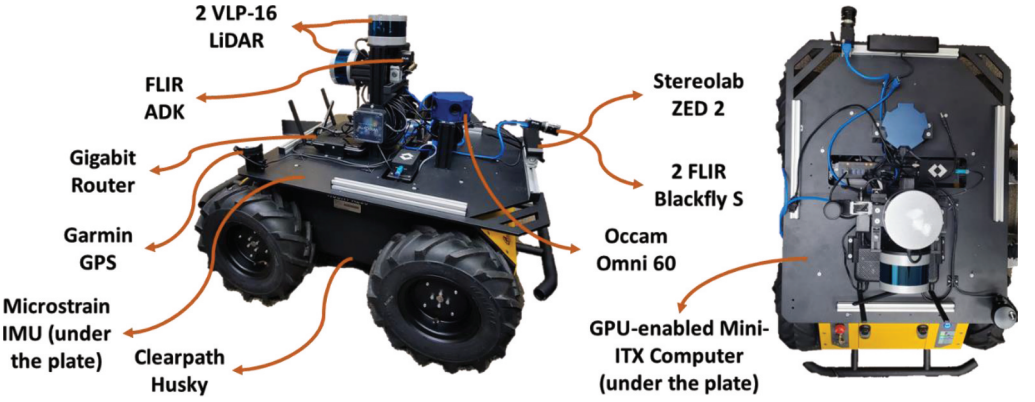

Figure 1. Cypector and its configurations.

3 METHODOLOGY

3.1 *The mechanical test room*

The mechanical room within the research building serves as a critical hub for maintaining the structural and environmental integrity of the facility. Dominated by an intricate network of industrial machinery, the room houses an array of essential components responsible for the building's operational functionality, such as the HVAC system for maintaining optimal conditions within the building. Robust piping, suspended from the ceiling and attached to the walls, facilitates the distribution of vital fluids such as coolant and heating agents throughout the facility. In Figure 2, the images of the mechanical room are given. The data collection efforts are centered on deploying the UGV in addition to TLS in this environment.

3.2 *Data collection via UGV*

The data collection procedure via Cypector is illustrated in Figure 3. The whole data collection process took around 5 minutes. During the collection, Cypector (the UGV) is navigated through the mechanical room following the route depicted in the figure. Note that the route in the figure is not the exact trajectory Cypector took but shows the overall route. Throughout the rover, Cypector collected various types of data samples constantly, such as image data via 360-degree images, depth, confidence, and stereo views, LiDAR scans via horizontal and vertical LiDARs as well as point clouds generated real-time by the depth images using ZED 2.

Figure 2. The mechanical room in the research building.

These data samples through the collection are also viewed online in rviz (a 3D visualization platform for the Robot Operating System - ROS), as shown in Figure 3. In addition to the image data, vibration data of the room is collected through different acceleration sensors, such as the IMU and ZED 2's internal sensors. For that reason, at one point during the collection, Cypector is commanded to stop for a brief period in order to collect the acceleration data, as the noises from the rover could disrupt the monitoring data quality. During vibration data collection, it is also possible to view the Fast Fourier Transform (FFT) of the sets of vibration data instances in real-time, as shown in the figure.

In addition to the visual data, monitoring data of the room could reveal critical characteristics of the operating conditions of the machinery equipment in the mechanical room for different scenarios (e.g., pre and post-disasters). Lastly, using the horizontal and vertical LiDAR scans, the environment of the mechanical room, which is unknown to Cypector, is 2D mapped in real-time. For that, Google's Cartographer Simultaneous Localization and Mapping (SLAM) is utilized (Hess et al., 2016b). In short, SLAM is a technique that allows robots to create and update a map of their environment while simultaneously determining their own location within that environment (Dwijotomo et al., 2020; Hess et al., 2016a; Sobczak et al., 2022; Weerakoon et al., 2022).

3.3 *Some results*

While this study "only" explores the rapid mobile robot-based data collection exemplar application for generating the 3D models of civil systems, the real-time generated 2D mapping of the surroundings of the mechanical room by Cypector using SLAM is presented in Figure 4. As depicted in the figure, the general visual accuracy, when compared with the actual environment (floor plan of the room), exhibits a commendable level of precision while having some loop closure issues at some edges, such as near the entrance to the room. Generating mappings of the interior as well as exterior is important for autonomous applications, providing essential information for navigation, obstacle avoidance, human interaction, and overall situational awareness in interior environments during the data collection for structural assessment procedures.

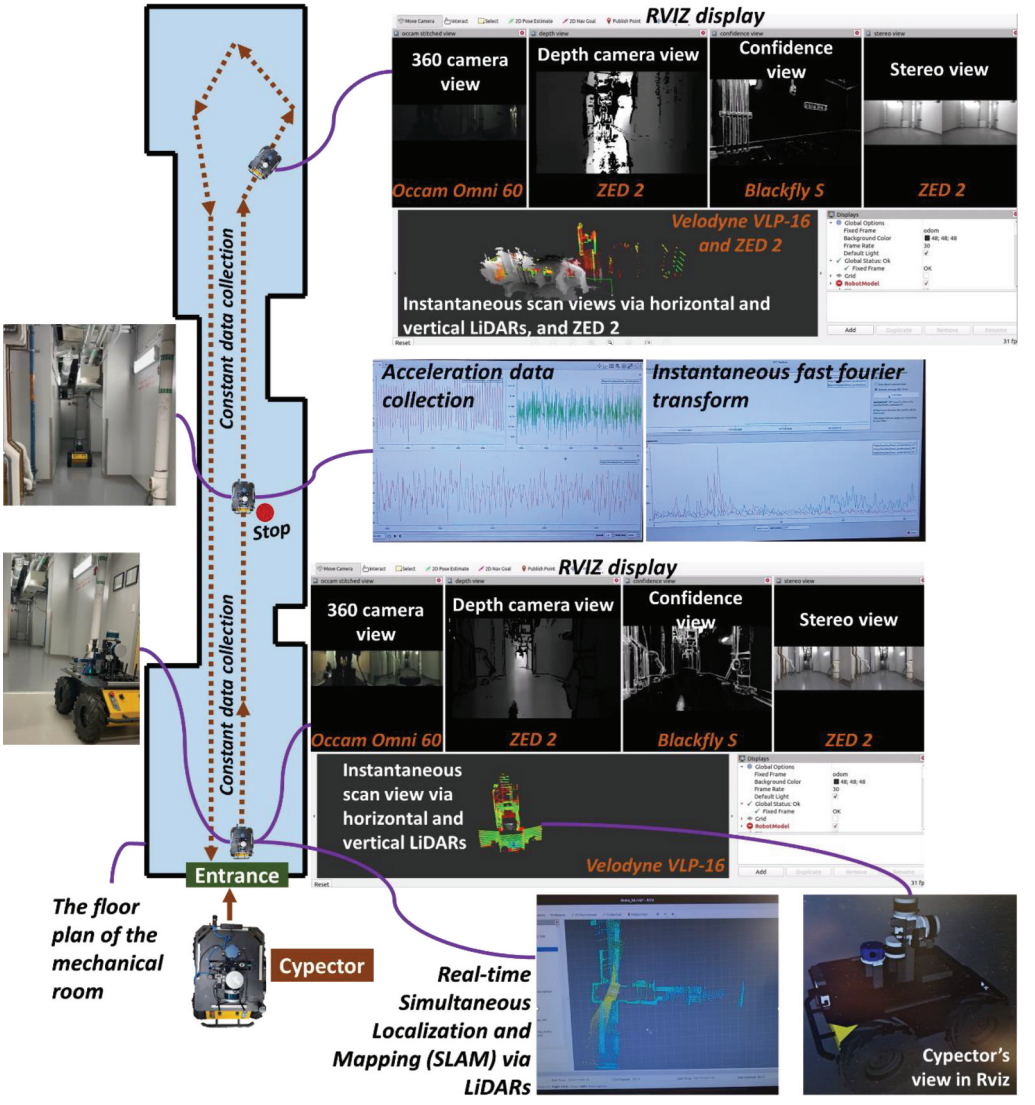

Figure 3. The overview of the data collection procedure carried out by Cypector in the mechanical room.

The generated 2D map can also be extended to 3D models, enabling a more comprehensive understanding of the physical environment in three dimensions, and Cypector is capable of doing so as it is equipped with horizontal and vertical LiDARs as well as stereo camera (ZED 2), enabling depth sensing to generate the 3D representation of the environment. Yet, this is computationally more demanding, especially when processing dense 3D point clouds, occasionally interfering with the generated 3D map quality. The subsequent studies will encompass the development of comprehensive 3D models on a full scale, accompanied by additional analysis of the assessment data, just like the 3D model of a pedestrian bridge structure generated by registering multiple LiDAR scans, as shown in Figure 5 (Catbas et al., 2024; Luleci et al., 2024).

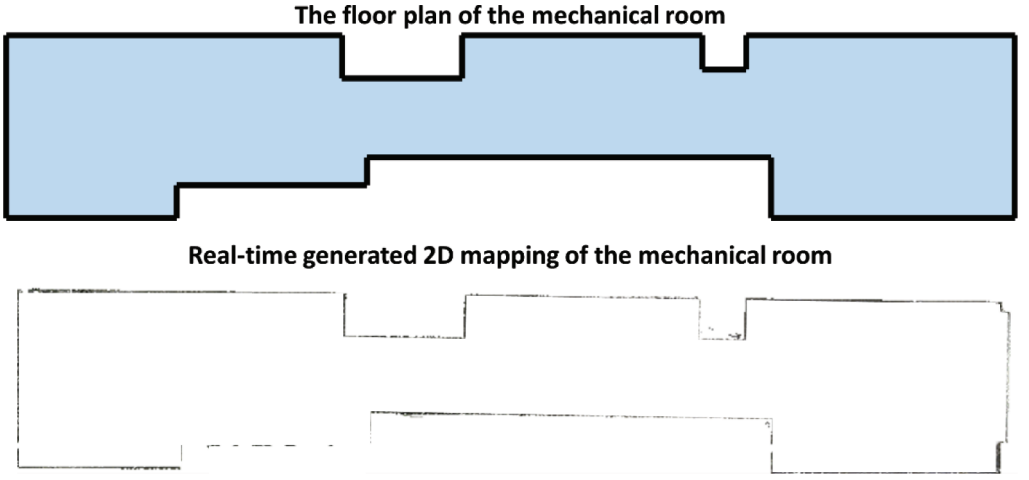

Figure 4. The floor plan of the mechanical room (top) and the generated 2D map via SLAM (bottom).

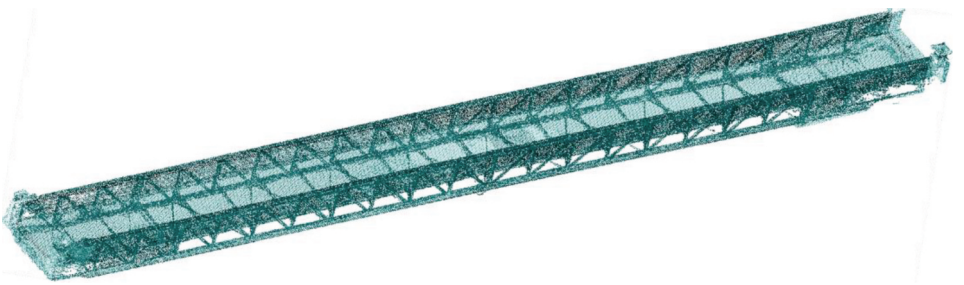

Figure 5. An example 3D model of a bridge formed by multiple LiDAR scans (Catbas et al., 2024).

This study holds significant importance in addressing the challenging task of assessing existing civil structures with insufficient documentation. By employing mobile robots equipped with advanced sensors like LiDARs and cameras, the research aims to overcome obstacles posed by inaccessible or hazardous environments, ensuring a non-intrusive yet comprehensive approach to data acquisition. The emphasis on creating 3D digital models from collected data allows for a thorough structural integrity assessment, particularly relevant for historical or aged civil systems. Integrating multiple data modalities, including visual and monitoring data, enhances the depth of structural assessments. The real-world application of this methodology in a mechanical room underscores its practical viability. Moreover, the study sets the groundwork for future research endeavors, promising further development and analysis of full-scale 3D models.

4 CONCLUSION

In conclusion, this study highlights the significance of addressing the challenging task of assessing aging civil structures and infrastructure systems that lack proper documentation. Mobile robots equipped with advanced sensors like LiDARs and cameras play a crucial role, particularly in data acquisition within hazardous environments in civil systems affected by disasters or external stressors. The emphasis on creating 3D digital models from collected data enables a comprehensive approach to structural integrity assessment, which is particularly beneficial for historical or aged civil systems facing limitations in traditional assessment methods.

Through the use of robotics, integrating multiple data modalities, including visual and monitoring data, provides valuable insights into structural assessments. The real-world application of this methodology in a mechanical room demonstrates its practical viability. The subsequent studies will include in-depth data analysis and full-scale 3D models. Overall, this study showcases the potential for mobile robotics for rapid structural assessments of civil systems.

Qatar University, Doha, Qatar

M. Nogal
Delft University of Technology, Delft, The Netherlands

ABSTRACT: Regardless of the current challenges and limitations of Digital Twins, there seems to be only one school of thought and a consensus toward their future adoption for design, construction, management, operation, and decommissioning of bridges. This novel paradigm surged within the Industry 4.0 context and was fostered by evolving technologies such as artificial intelligence, internet of things, big data, among others. Digital twins have now been recognized as an enabling technology towards the development and adoption of Industry 5.0 principles. Such principles are human-centrism, resilience, and sustainability. In this paper we explore the increasingly important role that humans will have within existing bridge digital twin frameworks and how the human-centrism principle could be better implemented within such context. Moreover, we also discuss how a successful implementation of human centrism could uphold and maximize the resilience and sustainability of existing bridges, especially those with cultural heritage value.

1 INTRODUCTION

Most bridges in Europe were constructed after 1945. Originally designed with a lifespan of 50-100 years, many have already begun to deteriorate (Gkoumas et al., 2021). In fact, it is estimated that 10% of these bridges suffer from structural deficiencies (Wenzel, 2009). On another note, numerous historic European bridges hold significant cultural value, with seven of them being listed on the United Nations Educational, Scientific and Cultural Organization (UNESCO) World Heritage List (UNESCO WHC, 2023). Besides the human and economic losses, the damage or collapse of a historical bridge also signifies the painful loss of a cultural asset.

In recent times, the field of bridge engineering has greatly benefited from technological advancements associated with Industry 4.0. These include the use of digital twins (DT) and building information modeling (BIM) to enhance bridge management (Tita et al., 2023), the application of DT for enriched structural health monitoring of bridges and other infrastructure assets (Pillai et al., 2022), the utilization of DT to aid during the construction process of bridges (Hu et al., 2022), the implementation of advanced anomaly detection algorithms to optimize the management and operation of bridges within a DT framework (Jiménez Rios et al., 2023a), among others.

As observed by the non-exhausting list of examples mentioned, the development and adoption of DT is particularly noteworthy to various stakeholders in the Architecture, Engineering, Construction, Management, Operation, and Conservation (AECMO&C) industry. DT are virtual replicas of physical assets capable of real-time performance monitoring and the early identification of potential issues, ultimately enhancing safety and reducing maintenance costs (Schleich et al., 2017). Within the context of cultural heritage bridges, DT can as well be used to validate the proposal of novel intervention techniques (Jiménez Rios & O'Dwyer, 2019; Zampieri et al., 2023) before they are applied in the asset thus preventing incompatibility damages.

DOI: 10.1201/9781003483755-87

The consensus in the industry is strong, as there is widespread agreement on the value of DT for all phases of the life cycle of bridges, including design, construction, management, operation, and decommissioning. Nevertheless, creating Industry 4.0 DT presents several significant challenges, among which, i) the lack of compatibility among various proprietary and open-source software used in the DT model generation process, ii) lack of consensus regarding the development of macro-DT that combine DT models of individual assets, and iii) the absence of Findable, Accessible, Interoperable, and Reusable (FAIR, (Wilkinson et al., 2016)) benchmark databases suitable for prototyping and validating digital twins (Jiménez Rios et al., 2023b, 2023c).

While the concept of Industry 4.0 has driven an increased industrial digitalization and higher productivity, it has also brought about unanticipated challenges (European Commission, 2020). These challenges include the environmental impact of intensified industrial activities (United Nations, 2023) and the potential risks posed by an increasingly automated industrial system to the human element within the socio-economic chain (Ellingrud et al., 2023). Regrettably, as emphasized in the United Nations (UN) Emissions Gap Report 2022 (United Nations, 2022), insufficient action has been taken so far to address the global climate crisis. There is an urgent need for a rapid transformation in the energy supply, industry, transport, and buildings sectors to meet the goals of the Paris Agreement (United Nations, 2015). This transformation is also supported by the European Union (EU) and promoted through the European Green Deal (EGD) (European Commission, 2019).

Consequently, Industry 4.0 is now considered insufficient to achieve European goals by 2030 (European Commission, 2022), leading to the emergence of a new paradigm, Industry 5.0, primarily built upon three core principles (European Commission, 2021): i) human-centrism, resilience, and sustainability. Moreover, DT and simulations have been recognized as one of the key enabling technologies of this transformative vision. Despite being a relatively recent concept, Industry 5.0 has quickly attracted the interest of many researchers. They have conducted in-depth analysis of its fundamental principles and the technologies that make it possible (Maddikunta et al., 2022). Additionally, researchers have put forth fresh frameworks for its application (Yang et al., 2022) and have begun to create practical applications across various domains, including manufacturing, education, data privacy, food security, and wind energy infrastructure (Chen et al., 2021). However, it's worth noting that the AECMO&C industry has yet to explore, let alone implement, Industry 5.0 principles.

A plausible framework for Industry 5.0 principles implementation is the one proposed by an augmented digital twin, also referred to as a human-centric digital twin (see Figure 1). In this novel framework, an additional "human asset" (besides from the Industry 4.0 components corresponding to the "physical asset" and "digital asset") component is considered. This component is composed by the series of digital technologies capable of enhancing human stakeholders' performances, which could ultimately result into a sustainable and resilient built environment. The different digital tools proposed include exoskeletons, augmented reality, virtual reality, wearable trackers, intelligent personal assistants, collaborative robots, social networks, and big data analytics, all of which have been thoroughly discussed elsewhere (Mourtzis et al., 2022).

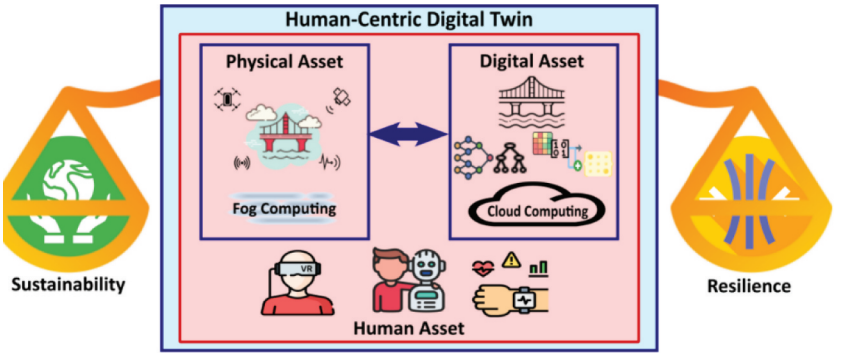

Figure 1. Novel Industry 5.0 Human-Centric digital twin framework.

In this paper, we explore the increasingly important role that humans will have within existing bridge DT frameworks and how the human-centrism principle could be better implemented within such context. We carried out a six-steps stakeholder analysis and discuss how a successful implementation of human centrism could uphold and maximize the resilience and sustainability of existing bridges, especially those with cultural heritage value.

2 METHODOLOGY

A system analysis approach has been applied to analyze the complex adoption of Industry 5.0 principles by different stakeholders of the AECMO&C industry. The stakeholder analysis method proposed by Enserik et al. (Enserink et al., 2022) has been followed. More specifically, this methodology has been implemented in a study case involving the conservation of existing bridges, in particular those with a cultural heritage value, in the city of Oslo, Norway. The case study presented assumes the educational institutions of the city to be the "*problem owners*".

The problem was first clearly formulated through the construction and interpretation of a means-ends diagram. A means-ends diagram was built by first identifying a dissatisfaction about an actual situation. A verb sentence was used to expresses the desired situation (end). Then a series of consecutive "why" questions related to the identified desired situation were asked. Answers were again placed in rectangles linked through arrows (pointing upwards). When no meaningful answer could be given anymore, a "back propagation" process started asking "how" each one of the identified ends could be achieved (means). This process allowed to map a comprehensive view of the situation and helped to select, together with appropriate spatial and temporal demarcations, an adequate level of analysis. The selected problem was then re-written in the form of a focal objective, which was no longer a "verb" phrase, but a "noun" one.

As the focal objective obtained from the means-ends diagram usually has an abstract nature or involves different complex aspects, it must be further refined by the means of an objectives tree. Objectives trees help to simplify the problem by operationalizing it into lower-level objectives and providing measurable criteria parameters. Once the problem has been defined and the factors related to it identified, the effect of each factor in the outcome (and in other factors) can be qualitatively observed through a causal relation diagram, also known as a causal map. Means-ends analysis, objectives tree, and the casual map are all summarized by the means of a system diagram. The path between means and external factors was traced to qualitatively assess their influence in the system criteria. Such influences were summarized in consequence tables.

The following step was to create an inventory of involved stakeholders. To do this, two different identification techniques were followed, so that, although partially overlapping, individual results could complement each other. The techniques followed were: i) positional approach where actors were identified based on their formal position in policymaking, and ii) opinion leadership approach where stakeholders with an influence on others were identified and included. Stakeholders' information on rights, responsibilities, and organizational charts along with established procedures, legislation, and laws, was collected to draw a formal chart. In this chart it was possible to visualize the mutual relations between different stakeholders and to sketch the arena within which they could interact to solve the problem under study.

The main characteristics of the inventoried stakeholders were then studied based on their interests, objectives, and perceptions. In this context, interests represent stakeholder's matters of importance and point towards a fixed direction, objectives are dynamic and indicate stakeholders wishes under the current problem context, and perceptions are stakeholder's interpretations of the situation. A stakeholder overview table tool was developed and extended with each stakeholders' resources, importance, and replaceability level. With all this information and based on a systematic comparison, stakeholders' dependencies were determined, and finally presented in the form of a power-interest grid.

3 RESULTS AND DISCUSSION

The adoption of Industry 5.0 principles could be described as an "*untamed*" problem in the classification proposed by (van de Graaf & Hoppe, 1996) as it requires a large degree of social

consensus and involves a high degree of technological uncertainty. Thus, this problem requires a multi-actor engagement and agreement to be solved. Why should Industry 5.0 principles be adopted? This question leads to a series of positive outcomes among which are the achievement of emissions neutrality, to increase industry competitiveness, and to improve working conditions. Ultimately, the question "why all these should be done?" leads to the end of generating economic, ecologic, and societal value. But what are the means needed for the adoption of Industry 5.0 principles? According to our analysis, this problem could be tackled if efforts are put in four different aspects: i) the modification of current business models, ii) the investment on enabling technologies (mainly in the implementation of the discussed human-centric digital twin), iii) the establishment of interdisciplinary collaborations between diverse stakeholders, and iv) the up-skilling/re-skilling of the AECMO&C industry workforce. The means-ends diagram developed to support the system delimitation for the study case selected is presented in Figure 2.

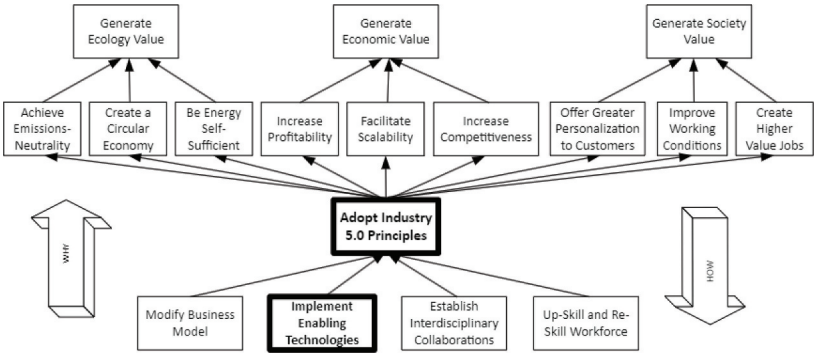

Figure 2. Means-Ends diagram on the adoption of industry 5.0 (It is not limited to the study case under discussion, But it is of general application character).

We can now re-write the problem under study in the form of a focal objective such as that we obtain "Adoption of sustainability, resilience, and human-centrism". This objective should be achieved while aiming at avoiding a series of undesirable side effects. A key issue for our study case is the hampering of technology development. An objective tree was created (not shown here for the sake of brevity) to identify the outcomes of interest on achieving this focal objective through the implementation of human-centric digital twins. These items were formulated as measurable criteria. Namely, high return of investment [profit/initial cost], high regulatory compliance [days/regulatory approval], low energy consumption [watts/hour], high acceptation [perception level], many jobs generated [jobs generated/year].

The relationship between means (see Figure 2) and identified measurable criteria was better understood thanks to the creation of a causal map (not shown here for the sake of brevity). Eventually, both means-end diagram and casual map were used to depict a conceptual model of the study case analyzed through a system diagram, as presented in Figure 3. In this diagram a more elaborated structure of the problem can be observed. Means are placed in the left side of the boundary. We focus our attention on the implementation of enabling technologies (i.e. human-centric digital twins, the detail analysis of the remaining means is outside of the scope of this paper) and their effect on internal system factors and the identified criteria, which are placed on the right border of the diagram. The path from means to criteria is qualitatively assessed based on the arrow connectivity and sign. These causal pathways are tabulated in the consequence table shown in Table 1.

Table 1. Consequence table on the implementation of enabling technologies for the case under study.

Means/Criteria	Return of Investment	Generated Jobs	Acceptation	Energy Consumption	Regulatory Compliance
Implement Enabling Technologies	+, +, -	-, -	+, +	+, - and +, +	+, -

From these results it can be observed that the adoption of Industry 5.0 principles by the educational institutions of the city would bring with it higher complications to comply with regulatory frameworks. Moreover, such regulations may not even be in place now, but being under development, such as the discussed European Union legislation on Artificial Intelligence (Madiega, 2023). It can also be said that initially the adoption of Industry 5.0 principles would negatively affect the return of investment of the problem owners. Nevertheless, it has been shown that early adoptions require of small monetary investments, whereas that to maintain competitiveness, later adopters require higher amounts of investment (Della Seta et al., 2012). On the other hand, positive impacts are expected in terms of job generation and perception level. Whereas that the energy consumption criteria would receive mixed inputs. From one point of view, an enhanced technological efficiency would reduce the amount of energy consumption. The proposed human-centric digital twin technology would require great amounts of data processing/storages, which would ultimately be reflected on a higher energy consumption.

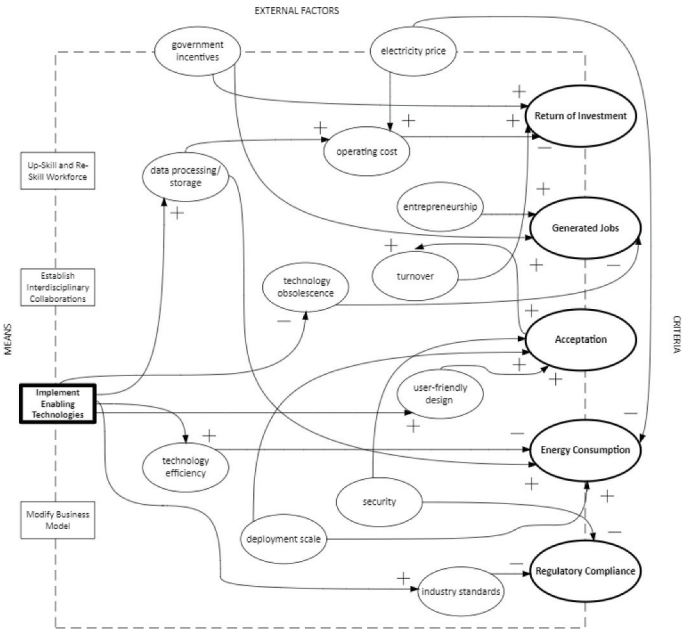

Figure 3. System diagram.

The adoption of such an important paradigm shift is a complex problem that cannot be fixed in isolation by the problem owner itself. Therefore, an inventory of relevant stakeholders which may contribute to reach a solution was created. Stakeholders at international (lately discarded as deemed irrelevant for the case study), regional, national, and local level were identified and clustered in accordance with their issues of interest into governance, infrastructure, conservation, education/R&D, industry, and society. More importantly, the formal relationships among them were map through a formal chart, as shown in Figure 4.

The two stakeholders in Oslo offering educational programs specialized on the AECMO&C industry, and considered on this study, are Oslo Metropolitan University (OsloMet, through its Department of Built Environment) and the Oslo School of Architecture and Design (AHO). They obtain research funding both from European and National institutions and can participate in the co-creation and delivery of teaching/research projects with two important stakeholders involved in the conservation of cultural heritage: the Norwegian Institute for Cultural Heritage Research (NIKU) and the National Trust of Norway (Fortidsminneforeningen). Interdisciplinary research and professional practices can be performed between these education institutions and the main players in the infrastructure sector at national level (Statens Vegvesen, who is responsible for the management of two protected bridges in Oslo under the National Conservation Plan for

the Norwegian Public Roads Administration) (Klima- og miljødepartementet, 2022). Finally, these Universities can play a key role in the up-skilling and re-skilling of the AECMO&C industry workforce (represented by some consulting and contracting companies in Figure 4).

The key players identified for the adoption of Industry 5.0 principles in the context of conservation of existing bridges with cultural heritage value in Oslo, Norway (see Figure 5), are those of governance nature both at national and local level. The ministry of Transport and the Ministry of Climate and Environment with their subordinate agencies, Statens Vegvesen and Riksantikvaren respectively, along with Oslo Komunne and its Cultural Heritage Office Agency possess the monetary and authority irreplaceable resources to adopt such principles while incentivizing the remaining stakeholders to follow.

It is hypothesized that if such resources are driven towards a suitable business model, the adoption of human-centric digital twins as enable technology, the establishment of interdisciplinary collaborations between the identified stakeholders, and the up-skilling/re-skilling of the

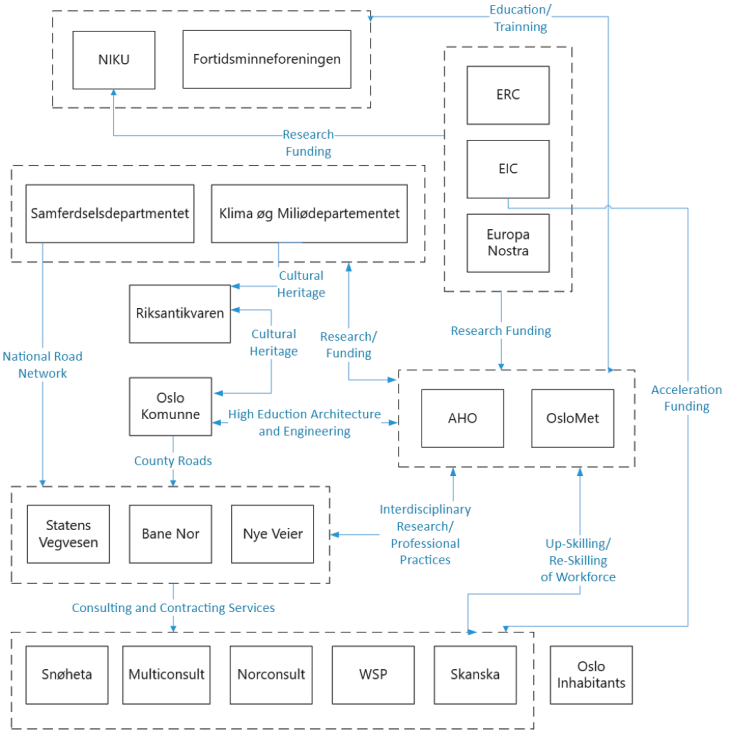

Figure 4. Formal chart.

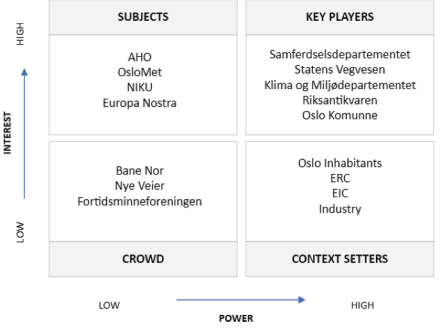

Figure 5. Power-Interest matrix.

AECMO&C industry a successful adoption could be achieved. These efforts would ultimately result in the creation of economic, ecological, and societal value.

4 CONCLUSION

Industry 5.0 has recently surged as a novel paradigm to tackle the unforeseen negative consequences of its predecessor and is rapidly being adopted in different sectors. In this paper, we explored how the human-centrism principle fostered by Industry 5.0 could be better implemented within the context of bridge engineering. The work was carried out following a six-steps stakeholder analysis methodology which was applied in a study case involving the conservation of existing bridges, in particular those with a cultural heritage value, in the city of Oslo, Norway. The educational institutions of the city were assumed to be the "*problem owners*".

Despite of the pragmatic and systematic nature advantages of stakeholder analysis, it does not come without cons. Some limitations of this methodology include the fact that stakeholder classification is static while in the real world stakeholders evolve constantly and dynamically, its lack of specificity and the reliability of the information upon which it is constructed (Hermans & Thissen, 2009). Luckily its main drawback could be greatly mitigated through a participatory approach. The involvement of different stakeholders and citizens in scientific research and/or knowledge production through a co-creation workshop for example, could significantly enhance the outcomes of this kind of work (Fritz et al., 2019).

Arup, Birmingham, UK

Y. Li
Arup, London, UK

ABSTRACT: The HS2 tunnelling works in the United Kingdom required extensive ground movement assessment (GMA) for existing third party bridges to identify which assets might be susceptible to damage and require mitigation measures, and to provide a basis for screening out structures likely to suffer negligible damage. This paper presents an overview of the GMAs conducted on approximately 80 existing bridges located above the future twin-bored, tunnelled, HS2 route, focusing on the challenges faced, methodologies employed, and findings obtained. The GMAs ensured that detrimental effects of HS2 construction on existing assets were identified early and impacts to those assets were minimized, reducing overall project expenditure with risk-based damage assessment. This paper shares the learning points from assessing a large sample of bridges of various ages and structural types under the influence of tunnel-induced ground movement. Findings include recommended monitoring, remedial works, or mitigation outcomes grouped by bridge type.

1 INTRODUCTION

The development of high-speed railways brings numerous opportunities for economic growth and improved transportation networks. In the United Kingdom, the construction of the High Speed 2 (HS2) railway is a flagship project aimed at enhancing capacity, stimulating growth to connected cities, and reducing carbon emissions. Once operational, HS2's trains will journey between London and the Midlands in the UK.

This paper focuses on the S1/S2 contracts of HS2 delivered by Skanska Costain Strabag (SCS) Joint Venture, with design support from Design House Joint Venture (Arup, Typsa, & Strabag). The S1/S2 contracts cover the first portion of Phase 1, shown in Figure 2, trains running largely in tunnel from Euston station in Central London to West Ruislip on the edge of the conurbation. The new twin-bored, tunnelled, HS2 route is largely constructed using an Earth Pressure Balance (EPB) tunnel boring machine (TBM). While TBM construction has proved to be safe and controlled, inherent volume loss at the face can cause vertical and horizontal ground displacements along the tunnel paths, as seen in Figure 1. As part of this contract, SCS were required to undertake GMAs of existing infrastructure with a moderately conservative volume loss (VL) modelled at 1% for tunnel boring machine type (EPB) and 1.5% for sprayed concrete lining (SCL) tunnel construction.

Tunnelling construction below London and consideration of VL on existing surface assets is well documented, particularly for building structures. For the HS2 project, a similar GMA methodology has been adopted as described by Lazarus & Jung (2018) for the construction of Crossrail (now the Elizabeth Line) which focused largely on the impact of tunnelling on

DOI: 10.1201/9781003483755-88

buildings. GMA methodologies specifically for bridges have been previously described for London projects including Crossrail (Bradley et al., 2015; McCarthy, 2016) and Channel Tunnel Rail Link (CTRL) (Jacobsz et al., 2006). The HS2 S1/S2 packages of work are unique in that they contain a relatively large sample of bridge structures undergoing ground movement assessment. This paper presents a summary of the GMA methodology, findings grouped by bridge type, and observations or conclusions that may be useful for future bridge GMAs. Please note that due to the sensitive nature of the project, any identifying information about specific assets has been removed, and results are only presented in amalgamation.

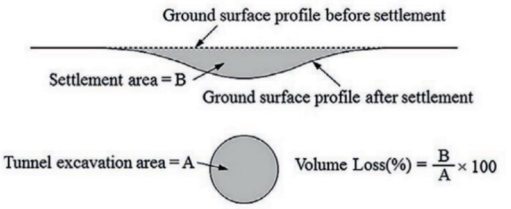

Figure 1. Definition of volume loss as shown in Lazarus & Jung (2018).

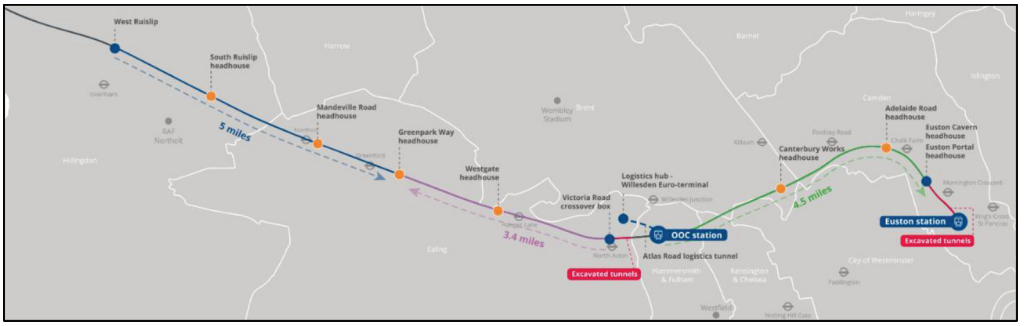

Figure 2. Proposed Hs2 route largely in tunnel below London (SCSJV, 2023).

2 OBJECTIVES

The GMA identified the degree of intervention required for each bridge asset to safeguard it from the effects of HS2 tunnelling. The analyses aimed to identify potential risks associated with ground movement due to permanent works and temporary works dewatering, and to highlight where mitigation measures might be necessary to ensure the safety and durability of these critical assets. The three main outcomes for each bridge asset were monitoring only, remedial works, and mitigation, described in more detail in Section 4 of this paper. The assessment mitigated the risk to the project while reducing its potential carbon footprint by eliminating the need for extensive asset replacement. Bridge assets are considered critical infrastructure and the consequences of ultimate limit state or service limit state failure causing closure of the bridge are expensive and could result in harm to the public. By completing a GMA, time and resources are saved by employing a risk-based approach that initially screens out assets that will remain unaffected by construction activity. Some assets that are affected by construction activity but experience negligible movement are concluded to require monitoring only. Those assets moderately impacted by construction activity but that can withstand the impact may only require remedial works after the completion of construction. Only those assets which are deemed impacted by construction and the movements may impact the

ability of the asset to function as intended are recommended for proactive mitigation measures. This ranked approach reduces risk while utilising project funds effectively.

3 METHODOLOGY

The ground movement assessment involved a multi-disciplinary and phased approach, combining geotechnical investigations and structural analysis. The phased approach allowed for many of the assets to be reviewed quickly and at a high level to rule out the need for mitigation interventions. However, as bridge assets are considered "critical" infrastructure, bridges inside the zone of influence (ZoI) were pushed to the most in-depth level of assessment. The GMAs considered the vertical and horizontal ground movements across all phases of construction. Defining the most impactful ground movements and structural checks to be carried out is dependent on bridge type and required engineering judgement. The primary purpose of the GMA was to establish what impact (if any) the HS2 construction has on the existing bridges. The philosophy for the GMA was to demonstrate by the simplest means possible whether the bridges can accommodate the HS2 tunnel-induced ground movements or if mitigation measures are required to do this. A GMA is therefore *not* the same as a live load assessment where the objective is to determine the load capacity of all structural elements.

On occasion, limited information was available for some structures, such as no as-built drawings or lack of records of repairs or alterations to the structure. Topographical surveys and Inspections for Assessment were carried out on behalf of SCS to gain the necessary information to confirm assumptions about the bridges.

The initial steps of analysis for a GMA were often relatively simple, comprising hand calculations and structural analysis models using prescribed displacements from the ground movement models. Where simpler methods did not enable a conclusion to be reached about the need for mitigation measures, then more sophisticated analytical methods were employed.

For arch structures, a specific methodology was developed and is described in a separate paper - 'Ground movement assessment method for arch bridges affected by HS2 tunnelling' by Saavedra Justo et al. (2024).

Due to considerable interfaces between bridge assets and adjacent buildings, utilities, rail, and other asset types, extensive coordination ensures the GMA is completed with a multi-disciplinary approach in mind. The complexity of asset interfaces could be the subject of another paper and will only be touched on briefly here. In coordination with a geotechnical team, each bridge asset was modelled in Oasys XDisp, a ground movement software, along with the proposed tunnel design and alignment, cross passages, vent shafts, and other excavations that could impact the ground movement near the asset. The Oasys XDisp software utilises a methodology of sub-surface greenfield ground movements that can be calculated using empirical methods, as demonstrated by Mair et al. (1993) and Taylor (1995), where a settlement trough perpendicular to the new tunnel can be estimated using an inverted normal probability curve (Gaussian curve). The three-dimensional form of movement is calculated using the Attewell & Woodman (1982) methodology. The software models the longitudinal "bow wave" settlement data around the tunnel and transforms it to vertical and horizontal displacements at the bridge location. The "bow wave" in the context of this paper refers to ground movement at the face of the TBM, which behaves similarly to the wave that forms at the bow of a ship when it moves through the water. As the ship's bow wave spreads out, it defines the outer limits of a ship's wake, which is the analogy for the ground movement ZoI in this paper.

Due to prevailing ground conditions in certain areas of the project, it has been identified that some locations along the construction route will require temporary works dewatering to enable their construction, such as some vent shafts and cross passages between tunnels. Settlement due to tunnelling is permanent, whereas settlement due to temporary works dewatering is a transient effect. It is anticipated that full or partial reversal of the additional settlement will occur after the dewatering systems are switched off as the water levels recover and effective stress returns to its original state. Temporary works dewatering will result in additional

vertical settlement only in areas where it is deployed due to the increase in vertical effective stress. No horizontal movement is predicted to occur due to dewatering.

The Oasys XDisp ground movement software allows the settlement analysis to be carried out along different phases of construction. This enabled detailed analysis of displacements on structures at various stages of construction, including the impact of temporary works dewatering, and progressive shaft, tunnelling, and cross passage construction on the structure. In many cases the worst-case movement on the structure did not take place at the final stage, but at an interim stage where differential settlement peaked due to offset Up Line and Down Line TBM progression.

4 POTENTIAL OUTCOMES

The GMA work identified the degree of intervention required on a bridge asset to safeguard it from the effects of HS2 tunnelling. This was achieved by splitting the assets into several predicted outcomes: monitoring only, remedial works, or mitigation, based on their individual risk profiles (due to condition, age, predicted impact, etc.). Where the identified need for intervention was minimal – for example, monitoring only – then this also helped to reduce the risk profile for SCS and reduce the carbon footprint by avoiding any mitigation works to the structure.

4.1 *Instrumentation and monitoring*

All bridges within the ZoI, regardless of GMA outcome, require an instrumentation and monitoring (I&M) plan. The objectives of I&M are:

- To record ground movements and deflections of assets within the ZoI of the works and allow checks that these are in accordance with calculations;
- To provide evidence that the VL due to tunnelling is in accordance with the modelling assumptions; and
- To determine the effects of the construction works on third party assets and provide early warning of any need for additional mitigation measures if required.

After a period of baseline monitoring to establish seasonal effects, monitoring will continue for the duration of the HS2 tunnelling works and for a period after completion to confirm that the behaviour of the tunnel linings complies with the design intent and ground movements diminish as expected.

Based on predicted movement, asset-specific trigger values were calculated to alert the project if actual movements approach (or even exceed) the calculated values. A robust Monitoring Action Plan is in place with agreed actions relating to various levels of specified trigger values.

4.2 *Remedial works*

It was often recommended that remedial works could be required to repair minor damage after completion of HS2 tunnel construction. Examples of minor defects that might occur include spalling of concrete or cracking to masonry.

4.3 *Mitigation*

If the GMA for a bridge asset resulted in a suggested mitigation outcome, specialist mitigation solutions were recommended to protect the asset and ensure continued service on which the pedestrians, rail, vehicles, etc. rely. An example of one such mitigation solution for the HS2 S1/S2 project can be seen in the paper by Carlucci & Godden (2022).

5 FINDINGS

As expected, the data confirmed that generally bridge assets experienced lower overall ground movements if they were located further away from the tunnels (Figure 3), where distance is three-dimensional (measuring both plan distance and depth beneath ground level). In fact, of the assets reviewed, primarily in London Clay with an excavated tunnel diameter between 8.53m - 9.84m and ranging from approximately 5m to 50m below ground level, no assets greater than 20m in plan from the tunnels required mitigation, regardless of asset age or structural type. Foundation position relative to the tunnels influences ground movements experienced by the asset. An asset with a deep foundation (piles) and directly above the tunnels in plan is expected to experience higher vertical settlements than the same asset with a shallow foundation at the same location. However, an asset positioned on the edge of the Gaussian settlement curve with a deep foundation may experience smaller ground movement than an asset with a shallow foundation. This is because deep foundations may potentially be founded in ground that is only minimally affected by the tunnels. A visual example of this can be seen in Figure 4.

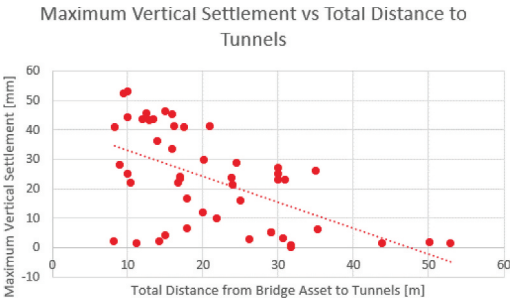

Figure 3. Plot of maximum vertical settlement versus total distance from the bridge asset to the tunnels. trend line verifies the correlation.

Due to the scope and complexity of assessing such a large quantity of structures, it was invaluable to have a set of standard diagrams and templates for presenting information. Clear report templates and automated tools to create graphical outputs helped illustrate the information in a consistent and easy to understand format. The output could then be easily compared against similar bridge types for a quick comparison between other similar structures to pick up any anomalies in their analysis as a way of further validating the results on top of the usual check and review process. One such example is the vertical settlement curves used to illustrate the ground settlement at all construction stages shown concurrently with structure and tunnel depth (see Figure 4).

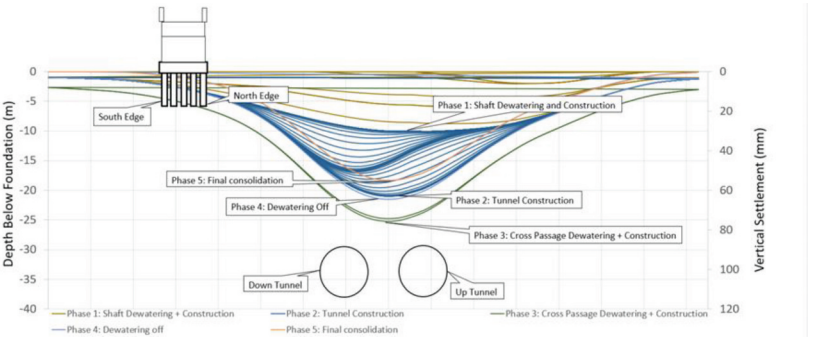

Figure 4. Vertical settlement curve across the bridge (including the effects of temporary works dewatering). key construction stages are labelled.

Figure 4 shows the vertical settlement curve across a bridge, which shows the settlement imposed by the passing of the Down Line and Up Line tunnels individually as a series of blue curves. The Down Tunnel passes first leading to a shallow settlement curve adjacent to the bridge. When the Up Tunnel passes, the settlement curve widens and becomes centred over the tunnels. Throughout the phases, differential settlement from the offset tunnel progression was found to be the most prevalent issue, particularly in structures with limited ability to accommodate the additional movement. Another notable outcome of the modelling process was the impact of the TBM on the structure before it reaches the asset. The tunnel settlement bow wave impacts the asset before the TBM is directly below the asset and continues to impact the asset until it is several tunnel diameters past. This early- and late-stage settlement can be seen in the diagram of the tunnel progression in Figure 5.

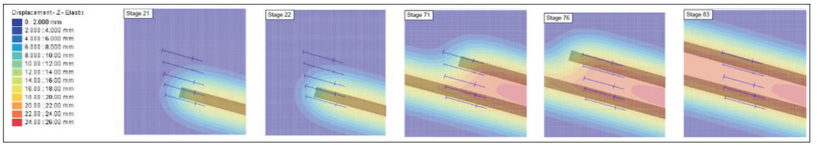

Figure 5. Vertical settlement at key construction stages. bridge piers are shown as blue lines with tunnels in brown.

Figure 6 below shows the split of suggested interventions per structure type. Some general trends can be observed, one of which is that arch structures in the study proved to be more resilient than steel girder bridges. This may be because, for many steel girder bridges, relative displacement of adjacent piers led to bearing and expansion joint tolerance exceedance as aging bridges normally have limited residual capacities for bearings and expansion joints. The specific arch analysis methods are detailed in 'Ground movement assessment method for arch bridges affected by HS2 tunnelling' by Saavedra Justo et al. (2024).

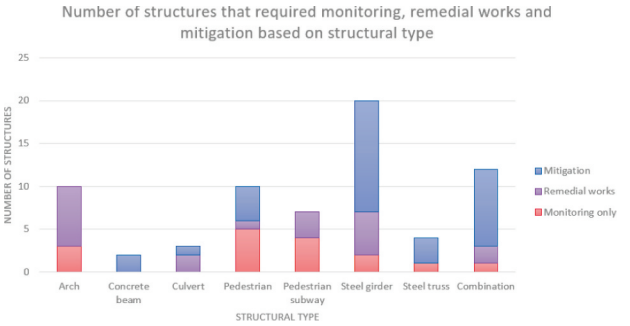

Figure 6. Number of structures that required monitoring, remedial works, and mitigation, grouped by structural type. n.b. combination structures are those that were added onto over time (e.g. road widening). [work is still progressing on gma refinement and may result in updated recommendations, changing the values presented above].

In Figure 6, the "combination" grouping of structures represents the assets, of those analysed, that were originally constructed in one bridge structural form, then added onto with one or more different structural types over time. These "combination" type assets proved to be prone to mitigation recommendations as the interfaces between the different structural types were not adaptable to differential settlement.

Interestingly, as can be seen in Figure 7 below, no clear difference can be interpreted from the bridge data based on foundation type. There was no discernible favour between shallow foundations and deep foundations in terms of resiliency against ground movement. This may

be due to the limited number of deep foundation assets available to study and the fact that settlement for bridges with deep foundation can be higher or lower depending on their relative location to the tunnel alignment. Mitigation was the suggested outcome for approximately half of both shallow and deep foundation type assets.

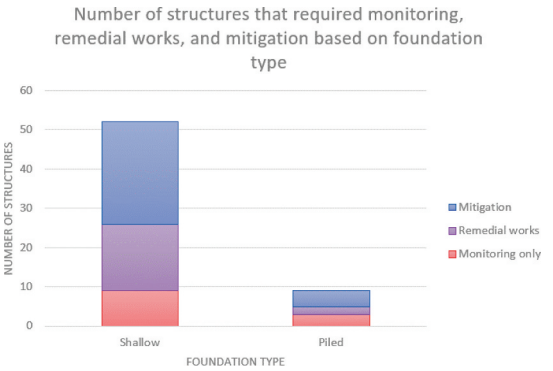

Figure 7. Number of structures that required monitoring, remedial works, and mitigation based on foundation type. [work is still progressing on gma refinement and may result in updated recommendations, changing the values presented above].

At the start of the ground movement assessment work, it was unclear if age of asset would relate to recommended asset outcome. Estimating how much ground movement a historic bridge can accommodate can be difficult because of historic approaches to bridge articulation, and sometimes a lack of records. For instance, one asset had combination pin/roller bearings where the roller base was completely encased and therefore difficult to visually confirm the range of allowable movement. Only a note on the drawings indicated the ability of the bearing to accommodate longitudinal movement. Some of the newer bridges with designed mechanical bearings (e.g. rocker bearings, sliding bearings) analysed as part of the GMAs were least able to accommodate ground movements due to their limited articulation ranges. Lead plate bearings fared better at accommodating horizontal movement, however, could induce a friction force into the structure due to the movement. An advantage of some older bridge forms, notably arch structures, was better accommodation for ground movements than some newer bridges with bearings with prescribed movement ranges. However, as can be seen in Figure 8, date of construction/age of structure was not a strong indicator of mitigation outcomes.

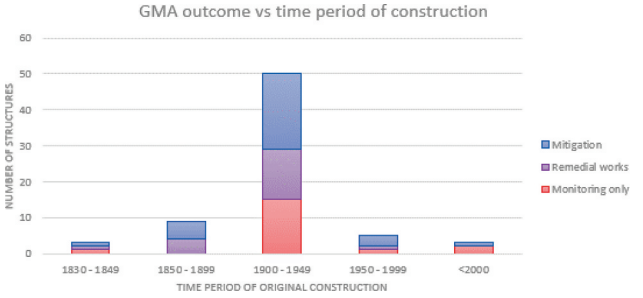

Figure 8. Number of structures that required monitoring, remedial works, and mitigation based on date of original asset construction. [work is still progressing on gma refinement and may result in updated recommendations, changing the values presented above.]

While it can be related to asset age but is not necessarily linked (assets that are well-maintained over their lifespan can potentially perform very well in old age), condition of the asset was another key indicator for GMA outcome. Poor asset condition or reduced existing

capacity of a structure was often more critical than the effects of ground movements. There were bridges where ground movements had negligible effect, but there were health and safety concerns because of underlying and pre-existing issues with the bridge.

6 CONCLUSIONS

The HS2 ground movement assessment programme has provided valuable insights into the potential challenges and risks associated with tunnelling under a major city. Key indicators for mitigation outcomes included bridge vicinity to tunnelling works, foundation depth (favourable or unfavourable depending on the location among the Gaussian settlement curve), and bridge type (arches were found to be more adaptable to ground movement than steel girder bridges, "combination" bridges were more susceptible to ground movement than single-structural-type assets). Age of asset and foundation type did not strongly correlate to a specific recommended outcome, but asset condition was even more important than the effects of ground movement. The findings underscore the importance of thorough structural assessments, continuous monitoring, and appropriate mitigation measures to ensure the safety and resilience of aging bridge infrastructure adjacent to tunnelling projects. With careful consideration, project risk can be reduced with sustainable outcomes.

Comparison of modal parametric and nonparametric vibration-based techniques

A. Dia & N. Makhoul
ESTP - Ecole Spéciale des Travaux Publics, Cachan, France

ABSTRACT: Ensuring the structural integrity of bridges is of paramount importance for public safety and the longevity of these critical infrastructures. Early detection and assessment of damage are essential to prevent catastrophic failures and optimize maintenance efforts. Vibration-based methods have emerged as effective tools for structural health monitoring (SHM) in bridge structures due to their non-intrusive nature and sensitivity to subtle changes in structural behavior. In this study, we present a comprehensive comparative analysis between two prominent vibration-based (VB) approaches: modal parametric and nonparametric methods, for damage characterization in bridges. The modal parametric approaches rely on interpreting the variation of the dynamic response of the structure based on identified modal parameters like natural frequencies and damping ratios sensitive to damage. While modal parametric approaches require system identification for damage characterization, these non-parametric methods involve extracting features from raw signals that are sensitive to damage, utilizing time series modeling techniques. After conducting a brief and comprehensive literature review, data collected from tests conducted on bridge cables were analyzed using both modal parametric and data-driven VB damage identification techniques. We then evaluate their performance in terms of sensitivity to damage characterization.

Keywords: SHM, damage, parametric methods, nonparametric methods, bridges

1 INTRODUCTION

The safety of daily users and the continuous operation of economic activities in cities depend on the proper and sound functioning of infrastructures such as bridges and their load-bearing components, such as metallic cables. These cables are exposed to cyclic mechanical, chemical, and thermal loads that can lead to damage resulting from pathologies, mainly corrosion and fretting fatigue (Dieng et al., 2009). Therefore, it is essential to integrate Structural Health Monitoring (SHM) and nondestructive techniques (NDT) into the management of structures to achieve a comprehensive characterization of damage and ensure the long-term safety and functionality of the bridges' cables. In response to these needs, several NDT techniques have been adopted such as visual inspection, ultrasonic methods, electromagnetic field methods, acoustic emission, and vibration-based methods. Vibration-based (VB) NDT allow the extraction, from measurements, of the global parameters of a mechanical system or a structure. Indeed, a change in the structural parameters (mass loss, stiffness, damping) leads to a change in the global modal parameters such as natural frequencies, mode shapes, and damping coefficients. This variation can also be reflected in the signals that can be recorded such as accelerations, velocities, or displacements. VB techniques can then be classified into two categories: parametric-based ones and non-parametric methods. Parametric methods refer to those based on system identification (Yan et al., 2019), i.e. the variation of modal and physical parameters such as frequencies, mode shapes, and damping ratios for modal parameters and/or stiffness, mass, and damping for physical parameters. As for non-parametric methods, they refer to methods that use statistical means, time series modeling tools, to characterize damage directly from recorded accelerations, displacements and/or velocities signals (Avci et al., 2021).

DOI: 10.1201/9781003483755-89

These methods make it possible to overcome the local nature of certain methods (acoustic emission, ultrasound, electromagnetic methods) and allow us to have an overview of the global health state of a structure with limited measurement points. Therefore, VB methods are qualified as global methods; even if a network of closely spaced measurement points (sensors) can, in some cases, provide local information. These vibration measurements are mainly carried out on a structure for four reasons that can be summarized as follows (Cremona, 2005):

1. perform vibration tests to assess the resistance of a structure to possible events that may solicit it during its operation such as strong winds, shocks, etc.
2. perform structural analysis for a better design through numerical model updating.
3. perform comfort measurements to measure the vibration levels of the structure.
4. and/or perform monitoring and diagnosis to reveal defects occurring in the structure.

The approach adopted in the context of this study falls within this last point and much research in damage characterization using VB techniques has been widely developed and documented (Das et al., 2016).

These literature reviews make it possible to identify different dynamic methods and their fields of application. The interest of this study, in addition to applying these methods on cable-type structures, a case study rarely addressed in the literature, is to indicate among the four levels of damage's characterization (Rytter, 1993), those that are achieved by these VB techniques (detection, location, quantification, and prediction of the structure's residual lifetime).

Also in this study, using experimental data obtained on cables and addressed in our previous study (Dia et al., 2021), we will go further and discuss the comparison of damage characterization through parametric and non-parametric methods.

2 METHODS AND MATERIAL PRESENTATION

2.1 *Methods description*

The global VB NDT techniques can be classified into different categories depending on the approaches, parameters, and tools used to perform analysis on vibration responses of monitored structures. As stated in the introduction, in this study we focused on classifying these techniques depending on the extracted parameters to perform damage characterization: modal parameters and non-(modal)-parameters. Whatever the used technique, the first step in damage identification is modal identification for parametric-based (P-based) techniques or time series modeling for the non-parametric (NP) approach. Thus, the following tree (Figure 1) gives a glance at those steps and their ramification allowed by technologies (sensors, computing, storage) advances.

The development of computational capabilities and reliable algorithms first led to classical modal parameters identification techniques known as experimental modal analysis (EMA) where both input (excitation force) and output (measured response, e.g., accelerations) data are used for modal parameters identification. This procedure can be applied in the frequency domain, through frequency response functions (FRFs), in the time domain, based on impulse response functions (IRFs) or in the time-frequency domain (TFD), through wavelet analysis. Depending on these domains respectively, Linefitting, PolyMAX - *Polyreference Least-Squares Complex Frequency-domain* or Hilbert-Huang Transform (HHT) are examples of each of these system identification techniques (Orlowitz & Brandt, 2017; Yang et al., 2021).

To address the main drawback of these EMA techniques regarding large-scale civil structures in operating conditions, i.e. the need for a known input force, operational modal analysis techniques (OMA) were developed. These refer to methods where the input force is not known or not measurable. The idea of OMA is thus to replace the artificial excitations used up to now with natural excitations such as wind, traffic, waves, etc. However, OMA and EMA methods share a common theoretical background. The main difference lies in the formulation of the input, which is known in EMA while it is random and unmeasured in OMA. Thus, while EMA procedures are developed in a deterministic framework, OMA methods can be considered as their stochastic counterpart (Rainieri & Fabbrocino, 2014). As a result, for OMA,

instead of FRFs, *power spectral densities* (PSDs) or *Singular Values Decomposition* (SVD) (Brincker et al., 2001) will be used and autocorrelation functions (ACFs) instead of IRFs. These mathematical transformations lead to algorithms such as the *Enhanced Frequency Domain Decomposition (EFDD),* the *covariance-driven Stochastic Subspace Identification)* (Peeters & Roeck, 2001). Given the fact the above-mentioned natural excitations cannot be always modeled as white noise, the supposed behavior of the input force in OMA methods, researchers have proposed systems identification techniques based on transmissibility functions (TFs) such as the *polyreference Transmissibility-based OMA (pTOMA)* (Weijtjens et al., 2014).

Modal analysis-based damage detection techniques rely on the identification and estimation of modal parameters. However, these techniques face several challenges, particularly in detecting early-stage damage where modal parameters variation is very low to be detected. Thus, particular attention has been paid to non-parametric methods to detect structural defects directly from the recorded signals using statistical and probabilistic tools (Tseng & Naidu, 2002). These techniques are mainly based on time series modeling (TSM) and extracting damage-sensitive features (parameters) from the models. In the field of SHM with VB techniques, autoRegressive (AR) and moving average (MA) models and their variants: AutoRegressive moving average (ARMA), AutoRegressive eXogenous (ARX), etc. have been the most widely used for signals modeling . For damage sensitive features extraction using NP-based tools, machine learning (ML) algorithms have been also used, alone or combined with AR-MA models, i.e., Gaussian Mixture Models (GMM), Principal Component Analysis (PCA), Genetic Algorithm (GA) (Silva et al., 2016).

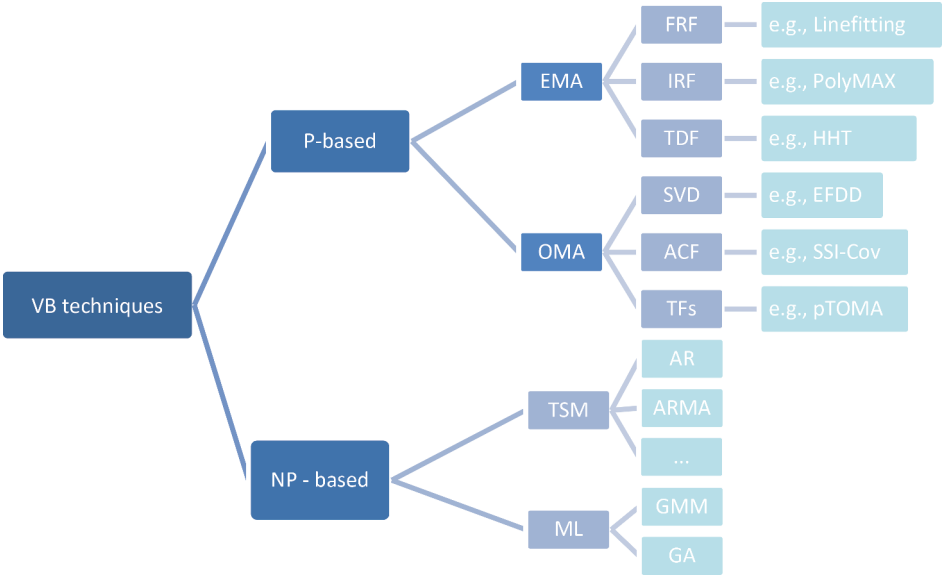

Figure 1. Modal analysis and time series features identification techniques.

Whatever the technique used, the final objective of each of these methods is to be able to detect damage and its level of severity to deduce the actions that must be taken. Thus, after the identification of parameters, the next step is to define indicators based on these parameters, which allows to identify the presence or not of damage and their possible severities for the structures' lifespan. Hence, in the following Table 1, we give some of the defined indicators/criteria in the literature for damage characterization and the performance achieved concerning to detection (D), localization (L), and severity estimation (S). For each of the mentioned indicators in Table 1, we only mentioned the main principle behind the most defined indicators in the literature and the interested reader can find more details in these references: (Silva et al., 2016; Yang et al., 2021).

In the following section, considering bridges' cables, we will discuss damage detection using well-established modal analysis techniques and ARMA-based methods.

Table 1. Damage characterization indicators and criteria from P-based and NP-based methods.

VB technique	Indicators	Definition and performance	Pros (+) and Cons (-)
P-based	Δf_s^d	• Structures' frequencies variation between safe (s) and damaged (d) state. • D, S	+: frequencies are easy to determine and sensitive to damage. -: sensitive to thermal variations
	ΔDR_s^d	• Damping ratios (DR) variation • D (eventually)	-: important variability, difficult to measure
	$\Delta \Phi_s^d$	• Mode shapes variation • D, L, S	+: sensitive to damage, less sensitive to thermal variations -: more difficult to identify, need more sensors
	ΔSE_s^d	• Strain energy (SE) variation • D, L, S	+: Stability when noisy signals -: Not efficient for small damage, need more sensors
	ΔTF_s^d	• Transfer functions variation (transmissibility functions or FRFs) • D, L, S	+: use of a range of frequencies and mode shapes (not only the resonant poles as for the above indicators) -: High computational demand, sensitive to ambient conditions
NP-based	MSD	• Mahalanobis (Squared) Distance between mean values features. • D, S, L	+: ability to identify outliers; use in real scenarios. -: Assume a Gaussian distribution, slow training phase, can be sensitive to operational and environmental variability
	$D_{centroids}$	• Distances of clusters' centroids • D, L, S	+: ability to identify outliers. -: computational cost, and stabilization issues depending on the used algorithm, can be sensitive to operational and environmental variability

2.2 *Experimental setup: Case study*

The above-described techniques were applied to data collected from tests conducted on a bilayer cable. Its geometric and mechanical characteristics are given in Table 2.

Table 2. Geometric and mechanical characteristics of the used bilayer cable.

Cable	Length (mm)	Young's modulus (MPa)	Density (g/cm^3)	Breaking strength (kN)
Bilayer	6230	200	7.8	513

The cable is installed on a load test bench with a capacity of 300 kN and wedge anchor sockets have been used to fasten it to the load test bench with the help of a tensioning hydraulic jack. The loads are applied with an instrumented hammer.

The vibration data are stored as displacements using contact-less laser sensors so that additional masses are not impacting the global mass of the cable. The eight laser sensors are coupled with QuantumX MX 1615B and 1610 data acquisition systems and the CATMAN software. The arrangement of the laser sensors on the cable is shown in Figure 2.

Considering these means, the tests are first done on a safe cable considered as the reference state of the cable and the damage are introduced later by cutting wires gradually in the indicated position in Figure 2. The chosen experimental procedure can then be summarized in these six steps:

- Step 1. Tension of the cable at 30 % of its maximum breaking loads
- Step 2. Lasers and data acquisition systems mounting

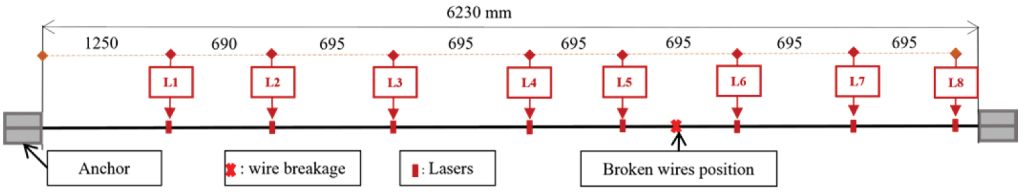

Figure 2. Laser arrangement on bilayer cable.

- Step 3. Excitation of the cable by hammer impacts and data storage at the sampling rate of 300 Hz for 45 seconds. Near each sensor, we repeat the impact four times.
- Step 4. Removal of the acquisition system and introduction of damage (wire breaks)
- Step 5. After a wire break, the tension of the bilayer cable is maintained at its post-breakage values, i.e. the cable is not re-tensioned to the initial tension value.
- Step 6: data analysis.

3 RESULTS COMPARISON AND DISCUSSION

3.1 *Extraction of modal and signal-based parameters*

Either method used, one should make sure that the parameters are correctly extracted from the raw signal. For parametric VB techniques, based on the FRFs curves, the cables dynamic natural frequencies and mode shapes are determined. This step is carried out using the Line-Fitting method (Ewins, 2000) which gives stable results according to modal assurance criterion (MAC) coefficients (for mode shapes) and coefficients of variation (for natural frequencies). The MACs are defined as:

$$MAC(\phi_A, \phi_B) = \frac{\left|\{\phi_A\}^T\{\phi_B\}\right|^2}{\left(\{\phi_A\}^T\{\phi_A\}\right)\left(\{\phi_B\}^T\{\phi_B\}\right)} \tag{1}$$

where ϕ_A and ϕ_B represent mode shapes extracted from data collected under same conditions (e.g., safe) at distinct points A and B on the cable. The coefficients of variation are defined as:

$$C_v(\%) = 100 \times \frac{\sigma_\omega}{\mu_\omega} \tag{2}$$

σ_ω and μ_ω represent the standard deviation and mean of natural frequencies obtained for the same vibration mode from different excitation data.

For non-parametric VB techniques, correct signal modeling is also a must, as from extracted features, will be performed damage characterization. Therefore, before fitting the displacement signal (X) from a sensor with the Python statsmodels module, they are first normalized $(\tilde{X})$:

$$\tilde{X}(t) = \frac{X(t) - \mu}{\sigma} \tag{3}$$

After normalizing the data, we use stationarity tests to ascertain whether further transformations are required to make the time series data stationary (mean, variance and autocorrelation are constant over time). The augmented Dickey-Fuller (ADF) test's p-values are employed for this purpose. The ADF test assesses the null hypothesis that a unit root exists in a time series. If the p-value is less than 0.05, we can reject the null hypothesis and conclude that the time series is stationary.Once the initial data preprocessing is complete, the optimal $ARMA(p, q)$ model order and its coefficients are estimated:

$$\tilde{X}(t) = \sum_{i=1}^{p} \varphi_i \tilde{X}(t-i) + \sum_{i=1}^{q} \theta_i \varepsilon(t-i) + \varepsilon(t) \tag{4}$$

where φ_i and θ_i are the model parameters and ε_i are the error terms.

For the best model order selection, we fit many $ARMA(p, q)$ models with different combinations of values for p and q. The best model is selected according to the Akaike information criterion (AIC), and we assess its viability by analyzing its residuals (difference between actual and modeled values of signals) which should be like white noise: uncorrelated and normally distributed.

Once all these steps have been taken, for P-based and NP-based techniques, we can then proceed to damage characterization.

3.2 *Damage characterization with P-based and NP-based techniques*

Using the natural frequencies thus obtained, we first performed the detection of wire breaks in the bilayer cable with five broken wires. The detection is based on the variation of the natural frequencies between the safe and the damaged cable $\left(C_i^{s-d}(\%)\right)$:

$$C_i^{s-d}(\%) = 100 \times \frac{f_n^s - f_n^d}{f_n^s} \tag{5}$$

In Figure 3, the C_i^{s-d} values increase with the severity of the damage (number of cut wires). This combined with the low variability of the natural frequencies observed with the coefficients of variation ($C_v < 1\%$), we can conclude that these parameters (C_i), of the order of 3% for one cut wire $\left(C_i^{s-1d}\right)$ and greater than 6% for two or more cut wires, allow to detect the presence of damage, whatever the chosen frequency mode.

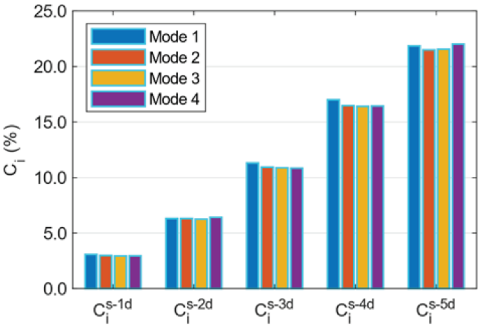

Figure 3. Evolution of C_i^{s-d} coefficients from one (1d) to five (5d) broken wires.

For NP-based analysis, for the same excitation, after choosing the best model order (the optimal values of p and q) based on the data recorded on one sensor, this order is applied to the data recorded on the other seven sensors. Once the best model order is selected and the parameters determined, inspired by the work of (Nair et al., 2006), we contribute by suggesting two new parameters based on damage sensitive features (DSF). The first one (Equation 6) is a generalization of the (Nair et al., 2006) formula, which considered the first 3 AR), by considering the p AR coefficients from the best model, the φ_i in equation 4:

$$DSF_{AR} = \frac{\varphi_1}{\sqrt{\sum_{i=1}^{p} \varphi_i^2}} \tag{6}$$

The second proposed parameter (Equation 7) is based on the q MA coefficients, the θ_i in equation 4. This damage sensitive features are defined as:

$$DSF_{MA} = \frac{\theta_1}{\sqrt{\sum_{i=1}^{p} \theta_i^2}} \tag{7}$$

According to these two parameters, the results for the safe and damaged cable (with 2 to 4 cut wires) are given in Figure 4. From this latter, the DSF_{AR} parameters (at left) do not show any

correlation with the severity of the damage. However, the DSF_{MA} parameters do show an upward trend with increasing damage severity for almost all the sensors (L1 to L8). This suggests that the DSF_{MA} parameters may be a more effective way to detect and quantify damage in cables. Nevertheless, in their current state, these DSF_{MA} factors cannot be used to reliably attest the presence of defects in the cable. Indeed, their variances remain quite high as shown with the error bar for the safe cable values on sensor L1.

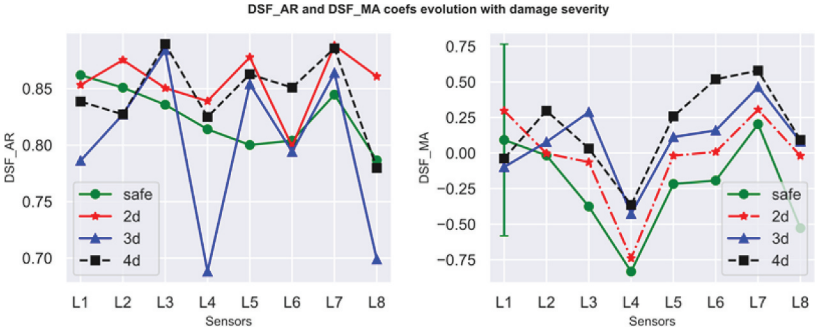

Figure 4. Evolution of damage sensitive features (DSF_{AR} & DSF_{MA}) with damage severity.

These results from DSF show the need to fit all data from each sensor to search for its own best model even if the data are collected from one excitation force and in the same conditions, as each location point of the sensor may have its specificities. Based on this observation, preliminary studies to improve the models are conducted. Each 45-second signal from each sensor is divided into 3-second segments (a total of 15 segments for one sensor signal) and the transformations mentioned in the previous chapter are applied to each of these segments. The results of the ADF stationarity tests show that the p-values are slightly higher than 0.05 for some 3-second segments (see Figure 5). Using $ARIMA(p, d, q)$ modeling techniques the best model is found for each of these stabilized chunks. The $ARIMA(p, d, q)$ models add the integration order d in the process to make time series stationary. The preliminary results are promising as shown in Figure 6. As with Figure 4, these results shows also that DSF_{MA} values are more suitable for damage characterization as the Euclidian distance between DSF_{MA} of safe and damaged cable is superior to that between DSF_{AR} values.

4 CONCLUSION

This study emphasizes the significance of vibration-based methods in ensuring bridge structural integrity, offering a comprehensive and concise review of modal parametric and non-parametric approaches. Through a case study on cables, while modal parametric methods

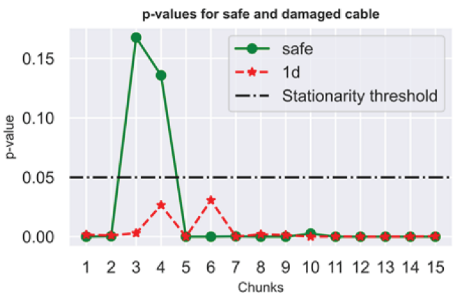

Figure 5. P-values of signal chunks.

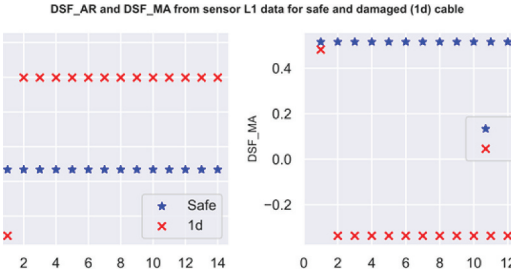

Figure 6. DSF_AR and DSF_MA values for each L1 data chunk.

exhibit sensitivity to damage severity, non-parametric techniques, especially those based on moving averages coefficients (DSF_{MA}), show promise in capturing damage trends, better than those based on autoregressive ones. This new suggested parameter improved the results and contribute to the stat of arts in this field. However future ongoing research will focus on refining non-parametric methods modeling, considering sensor location specificity, and exploring hybrid approaches. Extending the study to diverse structural components and real-world applications will further validate and enhance the practicality of these approaches in advancing bridges' structural health monitoring.

ABSTRACT: Digital models are often only used in the construction process of a structure and lose their meaning after completion. The goal is to continue to use these models during the operational phase and for maintenance, to generate added value from them. The continuous use of a digital model as a digital twin is a viable approach to specifically analyze the relevant structure components and simulate effects from changing conditions such as the long-term behavior of the structure. However, the development of numerical digital twins reaches its limits very easily due to a lack of information about boundary conditions or material properties and their development over time as well as the lack of suitable monitoring systems. In this study, the development of a digital twin of a tunnel profile is presented, in which analyses regarding suitable monitoring systems for the SLS and ULS behaviour of the profile were also carried out. It was also of particular interest to show the added value that can be generated by the detailed digital twin in terms of safety or safety formats.

1 INTRODUCTION

In infrastructure sector, planners and operators invest a lot of time and money in the creation of analysis models to document the design of tunnels and rock drives and to carry out simulations. However, once the construction phase is complete, construction models are often only used to a very limited extent. An important goal is to continue using these highly complex models as digital twins during the operating phase for monitoring and maintenance. In particular, any extensions or changes can be effectively considered in the existing models. By using a virtual model in parallel as a digital twin during operation, all important structural elements can be visualized and specific calculations can be carried out. In addition, a detailed understanding of the long-term behavior of the structural and functional components of e.g. tunnels and the rock formations during operation is obtained. This allows new scenarios to be simulated and more targeted measures to be taken before damage occurs. In addition, a proof load can be carried out to reduce the model uncertainty of the structural behavior. It enables robust statements about structural safety, the interaction of structural elements, the influence of damages and the effectiveness of previous repair measures (Model Code 2020).In cooperation between the University of Natural Resources and Life Sciences, Vienna, the Austrian Federal Railways and the Vienna University of Technology, a test load was applied to a tunnel pilot using a combination of modern monitoring systems (Strauss et al., 2020, Strauss et al., 2018, Neuner et al., 2022, Strauss et al., 2022, "MONTUN" project). Based on these findings, the opportunities, challenges and limitations of digital twins are highlighted. In this project, the digital twin was set up as a non-linear finite element model and analyzed with the measurement results of the test loads.

DOI: 10.1201/9781003483755-90

As indicated previously, the monitoring systems play a very important role in the development of digital twins. Therefore, in the first phase of the project, monitoring systems were put into operation under laboratory conditions and subjected to various test procedures. The focus was on determining the noise level, identifying possible drift phenomena and recording processes as well as the influence of magnetic fields. The second phase comprised the installation of the measuring systems in the tunnel-like test pilot in the outdoor area. For this purpose, a so-called mouth profile with a length of 2.7 m, an opening of around 2 m and a total weight of 9.5 tonnes was designed and built. This phase was divided into a long-term monitoring study, which lasted around three months, and a short-term capacity study. In the long-term study, the long-term stability of the monitoring systems and the influence of atmospheric parameters and weather conditions were analysed. The accuracy in detecting changes in the range of a few tenths of a millimetre up to 1.5 cm was quantified by means of a proof loading of the mouth profile. A laser tracker and a total station served as reference measuring systems. Based on various criteria for accuracy, robustness, technical and economic cost estimation and expertise, the monitoring systems were evaluated and further recommendations were formulated, including the setup of the digital twin. Overall, all these procedures, including the analysis of the monitoring system, were used to create and gradually optimise the digital twin of the mouth profile and to check its suitability for extended safety formats.

2 CHARACTERISTICS OF THE DIGITAL TWINS

2.1 *General details*

This study presents the design of the digital twins with the measurement systems in the tunnel-like test pilot in the outdoor area. The details of the preliminary laboratory tests on the monitoring systems used to set up the digital twins are reported in Neuner et al. (2022). A reinforced HABA concrete profile 3600mm/2250mm was used as the tunnel test pilot, see Figure 1(a). The pilot profile was manufactured according to ÖNORM EN 1916 and ÖNORM B5074 and has a similar geometry to real tunnel profiles. In order to reduce the bending stiffness of the profile and allow to induce significant deformations, the cross-section was configured with slots measuring 30 cm in depth and 20 cm in width, strategically placed in the crown region as well as the upper and lower strut areas. The load was applied in stages via tension rods and hydraulic cylinders running through the cross-section, see Figure 1(a).

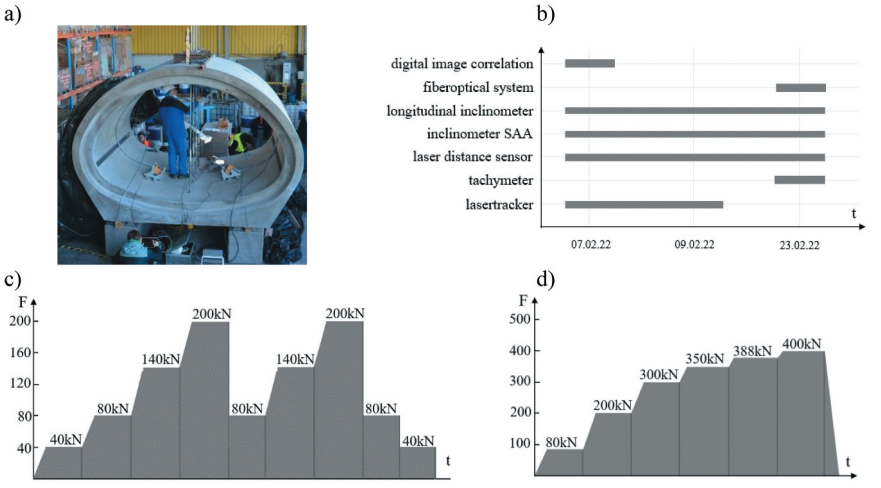

Figure 1. Characteristics of the tunnel digital twins, a) test object, b) chronological overview of the monitoring systems, c) load plan 09.02.22 and d) 23.02.22.

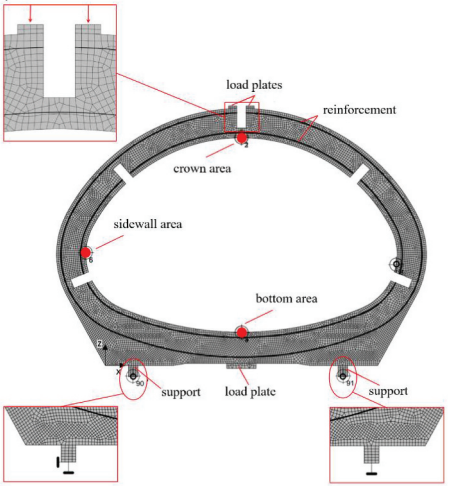
2.2 *Proof loading procedures*

The proof loading procedures on the tunnel pilot was carried out on a total of three different days. Figures 1(c) and 1(d) present the proof loading steps/plan from 9 February 2022 and 23 February 2022. In order to record the pilot reaction in a comprehensive manner, various monitoring systems were used. An overview of the use of the monitoring systems during the test period is shown in Figure 1(b). The load test on 7 February 2022 was carried out with a maximum load of 80 kN (4 x 20 kN threaded rod load), with the main objective being to record the response of the elastic system and the profile stiffness information to create the digital twin. The load test on 9 February 2022 was carried out with a maximum load of 200 kN (4 x 50 kN threaded rod load) (Figure 1(c)). The load configuration with load cycles was intended to generate a non-elastic system reaction and initiate cracks in order to compare the occurring behavior and the existing crack distribution with the NLFEM. In addition, the ability of the measurement systems used to detect cracks and plastic deformations, which are also of great importance for the alignment of digital twins, was investigated. Visible cracks on the inside and outside of the profile occurred at approximately 120 kN.



The aim of the test on the last day, 23 February 2022, was to generate high deformations and thus initiate significant cracks in the profile in order to validate the digital twin in the area of load-bearing capacity. Therefore, it was analyzed to what extent the states of reduced stiffness characterized by local bending stresses can be simulated with the NLFEM and what accuracies can be achieved.

3 MODELLING OF DIGITAL TWINS

3.1 *General details*

A dual modelling approach was chosen to create the digital twin of the tunnel twin pilot. On one hand, a replica of the mouth profile was created using a digital 2D model of non-linear finite elements and, as a second approach, the model was reproduced using a non-linear 3D twin of finite elements. This two-part procedure was chosen to gain an understanding of the important elements in the development of the digital twin in the first phase and to analyse the model update procedure using the monitoring information in 2D and then transferring it to the 3D model. The focus of the presented analysis is on the 2-dimensional modelling and the chances and limitations. The primary aim of the modelling was, in a first step, to simulate the load paths resulting from the circula proof loading and to compare these model results with

Figure 2. Details of the digital twin models, a) boundary conditions and b) material parameters.

the results of the monitoring systems, for which the ATENA Science software from Červenka Consulting (Červenka et al., 2013) was used. Subsequently, the crack formation developments were also included in the modelling of the digital twin.

A common first step in digital twin modelling is the definition of the geometric boundary conditions and the material parameters. An overview of the defined boundary conditions of the supports, the geometry and location of the reinforcement (solid black lines) as well as a first approximation of the loading type of the model can be seen in Figure 2(a). The concrete material was modelled using the non-linear 3D cement model in ATENA 2D and plane strain properties, a bi-linear material model was used for the reinforcement, as is generally the case. An overview of the selected material models, parameters and values is given in Figure 2(b).

3.2 *Updating processes*

Additional steps were necessary in addition to the classic procedure of updating the model of the material properties and support conditions, for example using sequential updating procedures or sensitivity analyses (Figure 3). As the position of the reinforcement and the load shape have a major influence on the simulation results, additional geometric adjustment steps were necessary. For example, the geometric positions of the circumferential reinforcement in the profile and the depth of the cut-outs in the crown area and in the side wall areas of the profile were updated. An essential part of the construction of the digital twin was also to model the proof load application effectively and realistically in order to be able to simulate the load paths resulting from the test days. To this end, various approaches to load application (force- and displacement-controlled) were analysed and a model update was carried out. The data from the laser tracker and total station monitoring systems from the various load phases served as a reference for the modelling results.

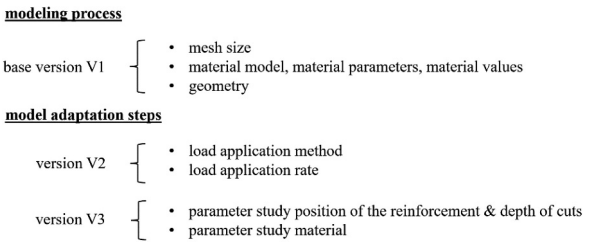

Figure 3. Digital twin, process of modeling.

Figure 4(a) shows the analyzed load scenarios with (1) the force-controlled approach, (2) the displacement-controlled approach and (3) the approach with two externally applied tendons, whereby a displacement-controlled variant with temperature loading and a force-controlled loading approach with a prestressing force were investigated. For the planned analyses of the load paths, the approaches must also fulfill the possibility of precise load control and effective analysis in addition to the results obtained. Due to the fact that no maximum load levels can be precisely simulated with the displacement-controlled load approaches, only the force-controlled approaches meet the requirements. With displacement-controlled approaches, it is not possible to control load levels without manual intervention and adjustment of the displacement variable, which leads to a more time-consuming simulation and makes automated sensitivity analyses significantly more complicated. In the process of modeling, it became clear that the forming inner lever arm between the reinforcement and the lower edge of the cut-outs has a considerable influence on the model behavior. Since the exact position of the reinforcement on the test object could not be clearly localized on site, parametric studies were carried out with various lever arm enlargements. For this purpose, concrete elements were modeled in the cuttings, which serve to enlarge the lever arm (Figure 4(b)). For these concrete elements, the modulus of elasticity is scattered in a range of 10000 N/mm² -

40000 N/mm², which causes the lever arm to be activated at high values or to drop out at low modulus of elasticity.

The simulation analyzed below is based on the force-controlled loading approach using two externally applied prestressed tendons, whereby the prestressing force is increased in predefined steps. By specifically controlling the desired maximum load, load cycles such as those carried out as a result of the test load on 09.02.2022 (Figure 1(c)) can be simulated and any non-elastic system reactions that occur can be investigated. In addition, this loading approach best reflects the test setup by directly coupling the crown and base areas of the cross-section.

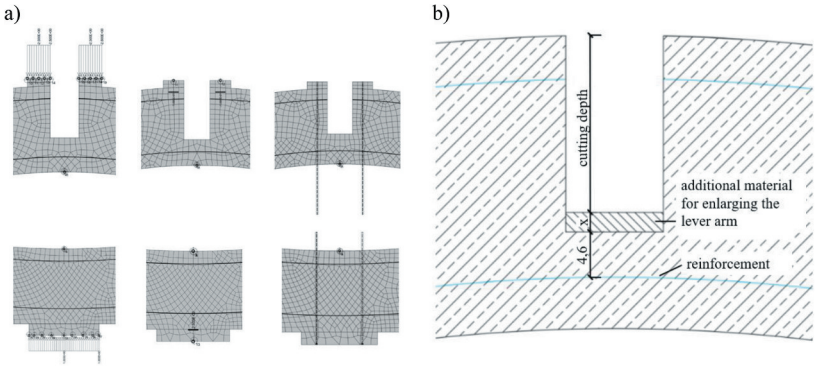

Figure 4. Updating of the a) load scenarios and b) lever arm.

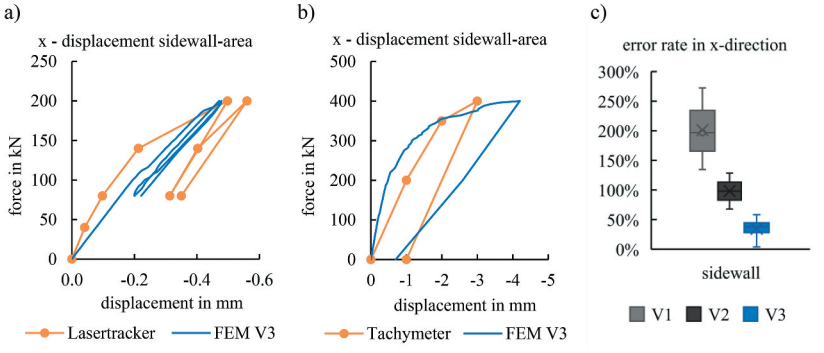

Figure 5. Findings in the horizontal displacements in the sidewall area a) 09.02.2022 and b) 23.02.2022 and the error rate in this area.

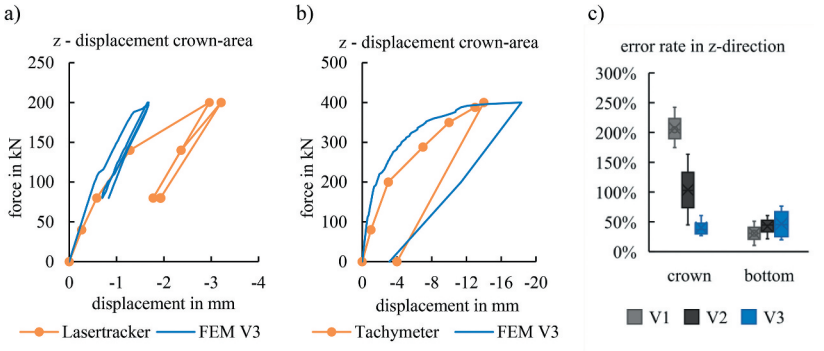

Figure 6. Findings in the vertical displacements in the crown area a) 09.02.2022 and b) 23.02.2022 and c) the error rate in this area.

3.3 *Findings*

The results of the simulation are compared below with the results of the reference monitored values and their percentage deviation per simulation version is shown. As shown in Figure 3, Version 1 represents the basic version of the simulation. Version 2 corresponds to the modelling with updated load model and version 3 represents the digital twin with updated lever arm distance and material parameters.

The horizontal displacements in defined areas of the profile were of great interest in connection with the deformation of the profile. Detailed information about the deformation behavior of the profile along the entire load path was generated. Of particular interest was the possible formation of yield joints or rigid body movements. Figure 5 displays the results of the horizontal displacements in the side wall area of the simulation and reference from (a) 9 February 2022 and (b) 23 February 2022. It can be seen that the deviations of the digital twin from the reference measurement of the laser tracker are very small and therefore very good results were achieved. The model behavior in Figure 5(a) is slightly less rigid than the real deformation. The unloading and reloading paths show a good correlation with the measurement results. A stiffer model behavior can be seen in Figure 5(b), whereby the stiffness only decreases in the high load range. Figure 5(c) shows the deviations from the reference for each simulation version along the load paths. It can be seen that a significant increase in accuracy was achieved by updating the model from Version 1 to Version 3.

Apart from the horizontal displacements in the areas of interest, the vertical displacements were also of great importance for the model update. Figure 6 shows the vertical displacements in the crown area as a force-displacement diagram from (a) 09.02.2023 and (b) 23.02.2022. It can be seen, that in Figure 6(a) the deviations of the FE simulation from the reference measurement at a load of 140 kN ranges in the tenth of a mm. The highest deviation of 1.28 mm occurs at 200 kN. After the first unloading to 80 kN, a plastic deformation can be recognized. The calculated gradient of the unloading and reloading paths correlates very well with the measured values. The simulation of the load path up to 400 kN shows a slightly stiffer model behavior compared to the reference. A larger model deformation is recognizable in the high load range. Figure 6(c) shows the deviations from the reference for each simulation version along the load paths. Similar to the results in the horizontal direction, it is recognizable that with a continuous model update both the error size and the range of the errors occurring could be reduced.

4 LIMITS OF DIGITAL TWIN MODELING

4.1 *General aspects regarding the level of approximation*

All digital models used to calculate individual elements or complex structures represent an approximation of the real behavior of the studied object. These simplifications can be categorized into different levels of accuracy. The level of approximation approach is a step-by-step design strategy in which the accuracy of a model output is gradually improved through refined physical parameter inputs (Model Code, 2020). Applied to the modeling presented here, initial estimates using analytical formulas can represent the first level of accuracy. The next level of accuracy is the numerical calculation using non-linear finite element modeling. By refining the load application as well as geometry and material updates, the modeling can be categorized in the third accuracy level. A possible increase in accuracy is the extension to a probabilistic analysis. Figure 7 compares these steps with the time required for information gathering, model building as well as calculation and the achievable accuracy. The information on accuracy and time expenditure may vary from project to project and represents an expert estimate. An increase in accuracy is accompanied by an increase in effort, therefore the curve flattens out, reflecting the low information gain with constantly increasing time input.

4.2 *Limitations*

However, each model update must be assessed critically, as a model update does not automatically lead to an increase in accuracy. The evaluation of the various simulations has shown, for

example, that a refinement of the loading approach does not necessarily lead to a better output (Figure 6(c)). Basically, models are optimized for areas of particular interest, in terms of either location or load range. It should also be mentioned that the 2D modeling can be limited regarding the level of detail (Figure 8). As a result of the test load, significant cracks appear in the inner area of the crown area between the holes of the threaded rods. This aspect cannot be simulated in the 2D model due to the lack of dimension. If these holes, which act as weak points, are not taken into account in the simulation, a large number of hairline cracks occur at this point in the 2D simulation. A 3D simulation with simulated discontinuities removes this limitation and could be relevant for subsequent installations in building structures. As modelling and digital twins become increasingly refined, the number of detailed questions that can only be answered with assumptions in the modelling increases. In these cases, the effort no longer increases linearly, but almost exponentially, as, for example, not only the actual condition of the structure, but also the historical, e.g. curing, creep and shrinkage conditions, must be considered.

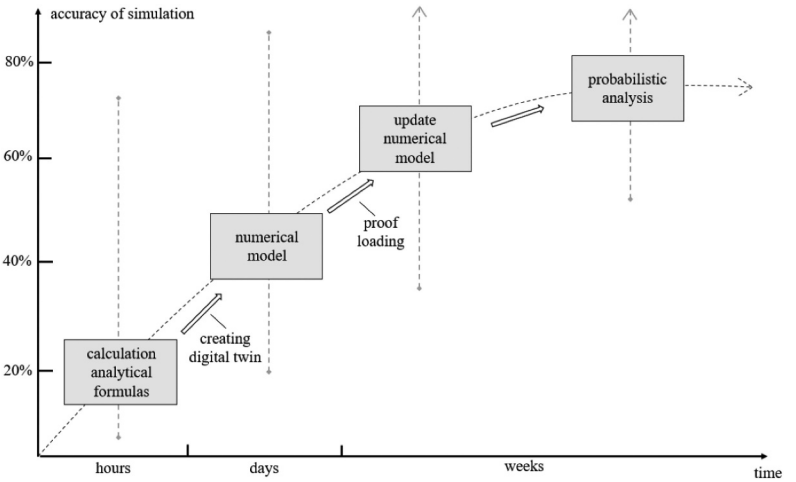

Figure 7. Level of approximation approach, time expenditure of information gathering, model building & calculation.

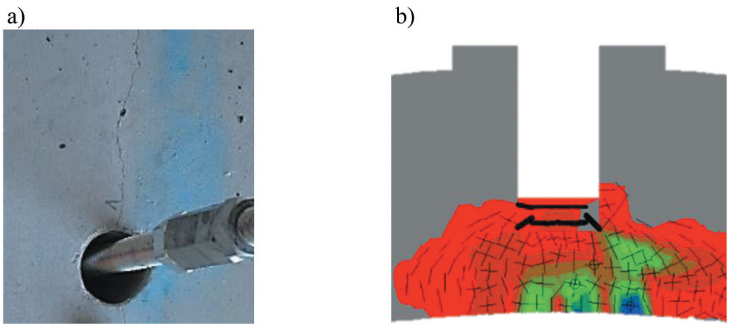

Figure 8. Model uncertainties due to crack distribution in a) in reality versus b) 2D-digital-twin versus.

4.3 *Modeling vs. extended safety formats*

The digital twins, which have been developed in this research with varying degrees of complexity, were used to determine the increase in reliability and safety associated with the modelling effort. In the case of the tunnel digital twin profile, there was an increasing capacity growth, which can

be seen in Table 1, but this may not always be the case. As with structurally unstable systems, an increasing level of modelling complexity can also lead to a reduction in load-bearing capacity.

Table 1. Computed reliability index in terms of the level of detailing of the digital twin.

	Analytical model	Numerical model (FORM)	Updated numerical model (FORM)	Probabilistic model
Reliability Index	4.7	5.3	5.4	5.7
Time	hours	days	days	weeks

5 CONCLUSIONS

By means of a tunnel pilot equipped with several monitoring systems, it was shown how the development of a digital twin is not a simple optimisation process, e.g. in the material parameters and support conditions. The chosen proof loading concept and the extensive monitoring concept made it possible to show that the digital twin development requires a complex interaction between modelling and system responses via different loading regimes. It was also possible to show the time required for modelling at different levels of detail vs. the changes in the reliability level and safety format.

ABSTRACT: In many European cities there are a considerable number of railway bridges with a minimum height above road overpasses. The number of impacts increases on these road overpasses, which automatically results in the closure of the railway operation. A procedure supported by non-linear finite element analysis (NLFEA) and monitoring systems has been developed which, through a detailed analysis of the impact energy, the impact effects, and the structural resistance behaviour, identifies the actual impact value that has occurred and determines the impact limit value that triggers the closure of the railway operation. Finally, guidelines can be proposed for calculating the impact limit values and the arrangement of intelligent monitoring systems to prevent interruptions to operations.

1 INTRODUCTION

One major problem with railway bridges is the impact of vehicle induced collision events on the superstructure, e.g. on reinforced concrete slabs or girder systems, as this usually leads to a temporary suspension of train operations in accordance with the provisions of railway law and a closure of the bridge. In the event of an vehicle impact, the bridge and its operation can only be released in accordance with the current alarm chain after a police report and visual inspection by a bridge expert, which can take a significant amount of time. In view of the increasing train traffic and also the very high frequency on the routes of the Trans European Network (TEN), the impact events and also the current alarm process chain are a relevant restriction and can lead to very large impairments of the railway lines. Impact processes are increasingly occurring in inner-city areas where the clearance heights are usually kept to the minimum permitted by law, which is not always in agreement with the railway operator. As surveys show, such bridge objects are not uncommon, as there are often complex interrelationships with other infrastructure systems. The obvious question is therefore whether there are monitoring systems that make it possible to prove the actual energy and shock input due to a vehicle impact and thus have a good basis for deciding whether railway traffic can continue to operate after an impact on the railway structure or whether operation must be interrupted and the classic alarm and testing process chain initiated. The surveys carried out have shown that monitoring systems for recording impact loads on railway bridges are not conventional or documented, as there is also a risk of the monitoring system failing. In-depth NLFEM analyses and dynamic test loads were therefore proposed in detailed discussions with experts in order to specify the possibilities of monitoring and also to determine those areas and components of the bridges in which the energy input of an impact can best be determined. The executed bridge specific bearings and regions around were characterised as the most suitable for determining the energy input from a vehicle impact and are identified as potential zones for the characterization of key performance indicators that can be monitored. The aim of this paper is to present the

DOI: 10.1201/9781003483755-91

initial results and procedural steps of the analytical and numerical investigations carried out, which enable the impact problem on railway bridges and the associated alarm process chain to be re-evaluated from a holistic system perspective.

2 MOTIVATION

Vehicle impacts on the superstructure of railway bridges occur particularly in urban areas in those cases where the permissible clearance height of driving road vehicles is not maintained (Schönfeld 2015, Ozdagli et al 2020). If vehicles collide with the superstructure of a railway bridge, structural damages are expected and thus, an immediate report is always made to the person responsible for the maintenance of the bridge structure, who in the first step orders the train traffic to be blocked. Hence, vehicle impacts on railway bridges currently lead to an immediate blockage of train traffic and thus to a restriction in route availability, regardless of the intensity of the impact. In this study information about the extent to which structural damage and/or permissible object-specific bearing forces occur on railway bridges as a result of a vehicle impact is obtained by carrying out "quasi-static" numerical calculations of the impact on a railway bridge. Exceeding the object-specific bearing forces is defined as decisive and in these cases, blockage of the train traffic is necessary. The aim is therefore to determine whether, for an existing railway bridge in Austria on route 2052, km 13.011, assuming a vehicle impact defined in accordance with current standards, the structural damage and/or bearing forces reach values that affect the railway bridge to continue to be used for train traffic. In addition, "quasi-static" impact calculations with increased impact loads are also to be carried out, from which the permissible sizes of the impact loads or impact forces specific to the considered bridge are determined. From the results obtained an assessment is made with regard to any necessary measures or unrestricted release for train traffic after an impact event occurs. For the Austrian Federal Railways as contracting body of the research project, the implementation of the research results has the advantage that impact events on railway bridges are assessed with regard to structural damage and/or exceeding permissible bearing loads and that measures such as the closure of the railway route are not necessary in all cases, i.e. availability of the route remains unrestricted even after an impact event.

3 NATIONAL AND INTERNATIONAL REGULATIONS

3.1 *National regulations*

The analysis and assessment of vehicle impact on the superstructure of railway bridges is regulated in the following national standards:

- ÖNORM EN 1991-1-7, Eurocode 1 - Actions on structures, Part 1-7: General actions - Extraordinary actions, edition: 2014-09-01.
- Background Document Eurocode 1, Part 1.7, Accidental Actions, January 2005.
- Designers' Guide to Eurocode I: Actions on Bridges. EN 1991-2, EN 1991-1-1, -1-3 to -1-6 and EN 1990 Annex A2.

Table 1. Equivalent static design forces due to vehicle impact on superstructures of railway bridges according to ÖNORM EN 1991-1-7.

Category of traffic	Equivalent static design force F_{dx} [a]
	kN
Motorways and country national and main roads	500
Country roads in rural area	375
Roads in urban area	250
Courtyards and parking garages	75

[a] x = direction of normal travel.

ÖNORM EN 1991-1-7 define the equivalent static design forces due to vehicle impact on superstructures of railway bridges as listed in Table 1. Impact calculations needs to be carried out on bridges with a clearance height of ≤ 6 m. It is seen from Table 1, that the equivalent static design force of F_{dx} = 250 kN must be applied for the category roads in urban areas, which is the suitable category for the railway bridge considered in this study.

3.2 *International regulations*

International regulations regarding the assessment of vehicle impact on the superstructure of railway bridges are:

- UIC-KODEX 777-1, Measures to protect railway bridges against impacts from road vehicles, and to protect rail traffic from road vehicles fouling the track (in German), 2nd Edition, June 2002
- DIN 1055-9, Actions on structures - Part 9: Extraordinary actions, Edition: 2003-08.
- Swiss Guideline, Impact of road vehicles on structural parts of engineering buildings (in German), Extension to Code SIA 261, Edition 2005

UIC 777-1 define the vehicle impact loads to be applied for overelevated vehicles with 500 kN in horizontal direction (driving direction) and 250 kN in vertical direction. With respect to urban areas the size of the impact load in horizontal direction is two times higher than the load defined in ÖNORM EN 1991-1-7, but UIC 777-1 does not distinguish between road categories. According to UIC 777-1 no impact calculation needs to be carried out on bridges with a clearance height of more than 6 m, i.e. this regulation is identical with ÖNORM EN 1991-1-7.

DIN 1055-9 defines the size of the "quasistatic" impact load for so-called frontal crash with 1000 kN for the category country roads in rural area, which is around 4 times higher than the value defined in ÖNORM EN 1991-1-7, see Table 1.

3.3 *Discrepancy of regulations in standards and mechanical impact equations*

As shown in section 4, the design forces according to national and international regulations are low in comparison to the result obtained by evaluating the mechanical impact. The discrepancy of mechanical impact equations and regulations in current standards needs deeper research.

4 THEORETICAL BACKROUND TO VEHICLE IMPACT LOADS

The impact of vehicles on the superstructure of railway bridges represents a shock-like load, where the size of the resulting interaction force (impact force) F_S depends on the impact mass (vehicle mass) m_F, the vehicle speed v_F, the impact duration Δt and the vehicle stiffness k_F. Annex C of ÖNORM EN 1991-1-7 specifies an analytical calculation method for determining the interaction forces (impact forces) F_S resulting from a vehicle impact, and a distinction is made between an impact as a "hard" and a "soft" impact. According to ÖNORM EN 1991-1-7 an impact is referred to as a "hard impact" if the impact energy is mainly dissipated by the impact object (vehicle). A "soft impact", on the other hand, is characterized by the fact that the object (railway bridge) that is impacted deforms and thereby absorbs impact energy and then dissipates it. In the case of railway bridges, however, the supporting structure itself only deforms negligibly in the direction of impact, and therefore the "hard impact" is considered to be decisive. The reality, however, will lie between a "hard" and a "soft" impact, since in the case of a structure supported on elastomeric bearings, a horizontal deformation of the bridge structure will take place and the impact energy will be partly dissipated. Assuming "hard" impact is on the safe side, the energy dissipation occurs exclusively through the impact object (vehicle).

Annex C of ÖNORM EN 1991-1-7 states that in the event of a hard impact, the equivalent static (quasistatic) forces according to Table 1 may be applied. Alternatively, a dynamic approximation calculation can be carried out using a simplified mechanical impact model, and this approximation procedure is presented for the "hard" impact.

In the event of a "hard" impact, the structure to be impacted is assumed to be completely rigid, i.e. there is no energy dissipation through the structure, while the impact object deforms

"linearly" and dissipates the impact energy. The maximum dynamic interaction force (upper limit) is expressed as:

$$F_S = v_F \sqrt{k_F m_F} \tag{1}$$

where F_S defines the quasistatic impact force, v_F the speed of the vehicle upon impact, m_F the mass of the vehicle and k_F the equivalent elastic stiffness of the impact object, i.e. the ratio of the impact force F_S to the total deformation w_F of the impact object. The impact process can be considered as a sudden square-wave impulse (Figure 1) acting on the superstructure to be impacted, e.g. the superstructure of a railway bridge, and equation (1) can be rewritten as:

$$F_S \cdot \Delta t = v_F m_F \tag{2}$$

If the impact duration Δt is known, equation (2) can also be used to directly determine the impact force

$$F_S = \frac{v_F m_F}{\Delta t} \tag{3}$$

In equations (2) and (3), the impact duration Δt now appears as an explicit quantity and is defined as:

$$\Delta t = \sqrt{\frac{m_F}{k_F}} \tag{4}$$

Equation (3) can also be interpreted as the impact object vibration period or reciprocal of the fundamental frequency of the impact object (vehicle).

Due to the variability of the actual vehicle stiffness k_F, the exact determination of the impact duration represents a major challenge when considering a real vehicle in practice and can only be solved approximately. A very short impact duration consequently leads to equally high impact forces, which can reach implausible values. In the case of a completely rigid impact object and a rigid supporting structure, an infinitely high impact force would result.

If it is possible to model the impact object as an equivalent elastic body with a uniform cross-section, in this case the following equations can be used to determine the equivalent vehicle stiffness and mass

$$k_F = \frac{EA}{L} \tag{5}$$

$$m_F = \rho A L \tag{6}$$

where E is the equivalent modulus of elasticity, A is the equivalent cross-sectional area of the impact object, L is the equivalent vehicle length and ρ is the equivalent mass density of the impact object. Figure 1 shows the mechanical model for the approximate calculation of the impact force F_S in the case of a "hard" impact. Since the impact duration Δt can only be determined very imprecisely based on purely theoretical considerations, so-called crash tests are carried out in practice to determine the impact forces F_S and the equivalent stiffness k_F of impacting vehicles. Table C.1, ÖNORM EN 1991-1-7 provides a deterministic value for the equivalent vehicle stiffness of k_F = 300 kN/m, and assuming a total vehicle weight of a multi-axle lorry of 25 t (m_F = 25,000 kg) results the impact duration Δt = 0.29 seconds from Equation (4). For an assumed vehicle speed of v_F = 50 km/h (realistic speed in urban areas), this results in an impact force of F_S = 1202.81 kN, see calculation and graphical representation in Figure 2.

The calculation results illustrated in Figure 2 for the impact force F_S determined in accordance with Annex C of ÖNORM EN 1991-1-7 show that, according to this conservative mechanical model of the "hard" vehicle impact, even light vehicles already exceed the impact loads defined in ÖNORM EN 1991-17 (Table. 1). For urban areas (applies to the railway bridge considered here to be examined for vehicle impact) a static equivalent impact force of F_{dx} = 250 kN must be applied according to ÖNORM EN 1991-1-7. Contrary, the impact force determined using the "hard" impact approximation method according to Annex C of ÖNORM EN 1991-

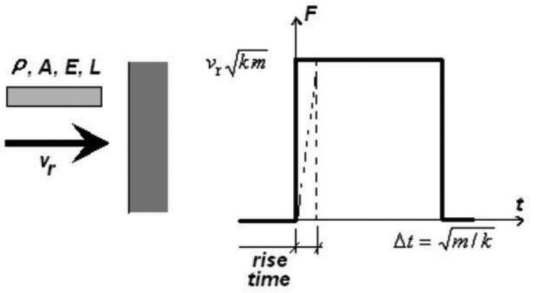

Figure 1. Mechanical model for approximate calculation of impact force F_S in the case of a "hard" impact according to Annex C, ÖNORM EN 1991-1-7.

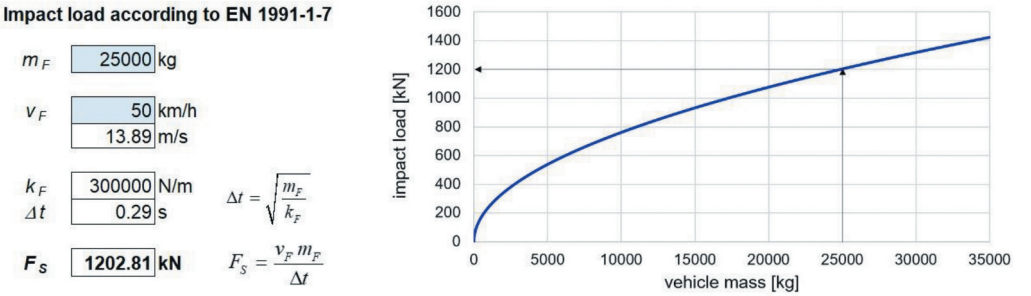

Figure 2. Determination of impact force F_S with assumed input parameters and graphical representation of impact force depending on the vehicle mass m_F.

1-7 for a 25,000 kg heavy truck is approximately 5 times higher. This discrepancy between normative regulations and mechanical impact models needs deeper research. It is assumed that railway bridges necessitate much higher requirements than road bridges because of their accuracy requirements regarding the rail position and track position stability.

5 RAILWAY BRIDGE EXAMINED FOR VEHICLE IMPACT

5.1 *General aspects*

Figure 3 shows photos of the railway bridge examined regarding the vehicle impact. It is located in Austria on route 2052, km 13.011. It is a two-track single span inclined bridge structure with a span of 9.49 m (measured along the bridge axis) and 8.45 m (normal to the abutment axis). The crossing angle is 63°. Figure 4 shows a cross section and ground view with bearing scheme of the railway bridge. The existing clearance height (headroom) is 3.23 m. The bridge deck plate (superstructure) is separated in the middle to the adjacent plate by a longitudinal joint, i.e. there are two individual bridge deck plates that each carry the traffic loads from one track. In the numerical calculation of the vehicle impact, only a single deck plate is therefore considered. With regard to the bearing construction, it can be seen that one roundly fixed and transversely fixed bearing as well as 4 roundly movable bearings are for each individual bridge deck plate. In the event of a vehicle impact, the resulting transverse impact force is therefore carried by the roundly fixed bearing and transversely fixed bearing. The forces used when dimensioning the bearing structures are as follows: load in longitudinal direction H_x = 700 kN (roundly fixed bearing) and load in transverse direction H_y = 280 kN (roundly fixed and transverse fixed bearing).

Figure 3. Photos of railway bridge examined for vehicle impact, located in Austria on route 2052, km 13.011.

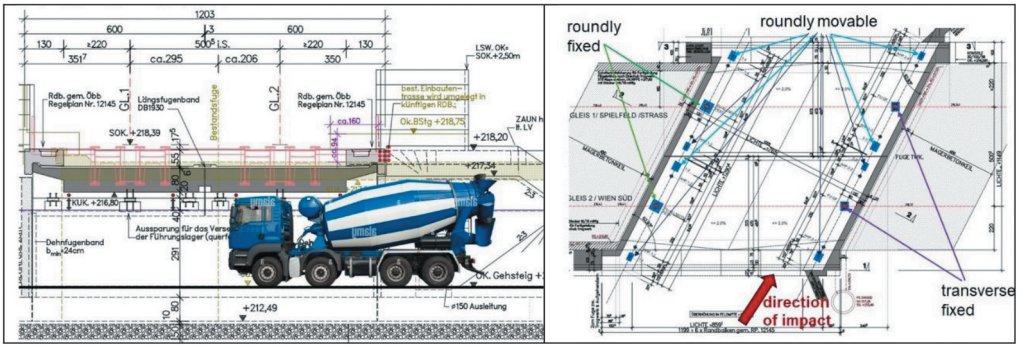

Figure 4. Cross section and ground view with bearing scheme of railway bridge examined for vehicle impact.

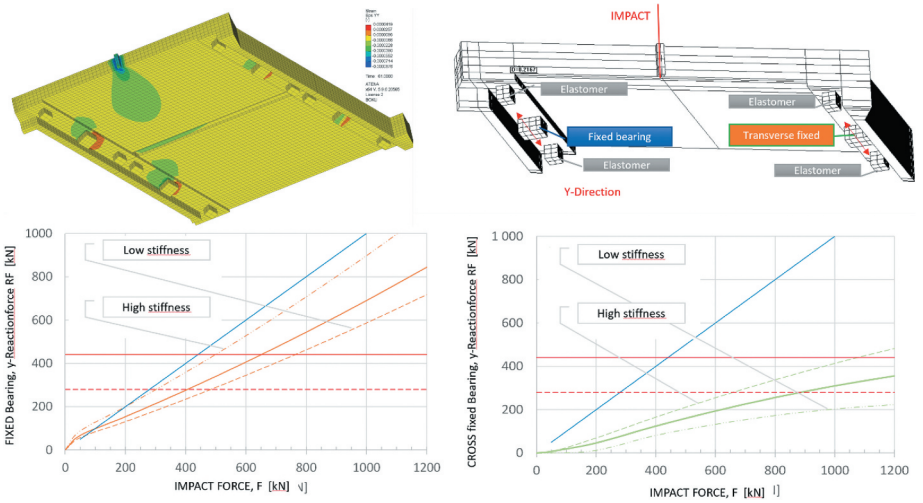
It is noted that the mentioned bearing loads are design values including partial safety factors that were determined by the responsible structural engineer in the ULS verification and specified for the bearing design. The bearing static resulted for the fixed bearing the proof "weld seam around the block shear connector" being decisive (calculated equivalent stress σ_v = 206 MPa < allowable equivalent stress $\sigma_{v,zul}$ = 241 MPa). For the transversely fixed bearing, the proof of "welded seams around the lower block shear connector" resulted to be decisive (calculated equivalent stress σ_v = 170 MPa < allowable equivalent stress $\sigma_{v,zul}$ = 241 MPa).

5.2 *Numerical digital twin analysis*

The modelling of the collision impact on the railway bridge on route 2052, km 13.011 was carried out using the ATENA Scientific 3D software to analyse the energy input, the force propagation and the resulting bearing force. The plan data served as the basis for the modelling is shown in Figure 4. Figure 5 shows the correspondingly high level of detail of the modelling and the selected macro zoning as well as the bearing arrangement and the position of impact in the centre of the bridge span. Figure 5 shows that the stiffness of the bearings has a significant influence on the transmission of the impact force to the bearings. It can be seen from the illustrated diagrams that on average approx. 70 % of the impact force is transferred to the fixed bearing for the optimal impact position in the bridge centre. If the bearing had already been designed for an average value of 700 kN, it could therefore accommodate an impact load of 1000 kN.



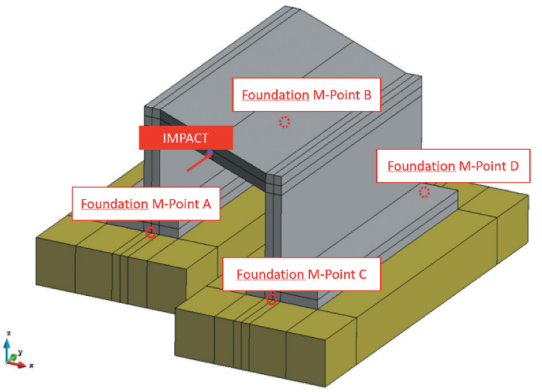


Figure 5. Fixed bearing reaction force vs. impact force in the theoretically optimal vehicle driving direction on the road under the superstructure (fixed bearing and transverse fixed bearing).

(a)

(b)

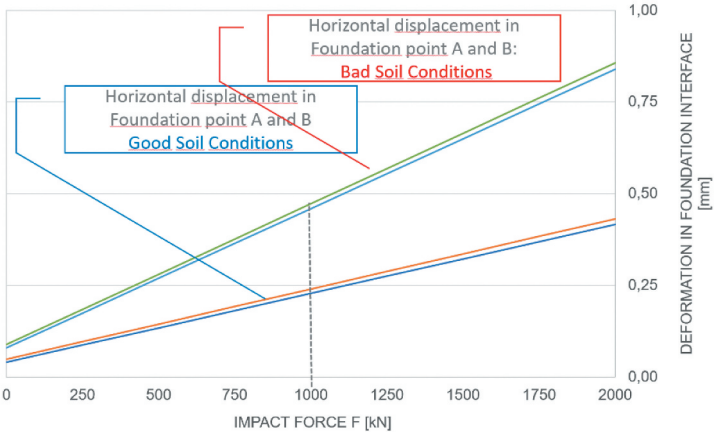

Figure 6. Analysis of the bridge system (a) adapted frame system with monitoring points in the foundation, and (b) impact vs. displacements in the foundation monitoring points A and B.

In addition to the investigations of the supported superstructure, the overall stability of the bridge system in terms of soil interaction was analysed for different soil conditions, as shown in Figure 6. For this purpose, as shown in Figure 6(a), an adapted spatial frame system was used, and monitoring points were placed in the foundation to analyse the "quasistatic" impact load induced displacements and stresses. Figure 6(b) shows that the maximum horizontal displacements of the foundation at an impact of 1000 kN are in a range of maximum 0.25 mm to 0.50 mm depending on different soil conditions. In all cases the static friction of the bridge system is not exceeded by far, which proves the structural stability and shows that no critical displacements for a rail closure occur.

6 CONCLUSIONS

The analyses conducted on the reinforced concrete railway bridge show that the impact forces can be absorbed by the executed bearings. If the up to 3-fold vehicle impact load (250 kN for the impact load in urban areas according to ÖNORM EN 1991-1-7 times 3, i.e. 750 kN), which is very likely to occur under unfavourable conditions, is applied, the numerical calculations carried out shows that only around 70% of the impact force can be absorbed by the executed bearings. The bearing forces resulting from the impact load of 750 kN should already be taken into account when planning the bearings. Nevertheless, a non-linear pre-analysis of the impact situation with alarm monitoring is generally strongly recommended. Based on the results, the design of the bridges could be reconsidered and adapted so that the impact loads can be safely absorbed.

ACKNOWLEDGEMENTS

This publication was produced on the basis of a commission from ÖBB-Infrastruktur AG (Austrian Federal Railways). The opinions and conclusions presented in this paper are those of the writers and do not necessarily reflect the views of the sponsoring organization. The authors would like to thank the expert team Thomas Simandl, Richard Zedlacher, Alfred Hüngsberg, Maximilian Autengruber and Josef Schorn of Austrian Federal Railways, bridge construction department, for their support.

ABSTRACT: The increasing need for mobility is fuelling interest in extending the service life of existing bridges. In case of the Jauntal Bridge, one of the highest railway bridges in Europe, a new structure with two tracks is placed on the existing massive concrete columns with a hight of almost 100 m compared to the old structure with one track. Non-linear innovative numerical analyses and advanced safety considerations were used to examine whether the significantly higher bearing-column forces can be sustained by the existing columns and column heads. This paper shows how the advanced modelling methods can be applied to ensure that the existing structures, can be safely maintained over their planned lifetime in service for sustainability reasons.

1 INTRODUCTION

The Jauntal Bridge in Carinthia, shown in Figure 1, crossing 96m above the Drau River valley, the single-track bridge with a total length of almost 430 meters has stood the test of time in remaining one of Europe's highest railway bridges. It was built in 1961 and is currently being replaced by a new structure with a double-track line and a footpath and cycle path underneath. In the construction work, the old steel structure was coupled with the new one and both were moved together in the longitudinal direction in order to bring the new structure in its final position. The new deck above the steel structure has already been partially erected and the reinforced concrete deck is being concreted with formwork carriages. An extensive monitoring system has already been installed on the bridge, monitoring both the construction phases and the operational phases and allowing a comprehensive performance assessment.

Planning and construction of the new structure, shown in Figure 2, was processed by the engineering office KOB and ÖBB Infra and accompanied by the scientific partners in the dynamic analyses and some detailed verifications of the bearings using shock transmitters. As can be seen in Figure 2(c) at the bottom of the bearing sketch is a special moving bearing system in which the braking and earthquake forces are absorbed by shock transmitters. Another special feature with respect to this bearing system was the analysis of the bridge as a continuous welded rail system with special track interaction situations due to the shock transmitter solution.

DOI: 10.1201/9781003483755-92

Figure 1. Jauntal Bridge in Carinthia: New structure under construction with a double-track line and a footpath and cycle path underneath. (ÖBB, 2023).

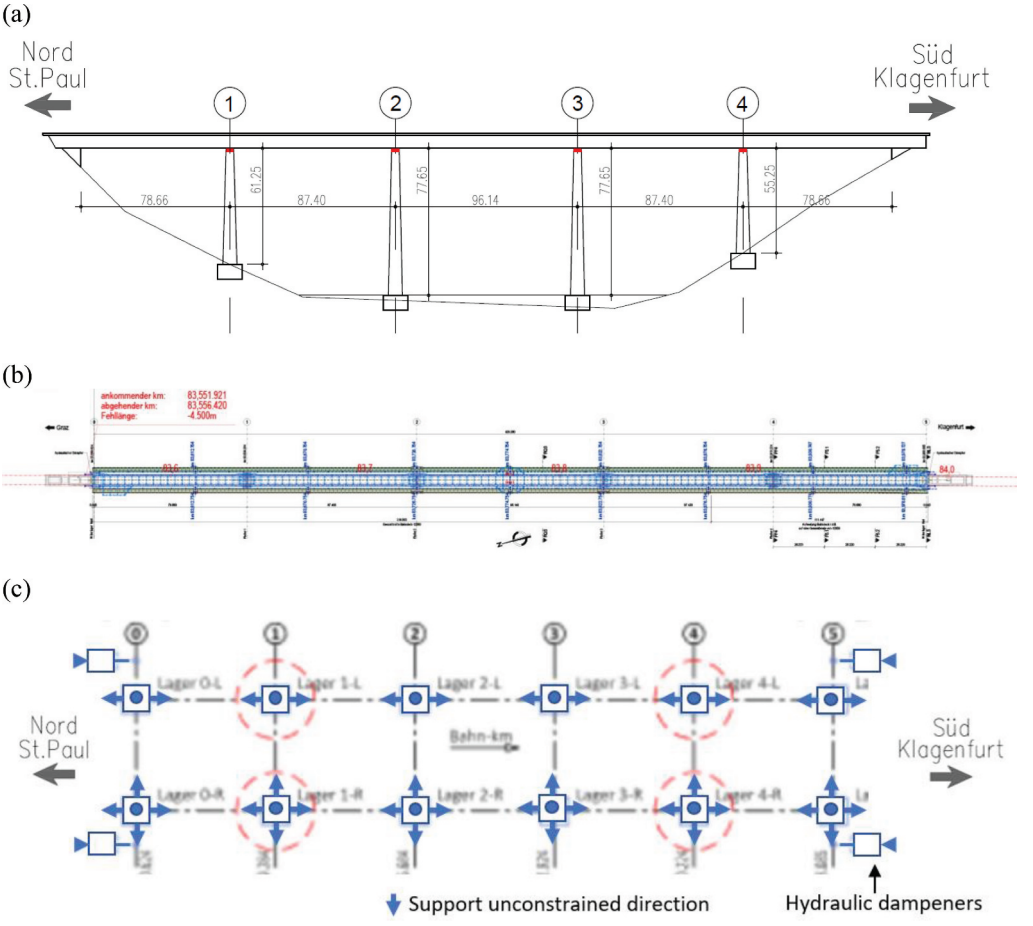

Figure 2. Jauntal Bridge in Carinthia, Austria (a) side view south, (b) top view on the double-track line of the new bridge, (c) bearing system of the bridge.

In addition to the numerous innovative solutions that were necessary to place the double-track line on the existing columns and to continue operating it in terms of sustainability, special investigations and, in some cases, reinforcements of the column heads were also required. This study deals with the discussion of these investigations and analyses. It is shown how the load-bearing capacity of the historical support heads can be verified using a reliable

procedure, which also had to be approved by an external expert, and analysed using innovative Level III methods and extended safety format concepts.

2 HEAD PERFORMANCE OF EXISTING COLUMNS

2.1 *General aspects*

The new supporting structure, a reinforced concrete-steel composite structure, is a continuous girder system supported by the columns with a steel truss as the main girder under the track slab. The loads of the new structure must be transferred to the old existing reinforced concrete columns via the bearings and bearing bases, as shown in Figure 3a to 3c. The bearing force at design level, which results from the self-weight, the removal loads and the live loads of the structure, is a design load of 50 MN. The partial area pressure verifications for new concrete bearing bases on old concrete column heads, shown in Figure 3, are usually interpreted very differently by the experts in accordance with EN 1992 (ASI, 2018) and sometimes lead to very unrealistic results. The planners and the client were therefore very interested in having the verifications and thus the load-bearing capacity of the bearings/columns checked using reliable methods. As a result, the scientific partners created a real-life digital twin in line with the possible verification procedures of level III of MC2020 (fib, 2024(expected)) and B4008 Part 2 (ASI, 2019) using non-linear finite element methods. Moreover, due to significant uncertainties involved, probabilistic approaches to verify the existing capacity and the existing safety were used. As can be seen in Figure 3d, the column head was additionally reinforced with appropriate tension rods to create a confinement and increase the load-bearing capacity of the column head; the effects of these rods have to be taken into account in the analyses.

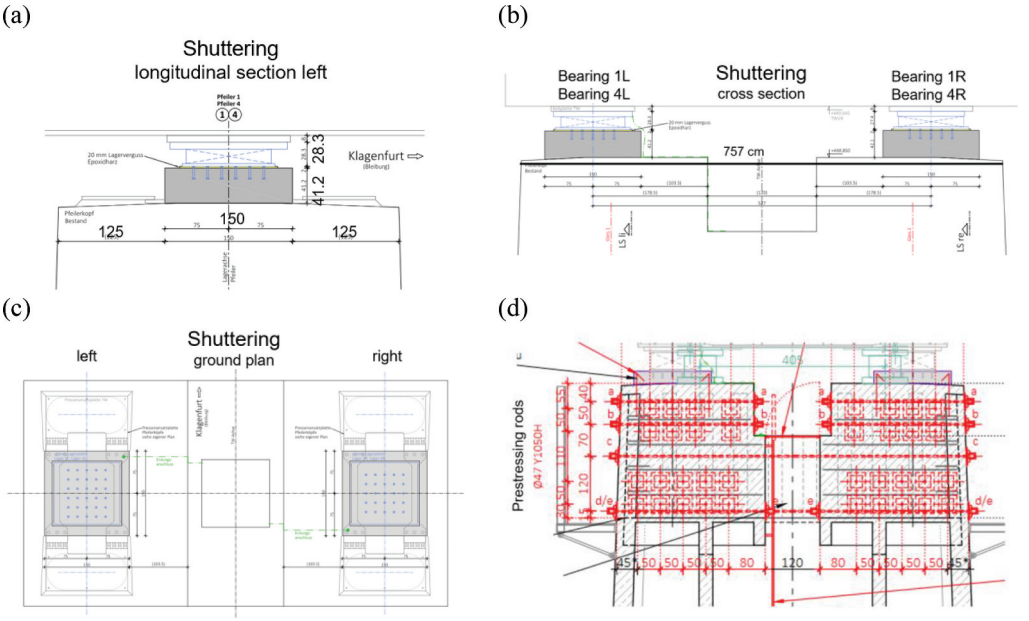

Figure 3. New concrete bearing bases associated with the new steel-concrete composite structure of the Jauntal bridge: (a) side view on the concrete bearing bases, (b) longitudinal view on the concrete bearing bases, (c) top view on the concrete bearing bases and (d) confinement to increase the load-bearing capacity of the column head.

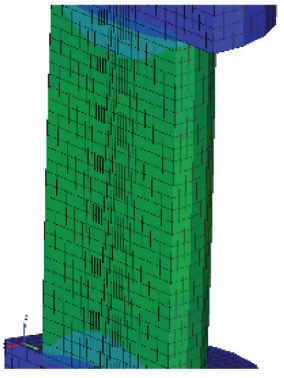
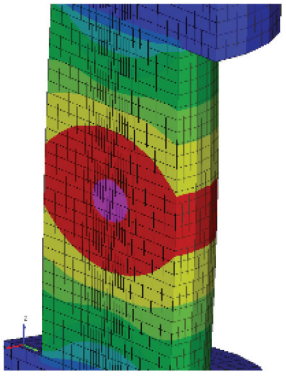
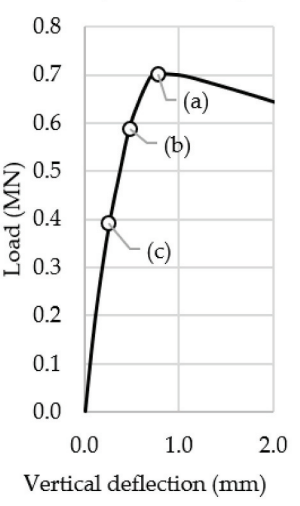
The material parameters of the old concrete from the columns, the results of the conformity check of the new concrete and the detailed reinforcement drawings were provided. In the

subsequent analysis, verification steps were defined as follows: (a) checking the use of the correct material laws in the modelling for the old and new concrete, (b) modelling of the column head without strapping, (c) modelling of the column head with confinement but without prestressing, and (d) modelling of the column head with confinement and prestressing. In addition to these validation steps, the crack width of 0.1 mm was defined as the decisive load-bearing capacity criterion, i.e. the maximum load of 50 MN must not cause a crack width larger than 0.1 mm.







2.2 *Characterisation of material models – step a*

The concrete properties of the existing column heads were experimentally determined with a characteristic cube compressive strength of f_{ck} = 29 MPa. Using the concrete model CC3DNonLinCementitious2 based on the CEB-fib Model Code 90 (CEB-FIB, 1993)

Table 1. Material properties of existing column concrete.

Material parameter of old concrete	value	unit
Modulus of elasticity E	33253.6	MPa
Compressive strength f_c	-37.0	MPa
Tensile strength f_{ct}	2.83	MPa
Poisson's-ratio μ	0.2	-
Fracture energy G_f	0.00014	MN/m
Plastic strain at strength f_c ε_{cp}	-0.00133	-
Onset of crushing f_{c0}	-5.95	MPa
Critical compressive displacement w_d	-0.0005	m

Table 2. Development of the maximum load when creating models using cylinder compressive strength.

95% (667,6 kN) σ = 37.8 N/mm²	100 % (702,7 kN) σ = 39.8 N/mm²	
		

(a) Max. Value = N_{cm} = 702.7 kN, (b) Characteristic Value = N_{ck} = 586.5 kN, (c) Design Value = N_{cd} = 391.0 kN

Note: 100% chosen according to maximum in the load displacement diagram

available in the ATENA (Červenka, 2016) programme package, see Table 1, it was possible to take into account the material and geometric non-linearity as well as the material degradation due to crack development with the help of this material model. The concrete properties of strength class C40/50 according to ÖNORM EN 1992-1-1 were used for the new structural concrete.

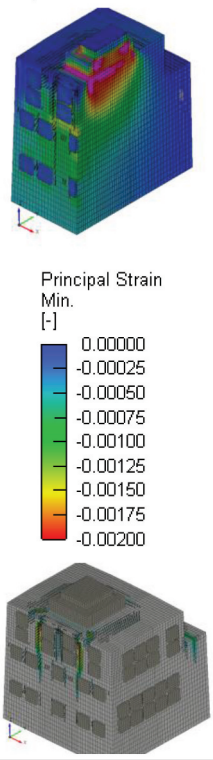
The results of the analysis with the concrete properties determined for the existing column head are shown in Table 2. The properties are based on the experimental tested cylindrical specimens. The principal normal stresses determined step by step for 95% and 100% of the maximum load are shown, whereby the load was applied in about 250 load steps. The stress curves concentrate in the centre of the longitudinal axis of the cylinder as the load increases. The maximum load carrying capacity of 702.7 kN was also reached when the first cracks appeared. These results are consistent with the experimentally observed behaviour of the samples and confirm the appropriateness of the chosen material laws. The computational modelling showed almost no cracking up to the maximum value of 702.7 kN, as can be seen in Table 2, and only then significant cracks occurred, which also corresponded very well with the tests carried out. The characteristic and design values indicated in Table 2 show a very good agreement with the standard concrete strength C30/35 of the concrete of the existing column, so that the modelling and discretisation of the cylinder could be assumed to be validated.

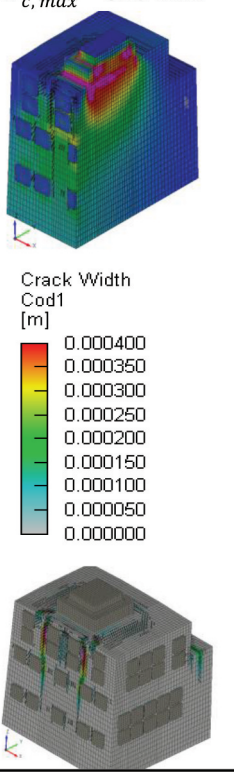
2.3 *Column head performance with confinement and prestressing - step d*

After the characterisation and validation of the material laws, the column heads and the bearing base interaction were modelled in steps (b) and (c) without and with prestressing and confinement, as briefly outlined in Section 2.1. Finally, in step (d), the real-world structure was modelled with prestressing and confinement of the column head, as shown in Figure 4. The pre-stressing force was set at P = 1275 kN. To simplify matters, no bond between the bar tendons and the concrete structure was assumed. A linear elastic material with an elastic modulus of steel was adopted for the pressure distribution plates. The material parameters used are shown in Table 3. The main normal stresses obtained step by step and the crack developments are shown for 95% and 100% of the load, where the load was applied in approximately 250 load steps. As can be seen from Figure 5, the maximum load capacity is around 141.1 MN.

(a) (b)

Figure 4. FE model of the pier head: (a) presentation of the pier head model with prestressed FE mesh; (b) presentation of detail of the prestressing system.





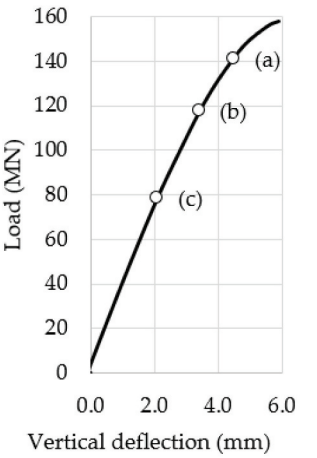


Table 3. Material parameters of pre-stressing rods.

Parameter	Value	Unit
Modulus of elasticity E	200000	MPa
Diameter d	47	mm
Yield strength YS	950	MPa
Strain at bar rupture	0.025	-
Stress at bar rupture	1050	MPa

2.4 *Non-linear finite element digital twin analyses of stages (b) to (d)*

The analysis results of stages b, c and d are presented in Table 4 and Figure 5. In Table 4 the derived force mean value (N_{cm}), characteristic value (N_{ck}) and design value (N_{cd}) are shown.

Table 4. Real world digital twin of the column head - load capacity curve vs. the crack width development.

95% (134.05 MN)	100 % (141.10 MN)	
$\sigma = 59.6$ MPa $w_{c,max} = 0.38$ mm	$\sigma = 62.7$ MPa $w_{c,max} = 0.49$ mm	
		
		(a) Max. Value = N_{cm} = 141.1 MN, (b) Characteristic Value = N_{ck} = 117.7 MN, (c) Design Value = N_{cd} = 78.5 MN

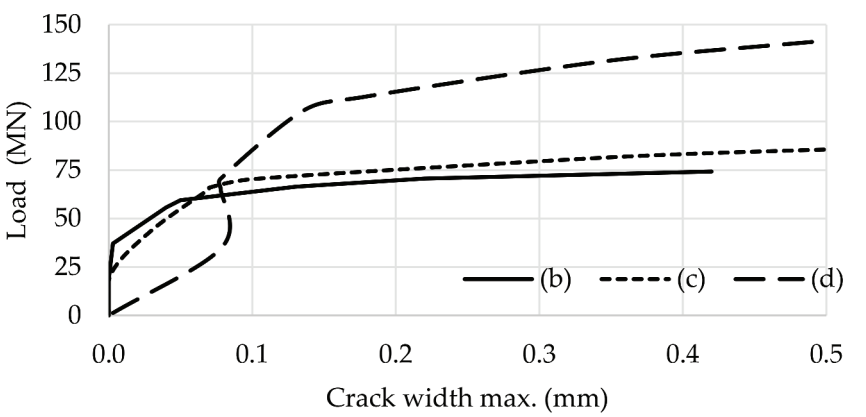

Figure 5. Load vs max. crack width diagram for pier head models: (b) modelling without reinforcement, (c) modelling with non-tensioned reinforcement, (d) modelling with prestressing.

The values in Table 4 were used to formulate and evaluate a limit state in which a maximum crack width of 0.1 mm was defined. Figure 5 compares the load with the crack width max. results of the three stages. The rebound in the long dashed curve in Figure 5 also shows the interesting effect that the cracks formed during prestressing close again due to the increasing load and larger cracks form elsewhere. On the whole, this real-world digital twin of the column head demonstrated that the interaction of the load-bearing base with the old concrete allows a maximum bearing load of 141 MN while maintaining a crack width of maximum 0.5 mm.

3 CONCLUSIONS

In this study, an application-oriented development of a real digital twin of the structural column interaction of the Jauntal bridge (new/old concrete interaction) was demonstrated. With the non-linear finite element-based real digital twin, an iterative adaptation of the constitutive laws of the existing concrete was carried out in stage I by simulating the drilled core specimens. In a further step, a systematic step-by-step procedure has to be used to show how the complex 3D prestressing of existing columns could be realistically included in the real digital twin calculations and finally how the maximum load-bearing capacity could be characterized using a crack width criterion.

Generation of digital twins for bridges of medium spans - Schwindegg Bridge pilot project

J. Wimmer & T. Braml
Institute for Structural Engineering, University of the Bundeswehr Munich

ABSTRACT: In the coming years, bridge maintenance will be an essential task for the upkeep of the infrastructure. Especially in the case of bridges with small and medium spans in the municipal road network, in many cases there are no longer sufficient personnel available for the inspection and maintenance of structures. Therefore, it will be necessary in the future to develop concepts for a partially automated bridge inspection. If information is available from the actions and resistances of structures, the measured values contain important information on the condition of the structure. One concept for this can be digital twins. Based on digital twins and the information they contain; intelligent maintenance management can be implemented. In this paper, we present the challenges and chances of implementing the digital twin concept on a single-span prestressed concrete frame bridge.

1 INTRODUCTION

The construction industry, like many other fields, faces a dearth of proficient labour. According to a recent statistic from the German IAB (Bossler & Popp 2023), the labour market has been becoming increasingly constrained since 2010. The private individual's most noticeable effect of this situation is the long wait times for appointments with craftsmen. Moreover, the absence of workforce is perceptible in the public sector as well, resulting in long wait times for building applications among other things. Not only individuals, but also critical infrastructure such as bridges, experience prolonged wait times due to the shortage of skilled workers in many office positions (Böhme 2022). Consequently, the maintenance of bridges falls into backlog and their structures deteriorate at a faster pace. Notably, broken bridges do not only cause inconvenience to private citizens, but also imperil a country's economic performance (Vorländer 2023). A potential solution to saving valuable labour lies in the simplification and digitalisation of planning processes using intelligent technologies, according to Böhme (Böhme 2022). In recent decades, extensive research has been conducted on digitalisation within the construction industry. In Germany, the first step towards digitalisation is the implementation of ASB-ING, which regulates the mapping infrastructure structures in databases (Bundesministerium für Verkehr, Bau- und Stadtentwicklung 2013). This led to the development of the SIB-BW software, which can create a structure book for each bridge structure, documenting its condition, including any damage. The database resulting from this endeavour serves as a documentation of the structure's condition, particularly in cases of damage. However, it does not possess any intelligent capabilities.

Based on Building Information Modelling (BIM), there are efforts towards digitally mapping processes. The process initiates with the planning of new bridge constructions with BIM. To use the created up to7-dimensional models (Kainz & Wolf 2023) over the life cycle, it is imperative to integrate maintenance and damage management. For German systems, the semantics again rely on ASB-ING since logic has already been specified here. BIM models are not usually available for existing buildings, so current efforts focus on researching the

DOI: 10.1201/9781003483755-93

semantic segmentation of 3D point clouds (Schellen, et al. 2023). Furthermore, ASB-ING approaches are implemented in this area. Investigative efforts are directed towards syntax, enabling semantic assignment of processes and data management to the models via the Semantic Web (Hagedorn, et al. 2023). The next step in this process is to develop an automated real-time evaluation system for the structure's condition and subsequent control. In the field, the notion of digital twin has gained prominence, with increasing application in the construction industry. However, a transition to the digital shadow frequently does not occur (Hindersmann, et al. 2023). This can be attributed to various factors, such as the inadequacy of BIM systems in handling real-time data, gained by Structural Health Monitoring (SHM). Practitioners have thus explored alternatives in linked data frameworks (Naraniecki, et al. 2023). Industry 4.0 (I4.0) systems are designed objectively with predictive maintenance in mind, processing data in a streamlined manner. Commercial software is traditionally implemented for monitoring and controlling machines. Additionally, Asset Administration Shells (AAS) are being researched, mainly using open source. Braml et al. have introduced the AAS configurator, known as BridgeBox (BBox), to create AAS for bridge structures (Braml, et al. 2022). In the following sections, we will outline the potential opportunities and tasks related to digital twins, assess the relevance of AAS in this context, and categorize them through a practical case study of the digital bridge prototype in Schwindegg (Germany) shown in Figure 1.

Figure 1. Western view of the Isenbridge in Schwindegg (Wimmer & Braml 2023a).

2 DIGITAL TWINS AND ITS BENEFITS

2.1 *Definitions*

The definition of a digital twin depends on its intended use. Siemens defines an industrial digital twin as a virtual replica for real-world products and processes, contributing to improved comprehension and prediction of performance (Siemens Digital Industries Software 2019). It utilises multi-physics simulation, data analytics, and machine learning for the purpose of enhancing design, usage scenarios, and environmental conditions, thus reducing the requirement for physical prototypes and augmenting the quality of final products or processes. By using real-time sensor data from physical objects, digital twins can update themselves continuously during the product's lifespan. They define three types of twins: Product, Production, and Performance twins (Siemens Digital Industries Software 2019). Further definitions are summarized in (Schleich, et al. 2017; Stavropoulos & Mourtzis 2022). However, digital twins are defined as interconnected and interacting models that are suitable for predicting the behaviour of products, rather than as a singular model. To maximize advantages, they must be fed with all available data (Schleich, et al. 2017). Company-specific philosophies vary

regarding whether they should be mapped for processes, product life cycles, or products (Schleich, et al. 2017). This is shown in Figure 2 as application levels.

The definition of a digital twin's maturity is currently absent, despite knowing what it can be and how it is used in I4.0. Kritzinger et al. have categorised digital models, digital shadows, and digital twins, based on the extent of data integration, however, shown in Figure 2 (maturity level)(Kritzinger, et al. 2018). Meanwhile, the I4.0 platform developed AAS, which differ in the communication of digital twins amongst themselves (Plattform Industrie 4.0 2021). There are three types of AAS: passive type 1, reactive type 2, and proactive type 3 (Figure 2, maturity level) (Plattform Industrie 4.0 2021; Jacoby, et al. 2023).

In the construction sector, the life cycle of buildings provides a means of translating these definitions. Kosse et al. identify four components of the life cycle: Planning, detailed design, fabrication or construction and operation and maintenance (Kosse, et al. 2022). It is clear that for structures that are intended to endure, the long-term factor is of utmost significance. An example of this can be found in the notably shorter lifespan of industrial tools in comparison to the components of bridge structures.

After defining digital twins and their requirements, Ye et al. examined three approaches for handling measurement data from Structural Health Monitoring (SHM): data-driven, physics-based, and data-centric engineering (Ye, et al. 2019). The data-centric approach combines both physics- and data-driven digital twins within a single framework, and specifically addresses building construction and operation. In (Danwitz, et al. 2023), this approach is referred to as the "Hybrid Digital Twin". This comprises a data-driven model, a model based on physics, a model with reduced dimensions and a basic model, all working in conjunction to represent a level of modelling, shown in Figure 2 with the modelling level.

Progressive literature on digital twins in the construction industry incorporates the definitions of I4.0, but there is often a conflation of the terms digital model, digital shadow, and digital twin. This issue is also observed in I4.0 literature (Kritzinger, et al. 2018).

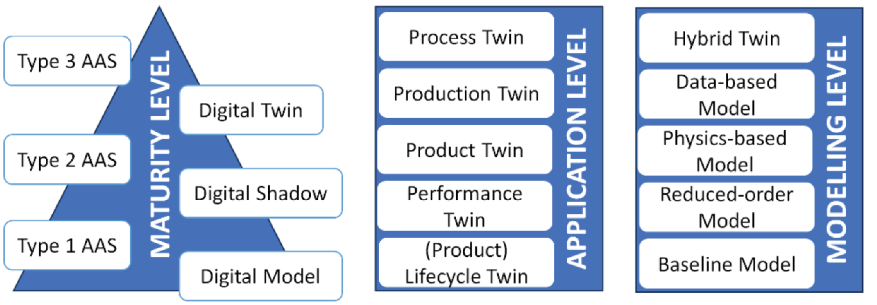

Figure 2. Maturity level, degree of application and degree of modelling as alternatives to the definition of a digital twin.

2.2 *Use of digital twins*

Digital twins are not limited to I4.0; progress in the concept is also evident in healthcare and smart cities. Reviews of the respective sectors summarise the use cases. Within I4.0, the manufacturing industry stands out for exploiting digital twins to enhance production, alter and simulate prototypes or demonstrate the product life cycle (Kenett & Bortman 2022). However, limitations arise during the development of a cyber-physical system as existing software encounters difficulties in logically linking the data and utilizing it as a factual digital twin. Currently, real digital twins are utilized to support physical experiments. Kenett & Bortman offer digital twins of I4.0 in their text (Kenett & Bortman 2022), showcasing gear fault diagnosis using the digital twin of a rotating machine, electronics, material properties, and production process. Additionally, (Stavropoulos & Mourtzis 2022) explore further digital twin applications such as personalised manufacturing, ergonomic production, or human-machine interaction.

The healthcare sector has experienced a significant surge in scientific literature concerning digital twin technology in recent years. According to reviews, hospitals' and devices' digital twins have achieved exceptional development due to their proximity to the industry. Nevertheless, these digital twins remain restricted to specific areas of concern (Machado & Berssaneti 2023). For digital twins of patients and processes, however, political paths need to be paved first, as described in scientific papers. No report of a digital twin of a physical body has been published yet, as per (Machado & Berssaneti 2023). Other reviews, like (Sun, et al. 2023), discuss specific use cases of digital twins. They describe various aspects, including gene composition, diagnosis, and treatment, as well as measurement data from examinations or patient data at the patient level. These features are integrated into the digital twin, providing clinical decision support, personalised recovery paths, real-time monitoring, a mechanism model, opportunities for scientific research, and educational support (Sun, et al. 2023).

The concept of Smart Cities is gaining traction in urban planning. The term Urban Digital Twin or City Digital Twin is increasingly being used synonymously (Shahat, et al. 2021; Weil, et al. 2023). The main challenges revolve around the integration and analysis of data from diverse sources. Once resolved, City Digital Twins have the potential to significantly enhance the quality of life of city residents. For example, measuring commuter flows enables the optimisation of public transport and adaptation of traffic lights in response to traffic flows. This leads to more efficient energy systems (Shahat, et al. 2021). Nevertheless, publications also address environmental sustainability, as well as resources (workforce, finance) and ethics (Weil, et al. 2023). The resilience of the city is another application; for example, preparing for natural hazards or man-made dangers (Therias & Rafiee 2023). Digital twins of bridges and other critical infrastructure provide results that can be classified in this field and enhance the city's digital twin's sensory data or structural condition information. In seismic zones in Vancouver, for example, SHM is already being employed to gather measurement data from bridge monitoring projects (Kaya & Ventura 2019). Just like City/Urban Digital Twins, overcoming numerous challenges is crucial for its success. These will be presented in the following section.

2.3 *Challenges and chances on the way to a bridge's digital twin*

As there is ongoing basic research into digital twins of bridges, only some aspects of the concept have been standardised. The full benefits of a digital twin are realised when all accessible information can be gathered, accessed, and integrated automatically throughout the entire lifecycle. Robust measurement technology is necessary for installation and long-term stability. Additionally, freely available, standardised, and durable data formats that are both human- and machine-readable are needed. Intelligent data processing is required to compress large amounts of information, and bidirectional interfaces with other digital twins of bridges, routes, or even cities are necessary.

Several solutions exist for each of these technical building blocks of a digital twin, but a combination of the steps is paired with a proprietary solution. As most stakeholders of the elements do not cover all solutions, e.g., the large number of measurement principles available and used on the market, standardised interfaces are required. Braml et al. propose a concept from the perspectives of both research and industry, categorising the components into data collection, transfer, storage, and analysis (Braml, et al. 2023).

If the obstacles that have been faced are surpassed, enabling a digital twin to be established and operated effortlessly, and the whole process can act as a "plug and play" solution, then the digital twin's complete potential could be exploited. Intelligent maintenance management implementation takes priority in achieving this objective, intended specifically to support the infrastructure operators who are working to capacity. At best, this approach enables early recognition and repair of damage, thus extending the service life in accordance with predictive maintenance principles. The employment of metaverse approaches, whereby users can interact with pertinent data, is similarly plausible (Yaqoob, et al. 2023). The resulting increase of the bridge's service life could decrease (Wimmer & Braml 2023a).

3 MULTIUSE OF DIGITAL BRIDGE SCHWINDEGG – PROOF OF CONCEPT

3.1 *The bridge and the motivation to make it a digital bridge*

The Isenbridge, a single-span prestressed concrete frame bridge spanning approximately 20m, is located in Schwindegg, Germany (Figure 1). The main supporting structure comprises precast beams with in-situ concrete supplements and abutments founded on bored piles. The bridge facilitates the passage of a two-lane district road over the river Isen in Schwindegg, and it is connected to the local infrastructure via an overpass for power and telecommunications supply lines. The bridge's dimensions, geographical position and favourable environment create the ideal requirements for continuous measurement data gathering and transmission. The dtec.bw RISK.twin study on digital twins motivated the selection of this bridge as a living lab. Construction finalisation took place in 2022 and the sensors were installed simultaneously. The concepts of installation, monitoring, and measurement, along with the encountered challenges and corresponding findings during construction, were previously disclosed in (Wimmer & Braml 2023c). Details of the sensors used and installation process are displayed in (Wimmer, et al. 2023). Successful implementation guaranteed data collection from the outset of operation.

The aim of this project is to provide a proof of concept by showing the applicability of the sensors and their installation in construction operations. Additionally, it will demonstrate how multiple sources of measurement data can be connected to the BBox and then transmitted as a digital shadow to the AAS. The gathered measurement data will enable the development of intelligent evaluation methods, such as those based on principal component analysis, allowing for expedient feedback, fewer data transmissions, and the undertaking of later assessments of the bridge. The resulting Structural Health Information Patterns (SHIPs), as discussed in (Varabei, et al. 2022), will be used accordingly.

3.2 *Proof of concept*

By integrating the sensors and instrumentation into the site planning, the installations for operating the sensors are already in place. The ample provision of space allows for future installation of additional sensors, and cables can be safely laid within a secure environment (see Figure 3a). The analysis of the current sensors is used to define appropriate measurement

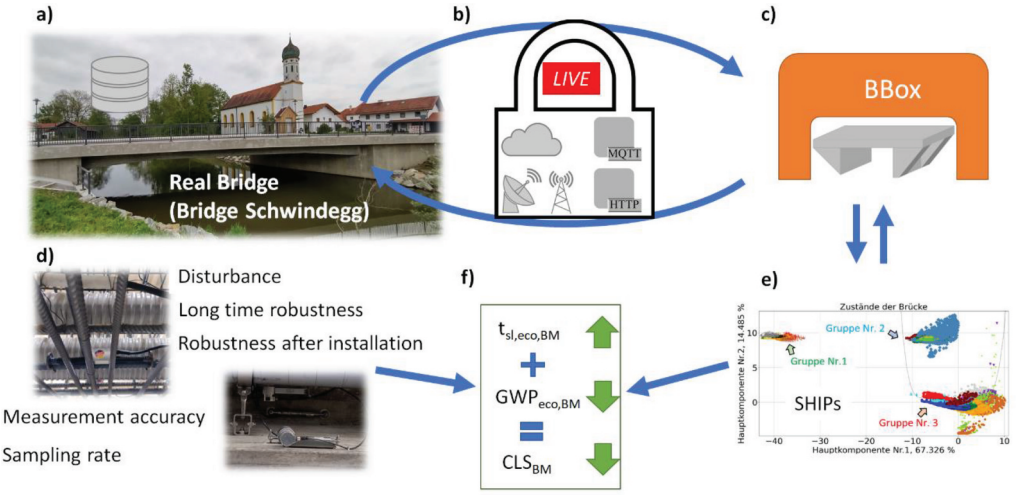

Figure 3. Chances and opportunities for data analysis using the digital Bridge (a) due to standardisation of data transfer with live connection (b) to the asset administration shell BBox (c), use of appropriate sensory systems (d) and intelligent analysis methods (here: SHIPs, (Varabei, et al. 2022)), extension of service life $t_{sl,eco,BM}$, reduction of GWP, lower utilisation of the climate limit state (CLS) (Wimmer & Braml 2023a)(f).

chains for installation and data provision. The categories of "robustness after installation," "measurement accuracy," "sampling rate," "disturbance," and "long time robustness" are distinguished (refer to Figure 3d). As of now, positive findings regarding robustness after installation are the only ones that can be reported, due to the short running time of less than a year. However, all commercially available sensors have exhibited suitability for their intended application. After extended use, the long-term stability of the measurement data (i.e. deviations) can also be determined by the use of various sensors and measurement systems.

Trials for data transmission between sensors and measuring devices through cable and wireless will be carried out. Spacious pathways have been designed to enable the testing of future systems with any technical advancements. The data flow shown in Figure 3b, linking real bridge and digital twin (BBox), is also under investigation, with a focus on data transmission media, data size, and transmission speed, for possibly suitable transmission protocols. Further details can be found in (Braml, et al. 2023).

The data collected is fed into the AAS BBox without any filtering to ensure there is no loss of information. Only a **preliminary plausibility check is conducted, which includes a functional** examination of the sensors or the correct indication of measured values. In the digital experimental environment, diverse analytical, statistical, and artificially intelligent processing techniques are employed to analyse the data. An instance of this is the SHIPs illustrated in Figure 3e, highlighted in (Varabei, et al. 2022). The generated patterns are based on principal component analysis and interpret the combined measurement data comprehensively. Any irrelevant sensors are identified and removed for further assessment.

Numerous sensors were installed in areas of static significance. A finite element model was formed for the structure, utilising load assumptions from structural calculations. Subsequent investigations involve examining various characteristic values, such as strains, temperatures, and pressures, through target/actual comparison.

For the first time, the measurement data is automatically entered in real-time rather than being manually entered into BBox after a measurement campaign (as explained in (Braml, et al. 2022)). This required the creation of various interfaces for the different measurement chains. We also analysed the handling of the measurement data in case of connection failure or power outage. In case of the former, the data is stored locally for a temporary period (Figure 3a). In the event of the latter, it is advisable to have an emergency power supply. Minor power outages can be easily resolved with the aid of the built-in battery packs. Another crucial aspect to consider is the sensor localisation in its digital image. The physical localisation is accomplished by georeferencing the sensors in the Gauss-Krüger coordinate system (Wimmer & Braml 2023b), while the digital localisation is carried out through separate submodels for the metering points in the AAS. The use of BIM to visualise the metering points is being investigated.

Finally, this analysis considers the potential for a digital twin to improve the carbon footprint of the bridge, starting from the moment it is opened to traffic. To assess this potential, we compare it against the Climate Limit State (CLS) concept presented in (Haist, et al. 2022), which verifies the structural climate compatibility of a given structure. On the one hand, the choice of materials for new construction affects this compatibility. Figure 3f displays the Global Warming Potential ($GWP_{eco,BM}$), which the Isenbridge prototype does not immediately provide results for. If new, more material-efficient construction methods are under investigation, a digital twin can effectively record the potential savings or construction method potential. Another variable, which is more apparent, is the extension of the service life ($t_{sl,eco,BM}$, Figure 3f). Predictive maintenance enables the building to have a longer service life, reducing the CLS and thus the carbon footprint (Wimmer & Braml 2023a).

4 CONCLUSION AND OUTLOOK

This paper examines prevalent definitions of digital twins within industry and categorises them based on maturity, application, and modelling levels. The definitions are found to be complementary. Examples of digital twin applications are presented in industry, healthcare, and infrastructure as smart cities. The assessment of digital twin approaches in bridge construction indicates that

most of the maturity lies in the digital shadow, but it is hard to scale due to proprietary closed solutions. Therefore, standardisation is crucial. The challenges of the digital twin are exemplified by Isenbridge Schwindegg in Germany, which utilises the Industry 4.0 platform Asset Administration Shell (AAS). On one hand, selecting appropriate sensors and establishing connections for collecting and transferring measurement data to the AAS, and on the other hand, intelligently processing data prior to and following data collection needs to be investigated. These elements, which may help to achieve predictive maintenance, are described in a proof of concept. Their potential for significantly reducing a building's carbon footprint is highlighted.

The collection of measurement data has been ongoing since December 2022 and is presently secured for an indefinite period. Currently, algorithms are being developed to detect and compress the relevant measurement data simultaneously. This process is carried out with the use of existent sensors. However, the potential of alternative sensors, such as distributed fiber optic sensors, is also under investigation. Research is currently being conducted into the characteristics of the current bridge condition and their evaluation. The potential added value that this information could provide for building operators, engineers, or even smart cities remains largely theoretical. Nevertheless, the Isenbridge in Schwindegg is a valuable source of data from the moment it is opened to traffic.

ABSTRACT: Normative specifications and guidelines for the supplementary use of sensor-based monitoring in the assessment of road bridges are currently insufficient. This leads to heterogeneous approaches in measurement-based recalculations. In the research project ANYTWIN, standardized measurement and analysis concepts are being developed for selected structural safety verifications. Engineers will benefit from recommendations for actions that can be applied to structures with similar issues. To ensure sustainable and interoperable usage, concepts for integrating structural safety verifications into Digital Twins are created. This will enable information to be interoperably utilized across generations. The automated and standardized integration and analysis of measurement data prospectively establish a crucial core functionality of Digital Twins in infrastructure. The concepts are validated with extensive data from the model bridge of the research project IDA-KI and the Digital Twin of the Köhlbrand Bridge. The ANYTWIN research project commenced in September 2023 and is funded for three years by the Federal Ministry of Digital and Transport (BMDV). Approaches and initial results are presented in this paper.

1 INTRODUCTION

The transportation infrastructure is both a cornerstone and a vulnerability of Germany's economy. Due to the high age of structures and the significant increase in heavy traffic, in 2020 approximately 12% of bridge surfaces were in an insufficient condition (Bast 2023). Reinforced concrete, prestressed concrete and steel bridges account for approximately 83% of the total bridge stock in the federal highway network. Over 80% of the damages observed on these bridges can be attributed to cracks, deformations, and welding seam issues. (Schnellenbach-Held et al. 2015) (Bartels et al. 2022). These damages may result from deficient maintenance

DOI: 10.1201/9781003483755-94

management or planning deficiencies in construction and structural analysis. Examples include the use of prestressing steels susceptible to stress corrosion cracking and the inadequate design of coupling joints in the sectional construction of prestressed concrete bridges.

Safety-relevant failure mechanisms that remain partly hidden and result in a sudden component failure pose a challenge. Therefore, a structural analysis is indispensable. However, the prevailing lack of information on existing bridges leads to conservative calculation assumptions. For the preservation of structures, especially those with high strategic importance in the infrastructure network, more innovative research approaches are required. Sensor-based monitoring can be utilized to conduct more realistic analyses and detect changes early on within the framework of continuous monitoring. The goal of the ANYTWIN project is to conceptualize a Digital Twin that enables a measurement-based structural safety assessment for road bridges. The project focuses on vulnerable areas of structures and typical deficiencies in structural analyses.

2 STANDARDIZATION OF MEASUREMENT-BASED VERIFICATIONS

Structures are based on the design calculations performed by structural engineers. These calculations are also conducted to assess the probability of specific failure mechanisms. The verifications are considered valid, and the structures are deemed structurally sound only as long as the initial computational assumptions remain applicable. Inadequacies in the original design approaches, changes in the structural condition, and variations in external influences, such as the increase in heavy traffic, often necessitate the reassessment of existing bridges. For German road bridges, there is a guideline for this purpose known as the recalculation guideline (BMVBS 2011). The procedure is structured in stages, with each stage increasing the computational effort and, consequently, the accuracy of the calculations (Figure 1).

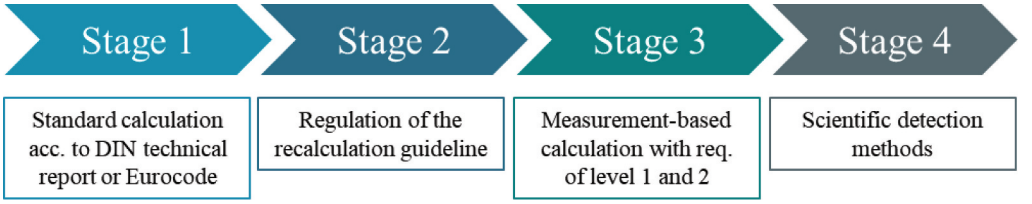

Figure 1. Stages of the recalculation guideline.

In Stage 3, additionally, sensor-based measurements of external influences or structural behavior can be integrated into a so-called monitoring- or measurement-based calculation. The verification result can extend the assessed lifespan of bridges without necessitating restrictions through traffic compensatory measures or costly reinforcement interventions (DBV 2018). While there are numerous practical examples for Stage 3, the recalculation guideline does not provide sufficient information on procedures. ANYTWIN aims to standardize these procedures.

2.1 *Examined failure mechanisms*

In (Fischer et al. 2016) and (Neumann & Brauer 2018), verification results of concrete, steel, and composite bridges were analyzed, evaluating the cause and effect of significant deficiencies. These analyses in ANYTWIN are used to determine the failure mechanisms to be investigated.

To verify and update these analyses and capture the impact of the optimized verification formats introduced since the implementation of the recalculation guideline, ANYTWIN will

conduct a survey of infrastructure operators in December 2023. This survey will gather the experiences and challenges of operators with existing regulations and frequently encountered verification deficiencies. Furthermore, infrastructure operators will be surveyed regarding their current handling of Stage 3 and potential support in the application of measurement technology in the context of bridge reassessment.

Initial results of the analyses indicate that the most common deficiencies in verifications arise from the following five failure mechanisms:

- Failure of Couplings in Coupling Joints (Fischer et al. 2016)
- Stress Corrosion Cracking (Fischer et al. 2016)
- Shear Cracking (Fischer et al. 2016)
- Plate Buckling (Neumann & Brauer 2018)
- Fatigue (Neumann & Brauer 2018)

These five failure mechanisms will be further examined in the ANYTWIN project.

2.2 *Investigation of optimization opportunities through sensor-based monitoring*

The failure mechanisms can be described by limit state equations. The parameters included in the equations are examined regarding their impact on the results (sensitivity analysis) and their measurability through sensor-based methods. In the development of standardized measurement concepts, reference is made to the sensitive parameters that have a significant impact on the failure mechanism.

As an example, the limit state equation for fatigue verification at coupling joints is formulated as follows, see Equation (2.1).

$$g(x) = D_{limit} - D \tag{2.1}$$

This is based on the Palmgren-Miner rule, which requires the stress amplitudes $\Delta\sigma$ of all crossings to determine the damage sum D and is described by Equation (2.2).

$$D = \sum_i D_i = \sum_i \frac{n_i}{N_i} = \sum_i \frac{n_i}{\frac{\Delta\sigma_{Rsk}^m \cdot N^*}{\Delta\sigma_i^m}} = \frac{1}{\Delta\sigma_{Rsk}^m \cdot N^*} \cdot \sum_i n_i \cdot \Delta\sigma_i^m \tag{2.2}$$

If strains are directly measured on the prestressing steel, they can be converted into stresses and directly integrated into Equation (2.2). However, this approach requires exposing the tendons, which is not always desired due to the additional damage it causes (Steffens 2019). As an alternative, it is possible to determine the damage sum according to (Zilch et al. 2001) using Equation (2.3), where the prestressing steel stress is calculated, for example, using a finite element model. It should be noted that the basic moment (M_0) in a prestressed concrete cross-section influences the stress range due to the non-linear structural behavior of prestressed concrete according to Figure 2.

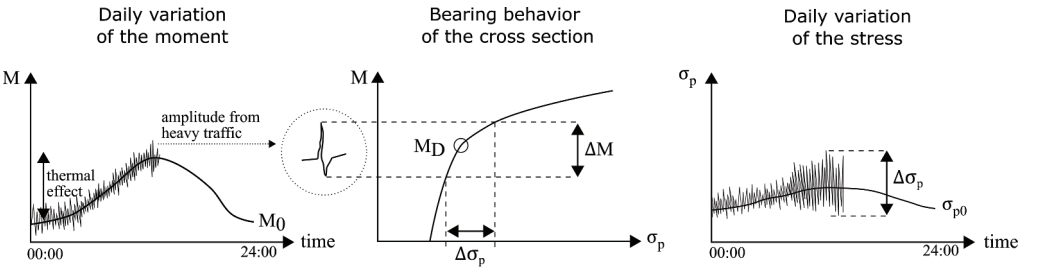

Figure 2. Stress amplitude ranges depending on the daily variations in temperature and vehicle loading.

As a result, the moment-stress relationship must be correctly recorded in the finite element model. Additionally, the actual basic moment is required to determine the stress range according to Equation (2.4).

The basic moment includes effects from dead loads, prestressing, settlements, and temperature. Whereby these can be assumed to act as constants, except for the cyclic temperature loading.

The influence of the basic moment on the stress range requires different temperature conditions to be considered when calculating partial damage from traffic-related alternating stresses (Krohn 2014).

$$g(x) = D_{limit} - N_{tot} \cdot \sum_{\Delta T=\min\Delta T}^{\Delta T=\max\Delta T} \left(\sum_{i=1}^{j} \left(\sum_{h=1}^{24} \lambda_{V,h} \cdot \lambda_{T,\Delta T,h} \cdot p_i \cdot D_{\Delta T,i} \right) \right) \tag{2.3}$$

$$\Delta\sigma(M_i) = \sigma\left(M_{perm} + M_{\Delta T} + M_{Q,max,i}\right) - \sigma\left(M_{perm} + M_{\Delta T} + M_{Q,min,i}\right) \tag{2.4}$$

where D_{limit} = limit of the total damage sum; N_{tot} = number of heavy vehicles in the period of use; $\lambda_{V,h}$ = share of heavy traffic during hour h in the total daily traffic volume; $\lambda_{T,\Delta T,h}$ = probability of the temperature gradient ΔT occurring during hour h of the day; p_i = share of vehicle type i; $D_{\Delta T,i}$ = partial damage of vehicle type i with simultaneous temperature gradient ΔT analogous to (2.2) by determining the stress ranges $\Delta\sigma_i$ according to (2.4).

Sensor-based measurements are primarily related to variable loads or stresses, as these represent measurable quantities affected by changing conditions. Nevertheless, the measurement of constant residual stresses typically entails significant effort. In the fatigue failure mechanism of the couplings, variable influences such as heavy traffic and temperature changes affect the magnitude of the stress range. Through long-term monitoring, the actual temperature gradients and traffic loads influences can be recorded. Traffic influences can be subsequently converted to the service life period, with or without considering traffic developments, as outlined in (Steffens & Geißler 2021). Furthermore, through short- or long-term measurements, it is possible to measure the behavior of the real structure, evaluate the basic moment and adjust the moment-stress relationship used for recalculation, as shown in (Zilch & Penka 2014) and (Weiher et al. 2015).

2.3 *Development of standardized measurement and analysis concepts*

For the measurement-based verification of failure mechanisms, standardized measurement concepts are developed. These include information on the type, scope, and location of sensors, as well as the respective measurement periods, sampling rates, and requirements for data processing. The challenge of standardization is to separate the measurement requirements from the uniqueness of each structure. To ensure the cross-structure usability of the measurement concepts, parameterized finite element models are developed, and influences on the choice of concept parameters are examined.

Like the approach of the recalculation guideline (Figure 1), ANYTWIN follows a stagewise progression in the measurement concepts, in which the complexity of the measurement task gradually increases. For example, in the case of coupling fatigue, in the first stage, over a limited period in summer (high temperature gradients) and under real traffic conditions, only the crack width of the coupling joint and the concrete strain in the uninterrupted area immediately adjacent to the coupling joint are measured and compared. Significant differences would indicate "joint breathing" and thus a potential fatigue problem. In subsequent stages, the scope and duration of the measurements can be expanded to pursue more complex approaches for calibrating the basic moment and the occurring temperature gradients and traffic loads. Figure 3 shows an exemplary excerpt from a measurement report with the positions of temperature sensors and displacement transducers, as well as exemplary data trends.

Evaluation concepts are intended to establish processes and conditions for substituting the verification-relevant physical parameters with a value based on raw measurement data. In the

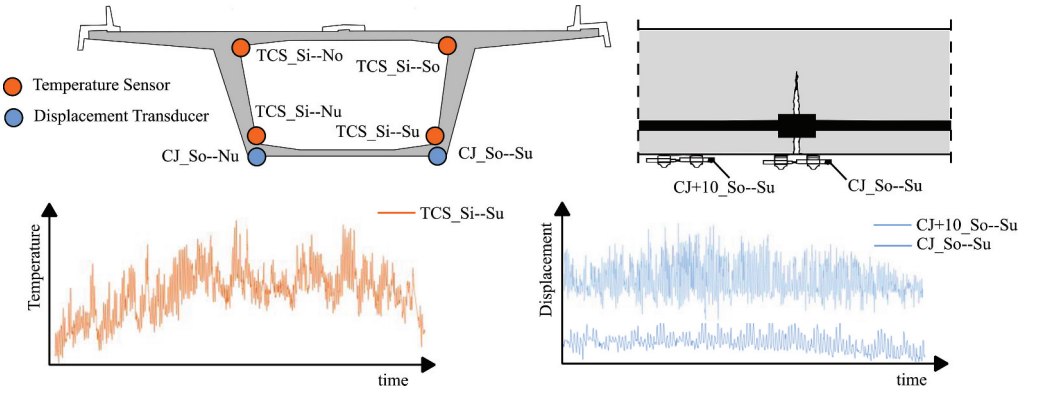

Figure 3. Exemplary measurement layout and corresponding data trends.

present example in Figure 3, this would involve converting the data from individual temperature sensors into a resulting vertical temperature gradient. Both the measurement and evaluation concepts need to be developed by the normative safety requirements of Eurocode 0.

3 CONCEPT OF A DIGITAL TWIN

Germany's sustainability strategy (BMVI 2020) is aligned with the 17 Sustainable Development Goals of the UN Agenda 2030. Goal 9 includes the establishment of a "resilient transportation infrastructure." The strategy prioritizes "maintenance over expansion and new construction" and the optimization of traffic flow. The German "BIM Master Plan" for Federal Highways (BMVI 2021) envisions the future scenario of maintenance and operation based on Digital Twins. After Building Information Modelling (BIM) has been established in the planning and manufacturing phases, the development and testing of Digital Twins are intended to create a "Master Plan" for Digital Twins. This perspective also includes integrating verifications of failure mechanisms, conducted either as a one-time assessment or continuously through sensor-based monitoring, into a Digital Bridge Twin. In ANYTWIN, a concept is being developed as a basis for this. The focus lies on the operational phase, where Digital Twins enable real-time monitoring.

3.1 *Definition and characterization of the Digital Twin*

The term "Digital Twin" originated in 2002 and 2003 when Grieves and Vickers described it as a "conceptual ideal for the product lifecycle management" using the example of a motor vehicle (Grieves & Vickers 2017). Today, the user-specific definition of a Digital Twin varies across different industries:

In the wind energy industry, the Digital Twin is primarily understood as a three-dimensional finite element model calibrated with real-time information for structural assessment (Solman, et al., 2022). In mechanical engineering, the Twin is defined as a virtual assistance system in connection with Mixed Reality in plant operations, enabling remote monitoring and maintenance of critical machine components (Schweiger-Recksiek et al. 2020).

In the construction industry, despite the ongoing digitization and the introduction of BIM, there are no uniform standards for the terms and definitions of Digital Twins. Additionally, there are no standardized definitions for linking with BIM and utilizing it in maintenance management. In bridge construction, the combination of real-time data with a BIM model is increasingly used to create Digital Twins (Lazoglu et al. 2023) (Ye et al. 2019).

The common element of collecting and evaluating information about the actual structure is shared in all definitions. Publications related to construction, like the one by (Boje et al. 2020), offer a general overview of progress in this field.

For most applications in construction, it is not necessary to digitize the physical object with all its information. For example, the use of sensors in construction is currently mainly event-driven, focusing on critical areas and specific damage or failure mechanisms of an object and its surroundings. Abstraction can be achieved through the definition of maturity levels (ARUP 2019). The choice of the maturity level to be developed depends on the engineers' and operators' individual requirements, considering the complexity of the object and its specific safety and relevance to society and the environment. Thus, infrastructure with high operational importance for the transportation network is particularly suitable for developing Digital Twins with higher maturity levels.

The first use cases of the Digital Twin were elaborated in (Nieborowski et al. 2023), serving as a basis for identifying use cases in ANYTWIN.

3.2 *Data integration, management, and provision in the Digital Twin*

The definition of use cases for Digital Twins requires consideration of relevant structural and environmental data. In the context of verifying failure mechanisms, these include e. g. computational results from finite element analysis, primarily evaluated measurement data and sensor states. The quality of this data significantly influences valid structural safety information. It is also necessary to integrate existing conditions and state information (such as damages and material properties) as they have a direct impact on the failure mechanism.

The challenge in data integration lies in the diversity of the heterogeneous data sources, some of which are not digital, machine-readable, or decentralized. In the ANYTWIN project, the current state is being explored, and based on use cases, proposals for data formats, quality requirements, and metadata, especially for monitoring data, are being developed.

In ANYTWIN, the Digital Twin is considered a Single Source of Truth, functioning as a database system where all relevant data, including BIM model information, is digitally stored. To address the size limitation of IFC-files, alternative approaches for integrating extensive monitoring data into Digital Twins are being investigated. Linked and Embedded Data methods are often favored in practice, where BIM structural and domain models are updated in a Common Data Environment (CDE). Additional databases may exist to link dynamic data (Wedel et al. 2022).

Efficient storage, management, and processing require the development of a data structure model, especially at higher levels of automation. In ANYTWIN, a generalized data structure model is being designed based on use cases, serving as the foundation for the development of a flexible database system. The focus is on cross-structure applicability and scalability for potential future use cases.

Approaches are being developed in ANYTWIN for the intuitive provision of relevant condition information in the Digital Twin. These approaches aim to deliver data based on user needs, providing maximum flexibility and efficiency. This supports engineers in making informed decisions about repair measures. It also enables rapid responses to change in structural conditions, with visualizations tailored to various user groups such as infrastructure operators, structural engineers, and the public.

4 VALIDATION OF THE CONCEPTS

4.1 *SmartBRIDGE Hamburg – monitoring system of the Köhlbrand bridge*

In the "smartBRIDGE Hamburg" project, a Digital Twin of the Köhlbrand bridge has been developed with continuous update through data from an extensive monitoring system with approximately 800 sensors (Grabe et al. 2020) (Wenner et al. 2021). The structure comprises a cable-stayed bridge with a steel superstructure and adjacent bridges with prestressed

concrete superstructures. Verifications for failure mechanisms such as shear failure, coupling fatigue, steel fatigue, and buckling have been successfully conducted in higher verification stages (including Stages 3 and 4). For the piloting of the Digital Bridge Twin these failure mechanisms have been monitored through measurements for nearly 2.5 years.

For example, strain gauges distributed on the steel box girder capture the stresses within the steel plates. These stresses contribute to an automated, probabilistically guided buckling verification, analogous to (Herbrand et al. 2021). The evaluation is automated by determining a failure probability expressed as a reliability index with a reference period of 50 years ($\beta_{50\,Y}$). This index, along with other condition indicators, is imported into the database of the Digital Twin and made available through the "Condition Control" platform (Herbrand et al. 2022).

The extensive dataset in the Digital Twin of the Köhlbrand bridge allows for the validation of concepts developed in ANYTWIN. Due to the collaboration of some authors in the conception and testing of fundamental concepts in smartBRIDGE Hamburg, synergies can be leveraged across projects.

4.2 *OpenLAB – research bridge in Bautzen, Germany*

As part of the research project IDA-KI, a research bridge, the "openLAB," was constructed as an open research structure (see Figure 4). It is approximately 45 meters long, 4.5 meters wide, and consists of three spans, made of prestressed concrete with tendons in immediate composite action. Additionally, post-tensioning strands were incorporated to enable the replication of a coupling joint issue. Specific structural vulnerabilities, such as damaged tendons, gravel nests, voids, and areas with reduced shear capacity, were deliberately included. To capture changes in condition, measurement technology was installed during the production of the components. A significant portion of the monitoring is conducted using distributed fiber optic sensors (DFOS).

Along the coupling joint, the arrangement of DFOS was carried out in a way that allows the capture of joint opening profiles and strain profiles across the entire cross-section. The extensive measurement equipment of the openLAB, the existing IT infrastructure, and the implementation of a Digital Twin enable the validation of concepts in ANYTWIN. For this purpose, the existing measurement and loading concept from IDA-KI is expanded to meet the requirements of ANYTWIN. Finally, there is the possibility of integrating the measurement data into the existing BIM-based Digital Twin of the openLAB. Further information on the research project IDA-KI and the openLAB can be found in (Herbers et al., in press).

Figure 4. Virtual representation of the research bridge IDA-KI (Hentschke Bau GmbH).

5 SUMMARY AND OUTLOOK

In the research project ANYTWIN, which commenced in September 2023, holistic measurement and evaluation concepts are being developed for the structural assessment of bridge structures and their integration into Digital Twins. Following initial research, the focus for standardizing measurement-based verification is placed on failure mechanisms such as buckling and fatigue in steel bridges, as well as stress corrosion cracking, coupling- and shear failure in prestressed concrete bridges. Standards are being developed for the entire verification process, ranging from sensor requirements (including necessary metadata) to data cleansing and integration into failure equations. The conceptual development for the verification of coupling fatigue is the starting point.

This article presents the results of an initial investigation into the definition and existing concepts and implementations of cross-industry Digital Twins. Subsequently, ANYTWIN aims to develop a data structure model for the Digital Twin, based on which the collected and analyzed data can be stored in a flexible database system and visualized appropriately for different user groups. This approach ensures the full utilization of the benefits of the Digital Twin, providing effective support for infrastructure operation. Standardization requires a comprehensive systematic compilation of ideas and concepts, as well as the implementation of numerous Digital Twins that must be carefully evaluated through pilot projects. ANYTWIN will play a crucial role in this process.

ACKNOWLEDGEMENT

This article presents the results of the research project ANYTWIN (Standardizing Monitoring Based Safety Assessments of Bridges and the Integration into Digital Twins), funded by the German Federal Ministry for Digital and Transport within the mFUND funding program (grant number: 19FS2248A-F).

Condition assessment of mechanical fasteners by use of smart bolts

M. Reiterer & R. Thukbatullin
REVOTEC gmbh, Department of Structural Dynamics, Vienna, Austria

ABSTRACT: The maintenance of the preload force in mechanical fasteners is of great importance to ensure the load bearing capacity and durability of engineering structures that are executed with bolted connections. An innovative method for condition assessment of mechanical fasteners is presented in this paper, the smart bolts. The special features of the smart bolts are that the bolt or nut itself is the measuring device, i.e. the bolt or nut is modified to a smart component, and that the smart bolts are complete wireless without any permanent power supply. Beside the development of the smart bolts the applied data-driven method is presented aiming to compute the Remaining Useful Lifetime (RUL) for preloaded mechanical fasteners based on the permanent recorded smart bolt data. An already executed application of the developed smart bolts to ripped base plates for rail fastening is also presented and indicates the high potential of smart bolts for permanent condition assessment and RUL estimation of mechanical fasteners.

1 INTRODUCTION

Mechanical fasteners are widely used when connecting two components, e.g., connecting steel girders with cover plate joints, or when connecting between a component and another construction material (concrete, masonry, etc.). In steel structures, the execution of preloaded screwed fasteners is well established, and the controlled introduction of the preload force is of great importance to ensure the load-bearing capacity, durability, and fatigue safety (VDI 2230, 2015). Thereby, it is of central importance to achieve a defined size of preload force after initial tightening and to maintain this force over the service life of the structure, especially in dynamically stressed steel structures. The controlled pretension of the mechanical fastener leads to a force and frictional connection between the connected components. This results in significantly lower fatigue stress ranges under dynamic loading compared to a non-preloaded connection (Reiterer 2019, Reiterer et al 2020, Schiborr 2016, Schiborr & Stranghöner 2017, Dümpelmann 2020). The positive effect of preloading under dynamic load actions in terms of reducing the force and stress variation range is described in detail in Schiborr (2016) for connections in steel structures and in DAfStb-Heft 541 (2003) for fastening elements in concrete structures.

Various visual and sensor-based methods are currently used to test and monitor the actual size of the preload force in mechanical fasteners, e.g., direct tensioning indicators (Schiborr & Stranghöner 2017), ring force sensors (Tränkler & Reindl 1998) and ultrasonic measuring devices (Schiborr 2016, Reiterer 2021). However, the visual methods allow just a rough estimation of the actual preload condition, and the sensor-based methods, e.g. ring force sensors, show several disadvantages like their high costs, wired design as well as their influence on the clamp length and support surface friction of the mechanical fastener. Hence, the installation of ring force sensors is not recommended because it results a completely different fastening systems, that differs from the origin system with regard to the setup and present preload force.

This contribution introduces an innovative complete passive and wireless smart bolt (*e-Bolt*®) for condition assessment and RUL prognosis of mechanical fasteners. The basic idea of the developed smart bolt is that an already present component of the screw set (screw or nut) itself is modified and expanded into a measuring component. This results in an intelligent, talking component that can temporarily or permanently communicate its current

DOI: 10.1201/9781003483755-95

preload force condition to a hand-held reader unit or a receiver device with internet connection. The steps carried out to develop and calibrate the smart bolts are presented. In addition, the applied data-driven method for condition assessment and RUL estimation is introduced and an application example of the smart bolts is presented.

2 DEVELOPMENT OF SMART BOLTS

2.1 *Mechanical operating principle of bolted connections*

The applied preload of a screw set presses several components together. The individual parts are thus connected to form a component by the force and friction connection. When the screw set is tightened by application of the tightening moment M_A, an installation preload force F_{SM} is generated (Figure 1). The installation preload force is equal to the preload force, i.e. $F_{SM} = F_V$. In the balance of forces in the assembly state, this is identical to the clamping force F_K in the components in the joints of the components (Figure 1).

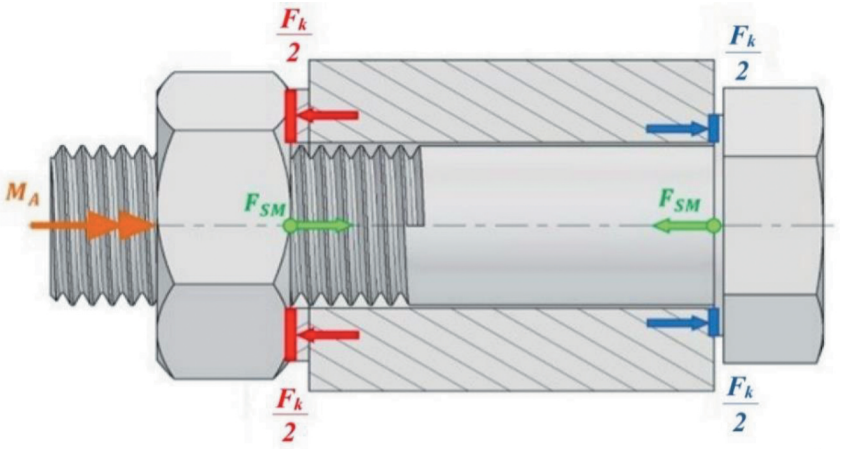

Figure 1. Principle of force equilibrium in a bolted connection.

The relation between the applied tightening moment M_A and the preload force F_V is given in Wittel et al (2019) and defined as follow,

$$M_A = F_V \cdot \left(\frac{d_2}{2} \cdot \tan(\varphi + \varsigma') + \mu_k \cdot \frac{d_k}{2} \right) \tag{1}$$

where d_2 = Pitch diameter of the screw thread; φ = pitch angle of the thread; ς' = thread friction angle; μ_k = friction coefficient in the headrest of the nut; and d_k = effective friction diameter in the nut pad. It is seen from equation (1) that the friction coefficient μ_k and the thread friction angle ς' highly influence the size of preload force that is generated by applying the tightening moment. In practice, the exact value of friction is not known and hence, applying the same size of tightening moment results in different sizes of the preload force in mechanical fasteners. This fact is important with respect to preload condition monitoring systems, that starts from different initial values although the identical tightening moment was applied.

Bolted engineering structures are very often dynamically loaded, e.g. through wind loads, rotating machines, traffic, or earthquakes, and hence the preload force in mechanical fasteners varies dynamically, i.e. a force variation range ΔF_V occurs and induces fatigue damages. The force variation range ΔF_V is therefore the effective fatigue stress for which proof of the durability or fatigue strength of the bolted connection must be carried out during the design phase. In the case of a preloaded bolted connection the dynamic load induced force variation range ΔF_V is significantly lower than in non-preloaded connections.

The prestressed bolted connection can only offer its advantage of low ΔF_V when the joint between the components is closed or over pressed. If the acting operating force is excessively high or the preload force is too low, the parting line can gap, causing the additional preload force to increase disproportionately. After exceeding the withdrawal limit the operating force-bolt force curves for the preloaded and non-preloaded connections are identical.

Based on the presented operating principle of bolted connections it is summarized, that a defined size of the preload force in mechanical fasteners is of great importance to keep fatigue damages as small as possible and to ensure the load bearing capacity over the total service life of bolted engineering structures. However, it is evident that the initial applied preload force decreases over the lifetime of structures, in dependence of the loading and boundary conditions. Because of this fact it is important to check the actual present size of the preload force periodically and a permanent method for condition assessment of mechanical fasteners, would enable both monitoring of the actual preload force and computing the Remaining Useful Lifetime (RUL) of bolted connections by application of data-driven methods.

2.2 *Development of smart bolts*

The basic idea of the developed smart bolts was to modify a standard worldwide used building product, in particular the screw and nut of the typical screw set, to an intelligent talking component. The aim was to avoid any cable connections to the smart component, i.e. wireless, and to apply a physical principle that enables a contactless energy transmission through air, i.e. no permanent power supply and battery are necessary to install to the smart bolt. After transmission of energy the actual measurement should be automatically carried out on the bolt and the data should be transmitted again through air. It is noted that two different smart components were developed, the smart bolt-bolt (*e-Bolt*®-*b*) illustrated in Figure 2a and the smart bolt-nut (*e-Bolt*®-*n*) illustrated in Figure 2b. A reader unit (Figure 2c) is used to transfer the energy through air and to receive the measured preload force from the smart bolt. Usually, depending on the boundary conditions of the structure to be equipped with smart bolts, either the *e-Bolt*®-*b* or the *e-Bolt*®-*n* is used as intelligent component.

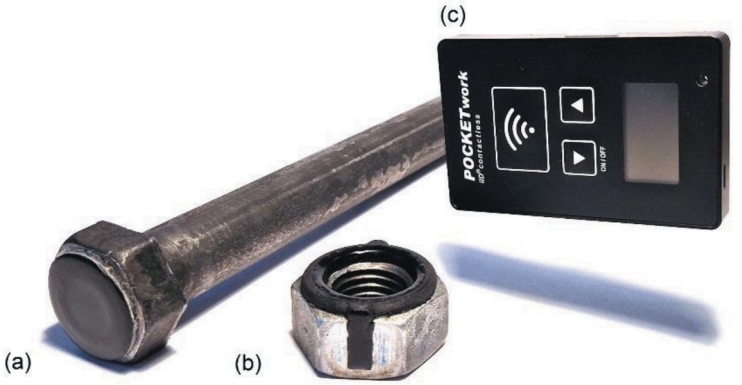

Figure 2. Photo of developed smart bolts: (a) smart bolt-bolt (*e-Bolt*®-*b*), (b) smart bolt-nut (*e-Bolt*®-*n*), (c) reader unit.

The physical principle that is applied for contactless energy and data transmission from a reader unit to the smart bolt and vice versa is in principle the Radio Frequency Identification (RFID) technology, but this principle was extended to be able to not only identify the components of mechanical fasteners, but also to carry out accurate measurements of the actual preload force. As a contactless identification and data transmission technology, RFID tags has been widely applied for access control and information tracking in logistics and industrial processes (Weinstein 2005). However, the application of the RFID technology for detecting the physical parameters of tagged structures, i.e. smart sensing, is currently very rare, and not common.

In our application the standard RFID tag is integrated with electronic components, i.e. sensors, Analogue-Digital Converter (ADC), and a Micro-Controller Unit (MCU) to get an integrated passive RFID-Sensor-Transponder module on the smart bolt. Thereby the RFID-Sensor-Transponder is used as a communication interface for data transmission. The modified RFID tag harvest the Radio-Frequency (RF) energy from RF radiation to power the circuit and carry out the measurement of the actual preload force, then save the measured data in the RFID chip to be accessed by the reading unit. The standard RFID reading unit as illustrated in Figure 2c is a handheld device and it needs a person to carry out discrete measurements, e.g. one measurement per day or per month. To avoid any personnel expenses and to record the preload data of the smart bolts continuously over time, e.g. one value per hour, a special low energy radio transducer that contains the electronic components of the reading unit and is powered by a battery has been developed.

2.3 *Calibration of smart bolts*

The developed smart bolts (*e-Bolt®-b* or the *e-Bolt®-n*) determine the actual preload force of the mechanical fastener through strain measurements, i.e. special configurated strain gauges are installed at defined locations on the smart bolts, and they measure the strain development during preloading of the bolt. In the case of the *e-Bolt®-b* so called submersible strain gauges are implanted in a 2.0 mm centric borehole of the bolt and connected to the RFID-electronic. In the case of the *e-Bolt®-n* strain gauges are installed to the side surfaces of the screw nut and connected to the RFID-electronic. For the *e-Bolt®-b* the preload force can in principle be calculated from measured strains by application of Hooke´s law. However, the material specific Young's modulus shows a scattering and the strain gauge in the borehole needs to be calibrated. For the *e-Bolt®-n* the measured strains on the side surface cannot assigned to a defined compressed area of the nut and hence, it is not possible to compute the preload force by applying Hooke´s law. Hence, the *e-Bolt®-n* needs in every case a calibration to deliver accurate preload force values.

Based on the mentioned facts, a special tightening test stand for calibration of smart bolts has been developed and is illustrated in Figure 3. The aim of the test stand is to determine the actual relation between the preload force F_V and the electrical voltage measured by the smart bolts during preloading. The test stand consists of an electric motor with planetary gear able to apply a torque moment up to 2000 Nm which is measured by a high-accurate calibrated torque sensor. An overload clutch prevents damages of the tested bolts in the case of uncontrolled torque moments generated from the electric motor. The smart bolts to be calibrated are installed to the torque support steel construction which is supported by a linear guiding. A high-accurate calibrated axial force transducer measures the preload force development during the preload process.

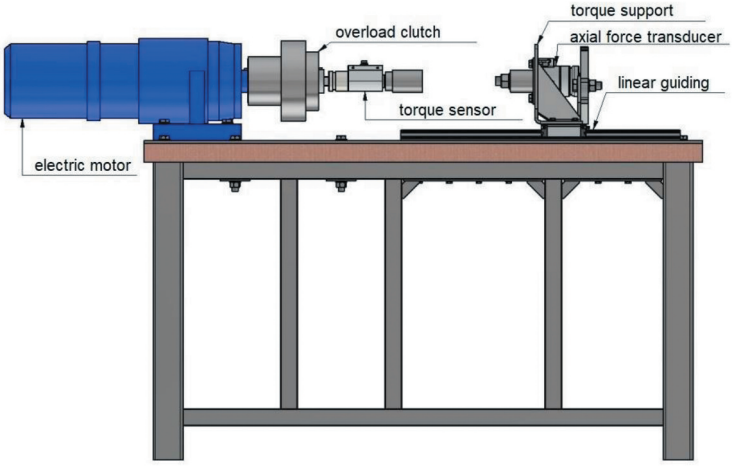

Figure 3. Principle sketch of the tightening test stand for calibration of smart bolts.

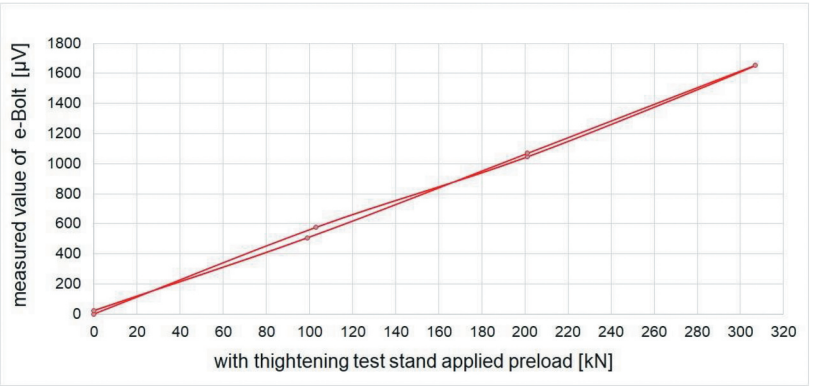

Figure 4. Calibration of *e-Bolt*®-*n* by use of the tightening test stand.

Figure 4 illustrates the result of a smart bolt calibration by use of the tightening test stand, carried out for the *e-Bolt*®-*n*. An almost linear relation between the voltage signal of the smart bolt and the preload force is indicated. It is noted that the two lines in Figure 4 depict tighten and untighten of the tested *e-Bolt*®-*n*. The determined calibration curve of the tested *e-Bolt*®-*n* is transmitted and saved to the Micro-Controller Unit (MCU) of the smart bolt and hence, the measured values are directly recorded as preload forces in Newton. In addition to the force calibration a temperature compensation of the measured preload is also taken into account and a correction curve is saved on the MCU. Therefore, temperature tests of smart bolts are carried out in climate chambers.

3 REMAINING USEFUL LIFETIME (RUL) ESTIMATION BASED ON SMART BOLT SENSOR DATA

Permanent recording of the actual preload condition of mechanical fasteners via application of smart bolts (*e-Bolt*®-*b* or *e-Bolt*®-*n*) in combination with low energy radio transducers for automatic data transmission allow to predict the Remaining Useful Life (RUL) of the degrading fatigue sensible parts of the bolted connection. Predicting RUL from permanent recorded sensor data is a central goal of predictive-maintenance algorithms (Kamariotis et al 2024). These RUL predictions form the basis for optimizing maintenance planning in a predictive maintenance paradigm. The task of optimal maintenance planning informed by the prognostic model output is known as health management.

Typically, the RUL of a structure or a component is estimated by developing a model that can perform the estimation based on the time evolution or statistical properties of condition indicator values, e.g. degradation model. Predictions from such models are statistical estimates with associated uncertainty. They provide a probability distribution of the RUL for the structure or component of interest.

Degradation models extrapolate past behavior to predict the future condition of the structure or component. This type of RUL calculation fits a linear or exponential model to the degradation profile of a condition indicator. It then uses the degradation profile of the test component to statistically compute the remaining time until the indicator reaches some defined threshold. These models are most useful when there is a known value of the condition indicator that indicates a critical state or failure.

In the case of dynamically loaded smart bolts the preload force is defined as a single condition indicator and critical losses of the preload are defined, in which case the fatigue damage would increase exponentially, i.e. a cumulative degradation occurs after a defined number of load cycles. Hence, for computing the RUL of smart bolts an exponential degradation model is chosen that describes the degradation behavior of the bolt as an exponential stochastic process with an offset term. If the amplitude of the degradation signal was observed (measured)

at discrete points in time, the amplitude at a given sampling epoch $A(t_i)$ is defined according to Gebraeel (2006) as,

$$A(t_i) = \phi + \theta \exp^{\beta t_i + \varepsilon(t_i) - \frac{\sigma^2}{2}} = \phi + \theta \exp^{\beta t_i} \exp^{\varepsilon(t_i) - \frac{\sigma^2}{2}} \quad (2)$$

where ϕ = is a constant deterministic parameter; θ = random variable; β = random variable; $\varepsilon(t_i)$ = normally distributed random error term with mean 0 and variance σ^2. In our case the amplitude of the degradation signal corresponds to the preload force measured by the installed smart bolts. It is noted that the random variable θ is lognormal-distributed and β is Gaussian-distributed. At each time step t_i, the distribution of the random variables θ and β is updated to the posterior based on the latest recorded preload measurement data of $A(t_i)$. It could be shown that $E[exp^{\varepsilon(ti)- \sigma^2/2}] = 1$ and, consequently, $E[A(t_i) \mid \theta, \beta] = \phi + \theta\, exp^{\beta(ti)}$.

The application of equation (2) for estimating the RUL of a smart bolt monitored connection used for a ripped base plate fasting system is demonstrated in section 4.

4 APPLICATION EXAMPLE: RIPPED BASE PLATE FOR RAIL FASTENING

4.1 *Smart bolt application to ripped base plates for rail fastening*

The application example presented in this paper shows the smart bolt nut (*e-Bolt®-n)* installation to ripped base plates fastening locations on a two-span railway steel bridges with a total length of 60 m span. Ripped base plates are used to support the rail clamps and during train crossing high dynamic loads act on all components of the rail fastening system. Every 0.65 m a ripped base plate is fastened by four M24 10.9 bolts to lateral steel girders and for installation a defined tightening moment of 1000 Nm is applied to the bolts (Figure 3). In case of the considered railway bridge with a length of 60 m a total of around 750 M24 bolts are executed at both rails and by application of the tightening moment of 1000 Nm an initial preload force in the range of 200 to 300 kN arises. The big spreading of the arising preload force results from the present thread friction and support surface friction, which always show a high spreading and directly influences the arising preload force in bolted connections. Hence, it is understandable that the application of the same tightening moment always leads to different values of the preload force in bolted connections.

It has been observed that due to the dynamic load actions some of the installed bolts lose their initial present preload rapidly and this may lead to critical conditions for crossing trains and railway users, respectively. Hence, the bolted connections must undergo a periodic check of the actual preload condition and to carry out this checks the railway track must be closed which lead to unwanted interruptions. In this project the *e-Bolt®-n* are installed to just 3 ripped base plates located at the beginning, end, and center of the railway bridge, i.e. 12 *e-Bolt®-n* are installed in total.

Figure 5. Photo of smart bolt nut (*e-Bolt®-n)* installed to the ripped base plates of a railway bridge and photo of fitted transducers for automatic preload data transmission.

Every of the installed *e-Bolt*®-*n* is equipped with a fitted radio transducer (Figure 3) for automatic data transmission to a nearby receiver unit with internet connection, i.e. it is not necessary to enter the railway track for getting the actual preload force value. The installation of the 12 *e-Bolt*®-*n* at 3 ripped base plates was carried out on 7th December 2022. It is noted that during the first 205 days after installation of the *e-Bolt*®-*n* only periodic preload measurements – once a month – were carried out by the hand-held reader unit (Figure 2c), and no permanent measurements were performed within this period. The radio transducers for permanent transmission of the preload force were installed on 1st July 2023, i.e. 205 days after installation of the *e-Bolt*®-*n*, and from this date, the estimation of RUL was carried out by application of equation (2). It is noted that the actual preload force of the installed *e-Bolt*®-*n* was measured and transmitted every 6 hours, i.e. 4 preload force values per day and per smart bolt.

4.2 *Results of data-driven Remaining Useful Lifetime (RUL) prediction*

The automatic preload data recording of the installed *e-Bolt*®-*n* offers the possibility to compute the Remaining Useful Lifetime (RUL) of the ripped base plate bolts according to the process described in section 3 and by application of equation (2). It is noted that in our considered application example the estimated RUL do not define the fatigue collapse of the installed bolts but a 40% loss of the initial preload value. The 40% threshold was chosen according to expertise knowledge regarding an unwanted increase of the fatigue stress variation range $\Delta\sigma_E$ in the smart bolts of the ripped base plate.

Figure 6a illustrates the computed result of the preload loss estimation based on 164 days of permanent reading of the actual preload force of the installed *e-Bolt*®-*n* (No. 41). It is again noted that the installation of the *e-Bolt*®-*n* was carried out on 7th December 2022 and the permanent measurements of the preload force did start around half a year later on the 1st of July 2023 after installation of the fitted radio transducers. Hence, the 164 days of permanent sensor signal reading run until 11th December 2023 and based on this data the RUL until 40% loss of the preload force occurs is computed by application of equation (2). It is seen from Figure 6 that the defined threshold of 40% preload loss is reached 383 days after the 11th of December 2023, i.e. on the 27th of December 2024. The total days until the 40% occurs, counting from the date of *e-Bolt*®-*n* installation on the 7th of December 2022 thus results to 752 days. Figure 6b shows the Probability Density Function (PDF) of the RUL computed based on 164 days of permanent reading of the *e-Bolt*®-*n* preload data.

In Figure 6a the horizontal red line defines the threshold of 40% preload loss. The dark blue line depicts the actual preload loss measured by the installed *e-Bolt*®-*n* and the light blue line is the computed exponential function of the considered degradation model. The confidence interval is defined by the red dashed lines. In Figure 6b the light blue line depicts the PDF of the RUL, and the red line defines the estimated RUL. The light green line defines the confidence interval.

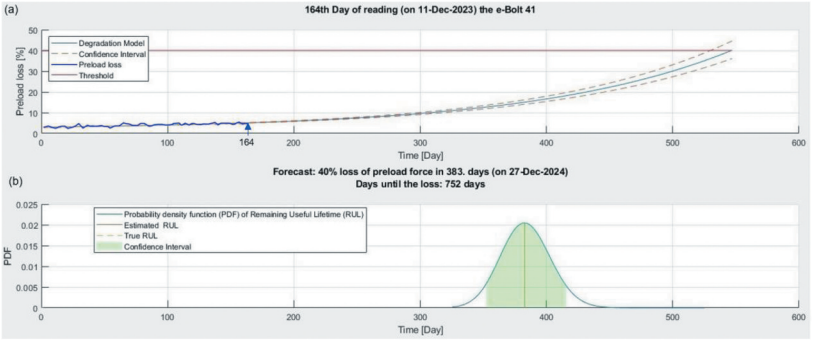

Figure 6. Preload loss estimation (a) and probability density function (b) of Remaining Useful Lifetime (RUL) until 40% loss of preload occurs.

5 CONCLUSION

Innovative passive and wireless smart bolts (*e-Bolt*®) were introduced for condition assessment and RUL prognosis of dynamically stressed mechanical fasteners. Two different smart bolts execution variants were presented, the smart bolt-bolt (*e-Bolt*®-*b*) and the smart bolt-nut (*e-Bolt*®-*n*). Usually, depending on the boundary conditions of the structure to be equipped with smart bolts, either the *e-Bolt*®-*b* or the *e-Bolt*®-*n* is used as intelligent component in mechanical fasteners. It was shown that either a hand-held reader unit or a fitted radio transducer can be used to transfer the energy through air to the smart bolt for carrying out the measurement and to transmit the actual preload force to the reader unit or transducer, respectively. The application of the radio transducer allows to carry out permanent measurements of the actual preload force and using of recorded data for predictive maintenance of bolted connections.

Besides the introduction of the *e-Bolt*® and its calibration, the applied data-driven method for condition assessment and prediction of RUL of the mechanical fasteners were also presented. Finally, to demonstrate the process of estimating the remaining RUL of bolted connections by use of smart bolts an application example of the *e-Bolt*®-*n* installed to ripped base plates of rail fasteners was presented. In this example a threshold of 40% of the loss of preload was chosen as condition indicator to be monitored and to be used for estimating the RUL. The permanent preload force measurements did start on the 1st of July 2023 and were considered until 11th December 2023. Based on these 164 days of permanent reading of the actual preload force of the exemplary considered *e-Bolt*®-*n* the RUL until 40% loss of the preload occurs turned out to 383 days, i.e. based on the actual available preload force measurement data maintenance work (re-tightening) of the installed *e-Bolt*®-*n* is necessary on the 27th of December 2024.

It is concluded that the installation of the developed smart bolts (*e-Bolt*®) in combination with radio transducers for permanent measurement of the actual preload force provide an optimal data basis for application of data-driven methods to estimate the RUL of bolted connections and effectively plan maintenance work, i.e. re-tightening of bolted connections.

Real-time scour depth estimation of a pier using vibration monitoring

D. Kawabe & C.W. Kim
Kyoto University, Kyoto, Japan

V. Sarhosis
University of Leeds, Leeds, UK

ABSTRACT: This study is intended to discuss a statistical real-time scour depth estimation by use of vibration monitoring of a railway bridge pier. Recently, scour has been one of the most critical threats for bridges crossing rivers around the world because of intensive rainfalls. One novel technology to assess the ground condition around the pier during a swollen river water period is to identify its natural frequency from microtremors. To make a fast and accurate decision for bridge operation during the swollen river water period, a way of providing real-time information on scour depth, which is intuitively acceptable, estimated from identified frequency and Finite Element Model is proposed. Long-term vibration monitoring data of in-service railway bridge pier is used to investigate the possibility of scour progress timely during a flood period and a proposed method demonstrated that the probability that scour progresses beneath the footing is extremely low.

1 INTRODUCTION

Scour is the localized erosion that undermines bridge foundations during flooding and is considered as one of the most critical threats for bridges crossing rivers around the world. Nearly 21,000 bridges are reported to be susceptible to having their foundations undermined during extreme storm events (ASCE, 2021). It is particularly difficult to visually determine the scour risk of a bridge over a river, as the condition of the ground beneath the water surface of a pier cannot be directly visualized. To keep bridges as sustainable as possible, a quantitative assessment of the scour is needed.

Bridge authorities have conducted several inspection methods for assessing the condition of the bridge foundation to help manage such risk (Briaud et al., 2009). Many Japanese railway companies have adopted a vibration-based method by means of the impact test that excites the pier by dropping a weight to identify the natural frequency of the rocking mode of the target pier as a promising scour detection method (RTRI, 2007, Bao and Liu, 2017). However, the impact test is a laborious and time-consuming method, and it is inapplicable for real-time scour monitoring to make a proper decision on the train operation during high water level. Therefore, when rivers start to rise, the authorities suspend operations until they deem conditions safe. However, the longer the suspension period is, the greater the economic loss and user disruption are likely to be.

A real-time monitoring scheme utilizing ambient vibrations, thus, has been studied as an alternative method for scouring assessment during flooded rivers. In addition, a cloud-based remote sensing system using the Internet of Things (IoT) has been developed to enable high-precision structural identification to provide information on the natural frequency of monitored pier in real-time (Prendergast and Gavin, 2014). Kim et al (2020, 2021) demonstrated

DOI: 10.1201/9781003483755-96

the possibility of real-time scour monitoring by developing a remote sensing system in a real railway bridge pier as a practical application of ambient vibration-based scour detection.

Figure 1. Monitoring bridge overview.

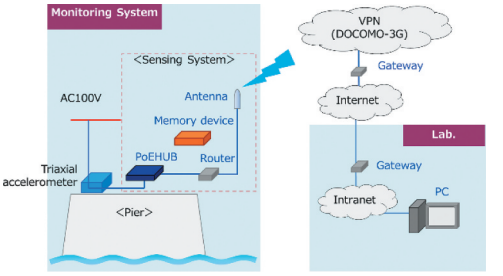

Figure 2. Remote sensing system.

In addition to scouring detection, real-time information on structure performance, such as scour depth, is also crucial for faster and more accurate decision-making on suspending or resuming traffic under uncertainties. It is, therefore, expected that the identified frequencies will be used to update numerical models to estimate the structural performance of the pier. However, there is insufficient study to propose a real-time scour assessment method that uses the modal parameters of the pier to provide information on the performance and safety of the structure.

This study proposes a way of estimating the scour depth around the vibration-monitored bridge pier for real-time assessment during the swollen river water period. A finite element model (FEM) is being built to express a soil-structure interaction and clarify the relationship between soil spring stiffnesses and the frequency of the rocking mode of the pier. Since the identified frequency of the real bridge pier using ambient vibration has a significant uncertainty due to weak signal responses, this study introduces the Bayesian model updating method to express the uncertainty of its properties. Assuming that the soil spring stiffness decreases with scour progression, the relationship between eigenvalues and scour progression is determined. Finally, the multivariate probability density function (PDF) to estimate the probability of scour depth is approximated using the polynomial curve fitting. The proposed method using the long-term vibration-monitored data of a railway bridge pier is applied to the observed data during the flood period. This study also discusses the probability of scour progress during the flood period. It is noted that this study only focuses on the spread footing type as many older railway bridges adopt spread footings.

2 MONITORING BRIDGE

2.1 *Target bridge pier and monitoring system*

The Target bridge is a steel plate girder railway bridge with a single railway track, and the span length of the bridge is 22.5m. The monitoring pier is one of its piers with a height of 9 m and a width of 3 m as shown in Figure 1. Two accelerometers were installed on top of the pier, one on the upstream and another on the downstream sides. The sampling frequency was 200Hz. For a real-time scour assessment, the remote monitoring system shown in Figure 2 was instrumented at the bridge. A long-term vibration monitoring was started in September 2017 and 24-hour measurements were conducted. The result of the impact test conducted before the long-term monitoring campaign was 9.2Hz, which is called "target frequency" of the rocking mode of the pier.

2.2 *Long-term monitoring of the identified frequency of the pier in normal condition*

A swollen river water period was observed on 3rd July 2019. Therefore, this study focuses on a monitoring period from 12th June to 3rd July 2019. Since there was no significant high water level period in June, this period is defined as a normal condition. The natural frequencies of the pier under normal conditions using ambient vibration, excluding train-induced vibration,

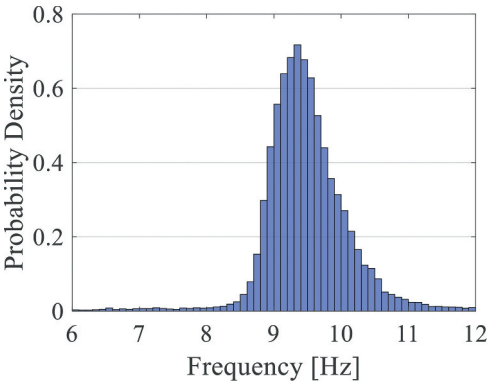

Figure 3. Identified frequency in normal condition.

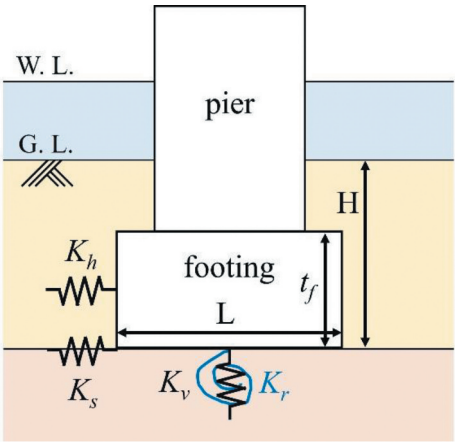

Figure 4. Location in soil springs of FEM.

were accumulated and are shown in Figure 3. A Fast Bayesian FFT (Au 2012a, b) is used to identify the target modal properties. The identified frequency ranges from 6 Hz to 12Hz, showing a wide range, and the variation is significant. This is considered that the high rigidity of the concrete pier results in small signal responses and the signal-to-noise ratio becomes relatively small. The normal distribution is considered as probability distribution function of the observed frequency, and the maximum likelihood estimation is used to estimate the parameters, such as mean value and variance. Eq. (1) shows the estimated parameters.

$$X_n \sim \mathcal{N}(9.47,\ 0.56) \tag{1}$$

3 FINITE ELEMENT MODEL

3.1 *Soil spring stiffnesses*

To estimate the scour progression of the target bridge pier, FEM is being developed in this study. The target pier is modeled with three-dimensional beam elements. Material properties are assigned to the model based on the given design code of materials. The superstructure is simplified as a point mass and attached to the pier top. The footing is modeled as a rigid body.

Adding springs are common modeling and analyzing method for the soil-structure interaction. In most cases, the foundation soil has a finite stiffness and springs can be applied in appropriate positions of the structure to present the finite stiffness of foundation soil. Horizontal, shear, vertical, and rotational springs denoted respectively as k_h, k_s, k_v, and k_r are considered following the Japanese design document (RTRI, 2012) and standard penetration test in 2015. The modeling scheme of the pier with footing is shown in Figure 4 and the dimension is summarized in Table 1. k_v and k_r are set at the center of the bottom of the footing, while the location of k_h is the same as center of gravity of the footing and k_s is located at the next to the bottom of the footing. The spring constants are summarized in Table 2.

The rocking frequency obtained from the eigenvalue analysis was around 9.57Hz which is a bit higher than the impact test and long-term monitoring result as shown in Eq. (1). To reduce this difference, the model will be updated for calibration of the soil spring parameters. Sensitivity analysis is firstly conducted. Figure 5 shows the sensitivity analysis results, in which the horizontal axis shows each soil spring stiffness, and the vertical axis indicates rocking frequency by eigenvalue analysis. Sensitivity analysis demonstrates that the rotational soil spring stiffness has a stronger influence on changes in the rocking frequency of the pier than the other springs. Therefore, the value of rotational soil spring stiffness is updated and updated rotational soil spring stiffness is shown in Table 3, while other springs use the same values in Table 2.

Table 1. Key sizes of the target bridge.

Size name	Character	Value	Unit
Footing length	L	7.8	m
Footing width	B	4.5	m
Footing height	t_f	2.0	m
Length below grade	H	3.5	m

Table 2. Soil spring stiffnesses.

Soil spring	Character	Value of Stiffness	Unit
Horizontal	k_h	7.225×10^4	N/mm
Shear	k_s	2.842×10^6	N/mm
Vertical	k_v	8.528×10^6	N/mm
Rotational	k_r	4.324×10^{14}	$N \cdot mm$

Table 3. Updated rotational soil spring stiffness.

Soil spring	Character	Value of Stiffness	Unit
Rotational	k_r	5.600×10^{13}	$N \cdot mm$

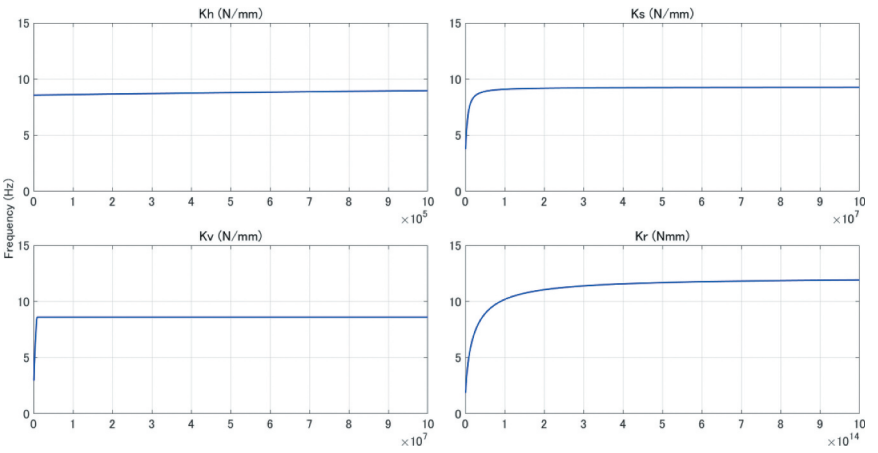

Figure 5. Sensitivity analysis result: rotational soil spring stiffness of the right bottom figure has a stronger influence than other stiffnesses.

3.2 *Identifying uncertainty of rotational soil spring stiffness by MCMC*

Since identified frequencies show a probability distribution as shown in Figure 3, the Bayesian model updating approach (Beck and Katafygiotis, 1998, Katafygiotis and Beck, 1998) that considers uncertainty of properties attributable to measurement noise and modeling error is used in this study. Based on sensitivity analysis results, the contribution of the rotational soil spring to the rocking frequency is significantly larger than the contribution of other springs. This study, therefore, considers it only as the parameter distribution.

As a sampling procedure of the Bayesian model updating, the Markov chain Monte Carlo (MCMC) sampling algorithm is utilized (Mosegaard and Tarantola, 1995, Tierney, 1994). Although there are several adaptable algorithms to cope with intensive computational cost, this study employs the Metropolis-Hastings (MH) algorithms (Metropolis et al., 1953, Hastings, 1970) which is one of the fundamental algorithms within the MCMC framework as the

uncertain parameter is only rotational spring. The target frequency from the updated model is calculated and expressed in Eq. (2).

$$X_n^{upd} \sim \mathcal{N}(9.50,\ 0.24) \tag{2}$$

Although the standard deviation from the updated model is still smaller than that of identified frequencies in the field, the eigenvalue results by the updated model can express the uncertainty. Figure 6 portrays a marginal distribution of the updated spring stiffness, in which the red line represents a PDF of updated rotational soil spring stiffness as the normal distribution shown in Eq. (3).

$$K_r \sim \mathcal{N}\left(6.72 \times 10^{13},\ 7.21 \times 10^{12}\right) \tag{3}$$

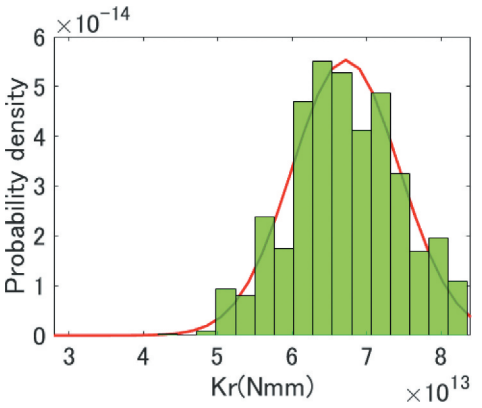

Figure 6. Marginal distribution of rotational soil spring stiffness and PDF of normal distribution.

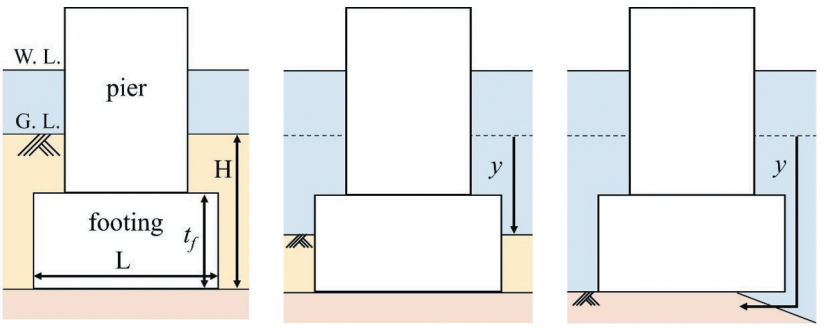
3.3 *Assumption of the relationship between soil stiffnesses and scour progression*

Scour progression can be divided into two stages. The scenario where the scour progresses above the bottom of the footing is defined as Stage 1 shown in Figure 7b), and the scenario where the scour erodes under the footing is defined as Stage 2 shown in Figure 7c). At Stage 1, horizontal spring stiffness k_h is strongly affected by scour progress. On the other hand, k_v and k_s are assumed to have little effect on scour progression, as most of the resistance area is occupied by the bottom of the footing and has not yet been eroded. Therefore, this study assumes that values of k_v and k_s do not change at Stage 1. At Stage 2, since scour progresses under the bottom of the footing and the resistance area is reduced, k_v and k_s assume decreasing.

For k_r, the resistance area includes the bottom and front side of the footing, and the front side of the pier under the ground. If scour progressed within stage 1, the resistance area of the front side of the footing and that of the pier would be reduced. Therefore, it is assumed that k_r would be decreased following the decreasing ratio of the resistance area. It is noted that the resistance area also includes the top surface area of the footing, but since the pressure due to soil cover is small and negligible, the resistance area of the top surface of the footing is neglected. Furthermore, it is difficult to predict how the variation in k_r, shown in equation (3), will change as the scour progresses. Therefore, it is assumed that the standard deviation of the rotational spring stiffness remains constant regardless of scour stages. All assumptions are summarized in Figure 8.

3.4 *Probability of scour depth given identified frequency*

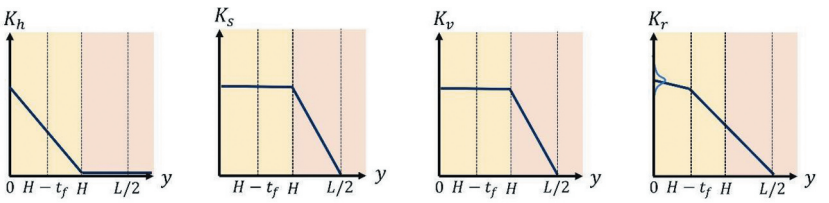
Figure 9 shows the relationship between the amount of scour progression and target frequency obtained from eigenvalue analysis from soil spring stiffnesses assumed in Figure 8. In Stage 1, the decreasing trend in frequency is relatively gradual, but this trend increases in Stage 2. Furthermore, the variance in frequency becomes larger at Stage 2. A deterioration function is



considered to explain these trends. A joint probability distribution model of scour progression y and identified frequency x is calculated in Eq. (4).

$$f(y,x) = \frac{1}{\sqrt{2\pi}\beta(y)} e^{-\frac{1}{2}\left(\frac{x-\alpha(y)}{\beta(y)}\right)^2} \tag{4}$$

Here, hyperparameters α and β are obtained from a procedure of fitting a polynomial curve. The optimal order of the polynomials for the hyperparameters is chosen taking into account the convergence of the root mean square error and is shown in Eqs. (5) and (6), including the identified coefficients.



$$\alpha(y) = 0.017y^3 - 0.161y^2 + 0.687y + 8.335 \tag{5}$$

$$\beta(y) = -5.000 \times 10^{-4}y^4 - 5.000 \times 10^{-3}y^3 + 0.048y^2 - 0.137y + 0.389 \tag{6}$$

a) Intact condition. b) Stage 1: Scour depth above the bottom of footing. c) Stage 2: Scour erodes under footing.

Figure 7. Scour progression stages: y represents the scour progression.

Figure 8. Assumption for decreased trends of each soil spring stiffness following scour progression.

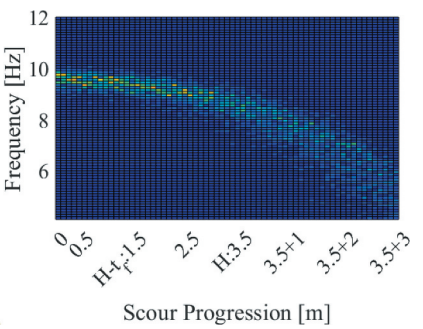

Figure 9. Estimated relationship between identified frequency and scour progress.

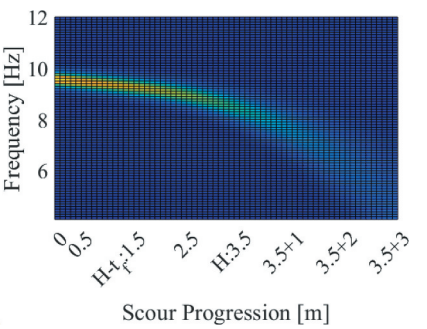

Figure 10. The relationship is approximated utilizing polynomial curve fitting.

Finally, the multivariate PDF in Eq. (4) is shown in Figure 10. The probability of a designated scour progress y_t given identified frequency x_t at a time t can be calculated by Eq. (7).

$$f(y_t, x_t) = 1 - \int_0^{y_t} \frac{1}{\sqrt{2\pi}\beta(y)} e^{-\frac{1}{2}\left(\frac{x_t - \alpha(y)}{\beta(y)}\right)^2} dy \tag{7}$$

4 REAL-TIME SCOUR DEPTH ESTIMATION

To investigate the performance of the proposed method, the ambient vibration monitored on 3rd July 2019 when there was intensive rainfall around the region is examined. Figure 11a) shows the time series of the identified target frequency plotted as black dots and its 30-minute moving average drawn as a red line with the time series of water level drawn as a blue line. As the water level rises, the scattering of the identified frequencies tends to decrease because the river water flow strongly excited the bridge pier, i.e. the signal-to-noise ratio was improved.

Figure 11b) shows the probability that scour depth reaches the bottom of the footing of the target pier expressed as $f(y_t = 3.5, x_t)$. It means the probability that the scour reaches Stage 2. The probability of scour is estimated to be almost less than 0.2 when the water level falls, and the probability converges to zero even though there are several outliers when the water level has stabilized enough. Therefore, it is concluded that the probability of scour reaching Stage 2 is extremely low in this event.

One of the advantages of the proposed method is a flexibleness of setting scour depth. A bridge authority might request an alert the scour progression within Stage 1 considering social impacts. Then, the proposed method can address such requests by setting the value of $y_t = 2$, for example.

5 CONCLUSION

This study proposes a way of estimating the probability of scour depth by means of ambient vibration monitoring of the bridge pier during the swollen river water period. The proposed method, firstly, builds FEM to grasp the relationship between the rocking frequency of the pier and the soil stiffnesses modeled as springs, and investigates springs having a strong influence on changes in the rocking frequency of the pier. Then, as the variance of identified

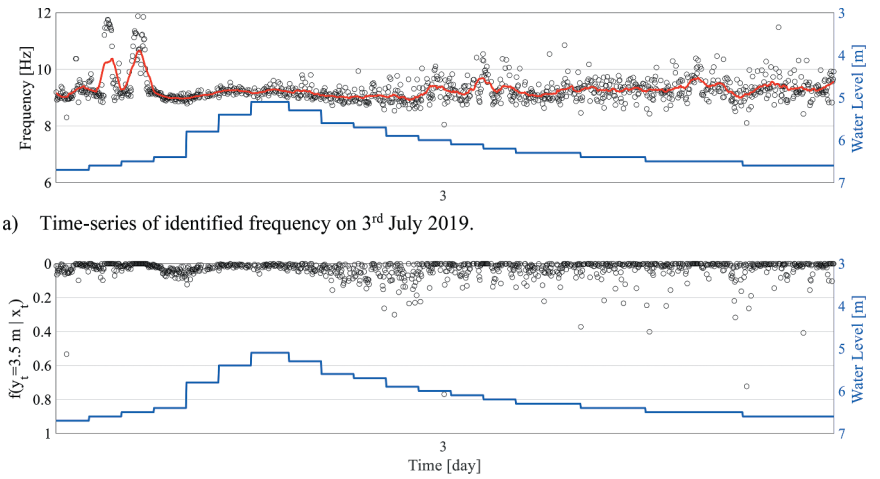

Figure 11. The result in the proposed probability of scour depth estimation when the water level is high.

frequency is significant when ambient vibration of the bridge pier is used, the marginal distributions of the investigated springs are identified utilizing the Bayesian model updating. This study applied MH algorithms and the PDF of rotational soil spring stiffness is updated modeling its uncertainty. Finally, the relationship between soil springs taking into account the footing resistance and the scour depth are assumed, and the deterioration function representing decreasing trend of the natural frequency following the scour progression is estimated utilizing polynomial curve fitting.

The proposed method was applied to the ambient vibration of the bridge pier where the remote sensing system had deployed and estimated the probability that scour depth reaches the bottom of the footing of the pier timely during the swollen river water period. The results of the probability were estimated to be almost less than 0.2 when the water level falls, while the probability converged to zero when water level had stabilized enough. It demonstrates that the probability that scour progresses under the bottom of the footing is extremely low during the considered flood event.

ACKNOWLEDGMENT

This work was supported by a Japanese Society for the Promotion of Science (JSPS) Grant-in -Aid for Scientific Research (B) under project No. 22H01576 and the CDRI fellowship program 2022-23, which are greatly appreciated.

Structural integrity estimation of bridges based on acceleration measurement

Hanliang Yu & Chul-Woo Kim
Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: As the ages of bridges in Japan continue to increase, the demand for monitoring these bridges is also increasing. However, there might be some problems while conducting BSHM. Practically, collecting displacement data is much more challenging than collecting acceleration data. In terms of theoretical analysis, FE models are very complex. Both creating datasets and updating models require a significant amount of computational resources. To solve these problems, this study uses accelerometers to identify the displacement of bridges for structural integrity estimation. A scaling factor is developed to solve the problems of discrepancies between measured physical response and FEA response, and help to create a model that can reduce the computation time of updating. Finally, the damage detection is achieved by a CVAE which uses displacement data as its interface. The feasibility of the proposed method is verified through an in-house experiment.

1 INTRODUCTION

1.1 *Background*

There are currently about 730,000 bridges in Japan, of which about 660,000, or more than 90%, are managed by local governments and local public agencies. Approximately 34% of them are over 50 years old. This is expected to increase to about 59% in 10 years. Of the 27,938 bridges constructed between 2018 and 2021, 13,833 (49.5%) bridges have been identified as having abnormal deformation, and they need to be observed for a certain period. Therefore, the maintenance of bridges is a crucially important technical issue. Currently, according to the guidelines of the Ministry of Land, Infrastructure, Transport and Tourism (MLIT) in Japan, close-up visual inspections should be carried out on each bridge once every five years. Periodic close-up visual inspections require experience although the accuracy of this method is not high enough. However, the time and cost of visual inspection are considerably high. A more efficient and accurate method of bridge inspection is required. A challenge is to establish a method that can diagnose damage on bridges with lower cost, higher efficiency, and higher accuracy.

1.2 *Vehicle drive-by test*

Utilizing the bridge responses under traffic is popular in BSHM, and vehicle drive-by test provides more accurate and organized data although it needs to interrupt the traffic. To conduct a vehicle drive-by test, sensors are set on the structures to collect real-time acceleration, displacement, or strain when the vehicle traveling on the bridge. Then, a data-driven model (DDM) could be established based on the data. Among all the indicators, displacement is one of the most useful responses because it contains the most direct information on the structural behavior. However, practically, collecting displacement data is not an easy task as displacement transducers or high-definition cameras always need a stable platform to set. Utilizing

DOI: 10.1201/9781003483755-97

accelerometers is an alternative of the displacement transducer if displacement is accurately identified using acceleration because accelerometers could be directly instrumented on the bridge. In this study, displacement is estimated based on the acceleration measurement.

1.3 *Data-driven FE model*

To assess the current performance of the bridge, the finite element method (FEM) based SHM has become very popular in the last decades (Singh 2022). FEM is a general numerical method to solve partial differential equations. It divides large systems into smaller, simpler parts called finite elements (FE). The simple equations of each element are assembled into a larger system of equations to model the entire problem completely. In general, FEM involves creating a simplified 2D or 3D model of the structure on a FEM solver and obtaining a unique solution. The FE models are often simplifications of real structures while ensuring the accuracy of the calculation. Data-driven modeling (DDM) (Solomatine 2008) is another commonly used method. DDM uses the collected data as a model and does not pay too much attention to the principle of the structural system. Instead, it predicts possible future changes in the structure based on experience. This model has been very successful in weather prediction (Ashesh 2022). It handles uncertain errors better than physical models.

1.4 *Existing problems*

Acceleration is often used in BSHM to estimate the modal frequency, modal damping, and mode shapes of bridges. Displacements and rotation angles are commonly used to assess the bridge's structural integrity. However, in practice, monitoring displacements accurately can be challenging. Specifically, for long-term monitoring, factors such as labor cost, equipment maintenance expenses, and equipment stability need to be considered, leading to a limited number of feasible methods that can be implemented (Gosliga 2022). Several techniques support direct displacement measurement. The use of high-precision physical displacement transducers enables long-term data collection. However, these sensors often require a relatively fixed platform or reference for device placement, making them unsuitable for bridges crossing rivers and seas. Thus, if displacement could be estimated through acceleration, those problems would be solved.

In FEM-based damage detection, several FE models are created based on multiple assumed damage scenarios (Nizar 2018). The difference between the FE models is achieved by changing the area of the section, changing the bending stiffness, or eliminating elements. In practical engineering, the internal parameters of the structure change over the years due to various reasons such as material degradation, crack, or creep. Timely updating of the FE model is an important process to keep generating highly comparable structural responses with the actual structure. Detecting the damage and deciding how to update the FE models may not be difficult, but calculations must be performed on all updated models. Computing time for each model will also rise drastically due to increasing complexity.

Surrogate models, also called metamodels, are common in DDM. A surrogate model aims to create a mapping from the input to the output, while the inner workings of the code remain unknown. If there is no damage to the structure, it is impossible to obtain the structural response under damage states. Therefore, the training data for damage states of the structure cannot be generated from the measured data. Recent research hopes to use the surrogate model as a replacement for the FE model (Hoffer, 2021) expecting that updating the surrogate model could be simpler, less time-consuming, and more practical to use. However, it is difficult to control changes to internal parameters.

This study aims to solve the following problems in damage detection by BSHM: a) to develop a method to estimate deformation using acceleration; b) to solve the problems of discrepancies between measured physical response and FEA response; c) to create a numerical model that can reduce the computation time of updating; and d) to develop a surrogate model which can detect damage and uses displacement data as its interface.

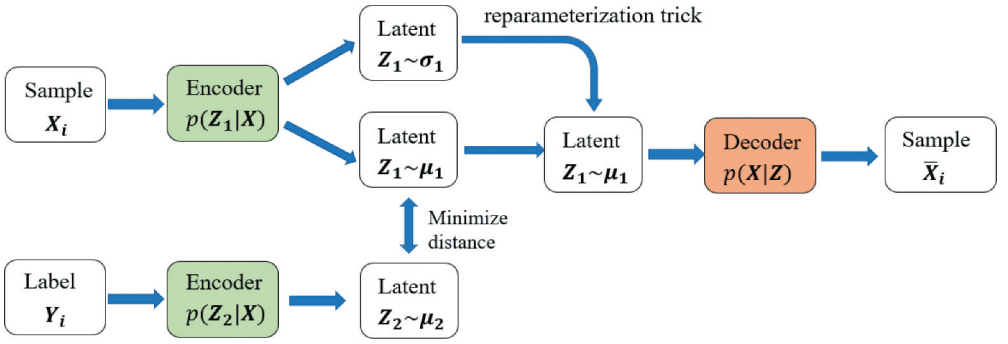

Figure 1. Algorism of CVAE.

2 METHODOLOGY

2.1 *Displacement estimation in vehicle drive-by test*

In the vehicle drive-by test, the rotation angle of one point on a bridge is a binary function of position and time. If the shape function of the bridge rotation is continuous and could fit a polynomial, the deflection $\delta_z(x, t)$ can be an integral along location x of rotation angle $\theta(x, t)$ shown in Equation (1).

$$\delta_z(x,t) = \int_L \theta(x,t)dx = \int_L \arctan\left(\frac{\hat{a}_x(x,t)}{g}\right)dx \tag{1}$$

where $\hat{a}_x(x,t)$ denotes the acceleration in the horizontal direction

The shape function of the bridge rotation is fit by a polynomial as:

$$\boldsymbol{Y} = \boldsymbol{\theta}(\boldsymbol{X}) = a_0 + a_1\boldsymbol{X}^1 + a_2\boldsymbol{X}^2 + \ldots + a_{m-1}\boldsymbol{X}^{m-1} + a_m\boldsymbol{X}^m = \boldsymbol{aX} \tag{2}$$

The boundary condition could be determined by physical knowledge. For a simply supported beam of length L, the boundary condition would be:

$$[\boldsymbol{M}, \boldsymbol{D}]^T\boldsymbol{a} = \boldsymbol{b} \tag{3}$$

where $\boldsymbol{M}$ denotes the boundary condition given by the moment, $\boldsymbol{D}$ denotes the boundary condition given by the displacement, and $\boldsymbol{b} = \{\boldsymbol{0}, \boldsymbol{0}, \boldsymbol{0}, \boldsymbol{0}\}$ when the beam is simply supported. According to the least-squared method, the best-fitted polynomial could be calculated by minimizing the Equation 4:

$$L(a_0, \ \ldots, \ a_m) = \frac{1}{2}\sum_{i=1}^{n}\left(\theta(x_i) - \hat{\theta}_i\right)^2 = \left|\left|\boldsymbol{Xa} - \widehat{\boldsymbol{\theta}}\right|\right| \tag{4}$$

The physical boundary condition acts as a strong constraint of the DDM. If there exists a $\boldsymbol{c}$ such that the equation holds, the coefficients $\boldsymbol{a}$ of the polynomial could be calculated according to Karush-Kuhn-Tucker (KKT) equations:

$$\begin{bmatrix}\boldsymbol{a}\\ \boldsymbol{c}\end{bmatrix} = \begin{bmatrix}\boldsymbol{X}^T\boldsymbol{X} & [\boldsymbol{M}, \boldsymbol{D}]\\ [\boldsymbol{M}, \boldsymbol{D}]^T & \boldsymbol{0}\end{bmatrix}^{-1}\begin{bmatrix}\boldsymbol{X}^T\widehat{\boldsymbol{\theta}}\\ \boldsymbol{b}\end{bmatrix} \tag{5}$$

Once the expression for the rotation angle is obtained, deflection shape functions can be directly computed by integrating the polynomial. In this process, we avoid using numerical integration to reduce noise.

2.2 *Conditional Variational Auto-Encoder (CVAE)*

A CVAE is used in damage detection using the identified displacement from the acceleration. It is generally an auto-encoder, a kind of neural network specialized in recognition and random generating (Kingma 2022). The encoder creates a mapping from the deformation response to the latent layer, and the decoder creates a mapping from the latent layer to the deformation response.

In a Variational Autoencoder (VAE), for the encoder, assuming all samples are drawn from the prior distribution $p(\boldsymbol{Z})$, there exists a posterior distribution $p(\boldsymbol{Z}|\boldsymbol{X_i})$ for each sample $\boldsymbol{X_i}$. Assuming this posterior distribution $p(\boldsymbol{Z}|\boldsymbol{X_i})$ follows a normal distribution $N(\mu_i,\ \sigma_i^2)$, the generator $\boldsymbol{X} = g(\boldsymbol{Z})$ can reconstruct $\boldsymbol{X_i}$ from a sample $\boldsymbol{Z_i}$ drawn from the distribution $p(\boldsymbol{Z}|\boldsymbol{X_i})$. This process extracts a set of information of $p(\boldsymbol{Z}|\boldsymbol{X_i})$ from the real sample $\boldsymbol{X_i}$ and reconstructs $\widehat{\boldsymbol{X}}_i$ through sampling. Hence, we can train a neural network by minimizing the distance between $\boldsymbol{X_i}$ and the reconstructed $\widehat{\boldsymbol{X}}_i$. Typically, this distance is measured using Kullback–Leibler divergence (KL divergence).

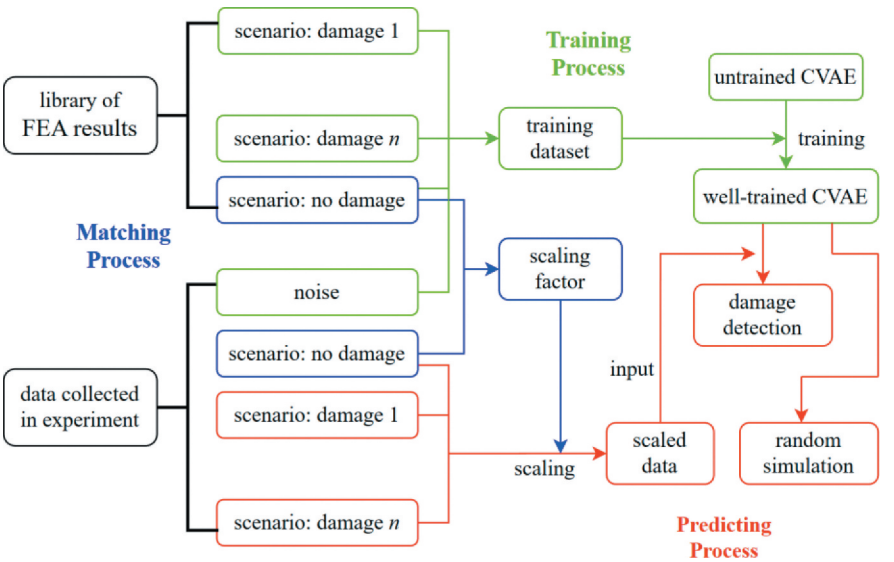

Figure 2. Flow chart of training a data-driven FE model.

In this study, the actual structural response data is treated as sample $\boldsymbol{X}$. Through training the encoder $\boldsymbol{Z}_1 = f_1(\boldsymbol{X})$, the mean of the sample is obtained. Simultaneously, the structural damage field is set as the label $\boldsymbol{Y}$ and, by training the encoder $\boldsymbol{Z}_2 = f_2(\boldsymbol{Y})$, features of the label are obtained. Then we assume this posterior distribution $p(\boldsymbol{Z}|\boldsymbol{Y_i})$ follows a normal distribution $N(\mu_i^*,\ 1)$. Therefore, during the training of the VAE, we achieve directed training of the latent layer. The VAE is now a conditional variational auto-encoder (CVAE) as shown in Figure 1. Making these two normal distributions as close as possible results in an advanced formula for KL divergence as Equation (6).

$$KL(N(\mu_i,\ \sigma_i^2)||N(\mu_i^*,\ 1)) = \int \frac{1}{\sqrt{2\pi\sigma_i^2}} e^{-(x-\mu_i)^2/2\sigma_i^2} \log\left\{ \frac{e^{-(x-\mu_i)^2/2\sigma_i^2}/\sqrt{2\pi\sigma_i^2}}{e^{-(x-\mu_i^*)^2/2}/\sqrt{2\pi}} \right\} dx \qquad (6)$$

The loss could be written as:

$$L_{KL} = \frac{1}{2}\sum_{i=1}^{n}\left[\left(\mu_i - \mu_i^*\right)^2 + \sigma_i^2 - \log\left(\sigma_i^2\right) - 1\right] \tag{7}$$

2.3 *Data-driven FE model*

The flow chart of training a data-driven FE model is shown in Figure 2. In the 'Training process', finite element analysis (FEA) is carried out to provide a dataset for training the CVAE. Within the finite element model, the structure is divided into multiple regions. Structural damage is defined as a reduction in the stiffness (EI) of these regions, and damage fields are randomly generated. FEA is performed for each randomly generated damage field, producing structural displacement response curves. The displacement response serves as the training dataset for the CVAE, and the directed training of the CVAE is accomplished using the damage fields. The noise collected during the experiment is analyzed. According to the distribution of the signal, the noise data could be generated randomly. Training data is then obtained by applying random noise to the FEA results. This method is a solution to the problem of insufficient training data. After the training is completed, the inner parameter of the CVAE will never change. In this case, the encoder can detect the damage in the FE model.

In the 'Matching process', due to the discrepancies between the FEA results and the measured data, the measured data cannot be used directly as input to the CVAE. A scaling factor is used for the assimilation of two data sets: the FEA results of a scenario with no damage, and the data collected in a 'current' state. The encoder is then able to detect the change in the

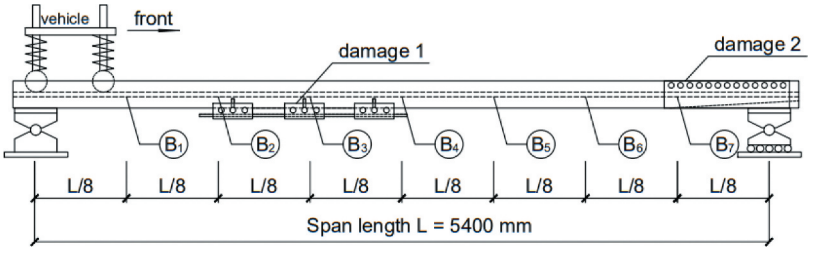

Figure 3. Model bridge.

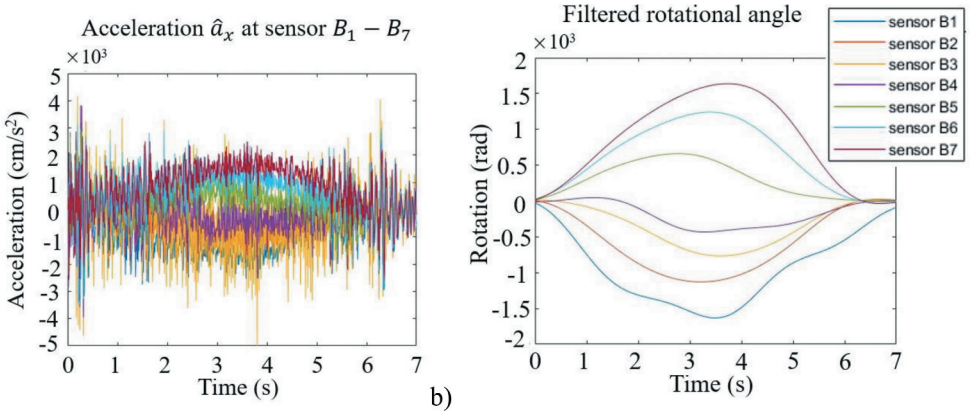

Figure 4. Time histories of acceleration and rotation in scenario dmg00: a) acceleration; b) rotation.

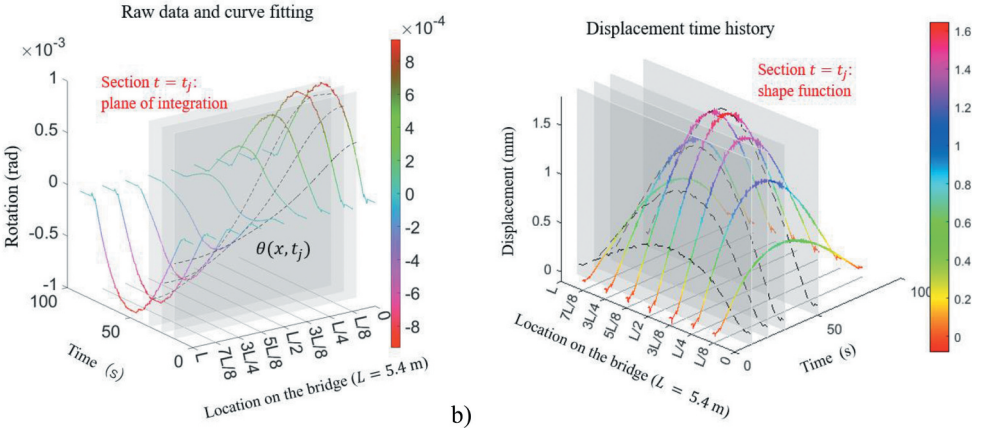
damage and compare it to the current state. When damage happens, instead of updating the FE model or CVAE, the current state and scaling factors are updated. The scaling factor $\boldsymbol{H}$ could be obtained by using the element-wise operation given by Equation (8).

$$H_{ij} = \frac{X_{ij,FEM}}{X_{ij,Exp}} \tag{8}$$

In the 'Predicting process', after the scaling factor has been obtained, it is used to scale all of the collected data to resolve the discrepancies. The scaled data is used as input to the VAE. The output results of the latent layer will show the prediction of the damage. We can also predict structural behavior under different damage conditions by sampling from the latent layer to obtain results for various damage scenarios.



In summary, FEA computation time is reduced by avoiding FE model updates. Discrepancies between measured physical response and FEA response are solved using a scaling factor. Damage detection could be achieved without the need for data collection through the creation of a library of FEA results. The FEA and the training of the CVAE are performed only once. Updating the model is achieved by updating the scaling factor, which is completely independent of the CVAE and the FE model.

3 DEFLECTION ESTIMATION

3.1 *In-house experiment*

An experiment is carried out on a simply supported steel beam in the laboratory. Figure 3 shows the experimental bridge with sensor deployment. The bridge has a length of 5600 mm, a span of 5400 mm, a width of 287 mm, and a height of 66 mm. The support on one side is a pin and the support on the other side is a roller.

The cross-section of the model bridge is an "H" shaped section. The Area of cross-section (A) is 6.5483×10^{-3} m^2, the second moment of area (I) is 5.7480×10^{-7} m^4, and the material of the bridge is SS400 steel whose Young's modulus (E_0) is 206 GPa, density is 7850 kg/m^3, and Poisson's ratio is 0.34. When the vehicle moves on the bridge, accelerometers set at location $B_1 \sim B_7$ collect real-time acceleration.

a) b)

Figure 5. Estimation of deformation: a) integration of rotation; b) displacement field.

There are two reinforcements on the bridge, marked as damage 1 and damage 2, and this state is denoted as a "no damage" state. When each of the reinforcement is removed, the bridged is considered to be damaged and denoted as "damage 1" and "damage 2" states respectively.

3.2 *Rotation estimation*

The horizontal acceleration ($\hat{a}_x(x,t)$) time history obtained from the sensor is shown in Figure 4 a). The sampling frequency was 200 Hz. By applying a Butterworth lowpass filter with a cut-off frequency of 0.5 Hz, the noise in the signal was well eliminated. The filtered signal is shown in Figure 4 b).

3.3 *Displacement estimation*

In the test, after filtering, the motion of the vehicle on the bridge can be considered quasi-static. The sampling frequency during the experimental process is 200Hz. At each time plane $t = t_j$, constrained least squares curve fitting is applied to the collected data. This process yields the relationship between the bridge's rotation angle and position at the current moment, denoted as $\theta(x, t_j)$ shown in Figure 5 a).

Once the rotation-position curve $\theta(x, t_j)$ is obtained, the displacement shape function $\delta(x, t_j)$ can be obtained by integrating the position in that plane. After performing integration calculations in each plane, a displacement field $\delta(x, t)$ could be obtained, which contains the displacement information of the whole structure at any time increment.

On the plane $x = x_i$ ($i \in [0, L]$, $i \in \mathbb{R}$, continuous), the displacement-time history $t - \delta(x_i)$ at a point x_i on the bridge under the moving vehicle can be obtained. Dividing it by the vehicle weight will provide the influence line of displacement. On the plane $t = t_j$ ($j \in [0, L/v]$, $j \in \mathbb{R}$, continuous), the displacement shape function $x - \delta(t_j)$ at a specific time increment t_j when the vehicle travels on the bridge can be obtained as shown in Figure 5 b).

4 DAMAGE DETECTION IN THE EXPERIMENT

4.1 *FEM simulation*

In the FEM simulation, the bridge is divided into 20 elements. A random damage field is applied to the structure. The displacement time history at the location from B_1 to B_7 is selected to be the input data. Figure 6a) shows the FE model and an example of a randomly generated damage field.

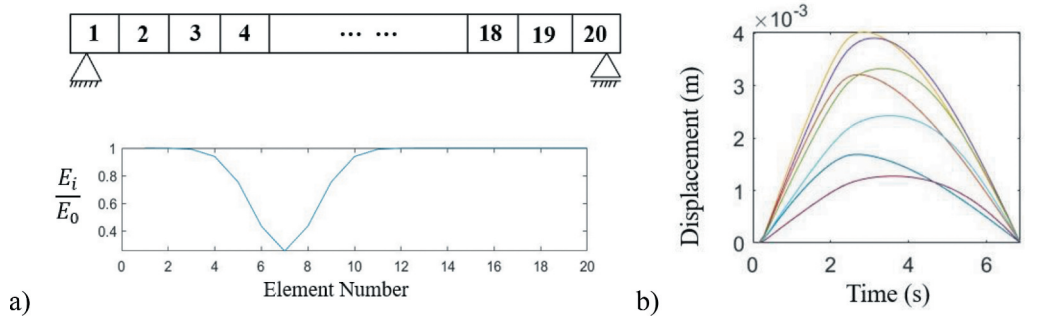


Figure 6. FE model: a) Damage field; b) result of FEA.

4.2 *Damage detection*

Figure 7 Depicts the CVAE's discrimination of damage on the test dataset. The color bar displayed on the right side indicates the location with the highest likelihood of damage occurrence. It can be observed that the entire latent variable exhibits a radial distribution in space. As the severity of damage is random during the generation of

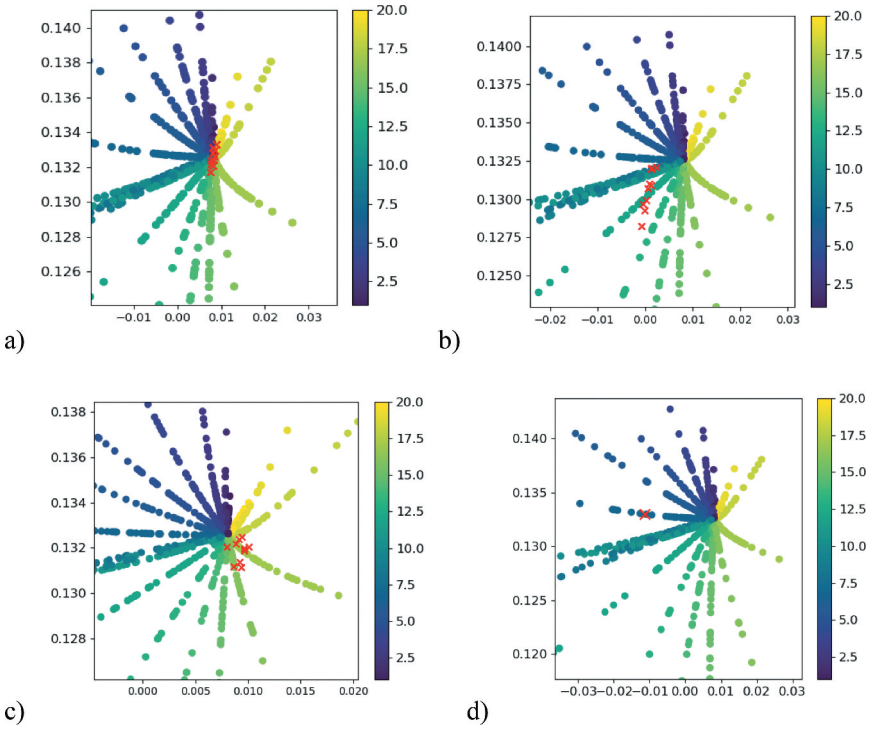

Figure 7. distribution of variable in latent layer **Z**: a) scenario: no damage; b) scenario: damage 1; c) scenario: damage 2; d) a sample for the generator (the example in 4.1).

damage fields, determining minor damage conditions is more challenging, naturally leading to proximity to the central region. It is clear that the CVAE successfully detects two types of damage, and also it does not interfere with the no damage scenario.

4.3 *Scenario generation*

For the experimental data, after modifying it with a scaling factor, the distribution of the data in the latent space after encoding is shown in Figure 7 d). We can obtain a specific damage field by sampling values from the latent space (Figure 7 d)). This value, once decoded, can output a predicted structural response. Comparing it with the finite element calculation results for this damage field is illustrated in Figure 8. It can be concluded the estimation is quite comparable.

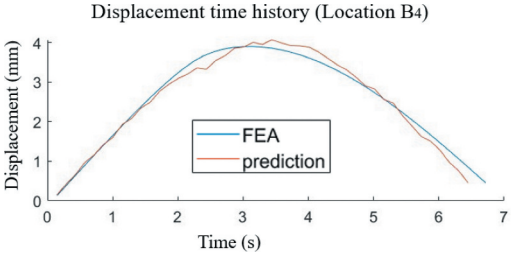

Figure 8. Displacement time history at location $\boldsymbol{B}_4$.

5 CONCLUSION

This study investigates a method that estimates displacement using only acceleration data. The deformation could be used for damage detection, aiming to improve existing FEM model updating methods. To solve the discrepancies between the FEA results and the real data. This study solves the problem by establishing a mapping called scaling factor to map the real data set to the result generated by the FEA. In this way, CVAE can also be used for damage detection on real data.

Next step for this study is feasibility of damage detection with reduced number of sensors. If this can be achieved, the practical value of this method would significantly increase. It is noted that the latent layer of the CVAE is used to visualize the classification results. If Bayesian theory can be applied to the post-processing of the data, the specific determination of the damage location can be converted into a probability of occurrence of damage at each location. The results would then be expected to be more intuitive.

Research on application of real-time dynamic safety monitoring system for medium and small span bridges

Hua Hong, Su-gong Cao, Jun-lei Fu & Yue-kai Xu
Zhejiang Scientific Research Institute of Transport, Hangzhou, China
Key Laboratory of Road and Bridge Inspection and Maintenance Technology of Zheng jiang Province, Hangzhou, China

ABSTRACT: In view of the lack of economic and practical structural health monitoring system for medium and small span bridges in china, A new idea of health monitoring for small and medium span bridges based on displacement is proposed. The economical bridge health monitoring system with displacement monitoring combined with heavy vehicle capture as the main monitoring content has been designed and developed, The application research of practical bridge was carried out. A 2×25m span prestressed reinforced concrete T beam is selected as the research object, Real-time monitoring of vertical displacement of beam, Statistics of out of limit quantity, Record the out of limit value. The response law of bridge structure under external load during operation period is discussed and the trend of structural bearing capacity is monitored. The results showed that: The R&D system can accurately capture the effect of causing structural overrun response, and conduct real-time early warning for emergencies; The monitoring and analysis results can effectively guide the scientific management and maintenance of the bridge.

1 INTRODUCTION

By the end of 2021, In china's highway bridge operation system, the medium and small span bridges account for 85%[1]. However, Due to the aging, corrosion, fatigue and other factors of medium and small span bridges, the increasing traffic flow, construction quality and maintenance attention, the safety factor of medium and small span bridges is much lower than that of large span bridges, and the probability of sudden damage, collapse and other safety accidents is much higher than that of large span bridges[2~3]. Therefore, It is extremely necessary to monitor the structural health status of small and medium span bridges in real time, The evaluation of structural safety and operational stability should be included in the daily management of bridge operation.

Scholars at home and abroad have conducted some useful research on the dynamic safety monitoring of bridges. Zhang Jian-long et al. [4] proposed a bridge health monitoring and early warning platform based on neural network. The platform has the functions of data collection, transmission, persistence, etc., and also supports multiple types and quantities of bridge data visual interaction and bridge health assessment functions. David et al. [5] combined the global positioning system (GPS) and linear variable differential sensor (LVDT) to monitor the structural deformation of the bridge, and finally determined some slight displacements of the bridge in the horizontal direction. Xin Guang-tao et al.[6] systematically analyzed the requirements of structural health monitoring system for long-span bridges, and introduced the design principles of the system from the aspects of software and hardware design and development. Roshandeh A M et al.[7] summarized the bridge big data platform as data entry module, data display module, data exit module and data early warning module, and introduced the functions of each module. Ren Pu et al.[8] proposed a bridge health monitoring system platform based on big data. The system platform utilizes a distributed file system with high fault tolerance and a parallel data processing engine with high

DOI: 10.1201/9781003483755-98

computational efficiency, which has high reliability, availability and storage efficiency, and is easy to expand, and can provide real-time early warning for bridge safety.

The existing research results on bridge health monitoring mostly focus on the research and development of long-span bridge monitoring system and monitoring equipment, while few research on real-time online early warning system for small and medium span bridges. However, the current situation of bridges in china is that the proportion of medium and small span bridges is large, and the probability of safety accidents is high. Therefore, the research on real-time online monitoring of medium and small span bridges at important nodes is of great significance. In view of the current situation that there is no economical and practical structural health monitoring system for medium and small span bridges, this paper proposes a new idea of health monitoring for medium and small span bridges only based on displacement. At the same time, a bridge health monitoring system based on displacement monitoring combined with heavy vehicle capture is designed, which is quite economical. To achieve the reasonable, practical and cost-effective goals of the structural monitoring system for medium and small span bridges.

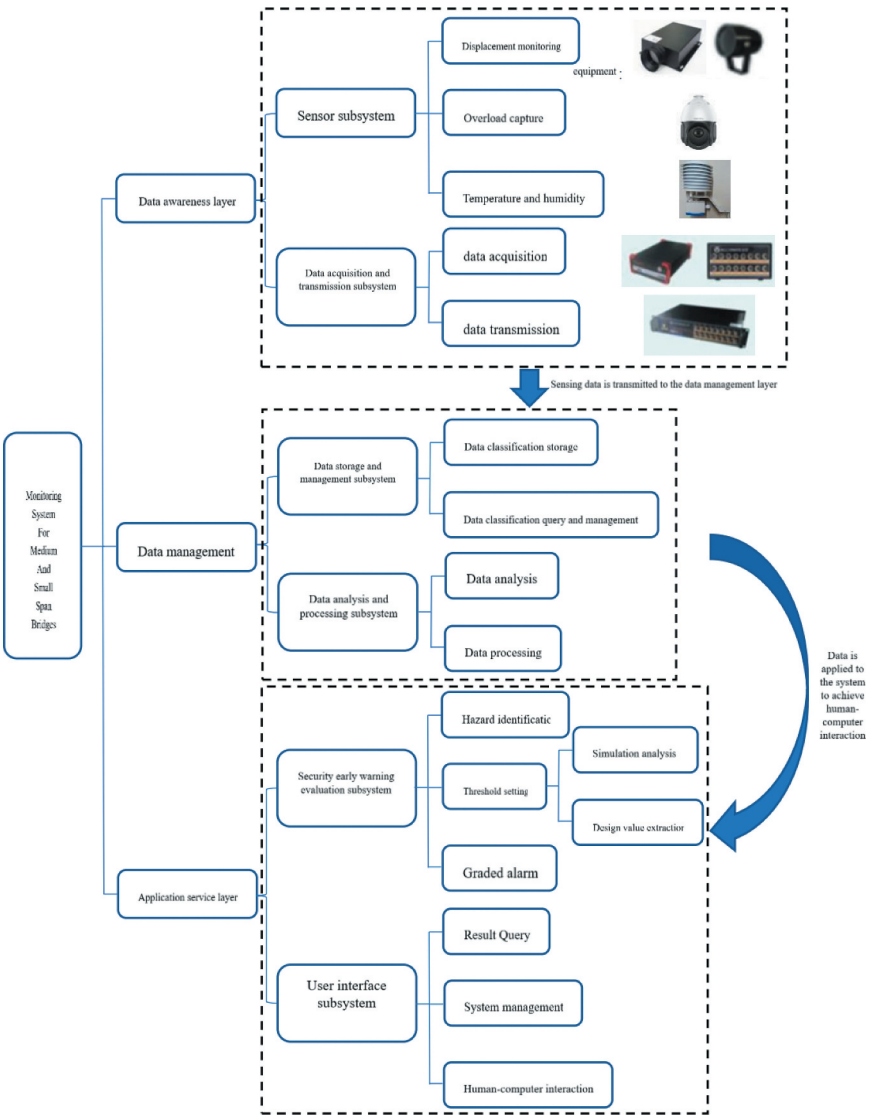

Figure 1. Design idea map.

2 DESIGN IDEAS

The basic connotation of the bridge health monitoring system is to use modern sensing and communication technology to real-time monitor the structural response of the bridge under various environmental conditions during the operation stage, Obtain various information reflecting structural conditions and environmental factors, From this, the health status of the structure is analyzed and the reliability of the structure is evaluated, To trigger the early warning signal when the operation condition of the bridge is abnormal, To trigger the early warning signal when the operation condition of the bridge is abnormal, At the same time, it provides scientific basis for bridge management and maintenance decision.

Based on this, the overall design of monitoring system for medium and small span bridges should include three functional layers, namely, data perception layer, data management layer and application service layer. Among them, the data sensing layer is the underlying structure, including the sensor subsystem, data acquisition and transmission subsystem, Displacement acquisition should be the main objective, supplemented by overload linkage capture, environmental temperature and humidity monitoring; The data management layer is the middle layer, including the data storage and management subsystem, the data processing and analysis subsystem and the data reporting subsystem; The application service layer is the top-level structure, including the security early warning evaluation subsystem and the user interface subsystem. The design idea diagram is shown in figure 1.

3 SYSTEM LAYOUT

The main user of the system is the bridge management and maintenance institution, It is one of the key contents of system interface design to establish the management and visual display of various data of the system. At the same time, combined with the current situation and stress characteristics of medium and small span bridges, Considering the economy and practicality of the system, The main monitoring content of the system design is displacement monitoring combined with heavy vehicle capture. Based on this, the visual display of the monitoring system, data analysis, early warning, linkage capture and evaluation are considered in the system layout.

3.1 *System display*

Provide friendly interactive graphical user interface, The main display screen includes the system home page, structure home page, etc; Display of data, including: 3D model, measuring point position, attributes, real-time historical curve and other information; Heavy load capture display, including: synchronous display of heavy load capture overrun monitoring curve,

Figure 2. System display interface.

capture image and dynamic deflection; Display of other statistical data, Including: display of statistics of times of different warning levels. The system display interface is shown in Figure 2.

3.2 *Early warning setting*

For this system, settings are made from the following aspects: early warning method design, early warning threshold confirmation, early warning value configuration, early warning push and early warning history.

The early warning method is designed from the threshold value, data deviation, data change rate and joint analysis between different data, The monitoring structure is simulated and analyzed by numerical simulation, Combined with the corresponding provisions of 《Technical Specifications for Structure Monitoring of Highway Bridges》(JT/T 1037-2022), Determine the threshold corresponding to different warning levels of each monitoring parameter.

It provides the editing of batch alarm and single point alarm, According to the different alarm level information is pushed to different roles and users by sms, email and other means, and the existing alarm information is counted.

3.3 *Linkage capture arrangement*

Moving load is the main load of small and medium span bridge during operation, Vehicle overload is the main cause of structural damage.Using the structural deflection response feedback, linkage with the capturing camera, When the deflection exceeds the corresponding threshold of different levels, record the measured data of heavy vehicles crossing the bridge and the relative deformation caused only by vehicle load, Capture images of heavy vehicles crossing the bridge, It can provide data guidance for maintenance inspection work and load supervision and control work.

4 REAL BRIDGE APPLICATION

4.1 *Bridges overview*

The total length of the bridge is 342.0m, with a total of 20 spans, The layout of the bridge span is: 10 × 16m+2 × 25m+8 × 16m, This project requires Establish long-term health monitoring for the 2×25m span (11th and 12th spans). The upper structure of this unit is prestressed reinforced concrete T-beam, and the structure is discontinuous. The lower structure is double column pier and bored Pile foundation, and the bridge deck is paved with asphalt concrete pavement. The transverse arrangement of the bridge is: 0.5m(guardrail)+11.8m(carriageway)+0.5m(guardrail), and the edge plate is equipped with concrete anti-collision guardrail.

4.2 *Structural theory analysis*

4.2.1 *Calculation model*

Design load class: Highway - Class I.

Based on the short-term action effect calculation method of the limit state of normal use, Mainly according to the bridge construction specifications, The content of this checking calculation is formulated according to the "Design Specification for Highway Reinforced Concrete and Prestressed Concrete Bridges and Culverts"(JTG 3362-2018).

4.2.2 *Warning value setting*

According to the principles of hierarchical early warning and security control, Combined with the requirements of the "Technical Specifications for Highway Bridge Structure Monitoring" (JT/T 1037-2022), Implement second-level security early warning control for this bridge, The basis and values for setting up early warning values are as follows:

Table 1. Setting of warning value.

Serial Number	Warning level	early warning value	Unit	Establishment basis
1	Second level	4.88	mm	Meet the requirement of 0.8 times the effect of Class I moving load on highways
2	first level	6.1	mm	Meet the requirements for the effect of Class I moving load on highways

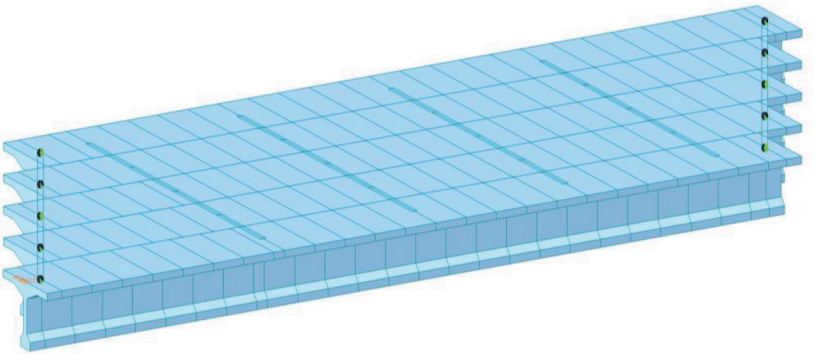

Figure 3. Calculation model.

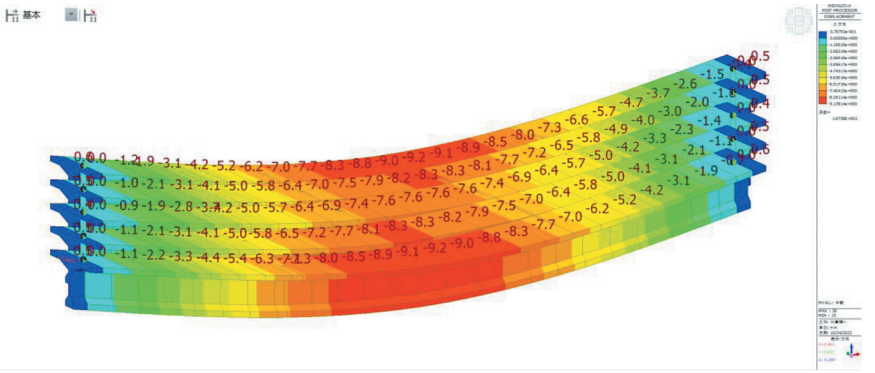

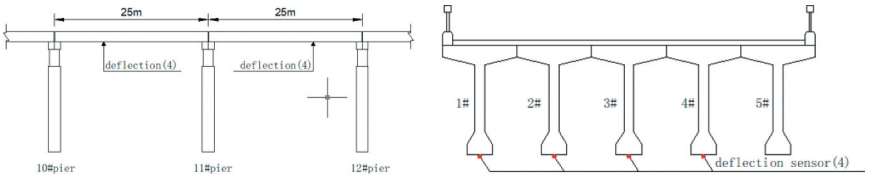

Figure 4. Calculation results of deflection.

4.3 *Monitoring point layout*

The layout of monitoring points plays an important role in the Structural health monitoring of bridges, The quality and scientificity of the layout of measurement points directly affect whether the monitoring data can accurately reflect the actual state of the bridge. For this bridge combined with the actual situation on site, the layout of monitoring points is shown in Figure 5.

(a) Elevation Diagram of Measuring Point Layout

(b) Schematic Diagram of Cross Section of Measuring Point Arrangement

Figure 5. Layout diagram of monitoring points.

4.4 *Monitoring results*

4.4.1 *Data presentation*

Real time monitoring of the structural deflection of the main beam under moving loads, To evaluate the overall stiffness characteristics of the structure, It provides the basis for the evaluating of the overall health status of bridge structure, the verification of bridge design theories and the standardization of operation management. The system provides real-time data query function, as shown in Figure 6. According to the results of the monitored data, the data can be traced online and the corresponding data can be analyzed longitudinally, as shown in Figure 7.

Figure 6. Real-time data.

Figure 7. Historical data in any period.

4.4.2 *Overlimit linkage capture*

Triggered by structural deflection response, Linkage capture camera, When the dynamic deflection exceeds the threshold set for the corresponding level, record the deflection of the bridge when the heavy vehicle crosses the bridge, and capture the image when the heavy vehicle crosses the bridge. The bridge adopts the capturing system and monitoring deflection linkage to capture and record heavy vehicles. The results are as follows:

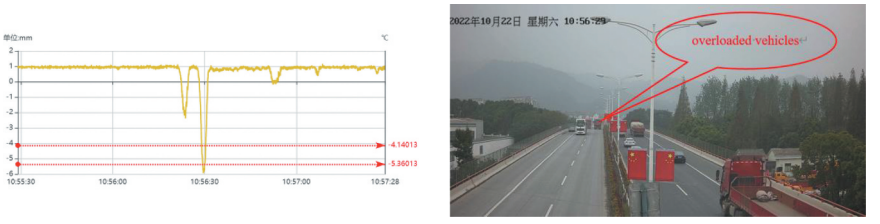

Figure 8. Real-time capture of early warning at 10:56:29 on October 22, 2022.

4.4.3 *Early warning statistical*

For this bridge, According to the statistical data from October 18, 2022 to November 17, 2022, A total of 203 first-level warnings and 764 second-level warnings have been monitored. The results are as follows:

(a) Statistics Results of Level I Early Warning

(b) Statistical Results of Level II Early Warning

Figure 9. Statistics of early warning results.

4.5 *Data analysis*

4.5.1 *Statistical analysis*

Conduct statistical analysis on the alarm data from October 18, 2022 to October 25, 2022, The results are shown in the following figure.

For this bridge, Based on the following statistical data, it can be inferred that:

(1) Only 8 days from October 18, 2022 to October 25, 2022, The number of alarms has reached 470 times, with frequent alarms. According to the results of the scene capture, the cause of alarm was caused by heavy-duty truck. Frequent alarm in a short period of time can easily lead to fatigue of in-service structure, seriously affect the durability and then affect its bearing capacity.
(2) According to the monitoring statistical results, there are often alarms in the evening, indicating that there are still excessive loads crossing the bridge at night.
(3) Since October 23, 2022, the number of alarms has significantly decreased, indicating: Based on the monitoring data of the system, reasonable control and guidance measures can effectively suppress overloading.

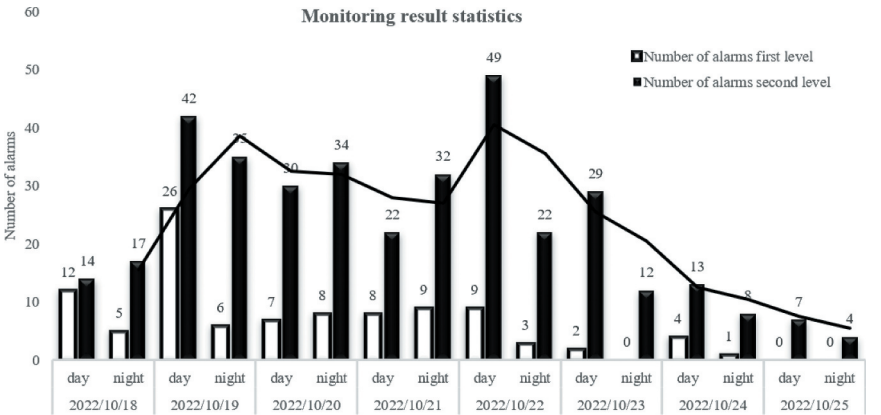

Figure 10. Statistical analysis of monitoring results.

4.5.2 *Trend analysis*

Based on the system monitoring and early warning data from October 18, 2022 to November 17, 2022, Trend analysis was conducted on the "Level one alarm" data, and the results are as follows:

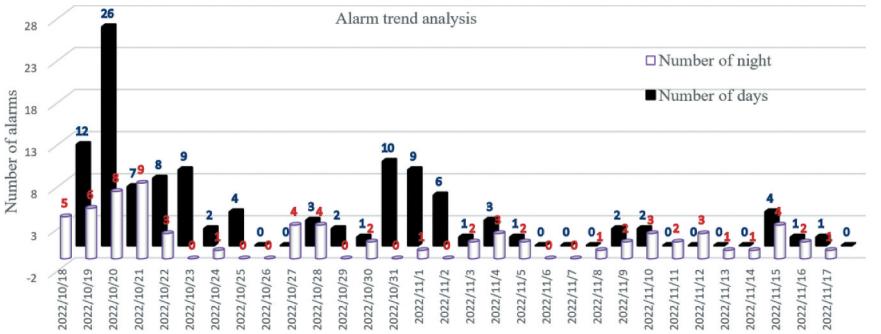

Figure 11. Alarm trend analysis.

Based on the trend analysis results of early warning data, it can be inferred that:

(1) Starting from October 23, 2022, on-site control measures will be taken, From October 23 to October 29, the number of first-level alarms during the day and night decreased significantly, with the maximum number of alarms being 4 and the minimum number of alarms being 0; However, during the period from October 30th to November 1st, the situation was abnormal, with the maximum number of alarms reaching 10.

(2) Starting from November 2nd, on-site control will be strengthened, From November 2nd to November 17th, The number of alarms has significantly decreased, the maximum number of alarms is 4 times, the minimum number of alarms is 0 times, However, during this period, there was an obvious trend of more alarm times at night than in the day, indicating that the overload at night was more serious than in the day, and overload control at night was relatively severe.

4.5.3 *Analysis of occurrence interval*

In order to understand the concentrated time range of overload occurrence, Perform interval probability statistical analysis on the overload data after control (October 23rd to November 17th), and obtain the time range of concentrated overload occurrence. The analysis results are as follows:

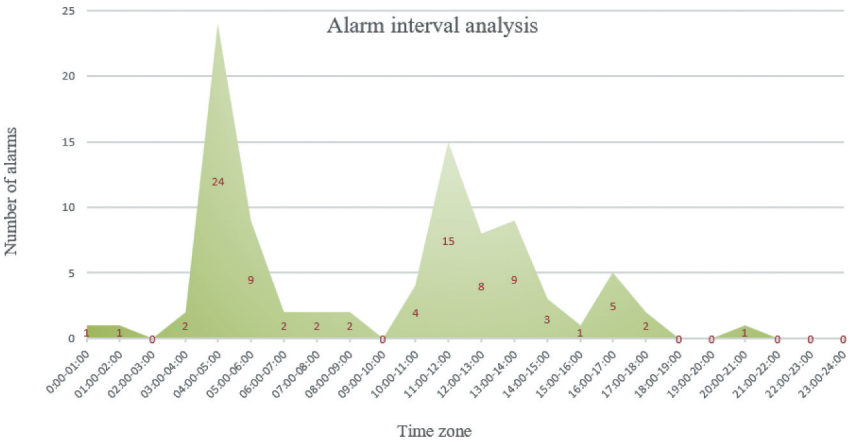

Figure 12. Analysis of overload occurrence interval.

Based on the above analysis results, it can be inferred that: Overloading is prone to occur between 04:00~06:00 and 11:00~14:00, The number of overloads that occurred between 04:00 and 06:00 reached 33, accounting for 36.3% of the total number of overloads, The number of overloads that occurred between 11:00 and 14:00 reached 32, accounting for 35.2% of the total number of overloads, They account for 71.5% of the total overload times.

5 CONCLUSION

This article is based on the self-developed health monitoring system for small and medium-sized span bridges, Real bridge application research on real-time dynamic safety monitoring of small and medium span Bridges is carried out, The rationality, practicability and advancement of this system applied to real bridge are discussed. The main conclusions are as follows:

(1) The R&D system can accurately capture the effects that cause the structure to respond beyond the limit, Real-time early warning for emergencies;
(2) Monitoring and analysis results can effectively guide the scientific management of real bridge, For example, the conclusion that the overload of bridge is serious (470 overload times in only 8 days), the increase trend of overload at night, and the occurrence of overload is easy to occur at 04:00~06:00 (36.3% probability) and 11:00~14:00 (35.2% probability) can timely and effectively guide the field scientific management.
(3) Using displacement monitoring big data, real-time statistical analysis is made on the change trend of the monitoring deflection value, the analysis results can be used to infer the trend of structural stiffness changes, and then determine the change law of the structural bearing capacity, providing data support for the safe operation of small and medium-sized span Bridges.

Enhancing structural performance evaluation of PC girder bridges through Bayesian model updating

D.B. Chen & C.W. Kim
Department of Civil and Earth Resources Engineering, Graduate School of Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: This study aims to improve the evaluation of structural performance in prestressed concrete (PC) girder bridges by employing a calibrated FE model. This is achieved through Bayesian model updating, utilizing measured responses in the elastic stress state. Bayes' theorem is employed to quantify uncertainties in FE model parameters by inferring the joint posterior probability density function (PDF). The Transitional Markov Chain Monte Carlo (TMCMC) sampler is utilized to generate samples for estimating the posterior PDFs of model parameters. The selection of a suitable model class is guided by sensitivity analysis of model parameters and a comprehensive discussion of the updating outcomes from linear models. The nonlinear static simulation results obtained through the calibrated model are rigorously compared with the measured crack pattern and load-deflection curve to validate the effectiveness of Bayesian model updating. Observations showed that structural damage resulting from concrete cracking minimally affects the 1st bending frequency. Consequently, vibration characteristics exhibit specific limitations in their application for assessing damages caused by concrete cracking. The proposed high-fidelity model updating approach, driven by multi-source data, establishes a reliable digital twin model suitable for SHM of PC bridges.

1 INTRODUCTION

The proportion of bridge infrastructures in Japan that have been in service for over 50 years is experiencing a rapid increase. Approximately 45% of existing bridges in Japan adopt prestressed concrete (PC) (Road Bureau 2020). Instances of deterioration, such as inadequate grout filling, corrosion, and rupture of PC tendons, have been documented. Many aging PC bridges necessitate inspection and maintenance to address potential degradation damages. However, lack of experienced inspectors and the rise in maintenance costs pose inevitable challenges in bridge maintenance. Consequently, there is an urgent need to develop a quantitative method for evaluating the structural integrity of these aging bridges. To this end, obtaining validated finite element (FE) models is crucial for bridge health monitoring and inspection. In contrast to direct model calibration, data-driven model updating based on Bayesian inference methods may offer a promising way to acquire validated models.

In recent years, Bayesian model updating has gained prominence owing to its ability to derive posterior probability density functions (PDFs) for model parameters. Beck and Katafygiotis (1998) formulated the Bayesian model updating framework, encompassing model class selection for structures and probability models for characterizing system errors. Subsequent investigations in this domain have been pursued by other researchers. The Bayesian model updating approaches have found application in reliability analysis and damage detection

DOI: 10.1201/9781003483755-99

across numerous instances, encompassing both laboratory experiments and real-world engineering structures (Zhou et al. 2022).

Given the limitations inherent in the one-dimensional (1D) beam model, Yoshida et al. (2021) recommended employing an FE model capable of simulating three-dimensional (3D) features when assessing the load-carrying capacity of PC girder bridges. Due to continuous advancements in computational performance, the creation of geometric digital twin models faithfully replicating intricate structural features has become achievable. Furthermore, studies on advanced 3D numerical modeling, incorporating Bayesian model updating techniques, are of great importance for the realization of a physical digital twin.

2 METHODOLOGY

2.1 *Bayesian model updating framework*

The posterior PDF of the uncertain parameter vector θ ($\theta \in \mathbf{R}^{N_\theta}$) conditioned on the system response D and specific model class M can be expressed as Equation (1).

$$P(\theta|D, M) = \frac{P(D|\theta, M)P(\theta|M)}{P(D|M)} \tag{1}$$

Under the assumptions that the measurements D_k (for k=1, …, n) are independently and identically distributed (iid), and that the error term $\boldsymbol{e}$ between the observation and the model prediction follows a zero-mean Gaussian distribution with fixed variance, the likelihood function for model updating is expressed as Equation (2).

$$P(D|\theta, M) = \prod_{k=1}^{n} P(D_k|\theta, M) = ce^{-J(\theta)/2\sigma^2} \tag{2}$$

where $J(\theta)$ denotes the goodness-of-fit function used to minimize errors as shown in Equation (3).

$$J(\theta) = \sum_{i=1}^{N_m} \left((1 - \langle \varphi_i(\theta), \hat{\varphi}_i \rangle)^2 + \left(1 - f_i(\theta)/\hat{f}_i\right)^2 \right) + \sum_{i=1}^{N_d} \left(1 - \delta_i(\theta)/\hat{\delta}_i\right)^2 \tag{3}$$

where $f_i(\theta)$ and $\varphi_i(\theta)$ represent the frequencies and mode shapes derived from the eigenvalue analysis using FEM, respectively; $\hat{f}_i$ and $\hat{\varphi}_i$ denote the measured modal properties obtained from the experiment, respectively; $\delta_i(\theta)$ and $\hat{\delta}_i$ denote the simulated deflection using FEM and the measured deflection, respectively.

2.2 *Computational tool*

In practical applications with multiple parameters, the computation of joint and marginal PDFs often involves solving high-dimensional integrals, making sampling methods a common choice. In this study, the Transitional Markov Chain Monte Carlo (TMCMC) algorithm is employed to estimate the parameters of the FE model by generating samples from the posterior PDFs of model parameters. The principle of TMCMC involves generating intermediate PDFs in a series that progresses from the prior PDF to the posterior PDF (Ching & Chen 2007). The transitional distributions are defined as presented below.

$$P^j \propto P(\boldsymbol{D}|\boldsymbol{\theta})^{\beta_j} \cdot P(\boldsymbol{\theta}) \tag{4}$$

where j denotes the transition step number, and β_j signifies the tempering parameter, which takes values such that $\beta_0 = 0 < \beta_1 < \beta_2 < \cdots < \beta_m = 1$.

3 EXPERIMENT ON PC BOX GIRDER

3.1 *Specimen design*

The test specimen prototype is a post-tensioned PC box girder bridge, designed according to the specifications for highway bridges. As illustrated in Figure 1, the specimen represents a 1/2 scale simply supported box girder with a span length of 7.5 m and a girder height of 1000 mm. The prestressing tendons positioned on the web (No. 1 to No. 6 in Figure 1(c)) curve upward at the beam's end, while the prestressing tendons located on the bottom plate (No. 7 in Figure 1(c)) are arranged in a straight line.

(b) deflection diagram (P=446 kN)

Figure 5. Experimentally measured deflection.

3.2 *Static loading and vibration test*

As shown in Figure 1, the specimen was subjected to a four-point concentrated static load. Displacement transducers were placed at the five equidistant points along the span. The loading procedures, illustrated in Figure 2, involved four distinct phases: initial cracking load (Load 1), shear cracking load (Load 2), stirrup yield load (Load 3), and ultimate load (Load 4). To assess vibration characteristics simultaneously, three vibration tests (St. 1~3) were conducted. Ten accelerometers, each with a sampling frequency of 2000 Hz, were positioned at the six equidistant points of the span, with five accelerometers on each side. The specimen was excited with an impact hammer, and the same excitation was replicated ten times at each accelerometer position. Figure 3 shows the photo of the static loading test.

The modal parameters for the first two bending modes are shown in Figure 4, which are extracted from the frequency response function (FRF) using acceleration data measured at St. 1. The load-deflection curves measured experimentally, along with the deflection diagram illustrating measurements under a 446-kN load, are presented in Figure 5. At this load level, the PC girder stays within its elastic stress range.

4 MODEL UPDATING

4.1 *Finite element model*

A three-dimensional (3D) finite element (FE) model is established using Diana 10.6 for model updating, as shown in Figure 6. The concrete beam is modeled using 8-node hexahedral solid elements, while rebars and prestressing tendons are represented by line elements embedded in the concrete, assuming a perfect bond between the reinforcement and the surrounding concrete. Rotational and translational constraints at supports are included using springs, as illustrated in Figure 7. To address the influence of the self-weight of the steel loading beam on the free vibration of the PC girder during the vibration test, additional concentrated masses are introduced at the loading points.

4.2 *Sensitivity analysis*

Potential candidates for updating parameters include modulus of elasticity of concrete (E_c), mass density of concrete (ρ_c), modulus of elasticity of rebar (E_r), modulus of elasticity of prestressing tendon (E_p), spring constant of rotational spring (K_r) and spring constant of translational spring (K_t).

The results of the sensitivity analysis revealed that the modulus of elasticity and mass density of concrete significantly affect the frequencies. Nevertheless, these two parameters hardly

affect the Modal Assurance Criterion (MAC), a normalized measure employed to evaluate the similarity between two mode shapes. The modal parameters are insensitive to changes in the modulus of elasticity of the rebar and prestressing tendon.

It is noted that increasing the spring constants of both rotational and translational springs at supports will lead to higher frequencies. However, the experimentally measured frequencies for bending modes were smaller than those simulated using the initial FE model. Therefore, careful consideration should be given to the decision of whether to employ springs or not to the supports in the eigenvalue analysis.

Deflection is exclusively responsive to variations in the modulus of elasticity of concrete, with density changes exerting no influence. Moreover, deflection remains largely unresponsive to shifts in the modulus of elasticity of the rebar and prestressing tendon. The addition of rotational and translational springs to the boundary conditions has only a marginal effect on deflection, unlike the modal parameter.

Based on the sensitivity analysis results, the selected uncertain parameters for the model update comprise the modulus of elasticity of concrete (E_c), mass density of concrete (ρ_c), spring constant of rotational spring (K_r), and spring constant of translational spring (K_t).

4.3 *Model class selection and updating scenarios*

This study explores three model classes: M_1, characterized by four parameters (E_c, ρ_c, K_r, K_t), M_2, distinguished by three parameters (E_c, ρ_c, K_r), and M_3, defined by two parameters (E_c, ρ_c). The model responses employed for model updating are categorized into two groups. Exp 1 incorporates the frequencies and mode shapes of 1st and 2nd vertical bending modes (Figure 4) into the goodness-of-fit function. Meanwhile, Exp 2 includes the frequency and mode shape of the 1st vertical bending mode, along with elastic deflection (Figure 5 (b)), in the goodness-of-fit function.

Note: Exp.: Experimental, Upd.: Updated.
R: Rotational spring, T: Translational spring, 1: Indicates the use of springs, 0: Indicates no use of springs.
e.g. Exp1_R1_T1 indicates that the model utilizes both rotational and translational springs, incorporating the frequencies and mode shapes from Exp 1 scenario into the goodness-of-fit function.

4.4 *Model updating results*

Table 1 compares the most probable values (MPVs) of model parameters and their corresponding reference values. Furthermore, Table 2 provides a summary that includes both experimentally measured responses and simulated responses obtained by applying the MPVs of model parameters. The 1st. Freq (MAC) and 2nd. Freq (MAC) in Table 2 correspond to the 1st and 2nd bending modes, respectively. Additionally, the 3rd. Disp and 4th. Disp represent the deflection data measured by the 3rd and 4th sensors, as illustrated in Figure 5 (b). As an illustrative example, Figures 8 and 9 display histograms of samples for scenarios Exp1_R1_T1 and Exp2_R0_T0.

It is inferred that the identification error for the 2nd bending mode is relatively large compared to the 1st bending mode. The potential sources of this error can be attributed to two factors. Firstly, the specimen's cross-sectional dimensions are scaled in alignment with the static experiment, resulting in a significantly large overall bending stiffness for the main girder. Consequently, the higher stiffness leads to elevated frequencies, making it more challenging to induce vibration during the experiment. Secondly, environmental noise has exhibited a noticeable impact on the vibration characteristics.

Owing to the notable disparity between the observed modal parameters for the 2nd bending mode and the computed values from the FE model, the MPV values for the concrete's modulus of elasticity and the mass density in the calibrated models of three Exp 1 scenarios substantially deviate from their reference values.

The utilization of static-dynamic data, encompassing the 1st bending mode and elastic deflections, in the model updating process for the three Exp 2 scenarios has yielded accurate estimates of material parameters that closely align with the reference values. Furthermore, the computed responses from the calibrated model exhibit excellent agreement with the measured data.

Upon comparing the updated results of the three Exp 2 scenarios, it can be concluded that the additional constraints at the supports have a negligible effect on the model responses compared to the material properties. This is attributed to the consistency of the boundary conditions in the 3D FE model with the experiments, in contrast to the 1D beam model, which simplifies the constraints at the supports. Therefore, the calibrated FE model in scenario Exp2_T0_R0, characterized by its adoption of the simplest model class, is utilized for subsequent analysis and discussion.

4.5 *Structural performance assessment using the calibrated FE model*

Model-based structural health monitoring (SHM) requires high-fidelity FE models to accurately predict the performance of structures throughout their service life. Following the Bayesian model updating with measured data from the elastic stress state, the calibrated FE model is then utilized for assessing structural performance in subsequent states. It is crucial to validate the model's effectiveness in capturing nonlinear stress states to ensure the reliability of the model updating process.

Table 3 presents a comparison of 1st bending frequencies obtained from both the experiment and the calibrated FE model across intact (St.1) and cracked (St.2 and St.3) states. The table incorporates the frequency response function (FRF) and Bayesian operational modal analysis (BAYOMA) as two distinct methods employed for identifying modal parameters

based on measured acceleration signals. It has been discovered that structural damage resulting from concrete cracking has minimal impact on the 1st bending frequency. The calibrated model, using measured data from St.1, accurately calculates the frequencies of post-cracking states.

The nonlinear behavior of concrete is described using the total strain crack model with the Maekawa cracked concrete curves (Maekawa et al. 2003), as illustrated in Figure 10. Additionally, the uniaxial stress-strain curves of rebars and prestressing tendons are characterized by the simplified quadratic plastic flow model and trifold elasto-plasticity model, respectively.

Figure 11 and Figure 12 show a compassion of measured and simulated crack patterns and load-deflection curves, respectively. The simulation results generated by the calibrated FE model demonstrate a favorable alignment with the experimental outcomes. This underscores the capability of the FE model, updated by the model responses of the elastic state, to accurately predict the nonlinear structural responses of PC girders. As a result, it establishes a reliable digital twin model suitable for SHM.

5 CONCLUSIONS

This study proposes a new approach to improve the structural performance assessment of PC girder bridges using a Bayesian model updating method. A high-fidelity 3D FE model was developed, and its parameters were updated based on measured responses in the elastic stress state. The selection of an appropriate model class was informed by sensitivity analysis of model parameters and a comprehensive discussion of linear model updating outcomes. Our findings demonstrate that the calibrated FE model exhibits notable efficacy in predicting nonlinear structural behavior, particularly in capturing crack patterns and bending stiffness. As a result, it serves as a reliable digital twin model for SHM applications in PC girder bridges. Additionally, our case study reveals that structural damage induced by concrete cracking has minimal impact on the 1st bending frequency, and operational modal parameters are susceptible to noise interference, thereby highlighting specific limitations in their applicability for model updating purposes.

Framework of UAV bridge inspection with computer vision and deep learning

Kuan Yen & Chia-Ming Chang
Department of Civil Engineering, National Taiwan University

ABSTRACT: Bridge integrity is one of the most critical issues for infrastructure. Natural disasters or aging problems can cause damage to the structure and even affect safety, while regular inspection is one practical approach to affirm the current conditions of bridges. Because sophisticated inspectors are short with respect to the number of bridges, traditional visual inspection should be improved to be efficient and address the drawbacks of being time-consuming and labor-intensive. Additionally, specific bridge components have accessibility problems for inspection, e.g., abutments and bottom of bridge decks. Unmanned aerial vehicles (UAVs) have significantly enhanced the efficiency of bridge inspection in recent years. Therefore, this study proposes a systematic framework for bridge visual inspection utilizing UAVs in conjunction with deep learning and computer vision. This framework involves image localization, defect recognition, and damage quantification as three sequential tasks in bridge visual inspection. By shooting azimuths and camera-to-objective depths, bridge surface images captured from UAVs can be localized from the camera coordinates to the global coordinates (e.g., aligned with the GPS coordinates). Then, the defects on a bridge are detected by a deep learning model featuring instance segmentation, which enables cracks, spalling concrete areas, and exposed reinforcements to be highlighted in images. These images are also tagged with a point of interest and linked to the global coordinates. Moreover, the geometric parameters of these defects can also be interpreted through photogrammetry based on available azimuth and depth, and these defects are consequently quantified. An example using the proposed framework for bridge visual inspection is provided in this study for demonstration. As shown in the results, this framework further improves the efficiency of bridge inspection with added information, such as the three-dimensional locations, types, and geometric quantities of defects.

1 INTRODUCTION

Bridge inspections are crucial for maintaining the integrity and safety of infrastructure. Traditionally, these inspections have relied mainly on manual visual assessments, which, while fundamental, present several limitations (Moore et al., 2001). The efficiency of these inspections is often hampered by the subjectivity inherent in human judgment, insufficient inspection capacity due to a shortage of qualified personnel, and the visual limitations of manual inspections. These factors contribute to a lack of accurate and complete data collection, challenging the integrity of historical data. However, advancements in AI, as shown by Yoshikura et al. (2022), have the potential to address these limitations. Moreover, the manual approach is labor-intensive and time-consuming, compounding the high bridge maintenance and repair costs.

In recent years, Unmanned Aerial Vehicles (UAVs) have emerged as a significant innovation in bridge inspection practices (Gong et al., 2023), offering several advantages over traditional methods (Kim and Irizarry, 2020). UAVs provide superior three-dimensional mobility, enabling access to hard-to-reach areas of bridges, such as abutments and the underside of bridge decks. These UAVs are also capable of digitizing collected data, which enhances the efficiency of inspections and reduces costs and traffic disruptions. The ability to operate autonomously and capture

DOI: 10.1201/9781003483755-100

high-quality images from various angles represents a considerable leap forward in bridge inspection techniques using UAVs, allowing for more comprehensive and less intrusive inspections.

Integrating Artificial Intelligence (AI), particularly deep learning, in bridge inspections marks a transformative step in identifying and quantifying structural defects (Zhou et al., 2022). AI algorithms, trained on extensive datasets of bridge images, have demonstrated remarkable proficiency in detecting a broad spectrum of bridge defects, such as cracks, spalling, and exposed rebar (Liu et al., 2022; Munawar et al., 2022). This technology not only surpasses the limitations of human visual inspection in terms of accuracy and objectivity but also provides a quantitative basis for assessing the severity and extent of detected defects. This advancement in defect detection is crucial for effective bridge maintenance, facilitating the prioritization of repair efforts based on the severity of the detected defects.

This study contributes to the evolving field of bridge inspection by proposing a comprehensive framework that synergizes UAV technology with advanced computer vision and deep learning techniques. By employing UAVs for data collection and utilizing AI for defect detection and quantification, this framework addresses the challenges of traditional inspection methods (Savino and Tondolo, 2022) and enhances the overall efficiency, safety, and cost-effectiveness of bridge inspections. The study demonstrates the practical application of this framework through detailed case studies, highlighting its effectiveness in real-world scenarios. This integrated approach streamlines the inspection process and aligns with standard inspection protocols, resulting in a valuable tool for bridge engineers and inspectors.

2 SMART BRIDGE INSPECTION FRAMEWORK

Through the integration of Unmanned Aerial Vehicles (UAVs) with advanced computer vision and deep learning technologies, the proposed method introduces a systematic approach to bridge inspection. This method is intended to address the limitations of traditional bridge inspection techniques, particularly in terms of efficiency, data accuracy, and accessibility.

2.1 *Framework of proposed method*

As shown in Figure 1, the framework for smart bridge inspection is proposed in this study. This framework consists of three main components: automated data collection with UAVs, establishing a bridge defects detection model using deep learning techniques, and connecting the detection results to a bridge assessment scale. By combining automated data collection, deep learning-based defect detection, and linking detection results to a bridge assessment scale, the proposed framework enables more efficient and accurate bridge inspections. Facilitating this framework reduces manual inspections, improves inspection coverage, and provides objective and quantitative information for better maintenance decision-making.

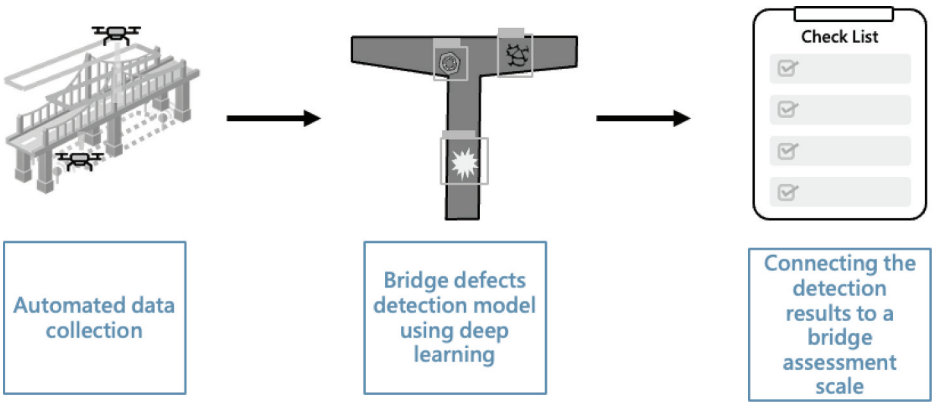

Figure 1. Smart bridge inspection framework.

2.2 *Data collection with UAV*

The first stage of the framework involves automated data collection using UAVs. UAVs are programmed to fly predetermined routes, capturing high-resolution images of various components from a bridge. Due to the lack of GNSS (Global Navigation Satellite System) signals under a bridge, a UWB network needs to be established to provide critical structural images of the beam, transverse diaphragm, and support (i.e., bearings) for the UAV. In this operational scheme, the establishment of the UWB positioning network consists of multiple UWB transmitters. These fixed-ground UWB transmitters create virtual GNSS coordinate signals to replace the real GNSS signals that may be unavailable due to structural obstruction. The relative coordinates are calculated and translated to the mobile aerial UWB, allowing the UWB device on the UAV to obtain absolute coordinates and complete spatial positioning.

This study chose to use open-source route planning software, i.e., the Mission Planner, as a tool for creating UAV-readable flight paths (Chintanadilok et al., 2022). Figure 2 shows the route planning procedure for UAV imaging acquisition, in which the images should contain the required scale and geometric transformations, coordinate data for subsequent safety assessment, and further plan the UAV's flight path. This study requires capturing images of the bridge deck, sides, and underside to establish a dataset for detecting bridge components.

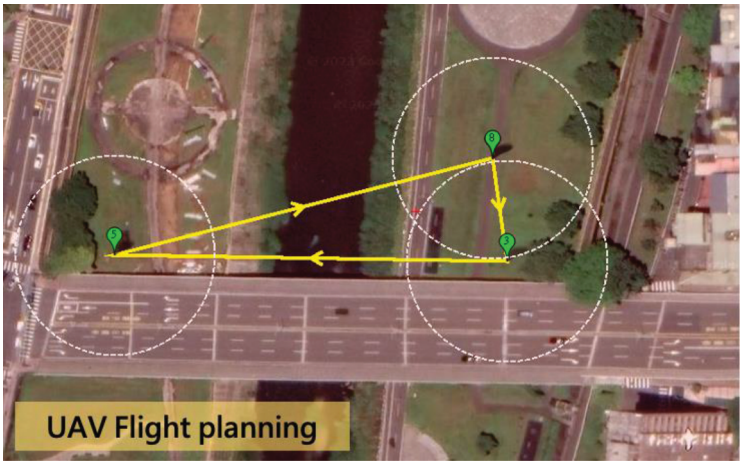

Figure 2. Flight route planning.

2.3 *Establish bridge defects detection model with deep learning*

This study primarily collects data through self-acquired sources and bridge inspection data provided by a consulting company. These sources include public datasets and self-collecting datasets. The public datasets mainly consist of street photos, including bridge images and are provided by the Mapillary Vistas (Neuhold et al., 2017). To be used in this research, only those images with clear and complete bridges are selected as training data. The self-collecting datasets are provided by the consulting sectors and mainly consist of images from previous manual inspections of bridges. In these datasets, over 10,000 bridge inspection images are included, e.g., steel bridges and concrete bridges, covering the important vehicle and pedestrian bridges and river crossings in Taipei City. Because this research targets concrete bridges, only concrete cracks, concrete spalling, and exposed rebar are considered as bridge defects. After selection, a total of 739 images featuring these defects, as shown in Table 1.

In this study, the bridge visual inspection deep learning model is constructed using the Detectron2 object detection library, which is open-sourced by Facebook Artificial Intelligence Research (FAIR) (Paszke et al., 2019). The model utilizes the Mask R-CNN

framework (He et al., 2018), and its hyperparameter settings are detailed in Table 2. These hyperparameters play a regulating role during the training process of deep learning. Specifically, the batch size refers to the number of training samples used for computing gradients and updating model weights through the loss function. The loss function evaluates the error between predicted results and actual observations, with the goal of minimizing this error to improve model accuracy. The learning rate controls the magnitude of weight updates, where it is multiplied by the computed gradient for weight updates. The optimization process of the model adjusts based on the value of the loss function. This study also adopts the warmup approach, which initially sets the learning rate to zero during training and gradually increases it to the default learning rate as the number of training iterations increases. The optimal combination of hyperparameters is usually determined through multiple experimental evaluations. Finally, the performance evaluation of the model uses the Average Precision (AP) metric, which is commonly used for object detection and instance segmentation. It comprehensively evaluates precision and recall at different thresholds and visualizes these data as a two-dimensional curve, with the area under the curve representing the AP value.

Table 1. Number of bridge defects datasets.

Types of defects	number	comment
Crack	300	Includes surface cracks on concrete piers.
Spalling	305	Deterioration of bridge structure and parapet

Table 2. Hyperparameter values.

Parameters	Value
Batch size	4
Learning rate	0.0001(warmup)
Epochs	1000 epochs

2.4 *Connection to the detection scale for identification results*

According to the 'Highway Bridge Inspection and Strengthening Specifications' in Taiwan, the widely adopted assessment standard is the D.E.R.&U. visual inspection. The assessment process of this criterion takes into account four main factors: "Degree," "Extent," "Relevancy" to bridge structural safety and serviceability, and "Urgency" of maintenance. These factors not only streamline the inspection work but also focus on critical components of the bridge and their impact on overall structural safety. D.E.R.&U. divides bridges into 21 inspection items and evaluates the degree of deterioration, scope, impact on safety, and urgency of maintenance, as shown in Table 3. Through integrating image processing, computer vision, and deep learning in artificial intelligence, this study has developed a specialized identification process for bridge components and defects. After analyzing the identification results, the specific location of the defect is determined. Based on the rating criteria set in the specifications, the corresponding DER&U value is calculated. Based on this value, an assessment of structural safety severity is conducted, and a classification of urgency is determined. The classification results will be used to prioritize inspection operations and prioritize the formulation of maintenance plans for more severe situations. After the identification stage, the study will conduct a thorough analysis of the D, R, and U values. Based on the reference values set in the specification table, the range and appearance features of the defect are

determined based on existing image data and past rating reports. Concrete DER&U values are provided for subsequent evaluation and management. Due to the significant differences in shape, size, color, and location of bridge components, it may be necessary for professional engineers to make rule adjustments or add exception judgment conditions based on specific situations to ensure the accuracy of identification in practical applications.

3 FIELD INSPECTION OF IN-SERVICE BRIDGE

This study selected the open field area of Pinghu No. 7 Bridge as the testing site. The total length of the bridge is 85 meters, with a maximum width of 12 meters and 2 lanes. The bridge has a total of 2 spans. The structure type is a beam bridge, where girders are prestressed concrete I-beams. Due to the lowest clearance height of 1.2 meters under the bridge, large machinery and vehicles are inaccessible, and UAVs are an excellent alternative for inspection.

3.1 *Prediction results of bridge inspection model*

This study employs deep learning techniques to analyze data obtained from unmanned aerial vehicle (UAV) inspections. The objective is to develop a Mask R-CNN segmentation model tailored for the visual detection of three distinct types of structural deficiencies in bridges: "cracks," "concrete spalling," and "exposed rebar." The model's performance is assessed based on the ability to identify and categorize these deficiencies from the UAV-collected imagery accurately.

Compared to traditional inspection methods, unmanned drone inspections have significant advantages. Not only does it reduce labor costs, but it also shortens maintenance and repair time. Drones can easily reach terrains and angles that are difficult for traditional inspections, as shown in Figure 3. Utilizing UAVs can comprehensively capture the perimeters of bridges, including the sides and railings that are difficult to inspect manually.

Figure 4 demonstrates the effectiveness of a deep learning model in detecting defects on bridges. This model can automatically pinpoint the specific defect locations. In Figure 4(a), a blue square is used to highlight the presence of cracks on a bridge pier. This type of defect is often overlooked during manual inspections, and the deep learning model becomes an invaluable tool. Figures 4(b) and (c) display spalling and exposed rebar. These defects are denoted by red and green squares. With the deep learning-based approach, these defects can be accurately identified without any subjectivity that may arise during manual inspections. By relying on data-driven machine learning algorithms, this method of defect identification offers more objectivity and accuracy, and more reliable results in bridge inspections are then successfully acquired.

Figure 3. (a) Visual inspection, (b) AI with UAV inspection comparison.

(a). (b). (c).

Figure 4. AI detection results of three defects.

3.2 *Bridge ratings based on deep learning results*

Take the example of Pinghu No. 7 Bridge to compare the use of UAVs combined with AI automatic deterioration recognition technology and manual visual inspection. The experimental results are shown in Table 4, which indicate that the automated deterioration recognition technology can provide comprehensive monitoring of the bridge from different angles and distances. It can also detect areas that cannot be reached by manual visual inspection, thereby compensating for the limitations of manual inspection.

As seen in Figure 5, visual inspection has limitations regarding angle and field of view, resulting in missing defects. On the other hand, the combination of unmanned drones and artificial intelligence offers high maneuverability and can detect more defects. Suppose the AI model has omissions or errors in recognizing certain defects. In that case, these data can be fed back to the model through human judgment and labeling, further improving the model's accuracy. Figure 5 presents the detection and assessment results for the Pinghu No. 7 bridge. The results show the quantitative values for each parameter (Degree, Extent, Relevancy, Urgency) for the components of the bridge. These values help determine the level of deterioration, the extent of deterioration, the impact on safety and functionality, and the urgency of maintenance required for each component. The higher the values, the more critical the component's deterioration is, indicating a higher urgency for maintenance. It necessitates assessments solely for elements exhibiting deterioration, thereby omitting evaluations for components in satisfactory condition.

4 CONCLUSIONS

This study developed an automated inspection framework using UAVs as patrol tools. In data collection, this research comprehensively assembled images of crucial bridge inspection components through a complete UAV flight planning process. The autonomous image collection was accomplished by UAVs using a UWB network. Through the Mission Planner, the UAVs can automatically operate and collect data along a predefined route. All the collected images were tagged with positions and recognition outcomes (i.e., defects, if any). Finally, these data and information were mapped to a bridge rating system, and the current condition of the bridge was determined. Moreover, the proposed framework was implemented on the Pinghu No. 7 Bridge. In the beginning, a UWB network was established through multiple UWB anchors and transmitters. A UAV with a consumer-graded camera was exploited to collect images over this bridge and also autopiloted using a predefined inspection route. A number of images were then collected and analyzed by a well-trained defect detection model. Various types of defects were identified and informed with locations. These detection results are finally interpreted by a rating system and converted into the DERU scores defined by the inspection code. As compared to the traditional approach, the proposed framework provided more detailed information and efficiency for bridge inspection.

College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Computer vision-based methods provide dense and accurate structural displacement measurements, countering the limitations of traditional contact-type sensors. However, storing the extensive data generated by full-field measurements, where each pixel acts as a sensor, poses a challenge. To address this, an optimal sensor selection strategy is proposed. First, the improved phase-based optical flow (IPBOF) method, which is resistant to illumination changes and phase wrapping, is used for displacement measurement. Subsequently, the obtained displacement matrix is decomposed into tailored bases through Singular Value Decomposition (SVD), and QR decomposition is then applied to determine the best pixels for reconstruction. The efficacy of the proposed method was verified using a laboratory video capturing the vibration of a 6-story building model. The results validate the method's ability to robustly reconstruct full-field dynamic displacement with high precision and a notable compression rate. This approach offers a solution to handle extensive data, retaining accurate full-field displacement information for long-term structural monitoring purpose.

1 INTRODUCTION

Structural displacement is an important indicator to assess the health condition of the structure. In the field of structural health monitoring (SHM), dynamic displacement signal can be utilized to obtain insights into the structural behavior and detect potential damage and risk of civil infrastructure at an early stage. Traditional displacement measurement approaches include linear variable differential transformer (LVDT), laser Doppler vibrometer (LDV) and global positioning system (GPS) (Celebi, 2000). LVDT requires one end to be being fixed on a stationary object as reference, which limits its application in actual practice. LDV can remotely measure the displacement with high resolution and accuracy but is restricted to limited measurement points and not cost-efficient. GPS is an indirect measurement approach and can provide the displacement signal without the need for a reference point. However, general GPS data can only provide centimeter level accuracy and a more accurate measurement, such as differential global positioning system (DGPS), usually comes at a high cost.

Over the past decade, computer vision-based structural vibration measurement has become a wide research topic with the rapid development of the computational hardware and the proliferation of high-quality low-cost cameras in the market. Compared to traditional sensors, vision-based approach is more cost-efficient and easier to instrument. Moreover, vision-based method provides the possibility of measuring the structural displacement remotely and densely. Each image pixel can be regarded as a virtual sensor, thus making the approach efficient for simultaneous multi-point measurement. Recently, Chen et al. (2015) developed the phase-based optical flow (PBOF) algorithm to estimate the displacement of a steel cantilever beam, which matched well with the reference provided by the laser vibrometer. The approach

DOI: 10.1201/9781003483755-101

was then successfully applied to measure the vibration of an antenna with a distance of over 175 meters in outdoor environment (Chen et al., 2017). Compared with the intensity-based methods, such as the Kanade-Lucas-Tomasi (KLT) tracker, the PBOF algorithm is more robust with respect to changes in contrast, scale, orientation, and speed (Fleet et al., 1990; Barron et al., 1992). The PBOF algorithm has been demonstrated to have the capacity of accurately measuring movements even with an amplitude of hundreds of times smaller than a single pixel (Diamond et al., 2017). However, conventional PBOF approach is prone to illumination changes and phase wrapping issue. Phase unwrapping techniques could potentially resolve this issue but require higher computational cost (Cai et al., 2023). Therefore, a more robust PBOF algorithm is urgently needed. In addition, since each pixel can be regarded as a virtual sensor, the full-field displacement data obtained using the PBOF algorithm requires a significantly large storage space, which is challenging especially for long-term monitoring.

To address these challenges, an improved phase-based optical flow (IPBOF) method and an optimal sensor selection strategy are proposed herein. First, the full-field displacement data is measured using the proposed IPBOF, which is invariant to illumination changes and phase wrapping. Subsequently, the displacement matrix is decomposed into a set of tailored bases using singular value de-composition (SVD), and the QR decomposition is applied to these tailored bases to determine the optimal number and locations of pixels that will be utilized for reconstructing the full-field displacement data. Finally, the tailored bases and the displacement data of the selected pixels are stored to compress the data size and facilitate full-field displacement reconstruction. The efficacy of the proposed approach was validated using a laboratory video capturing the vibration of a base-excited 6-story building model. The results demonstrated that the proposed method can robustly reconstruct the full-field dynamic displacement with high accuracy and compression rate.

2 METHODOLOGY

Figure 1 illustrates the workflow of the proposed vision-based displacement measurement and reconstruction method. This framework comprises two primary steps: vision-based full-field displacement measurement and optimal sensor selection for reconstruction. Further details for each step are elaborated below.

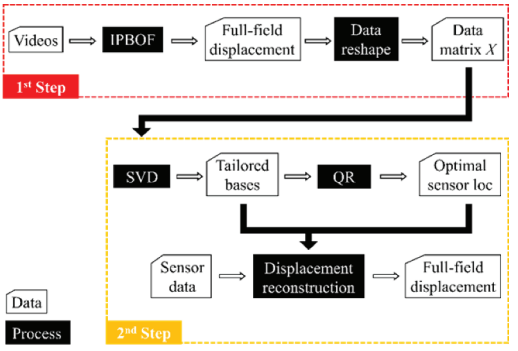

Figure 1. Workflow of the proposed vision-based displacement measurement and reconstruction method.

2.1 *Vision-based full-field displacement measurement*

Over the last decade, phase-based optical flow (PBOF) method has shown potential in measuring displacement up to a hundredth of a pixel. The PBOF is built on the theory that constant contours of the image local phase as a function of time correspond to the displacement signal, which can be expressed as

$$\phi_\theta(x, y, t) = c \tag{1}$$

where θ is a specified orientation at each pixel location (x, y) at time t, and c is the phase constant.

A quadrature pair of complex filters $G_2^\theta + iH_2^\theta$, where G_2^θ and H_2^θ have the same frequency response but differ in phase by 90°, is used to obtain the local phase information. The second derivative of a Gaussian function and its Hilbert transform approximation, as specified by Freeman et al. (1991), are employed herein for G_2^θ and H_2^θ, respectively. The video frame $I(x, y, t)$ is then spatially convolved with this nine-by-nine tap complex filter to obtain the amplitude $A_\theta(x, y, t)$ and phase $\phi_\theta(x, y, t)$ as

$$A_\theta(x, y, t)e^{\phi_\theta(x,y,t)} = \left(G_2^\theta + iH_2^\theta\right) \otimes I(x, y, t) \tag{2}$$

where (x, y) are the pixel locations, and t is the time index. By evaluating the filter $G_2^\theta + iH_2^\theta$ at $\theta = 0$, $\theta = \pi/2$ and substituting in Eq. (2), the local phase in the horizontal and vertical directions, respectively, are obtained.

The amplitude image, $A_\theta(x, y, t)$, contains edge strength information, while the phase image, $\phi_\theta(x, y, t)$, is sensitive to small motion. By differentiating Equation (1) with respect to time and setting the derivative in the orthogonal direction to zero, the local motion in pixels between two video frames can be expressed as

$$d_x(x, y, t) = \left(\frac{\partial \phi_0(x, y, t)}{\partial x}\right)^{-1} \frac{\partial \phi_0(x, y, t)}{\partial t} \tag{3}$$

$$d_y(x, y, t) = \left(\frac{\partial \phi_{\frac{\pi}{2}}(x, y, t)}{\partial y}\right)^{-1} \frac{\partial \phi_{\frac{\pi}{2}}(x, y, t)}{\partial t} \tag{4}$$

where d_x and d_y denote the local motions (velocities) in the horizontal and vertical direction, respectively.

However, conventional PBOF suffers from measurement error induced by possible illumination changes and phase wrapping. In response to these challenges, this study introduces an improved phase-based optical flow (IPBOF) algorithm. Initially, the mean intensity of each video frame within the region of interest (ROI) is standardized to mitigate the impact of uniform illumination changes. The ROI represents an m pixel area around each specific pixel location. In this context, the region size m is set at 9, aligning with the size of the complex filter utilized for convolution. The intensity adjustment process can be represented by

$$I'(x, y, t) = I(x, y, t) - [\bar{I}(t) - \bar{I}(1)] \tag{5}$$

$$\bar{I}(t) = \frac{\sum_{\mathrm{ROI}}[M(x, y) \cdot I(x, y, t)]}{\sum_{\mathrm{ROI}}[M(x, y)]} \tag{6}$$

where $\bar{I}(t)$ is the ROI mean intensity at time step t; M is a pixel mask employed to select areas with good contrast because displacement signals in textureless regions are usually noisy and should be discarded. Herein, the initial amplitude image $A_\theta(x, y, 1)$ is used to determine the pixel mask, which can be expressed as

$$\begin{cases} M(x, y) = 1 & \text{if } A_\theta(x, y, 1) \geq A_t \\ M(x, y) = 0 & \text{if } A_\theta(x, y, 1) < A_t \end{cases} \tag{7}$$

where A_t is the amplitude threshold set to be half of the median of the 30 pixels with the largest amplitude.

Subsequently, the phase information is obtained by spatially convolving the intensity adjusted images $I'(x, y, t)$ with the complex filter $G_2^\theta + iH_2^\theta$, as indicated in Equation (2). The phase derivatives $\partial\phi_0/\partial x$, $\partial\phi_{\frac{\pi/2}{2}}/\partial y$ and $\partial\phi_\theta/\partial t$ can be computed via

$$\frac{\partial\phi_0(x,y,t)}{\partial x} = angle\left(\frac{A_0(x+1,y,t)}{A_0(x,y,t)}e^{i[\phi_0(x+1,y,t)-\phi_0(x,y,t)]}\right) \tag{8}$$

$$\frac{\partial\phi_{\frac{\pi}{2}}(x,y,t)}{\partial y} = angle\left(\frac{A_{\frac{\pi}{2}}(x,y+1,t)}{A_{\frac{\pi}{2}}(x,y,t)}e^{i\left[\phi_{\frac{\pi}{2}}(x,y+1,t)-\phi_{\frac{\pi}{2}}(x,y,t)\right]}\right) \tag{9}$$

$$\frac{\partial\phi_\theta(x,y,t)}{\partial t} = angle\left(\frac{A_0(x,y,t)}{A_0(x,y,1)}e^{i[\phi_0(x,y,t)-\phi_0(x,y,1)]}\right) \tag{10}$$

where $angle(\cdot)$ is the four-quadrant inverse tangent operator. By computing phase variations before taking the inverse tangent operation, the proposed method can avoid potential phase wrapping caused by the intrinsic phase.

2.2 *Optimal sensor selection for full-field displacement reconstruction*

Vision-based sensors offer accurate and dense displacement measurements compared to conventional contact-type sensors. However, they possess larger dimensions and require more storage space for data. For instance, an image with a resolution of 1920×1080p encompasses 2,073,600 dimensions, as each pixel acts as a virtual sensor. Storing such large displacement datasets can pose challenges, especially in the context of long-term monitoring. To tackle this issue, an optimal sensor selection strategy is employed to compress the full-field displacement data by leveraging its sparse data structure. The high-dimensional full-field displacement $\mathbf{d}_t$ at time step t can be efficiently represented as a superposition of a set of structural vibration modes $\mathbf{\Psi}$, as illustrated below:

$$\mathbf{d}_t = \mathbf{\Psi}\mathbf{s}_t \tag{11}$$

where $\mathbf{d}_t$ represents an n dimensional displacement vector at time step t, $\mathbf{\Psi}$ is a $n \times n$ transformation basis containing all potential structural vibration modes, and $\mathbf{s}_t$ denotes an n dimensional sparse coefficient vector at time step t, wherein most elements are either zero or close to zero.

By discarding the structural vibration modes corresponding to zero or near-zero elements in the sparse vector, a $n \times r$ tailored transformation basis $\mathbf{\Psi}_r$ can be constructed. Consequently, Equation (11) can be reformulated as:

$$\mathbf{d}_t = \mathbf{\Psi}_r\mathbf{a}_t \tag{12}$$

where $\mathbf{a}_t$ is an r dimensional sparse coefficient vector at time step t that corresponds to the non-zero elements in $\mathbf{s}_t$.

Given that the tailored basis $\mathbf{\Psi}_r$ has a much lower rank compared to the original transformation basis $\mathbf{\Psi}$, retaining data from only r sensors (pixels) can significantly reduce the storage space for displacement data, as illustrated below:

$$\mathbf{y}_t = \begin{bmatrix} \mathbf{d}_{t,\gamma 1} & \mathbf{d}_{t,\gamma 2} & \cdots & \mathbf{d}_{t,\gamma r} \end{bmatrix} = \mathbf{C}\mathbf{d}_t = \mathbf{C}\mathbf{\Psi}_r\mathbf{a}_t \tag{13}$$

where $\mathbf{y}_t$ denotes the displacement data from the r selected sensor locations γ, $\mathbf{C}$ is a $r \times n$ sensor selection matrix.

With Equation (13), the full-field displacement vector $\mathbf{d}_t$ can be reconstructed as

$$\mathbf{d}_t = \mathbf{\Psi}_r(\mathbf{C}\mathbf{\Psi}_r)^{-1}\mathbf{y}_t \tag{14}$$

To robustly and accurately reconstruct the full-field displacement using Equation (14), the optimal determination of the tailored basis $\mathbf{\Psi}_r$ and sensor selection matrix $\mathbf{C}$ is crucial. According to the Eckart-Young theorem, singular value decomposition (SVD) offers the best least-squares approximation to the matrix reconstruction for a given rank r (Eckart & Young, 1936). Hence, the proper orthogonal decomposition (POD) modes $\mathbf{U}_r$ obtained via SVD of the full-field displacement matrix $\mathbf{D}$ can serve as the tailored basis $\mathbf{\Psi}_r$, as illustrated below:

$$\mathbf{D} = [\ \mathbf{d}_1 \quad \mathbf{d}_2 \quad \cdots \quad \mathbf{d}_t\ ] \approx \mathbf{U}_r \mathbf{\Sigma}_r V_r^T = \mathbf{\Psi}_r \mathbf{\Sigma}_r V_r^T \tag{15}$$

$$\sum_{i=1}^{r} \sigma_i / \sum_{i=1}^{n} \sigma_i > \varepsilon \tag{16}$$

where σ_i denotes the ith singular value of $\mathbf{\Sigma}_r$, and ε is the threshold used for determining the rank.

The determination of the sensor selection matrix $\mathbf{C}$ can be achieved by optimizing the condition number of the matrix $\mathbf{C\Psi}_r$ to ensure greater robustness in its pseudoinverse. However, direct optimization of $\mathbf{C\Psi}_r$ using its determinant or trace poses computational challenges. Manohar et al. (2018) demonstrated that QR decomposition with column pivoting can yield a near-optimal condition number, thereby providing r sensors that efficiently sample the tailored basis $\mathbf{\Psi}_r$,

$$\mathbf{\Psi}_r^T C^T = \mathbf{QR} \tag{17}$$

where $\mathbf{Q}$ is an orthogonal matrix and $\mathbf{R}$ is an upper triangular matrix.

Finally, with Equation (14) to (17), the n dimensional full-field displacement data can be reconstructed by using solely r dimensional sparse data.

3 VALIDATION

3.1 *Experimental setup*

A six-story shear building model with a weight of 2.8 kg per story, as shown in Figure 2, was employed for the validation. The model was affixed to a uniaxial shaking table and white noise excitation was applied to excite the model at both the beginning and end of the experiment. Modal frequencies for the first six modes were measured using accelerometers and recorded as follows: 1.657 Hz, 5.038 Hz, 8.138 Hz, 10.833 Hz, 12.930 Hz, and 14.339 Hz. The structural vibration was recorded using a DSLR camera with a resolution of 1570×430p and a frame rate of 59.94 fps.

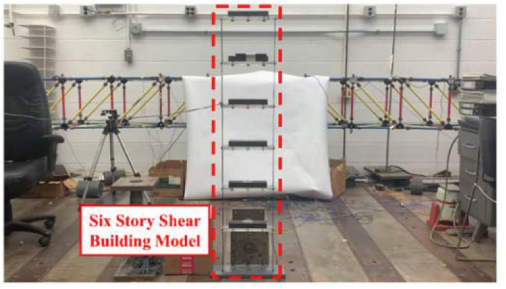

Figure 2. Six-story shearing building model used for laboratory validation.

3.2 *Experimental results*

The left column of the building model was selected, and its deformation was measured using the proposed IPBOF algorithm. The resulting valid measurement points consisted of 2925

pixels, and their corresponding displacement time histories are depicted in Figure 3. Subsequently, by conducting SVD on the obtained full-filed displacement matrix and truncating it a rank of six, the six POD modes can be generated and visualized as shown in Figure 4. Using Equation (17), the optimal sensor locations were determined through pivoting QR decomposition of the obtained tailored transformation basis. Figure 5 illustrates the distribution of the six optimal sensor locations and their corresponding displacement signals. The optimally obtained sensor positions closely match the positions on each story, aligning closely with the empirical judgment of civil engineers regarding sensor placements.

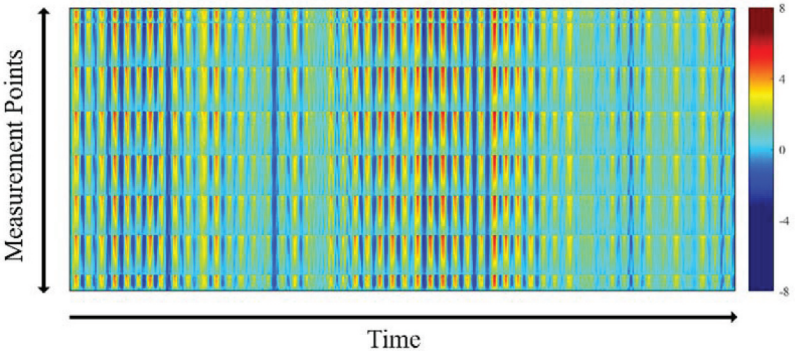

Figure 3. Visualization of the obtained full-field displacement matrix.

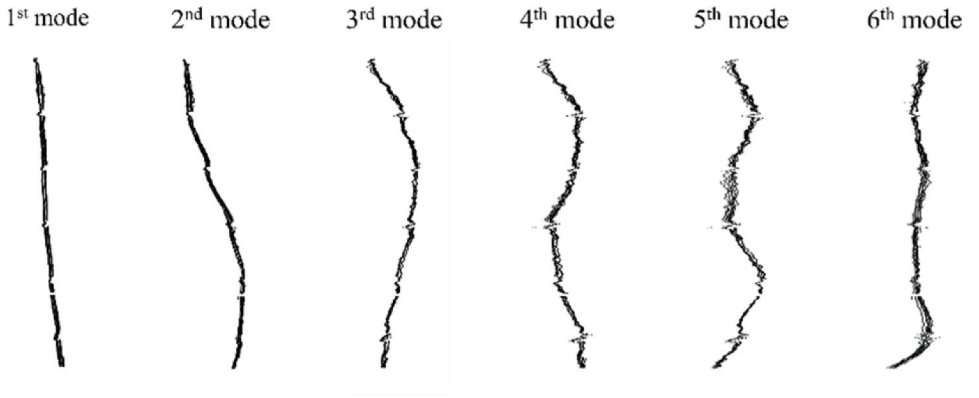

Figure 4. Visualization of the six POD modes.

To further assess the accuracy of the proposed displacement reconstruction method, the full-field displacement matrix is reconstructed utilizing the tailored basis and the displacement signals from the six optimal sensor locations, by employing Equation (14). Figure 6 shows the calculated reconstruction error and the average normalized root mean square error (NRMSE) yield a value of 1.07%. The results demonstrate the capability of the proposed method to compress high-dimensional displacement data at a remarkable compression rate of 0.33% while retaining a recovery rate of up to 98.93%.

4 CONCLUSION

This study presents an optimal sensor selection strategy to reduce storage space needed for full-field displacement data computed by the proposed improved phase-based optical flow

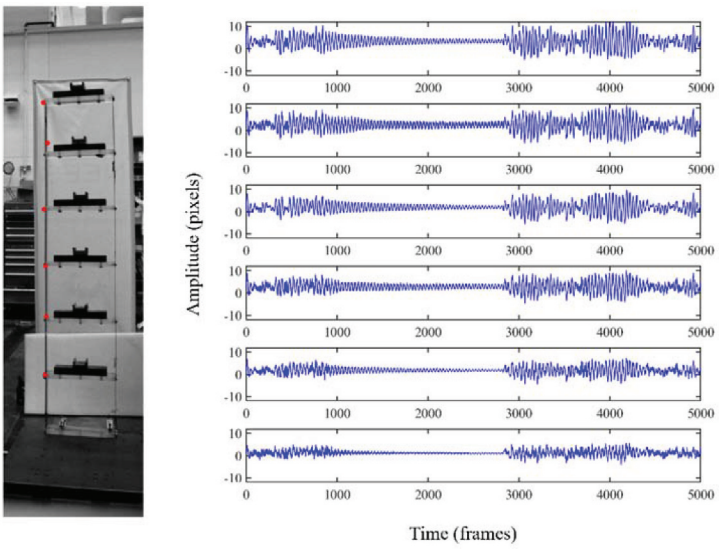

Figure 5. Six optimal sensor locations determined by the proposed method and their corresponding displacements.

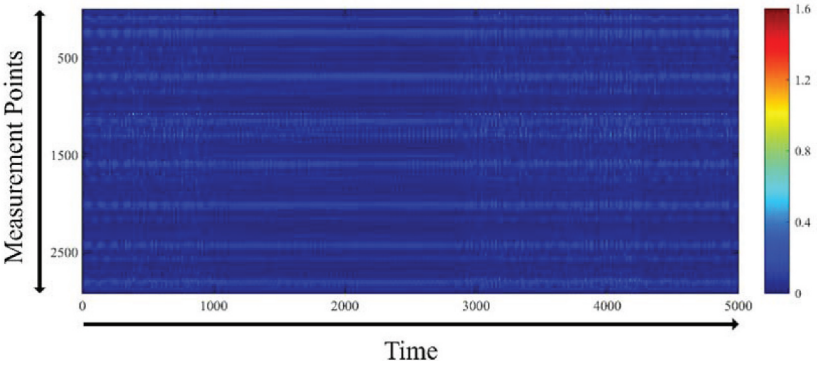

Figure 6. Full-field displacement reconstruction error.

(IPBOF) method. First, the method performs an SVD transformation on the full-field displacement matrix to construct a tailored transformation basis. Subsequently, a QR decomposition with column pivoting is used to determine the optimal sensor locations. Finally, the displacement signals of the selected pixels, as well as the tailored basis are stored and used to reconstruct the full-field displacement.

The effectiveness and accuracy of the proposed method are then verified using the video of a vibrating six-story shear building model in the laboratory. The results demonstrate the capability of the proposed method to compress high-dimensional displacement data significantly, achieving a compression rate of 0.33%, while retaining a recovery rate of up to 98.93%. Thus, the proposed method exhibits potential for vision-based long-term displacement monitoring.

Domain adaptation for bridge health monitoring via physics-informed generative adversarial learning

Liangfu Ge & Ayan Sadhu
Department of Civil and Environmental Engineering, Western University, London, Canada

ABSTRACT: Structural health monitoring (SHM) plays an important role in assessing bridge safety and detecting anomalies. However, significant discrepancies exist in the domain distribution of physical parameters between digital models and real structures. As a result, many bridge health monitoring theories struggle to be effective in practice, even if they perform perfectly in simulation. This paper proposes an unsupervised domain adaptation approach based on a physics-informed generative adversarial network (GAN), focusing on the mapping of structural responses for the mutual conversion between digital and physical models. To enhance the learning capability of the generative model for inherent characteristics of structures, physical constraints derived from the governing equations are incorporated in the time domain. Through a large number of free vibration tests on a simply supported bridge model, it was verified that the proposed approach can accurately complete the conversion between the measured responses and simulated responses in both time and frequency domains.

1 INTRODUCTION

Structural health monitoring (SHM) is essential for the safety management of infrastructure and cost-effective structural maintenance. Data from field measurement is the premise of SHM, but in most cases, obtaining sufficient data from real structures is labor-intensive and expensive. With this challenge, simulations are frequently employed, offering insights into potential structural behaviors across various scenarios. However, a notable obstacle in practical SHM is that the simulation data obtained by various theoretical models exhibits unpredictable discrepancies when compared with the measurements from actual structures, i.e., domain drifts. The domain drifts between simulation and real-world measurement often stem from modeling simplifications, variability in material properties, and impacts of the operating environment. Historically, model updating techniques have been favored to bridge these domain drifts for their clear physical interpretation (Ren & Chen 2010; Ferrari et al. 2019; Mao et al. 2020), however, they often requires iterative optimization, which can become computationally intensive as the complexity of structures increases. Also, these methods possibly get trapped in local optima when dealing with complex parameter spaces with limited experimental data.

Deep learning techniques (Seventekidis et al. 2020; Sony et al. 2021; Sony et al. 2022; Ge et al. 2023), which have recently garnered increasing attention due to exceptional robustness and generalization capability to real-world applications, provide another choice to cope with domain drifts of simulation and measurement. These approaches mostly adopt the strategy of exploring the parameter space in simulations, subsequently using the simulated data to train the latent mapping between observed responses and structural parameters. For instance, Yuan et al. (2023) trained a generative adversarial network (GAN) with simulated acceleration responses of a steel-concrete bridge tower under various combinations of structural parameters. The trained GAN was used to predict the structural parameter with the measured acceleration as input. Teng et al. (2023) generated digital twin models and their responses to random excitation force with different parameter distributions for the training of a damage

DOI: 10.1201/9781003483755-102

classification convolutional neural network (CNN). Similarly, Wang et al. (2021) successfully detected damages in a frame structure by using DenseNet trained from a simulated free vibration dataset. The aforementioned methods can predict the parameters of actual structures by leveraging computational results from numerous numerical models under different states. They can effectively bridge the domain drifts between simulations and measurements when the parameter range of the actual structure is determinable. However, the simulation using a large number of models with different initial parameters and even damage states requires a huge computational cost, rendering the training of deep learning models challenging to be finished within a practical timeframe.

Another strategy that has attracted significant interest recently is to conduct domain adaptation on the structural responses. Domain adaptation (DA) is a special case of transfer learning, which focuses on reducing the discrepancies between different data distributions from source and target domains (Singhal et al. 2023). For instance, Gardner et al. (2022) used a domain-adopted Gaussian mixture model for aligning frequency features in bridge data, while Wang & Xia (2022) developed a re-weighted adversarial domain adaptation network for finite element models. Similarly, Martakis et al. (2023) used Domain Adversarial Neural Networks for transferring simulation knowledge to real data for damage classification in building models. These methods have proven effective in aligning data distributions across domains and enhancing classifier performance on simulated data. However, they primarily function as "black boxes", labeling features without directly producing post-DA structural responses, which are essential for dynamic structural analysis.

Generative adversarial learning makes it possible for DA to present the changes in structural responses. Luleci & Catbas (2023) applied the Domain-Generalized Cycle-Generative model to perform DA on the responses of two prestressed bridge FE models with different parameters under the same excitation of Gaussian noise. The results showed that the translated bridge state has similar frequencies and mode shapes to the target bridge. Following this study, Luleci et al. (2023) modified the CycleGAN into a DA model for 1D time series and then employed it to translate acceleration responses from undamaged to damaged states. Gatti et al. (2023) applied a Representation GAN to simulate and assess the transient dynamic responses of shear-type multi-story buildings under earthquake loading, enabling accurate damage classification and severity assessment. The DA in these studies has achieved some success in the state translation among multiple FE models or varying states of a singular real structure. However, there is a very limited exploration of generative approaches to facilitate DA between simulated and actual structures, which can lead to more pronounced and unpredictable domain drifts.

Given the limitations identified in the above literature review, this research introduces an adapted CycleGAN. The proposed model uniquely integrates governing equations as physical constraints and the transformer for self-attention modules. Experiments show that the improvements not only offer better global feature extraction capability but also assures greater training stability compared to the original CycleGAN.

2 PHYSICS-INFORMED AND SELF-ATTENTION-ENHANCED CYCLEGAN

GANs are one of the most transformative ideas of deep learning that lie in two neural networks: the generator and the discriminator. They are used to generate samples with the input information and evaluate the generated samples, respectively. Specifically, the generator aims to produce synthetic data that the discriminator cannot distinguish from real data, while the discriminator aims to improve its ability to identify fake data. CycleGAN is a variant of traditional GAN to avoid the requirement of paired training data. CycleGAN can translate the datasets from two domains simutinously without labels, thus it is suitable for SHM applications where the data annotation is always costly. Different from GANs, the loss function of CycleGAN includes the adversarial loss $\mathcal{L}_{adv}$, cycle consistency loss $\mathcal{L}_{cycle}$ and identity loss $\mathcal{L}_{idt}$. For the mapping function $S(\cdot) : X \mapsto Y$ and its corresponding discriminator D_Y, $\mathcal{L}_{adv}$ can be expressed as (Zhu et al. 2017):

$$\mathcal{L}_{adv}(S, D_Y, X, Y) = \lambda_{aS}\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}\left[(D_Y(S(\ddot{x})) - 1)^2\right] + 0.5\Big(\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}\left[D_Y(S(\ddot{x}))^2\right] + \mathbb{E}_{\ddot{y}\sim p_{data}(\ddot{y})}\left[(D_Y(\ddot{y}) - 1)^2\right]\Big) \quad (1)$$

where λ_{aS} represents the weight for the adversarial loss of the generator S and $\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}$ denotes the expectation computed over all acceleration data in domain X that follows the statistical distribution $p_{data}(\ddot{x})$. The first term on the right side of Equation (1) is utilized for training the generator, while the second term is for training the discriminator.

The cycle consistency loss is for restricting the mapping functions to be cycle-consistent: for each acceleration sequence $\ddot{x}$ from domain X, the transformation cycle should be able to bring $\ddot{x}$ back to the original values, i.e., $\ddot{x} \to S(\ddot{x}) \to T(S(\ddot{x})) \approx \ddot{x}$, where $S(\cdot)$ and $T(\cdot)$ are mapping functions. Similarly, the domain adaptation from domain Y to domain X should also be cycle-consistent. To this end, $\mathcal{L}_{cycle}$ is given by:

$$\mathcal{L}_{cycle}(S, T) = \lambda_{cS}\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}[\|T(S(\ddot{x})) - \ddot{x}\|_1] + \lambda_{cT}\mathbb{E}_{\ddot{y}\sim p_{data}(\ddot{y})}[\|S(T(\ddot{y})) - \ddot{y}\|_1] \quad (2)$$

where λ_{cS} and λ_{cT} represent the respective weights for the cycle consistency losses.

The identity loss is designed to constrain the generator to retain the primary features of the input data while preventing unnecessary modifications. It is defined as:

$$\mathcal{L}_{idt}(S, T) = \lambda_{iS}\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}[\|S(\ddot{x}) - \ddot{x}\|_1] + \lambda_{iT}\mathbb{E}_{\ddot{y}\sim p_{data}(\ddot{y})}[\|T(\ddot{y}) - \ddot{y}\|_1] \quad (3)$$

where λ_{iS} and λ_{iT} are weights for the identity losses of S and T. Then, the training objective of CycleGAN is to minimize the sum of the above three loss fuctions.

CycleGAN may struggle to effectively learn the global features of input data, potentially leading to unstable training, when directly applied to long time series. Therefore, this paper introduces two improvements to the original CycleGAN: modifying the network architecture and updating the loss function. Figure 1 presents the network structure and the forward propagation process for the transformation from domain X to domain Y. The input to the generator is an N×C×L tensor from domain X, where N stands for the batch size, C for the number of channels, and L represents the length of the time series. The generator outputs a tensor of the same dimensions as the input, which is anticipated to align with the feature distribution of domain Y. The proposed model integrates an additional transformer encoder in the preliminary layers of both the generator and discriminator, enhancing the ability to learn global features. The transformer is noted for handling long-range dependencies in data without any significant loss in performance due to its self-attention mechanism (Vaswani et al. 2017). In addition, the transformer has flexibility regarding the length of the input time series. In this study, all the time series with a length of L are uniformly encoded into feature vectors of length 200 and noted as input embedding. To make use of the order of the time series and learn temporal dependencies, position encodings are separately assigned to each element of the input embedding using sine and cosine functions. The model uses a four-head attention module, followed by residual connections, normalization, and a dropout rate of 0.1. The transformer outputs embeddings going through convolutional blocks (ConvBlock), residual network blocks (ResNetBlock), and transpose convolutional blocks (TConvBlock), with the ReLU activation function replaced by LeakyReLU. The number of filters, convolution kernel size, padding, and stride are denoted as f, kz, p and s, respectively.

Besides the self-attention modules, the inclusion of a physical loss is the second highlight of the proposed DA model. For linear structural systems, the structural response can be obtained by modal superposition. The responses of the i^{th} mode $r_i(t)$ can be described by,

$$m_i\ddot{r}_i(t) + c_i\dot{r}_i(t) + k_i r_i(t) = p_i(t) \quad (4)$$

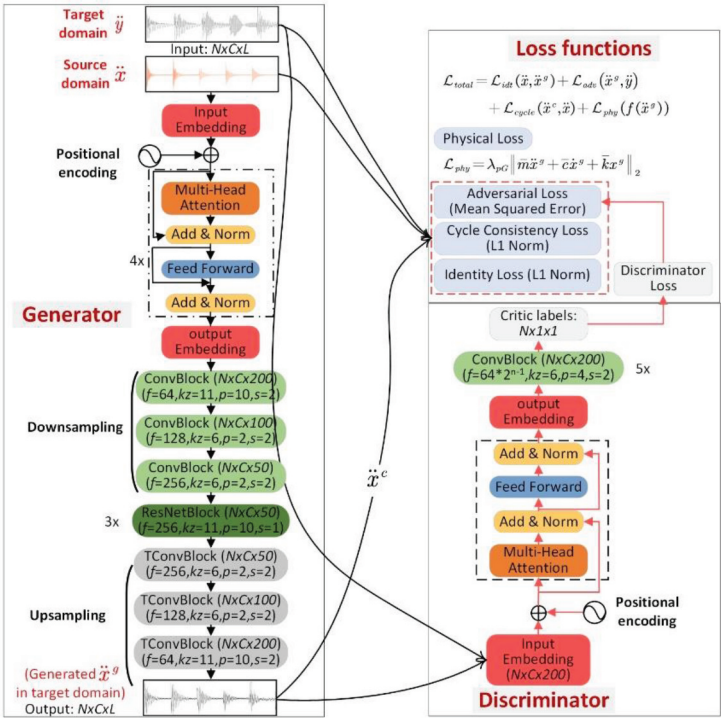

Figure 1. Structure of the single network from domain X to domain Y.

where m_i, c_i and k_i represent the modal mass, damping and stiffness, respectively, while p_i denotes the generalized force. In most cases, the structural response can be represented by the linear superposition of a few dominant modes. To describe the averaged effect of dominant modes, it is assumed that there exists an equivalent mode that satisfies

$$\bar{m}\ddot{r}(t) + \bar{c}\dot{r}(t) + \bar{k}r(t) = p(t) + \varepsilon(t) \tag{5}$$

In this equation, $\bar{m}$, $\bar{c}$ and $\bar{k}$ are equivalent parameters that are trainable in the DA model. $r(t)$ and $p(t)$ are the sums of the responses and generalized force of n dominant modes, i.e., $r(t) = \sum_{i=1}^{n} r_i(t)$ and $p(t) = \sum_{i=1}^{n} p_i(t)$. $\varepsilon(t)$ denotes the errors that can be physically regarded as a virtual time-varying force. The physical loss is to minimize $\|\varepsilon(t)\|_2$. For the free vibration, the $p(t)$ becomes zero. Then, by replacing $r(t)$ in Equation (4) with x, physical loss is defined as

$$\mathcal{L}_{phy}(S,T) = \lambda_{pS}\mathbb{E}_{\ddot{x}\sim p_{data}(\ddot{x})}\left[\left\|\bar{m}_S\ddot{x}^g + \bar{c}_S\dot{x}^g + \bar{k}_S x^g\right\|_2\right] + \lambda_{pT}\mathbb{E}_{\ddot{y}\sim p_{data}(\ddot{y})}\left[\left\|\bar{m}_T\ddot{y}^g + \bar{c}_T\dot{y}^g + \bar{k}_T y^g\right\|_2\right] \tag{6}$$

where λ_{pS} and λ_{pT} are weights respectively for the generator S and T. It should be noted that the displacement and velocity data in Equation (5) can generally be obtained through the integration of acceleration. Then, the total loss can be obtained by

$$\mathcal{L}_{total} = \mathcal{L}_{adv}(S, D_Y, X, Y) + \mathcal{L}_{adv}(T, D_X, Y, X) + \mathcal{L}_{cycle}(S,T) + \mathcal{L}_{idt}(S,T) + \mathcal{L}_{phy}(S,T) \tag{7}$$

3 EXPERIMENTAL VALIDATION

3.1 *Laboratory experiments for target domain dataset*

A simply supported beam with cantilevers at ends is selected for free-vibration tests. As shown in Figure 2, the test structure is a steel beam with dimensions of 2.49m × 20cm × 6mm and a 2.16 m distance between the supports. Six Opal wireless sensors are used for acceleration measurements. They are installed beneath the beam at positions of 1/6, 1/4, 1/2, 2/3, 3/4 and 5/6 spans, respectively, as shown in Figure 2(a) and (c) and are synchronized with a docking station before installation. The data streams from different sensors are transferred to the access point wirelessly and then recorded by the Motion Studio, a software suite bundled with the APDM monitoring system, as shown in Figure 2(b). The impact force was acted at around 5/12 span using a test hammer shown in Figure 2(d). A total of 100 repeated free vibration tests are carried out to obtain attenuation responses under different impact forces. The sampling frequency of accelerators is set as 128 Hz while the measurement range of $-2 \sim 2$g.

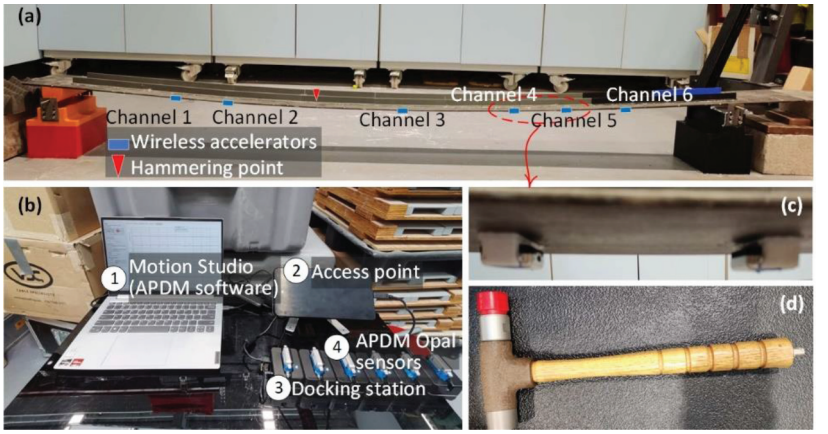

Figure 2. Experiment setup for the free vibration tests: (a) steel beam; (b) APDM system; (c) installed sensors; (d) test hammer.

Six measurement points are used to collect the vertical acceleration subjected to impact forces. The signals from different channels are well synchronized and exhibit typical patterns of free decaying. To eliminate the response segment during the contact period between the test hammer and the structure, the response at the mid-span is taken as the reference. The signal is truncated starting from the third peak, and the length of the signal is uniformly set to 3500 sample points. During the 100 repeated hammering tests, the magnitude of the applied force is left uncontrolled to reproduce unknown initial amplitudes of attenuation responses in real-world structures. However, for model training, it is still necessary to standardize the input responses to mitigate any adverse effects resulting from varying scales. Once again, Channel 3 is selected as the reference. The responses in Channel 3 from different tests are first individually normalized by dividing their maximum values, and then the responses of other channels are scaled by the same proportion. In this way, a dataset for the target domain is obtained, containing 100 sets of normalized time series from 6 channels in size of 3500×1.

3.2 *Numerical simulations for source domain dataset*

Real-world structures are generally regarded homogeneous with their FE models. The difference in data distributions between actual and simulated structures arise due to assumptions of material properties, boundary conditions and load patterns, etc. For the specific test beam, the FE model simplified it into a standard simply supported beam, omitting the cantilever at both ends. As shown in Figure 3, the model consists of 12 constant-sectional beam elements,

using an impulse force to simulate hammer loads. Six nodes are selected to analyze decaying responses responding to signals from six laboratory sensors.

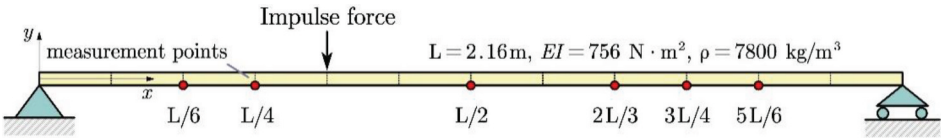

Figure 3. Finite element model of the simply supported beam.

The FE model is built with the parameters shown in the figure, incorporating Rayleigh damping with a damping ratio $\xi = 0.02$ for the first three modes. Acceleration responses are calculated using the Newmark β method at a 1/128 second interval, matching the sampling frequency of accelerators. The numerical simulation is also repeated by 100 times using the peak accelerations from Channel 3 as the impulse force for each iteration. To account for observational errors, white noise at levels of 1%, 5%, and 10% is added to the responses from the six channels, followed by normalization. This created a simulated dataset in the source domain with the same size as the measurements in the target domain data.

3.3 *Model training*

Experimental and FE simulation samples are used to train DA models. The proposed model enables bidirectional conversion between measurement and simulation domains in a single training session, benefiting from the idea of cycle consistency. To initially evaluate the correctness of the FE model and the distribution of simulated data, frequency analysis for structural responses in both domains is conducted. Table 1 presents the first three vertical bending frequencies of the test beam and the FE model with different bending stiffnesses. Their frequencies are shown close, indicating the modelling is reliable. However, as DA for such small differences is relatively easy and not ideal to demonstrate the performance of DA models, this section uses the FE model with 20% stiffness for the training and testing to increase the domain drifts.

Table 1. Modal frequencies of the test beam and FE models.

Model (Stiffness)	ω_1	ω_2	ω_3
FE model (EI)	3.07 Hz	11.81 Hz	24.03 Hz
Test beam (unknown)	3.09 Hz	10.77 Hz	26.42 Hz
FE model (20% EI)	1.37 Hz	5.39 Hz	11.90 Hz

The measured and simulated datasets are divided into training and test sets in a 9:1 ratio, and the size of each sample is 6×3500, representing the number of channels and data length, respectively. The parameters in Table 2 are used for the model training. The proposed model is trained for 250 epoches on a computer equipped with an Nvidia RTX A6000 GPU. Regarding the DA

Table 2. Hyperparameters for the training of the DA models.

λ_{aS}	20
$\lambda_{aT}, \lambda_{cS}, \lambda_{cT}, \lambda_{pS}, \lambda_{pT}$	10
$\lambda_{iS}, \lambda_{iT}$	0
Discriminator updating frequency	1 time per 5 epochs
Learning rate for Generators	0.0001
Learning rate for Discriminators	0.0001
Batch size	5

from simulation to measurement is more difficult than that in the opposite direction, the following discussion only focuses on the training from simulations to measurements.

3.4 *Model evaluation*

A 10% subset of the dataset is used for model testing. Differing from the training process, model testing involves utilizing single-domain data as input to generate synthetic samples while using the other domain data to assess the synthetic outputs. As discussed in Section 3.3, the DA from measurement to simulation tends to yield favorable results. Hence, to provide more robust validation, this section focuses on the testing of the trained DA model for the DA process from simulation to measurement, considering varying levels of noise. Figure 4 shows clips of the mid-span (Channel 3) acceleration responses before and after DA. It can be seen in Figure 4(a) that the simulated acceleration (with 5% additional noise) is significantly different from the measurement. However, when applying the trained DA model to the simulated data, a synthetic response, which is shown in good agreement with the measured one, can be obtained, as shown in Figure 4(b). Correspondingly, the value of the Mean Square Error is greatly reduced.

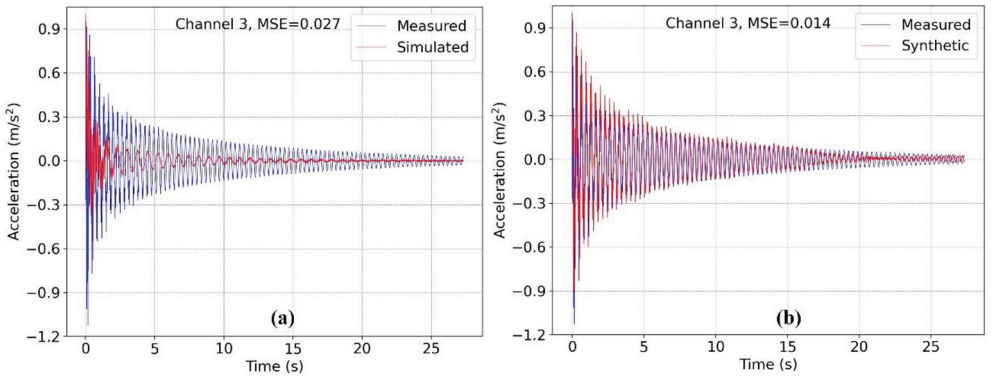

Figure 4. Comparison of the acceleration responses: (a) before DA; (b) after DA.

Besides the comparison in the time domain, Figure 5 presents the Fourier spectrums of acceleration responses. It is shown that the proposed DA model successfully generates synthetic responses on different noise levels, which have similar frequencies as the actual measurements.

Accordingly, the Mean Magnitude Squared Coherence (MMSC) scores, of which defination can be found in (Luleci et. Al 2023), are significantly increased. However, it is still noticeable that there are errors in the peak values of the frequencies, which may affect the accuracy of mode shapes.

For further investigation, modal identification is conducted on both the measured and synthetic responses using SSI-Cov algorithm (Reynders 2012). Figure 6 gives the identified mode shapes for 5% noise. It can be seen that the first two mode shapes identified from the generated responses are in good agreement with those from the measured ones. The third mode is possibly a torsional mode and cannot be reflected in the beam-like FE model, but it was still successfully reconstructed, suggesting the proposed model well learned the data characteristics of the measurement domain. The fourth mode has the smallest energy and is almost indistinguishable in Figure 5, resulting in more differences in the identification results of the mode shapes. To quantify the differences, the modal assurance criterion (MAC) is calculated for all modes and noise cases, of which the results are listed in Table 3. It is evident that using ten sets of synthetic samples can effectively identify the first three modes while maintaining a high degree of similarity with the measured mode shapes. However, the recognition rate (the rate of correctly identifying the mode shapes) and MAC for the fourth mode shape experienced a slight decrease. It is worth noting that noise has less influence on low-order modes with high energy proportion but more significant influence on high-order modes. Therefore, it is recommended to only focus on the few dominant modes in practical applications.

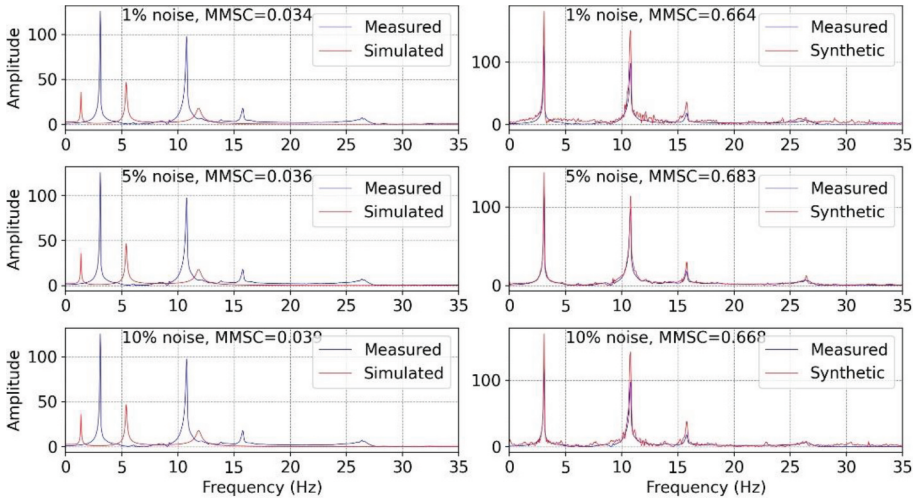

Figure 5. Frequency domain comparison of Channel 3 responses for different levels of noise.

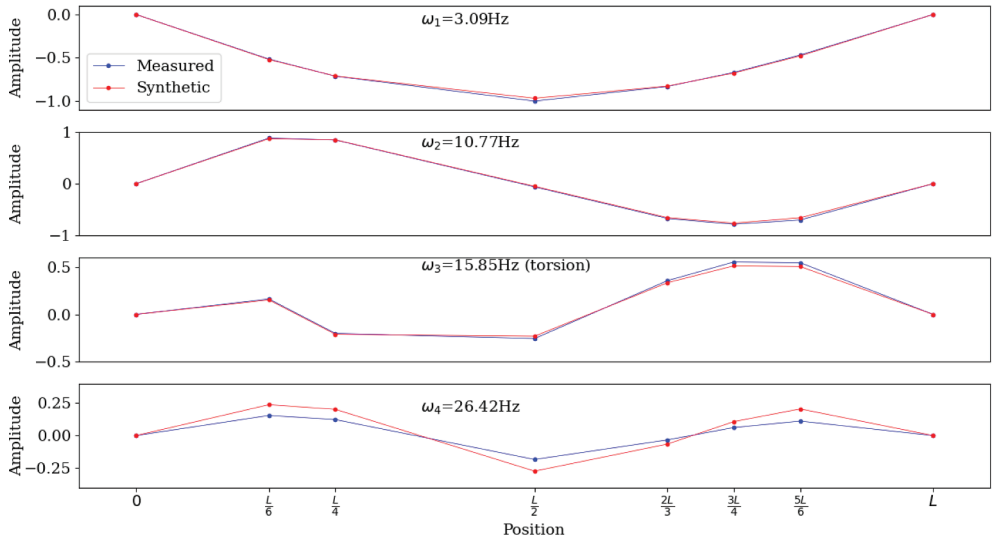

Figure 6. Comparison of the mode shapes identified from measured and synthetic responses.

4 CONCLUSIONS

In this paper, a novel generative DA model is proposed to achieve DA between the FE models and real engineering structures. The DA approach was verified effective through free-vibration tests on a steel beam model. The structure exhibits substantial discrepancies in structural parameters compared to its FE model. Nonetheless, the proposed DA model successfully learned the mapping relationships between the simulation and measurement domains and delivered good performance on previously unseen test data. The proposed method exhibits superior performance in the DA of low-order modal responses compared to higher-order models. Additionally, it demonstrates reduced sensitivity to noise interference. The proposed DA approach is demonstrated on the structures in unchanged structural states. For future endeavors, it is recommended to conduct DA research among multiple structural states to serve model updating and damage detection in SHM.

Table 3. Averaged MAC values between the measured and synthetic mode shapes.

Noise level	1st mode	2nd mode	3rd mode(torsion)	4th mode
1%	0.9997	0.9992	0.9912	0.9539
5%	0.9997	0.9995	0.9992	0.9899
10%	0.9994	0.9996	0.9804	0.9089
Recognition rate	100%	100%	100%	90%

Anomaly detection of bridges by Bayesian method with optimized sensor placement

C.W. Kim & Y. Hirate
Department of Civil and Earth Resources Engineering, Kyoto University, Kyoto, Japan

ABSTRACT: This study aims to investigate the effectiveness of a Bayesian hypothesis-based damage detection using sensor arrangement optimized by the effective independence (EFI) method. The feasibility of Bayesian anomaly detection is verified using vibration and damage experimental data on an actual steel plate girder bridge. It was found that the same vibration frequencies could be identified with the optimally located three sensors as when all sensors were used. Observations demonstrated that it is possible to detect damage and to identify the damage location approximately even with optimally arranged three sensors. In addition, the EFI method was also useful in Bayesian anomaly detection.

1 INTRODUCTION

Maintenance of aging bridges has become a major issue globally. However, considering the shortage of engineers who inspect bridges and the time and cost required for visual inspection, a more efficient and quantitative bridge inspection method is required. Structural health monitoring (SHM) has been studied as an alternative method to visual inspection (Ko & Ni 2005, Doehler et al. 2014). Vibration-based SHM is a useful technique if the modal parameters of a bridge can be identified effectively (Magalhaes et al. 2012), and the ambient vibration induced by wind and traffic is an effective way to monitor the bridge as it requires no traffic control. On actual bridges, however, traffic-induced vibrations presumably include unsteady noise that affects the identification results of the modal parameters (Kim et al. 2012). Therefore, pre-processing and post-processing should be applied carefully to improve the accuracy of modal parameter identification.

To avoid troublesome procedures in signal processing, direct decision-making methods have been investigated using damage indicators that are converted directly from acceleration, instead of the modal properties. Nair et al. (2006) investigated a damage indicator consisting of univariate autoregressive (AR) coefficients because the AR coefficients vary as the modal properties vary. The feasibility of the damage indicator has been examined for a modeled bridge (Kim et al. 2012) and an actual steel truss bridge (Goi & Kim 2017). Goi & Kim (2017) investigated a hypothesis-testing method using a vector autoregressive (VAR) model to support decision-making for bridge maintenance. Although those methods indicate changes in VAR models, noisy operational conditions in the field still hinder their practical use. One difficulty is that stochastic models involve epistemic uncertainty caused by a gap separating the models from actual phenomena. In other words, regressive parameters involve variance that is unrelated to a change in modal parameters, and handling uncertainty caused by operational conditions constitutes the primary difficulty.

Another keen issue in the SHM of bridges is how to reduce the number of sensors because it is necessary to install a large number of sensors in order to identify modal parameters and detect damage accurately. However, considering the huge amount of bridge stocks it is not always possible to instrument many sensors, and many researchers have investigated in terms

DOI: 10.1201/9781003483755-103

of sensor optimization aiming to reduce the number of sensors without sacrificing the performance of damage detection (Kammer 1991, Heo et al. 1997, Papadopoulos & Garcia 1998, Friswell & Castro-Triguero 2015, Li et al. 2020).

Bayesian theory enables quantification of the uncertainty involved in parametric models (Dzunic et al. 2017). This study thus adopts Bayesian theory to quantify the uncertainty involved in the model. The VAR model is adopted for Bayesian inference without MCMC, and input from the traffic was assumed Gaussian white noise even though it is non-stationary random loadings. Thus, non-stationary vehicle loads lead to biased estimates of the regression parameters. For robust damage detection, it is desirable to extract parameters related to damage-sensitive modal characteristics and exclude other parameters from damage detection. This study applies PCA to the input subspace of the VAR model for prompt modal identification. Bayes factor (Kass & Raftery 1995), which is defined as the marginalized likelihood ratio, is adopted as the anomaly indicator. The PCA enables the formulation of the Bayes factor to detect changes in damage-sensitive parameters. Therefore, measured acceleration is converted seamlessly to the anomaly indicator to detect changes in the modal properties.

This study aims to investigate the effectiveness of a Bayesian hypothesis-based damage detection using a small number of sensors. The minimal sensors arrangement is investigated using the effective independence (EFI) method (Kammer 1991). A parameter from the coefficient matrix of the VAR model of measured acceleration responses is adopted as damage sensitive feature. A Bayesian hypothesis test is used to detect anomalies as an outlier analysis. Vibration data from a damage experiment giving cracks in the steel plate girder bridge are used to verify the validity of the proposed approach. To examine the effect of the number of sensors, relationships between the number of sensors and the accuracy of the anomaly detection are investigated utilizing the Bayes factor (BF), which is a damage index in the Bayesian hypothesis test.

2 BAYESIAN ANOMALY DETECTION

2.1 *Vector autoregressive (VAR) model*

Let $\boldsymbol{y}_k \in \mathbb{R}^{m\times 1}$ denote a column vector of the discrete-time series of measured acceleration whose components correspond to m measurement locations. The following VAR model idealizes the linear time series with sufficient model order p and noise term (Kim et al. 2012).

$$\boldsymbol{y}_k = \sum\nolimits_{i=1}^{p} \alpha_i \boldsymbol{y}_{k-i} + \boldsymbol{e}_k \tag{1}$$

where, $\boldsymbol{\alpha}_i \in \mathbb{R}^{m\times m}$ is an autoregressive coefficient matrix of order i, and $\boldsymbol{e}_k \in \mathbb{R}^{m\times 1}$ is a time series of white Gaussian noise vectors. To simplify the discussion, transform Equation (1) as follows.

$$\boldsymbol{y}_k = \mathbf{W}\begin{bmatrix} \boldsymbol{y}_{k-1} \\ \vdots \\ \boldsymbol{y}_{k-p} \end{bmatrix} + \boldsymbol{e}_k = \mathbf{W}\boldsymbol{\phi}_k + \boldsymbol{e}_k \tag{2}$$

where, $\boldsymbol{\phi}_k \in \mathbb{R}^{mp\times 1}$ is a column vector. Furthermore, when $\boldsymbol{\Sigma}$ represents a covariance matrix of the noise vector $\boldsymbol{e}_k$, the probability density function of $\boldsymbol{y}_k$ is expressed as follows.

$$p\left(\boldsymbol{y}_k|\boldsymbol{\phi}_k, \boldsymbol{W}, \boldsymbol{\Sigma}\right) = \mathcal{N}\left(\boldsymbol{y}_k|\boldsymbol{W}\boldsymbol{\phi}_k, \boldsymbol{\Sigma}\right) \tag{3}$$

where, $p(\cdot|\cdot)$ represents the conditional probability density function, $\mathcal{N}(\boldsymbol{x}|\mu, \boldsymbol{\Sigma})$ represents the multivariate normal distribution with the expected value μ and the covariance matrix $\boldsymbol{\Sigma}$.

Consider the problem of estimating the regression coefficient $\boldsymbol{W}$ and the covariance $\boldsymbol{\Sigma}$ of the regression error from the observed value of the target variable $\boldsymbol{y}$ using Bayes' theorem, and a data set consisting of n target variables $\boldsymbol{y}_1, \ldots, \boldsymbol{y}_n$ and their corresponding inputs $\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_n$,

and define $\mathbf{Y} = [\mathbf{y}_1, \ldots, \mathbf{y}_n] \in \mathbb{R}^{m \times n}$ and $\boldsymbol{\phi} = [\boldsymbol{\phi}_1, \ldots, \boldsymbol{\phi}_n] \in \mathbb{R}^{mp \times n}$. Assuming that these data are generated independently, the following likelihood function is obtained for the parameters $\boldsymbol{W}$ and $\boldsymbol{\Sigma}$.

$$p(\boldsymbol{Y}|\boldsymbol{\phi}, \boldsymbol{W}, \boldsymbol{\Sigma}) = \prod_{k=1}^{n} \mathcal{N}(\boldsymbol{y_k}|\boldsymbol{W}\boldsymbol{\phi_k}, \boldsymbol{\Sigma}) \tag{4}$$

The next section explains how to calculate BF from this likelihood function using Bayes' theorem.

2.2 *Bayesian hypothesis test*

The parameters $\boldsymbol{W}$ and $\boldsymbol{\Sigma}$ will be collectively referred to as regression parameters. The posterior distribution of regression parameters is obtained according to the following Bayes' theorem.

$$p(\boldsymbol{W}, \boldsymbol{\Sigma}|\boldsymbol{Y}, \boldsymbol{\phi}) = \frac{p(\boldsymbol{Y}|\boldsymbol{\phi}, \boldsymbol{W}, \boldsymbol{\Sigma}) p(\boldsymbol{W}, \boldsymbol{\Sigma})}{p(\boldsymbol{Y}|\boldsymbol{\phi})} \tag{5}$$

where, $p(\boldsymbol{W}, \boldsymbol{\Sigma})$ on the right side is the prior distribution. $p(\boldsymbol{W}, \boldsymbol{\Sigma}|\boldsymbol{Y}, \boldsymbol{\phi})$ on the left side is the posterior distribution for the regression parameters obtained under the condition of observed accelerations and shows the posterior distribution. In the following discussion, the left side of Equation (5) is abbreviated as $p(\boldsymbol{W}, \boldsymbol{\Sigma}|\boldsymbol{Y})$ for simplicity.

In Bayesian inference, it is known that a closed solution can be obtained for the probability density function of the posterior distribution by assuming a prior distribution as a conjugate prior. Regarding the likelihood function expressed in Equation (4), it is known that the conjugate prior distribution of the regression parameter is the matrix normal inverse Wishart distribution defined by the following equation (Goi & Kim 2023).

$$p(\boldsymbol{W}, \boldsymbol{\Sigma}) = \mathcal{MN}(\boldsymbol{W}|\boldsymbol{M}, \boldsymbol{\Sigma}, \boldsymbol{L}^{-1}) \mathcal{IW}(\boldsymbol{\Sigma}|\psi, \nu) \tag{6}$$

where, $\mathcal{MN}(\mathbf{W}|\mathbf{M}, \boldsymbol{\Sigma}, \mathbf{L}^{-1})$ and $\mathcal{IW}(\boldsymbol{\Sigma}|\boldsymbol{\Psi}, \nu)$ are the matrix normal distribution and the inverse Wishart distribution, respectively,

The parameters $\mathbf{M} \in \mathbb{R}^{m \times mp}$, $\mathbf{L} \in \mathbb{R}^{mp \times mp}$, $\boldsymbol{\Psi} \in \mathbb{R}^{m}$ and $\nu \in \mathbb{R}$ in Equation (6) are the parameters that determine the shape of the prior distribution, so-called hyperparameters. The posterior distribution is expressed as follows (Goi & Kim 2023).

$$p(\boldsymbol{W}, \boldsymbol{\Sigma}|\boldsymbol{Y}) = M\mathcal{N}\left(\boldsymbol{W}|\boldsymbol{M}', \boldsymbol{\Sigma}, \boldsymbol{L}'^{-1}\right) I\mathcal{W}(\boldsymbol{\Sigma}|\boldsymbol{L}', \nu') \tag{7}$$

where,

$$\mathbf{L}' =, \mathbf{L} + \boldsymbol{\phi}\boldsymbol{\phi}^{\mathrm{T}} \tag{8}$$

$$\mathbf{M}' = \left(\mathbf{M}\mathbf{L} + \mathbf{Y}\boldsymbol{\phi}^{\mathrm{T}}\right)\mathbf{L}'^{-1} \tag{9}$$

$$\nu' = \nu + n \tag{10}$$

$$\boldsymbol{\Psi}' = \boldsymbol{\Psi} + \mathbf{Y}\mathbf{Y}^{\mathrm{T}} + \mathbf{M}\mathbf{L}\mathbf{M}^{\mathrm{T}} - \mathbf{M}'\mathbf{L}'\mathbf{M}'^{\mathrm{T}} \tag{11}$$

Since it is difficult to derive a strict non-information prior distribution for the prior distribution in Equation (6), A uniform distribution is assumed. The Bayesian hypothesis test in this study is performed by evaluating the BF defined as the ratio of the likelihood functions. When

$\boldsymbol{D}$ is the observation data set and $\boldsymbol{\theta}$ is the model parameter (regression parameter), the likelihood function of hypothesis H is generated as follows.

$$p(\boldsymbol{D}|\mathrm{H}) = \int p(\boldsymbol{D}|\boldsymbol{\theta}, \mathrm{H}) p(\boldsymbol{\theta}|\mathrm{H}) d\boldsymbol{\theta} \tag{12}$$

where, $p(\boldsymbol{D}|\boldsymbol{\theta}, \mathrm{H})$ and $\boldsymbol{p}(\boldsymbol{\theta}|\mathrm{H})$ represent the likelihood function and prior distribution under hypothesis H, respectively. From Bayes' theorem, the posterior distribution under hypothesis H is described as follows.

$$p(\mathrm{H}|\boldsymbol{D}) = p(\boldsymbol{D}|\mathrm{H}) p(\mathrm{H}) \boldsymbol{p}(\boldsymbol{D})^{-1} \tag{13}$$

If the null hypothesis H_0 denotes "the statistical model according to the observed values is the same as that of a bridge in a healthy state", and then, the alternative hypothesis H_1 denotes "prior information is uncertain about the statistical model that the observed values follow." Taking the ratio of the posterior distribution in each hypothesis obtained from Equation (13), it is expressed as follows.

$$\frac{p(\mathrm{H}_1|\boldsymbol{D})}{p(\mathrm{H}_0|\boldsymbol{D})} = \frac{p(\mathrm{H}_1)}{p(\mathrm{H}_0)} B \tag{14}$$

where B is expressed as BF as follows.

$$B = \frac{p(\boldsymbol{D}|\mathrm{H}_1)}{p(\boldsymbol{D}|\mathrm{H}_0)} \tag{15}$$

Equation (14) means that the ratio of the posterior distribution can be expressed by the ratio of probability distributions of the null hypothesis H_0 and the alternative hypothesis H_1 and the likelihood function assuming that each hypothesis H_0 and H_1. If the prior probabilities for two hypotheses are equivalent, then the BF corresponds to the updated posterior odds. The BF therefore provides evidence to assess whether observed data support the null hypothesis or alternative hypothesis.

Here, the BF when the acceleration data $\boldsymbol{D}$ represents all the sensors is called the Global Bayes factor (GBF). Since GBF uses the information of all the sensors attached to the bridge, it is possible to estimate the presence or absence and degree of abnormality of the entire bridge. On the other hand, the BF in each sensor uses the acceleration expressed by the following equation using the jth element of Equation (1).

$$\boldsymbol{y}_k^{(j)} = \sum_{i=1}^{p} \alpha_i^{(j)} \boldsymbol{y}_{k-i} + \boldsymbol{e}_k \tag{16}$$

where, $\boldsymbol{y}_k^{(j)}$ and $\alpha_i^{(j)}$ are j-th element of $\boldsymbol{y}_k$ and α_i. The BF calculated using the acceleration data of Equation (16) is called the Local Bayes factor (LBF). Since LBF is calculated using the acceleration data of each sensor, it represents the BF of each sensor. Therefore, the damage position can be estimated by comparing the BF values at each location.

In this study, BF is considered on the scale of the natural logarithm, and when $2lnB$ is larger than 10, the basis for rejecting the null hypothesis is "very strong" (Jeffreys 1946). Here, the acceleration data of a healthy bridge is defined as reference data, and that of a bridge with unknown abnormalities is defined as test data. In determining the AR order p, the Bayesian Information Criterion (BIC) (Bishop 2006) was used in this study. The stabilization diagram is used as a method for obtaining the order q that extracts the features sensitive to damage detection.

3 EFFECTIVE INDEPENDENCE METHOD FOR SENSOR LOCATION OPTIMIZATION

As the coefficient matrix of the VAR model contains information on the modal parameters, including the mode shapes of the structure, the optimal sensor placement by applying the EFI method to the regression parameter $\boldsymbol{W}$ is deemed to be effective.

The EFI method is a method for finding the optimum sensor placement using the mode shape matrix $\boldsymbol{\Phi}$, which is a matrix of mode vectors estimated from the measurements and normalized so that the norm is 1. When applying the EFI method, the number of measurement points and the positions at which the mode shape matrix □ is calculated are first determined in advance. Secondly, the mode of interest is determined, and thirdly, the number of sensors to be finally installed, N_0, is determined. When using the EFI method, the number of sensors to be finally determined, N_0 should not be less than the number of mode shapes to be considered (Kammer 1991).

The EFI method determines the sensor arrangement that maximizes the Fisher Information Matrix (FIM), F, shown in Equation (17), leaving the sensor with the largest FIM determinant and reducing the number of sensors one by one. This is repeated until the planned number of sensors is reached. This selection of sensors is determined based on the orthogonal projection matrix E shown in Equation (18).

$$\mathbf{F} = \boldsymbol{\Phi}^T \boldsymbol{\Phi} \tag{17}$$

$$\mathbf{E} = \boldsymbol{\Phi} \mathbf{F}^{-1} \boldsymbol{\Phi}^T \tag{18}$$

The diagonal component E_{ii} of matrix $\mathbf{E}$ represents the influence of the i-th component of the mode shape matrix $\boldsymbol{\Phi}$. In other words, the excluded ith component is removed as the sensor with the least impact on the target mode as shown in Equation (19).

$$\det(\mathbf{F}) = \det(\mathbf{F}_0)(1 - E_{ii}) \tag{19}$$

where $\mathbf{F}_0$ represents the original FIM and $\mathbf{F}$ represents the FIM after the i-th sensor has been removed. Therefore, the FIM determinant decreases as one row is removed from the mode shape matrix Φ, as shown in Equation (19). In this way, the number of sensors is reduced until the pre-determined number of sensors N_0 is reached and the optimum sensor arrangement is determined.

4 FIELD EXPERIMENT ON A STEEL PLATE GIRDER BRIDGE

The target bridge shown in Figure 1 is a simply supported steel plate girder bridge with a total bridge length of 40.5 m, an effective width of 4.0 m, and a depth of 2.0 m. The bridge was constructed in 1957 and was removed in 2017. The state of the bridge before introducing damage is regarded as a healthy state (hereinafter referred to as the INT scenario). The damage location is near sensor A1. In the first stage of damage, a through crack is introduced into the lower flange (hereinafter DMG1 scenario). In the second stage damage through cracks was introduced into the web plate in addition to DMG1 (hereinafter DMG2 scenario). As a safety measure, a bridge collapse prevention device was set at the girder end on the A1 side. Regarding the bearings, the A1 side is the plain sliding bearing and the A2 side is the pivot bearing.

A moving vehicle experiment was conducted and the vertical acceleration response of the bridge was measured. The vehicle speed was 20 km/h. The number of trials for each run is 60 for the INT scenario, 32 for the DMG1 scenario, and 30 for the DMG2 scenario, respectively. The traveling direction reciprocates from A1 to A2, and one way was counted as one trial. The sampling frequency was 200 Hz and the data length was 15 seconds (forced vibration was

five seconds and free vibration was ten seconds). A high-sensitivity accelerometer ARS-10A (Tokyo Instrument Research Institute) was used, and a multi-recorder TMR-200 series (Tokyo Instrument Research Institute) was used for data acquisition. Accelerometers were installed at ten locations as shown in Figure 1 (A1 to A10). The identified modal frequency under different damage scenarios is summarized in Table 1. Mode shapes up to the third bending mode under the INT scenario were identified as shown in Figure 2. These three bending modes are modes of interest in sensor location optimization.

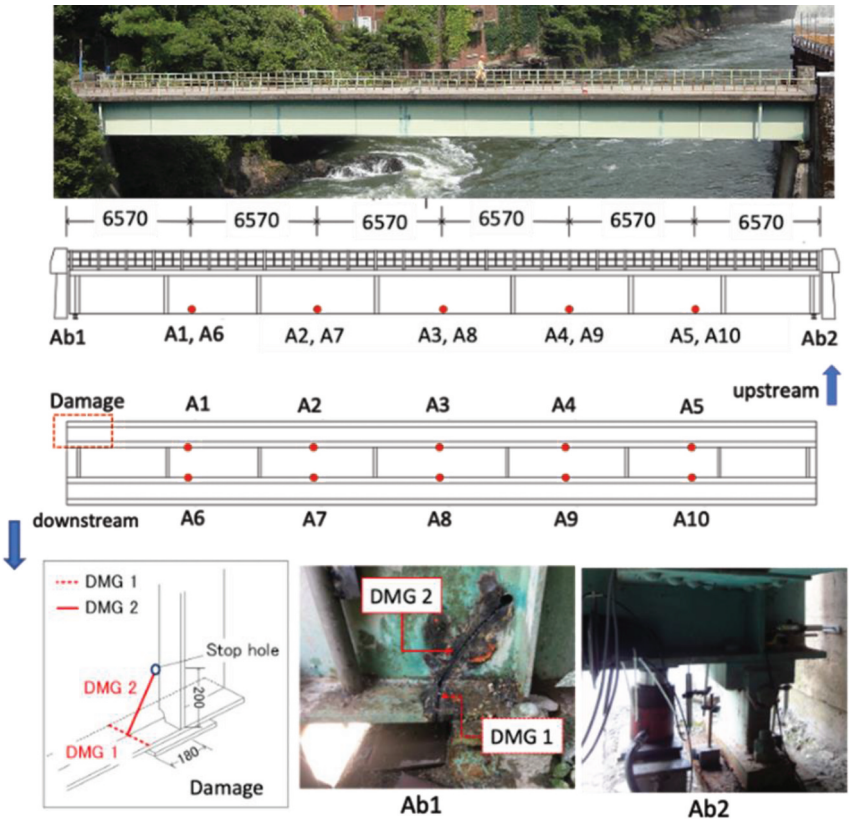

Figure 1. Experiment bridge and sensor deployment.

Table 1. Identified modal frequencies.

Mode		INT	DMG1	DMG2
1st bending	Freq. (Hz)	3.15	3.25	3.28
	CV	0.013	0.011	0.006
	MAC	-	1.000	0.999
2nd bending	Freq. (Hz)	9.53	9.24	8.85
	CV	0.009	0.005	0.005
	MAC	-	0.993	0.975
3rd bending	Freq. (Hz)	21.87	21.87	21.60
	CV	0.005	0.004	0.003
	MAC	-	0.998	0.991

5 DAMAGE DETECTION WITH OPTIMAL SENSORS

5.1 *Bayesian damage detection using a full number of sensors*

Using the identified posterior probability density autoregressive coefficient matrix from ten sensors, the Bayesian hypothesis test is carried out. Figure 3 shows the plots of the global Bayes factor (GBF) where the horizontal axis denotes the damage scenario and the vertical axis indicates the BF in the log scale. The CV shows the leave-one-out cross-validation (LOOCV) to measure how well the predictions made by the model match the observed data. It demonstrates that the GBF clearly indicates changes in vibration characteristic of the bridge, and even clearly shows higher evidence of supporting the alternative hypothesis H_1. Damage detection using the local Bayes factor (LBF) is summarized in Figure 4. It is obvious that A1 and A6 which are instrumented around the artificial damage at the girder-end show higher LBF, which also supports the feasibility of the LBF in terms of damage detection.

5.2 *Bayesian damage detection using an optimized number of sensors*

As discussed in the previous section, GBF and LBF successfully detected damage in the bridge. In this section optimal sensor location is discussed. The target number of sensors is assumed three. The removed sensor decided by means of the EFI method is summarized in Table 2 which shows the step-by-step reduction of sensors up to three sensors which is the target number of sensors. In other words, sensors A7, A9, A2, A4, A1, A8, and A5 were removed, and the remaining sensors A3, A6, and A10 were selected as the optimal sensors by

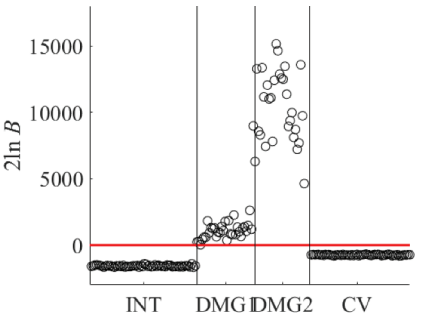

Figure 3. GBF of ten sensors.

det(**F**): determinant of FIM

means of the EFI method. Those GBF and LBF using optimal three sensors with respect to damage scenarios are summarized in Figures 5 and 6 respectively. The GBF in Figure 5 with three sensors demonstrates that the more severe the damage, the higher the GBF value. For the LBF shown in Figure 6, the A6 sensor which is the nearest sensor at the damage among the three sensors shows the highest LBF. To verify the validity of the optimal sensor group for damage detection, the GBFs of two artificially selected sensor groups are compared to the GBF of the optimal sensor group. Figure 7 shows those comparisons, and demonstrates the optimal sensor group that resulted in the most sensitivity to the damage compared to the other two artificially determined sensor groups.

6 CONCLUSIONS

A Bayesian damage detection method was used to investigate the possibility of estimating the extent and location of damage. A way to reduce the number of accelerometers used for

Bayesian damage detection was also investigated using the EFI method which is an optimal sensor placement method. In the application of the EFI method as the optimal sensor placement method, targeting the first, second, and third bending modes, with the number of sensors set to three. It was found that the same vibration frequencies could be identified with the optimally located three sensors as when all sensors were used. However, the reduced number of sensors resulted in weaker power of the dominant frequency in the PSD curve. Therefore, the damage detection accuracy can be decreased under a strong noise condition. The results of Bayesian damage detection using the sensor information of the optimum sensor arrangement under the above conditions suggest that Bayesian damage detection is effective even with three sensors.

ACKNOWLEDGMENT

This work was supported by a Japanese Society for the Promotion of Science (JSPS) Grant-in -Aid for Scientific Research (B) under project No. 22H01576 which is greatly appreciated.

ABSTRACT: Population-Based Structural Health Monitoring (PBSHM) has emerged as a promising approach to increase the understanding of structural health by leveraging data from a population of structures, surpassing the insights attainable from individual structures alone. For successful knowledge transfer in PBSHM, structural similarities need to be established to prevent negative transfer effects. Irreducible Element (IE) models, combined with graph theory, are the vehicles used within PBSHM to facilitate this process. This paper presents a Finite Element (FE) to Irreducible Element model converter. While FE models are conventional in civil engineering, IE models represent a novel technology tailored for PBSHM, with limited available tools for their creation. This paper details a procedure for transforming FE models into IE counterparts. By enabling the conversion of existing FE models into IE models, this tool mitigates the need for specialised IE model expertise, resulting in more accessibility and ease of adoption of PBSHM. The significance of the FE to IE converter in the field of bridge Structural Health Monitoring is that it can help bridge the gap between conventional SHM and emerging PBSHM. The conversion tool also significantly enhances the accessibility of PBSHM in the civil infrastructure industry. The converter's utilisation holds the potential to accelerate the adoption of PBSHM by enabling the incorporation of an expansive array of structures with pre-existing FE models into the PBSHM framework.

1 INTRODUCTION AND APPLICABILITY OF FINITE ELEMENT (FE) MODELS

PBSHM leverages data from multiple structures within a similar population, providing an understanding and insights into the population and other similar structure (Worden et al., 2020). Populations of bridges can be wide ranging an example of a very similar population may be 2 or more steel truss pedestrian bridges however induvial elements can also be considered such as a population of bridges that all contain a ladder deck. Monitoring a population of structures, PBSHM offers a distinct advantage over traditional single-structure monitoring approaches which is the potential for transfer learning. Transfer learning is a method where knowledge gained from training a model on one task is leveraged to improve the performance on a different but related task. Instead of training a model from scratch for each new task, transfer learning allows pre-trained models to serve as a starting point, with the hope that the knowledge gained from one domain can be beneficial in learning another. However, the effective application of transfer learning between structures within PBSHM, which seeks to harness the knowledge gained from one structure to provide insights into others, hinges on establishing structural similarities that prevent negative transfer. To this

DOI: 10.1201/9781003483755-104

end, Irreducible Element (IE) models, combined with graph theory, serve as a fundamental vehicle in PBSHM, facilitating the identification of structural commonalities and differences. More information about the foundations of PBSHM can be found in (Bull et al., 2021; Gardner et al., 2021; Gosliga et al., 2021; Tsialiamanis et al., 2021).

Concurrently, the field of civil/structural engineering has used Finite Element (FE) models as a fundamental numerical tool for analysing and simulating structural behaviour. FE models have a rich history of application, but as PBSHM is at the early stage of development, there is a growing need to bridge the gap between conventional SHM and emerging PBSHM. This necessitates the development of tools and techniques that promote the use of PBSHM within civil engineering industry.

One of the main challenges lies in the creation of IE models, for which there are currently limited available tools. To address this gap, this paper introduces the concept of an FE to IE model converter. The impact of this converter within the field of PBSHM has the potential to be significant as it empowers the transformation of existing FE models into their IE counterparts. By doing so, it not only mitigates the need for specialised IE model expertise, but also enhances the accessibility and ease of adoption of PBSHM.

This paper, presents a detailed procedure for converting FE models to IE models, encompassing two critical stages: the extraction of relevant information from FE models and the generation of IE models from the extracted data. The utilisation of this conversion tool holds the potential to accelerate the adoption of PBSHM by enabling the incorporation of an expansive array of structures with pre-existing FE models into the PBSHM framework.

2 IE MODEL OVERVIEW

In the second part of the 'Foundations of Population-based Structural Health Monitoring' series, (Gosliga et al., 2021) introduced the concept of an Irreducible Element (IE) model. The IE model is used in PBSHM to represent significant structural components and their interactions. It provides an abstract representation needed to assess the similarity of different structures in the network. The IE model only considers components belonging to the structure and describes where the interactions with external systems are, without providing information on how they interact with a model.

To create an Irreducible Element (IE) model, two lists are needed. The first list encompasses individual elements within a structure, each accompanied by attributes such as material and geometry. The second is a list of relationships which define how each element is connected to each other and the properties of each connection. In essence, an IE model is constructed through these two lists, encapsulating the structural elements and their relationships.

This is an oversimplification of how IE models are created and there are a lot of details that have to be considered when developing a system that is required to model structures ranging from aeroplanes to bridges. A more comprehensive description can be found in (Gosliga et al., 2021).

3 PROCEDURE FOR CONVERTING FE MODELS TO IRREDUCIBLE ELEMENT MODELS

The creation of IE models remains a challenge, as there is a limited availability of tools for their generation. To bridge the gap between conventional Structural Health Monitoring (SHM) and emerging PBSHM, we introduce the concept of a Finite Element (FE) to Irreducible Element (IE) model converter. This converter holds significant potential within the field of PBSHM, as it empowers the transformation of existing FE models into their IE counterparts. By doing so, it not only mitigates the need for specialised IE model expertise but also enhances the accessibility and ease of adoption of PBSHM in the civil infrastructure industry.

In this section, we present a detailed procedure for converting FE models to IE models, separated into two stages: the extraction of relevant information from FE models and the generation of IE models from the extracted data. The idea of this separation is that stage one would be software dependent, and stage two would be a generalised procedure that should work

with any FE software. This division of the procedures means that only stage one would have to be altered if a new FE software is used to create the FE models.

3.1 *Creation of the FE model*

Before the introduction of the conversion procedure, this section provides a brief overview of how an FE model is traditionally created. In FE analysis, structures are discretised into finite elements, which are interconnected to simulate their behaviour under various loading conditions. The Finite Element (FE) software, Lusas (version 19), was used for this research. The creation of an FE model typically involves:

- Geometry and Mesh Generation: Define the geometry of the structure and generate a mesh by dividing it into finite elements.
- Material Properties: Assign material properties to the elements, including information about stiffness, density, and other mechanical characteristics.
- Boundary Conditions: Specify boundary conditions to represent how the structure interacts with its surroundings.
- Loading conditions: Specify which parts of the structure are under loading and the magnitude of this loading.

In the context of this work, the primary difference in creating FE models for conversion to IE models lies in providing the elements with human understandable names, which is required for generating IE models with meaningful structural descriptions.

3.2 *Stage one: Extracting relevant information from the FE model*

To convert an FE model into an IE model, the first stage involves the extraction of key information from the existing FE model, this information includes positional, geometrical and material information for all of the elements. This information is vital for creating an accurate representation of the structure in the IE model. This information is required for any FE simulation and so the only unknown between different FE software is how this information can be extracted from the model. For this research, LUSAS version 19 software was used. After the model had been created in LUSAS there are a number of exported formats, two formats were selected as they contain all the required information. These were a Visual Basic for Applications (VBA) Script File and an Industry Foundation Classes (IFC). These are both common text-based file formats and the latter being an open file format used by Building Information Modelling (BIM) programs. These files were then parsed using Matlab and grouped into the following tables:

Regular Element Information

Contains data related to elements within the FE model that are the 'regular elements' within the IE model, including element name, element type (line/surface), geometry reference, material reference and the coordinates of the vertices. The vertices of a line are the two end points and the vertices of a surface are the 4 corner points.

Ground Element Information

Ground elements are unique to IE models and comprise unique element names to denote the location of where the model interacts with other external systems. At this stage of the process, the location of the support conditions within the FE model are recorded to create a list of equivalent ground elements with unique names.

Relationship Information

This table takes the vertices stored in the 'Regular Element' table and uses the shared vertices to determine which elements are connected to each other. By default, the connections are fully static within the FE model and so that is the default relationship that is defined in the IE model. At this point in the procedure, the algorithm determines which connections are 'perfect'. Perfect relationships within an IE model are defined as 'A relationship that represents the interaction between two elements where the two elements in question could be considered to be the same singular element'. To determine whether there is a perfect relationship there are two tests one for line elements and one for surface elements. For lines, if geometry matches and the lines are connected and parallel (to a defined tolerance), there is a perfect relationship.

For surfaces, if geometry matches and the surfaces share an edge there is a perfect relationship. For the relationships that are determined to be perfect, they are suffixed with an '_P' so they can be identified at a later stage.

Boundary Condition Information

Specifies the support conditions and locations of the boundary conditions applied to the model, such as fully fixed or pinned. These properties while not utilised in the current version of IE models may be implemented in future revisions.

Geometry Information

Includes geometric properties of the elements within the FE model, defining dimensions, shape, and spatial arrangement. At this point, the geometry of each element is matched to a predefined list of allowed geometry types in the IE model schema.

Material Information

Provides data on material properties assigned to each element, encompassing stiffness, density, and other mechanical characteristics. Again, like the geometry information, each unique material is matched to a predefined list of allowed material types in the IE model schema.

General Model Data Information

This table extracts the model properties of the FE model such as the units that are used for dimensions, loads etc and the vertical direction defined in the model.

These tables collectively constitute a comprehensive dataset that captures the essential characteristics of the FE model. The grouping of information into these categories facilitates a systematic and organised approach to the subsequent stages of IE model generation. Stage two in the process involves utilising this extracted information to generate an IE model in the specific format that is required by the IE model schema.

3.3 *Stage two: Generating IE model from extracted information*

Once the relevant information is extracted from the FE model, the second stage involves generating an IE model based on the extracted data. IE models are stored using a Javascript Object Notation (JSON) format. The conversion tool formats all of the information that is described in this section into the correct JSON format as outlined below. This stage includes; defining the structure properties and then defining the IE model section properties, which comprise the type of model, the elements in the model and the relationships between the elements.

Defining Structure Properties

To define the structure properties, three items are needed, the name of the structure, the population that the structure belongs to and the timestamp as to when the model is created. The name and the population field are user inputs, and the algorithm produces the timestamp in the correct format based on the clock of the system being used.

Defining the IE model

The first aspect of the IE model that needs to be defined is the type. This can be either 'free' or 'grounded'. The difference between these types is that the grounded model considers the boundary conditions and the free model does not. The type is selected by the user and if 'free' the information collected regarding the boundary conditions is ignored and if 'grounded', then the boundary condition information is incorporated into the IE model in the sequential steps.

Compiling the elements object

The elements object in an IE model is a list of both ground elements (assuming a 'grounded' model is being created) and regular elements with associated attributes. For the ground elements, the only information required is the name of the ground element a list of which has already been populated in stage one. Therefore, at this point, all that is required is collating all the ground elements in the correct format and adding the 'ground' type to each element.

The regular elements required more information than the ground elements to be valid against the current IE model schema. At a minimum, each regular element in the IE model requires the following information: name, type, contextual, geometry and material. The name and type information are straightforward as the names are extracted from the FE model and the tables extracted during stage 1 have already been separated into either 'ground' or 'regular'.

Further processing of the information extracted during stage 1 needs to be undertaken to determine the contextual, geometry and material properties needed for the regular elements.

The first step is to further divide the regular elements into line objects and surface objects depending on how they have been represented in the FE model. For the line objects the coordinates of the endpoints are used to calculate the length of the line and the vector of the line (compared with the global axis of the FE model). The vector of the line is used to select the context of the element from a predefined list which includes; 'beam', 'column', 'slab', 'cable' and other such contextual entities. The conversion tool has a series of rules to select the most appropriate context such as if a line object is parallel to the ground then its context is a 'beam' if perpendicular to the ground then its context is a 'column'. A similar procedure is then used for the surface elements, the vertices of the surface are used to calculate the centre of the surface and the lengths of each side of the surface. This information, along with other inbuilt rules, is then used to select the most suitable contextual information from the predefined list.

For the geometry properties of the regular elements there needs to be a map of how the geometry of the FE model translates to the allowable geometry type of the IE model schema. For example a 'Rectangular Solid' will be mapped to the IE model type 'beam > rectangular' and a 'Surface' geometry ID in the FE model will map to a 'plate > rectangular' IE model type. The most common types have been mapped in the conversion tool and new items will be added as they arise further into the development.

The material properties are handled in a similar way with a map embedded into the conversion tool that translates a FE material ID to an allowable IE material.

4 ILLUSTRATIVE CASE STUDY

To demonstrate the application of the Finite Element (FE) to Irreducible Element (IE) model conversion process, this section presents a case study featuring a simple bridge structure. This example structure was designed to contain a range of common bridge elements and a range of materials thus showing the range of capabilities of the conversion procedure.

4.1 *Description of structure*

A simple bridge was chosen to have key features of typical of real-world bridges while remaining simple enough to test all the features of the conversion tool without the complexity of a real bridge. While the bridge used here would be unrealistic in the real world it does provide a mix of material and geometric features that show the capabilities of the conversion tool. The bridge has a length of 10 meters and a width of 3 meters. Concrete columns, each with a 500 mm diameter and a height of 2 meters, are located at the four corners of the deck. The bridge deck consists of a 50 mm thick steel surface and is supported by rectangular concrete beams measuring 300 mm in height and 150 mm in width. Three transverse beams span the width of the bridge, and two longitudinal beams running along the deck's length. A schematic of the bridge can be seen in Figure 1.

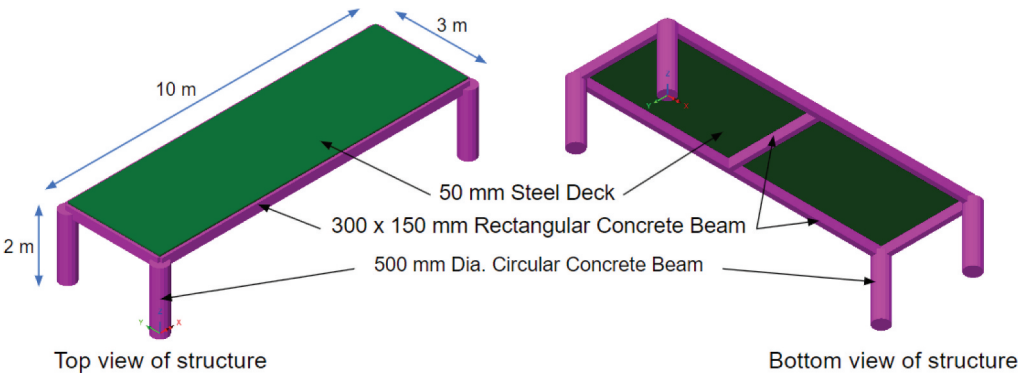

Figure 1. Schematic of simple bridge structure.

4.2 *Simple bridge FE model*

The Finite Element (FE) model of the simple bridge structure described above can be created in the conventional manner. The process involves defining the finite element mesh, geometric dimensions, assigning material properties, and specifying boundary conditions to simulate the structure as accurately as possible. It is noteworthy that creating the FE model for use with the Irreducible Element (IE) conversion tool involves minimal deviation from standard practices.

The key departure lies in the embedding of IE model element names during the creation of the FE model. This step is crucial for ensuring that the subsequent IE model, generated through the conversion process, retains human-understandable names for each element. This adjustment to the FE model means that no additional information is needed by the conversion tool. If this naming of the elements was moved to the conversion tool then the FE model would require no adjustment but the conversion tool would require more user inputs. Figure 2 shows the naming convention used for this simple structure.

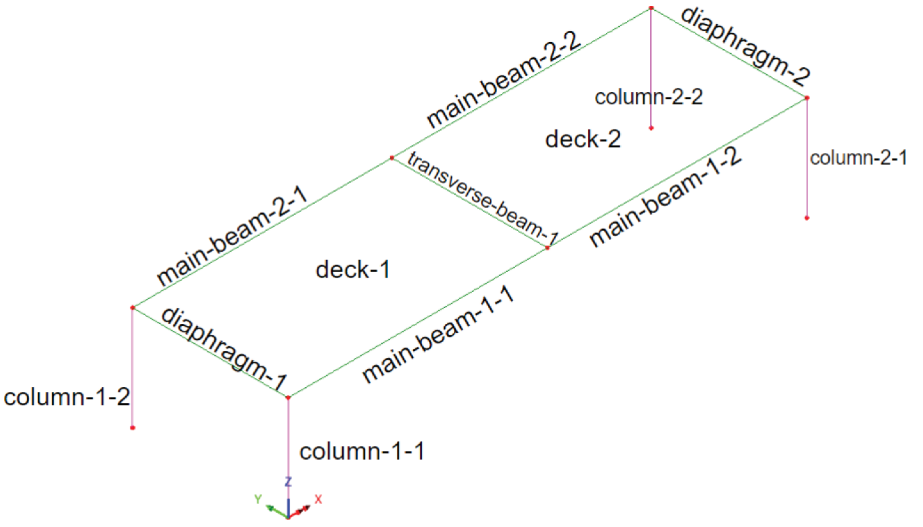

Figure 2. IE naming convention used for simple bridge structure.

Furthermore, the FE model serves another purpose during its creation. Beyond preparing for the IE conversion, it becomes a valuable tool for ensuring the structural behaviour of the model is as intended by the modeller. Deflections, obtained through the FE model, can be cross-referenced against theoretical calculations. Additionally, the model allows for the examination of the bending moment diagram and shear force diagram, providing a means to verify if the structure behaves as expected under various loading conditions. This gives a level of confidence that the structure has been modelled as intended.

4.3 *Application of the FE to IE converter*

4.3.1 *Extraction of relevant information*

After creating the FE model and checking the behaviour of the structure is as expected, the two required files can be exported from the Lusas software. Utilising the previously described in Section 3.2, the relevant information from the FE model is extracted and organised into tables, including Regular Element Information, Ground Element Information, Relationship Information, Boundary Condition Information, Geometry Information, Material Information, and General Modal Data Information. The 'Elements' tables showing the extracted information from the FE model can be seen in Figure 3, with the most significant columns labelled underneath the tables.

4.3.2 *Generation of IE model*

The extracted information is then processed through the FE to IE converter. The converter transforms the FE data into an Irreducible Element (IE) model using the process outlined in Section 3.3. The generation of the Irreducible Element (IE) requires very limited additional input (structure name and population) from the user beyond the extracted information from the FE model. All pertinent information easily embedded into the IE model is automatically included, allowing a high level of adaptability to future developments of the IE model and similarity comparisons. This approach goes beyond the minimal requirements of the IE model schema, providing a degree of future-proofing by capturing additional data that may prove valuable in evolving applications of the IE models.

Furthermore, the simplicity and efficiency of this conversion process enable easy iteration. In the event of amendments or updates to the FE model, the IE model generation can be repeated with little effort. This adaptability ensures that any modifications made to the underlying structure are seamlessly reflected in the corresponding IE model. The iterative nature of the conversion process allows any changes to the structure in real life to be reflected in the IE model, promoting a dynamic and responsive workflow for ongoing structural health monitoring processes. Figure 4 shows the attributed graph constructed using the IE model file. This graph is a simple form of validation, letting the user easily see if the elements of the IE model are in the correct location.

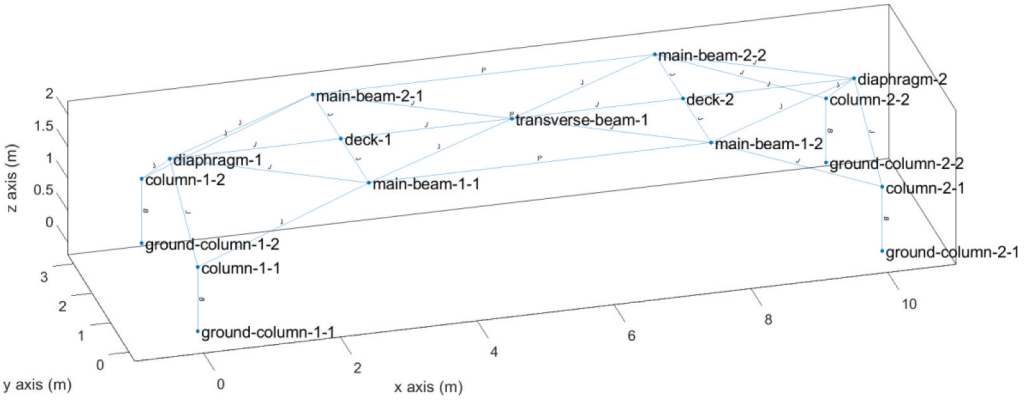

Figure 4. Attributed graph constructed from IE model.

5 CONCLUSION

In addressing the challenges posed by Population-Based Structural Health Monitoring (PBSHM) and the need for effective knowledge transfer among structures within a population, this paper has presented a novel approach through the development of a Finite Element (FE) to Irreducible Element (IE) model conversion tool. The research problem centred around the limitations in existing tools for creating IE models with the aim to bridge the gap between more traditional engineering models (FE) and the new technology of the IE model which can offer population based intelligence for informed decision making by asset owners. The outlined procedure for converting FE models to IE counterparts offers a systematic and accessible solution to developing IE models. The conversion tool was designed to operate with FE models created through standard practices with minimal required amendments to the FE model. The benefits of the FE to IE conversion tool extend beyond mitigating the need for specialised IE model expertise. By encapsulating essential structural information, the tool facilitates the incorporation of an expansive array of structures into the PBSHM framework, thereby accelerating the adoption of PBSHM in the civil infrastructure industry. The creation of an FE model prior to an IE model also has the benefit of allowing checks to be made to the behaviour of the structure. The implications of this conversion tool on PBSHM are significant. It provides a practical means to establish structural similarities among diverse members of a population which is essential in preventing negative transfer effects and enabling more effective knowledge transfer within the PBSHM framework.

ABSTRACT: This study aims to investigate the impact factor of a seven span continuous cable-stayed bridge planned for the extension of an expressway by means of a three-dimensional vehicle-bridge coupled vibration analysis. The validity of the three-dimensional analysis was verified comparing the vibration response of a single span steel cable-stayed bridge in service subjected to vehicle running tests with those numerical responses from the three-dimensional analysis. The impact factors of a seven span continuous cable-stayed bridge were found to be less than 1.07 for the main girder, less than 1.03 for the base of the main tower and less than 1.04 for the cable. The impact factor was highest when several vehicles were running at resonant headway.

1 INTRODUCTION

A new cable-stayed bridge construction is planned on the 14.5km-long Osaka Bay Line as a part of extension in Hanshin Expressway. The new bridge is a seven-span continuous cable-stayed bridge with a length of 2,730 m connecting two manmade islands, called Rokko island and Port island in Kobe respectively.

In highway bridge design, dynamic amplification of bridge responses due to traveling heavy vehicles are considered using the impact factor or dynamic amplification factor. In the Japanese highway bridge design code (Japan Road Association, 2017), the impact factor is defined as $i = 20/(50 + \mathrm{L})$ where L indicates the span length in meters. The impact factor is applicable to bridges with a span length of less than 200 m, however, the cable-stayed bridge in this study has a span length of 650m long which exceeds the applicable range of the impact factor. Cable-stayed bridges exhibit more flexible behavior than girder bridges and have more complex vibration characteristics due to their complex structure consisting of beams, cables, and pylons. Dynamic impact effects require evaluation of various factors such as road surface roughness, vehicle speed, vehicle vibrations, vehicle traveling style, and bridge structural type, but few studies examine the impact factor of the cable-stayed bridge with an extremely long span.

This study aims to investigate the impact factor of a seven-span continuous cable-stayed bridge with a maximum span length of 650m. The impact coefficient is estimated using the three-dimensional (3D) vehicle-bridge interaction (VBI) analysis. The validity the validity of the 3D VBI analysis, a moving vehicle experiment on a single span steel cable-stayed bridge in service, and those vibration responses from the experiment are compared to those from the 3D VBI analysis.

DOI: 10.1201/9781003483755-105

2 VERIFICATION OF IMPACT FACTOR ON REAL BRIDGE EXPERIMENT

2.1 *Moving vehicle experiment*

The validity of the 3D VBI analysis was verified through the comparison to the field-test data on girder bridges (Kawatani & Kim et al., 1998, 2005, 2008). However, in order to properly evaluate the impact factor of the cable-stayed bridge by means of the 3D VBI analysis, it is necessary to accurately reproduce the vibration characteristics and responses of cable-stayed bridges through 3D VBI analysis. Therefore, a field experiment on a similar type of the cable-stayed bridge was carried out to examine the validity of the VBI analysis for the cable-stayed bridge. The general layout and cross-sectional view of the target bridge are shown in Figure 1. The bridge is a steel cable-stayed bridge (Ehara et al., 1993) crossing the Aji River at the Hanshin Expressway No. 5 Bayside Route. The total length is 640m long and the span length is 120m+350m+170m long. The bridge consists of six lanes: three inbound lanes and three outbound lanes.

The acceleration of the girder, main tower, and experiment vehicles were measured, and the displacement at the center of the main girder was also measured using a laser displacement transducer. Figure 2 shows the measurement points and the corresponding analysis node numbers. Accelerometers are installed at three points on the top and middle stages of the main tower, and at L/4, L/2, and 3 L/4 of the main girder in the center span and side span. A laser displacement meter was installed under the center of the span between P11 and P12, which can be measured from the ground, and measured the vertical displacement of the girder. Figure 3 shows an overview of the test vehicle and the locations where the accelerometers are installed. The test vehicle was a dump truck with a front axle weight of 54.74 kN and a rear axle weight of 140.68 kN, and total weight was 195.42 kN (□196 kN). Accelerometers were installed near the center axis of the vehicle above and below the front and rear suspensions. Free vibration tests for the test vehicle were measured to identify the bounce frequency and axle hop frequency at the front and rear wheels. The bounce frequency at the front axle was 1.5Hz, and that at the rear axle was 3.5 Hz. For the axle hop frequency, 10 Hz was dominant at both the front and rear wheels. The vehicle speed during the moving vehicle experiment was set 80km/h.

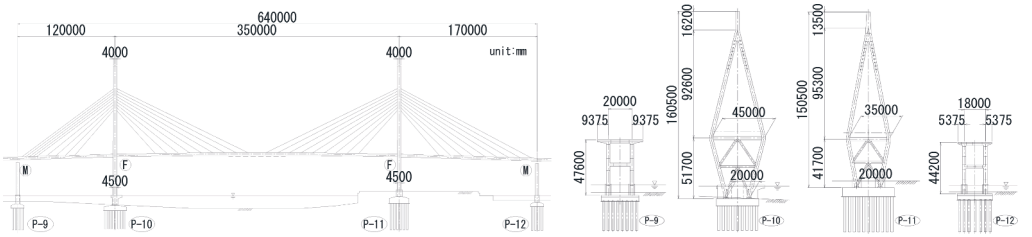

Figure 1. The general layout of the in-service cable-stayed bridge for the experiment (unit: m).

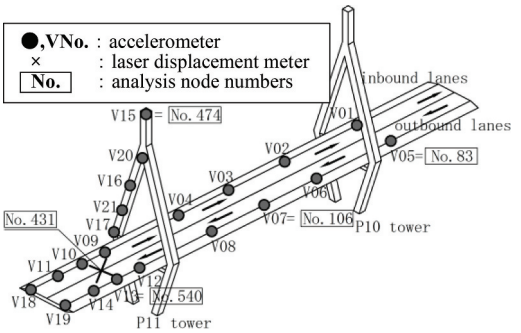

Figure 2. The measurement points and the node numbers in the corresponding analysis.

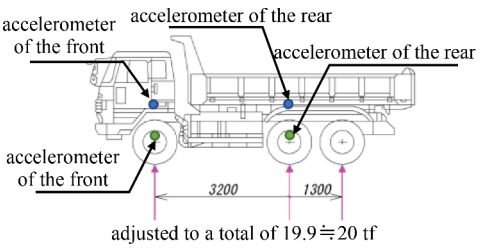

Figure 3. Overview of the test vehicle and the locations of the accelerometers.

2.2 *VBI analysis and impact factor verification*

Dynamic responses of the in-service bridge are obtained taken from 3D VBI analysis (Kim et al., 2005). It is based on the finite element method for the modal analysis using three-dimensional models for both vehicle and bridge. The numerical bridge model is shown in Figure 4 in which the beam element is used to model girders, the truss element is used for cables, and the spring element with two nodes with the same coordinate is adopted to model the elastomeric bearing. The vehicle model is composed of the body, tires, and suspension systems. Details of the vehicle model are shown in Figure 5 and Table 1 along with the eight degrees of freedom to describe its movement (Kawatani & Kim et al., 2005, 2008). The vehicle properties were estimated using the free vibration measurement on a 20 ton dump truck used in the test. Rayleigh damping was adopted in the 3D VBI analysis of the bridge, and the coupled equation of motion for vehicles and bridge interactive system were solved by the Newmark-β method assuming β = 1/4. In the 3D VBI analysis of the bridge, the roadway roughness on the bridge surface is simulated based on the PSD curves (ISO 8608, 1995). Since the road surface properties are not clear, the parameters α = 0.003 (cm^2/(m/c)), β = 0.05 (c/m), and n = 2.00 were assumed.

In the moving vehicle experiment on the bridge, the measured value of the acceleration response is converted into a dynamic displacement using Fourier transform, and the impact factor is calculated. Figure 6 shows the dynamic displacement extracted from the measured acceleration

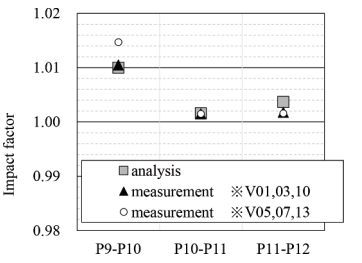

Figure 7. Impact factor.

response at the span center of each girder with the analytical ones, where "Ddy" denotes the response including both static and dynamic components while "Dst" denotes the static displacement. Figure 7 shows the impact factor determined from the dynamic displacement shown in Figure 6. It is observed from Figures 6 and 7 that the response and impact factor obtained from the VBI analysis are comparable with those from experiment, i.e. shows validity of the 3D VBI analysis.

3 3D VBI ANALYSIS AND IMPACT FACTOR OF SEVEN SPAN CONTINUOUS CABLE-STAYED BRIDGE

3.1 *Numerical models*

The general layout and cross-sectional view of the seven span continuous cable-stayed bridge (hereafter called "target bridge") are shown in Figure 8. The bridge is a seven-span continuous cable-stayed bridge. The total length is 2730m long and the span length is 130m+260m+3@650m +260m+130m long. The bridge has four A-shaped steel towers in the longitudinal direction, and has six lanes, three inbound lanes and three outbound lanes, as shown in Figure 8. Dynamic responses of the bridge are taken from the same way as the verification of analysis validity on real bridge experiment described above. The bridge model is shown in Figure 9. Two vehicle speeds, 80 km/h and 60 km/h, are considered in the 3D VBI analysis. The roadway roughness on the bridge surface is simulated based on the PSD curves, in which the roadway roughness is assumed to be categorized as Class A according to the ISO estimate (ISO 8608, 1995).

3.2 *Definition of impact factor*

The impact factor adopted in this study is defined as $DIF = 1 + y_{I,dmax}/y_{stmax}$ where $y_{I,dmax}$ denotes the maximum dynamic amplitude, and y_{stmax} denotes the maximum static amplitude. The definition of the impact factor is also illustrated in Figure 10. The impact factor is calculated based on vertical displacement for the main girder, bending moment for the main tower, and analytical tension for the cable.

Table 2. Analysis scenarios for impact factor.

	Driving lane	Vehicle speed (km/h)	No of vehicles	Resonant headway (m)	Road surface roughness
Case1	A to C	80	4/lane	165(=v/f=22.22(m/s)/0.136(Hz))	A-1; α=0.001
Case2	A to C	80	4/lane	165	A-2; α=0.004
Case3	A to C	60	4/lane	125(=v/f=16.67(m/s)/0.136(Hz))	A-1; α=0.001
Case4	A to F	80	4/lane	165	A-1; α=0.001
Case5	A to C	80	1/lane	165	A-1; α=0.001
Case6	A to C	80	10/lane	60	A-1; α=0.001

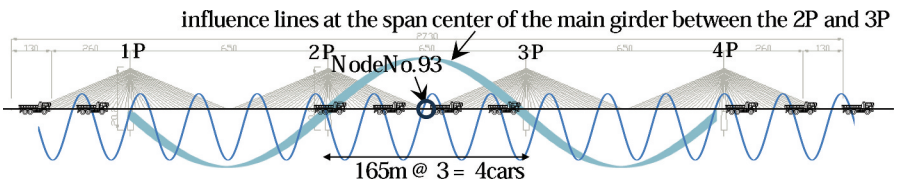

Figure 12. Vehicle placement for Case 1 to Case 4 of the analysis scenario.

3.3 *Eigenvalue analysis*

Selected mode shapes and frequencies of the bridge from the eigenvalue analysis are summarized in Figure 11. Therein, the bending mode of the bridge is observed in the 1st mode (0.136Hz). The 3rd mode (0.192Hz) is the 2nd bending mode of the main girder between the 2P tower and 3P tower. The 10th mode (0.356Hz) shows a sway mode of the main tower, and the 17th mode (0.499Hz) is the 2nd bending mode of all spans.

3.4 *Impact factor of main girders located between 1P and 4P towers*

3.4.1 *Analysis scenarios*

Analysis scenarios are summarized in Table 2 where the resonant headway indicates the distance between two vehicles which produces the most excessive vibration of the bridge. Two road surface roughness profiles denoted A-1 and A-2 are considered in the VBI analysis. The difference

between the A-1 and A-2 road surface roughness profiles is the amplitude of the profile, i.e. the A-1 profile is smoother than the A-2 profile. Since the vertical bending mode of the main girder and the sway mode of the main tower are dominant, the resonant headway is set as L=165m ($L = v/f = 22.22(m/s)/0.136(Hz)$). The number of vehicles traveling on one lane is set to four so that four vehicles with a headway of 165m place on the deflection mode of the main girder as shown in Figure12. Cases 5 and 6, which are vehicle running scenarios without resonance headway, were also employed to investigate the impact of resonant headway on the impact factor.

3.4.2 *Impact factor of the main span*

The estimated impact factors of the main girder are summarized in Figure 13, which shows that the impact factor ranges between 1.01 and 1.05. Although the amplitude of road unevenness is larger than in other scenarios, the impact factor for Case 2 shows the same value as Case 1. One reason is that the bridge vibration is dominated by the first bending mode at 0.136 Hz, and the contribution from the vehicle vibration with a frequency of around 3.5 Hz was extremely weak.

When multiple vehicles with resonant headway are traveling on all lanes like in Case 4, the largest impact factor is observed among six scenarios. On the other hand, lower impact factors were observed for slower vehicle speeds and fewer vehicles, as in Case 3 and Case 5. Even if the vehicle load is large, if there is no resonance, the impact coefficient is low as Case6. Figure 14 shows the maximum value and amplification factor of the dynamic response displacement of the main girder during vehicles traveling on 2P-3P span under the scenarios Case 1, Case 4, and Case 5. In Case 1 and Case 4, the amplification factor of dynamic displacement increases due to the resonance effect of the vehicle, and the impact factor increases.

The impact factors of the main tower at the middle section and tower base are calculated from the bending moment and summarized in Figure 15. The impact factors of cables, which are obtained from analytical tensions, are summarized in Figure 16. The impact factors for the main towers and cables were less than 1.05.

Table 3. Analysis scenarios for impact factor.

	Driving lane	Vehicle speed (km/h)	No of vehicles	Resonant headway (m)	Road surface roughness	hump at EJ
Case7	A to C	80	14+9/lane	46.7(=v/f=22.22(m/s)/0.476(Hz))	A-1; α=0.001	W/O hump
Case8-1	A to C	80	14+9/lane	44.5(=v/f=22.22(m/s)/0.499(Hz))	A-1; α=0.001	W/O hump
Case8-2	A to C	80	14+9/lane	44.5	A-1; α=0.001	W/ hump H=15mm
Case9	A to C	80	14+9/lane	40.2(=v/f=22.22(m/s)/0.553(Hz))	A-1; α=0.001	W/O hump

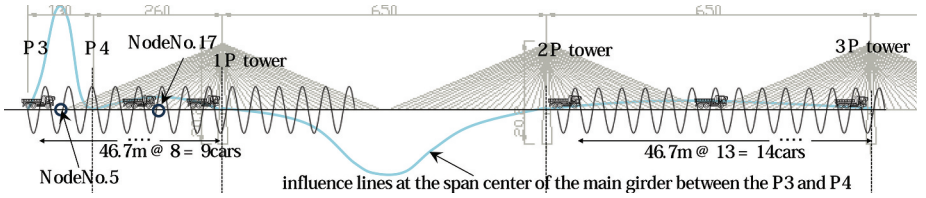

Figure 17. Vehicle placement for Case 7 to Case 9.

3.5 *Impact factor of the main girder at the side span center between P3 and 1P tower*

3.5.1 *Analysis scenarios*

In addition to impact factors of the main span under vehicle loadings considering the 1st bending mode of the main span, it is worth investigating the effect of vehicle loadings considering the dominant bending mode of the side span. The dominant first bending mode of the side span is different from the main span, the first bending mode of the side span observed in the 17th mode (0.499Hz) shown in Figure 11 is considered for the resonant vehicle loading. In addition, bending modes near the 17th mode (0.499Hz), that is the 16th mode (0.476Hz) and the 21st mode (0.553Hz), are also considered in the VBI analysis. Analysis scenarios are summarized in Table 3. The number of vehicles, road surface roughness profiles, and vehicle speed are not changed. Since the vertical bending mode of the main girder is dominant, the resonant headway is considered as L=46.7m for f = 0.476(Hz), L=44.5m for f = 0.499(Hz) and L=40.2m for f = 0.553(Hz). Humps at the expansion joint is considered in the VBI analysis for the side span. Case 8-2 is the scenario with the hump at the expansion joint on P3 located at the entrance of the side span. The depth of the hump was assumed 15mm and the length of the hump was assumed 2500mm. The impulsive vehicle wheel load generated when vehicles pass on the hump travels farther according to vehicle speed, and this study investigates the effect of vehicle speed and hump at the expansion joint on the impact fact of the bridge. Figure17 shows the vehicle placement for Case 7 to Case 9. 23 vehicles with the resonant headway place on the deflection influence line of the main girder.

3.5.2 *Impact factor of the side span*

The estimated impact factor of the main girder under the vehicle loadings considering the dominant bending mode of the side span is summarized in Figure 18. The impact factor between P3-P4 is found to be in the range of 1.05 to 1.07, those of P4-1P tower were found to be in the range of 1.01 to 1.02. The impact factor between P4-1P tower with short span length was smaller than that between 2P-3P towers because the displacement between the 2P and 3P towers is amplified much more due to resonance. The impact factor for Case 8-2 shows the same value as Case 8-1, which indicates that the dynamic responses of the girder at the span center is hardly affected by the hump since the observation point is far from the hump.

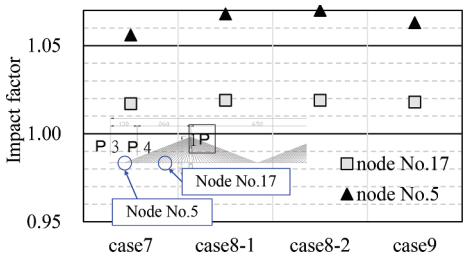

Figure 18. Impactor factor of main girder.

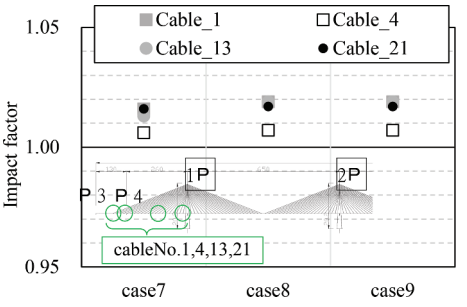

Figure 19. Impactor factor of main cable.

The impact factors of cables, which are obtained from analytical tensions, are summarized in Figure 19. The impact factors for cables were less than 1.05, the same as the main span section.

4 CONCLUSIONS

Impact factors of a seven span continuous cable-stayed bridge planned for the extension of an expressway by means of a three-dimensional vehicle-bridge interaction (VBI) analysis. The validity of the three-dimensional VBI analysis was verified comparing the vibration response of a single span steel cable-stayed bridge in service subjected to vehicle running tests with those numerical responses from the three-dimensional analysis. Impact factors of the seven-span continuous cable-stayed bridge were found to be less than 1.07 for the main girder, less than 1.03 for the base of the main tower, and less than 1.04 for the cable. The largest impact factor was observed when several vehicles are running with resonant headway at higher speeds. Additionally, it was confirmed that the impact coefficient was the largest in the case where multiple vehicles were driven with a resonant headway.

ABSTRACT: Post-tensioned concrete is currently one of the most common technology used to construct bridges. For decades it was used to build medium-span bridges over the world and now many of them require diagnostics due to their worsening technical condition. One of the novel diagnostic technique for such bridges can be distributed fiber optic sensing (DFOS). It allows the measurements to be taken continuously over the entire structural length, which is especially important in such structures. The advantages of this method have already been proven in civil engineering applications, especially those related to concrete structures. Thanks to their construction distributed fiber optic sensors can be used for both new and existing structures. The paper presents the research on two post-tensioned beams with curvilinear multiwire strands in which optic sensors have been installed before and after concreting. The main aims of the research was to measure strains, stresses, cracks and displacements, to compare results from monolithic sensors embedded in the concrete (for new structures) and those installed in pre-made near-to-surface grooves (for existing structures) and to identify defects in one of the beam thanks to sensors installed inside the cable duct and the strain itself. The DFOS measurements were also compared with reference measurements made with conventional spot techniques, achieving very good compliance. The research proved that a well-designed DFOS-based system, including appropriate measurement techniques, optical sensors, installation methods and post-processing algorithms, is the relevant tool for the diagnostics of post-tensioned concrete bridges.

1 INTRODUCTION

Due to the continuous development of road and railway infrastructure around the world, the number of bridge structures has been steadily increasing year by year, particularly in developing countries. For example over the last 20 years, the count of these structures on national roads in Poland has tripled. Bridges with such superstructure currently represent around half of all road bridges in Poland, whereas in 2002, their share was less than 20%. Presently, the most commonly chosen type of construction for small and medium-span road bridge structures is prestressed concrete (either post-tensioned or pre-tensioned). The increase in the number of prestressed bridges is expected to be driven in the coming years by the further expansion of the national road network and the construction of new railway lines. Similarly, in other countries prestressed bridges constitute an important part of the infrastructure system.

DOI: 10.1201/9781003483755-106

The primary driver behind the dynamic growth of such structures is the fact that properly designed and constructed prestressed bridges rank among the most durable constructions, requiring minimal maintenance during their operational lifespan. These structures undergo the introduction of substantial prestressing forces during construction, making them unfortunately highly sensitive to any design or construction errors. Incorrectly designed or constructed prestressed bridges are susceptible to the detrimental effects of environmental factors, resulting in a shortened operational lifespan and a gradual reduction in load-bearing capacity over time. In extreme cases, this can lead to the failure or catastrophe of these structures (Anania, Badalà, & D'Agata, 2018; Hurlebaus, Hueste, Karthik & Terzioglu, 2016; Powers, Sagues & Virmani, 2002). As a result, prestressed bridges require meticulous control during the construction phase and heightened attention from bridge inspectors during periodic condition assessments during operation. Identifying local damage in prestressed bridges is challenging and highly laborious with current methods due to the localized positioning of the tendons within the concrete cross-section (Mazzatura, Salvatore, Caprili, Celati, Mori & Gammino, 2023). Early-stage diagnostics of damage allow for the prevention of further deterioration to a level threatening the safety of the structure and prompt implementation of remedial measures, which are often less costly at this stage (Frangopol, Saydam, & Kim, 2012). A promising and continually evolving technique in the field of diagnostics and monitoring of concrete structures is the use of distributed fiber optic sensors (DFOS) (Alj et al., 2021; Bado, Casas & Kaklauskas, 2021; Bednarski et al., 2022; Buda-Ożóg et al., 2022).

This article presents research results on the development of a DFOS sensor system for monitoring and diagnosing post-tensioned concrete bridges, addressing the needs of the construction industry in this regard. It aims to fill the current gap in the control and management system for bridge structures during the operational phase. Initial studies have demonstrated that using the DFOS sensor system allows for the detection of damages, primarily voids in the grout inside cable ducts, which are the most common causes of failures (Piątek et al. 2023). By embedding sensors during the manufacturing phase of prestressed elements, valuable insights can be gained into their behavior during concrete pouring, prestressing, and concrete maturation. Additionally, continuous geometric measurements using DFOS sensors provide a comprehensive picture of deformations, displacements, and crack distribution along the length of the element, which is unattainable using typical point sensors (Fischer, Thoma & Crepaz, 2019; Liu, Huang & Yang, 2020).

2 RESEARCH PROGRAM

2.1 *Design of tested beams*

Two post-tensioned concrete beams were tested in order to examine DFOS system and check it's utility for diagnostics, first served as a reference (PT1) and second had simulated damages (PT2). The beams had a trapezoidal shape with a height of 60 cm and a width ranging from 45 to 55 cm (Figure 1). Both beams were made of C40/50 concrete with an experimentally determined compressive strength of 58.1 MPa, tensile strength of 4.7 MPa and elastic modulus of 44.2 GPa. Two cables were applied in each beam, each containing four strands with a diameter of ϕ15.7 mm (Y1860S7 steel). After concrete placement, the cables were prestressed with an initial force of 1500 kN each. The beam included reinforcement in the form of ϕ16 rods at the bottom and top edges, as well as circumferential reinforcement with ϕ10 rods (B500SP steel). Shear reinforcement was also applied using double stirrups with a diameter of ϕ12 mm (B500SP steel). Cross-sectional and longitudinal views of the beams are presented in Figure 1. In the beam with simulated damages during prestressing, the ducts were not fully filled with grout, leaving approximately 1.4 m of free space from the beam ends. This resulted in four unfilled sections of the ducts, the first was left completely empty (real void in the channel). In the second, corrosion simulation was conducted (real void and corroded prestressing tendon), while in the third and fourth sections, partial filling with polyurethane foam was carried out. The schematic of the simulated damages is shown in Figure 2.

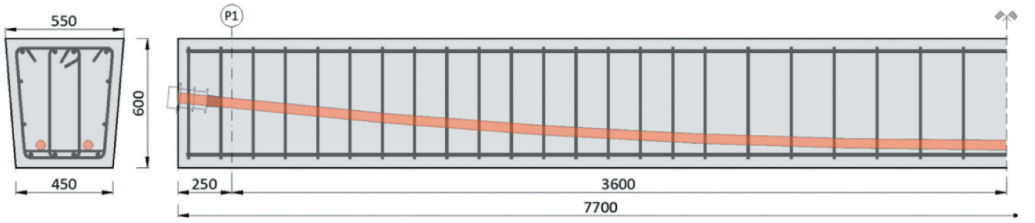

Figure 1. Cross-section and longitudinal section of the beams.

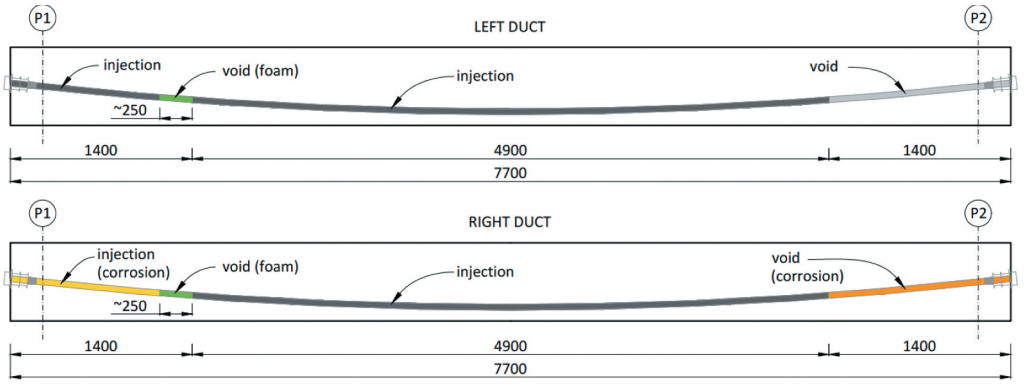

Figure 2. Damages simulated in the second beam (PT2).

2.2 *Test setup and instrumentation*

The beams were subjected to a four-point bending load scheme on specially designed testing stand equipped with two hydraulic actuators with a maximum pressing force of 630 kN placed at a spacing of 1.2 m. The theoretical span of the beams was 7.2 m. View of the beams on the testing stand is presented in Figure 3.

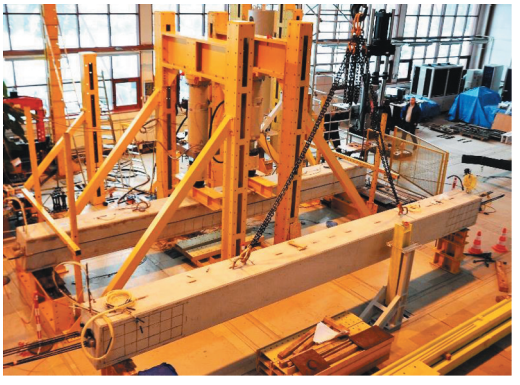

Figure 3. Cross-section and longitudinal section of the beams.

During the tests, the following distributed fiber optic sensors (DFOS) were utilized: EpsilonSensor (ES), 3D displacement sensors, and fiber optic sensors integrated with a prestressing strand, developed as part of the project. EpsilonSensor is made with monolithic

composite material with low elastic modulus (3 GPa) which provides precise strain reading and crack locations. In Figure 4, the markings and numbering of fiber optic sensors in the cross-sections of individual beams are presented. 3D displacement sensors consist of four optical strain fibres precisely positioned on the top and bottom of a rectangular composite core. It allows to determine deflections along the beams knowing the spacing between the fibres and the boundary conditions. Sensors were installed using three methods: embedding inside the concrete (EpsilonSensors), bonding to the surface (3D sensors) and near-to-surface installation inside a pre-made groove (EpsilonSensors). Additionally, reference measurements were conducted for comparison with DFOS techniques. Electro-resistance strain gauges were used for strain measurements, and linear variable displacement transducers (LVDTs) were employed for displacement measurements. Force measurements were carried out using sensors integrated with loading system.

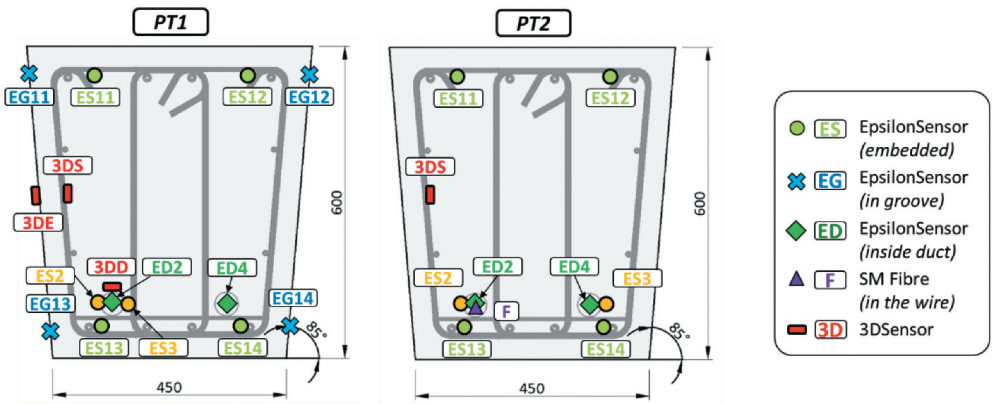

Figure 4. Locations and adopted symbols for sensors in the cross-section of the beams.

The Rayleigh-based method was employed for measurements using the Luna Innovations OBR optical backscatter reflectometer. In the post-processing of the data, a spatial resolution of 10 mm was configured, enabling a strain resolution of 1 με. Spatial resolution of 10 mm translates to 100 measurement points per meter of the DFOS sensor and 770 measurement points along the length of the post-tensioned girder (for a single sensor). With such a large number of points, statistical analysis and interpretation of the measured strain profiles is possible.

3 TEST RESULTS AND ANALYSIS

3.1 *Cracking identification*

In this section, sensor readings installed in exactly the same locations and in the same manner are compared, however, on two different beams: one without damages (PT1) and one with damages (PT2). To facilitate the physical interpretation of the measurements, data for the undamaged beam will be indicated by a dashed line, while data for the damaged beam will be indicated by a solid line. Cross-sectional diagrams with the marked location of the analyzed sensor are included in the charts. Since beam PT2 was not equipped with sensors in near-surface grooves, the results are presented for sensors embedded inside the concrete. Exemplary results of comparison between two beams under load of 350 kN in the upper and lower zone of the beam are presented in Figure 5 and Figure 6, respectively.

Based on the DFOS measurements, it was possible to identify existing cracks in the upper part of the beams, closing under the influence of compression induced by bending as well as new cracks forming in the lower part of the beams due to tensile forces induced by bending.

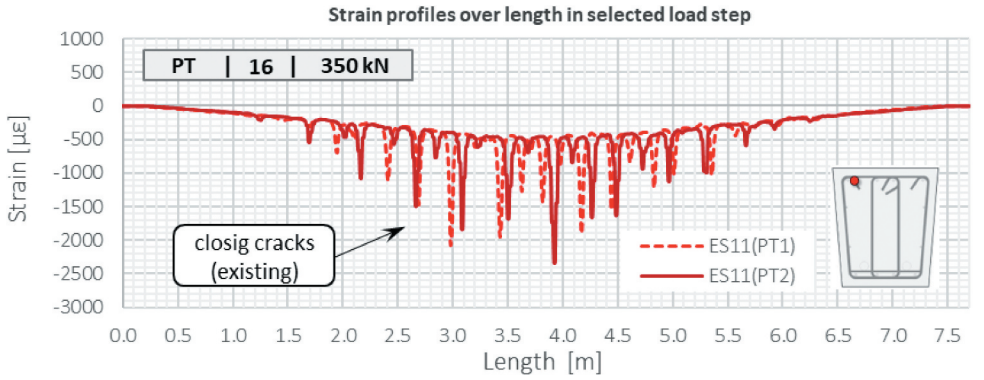

Figure 5. Strain profiles over length measured monolithic sensors ES11 in the upper zone of the beam under force of 350 kN.

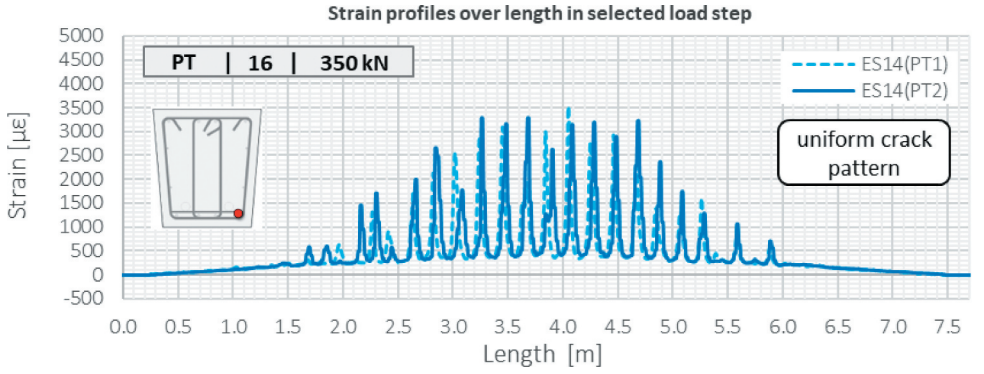

Figure 6. Strain profiles over length measured monolithic sensors ES14 in the lower zone of the beam under force of 350 kN.

The cracks in the upper part of the beams were caused by thermal-shrinkage deformations and under the influence of the compression process, causing stretching of the upper fibers. The characteristic and symmetrical distribution of cracks indicates that mechanical deformations from prestressing had a decisive influence. Despite performing zero measurements when the cracks already existed in the upper part of the beam, the change in deformation under bending allowed for their unambiguous identification. In existing, operational structures, this detection will be additionally supported by thermal deformations of the structural element.

Identification of the new cracks in the lower part of the beams was possible because zero readings were taken just before the test, i.e., after the prestressing of the element, from a measurement perspective, the sensor was subjected to tension from the very beginning (the analysis does not consider compression from prestressing). In the next subsection an analysis aimed at estimating the width of these new cracks is presented.

Since the simulated damages in the PT2 beam were not significant and located only near the end sections of the beams they did not influence on a global behavior and are not visible in Figures 5 and 6 because cracks have a dominant share in the measured values. The analysis of local damages will be discussed in details in subsection 3.3.

3.2 *Calculations of crack widths*

There are several ways to estimate the crack width based on the measured strain profile (Howiacki T. et al., 2023). The basic approach used in this analysis involves integrating (summing up) the strains over the effective length. In the case of a stabilized crack state, this length can be assumed between the midpoints of the segments determined between the cracks. However, it should be noted that this approach relies on the assumption that the strains in the concrete between the cracks are zero, which may not always be true. In reality, at the edge of the crack, the concrete relaxes completely, but as one moves away from the crack, tensile strains may accumulate (up to a value corresponding to the tensile strength of the concrete). The crack widths obtained using the above method will therefore be slightly overestimated, but previous experiences indicate that an accuracy of no worse than 0.05 mm can be safely assumed. From the perspective of the engineering assessment of the structural condition, such accuracy can be considered sufficient. In the case of analyzing a single crack, the effective length will strongly depend on the type of DFOS tool used (optical fiber, layered cable, monolithic sensor), the installation method (adhesive on the surface, embedding inside the concrete), as well as the properties of the concrete itself. In the following calculations, the effective length was defined as 14 cm.

The graphical representation of the example results under load of 350 kN is presented in Figures 7 and 8 for in-groove sensors in beam PT1 and embedded sensors in beam PT2, respectively. The widths of selected cracks are directly indicated in millimeters and are depicted in the pink and blue boxes, while the reference measurements are shown in the white

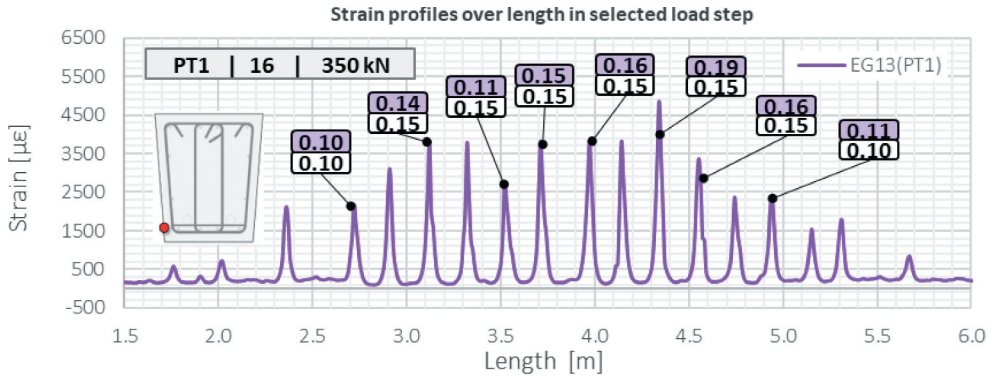

Figure 7. Crack analysis in beam PT1 based on the strain profiles measured by monolithic sensor EG13 installed in near-to-surface groove under force of 350 kN.

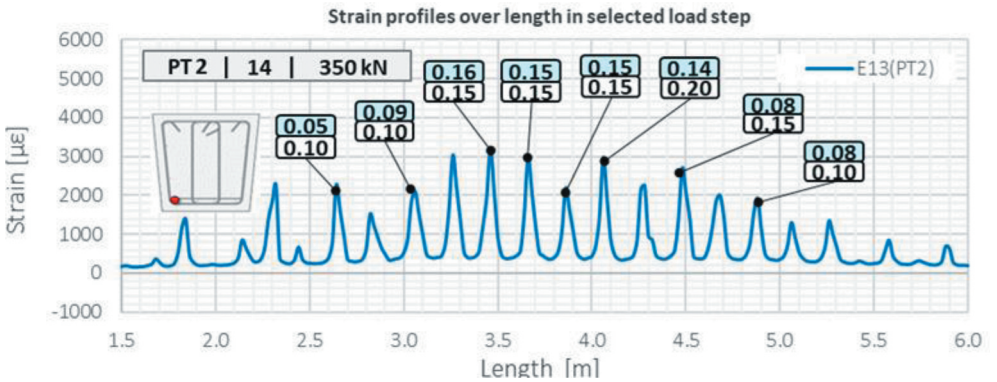

Figure 8. Crack analysis in beam PT2 based on the strain profiles measured by embedded ES13 monolithic sensor under force of 350 kN.

boxes. Reference readings were conducted on the lateral surface of the girder using a plastic plate crackmeter with an accuracy of ±0.05 mm. Due to the different measurement locations and the unpredictable course and width of the cracks, the comparison within the single crack can only be considered approximate. However, the statistical analysis of a larger number of cracks will give a more reliable indication of the range of possible errors.

The differences in the analysis of crack widths between the DFOS technique and conventional measurements are in most cases not greater than 0.05 mm. This value, in practical engineering applications, is sufficient for a proper assessment of the performance of a cracked structure. It is also worth emphasizing that ongoing efforts are being made to optimize computational algorithms, allowing for the estimation of crack widths based on fiber optic strain measurements with even greater precision.

3.3 *Identification of simulated damages*

The damages were simulated only in the initial and final areas of the 1.4 m long beams, i.e. in the areas where no cracking occurred. In these areas, significant differences between two beams can be noticed. Due to the loss of adhesion of the ED2 sensor to concrete in the areas of simulated voids, there is no characteristic, monolithic increase in deformation. On the other hand, in the location of the injection with simulated corrosion (the last 100-120 cm of the girder), the strain increment is accelerated compared to the undamaged girder. The details of the analysis are presented in the following figures. In turn, in the injection site with simulated corrosion (the last 100-120 cm of the beam), the increase in deformations is accelerated compared to the beam without damage. Details of the analysis are presented in Figure 9.

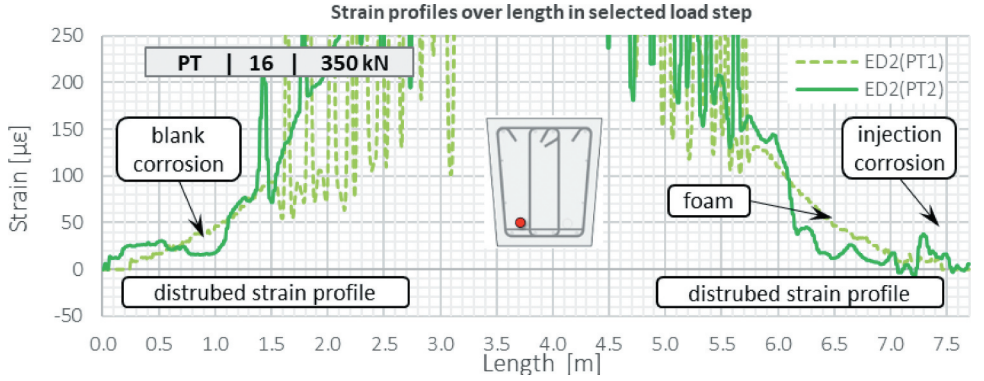

Figure 9. Comparison of strain profiles over length measured monolithic sensors ED2 inside the duct under force of 350 kN.

The analysis of local phenomena in the initial and final areas of the girder allowed for the diagnosis of damages. There is also the possibility of analyzing the global performance of the girder, involving the calculation of statistics (including average values) for selected load steps and comparing them with the results for the undamaged girder at the same forces. For each sensor pair, an increase in average strains was recorded. The smallest increases (of the order of a few percent) were observed for sensors in the compressed and tensioned zones, not located in the immediate vicinity of the simulated damage. On the other hand, the largest increments (of the order of several tens of percent) were shown by ED2 sensors inside the duct and ES2 sensors installed on the duct.

3.4 *Deflections*

Distributed fiber optic sensors can be also used to calculate displacements (deflections, shape changes) of the beams. For this purpose, 3D sensors were used, which contain four optical fibers

arranged around a rectangular core and are dedicated to displacement measurements. Additionally, the concept was employed in which, from the entire structural element equipped exclusively with optical deformation sensors, a displacement sensor is created. This schematic serves as an analogy to the internal structure of a 3DSensor. However, in this case, the composite core is replaced by the cross-section of the element, and the optical fibers are replaced by deformation sensors (EpsilonSensors). Measures from DFOS sensors were compares with reference method using linear variable displacement transducers. Exemplary results are presented in Figure 10.

The average difference between the readings of both DFOS solutions throughout the entire study did not exceed 0.7 mm, and in relation to the reference measurements, the errors were on average less than 1 mm, with measured absolute values at the level of several millimeters. The agreement is therefore considered accurate.

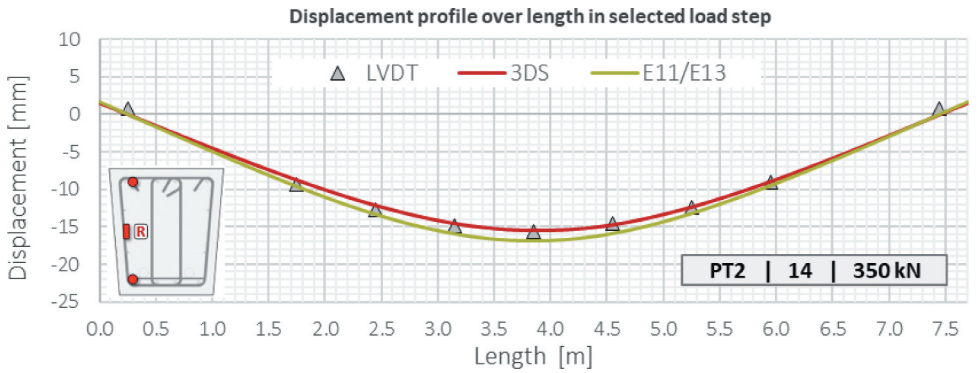

Figure 10. Comparison of displacement measured using 3D sensor (3DS), EpsilonSensors (E11 and E13) and linear variable displacement transducers (LVDTs) in beam PT2 under force of 350 kN.

4 CONCLUSIONS

Distributed fiber optic sensors can provide valuable information about the performance of the post-tensioned girders. A well-designed monitoring system using these sensors can be employed for periodic checking of strains and displacements in bridge structures, allowing inferences about their technical condition. The key conclusions from the presented research are outlined below.

- The DFOS technique provides information about the deformation changes along the entire length of the sensor (element). In the conducted studies, a spatial resolution of 10 mm was typically adopted, corresponding to one hundred measurement points per meter of the sensor.
- Apart from the global analysis of the sensor's behavior along the entire length of the examined element, the DFOS technique allows for the analysis of local phenomena, such as cracking and damage detection.
- Data from DFOS measurements can be utilized with suitable computational algorithms to accurately determine crack widths and deflections.

The research described in the paper was carried out at the Rzeszow University of Technology, Poland, as part of the R&D project: "Monitoring and diagnostic system for prestressed structures using integrated fibre optic sensors (DFOS)". It was funded by the Podkarpackie Center of Innovation, the grant no.: RPO.RB.22.004 – N3-056.

Modeling temperature impact on sensor data in prestressed concrete bridges

V. Coric, C. Wang, J. Gonzalez-Libreros, L. Elfgren & G. Sas
Department of Civil, Environmental and Natural Resources Engineering (SBN) Luleå University of Technology, Lulea, Sweden

ABSTRACT: Prestressed concrete bridges experience complex load scenarios throughout their lifespan which impacts their load capacity and overall performance. To ensure optimal functionality and safety it is crucial to understand the diverse responses from the structure under varying load. By deploying sensors in strategically placed locations, a numerical representation of varying responses can be attained during operation. Variation in temperature can affect the readings of a sensor. This can lead to false positive structural damage responses. Thus, it is important to differentiate between variations in structural properties induced by temperature fluctuations, and variations from structural damage. This paper presents a novel approach for mapping the temperature effect in structural responses. By employing an artificial neural network (ANN) and measurement data from a prestressed concrete bridge located in northern Sweden, a correlation between the temperature and the sensor values is achieved.

1 INTRODUCTION

Prestressed concrete bridges face different dynamic loads that affect their structural health and performance. Knowing how they react to these loads is crucial for their safety and continued use.

Structural Health Monitoring (SHM) of concrete structures involves differentiating the impact of environmental and operational conditions (EOCs) on sensor data from their impact on the structure itself. Thermal stresses caused by temperature fluctuations trough expansion and contraction in the concrete can lead to cracking and accelerated deterioration (Wałach, 2020), particularly in areas with extreme climates. Other environmental factors, such as freeze-thaw cycles and deicing chemicals, also contribute to internal stress and concrete damage. Chemical reactions from sulfate attack and alkali-aggregate reactions, induced by environmental exposure, cause further degradation (Portland Cement Association, 2002; Luo et al, 2013). A study by Shan et al, (2018) found that temperature is a major factor in changing modal frequencies. For instance, the Alamosa Canyon Bridge in USA and Z24 Bridge in Switzerland showed significant frequency variations (up to 18%) due to temperature.

Sensors, both analog and digital, can be affected by harsh conditions and may exhibit mechanical changes or calibration drift over time, leading to inaccurate data measurements (Xiang et al, 2018; Yan et al, 2022). This misrepresentation can result in false diagnostics of the structure's condition. Therefore, it is critical to consider EOCs when interpreting sensor readings, as they can obscure the true state of structural damage. A study by Keshmiry et al, (2023) emphasize the importance of accounting for variables like temperature, humidity, and wind, which can alter sensor responses and hide damage indicators, affecting the dynamic response and physical properties of the structures. Another study by Gianesini et al, (2021) highlighted the use of the electromechanical impedance (EMI) technique in SHM for real-time damage detection. However, EMI is sensitive to temperature changes, which can mimic structural

DOI: 10.1201/9781003483755-107

damage. Showcasing the impact EOCs has on sensors and highlights the importance to handle the EOC impact on sensor data while not removing its effects on the structure itself.

The growth of computational power has significantly changed the use of machine learning (ML) in engineering. With better processing abilities and large datasets, similar to what's seen in big data, engineers are better equipped to handle structural analysis on structures. Research has explored these effects using various techniques, Malekloo et al, (2022) discuss the shift from traditional damage detection to advanced, smart monitoring and decision-making with ML. This enables near real-time damage assessment, enhancing safety and reliability for structures like bridges. Methods like Principal Component Analysis (PCA) have been suggested. Zhang et al, (2013) used PCA to filter out environmental disturbances from sensor data, improving SHM system performance. Their simulations showed that combining PCA with the Hilbert-Huang transformation (HHT) greatly increased SHM accuracy against environmental factors. However, even with these advancements in ML approaches, there's no universal solution and often depends on the engineer's expertise (Zinno et al, 2022).

Operational conditions like traffic and environmental factors such as wind and ice accumulation present challenges in SHM. Traffic and wind alter the load on a structure, causing different stress responses, while ice adds weight, complicating the analysis. Sensors capture these varying responses, but accurate interpretation is key; not all recorded changes point to damage. Correctly categorizing these operational and environmental impacts is critical for reliable SHM (Keshmiry et al, 2023). Unaccounted EOCs can lead to misidentification of structural damage, resulting in inaccurate damage assessments. Properly distinguishing between actual damage and EOC effected values is essential for the safety and longevity of structures. By effectively filtering these effects, we can allocate maintenance resources more efficiently, focusing on real structural issues rather than false alarms.

Another challenge today is integrating ML into SHM systems. Effective SHM requires high-quality data, but many structures aren't built with ML principles in mind, leading to poorly placed sensors and inadequate data. Preprocessing this data for ML use is complex, particularly for those without expertise in structural engineering or ML (Flah et al, 2021). This creates a barrier to adopting advanced ML techniques for SHM, required specialized training or significant time and resource investment.

This article introduces a novel method to understand and track the impact of temperature on prestressed concrete bridges using an ANN. The method is demonstrated on data recorded from a bridge in Northern Sweden. The study finds a strong correlation between temperature and sensor values indicating the temperature variations and the bridge's structural behavior.

1.1 *EOC effects on structural sensor data*

Addressing the effects of EOCs is crucial in SHM. This not only optimizes resource utilization but also ensures the structural integrity of important public infrastructures like bridges. Accurate SHM data is vital for making informed decisions about necessary repairs, preventing minor problems from developing into major failures, thus maintaining both public safety and confidence in these structures (Gharehbaghi et al, 2022; Kaloop et al, 2018).

2 METHOD

2.1 *Regression analysis and artificial neural networks*

Building on the challenges presented by the impact of EOCs on measurement data in SHM systems is crucial to explore how modern ML techniques can revolutionize this field. These advanced methods have the potential to significantly reduce the need for domain-specific knowledge and can be tailored to fit various structures, making them highly versatile. One such method is regression analysis.

Regression analysis, a fundamental technique in ML, excels in establishing relationships between variables. In SHM, this translates to correlating sensor data with indicators of

structural health. The essence of regression lies in its mathematical foundation, where the goal is to find the best-fit line or curve that models the relationship between independent variables, such as values from sensors on the structures, and a dependent variable, which in this case is the temperature.

The process typically begins with defining a regression function. For instance, in linear regression, the simplest form, this function is a straight line described by Eq 1.

$$y = \beta_0 + \beta_1 x + \varepsilon \tag{1}$$

Here, y represents the structural health indicator, x is an EOC factor, β_0 is the y-intercept, $\beta_1 x$ is the slope of the line, and ε accounts for deviations in the data. The objective here is to determine the values of β_0 and $\beta_1$that best fit the observed data, a process known as Ordinary Least Squares (OLS).

Multiple regression is used when we deal with many variables affecting an outcome. It adjusts to include each variable and measures its specific impact. This makes regression models versatile for analyzing different structures and EOCs, providing a custom solution for monitoring structural health.

Regression analysis is also valuable for its predictive abilities. It helps predict how EOC changes could affect structural integrity, guiding the planning of maintenance and repairs. It can separate the influence of different variables using techniques like multivariate analysis. This ensures that the effect of each EOC is clearly understood, which is essential for accurate health assessments of structures.

The clear results from regression analysis support informed decision-making for maintenance and repairs, giving precise information about the impact of each EOC. This allows for focused interventions and efficient resource allocation to the most critical structural issues.

ANNs add another layer to SHM. Unlike simpler models, ANNs can learn complex, non-linear relationships within data. They improve as they process more information, becoming better at predicting structures' responses to various conditions. With enough data, ANNs can uncover subtle patterns, greatly enhancing SHM's precision and dependability.

2.2 *Model overview*

The model used in this study is novel sequential neural network. It is a type of ANN where each layer is arranged in a sequence, with each layer feeding its output directly to the next layer. This ANN is designed for regression learning to predict the temperature of prestressed concrete bridges, utilizing the principles from the previous section. The ANN utilizes input from 15 distinct sensor parameters. This array of sensors captures comprehensive structural data, enabling precise temperature prediction crucial for assessing the bridge's structural health. A simple overview of the model can be seen in Figure 1.

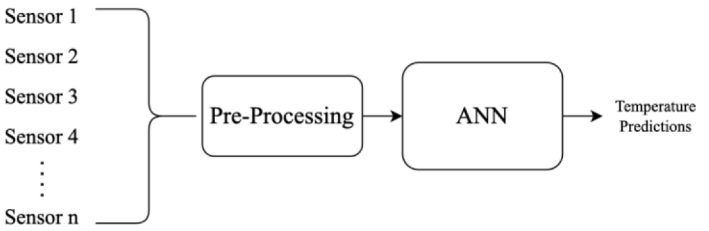

Figure 1. Model overview.

2.3 *Data acquisition and preparation*

Data was collected from a network of sensors installed on a prestressed concrete bridge. The sensor suite included LVDTs, FTGs, and Noptel sensors. LVDTs were utilized to quantify the bridge's deflections, capturing the displacements indicative of the bridge's load-bearing performance. FTGs

measured the strain, relating to the internal stresses under varying loads. Noptel laser sensors provided deformation data.

Upon such an event, the sensors' data is automatically transmitted to a Secure File Transfer Protocol (SFTP) server, from where it is readily accessible via the internet. To facilitate the handling of this data, specialized software was developed to parse and organize the data into an array format. This format is particularly beneficial for feeding into ML algorithms as input data. The data used in this study was gathered over a span of 1 month.

Prior to training the ANN, a preprocessing step involved conducting a covariance analysis on the collected sensor data. This analysis aimed to understand the degree of linear relationship between each sensor parameter and the bridge's temperature. Covariance values were calculated between the temperature and each of the 15 sensor parameters. These values provided insight into how strongly each parameter influenced the temperature, with values closer to ±1 indicating a stronger linear relationship.

The ANN was structured with multiple layers, each designed to process the input data sequentially for precise temperature prediction. A distinctive feature of this ANN is its weight initialization strategy. Instead of random weight assignments typically used in ANNs, this model utilized the covariance analysis results. Initial weights were adjusted to correlate with the covariance values associated with each sensor parameter. Parameters with higher covariance values were assigned greater initial weights, denoting their substantial impact on the ANN's output. This method of weight initialization aimed to enhance the learning efficiency and accuracy of the model from the outset.

2.4 *Training process*

The ANN underwent a supervised learning process using the preprocessed dataset. The training phase involved adjusting the network's weights to minimize the error between the predicted temperatures and the actual measurements. Performance metrics such as mean squared error (MSE) and R-squared were utilized to evaluate the accuracy and effectiveness of the model. A complete process pipeline of the ANN is shown in Figure 2.

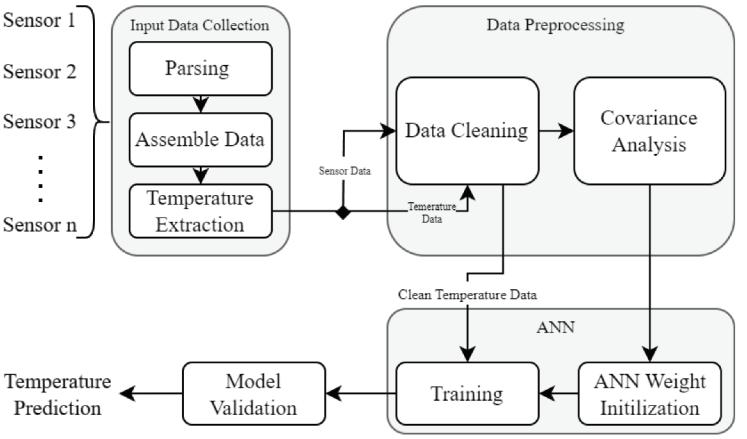

Figure 2. Process overview of the model.

2.5 *Case study – data from autio bridge*

The Autio Bridge, see Figure 3, is a prestressed concrete structure over the Torne River located in Northern Sweden, and was constructed in 1963. It spans a total length of 134.8 meters, with three segments of 36.4, 62.0, and 36.4 meters. Its width measures 7.48 meters. The bridge's beams and deck were made from concrete K450 (C45) and reinforced with Ks40 (400 MPa) and Ks60 (600 MPa) steel. Prestressing strands used were 6 mm BBR with stress ranges 1500/1700 MPa. Specifically, the prestressing reinforcement in the bridge includes curved tendons in steel ducts.

Between 2012-2014 and resuming in 2019, mining-related transport resulted in the bridge bearing loads from trucks totaling 90 tons. Cracks in the beams were observed during time, however it is not clear when they first emerged. The monitoring of crack progression was conducted manually until 2020, when it was supplemented with automated instrumentation using strain gauges and LVDTs. These cracks typically range in width from 0.1 to 0.3 mm and extend longitudinally over time. In November 2020, notable increases in strain gauge readings on the concrete prompted the closure of the bridge to all traffic for safety reasons. To further evaluate the structural integrity, additional strain gauges were installed to the vertical reinforcement bars, leading to a comprehensive assessment of the bridge's fatigue strength (Agredo Chavez et al, 2022).

Figure 3. Prestressed concrete bridge over Torne River at Autio built in 1963.

3 RESULTS AND DISCUSSION

3.1 *Predictive performance*

The sensor suite operates under the trigger of specific load conditions on the bridge, capturing data within a limited timeframe spanning from October to November. Despite the restricted period and conditional data collection, the ANN regression model achieved an R-squared score of 99.8%, suggesting nearly perfect predictiveness in mapping sensor data to external temperature.

3.2 *Analysis of model predictions*

Figure 4 shows a comparison between the actual and predicted temperatures, delineating a congruence as evidenced by the superimposed trend lines. The graph showcases a random sample of the model outputs, further validating the predictive accuracy across the data set.

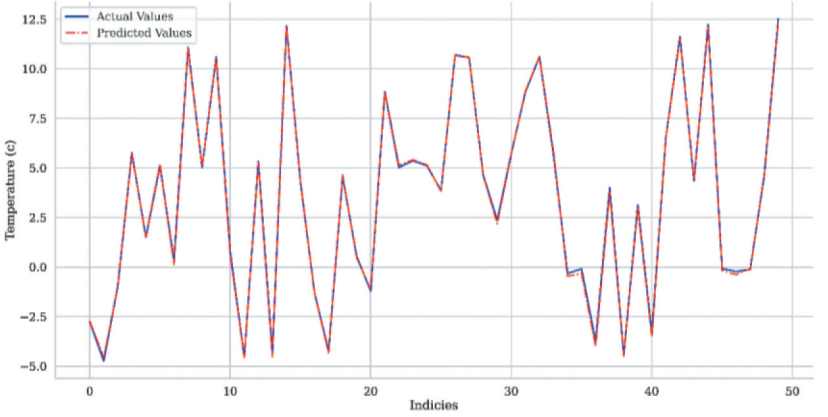

Figure 4. Random sampling of actual vs predictive values.

In Figure 5 the Locally Weighted Scatterplot Smoothing (LOWESS) technique is applied to sensor data associated with temperature fluctuations. This presentation includes a non-parametric smoothed curve and a confidence interval to assess prediction uncertainty. An examination of the residuals and the LOWESS fit reveals a clustering effect near the zero line, indicating minimal and randomly distributed model errors. Furthermore, the absence of any

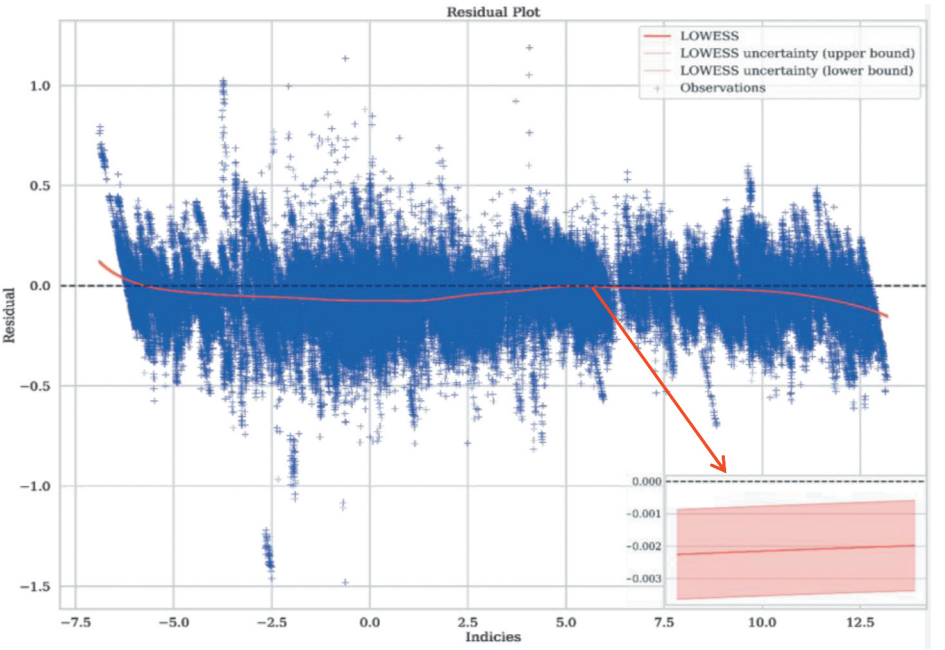

Figure 5. Residual plot with LOWESS representation.

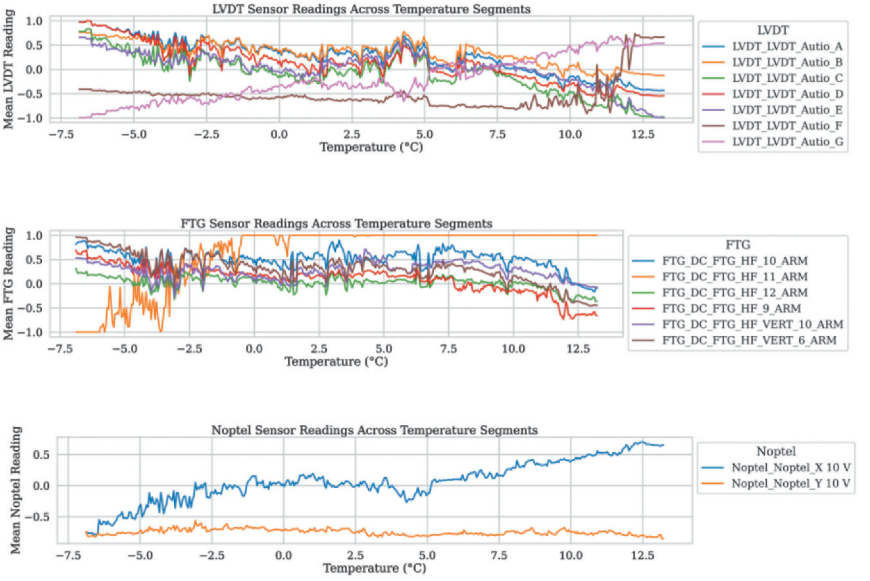

Figure 6. Dynamic sensor response to temperature fluctuations.

discernible systematic pattern in the residuals, which scatter randomly above and below the zero line, confirms the successful capture of the primary trend by the LOWESS method. The inset in the bottom-right corner zooms in on a portion of the residual plot, clearly illustrating the constrained fluctuation range of the residuals and emphasizing the model's precision.

Figure 6 illustrates the responsiveness of the Autio Bridge's monitoring system to ambient temperature variations, as captured by the normalized readings of the installed sensors. The graphical representation synthesizes the behavior of the bridge's instrumentation, including LVDTs, FTGs, and Noptel sensors, under the influence of external temperature changes. By segmenting the temperature data and applying a moving average smoothing algorithm, we have attenuated transient noise, enabling the delineation of more pronounced trends that are indicative of the bridge's thermally induced strain responses.

4 CONCLUSION

In conclusion, this study has demonstrated the use of an artificial neural network (ANN) for analyzing the effects of temperature on a prestressed concrete bridge. The ANN model, supported by comprehensive field data, effectively differentiates temperature-induced structural behaviors from those caused by other factors. This distinction is important for precise structural health monitoring and life-span enhancement of bridges.

The importance of ongoing monitoring is emphasized, highlighting continuous data collection as essential for the analysis and prediction of bridge performance under various environmental conditions. The integration of machine learning and empirical data has shown potential, leading to more efficient and proactive maintenance strategies.

Future research is directed towards expanding the study to different bridge structures and environmental conditions to confirm the model's utility. Enhancements to the ANN model to include additional environmental factors could improve its predictive accuracy. Additionally, the adoption of real-time data processing in bridge management systems is recommended for prompt and informed decision-making.

Lastly, the potential of self-learning algorithms for increasing the durability and adaptability of the model over time is suggested as an important area for further study. These developments are expected to refine model precision and aid in the development of smart infrastructure with enhanced longevity.

ACKNOWLEDGEMENTS

The research presented in this paper was significantly guided by the goals of the SCABEAC (Sustainable Construction and Build Environment in Arctic Climate) project, a component of the Interreg Aurora program. The focus of SCABEAC on sustainable building practices and the longevity of structures in the challenging Nordic climate provided a compelling motivation for our exploration in this field. Their commitment has played a vital role in broadening our understanding of essential new technologies and methods relevant to construction in Arctic conditions. This inspiration has been a key factor in shaping the direction and depth of this study.

Field testing of the longest Polish footbridge made of FRP composites using distributed fibre optic sensor system

Maciej Kulpa & Tomasz Siwowski
Rzeszow University of Technology, Rzeszow, Poland

ABSTRACT: Excellent mechanical properties and high durability of fibre reinforced polymer (FRP) composites cause the increasing popularity of using these materials for the construction of pedestrian and bicycle bridges. The spans of bicycle footbridge at the Carpathian Bridge in Rzeszów (Poland) were constructed in the form of sandwich panels. Since FRP composite is a relatively new construction material and the footbridge is of significant size, the structural health monitoring (SHM) system based on distributed fibre optic sensors (DFOS) was designed and implemented for condition assessment. The optical fibres were placed inside the sandwich structure between the fabrics of the selected laminates, before the infusion process. It enables the high durability and reliability of the monitoring system because the sensors are not exposed to damage or the influence of the environment. Before the footbridge was open to public use, the static and dynamic proof load tests were performed. DFOS operation as well as design assumptions and the static and dynamic behavior of the lightweight structure had been checked.

1 INTRODUCTION

Since 2016, when the first bridge in Poland made of FRP composites was built (Siwowski et al. 2017), the popularity of composite bridge structures in Poland has been systematically increasing. The main reason for this is the excellent mechanical properties and high durability of FRP composites. FRP composite structures are most often used in the construction of new pedestrian and bicycle footbridges and in the redecking as well as the widening of existing bridges (e.g. Chróścielewski et al. 2017, Sonnenschein et al. 2016, Kossakowski and Wciślik 2022). In each of these cases the following advantages of FRP composite structures are also important: low weight (lightness) and full prefabrication, as well as the ease and quick assembly on site. Among the several available technologies for manufacturing FRP composite structures, sandwich panels manufactured using the vacuum assisted resin transfer molding (VARTM) method are currently dominant.

The implementation of the FRP bicycle footbridge at the Carpathian Bridge in Rzeszów described in the paper combines the two above-mentioned areas of application: it is a new, individually designed FRP composite structure, placed on the supports of the adjacent bridge and thus widening it. This method of widening bridges is one of the most effective and frequently used worldwide (Radomski & Kasprzak 2017). In such a case, a lightweight and durable FRP composite structure is the optimal technical and economic choice. In addition, the use of built-in and persistent DFOS monitoring further increases the value of such a solution.

2 FRP FOOTBRIDGE STRUCTURE

2.1 *Assumptions for design*

The construction of new bicycle footbridges near existing road bridges has been a long demand of Rzeszów cyclists. There are many bicycle paths in Rzeszów, but the problem is

DOI: 10.1201/9781003483755-108

their lack of continuity over Wisłok river, which prevents smooth and collision-free communication. The three existing bridges in Rzeszów city centre (the Lviv Bridge, the Narutowicz Bridge and the Carpathian Bridge) do not have bicycle paths. Therefore, the municipality authorities decided to build bicycle footbridges next to the mentioned bridges (i.e. to widen them), because it is not possible to isolate bicycle paths on any of these bridges.

The Carpathian Bridge, located along national road No. 94, is the most heavily trafficked bridge in Rzeszów, both by cars and pedestrians. Therefore it was chosen to be widened to include a two-way bicycle path. A FRP composite structure placed on steel cantilevers attached to the existing supports of the bridge turned out to be the optimal solution. Due to the fact that the new footbridge was to be supported on the piers of the existing bridge (from 1973), the designers decided to use a construction solution with minimum dead weight. Of the two design options considered: aluminum and FRP composite, the latter was chosen. The span length of the new bicycle footbridge was determined by the existing piers. This FRP sandwich structure consists of five simply-supported spans of 4.17 + 23.55 + 23.67 + 23.67 + 23.47 m. The total length of the superstructure is 104.95 m, and thus it is believed to be the longest Polish footbridge made of FRP composites. The service width for bicycle path is 2.50 m (Figure 1). Since FRP composite is a relatively new construction material and the footbridge is of significant size, the SHM system based on DFOS was designed and implemented for condition monitoring.

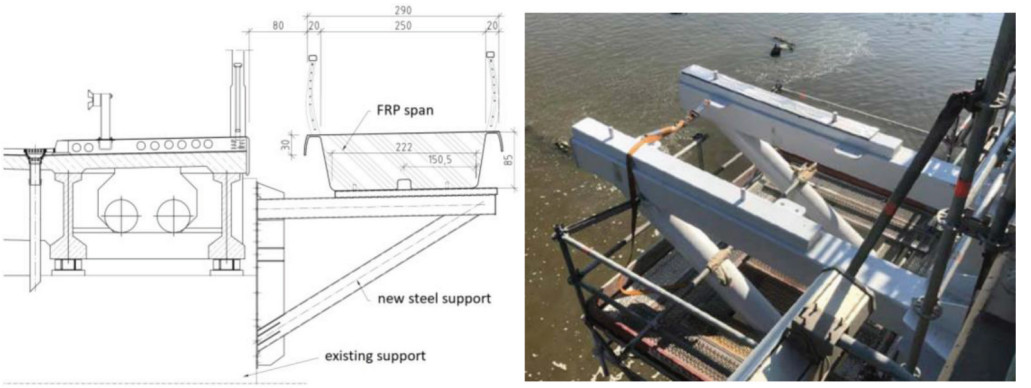

Figure 1. The cross-section of existing bridge and new footbridge (on left) and steel cantilevers mounted on existing piers.

2.2 *Design of the FRP structure*

The initial design of the footbridge assumed a span structure made of two U-shaped composite thin-walled girders, connected with a composite deck slab with a sandwich structure using adhesive joints. Such kind of structure was implemented on one of the first Polish all-composite road bridges (Siwowski et al. 2018). However, on the initiative of the contractor, an alternative design was considered, based on the Dutch InfraCore® Inside FRP composite panel technology (Veltkamp 2019).

The sandwich panel structure of FRP composite spans was proposed by the manufacturer, the Dutch company FiberCore Europe B.V., the creator and main European manufacturer of composite panels using the InfraCore® Inside technology. The panel consists of upper and lower laminates and vertical ribs stiffening the panel core. The laminates and ribs are made of E-glass fibre fabrics and polyester resin. The foam core made of PUR foam with a density of 38 kg/m^3 only serves to fill the panel and is not included in the calculations (Figure 2).

A numerical model built in the SOFiSTiK environment was used to design the FRP composite structure (Figure 3). The laminates and ribs were modeled with 4-node Timoshenko-Reissner shell finite elements with bilinear shape functions with enrichment of the deformation

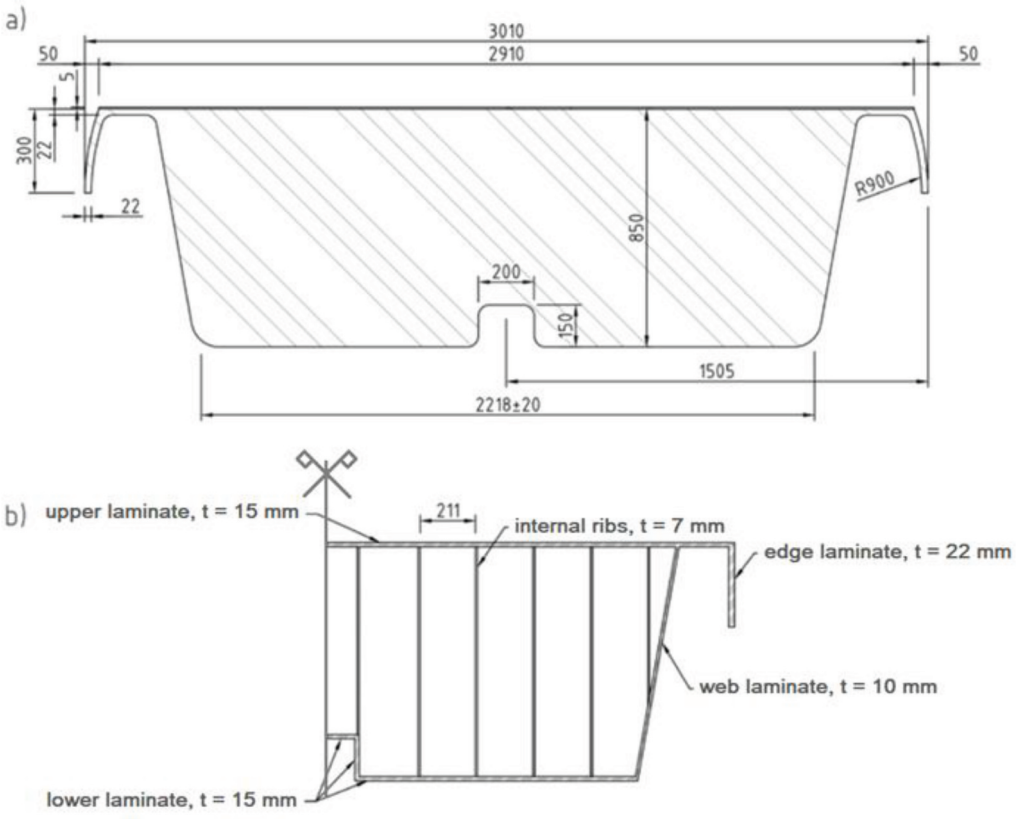

Figure 2. FRP composite span: a) cross-section with general dimensions; b) detailed dimensions of the span components.

state eliminating the locking effect and taking into account the shear effect. The shell elements were assigned a designed thickness and a sequence of arrangement of individual layers in laminates. The properties of the finite elements were assumed based on the results of material tests and the designed lamina sequences in each element. The target global material parameters for individual finite elements were determined as resultants, in accordance with the classical lamination theory. The effect of the core foam as filler material was conservatively omitted from the model. The footbridge load models were adopted in accordance with Eurocode 1 and the limit states of particular FRP components were checked in accordance with the pre-standard EuCIA (2019) .

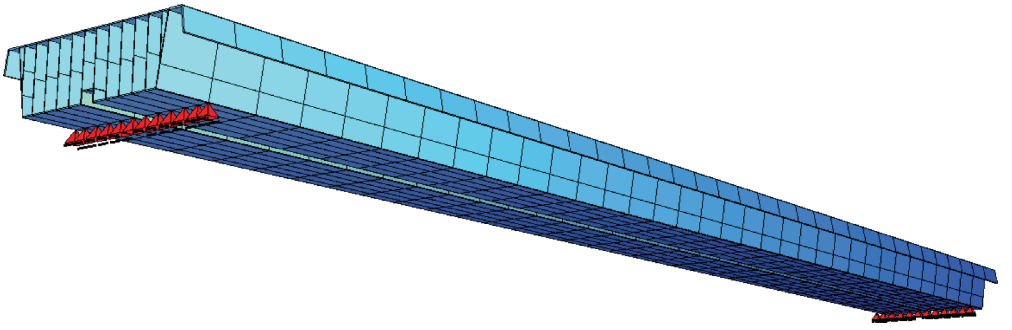

Figure 3. Numerical model of a composite footbridge.

2.3 *Manufacturing technology*

The footbridge spans were manufactured using the VARTM method in the workshop of FiberCore Europe B.V. in Rotterdam, Netherlands. Each of them was created in a special mold in which glass fabrics were arranged in the sequences necessary to obtain the designed thicknesses and strength of the laminates. Core foam elements with a height of 820 mm were placed between the fabrics, the main task of which was to form volume of panels and creating vertical laminates of the internal ribs. After placing all the materials in the mold, it was sealed and then the infusion process began, which involved saturating the content with liquid polyester resin using a vacuum. After filling the mold with resin, its supply was closed and the process of hardening (cross-linking) of the resin began. After complete hardening, the span was pulled out of the mold to a station for finishing and protecting the outer surface of the laminates. A chemically hardened surface was also made at this stage.

After manufacturing, all five spans of the footbridge were transported in two transport sets from the factory in Rotterdam (the Netherlands) to Rzeszów (Poland). Due to the relatively low weight of the spans (the weight of a single span over 24 m is approximately 10 tons), it was possible to transport two spans simultaneously on one truck. The spans were installed on site directly from the truck trailer on previously mounted steel cantilevers, which created direct supports for the spans (Figure 4a). The spans on the supports were stabilized using φ 36 mm steel pins, which were placed in special sockets created in the lower laminates of the spans. Some of the sockets were made "to measure", blocking the structure's ability to move, while others were made with appropriate "clearances", ensuring the free elongation of the spans under the service load and due to temperature. The assembly of a single span of the footbridge took approximately 30 minutes (Figure 4b).

Figure 4. Installation of the footbridge spans (from left): transport of the span; assembly of the span using cranes; all footbridge spans on supports.

2.4 *Monitoring system*

Due to the pioneering nature and size of the FRP composite structure, monitoring of the footbridge's behavior in service was planned. A SHM system based on DFOS fibre optic sensors was chosen. However, it was decided to use in practice the newly designed monitoring system for FRP composite structures using fibre optic sensors integrated with the composite laminates (Kulpa et al. 2020).

Unlike classic measurement sensors, which are mounted on a ready-made structure, in the integrated DFOS system the optical fibres were placed inside the composite between the laminate fabrics, before the infusion process. Therefore, they are not exposed to damage or destruction as a result of environmental influences or acts of vandalism, and the entire measurement system is characterized by high durability. To limit interference in the structure of laminates, fibre optic sensors were used without cover (Figure 5). As a result, the diameter of the sensors was reduced from a few millimeters to 250 μm, limiting the risk of entering structural notches that weaken the laminates. Connection terminals were welded to the measurement fibres and reinforced with yellow covers, which made it possible to lead them out of the structure. During sensors installation, their continuity were checked using laser testers. After infusion of the composite structure, the sensor tips were temporarily protected for transport, and after the span assembling at the construction site, they were placed in a box attached to the structure.

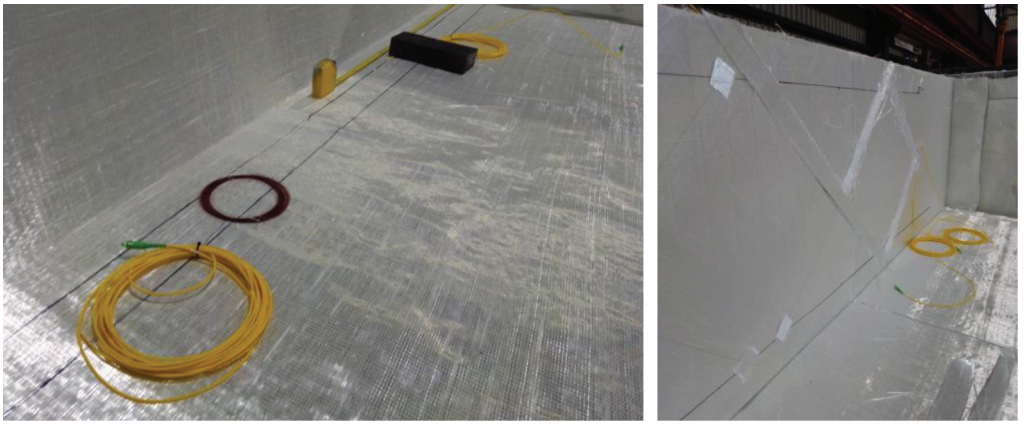

Figure 5. Installation of optical fibres between fabrics of the lower laminate (left) and in vertical ribs (right).

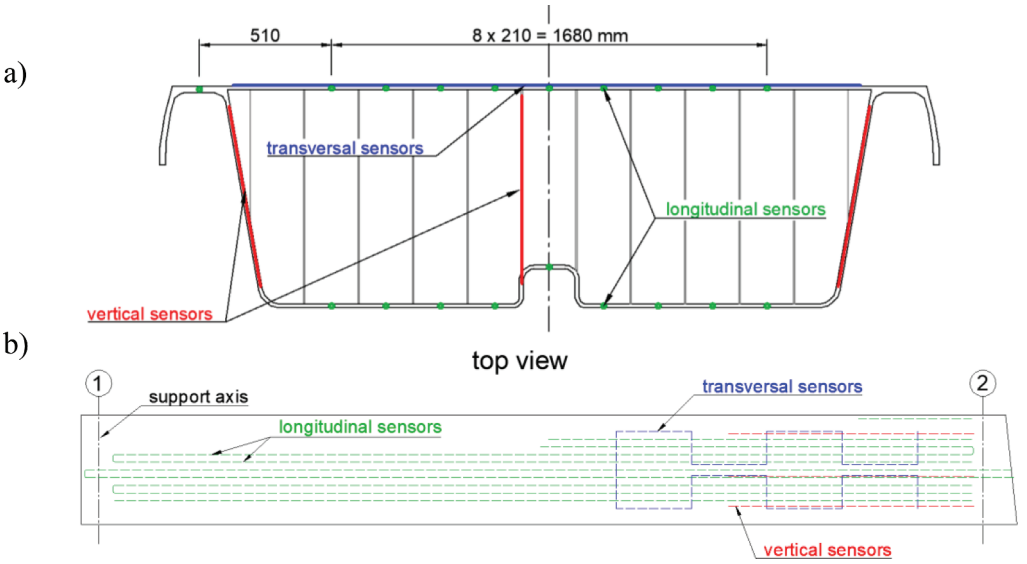

Figure 6. Fibre optic sensor system: a) cross-section; b) top view.

The FRP composite spans of the footbridge were equipped with measurement sensors in the form of single-mode fibres of the SM9/125 type with an acrylic coating. The fibre system was divided according to the orientation of the sensor into longitudinal fibres, transverse fibres and vertical fibres. The first two groups were placed in the plane of the upper and lower face laminates. The vertical fibres were placed in the three ribs and were oriented in the direction of the principal stresses (±45°). The DFOS system is shown in Figure 6. In total, over 200 meters of fibre optic sensors were placed in the structure of a single span. The DFOS system can measure strains of the structure at 5 mm intervals and is equivalent to a measurement system containing over 40,000 single spot sensors. Moreover, thanks to the division of fibre optic sensors, the measurement can be limited to a smaller number of points (e.g. only in critical sections/points) or a local part of the structure (e.g. support zone). This enables flexible measurement depending on demands and reduction of collected data in very complex high-frequency sensor systems.

3 FIELD TESTING

3.1 *Static test*

Concrete slabs with dimensions of 300 × 150 × 15 cm weighing 1,656 kg (corresponding to 16.25 kN) were used to load the structure statically during field test. The test was carried out at night, and the slabs were placed using two cranes from the adjacent, existing road bridge (Figure 7). The slabs were placed in two layers, and there were a maximum of 16 slabs per span. Due to the fact that two footbridge spans are supported on one steel cantilever support, a scheme was also planned in which 32 slabs were placed on two adjacent spans. Static load during field load test was 85% of the characteristic load for which the footbridge was designed (5 kN/m^2).

The tests began with control measurement of unloaded structure and followed by placing the subsequent slabs starting from one of the supports. After placing the first layer of slabs, the measurements were compared with the design values and after a positive result, the second layer was laid. The load on the span was placed for 30 minutes and then removed in the reverse order of installation.

Figure 7. Static load placed on the footbridge: in one layer (left) and in two layers (right).

Figure 8 shows an example of the distribution of axial strains in the upper laminate caused by subsequent loading slabs.

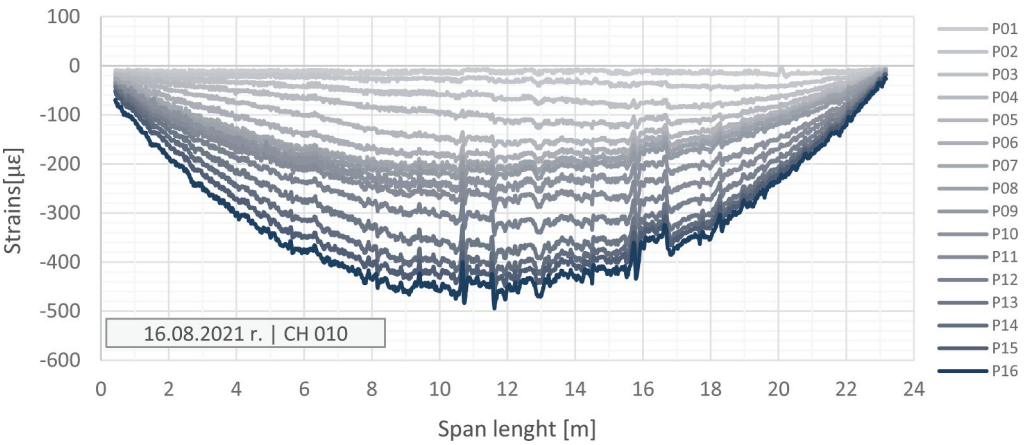

Figure 8. Distribution of axis strain along the length of the upper laminate after placing individual load slab (P1-P16).

Due to the use of distributed sensors running along the entire length of the single span, it was possible to determine not only the strains (measured directly), but also to calculate the vertical displacements of the span (measured in-directly). For this purpose, the laws of mechanics and strength of materials (f.e. the Euler-Bernoulli hypothesis) were used. This calculation procedure was developed and tested in laboratory conditions by Kulpa et al. (2020).

To check and verify the DFOS monitoring system, during the field test, measurements of spans' and piers' displacements were also measured using reference, high-precision geodetic techniques with an accuracy of 0.1 mm. The comparison of vertical displacements under the maximum load along the length of the span determined by the DFOS system and reference, as well as design values is shown in Figure 9.

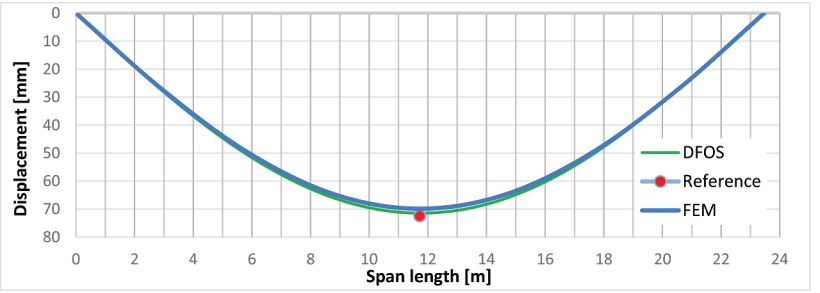

Figure 9. Distribution of vertical displacements along the length of the span measured by DFOS system, reference method and design value.

The elastic deflections in three of the four spans accounted for from 93 to 98% of the design (calculated) values. Only in one span the elastic deflections were greater, reaching 103% and 105% of the design values. This slight exceedance of the design values in one of the spans can be considered acceptable, most likely resulting from the specificity of the composite structure, which was made manually and therefore is characterized by a slight variability of strength and elastic parameters and dimensions inconstancy in individual spans.

3.2 *Dynamic test*

Dynamic identification test included a series of dynamic excitations of the footbridge in order to record its dynamic response. For synchronous excitations, it was necessary to use a tactometer synchronized with the forced natural frequency of the structure. The excitations included, among others: natural passing, synchronized passing, running and jumping of a group of people (1, 2, 3, 4, 12 and 30). A group of 12 and 30 people corresponds to a load density of 0.2 and 0.5 person/m^2 of the deck area, respectively. The latter is treated as a "intense (dense) pedestrian traffic". This type of load may occur occasionally, e.g. during mass events. In total, 29 individual loading patterns were performed (Figure 10).

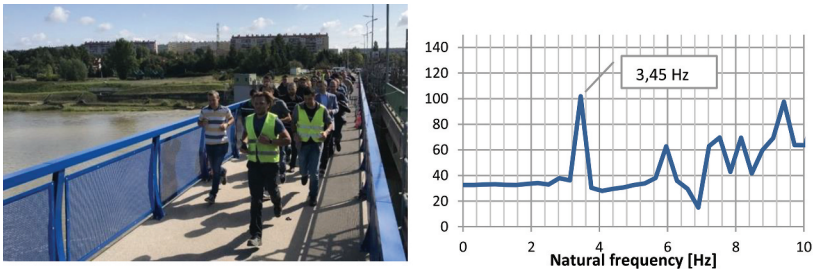

Figure 10. The dynamic tests (left) and an example of the natural frequency spectrum distribution obtained from the DFOS system (right).

During the dynamic test, the DFOS system measured strains in selected sensors with a frequency of up to 250 Hz. From the obtained function of strain over time, fragments when the structure vibrated freely were isolated. Based on this data, the Fast Fourier Transform was performed, and the obtained spectrum identified natural frequencies (Figure 10).

To verify the dynamic measurements performed using DFOS monitoring system, the typical acceleration gauges PCB393A03 were mounted in ½ and ¼ of span length to compare both measurement methods. The first natural frequency measured using the DFOS system (3,45 Hz) and the reference acceleration sensors (3,56 Hz) were very similar to each other, and the slight difference is due to the fact that these values were determined with different types of excitation. Moreover, the measured first natural frequency was very close to the calculated value (3,47 Hz) which proves that the numerical model correctly simulates the behaviour of the FRP composite structure.

4 CONCLUSION

Field test results confirmed the proper behavior of the footbridge under static and dynamic loads. The FRP footbridge structure behaved elastically - permanent deflections of spans did not exceed 6% of the total deflections. The compliance of the measured and calculated displacements for the spans was in the range of 93-98%, which proves the correctness of the numerical model. The slight (3- 5%) exceedances of elastic deflections in one of the tested spans can be considered acceptable, resulting from the specificity of the composite structure.

The installed DFOS monitoring system showed high compliance with conventional measurements carried out during the load test. This confirms correct operation and the possibility of measuring longitudinal strains and based on them accurate calculation of vertical displacements. Thanks to the sensors being placed inside the structure itself, the system is very durable and is planned to operate it for the future.

Online noise parameters estimation for sigma-point Kalman filter using sequential importance resampling

Weixiang Liu
Master Student, School of Civil and Environmental Engineering, Harbin Institute of Technology, Shenzhen, China

Feng-Liang Zhang*
Professor, School of Civil and Environmental Engineering, Harbin Institute of Technology, Shenzhen, China

ABSTRACT: The sigma-point Kalman filter (SPKF) is a widely-used method for system state and structural parameters estimation. It assumes that the state prediction errors are minimized when the structural parameters correspond to the noise covariance matrices. However, in practice, the covariance matrices for process noise and measurement noise are usually unknown. Arbitrary selection of these covariance matrices may lead to unreliable state predictions and potentially diverging estimation results. To address this problem, we propose a method by integrating the sequential importance resampling algorithm into the traditional SPKF for the estimation of the noise covariance matrices based on the acceleration response measurement. The effectiveness of the proposed Sequential Importance Resampling Sigma-point Kalman Filter (SIR-SPKF) is demonstrated through a numerical application to a bridge structure and a laboratory experiment involving a 3 degrees of freedom model.

Keywords: noise covariance matrices, system identification, sigma-point Kalman filter, sequential importance resampling

1 GENERAL INSTRUCTIONS

In recent decades, online structural health monitoring (SHM) has gained widespread attention and been extensively investigated [1-3]. The sigma-point Kalman filter is one of the promising methods for structural identification using dynamic response measurement. It has demonstrated significant potential in excitation smoothing [4], identification of structural parameters [5], and damage identification [6].

The sigma-point Kalman filter (SPKF) is a method that implements the Kalman filter procedure using a number of sigma points in a sampling manner [7]. Similar to Kalman filter, the determination of the covariance matrices of the process noise and measurement noise remains a critical issue for achieving optimal and stable results [8].

To address these issues, the sequential importance resampling algorithm is integrated with SPKF to simultaneously estimate the covariance matrices of the process noise and measurement noise. In this algorithm, the two covariance matrices are parameterized with the noise parameters. The optimal noise parameters are estimated by calculating the expected value of the candidate noise particles based on their weights, which are related to the most recent measurement at each time step. The effectiveness of the proposed method is demonstrated through a numerical application on a bridge structure and a laboratory experiment involving a 3-degree-of-freedom model.

2 SEQUENTIAL IMPORTANCE RESAMPLING SIGMA-POINT KALMAN FILTER

Consider the equation of motion of a structural system:

$$\boldsymbol{M}\ddot{\boldsymbol{X}} + \boldsymbol{C}\dot{\boldsymbol{X}} + \boldsymbol{K}\boldsymbol{X} = \boldsymbol{\Gamma}\boldsymbol{f} \tag{1}$$

where $\boldsymbol{M}, \boldsymbol{C}$ *and* $\boldsymbol{K}$ are the mass, damping and stiffness matrix, respectively; $\boldsymbol{X}$ is the generalized displacement vector; $\boldsymbol{\Gamma}$ is the excitation distribution matrix; and $\boldsymbol{f}$ is the unknown external excitation (i.e., the process noise), which is modeled as a zero-mean Gaussian process. The mass matrix $\boldsymbol{M}$ is assumed to be known while the damping and stiffness matrix $\boldsymbol{C}(\boldsymbol{\theta}_c)$ *and* $\boldsymbol{K}(\boldsymbol{\theta}_k)$ are assumed to be unknown and parameterized using the damping parameter vector $\boldsymbol{\theta_c}$ and stiffness parameter vector $\boldsymbol{\theta_k}$. Consequently, the structural parameter vector $\theta \equiv \left[\boldsymbol{\theta}_k^T, \boldsymbol{\theta}_c^T\right]^T$ is defined.

To estimate the system state and uncertain structural parameter vector $\boldsymbol{\theta}$, the augmented state vector $\boldsymbol{Y} \equiv \left[\boldsymbol{X}^T, \dot{\boldsymbol{X}}^T, \boldsymbol{\theta}^T\right]^T$ is defined. Then the augmented state-space equation can be expressed as follows:

$$\dot{\boldsymbol{Y}} = \boldsymbol{A}\boldsymbol{Y} + \boldsymbol{B}\boldsymbol{f} \tag{2}$$

$$\boldsymbol{A} = \begin{bmatrix} \boldsymbol{0} & \boldsymbol{I} & \boldsymbol{0} \\ -\boldsymbol{M}^{-1}\boldsymbol{K}(\boldsymbol{\theta}_k) & -\boldsymbol{M}^{-1}\boldsymbol{C}(\boldsymbol{\theta}_c) & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{0} & \delta\boldsymbol{I} \end{bmatrix}, \boldsymbol{B} = \begin{bmatrix} \boldsymbol{0} \\ \boldsymbol{M}^{-1}\boldsymbol{\Gamma} \\ \boldsymbol{0} \end{bmatrix} \tag{3}$$

where $\boldsymbol{0}$ and $\boldsymbol{I}$ are the zero matrix and identity matrix, respectively; $\delta = -10^{-10}$ is a very small negative number introduced to prevent singularity in the transition matrix $\boldsymbol{A}$. Eq. (2) represents the state-space equation in continuous-time and can be discretized based on sampling frequency *fs* as:

$$\boldsymbol{Y}_{k+1} = \boldsymbol{A}_k\boldsymbol{Y}_k + \boldsymbol{B}_k\boldsymbol{f}_k \tag{4}$$

where $\boldsymbol{Y}_k \equiv \boldsymbol{Y}(k/fs)$; $\boldsymbol{A}_k = \exp(\boldsymbol{A}/fs)$; $\boldsymbol{B}_k = \boldsymbol{A}^{-1}(\boldsymbol{A}_k - \boldsymbol{I})\boldsymbol{B}$; $\boldsymbol{f}_k \equiv (k/fs)$; and the unknown external excitation $\boldsymbol{f}_k$ at the k^{th} time step is Gaussian with zero-mean and covariance matrix $\boldsymbol{Q}_k$.

The observation equation is given by:

$$\boldsymbol{Z}_{k+1} = \boldsymbol{h}(\boldsymbol{Y}_{k+1}) + \boldsymbol{v}_{k+1} \tag{5}$$

where $\boldsymbol{Z}_{k+1}$ is the contaminated measurement vector at the $(k+1)^{th}$ time step. The measurement noise vector $\boldsymbol{v}_{k+1}$ is modeled as Gaussian with zero-mean and covariance matrix $\boldsymbol{R}_{k+1}$.

2.1 *Sigma-point Kalman filter*

The detail formulation of sigma-point Kalman filter can refer to [7]. The overall procedure of sigma-point Kalman filter can be summarize as the follow equations:

2.1.1 *Predicted state and covariance matrix*

A set of N sigma points $\boldsymbol{y}_{i,k|k}$ can be generated through:

$$\boldsymbol{y}_{i,k|k} = fun(\boldsymbol{Y}_{k|k}, \boldsymbol{P}_{\boldsymbol{Y},k|k}) \tag{6}$$

$$\boldsymbol{y}_{i,k+1|k} = \boldsymbol{A}_{k,i}\boldsymbol{y}_{i,k|k} \tag{7}$$

$$\boldsymbol{Y}_{k+1|k} = \sum_{i=0}^{N} w_i\boldsymbol{y}_{i,k+1|k} \tag{8}$$

$$\boldsymbol{P}_{\boldsymbol{Y},k+1|k} = \sum_{i=0}^{N} w_i(\boldsymbol{y}_{i,k+1|k} - \boldsymbol{Y}_{k+1|k})(\boldsymbol{y}_{i,k+1|k} - \boldsymbol{Y}_{k+1|k})^T + \boldsymbol{B}_k\boldsymbol{Q}_k{\boldsymbol{B}_k}^T \tag{9}$$

$$\boldsymbol{y}_{i,k+1|k} = fun(\boldsymbol{Y}_{k+1|k}, \boldsymbol{P}_{\boldsymbol{Y},k+1|k}) \tag{10}$$

where $fun(\cdot)$ is a sigma-point generation function (e.g., unscented transform, cubature transform); w_i and N denote the weight of the corresponding sigma-point and the number of sigma points, respectively, which are determined by the selection of the generation function; $\mathrm{Y}_{k+1|k}$ represents the predicted state vector; and $\boldsymbol{P}_{\boldsymbol{Y},k+1|k}$ denotes the associated covariance matrix.

2.1.2 *Predicted measurements*

The above sigma points $\boldsymbol{y}_{i,k+1|k}$ are propagated as follow:

$$\boldsymbol{z}_{i,k+1|k} = \boldsymbol{h}(\boldsymbol{y}_{i,k+1|k}) \tag{11}$$

$$\boldsymbol{Z}_{k+1|k} = \sum_{i=0}^{N} w_i \boldsymbol{z}_{i,k+1|k} \tag{12}$$

$$\boldsymbol{P}_{\boldsymbol{Z},k+1|k} = \sum_{i=0}^{N} w_i (\boldsymbol{z}_{i,k+1|k} - \boldsymbol{Z}_{k+1|k})(\boldsymbol{z}_{i,k+1|k} - \boldsymbol{Z}_{k+1|k})^T + \boldsymbol{R}_{k+1} \tag{13}$$

2.1.3 *Kalman gain*

The cross-covariance matrix $\boldsymbol{P}_{\boldsymbol{YZ},k+1|k}$ and Kalman gain matrix $\boldsymbol{K}_{k+1}$ can be obtained:

$$\boldsymbol{P}_{\boldsymbol{YZ},k+1|k} = \sum_{i=0}^{N} w_i (\boldsymbol{y}_{i,k+1|k} - \boldsymbol{Y}_{k+1|k})(\boldsymbol{z}_{i,k+1|k} - \boldsymbol{Z}_{k+1|k})^T \tag{14}$$

$$\boldsymbol{K}_{k+1} = \boldsymbol{P}_{\boldsymbol{YZ},k+1|k} \boldsymbol{P}_{\boldsymbol{Z},k+1|k}^{-1} \tag{15}$$

2.1.4 *Updated state and covariance matrix*

Finally, the updated state vector $\boldsymbol{Y}_{k+1|k+1}$ and the associated covariance matrix $\boldsymbol{P}_{\boldsymbol{Y},k+1|k+1}$ are readily obtained:

$$\boldsymbol{Y}_{k+1|k+1} = \boldsymbol{Y}_{k+1|k} + \boldsymbol{K}_{k+1}(\boldsymbol{Z}_{k+1} - \boldsymbol{Z}_{k+1|k}) \tag{16}$$

$$\boldsymbol{P}_{\boldsymbol{Y},k+1|k+1} = \boldsymbol{P}_{\boldsymbol{Y},k+1|k} - \boldsymbol{K}_{k+1} \boldsymbol{P}_{\boldsymbol{Z},k+1|k} \boldsymbol{K}_{k+1}^T \tag{17}$$

2.2 *Sequential importance resampling*

The augmented state vector can be updated according to Eq. (16) and Eq. (17). However, the matrices $\boldsymbol{P}_{\boldsymbol{Y},k+1|k}$ and $\boldsymbol{P}_{\boldsymbol{Z},k+1|k}$ from Eq. (9) and Ed. (13) depend on the process noise covariance matrix $\boldsymbol{Q}_k$ and the measurement noise covariance matrix $\boldsymbol{R}_{k+1}$, respectively, which are typically unknown in practical applications. Inappropriately assigned noise covariance matrices may result in divergence.

The noise covariance matrices can be updated using the noisy responses collected from the dynamic system [8]. Similar to the parameterization of structural stiffness and damping matrix, the noise covariance matrices can be parameterized as: $\boldsymbol{Q}_k = \boldsymbol{Q}_k(\boldsymbol{\varphi}_{\boldsymbol{Q},k})$ and $\boldsymbol{R}_{k+1} = \boldsymbol{R}_{k+1}(\boldsymbol{\varphi}_{\boldsymbol{R},k+1})$. Subsequently, the noise parameter vector is formed as: $\boldsymbol{\varphi}_{k+1} = \left[\boldsymbol{\varphi}_{\boldsymbol{Q},k}^T, \boldsymbol{\varphi}_{\boldsymbol{R},k+1}^T\right]^T$. According to sequential importance sampling and the theorem of large numbers, the expected value of the noise parameter vector can be estimated without knowing the posterior PDF of the noise parameters $p(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1})$:

$$\begin{aligned} \boldsymbol{\varphi}_{k+1} = E(\boldsymbol{\varphi}_{0:k+1}) &= \int \boldsymbol{\varphi}_{0:k+1} \frac{p(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1})}{q(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1})} q(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1}) d\boldsymbol{\varphi}_{0:k+1} \\ &\approx \frac{1}{n} \sum_{i=1}^{n} \boldsymbol{\varphi}_{k+1}^{(i)} \omega_{k+1}^{(i)} \end{aligned} \tag{18}$$

where $p(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1})$ is the joint PDF; $q(\boldsymbol{\varphi}_{0:k+1}|\boldsymbol{D}_{k+1})$ is an importance density; n indicate the number of the noise parameter particles; and $\omega_{k+1}^{(i)}$ signify the weight of the i^{th} associated noise parameter vector particle. Assuming $q(\boldsymbol{\varphi}_{k+1}^{(i)}\left|\boldsymbol{\varphi}_{k}^{(i)}, \boldsymbol{Z}_{k+1}\right.) = p(\boldsymbol{\varphi}_{k+1}^{(i)}\left|\boldsymbol{\varphi}_{k}^{(i)}\right.)$, the expression for $\omega_{k+1}^{(i)}$ can be reformulated as follows:

$$\omega_{k+1}^{(i)} \propto \omega_{k}^{(i)} \left|\boldsymbol{P}_{\boldsymbol{Z},k+1|k}\right|^{-\frac{1}{2}} \exp\left[-\frac{1}{2}(\boldsymbol{Z}_{k+1} - \boldsymbol{Z}_{k+1|k})^{T} \boldsymbol{P}_{\boldsymbol{Z},k+1|k}^{-1}(\boldsymbol{Z}_{k+1} - \boldsymbol{Z}_{k+1|k})\right] \tag{19}$$

where $\boldsymbol{P}_{Z,k+1|k}$ is the covariance matrix of predicted measurement vector $\boldsymbol{Z}_{k+1|k}$; and $\boldsymbol{Z}_{k+1}$ is the noisy measurement at $(k+1)^{th}$ time step. Then the covariance matrix $\boldsymbol{P}_{\boldsymbol{\varphi},k+1}$ is given by:

$$\boldsymbol{P}_{\boldsymbol{\varphi},k+1} = \sum_{i=1}^{n} \bar{\omega}_{k+1}^{(i)} (\boldsymbol{\varphi}_{k+1}^{(i)} - \boldsymbol{\varphi}_{k+1})(\boldsymbol{\varphi}_{k+1}^{(i)} - \boldsymbol{\varphi}_{k+1})^{T} \tag{20}$$

where $\bar{\omega}_{k+1}^{(i)}$ is the normalized weights.

After a few iteration steps, all but one of the normalized weights are very close to zero, leading to a degeneracy phenomenon. To address this, the current particle set can be replaced with new ones, where particles are distributed according to their normalized weights, and the weights of the particles are reset as $\bar{\omega}_{k+1}^{(i)} = 1/n$.

2.3 *Sequential importance resampling sigma-point Kalman filter*

In this section, the sequential importance resampling method is integrated into the SPKF to jointly estimate the system state, structural parameters and noise parameters. The procedure of the proposed method is outlined in Table 1.

Table 1. Sequential importance resampling sigma-point Kalman filter (SIR-SPKF).

S-1: Set initial value for $\boldsymbol{Y}_{0|0}, \boldsymbol{P}_{\boldsymbol{Y},0|0}, \boldsymbol{\varphi}_0, \boldsymbol{P}_{\boldsymbol{\varphi},0}, \left[\boldsymbol{\varphi}_0^{(1)}, \boldsymbol{\varphi}_0^{(2)}, \cdots, \boldsymbol{\varphi}_0^{(n)}\right]$.
S-2: Calculate the predicted state $\boldsymbol{Y}_{k+1|k}$.
S-3: Generate particles set $\left[\varphi_{l,k+1}^{(1)}, \varphi_{l,k+1}^{(2)}, \cdots, \varphi_{l,k+1}^{(n)}\right] = 2^{r_k * randn(1,n)} . * \left[\varphi_{l,k}^{(1)}, \varphi_{l,k}^{(2)}, \cdots, \varphi_{l,k}^{(n)}\right], r_k = \max(1 + \frac{1}{\sqrt{n}} - \frac{k}{fs}, \frac{1}{32})$.
S-4: Update the noise parameter vector $\boldsymbol{\varphi}_{k+1}$ and the associated covariance matrix $\boldsymbol{P}_{\boldsymbol{\varphi},0}$ by Eqs. (18) and (20).
S-5: Calculate the updated state $\boldsymbol{Y}_{k+1|k+1}$ and covariance matrix $\boldsymbol{P}_{\boldsymbol{Y},k+1|k+1}$ by Eqs. (16) and (17).
S-6: Go to S-2 for the next time step.

where $\varphi_{l,k+1}^{(i)}$ is the l^{th} element of the noise parameters vector $\boldsymbol{\varphi}_{k+1}^{(i)}$.

3 NUMERICAL APPLICATION

In this section, a bridge structure [8] comprising five spans and four piers, as depicted in Figure 1, under stationary response scenarios was considered to showcase the efficacy of the proposed SIR-SPKF. The entire bridge model consisted of 72 degrees of freedom (DOFs), discretized into 28 elements and partitioned into 14 substructures. The length between two adjacent nodes of each span was $26m$, $24m$, $27.5m$, $24m$ and $26m$, respectively, while it was $20m$ for all piers. The material properties and section properties of the bridge are detailed in Table 2.

The Rayleigh damping model in form of $\boldsymbol{C} = \alpha\boldsymbol{M} + \beta\boldsymbol{K}$ was utilized, with the Rayleigh damping coefficients set as $\alpha = 0.0670s^{-1}$ and $\beta = 0.0015s$. The global stiffness matrix of the bridge was parameterized and assembled as $\boldsymbol{K} = \sum_{i=1}^{14} \boldsymbol{\theta}_{ki}\boldsymbol{K}_i$, where $\boldsymbol{K}_i$ represented the known stiffness matrix of the i^{th} substructure and $\boldsymbol{\theta}_{ki}$ denoted the corresponding stiffness parameter. Due to potential discrepancies between design and construction in engineering, the actual stiffness parameters might vary, and thus were assigned different values denoted by

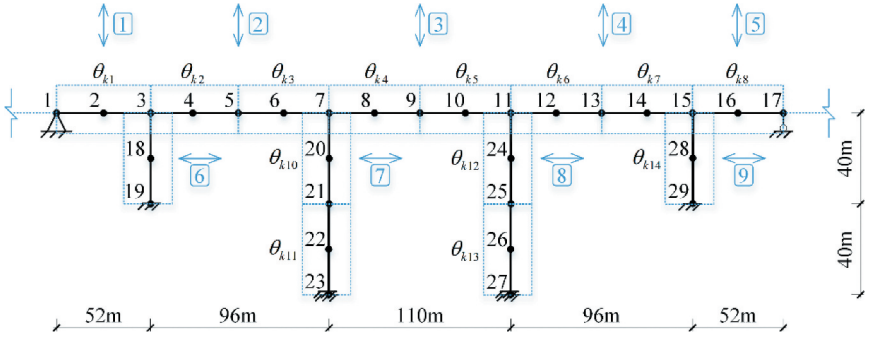

Figure 1. Bridge model.

Table 2. Material properties and section properties of the bridge.

Properties of girder		Properties of pier	
m_g(kg/m^3)	2700	m_p(kg/m^3)	2600
E_g(GPa)	34.5	E_p(GPa)	32.0
A_g(m^2)	9.8	A_p(m^2)	18.5
I_g(m^4)	10.7	I_p(m^4)	55.5

$\bar{\boldsymbol{\theta}}_k = [1.10, 1.15, 1.05, 0.98, 0.90, 0.95, 1.00, 0.97, 1.07, 0.95, 0.98, 0.95, 0.90, 0.90]^T$. Consequently the uncertain structural parameter vector was defined as $\boldsymbol{\theta} = [\boldsymbol{\theta}_k{}^T, \boldsymbol{\theta}_c{}^T]^T = [\boldsymbol{\theta}_k{}^T, \alpha, \beta]^T$.

The bridge was subjected to horizontal ground acceleration of $\boldsymbol{\varphi}_Q = 0.0025$. The stiffness of the 4^{th} and 10^{th} substructures was reduced abruptly to 0.95 and 0.90 at $t = 30s$, respectively. Afterwards, the stiffness of the 13^{th} substructures was reduced to 0.85 at $t = 70s$. The nodes and directions of the acceleration responses collected are depicted in Figure 1, with a sampling frequency of 200 Hz over a period of 150 s. The measurement noise level was set at 5% root-mean-square (RMS) of the noise-free response of the DOF corresponding to the 2^{nd} and 8^{th} sensors for those in the girders and those on the piers, respectively.

The initial noise parameters were assigned with $\boldsymbol{\varphi}_0 = [1, 1, 1]^T$ and $\boldsymbol{P}_{\boldsymbol{\varphi},0} = \boldsymbol{I}_3$. The initial augmented state vector and the associated covariance matrix were determined as follows:

$$\boldsymbol{Y}_{0|0} = [\boldsymbol{\theta}, a_0^{(1)}\bar{\theta}_{k1}, a_0^{(2)}\bar{\theta}_{k2}, \cdots, a_0^{(14)}\bar{\theta}_{k14}, a_0^{(15)}\alpha, a_0^{(16)}\beta]^T \tag{21}$$

$$\boldsymbol{P}_{\boldsymbol{Y},0|0} = diag([10^{-10}\mathbf{1}, (0.1a_0^{(1)}\bar{\theta}_{k1})^2, (0.1a_0^{(2)}\bar{\theta}_{k2})^2, \cdots, (0.1a_0^{(14)}\bar{\theta}_{k14})^2, (0.1a_0^{(15)}\alpha)^2, (0.1a_0^{(16)}\beta)^2]) \tag{22}$$

where $a_0^{(1)}, a_0^{(2)}, \cdots, a_0^{(16)}$ follow the uniform distribution in [0.7,1.3]. The number of the noise parameter particles n was set as 30.

The estimation results of the structural parameters estimated by SIR-SPKF are illustrated in Figure 2. The solid lines denote the values estimated by SIR-SPKF, while the dotted lines indicate their associated 99.7% credible intervals. The dashed lines correspond to the actual values. Figure 2(a)-(g) display some representative estimation results of the stiffness parameters, while Figure 2(h)-(i) depict the estimation results of the damping parameters. The results identified by SIR-SPKF revealed the following: (1) there was a time lag in estimating the abrupt changes of stiffness parameters, as the estimation results at the current step also depended on the historic measurements; (2) the estimated values and credible intervals of the stiffness parameters on the piers fluctuated violently at the time step when the stiffness parameters in the girders suddenly changed, since the reduction of the stiffness in the girders would also lead to reduction in the horizontal constraint of the piers, causing the amplitude of the response on the piers to change rapidly.

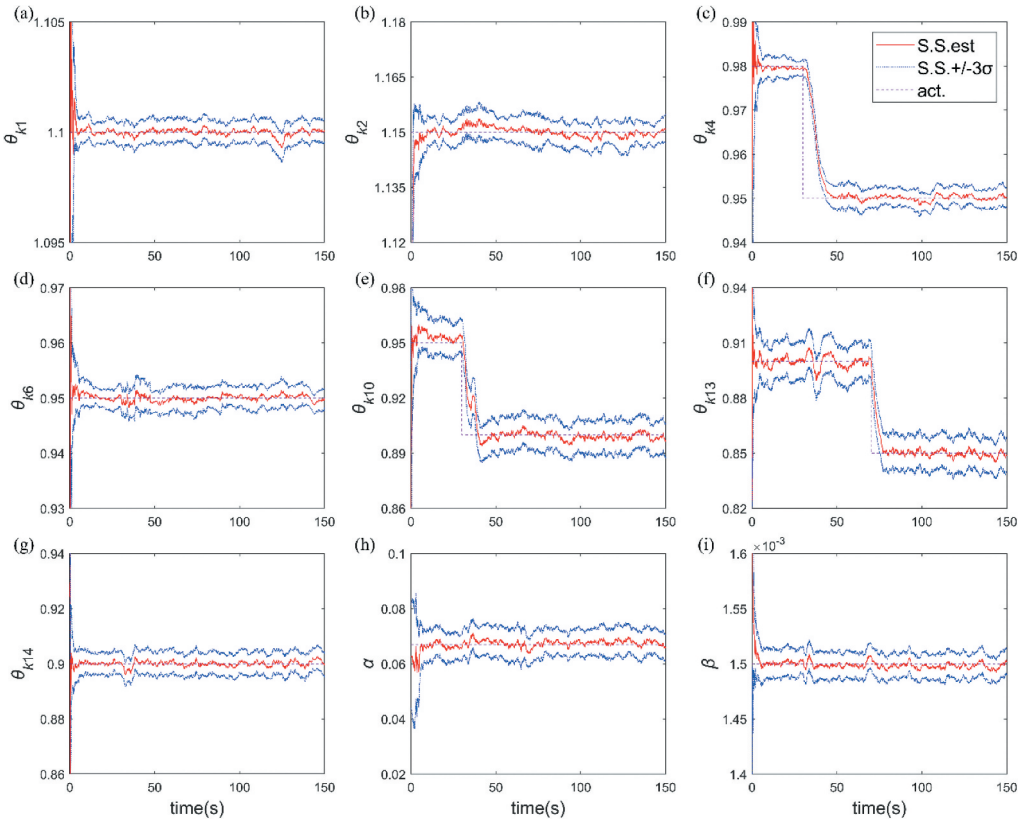

Figure 2. Estimation results of structural parameters by SIR-SPKF (S.S.).

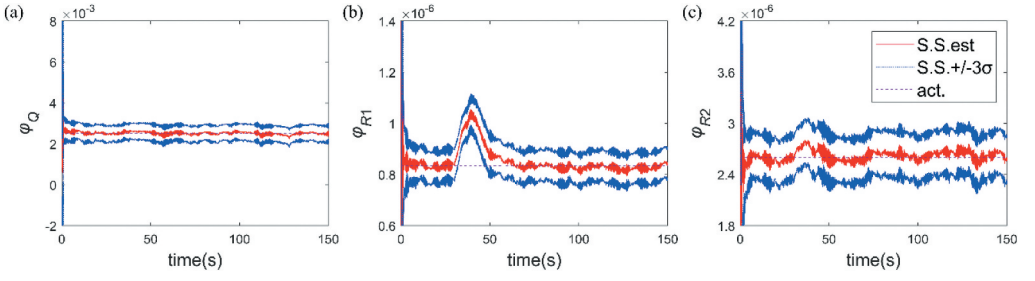

Figure 3. Estimation results of noise parameters by SIR-SPKF (S.S.).

The estimation results of noise parameters, estimated simultaneously by SIR-SPKF, are depicted in Figure 3. Regarding the results obtained thorough SIR-SPKF: (1) the estimated values quickly approached the vicinity of the actual values since the noise parameters particles were generated using a scaling model and updated based on their respective weight; (2) the estimated values φ_{R1} and the corresponding credible intervals deviated from the actual values at the time step that the stiffness parameters suddenly changed, due to the combination impact of the sudden change of the stiffness parameters θ_{k4} and θ_{k10}. Apart from this time interval, the estimated noise parameter values closely matched the actual values, and the 99.7% credible intervals effectively encompassed the actual values.

In summary, the proposed SIR-SPKF method demonstrated the capability to accurately estimate both structural parameters and noise parameters.

4 EXPERIMENTAL STUDY

In this section, the effectiveness of the proposed SIR-SPKF was further validated using experimental data obtained from a three-story shear model [9], which was simplified as a 3-DOF shear model. The mass of each floor was 25.2 kg, and the linear stiffness of each floor were found to be $k_1 = 3.1$ N/mm, $k_2 = 10.4$ N/mm and $k_3 = 11.3$ N/mm.

The experimental study was conducted under ambient conditions. Sensors were connected to a data acquisition system and controlled by a laptop. Acceleration response data were collected for 600 seconds from the first and third floor, with a sampling frequency of 2048 Hz. Subsequently, the data was decimated by a factor of 8 to achieve a frequency of 256 Hz for further analysis. The coefficients $\theta_{ki}(i = 1, 2, 3)$ of the corresponding stiffness parameters k_i were then estimated. Rayleigh damping model in form of $\boldsymbol{C} = \alpha\boldsymbol{M} + \beta\boldsymbol{K}$ was adopted.

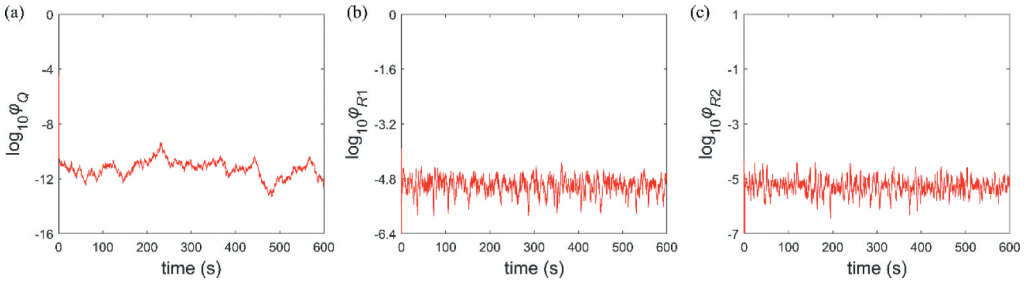

Figure 4. Estimation results of noise parameters in the experimental study.

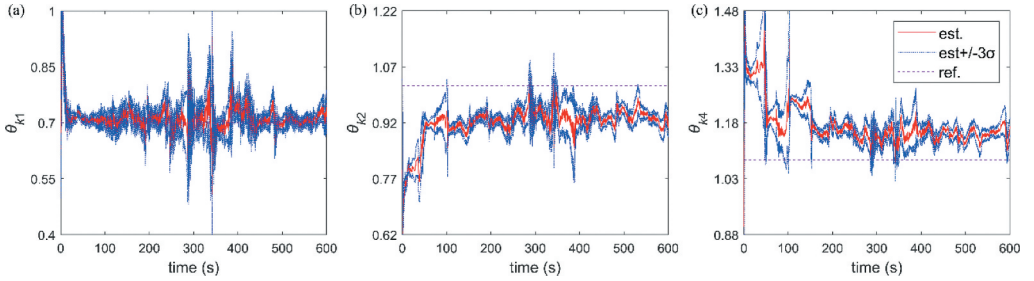

Figure 5 . Estimation results of stiffness parameters of the 3-DOF shear model.

Table 3. Average values of the estimated structural parameters and those in [10].

	θ_{k1}	θ_{k2}	θ_{k3}	ξ_1	ξ_2
Literature [10]	0.709	1.019	1.081	0.00341	0.00169
SIR-SPKF	0.709	0.938	1.148	0.00847	0.00196

The initial conditions were set as the ways as those in Section 3. The unknown noise parameter vector was denoted as $\boldsymbol{\varphi}_{k+1} = \left[\varphi_{Q,k}, \boldsymbol{\varphi}_{R,k+1}^T\right]^T = \left[\varphi_{Q,k}, \varphi_{R1,k+1}, \varphi_{R2,k+1}\right]^T$. A logarithmic plot displaying the estimation results of the noise parameters is presented in Figure 4. It is evident from the plot that the estimated values of the unknown noise parameter are significantly smaller than the initial values [1,1,1].

The estimation results of the stiffness parameters are depicted in Figure 5. The solid lines denote the estimated values, the dotted lines illustrate the 99.7% credible intervals, and the dashed lines indicate the reference values according to [10]. It is noticeable that the estimated values

closely align with the reference values. However the estimated values of the stiffness parameter coefficients θ_{k1} and θ_{k2} consistently deviate to be smaller or larger than the reference values. This deviation may arise from variances in the identification methods. Additionally, it should be noted that the signal-to-noise ratio of the response data on the first and third floors were calculated to be -7 and -3 respectively, based on the estimated measurement noise parameters. This may also contribute to the deviation between the estimated values and the reference values.

The order of magnitude of the estimated value of the process noise parameter is -11, which is reasonable under ambient conditions. The average values of the structural parameters estimated in the latter 350 seconds, along with those mentioned in [10], are listed in Table 3. It is observed that the proposed SIR-SPKF method satisfactorily estimate the structural parameters.

5 CONCLUSION

In this work, a sigma-point Kalman filter based method for system state and structural parameters, which considers modeling error and measurement error, has been developed. The modeling error and measurement error are reflected by the covariance matrices of the process noise and measurement noise in the mathematic framework and are usually unknown in practical scenarios. To address this issue, a sequential importance resampling algorithm is employed. This algorithm facilitates the estimation of noise covariance matrices by utilizing noisy responses obtained from the dynamic system through a set of particles. The particles are then updated using a random walk model. By reliably estimating the noise parameters through the proposed method, reliable system identification can be ensured. The efficacy of the approach is verified through a numerical application to a bridge structure under stationary response scenarios and an experimental study on a shear building model. The results demonstrate that the proposed SIR-SPKF method is effective and robust in identifying the structural system.

ABSTRACT: The present research aims to furnish a proper methodology for the reliability assessment of non-destructive tests in the particular field of inspection of post-tensioned (PT) structures. The focus is on the Ultrasonic Tomography used in the inspection of grouting defects inside the PT ducts. The presence of such defects is the most dangerous scenario for triggering the mechanism of corrosion in the prestressing steel and, therefore, for structural safety. Many studies exist about the application of ultrasonic tomography (UT) in the inspection of PT structures and bridges. However, the reliability of the technique is still not known when applied to field inspection of existing bridges. This paper explains the execution of a laboratory testing campaign on many specimens presenting different sizes and types of simulated grouting defects. The tested specimens are designed to represent the most typical source of grouting defects (voids, water) and the most spread typology of ducts (metallic and plastic) and post-tensioning elements (strands and bars). The inspection outcomes are modelled through the Probability of Detection (POD) curve, which gives information about the maximum defect size that the inspection method, UT, can miss, stating a certain confidence level. Since the number of tests is limited due to practical issues, as will be also the case in a real bridge, a Bayesian-updating approach is employed to better estimate the model parameters of the POD curve. In this way, the reliability of the inspection methodology can be derived, which is of great importance in the posterior capacity assessment of the existing structure.

1 INTRODUCTION

The investigation of structures with bonded posttensioned (PT) cables is a challenging issue, mainly for the configuration of the system itself. The rise of such technology, jointly with the euphoria of reconstruction after the II World War, and the total confidence in the full prestressing (because of the belief that concrete under compression is watertight) (Godart 2001), led to an underestimation of the durability's issues potentially affecting these structures, as well as to an absence of consciousness in their investigation.

The PT system can be both internal and external, bonded and unbonded. The present research focuses on the investigation of structures with bonded PT system. The core of the system are the high-strength steel cables, which are protected by three layers against corrosion, i.e. the concrete cover, the metallic sheet of the ducts, and the grout. The triggering of corrosion on the cable

DOI: 10.1201/9781003483755-110

happens if the protecting layers are affected by degradation and/or by conditions promoting the formation of an aggressive environment. The carbonation of concrete, and the penetration of aggressive ions (such as chlorides and sulphites) due to the use of de-icing salts jointly with an inappropriate waterproofing system, represent only a few of the conditions promoting corrosion. Also, bad execution of the grouting, as well as the use of an inappropriate mixture, can facilitate damage to the cables. The corrosion of the cables is often associated with voids inside the ducts (Carsana and Bertolini 2015). Possible reasons for the voids' formation are the evaporation of bleed water, poor grouting, and/or poor construction practices (Trejo et al. 2009). While the presence of voids is not a sufficient condition for the trigger of corrosion, in most cases the presence of corrosion is associated with the presence of voids. Thus, associating voids with corrosion is a conservative assumption. Moreover, sudden collapses without any visible deficiencies are documented by the state of the art (Woodward 2001). Therefore, one of the possible approaches in investigating damage (i.e. corrosion) in PT structures, is searching for voids inside the ducts. It's easier to search for air pockets through non-destructive techniques (NDTs), rather than directly the corrosion. Many technologies exist to detect defects inside the ducts, e.g. thermography (Garrido et al. 2020), X-ray (Innocenzi et al. 2022) and gamma-ray imaging (Freij et al. 2021), Impact Echo (IE) (Carino 2004; Muldoon et al. 2007), acoustic emission-based methods (i.e. Ultrasonic Echo (UE) and Ultrasonic Tomography (UT) (Schickert, Krause, and Mü Ller 2003; Terzioglu et al. 2018)). To optimize results and minimize errors, more NDTs can be used (Terzioglu et al. 2018). UT was selected as the reference technique for the present application because of its quick and easy application. Although much research exists on the application of UT in the investigation of voids through PT ducts, a numerical evaluation of its effectiveness is lacking. The application of the Probability of Detection (PoD) model represents a possible way to carry out this evaluation. The PoD evaluation is widely used in the non-destructive evaluation (NDE) of technologies employed in aerospace and nuclear engineering (Gandossi and Annis 2010; Virkkunen et al. 2019), and it is standardized by ASTM and the American Department of Defence (Anon 2009; ASTM International 2015, 2018). This evaluation allows the determination of the largest flaw that the technique can miss, stating a certain confidence level and for a given probability. The basic assumption of the PoD model is that the probability of success of an NDT depends only on a measurable entity, usually the flaw size. All the other parameters, potentially influencing too, are ignored and converge in potential errors in the probabilistic model. Indeed, it is important to carefully discriminate homogeneous cases in constructing a PoD curve. It is also fundamental to dispose of a large number of tests and a representative range of sample sizes. One way to improve the probability of detection by using a small number of samples is to use them with Bayesian inference to update the "a priori" obtained curve.

In the present research, six reinforced concrete walls with several ducts with simulated grouting defects of different sizes were designed and UT was then applied with the aim of analysing its efficiency in defect detection. The Bayesian approach is proposed to compare different scenarios composed of different number of samples.

2 PROBABILITY OF DETECTION

2.1 *Basic framework*

The PoD relates the probability of successfully detecting a flaw to its size (or to other geometrical characteristics). The standard practice offers two variants of PoD estimation, the so-called *â vs a* approach and the *hit/miss* approach. The first one deals with continuous data, while the *hit/miss* approach is based on binary results, which are hits (correctly found flaws) and misses (flaws not found). The focus will be on the latter since it is the approach adopted in the present research.

The PoD curve is solved using a generalized linear model and a chosen link function (typically logistic) that gives the shape of the PoD curve using the maximum likelihood fit of the data (Virkkunen et al. 2019). The response (y) is related to the controlling variables functionally, $y = f(X)$, where X is the value of controlling variables. Binary (hit/miss) data are bounded and discrete, having only 0 (miss) or 1 (hit) as possible values. A Generalized Linear Model

(GLM) overcomes this difficulty by linking the binary response to the explanatory variables through the probability of either outcome, which does vary continuously from 0 to 1. In other words, a function of y is necessary to *link* (through the probability of the outcome) the binary response to the function of X, in other words, $g(y) = f(X)$.

The binary linear regression model can be expressed as a linear function of the explanatory variable x by Equation (1):

$$f(X) = h[PoD(x)] = \Phi^{-1}(p) \tag{1}$$

where the function $h(p) = \Phi^{-1}(p)$ is the inverse Cumulative Distribution Function (CDF), also known as the quantile function of a standard location-scale distribution and is known in the statistical literature as a *link function*. One of the most used link functions is the *logit* (or log-odds) one. Therefore, it is possible to express the PoD as (2):

$$PoD(x) = \frac{e^{\beta_0+\beta_1 x}}{1 + e^{\beta_0+\beta_1 x}} \tag{2}$$

The PoD depends on (x ; β_0, β_1). β_0 is the slope, while β_1 is the intercept of the logistic regression model.

2.2 *The Bayesian approach*

Unlike the frequentist approach, for which the vector parameter θ of a certain distribution is unknown, but a deterministic quantity, the Bayesian approach considers θ as a random variable with a certain probability distribution. Three key components are associated with the parameter estimation: the prior distribution ($P(\theta)$), the likelihood function ($P(y|\theta)$), and the posterior distribution ($P(\theta|y)$), Equation (3):

$$P(\theta|y) \propto P(y|\theta)P(\theta) \tag{3}$$

The likelihood function gives information contained in the sample and these are combined with information about the prior distribution to obtain the posterior distribution. Therefore, the posterior distribution contains all the available knowledge about the parameters in the model as obtained with the samples. The likelihood function for the logistic regression, assuming that the experimental samples are independent of each other, can be written as (4):

$$Likelihood = \prod_{i=1}^{n} P_i^{y_i} \cdot (1 - P_i)^{(1-y_i)} = \prod_{i=i}^{n} \left(\frac{e^{\beta_0+\beta_1 x_i}}{1 + e^{\beta_0+\beta_1 x_i}}\right)^{y_i} \cdot \left(1 - \frac{e^{\beta_0+\beta_1 x_i}}{1 + e^{\beta_0+\beta_1 x_i}}\right)^{(1-y_i)} \tag{4}$$

The prior distribution can be informative or non-informative. It can be assumed that the parameters of the prior distribution are normally distributed, with a certain mean (μ) and standard deviation (σ). The choice of a normal distributions simplifies the calculation.

$$\beta_j \sim Normal\left(\mu_j, \sigma_j\right) \tag{5}$$

The posterior distribution is derived by multiplying the prior distribution over all the parameters by the full likelihood function, so (6):

$$Posterior \propto \prod_{i=1}^{n} \left(\frac{e^{\beta_0+\beta_1 x_i}}{1 + e^{\beta_0+\beta_1 x_i}}\right)^{y_i} \cdot \left(1 - \frac{e^{\beta_0+\beta_1 x_i}}{1 + e^{\beta_0+\beta_1 x_i}}\right)^{(1-y_i)} \times \prod_{j=0}^{p} \frac{1}{\sqrt{2\pi}\sigma_j} exp\left\{-\frac{1}{2}\left(\frac{\beta_j - \mu_j}{\sigma_j}\right)^2\right\} \tag{6}$$

The latter part is the normal distribution for the β_j parameters. The expression has no closed form; therefore, it is necessary to employ a Markov Chain Monte Carlo (MCMC) method or similar (Chib 2001; Hoffman and Gelman 2014a; Roberts and Richardson 1998), to solve and approximate the mean and standard deviation of the posterior distributions for each parameter.

3 THE EXPERIMENTAL CAMPAIGN

3.1 *Samples*

Six concrete walls with a total of 40 embedded ducts, both plastic and metallic, and with pre-stressing strands and bars were realized. Both voids and water defects of different size were simulated in each duct. The voids were realized through the use of polyurethane foam with the actual dimension of the defects (Figure 1a) or by creating a "stopper" for the grouting (Figure 1b). The water defects were simulated using plastic bags filled with water as shown in Figure 1c.

a) b) c)

Figure 1. Samples with simulated defects before deployment in the concrete wall and grouting. a) three defects of different sizes (3, 5, and 8 cm). b) simulation of a defect of 33 cm. c) simulation of a void filled with water.

A total of 40 samples, including samples with perfectly executed grouting for comparison, were produced.

3.2 *Tests' execution*

Two devices (A1040 MIRA and A1040 MIRA3d) were employed, both using he Ultrasonic Shear-wave (MIRA) technique with an array of Dry Point Contact (DPC). The main parameter to be calibrated to perform the investigation are the velocity and the analog and digital gain.

The velocity of the shear waves through the concrete was estimated by the relation (7) (Krautkrämer and Krautkrämer 1990):

$$c_t = \sqrt{\frac{E}{\rho} \cdot \frac{1}{2 \cdot (1+\nu)}} = 2422\ m/s \tag{7}$$

Being the density (ρ) around 2500 $\frac{kg}{m^3}$, the Elastic modulus (E) up 34625 MPa, and the Poisson ratio (ν) of 0.18. The calibration is performed by comparing the actual thickness of the inspected body with the one derived by multiplying c_t . t (where t is the time required for the wave to come back). In addition, it is necessary to choose the proper values for the analog and digital gain. The analog gain is a parameter that increases the analog signal amplitude before the conversion into a digital signal; the digital gain is a parameter that operates directly on the digital signal (ACS Group 2021). A high value of the analog and the digital gain could lead to an irrelevant scan due to the high colour intensity, in fact the Synthetic Aperture Focusing Technique SAFT (Schickert et al. 2003; Stepinski and Lingvall 2010) algorithm provides a colour map representing the difference in acoustic impedance (Δ) between the base material and the object material in the section scanned. By selecting at least two ducts and performing scans for a length of at least 50 cm in the area in which the occurrence of grouting

defects was less probable, the best values of the analog and digital gain could be found by some attempts until the image given from the scans is not amplified continuously. The test was carried out by performing 10 scans per duct, being the chosen pitch equal to 10 cm and the total length to inspect up to 100 cm (Figure 2).

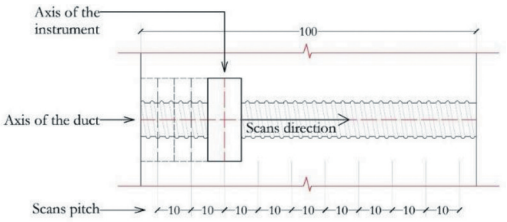

Figure 2. Graphical representation of the tests' execution.

3.3 *Data translation*

The results of the inspection are images computed by the SAFT algorithm. It was necessary to translate the qualitative output in a numerical value by assigning 1 in case the defect was hit by the colour amplification of the scan (i.e. a hit) and 0 if the defect was missed (i.e. a miss), as shown in Figure 3. The colour amplification in between "C" and "B" represents a false positive.

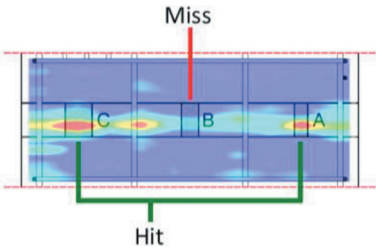

Figure 3. The meaning of "hit" and "miss". Grouting voids A and C are detected, but B is not.

As a consequence of what was presented above, a data set of 110 samples with metallic ducts was therefore considered.

3.4 *Resulting scenarios*

Since the main assumption of the PoD is that the detectability of a flaw depends only on its size, it is of basic importance to correctly discriminate the other potentially influencing parameter. In the present case the tests were divided into 6 scenarios (Table 1) depending on the calibration (i.e. the choice of the analog and digital gain), on the typology of the scan (i.e.

Table 1. Parameters characterizing each scenario.

Id. scenario	Calibration	Geometry	Scan Typology	N° of tests
SC1	1	15 cm	Linear	65
SC2	2	25 cm	Linear	40
SC3	All	15 cm	Linear	89
SC4	All	25 cm	Linear	62
SC5	1	All	Matrix	81
SC6	All	All	Linear	151

linear or matrix, meaning the way in which the sensors are employed by the instruments), and on the eccentricity of the ducts (15 cm or 25 cm).

4 DATA ANALYSIS

4.1 *Description of the hit/miss data*

A total of 232 inspections were performed on 12 flaw lengths from 3 to 100 cm. Figure 4 shows the number of tests for each flaw size. Figure 5 summarizes the percentages of hits and misses at each size. The PoD model seems to be well adapted for the modelling of the reliability and confidence of the inspection results, in fact from the size of 22 cm there are no misses, and for the flaw size less than 22 cm the percentage of misses grows as the length of the flaw decreases.

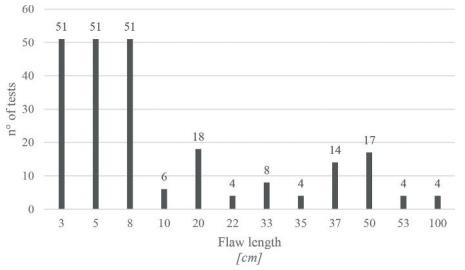

Figure 4. Number of tests in metallic ducts for each flaw length.

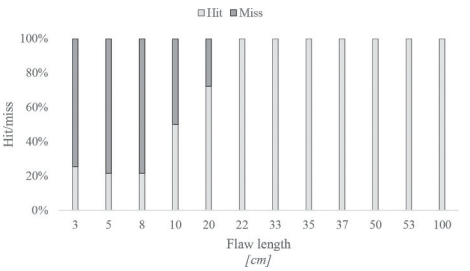

Figure 5. Hit/miss percentage for each flaw length.

4.2 *Construction of the PoDs curves*

A typical PoD is displayed in Figure 6. The most relevant parameters according to (ASTM International 2018) are the critical value of the defects' length for which there is a 50% probability of detection, with a confidence of 50%, to obtain a "hit" (a_{50}); the critical value of the defects' length for which there is the 90% probability, with a confidence of the 50%, to obtain a "hit" (a_{90}) and the critical value of the defects' length for which there is the 90% probability, with a confidence of the 95%, to obtain a "hit" ($a_{90/95}$).

To get comparable results for the different scenarios using different numbers of samples, the Bayesian approach is a solution as presented in (Aldrin, Knopp, and Sabbagh 2013; Kanzler, Müller, and Pitkänen 2013). The Bayesian approach was applied through the Python environment and by the PyMC3 package (Salvatier, Wiecki, and Fonnesbeck 2016). A normal distribution with 0 mean and 10 standard deviation was assumed for both β_0 and β_1 considering the prior distributions as non-informative. The likelihood function representing the probability of observing the actual data given the model parameters as displayed in equation (4) was evaluated. The sampler algorithm employed was the No-U-Turn Sampler (NUTS). This algorithm closely resembled Hamiltonian Monte Carlo (HMC), avoiding the need to choose the problematic number-of-steps parameter (Hoffman and Gelman 2014b). The analyses were performed by running 5 chains of 5000 iterations each. By performing several analyses and varying the number of iterations, it was possible to select 5000 iterations as an appropriate value.

Indeed, considering in the analysis:

$$intercept : \beta_0 \sim N(0, 10)$$

$$slope : \beta_1 \sim N(0, 10)$$

a good representation of a non-informative prior is obtained, as visible from Figure 7, where the mean values of the intercept are obtained for increasing values of the standard deviation

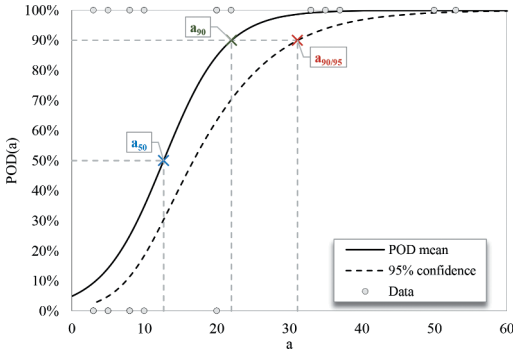

Figure 6. Typical PoD curve showing the most relevant points (a_{50}, a_{90}, $a_{90/95}$).

of the prior (increasing non-information). As seen there, 10 can be considered as the threshold marking the non-informative character of the prior.

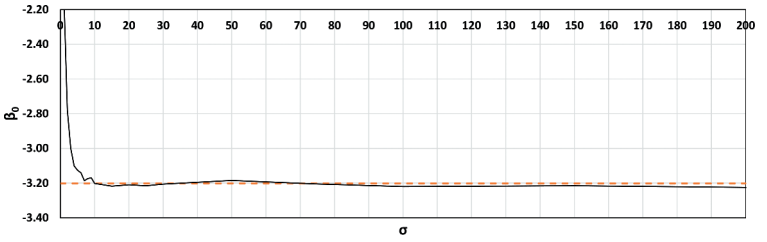

Figure 7. Evolution of the mean value of β_0 with increasing uncertainty of the prior distribution for scenario 1. The dotted line is the value of β_0 parameters considering $\sigma = 10$.

Figure 8 shows the "trace plot" of each chain for the β_0 parameter in the first scenario, i.e. a graph of the sampled parameter values as a function of step in the chain. The upper part in Figure 8 is a smoothed histogram. These plots are useful for a preliminary check of the convergence of the MCMC algorithm: if the traces of each chain in the trace plot overlap each other, then the chains are all representative of the posterior distribution; if any chain were isolated, then the convergence had not been achieved. A similar assessment can be performed on the density plot: if the density plots of the chains overlap, then the chains are producing representative values of the posterior distribution (Kruschke 2014). Similar convergence results were obtained for the rest of the scenarios.

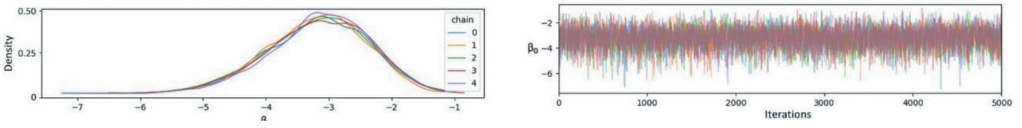

Figure 8. "Density plot" and "trace plot" of the β_0 parameter for scenario 1.

An example of the PoD plot is given in Figure 9, showing the curve obtained for the first scenario for which resulted $\beta_{0_{mean}} = -3.202$ and $\beta_{1mean} = 0.258$.

5 CONCLUSIONS

The main results of the analysis are displayed in Table 2, in term of critical values, i.e. a_{50}, a_{90}, and $a_{90/95}$.

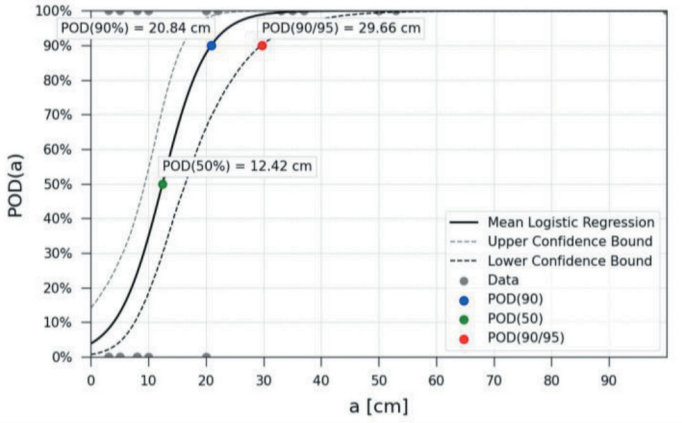

Figure 9. Bayesian PoD of scenario 1.

Table 2. Summary of results by Bayesian analysis.

			Bayesian method		
ID.	n_{hits}	n_{misses}	a_{50} [cm]	a_{90} [cm]	$a_{90/95}$ [cm]
SC1	36	27	12.42	20.84	29.66
SC2	24	16	17.23	23.65	32.46
SC3	47	42	11.02	21.84	32.26
SC4	27	35	16.43	25.65	35.67
SC5	32	49	10.82	24.25	49.50
SC6	74	77	13.23	24.65	32.26

Observing the results, the main conclusions that can be stated are:

- The concrete cover seems to be the most influencing parameter (SC1 vs. SC2, and SC3 vs. SC4). The thicker the cover, the less reliable the test.
- Varying the calibration introduce uncertainty. By comparing SC1 vs. SC3 and SC2 vs. SC4, it can be observed that higher critical voids are determined introducing different calibrations and fixing the other variables (i.e. concrete cover and scan typology).
- Since the most typical ducts' depth is around 15 cm, it seems a correct conclusion that the $a_{90/95}$ to be generally considered is around 30 cm (SC1, SC3, SC6).

The latter is the most important conclusion of the study since it allows to better design the investigation on PT structures. In detail, since is very likely to detect voids larger than 30 cm, the UTs can be performed using a pitch of 30 cm, higher than the one employed in the present research (10 cm), resulting in a significant save of resources.

Influence of repair interventions on the safety of a reinforced concrete road bridge subjected to chloride ingress

G. Lombaert
KU Leuven, Leuven, Belgium

ABSTRACT: Policymakers are increasingly faced with the challenge of managing aging concrete bridges subjected to deterioration. Rebuilding these structures often leads to significant downtime and construction costs. Therefore, repairing and upgrading the existing infrastructure is often preferred instead. Typically, interventions are scheduled after severe signs of deterioration, which might involve significant costs. On the other hand, scheduling preventive interventions during the early stages of chloride-induced corrosion can be highly beneficial as the chloride content at the reinforcement level can be significantly altered. As a result, the structure's lifespan can be extended in a more cost-effective manner compared to a corrective maintenance strategy. This study investigates the impact of the timing of an intervention to the concrete ingress at the concrete surface (e.g. by applying a coating) on the time-dependent safety level of a real-life prestressed bridge girder, which enables to assess the importance of a preventive maintenance strategy.

1 INTRODUCTION

Optimization of repairs and structural intervention in concrete structures is essential to extend the lifetime of deteriorating structures as efficiently as possible. A popular remedy are the so-called preventive strategies, which are repetitive small interventions already applied in an early stage of the structure, ensuring that the safety level of the structure does not drop below a certain threshold over time. In terms of chloride-induced corroding structures, this intervention is typically executed in the initiation phase of the concrete, where the steel is not yet corroding and the chloride concentration is still below a critical threshold. In this work, the repair intervention investigated is related to a complete blockage of chlorides at the surface of the concrete, which is able to slow down the ingress of chlorides, thus extending the initiation period and limiting the duration of the corrosion process.

In the first part of this work, the quantification of the corrosion duration in a probabilistic framework is explained, taking into account blockage of chlorides at the surface for a certain duration. Afterwards, the relation between the corrosion degree and the safety level of a real-life prestressed bridge girder is determined and the effect of the repair intervention is quantified. In the end, conclusions are drawn about the application intervention types and future research topics are proposed.

2 QUANTIFICATION OF INITIATION AND PROPAGATION TIME

2.1 *Without intervention*

Chloride ingress into concrete is a subject which has been investigated thoroughly in previous research, leading to a general consensus regarding the modelling of chloride ingress over time

DOI: 10.1201/9781003483755-111

(fib bulletin 34, 2006). Generally, the one-dimensional diffusion law is used, described by Fick's second law (Crank 1975):

$$C(x,t) = C_s\left[1 - erf\left(\frac{x}{2\sqrt{Dt}}\right)\right] \tag{1}$$

where $C(x, t)$ [*m%cem*] is the concentration at distance from the surface x [m] and time t [y], C_s [*m%cem*] is the constant surface concentration, D [m^2/y] the (apparent) diffusion coefficient and *erf*(.) the Gaussian error function. If the chloride concentration at the level of the reinforcement exceeds a certain critical chloride content C_{crit}, the steel is depassivated, which is generally considered as the starting point of the corrosion process, i.e. the propagation phase.

In order to assess the safety of a structure at a certain time T throughout its lifetime, the propagation time T_{prop} is combined with the expected corrosion rate, which leads to a loss of reinforcement and consequently a reduced safety level. In order to determine the propagation time T_{prop}, one states that the propagation time is equal to the age of the structure subtracted by the initiation time, i.e. $T_{prop} = T - T_{ini}$. The initiation time T_{ini} can be quantified by considering the instant in time at which the corrosion concentration at the reinforcement is equal to the critical chloride content C_{crit}, which has a certain variability due to the uncertain parameters involved.

2.2 *With intervention*

In order to extend the initiation phase, repair techniques are available which can delay the onset of the propagation phase and thus reduce the amount of corrosion over a structure's intended lifetime (fib bulletin 102, 2022). The repair strategy considered in this work is the blockage of new chlorides at the surface of the concrete substrate, which can be the result of a coating at the surface. As a result, the ingress of chlorides slows down and the initiation period is extended. This repair strategy is assumed to function for a limited duration as a coating typically loses its effectiveness after a while, after which the chlorides are able to penetrate again. It must be noted that the effectiveness of the chloride blockage might decrease steadily over time instead of instantly losing all its blockage properties at once. However, this is considered outside of the scope of this work.

Modelling the chloride migration during and after the blockage is done by solving the diffusion equation with the principle of separation of variables (Crank 1975). The boundary and initial conditions for the chloride blockage are:

$$\frac{\partial C(x,t)}{\partial x}|_{x=0} = 0 \tag{2}$$

$$C(x,t)|_{x=h_1} = 0 \tag{3}$$

$$C(x,t)|_{t=0} = \bar{C}(x) \tag{4}$$

and for the free flow with an initial chloride profile:

$$C(x,t)|_{x=0} = Cs \tag{5}$$

$$\frac{\partial C(x,t)}{\partial x}|_{x=h_1} = 0 \tag{6}$$

$$C(x,t)|_{t=0} = \bar{C}(x) \tag{7}$$

where $\bar{C}(x)$ is the initial chloride profile and h_1 the limit of the semi-infinite region, chosen equal to 300 mm in this work. The solution for both problems can be derived in the form of:

$$C(x,t) = C_k + \sum_{n=1}^{\infty} A_n f_n\left(\frac{\lambda_n x}{\sqrt{D}}\right) exp\left(-\lambda_n^2 t\right) \tag{8}$$

with:

$$C_k = \begin{cases} 0 \text{ for chloride blockage} \\ C_s \text{ for free flow} \end{cases} \tag{9}$$

$$f_n(y) = \begin{cases} \cos(y) \text{ for chloride blockage} \\ \sin(y) \text{ for free flow} \end{cases} \tag{10}$$

$$A_n = \frac{2}{h_1} \int_0^{h_1} \left[\bar{C}(x) - C_k\right] f_n\left(\frac{\lambda_n x}{\sqrt{D}}\right) dx \tag{11}$$

$$\lambda_n = \frac{\sqrt{D}}{h_1}\left(n + \frac{1}{2}\right)\pi \tag{12}$$

The number of terms n is practically limited to a finite number, which is chosen as 50 in this work, which has proven to be sufficient for convergence of the solution. In Figure 1 and Figure 2, an example is shown of an intervention which is applied after 20 years and which completely blocked the ingress of new chlorides for another 40 years. The situations with and without interventions are compared, which shows the ingress of chlorides is successfully delayed, extending the initiation period.

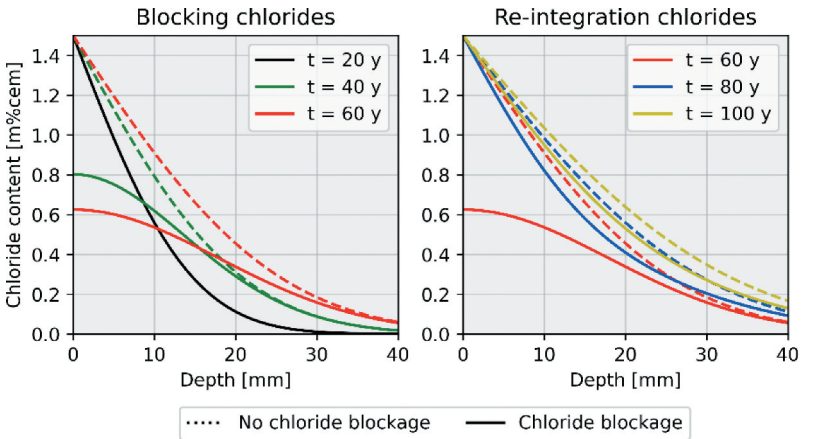

Figure 1. Chloride ingress during and after blockage from 20 to 60 years ($D = 0.2\frac{10^{-12}m^2}{s}$, $C_s = 1.5\ m\%cem$).

Considering the probabilistic properties from Table 1, the distribution of the initiation period T_{ini} is determined by the instant at which the chloride concentration at the cover reaches the critical content, as illustrated in Figure 2. Afterwards, the duration of the corrosion phase T_{prop} is determined at a certain time instant by subtracting the value of T_{ini}. The distribution for the duration of the corrosion phase after 100 years is shown in Figure 3 for a structure without intervention and a structure with chloride blockage applied at an age of 20 years. Three cases are considered, where the effectiveness of the blockage varies from 20 to 60 years. Blocking the chloride ingress at the surface for a certain duration leads to a longer initiation phase and, for this reason, shifts the distribution of the propagation period to smaller values, which shows the benefit of this intervention.

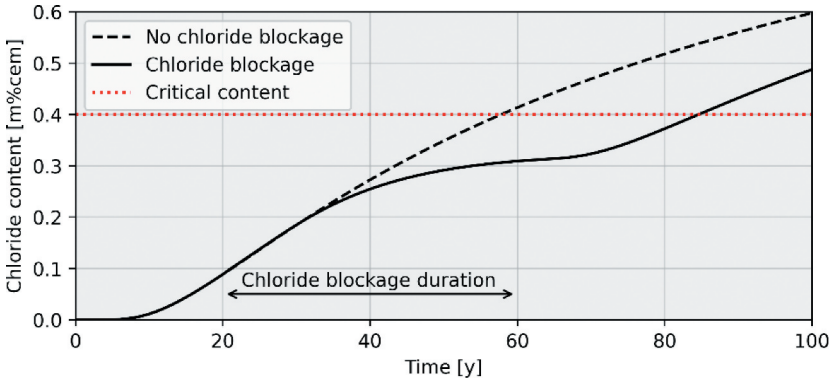

Figure 2. Influence of chloride blockage on chloride concentration over time at a depth of 30 mm after blockage from 20 to 60 years ($D = 0.2\,\frac{10^{-12}m^2}{s}$, $C_s = 1.5\ m\%cem$).

Table 1. Probabilistic models related to the chloride ingress.

Variable	Distr.	μ	V	Source

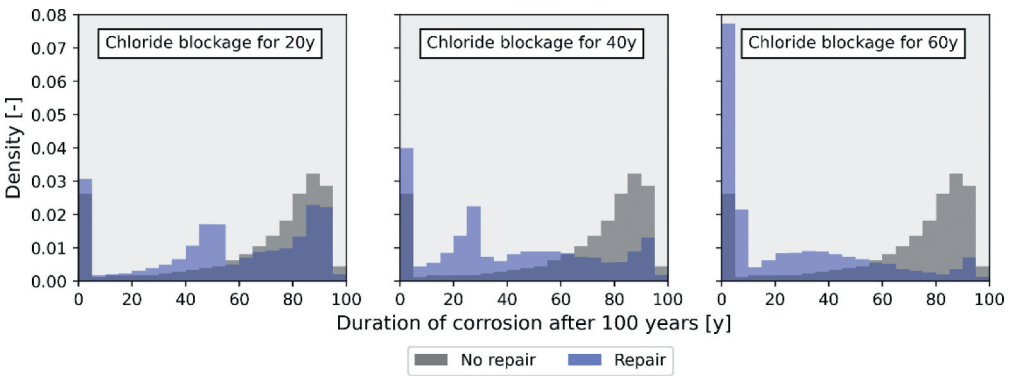

Figure 3. Distribution of duration of corrosion propagation after 100y, with and without chloride blockage at 20y.

3 RELATION BETWEEN SAFETY LEVEL AND PROPAGATION PERIOD FOR A BRIDGE GIRDER

By applying an intervention at an early age, the onset of the propagation period can be delayed significantly, leading to a shorter duration of the propagation period within a given lifetime, as illustrated in the previous section. In order to show how this change in propagation period influences the safety level of a structure, a case study of a prestressed bridge girder

subjected to chloride-induced corrosion is considered. First of all, the relation between the duration of the propagation period and the safety level of the girder is determined. Afterwards, the influence of the intervention discussed previously on the safety level is quantified.

3.1 *Structural capacity of the investigated prestressed girder*

A bridge girder, which is part of an actual bridge superstructure, is considered. The prestressing consists of thirty 52.8 mm^2 strands, leading to a total prestress steel area of 1584 mm^2. The dimensions of the girders are given in Figure 5, where the prestressing strands are assumed to be located at the same location within the cross-section, for simplification purposes. Only the bending failure mode of the prestressed girder is considered to be critical, and the shear capacity of the girder is not evaluated. Moreover, only the location at mid span is considered to be critical and hence this is the only location where the moment capacity is determined. As illustrated in Figure 4, the prestress is applied as an external load and the internal moment resistance is calculated as illustrated in Figure 5. For the concrete, a parabolic-rectangular stress-strain diagram is used with yield limit 2 ‰ and ultimate strain 3.5 ‰. For the prestressing steel, an elastic-perfect plastic stress-strain diagram is used where the ultimate strain is limited to 10 ‰ and the steel is assumed to be yielding in the ultimate limit state. The moment capacity M_R is determined as follows:

$$M_R = M_{R,cs} + M_P + M_0 \tag{13}$$

$$M_P \cong P \cdot 7.25\ m = A_p \cdot \sigma_{p\infty} \cdot sin\left(arctan\left(\frac{357 - 147}{7250}\right)\right) \cdot 7.25\ m \tag{14}$$

$$M_0 = A_p \cdot \sigma_{p\infty} \cdot (0.5\ m - 0.147\ m) \tag{15}$$

where $M_{R,cs}$ is the bending moment capacity of the cross-section analysis, including the model uncertainty of either concrete crushing or steel yielding given in Table 2, M_P the moment due

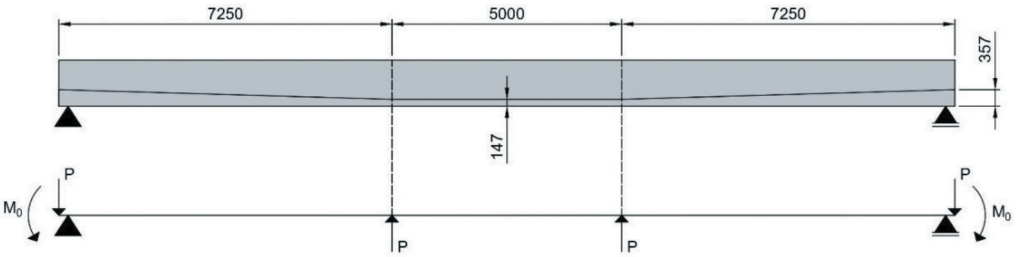

Figure 4. Calculation of prestress as external forces (dimensions in mm).

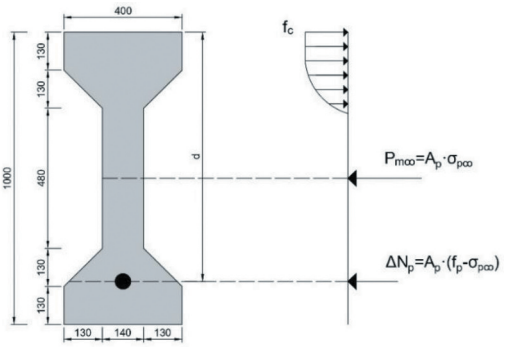

Figure 5. Calculation of internal forces prestressed girder (dimensions in mm).

to the localised force at the draping point and M_0 the external effect of the prestressing at midspan.

Using the probabilistic properties from Table 3, the distribution of the resistance M_R is determined. The resistance is calculated for multiple values of the total prestress area, in order to quantify the effect of corrosion on the resistance of the girder. Note that this is a simplified way of modelling the influence of corrosion, for a more detailed analysis is referred to (Franceschini 2021, 2022a, 2022b) and (Jeon 2019).The results are given in Figure 6, together with their fitted lognormal distribution. As the coefficient of variation V remains more or less constant, and the mean value changes linearly with the number of strands, the following distribution is chosen for the moment resistance of one girder:

$$M_R(A_{p,cor}) = LN\left(\mu = 2097 - 2027\frac{A_{p,cor}}{A_{p0}}\ kNm; \sigma = 0.045\mu\right) \tag{16}$$

where $A_{p,cor}/A_{p0}$ is the ratio of the corroded prestress area over the initial area.

Table 2. Probabilistic models for the variables related to the structural resistance of the investigated prestressed girder.

[b] $f(X_k) = 0.05\left(\frac{200}{X_k}\right)^{2/3}$

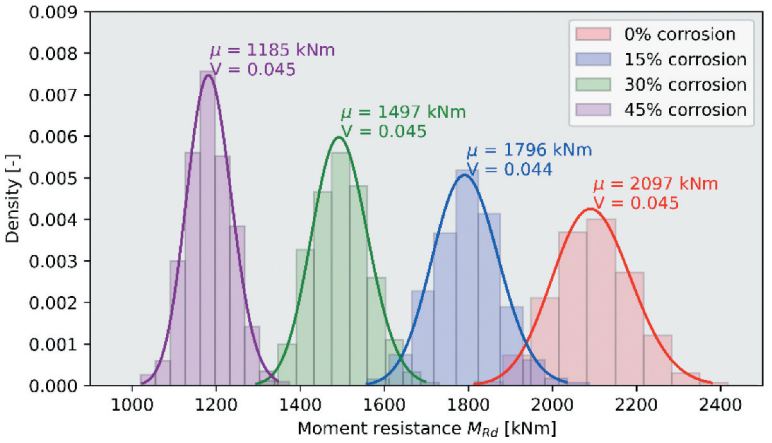

Figure 6. Moment resistance of prestressed girder for different ratios of the corroded prestress area over the initial area.

3.2 *Limit state equation for bending of prestressed girder*

The limit state equation for bending of a bridge girder is described as follows:

$$g_i(\boldsymbol{X}) = M_R\left(A_{p,cor}\right) - \theta_E\left[M_{E,g} + M_{E,p} + C_{0T}M_{E,q}\right] \tag{17}$$

where $M_R(A_{p,cor})$ is the moment resistance of a girder with $A_{p,cor}$ the corroded prestress area defined by Eq. (16) and the other parameters are defined in Table 3. The loads are based on an evaluation of the bridge superstructure subjected to a range of permanent loads and variable traffic loads corresponding to Load Model 1 of EN1991-2.

The corroded prestress area is governed by the propagation period T_{prop} and corrosion rate V_{corr}. The annual failure probability p_f of a girder at a given time instant t can therefore be defined as:

$$p_f(t) = \int_0^t f_{T_{prop}}(\tau)P[g_i(V_{corr}\tau, \boldsymbol{X}) < 0]d\tau \tag{18}$$

In this expression, it is assumed that the corrosion rate is a deterministic value which is expressed in $mm^2/year$. The duration of corrosion propagation has a certain distribution described by a probability density function $f_{T_{prop}}$, as discussed in the first part of this work. Practically, if the annual reliability index β_{1y} needs to be determined at a given time instant t, the distribution $f_{T_{prop}}$ (as illustrated in Figure 3 for $t=100$ years) is determined for this time instant, and applied in Eq. (18).

Table 3. Probabilistic parameters for loads on bridge superstructure.

Variable	Distr.	X_k	μ	V	Source

[a] corresponding to a 1-year reference period

3.3 *Influence of repair strategy*

A fictional chloride ingress problem is considered with properties given in Table 1 and a deterministic corrosion rate of 2.5 mm^2/year. From the moment the critical chloride at the cover depth level is exceeded, the corrosion process starts and the amount of prestress area decreases linearly over time. Note that the corrosion process is simplified as all strands are assumed to be located in one place, which is not the case in reality as the strands are distributed over different locations in the cross section.

In Figure 7, the time-dependent annual reliability index of the girder is evaluated over a lifespan of 100 years for a structure that is subjected to a chloride blockage intervention at an age of 20 years. Initially, the annual reliability index of the undamaged girder corresponds to a value of 4.0, which approximates the target reliability level for a structure with consequence class CC2 according to (JCSS 2001, ISO 2394:2015). The duration of the chloride blockage has a large influence on the final safety level of the girder, which shows the importance of the durability of the intervention.

Figure 8 shows the reliability index of the girder at an age of 100 years, for different chloride protection scenarios. Without intervention, an annual reliability value of 2.8 would be reached, which can be significantly improved when the chloride blockage is applied early enough. If the chloride blockage is applied after a lot of chlorides have already migrated into the concrete (e.g. age of 40 years), the benefit is much less compared to the situation where the chlorides are countered from an early age.

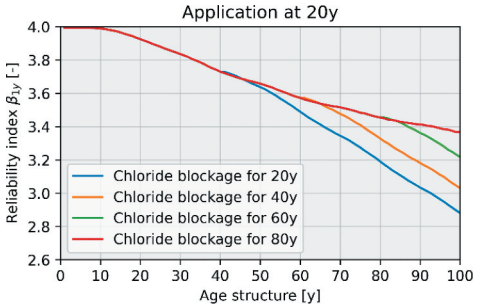

Figure 7. Annual reliability index over time of the bridge girder subjected to an intervention at an age of 20y.

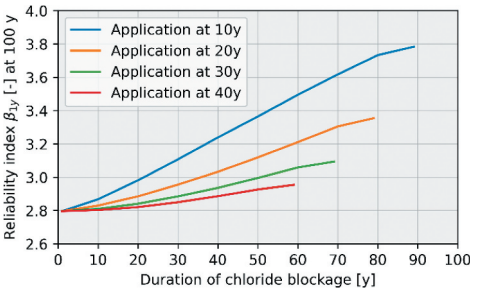

Figure 8. Annual reliability index of the center bridge girder at an age of 100y for interventions at 10y, 20y, 30y, and 40y.

4 CONCLUSIONS AND FURTHER WORK

This work proposes a framework to quantify the influence of a chloride ingress intervention in the initiation phase on the safety level of a structure over time. The framework is applied to a simplified case of an actual prestressed bridge girder. The intervention type considered is a blockage of chlorides at the surface, e.g. by applying a coating, which slows down the migration of chlorides within the concrete substrate. It has been shown that if this intervention is applied early enough in the lifetime of the structure, it is an efficient way to extend the initiation period of a structure and improve the safety level over time. In case the intervention is applied at a later time instant, its effect is much less pronounced as the steel still becomes depassivated by the large amount of chlorides that has already ingressed into the structure.

An important aspect that should be taken into account is the uncertainty regarding the corrosion rate, which is difficult to predict in an initial stage of a structure. However, if one expects a large corrosion rate and notices the ingress of chlorides might cause problems at an early age, the chloride blockage may be a good solution to the safety problems that may arise. In case the corrosion process has already started and one notices a high corrosion rate, other repair strategies might be more beneficial such as the replacement of (part of the) concrete cover in order to re-passivate the steel and stop the corrosion process.

Further work includes the implementation of other repair strategies in order to deal with situations as just described. Moreover, a more realistic corrosion process should be considered, taking into account the fact that the prestressing strands are spatially distributed over the cross-section and the corrosion process in the strands is not uniformly distributed over the strands. Lastly, also the safety level of a complete structure could be assessed, by extending the current analysis of a single bridge girder.

Probabilistic assessment of the moment-curvature response of PC beams with different corrosion scenarios

ABSTRACT: Corrosion of the reinforcement significantly affects the resistance and ductility of concrete members. While various approaches have been proposed to study the sectional response of corroded reinforced concrete structures, the effects of corrosion on prestressed concrete (*PC*) members still poses significant challenges. Therefore, this study focuses on investigating the bending resistance of prestressed concrete sections with different corrosion scenarios through probabilistic assessment using Monte Carlo simulations based on preliminary results of previous work. First, the mechanical properties of the materials and the investigated pit depths have been established as input parameters of the cross-sectional model. To account for corrosion in the constitutive behaviour of the prestressing strands, the Simplified Model for Corroded Prestressing Strands (*SCPS* model) has been adopted. Furthermore, different statistical distributions of the pit depths are derived to represent different corrosion scenarios. Subsequently, Monte-Carlo simulations are utilized to capture the inherent randomness associated with the mechanical properties and pit depths in the sectional response of *PC* elements. Based on the outcome of these simulations, the influence of corrosion on the moment-curvature response as well as the expected failure mode are assessed. Finally, the latter results are investigated for different scenarios of corrosion, providing a comprehensive understanding of the effects of corrosion in *PC* elements and the associated uncertainties. These findings are relevant to researchers, engineers, and practitioners involved in the design, assessment, and maintenance of prestressed concrete structures.

1 INTRODUCTION

The load-bearing capacity assessment of corroded reinforced and prestressed concrete (*RC* and *PC*) structures is a crucial topic in the engineering community. Over the years, the conducted studies have focused on corroded monolithic *RC* structures while few attention has been paid to prestressed structures (Vereecken et al., 2021). In recent literature, both experimental and numerical tests are available (Belletti et al., 2019, 2020; Coronelli et al., 2009; Galano et al., 2023a; Galano et al., 2023b; Rinaldi et al., 2010; Vecchi et al., 2020). Probabilistic studies on the bearing capacity of corroded *PC* members are still lacking, although approaches are available for wires (Lee et al., 2023). This work focuses on the probabilistic assessment - via Monte-Carlo (*MC*) simulations - of the moment-curvature M-χ response of naturally-corroded pre-tensioned concrete beams described in the experimental tests by Belletti et al. (2020) and Vecchi et al. (2020). The work is based on preliminary results of a previous study (Belletti et al., 2023). To consider the chloride-induced corrosion on prestressing strands, the *SCPS* model (Franceschini et al., 2022) is considered. Firstly, different statistical distributions of uncorroded and corroded properties in terms of pit depths are derived and different corrosion scenarios are established. Secondly, a model uncertainty is estimated, and statistical distributions of cracking and ultimate moments are provided and discussed. Finally, a practical estimation of the design resistance of *PC* members subjected to corrosion is carried out. A Matlab code was developed for the purpose.

2 METHODOLOGY, MATERIAL PROPERTIES AND CORROSION SCENARIOS

2.1 *General method*

Monte-Carlo (*MC*) analyses and probabilistic assessment (*PA*) have been carried through the following steps, as already described in a previous work by the authors (Belletti et al., 2023):

1. *MC* simulations are performed with as input data the geometry of the *PC* beam section and the random variation of the mechanical properties of concrete and prestressing strands by establishing corrosion scenarios. Refer to Sections 2.2, 2.3.
2. The output of the *MC* simulations for each scenario are the moment-curvature responses and failure modes. Refer to Section 3.1.
3. The *PA* is performed by evaluating the probability distributions and the design resisting moment based on different percentiles. Refer to Section 3.2.

Details about the number of simulations and corrosion scenarios are reported in Section 2.3.

2.2 *Reference PC beam section geometry and random uncorroded material properties*

The geometrical features of the reference pre-tensioned beam section are reported in Belletti et al. (2020) and Vecchi et al. (2020) and shown in Figure 1(a). The *PC* beam section has width, b, and height, h, equal to 150 and 300 mm, respectively. The lower reinforcement is formed by two seven-wire strands, with outer wires' diameter, ϕ_{out}, equal to 4.26 mm and the inner one, ϕ_{inn}, equal to 4.38 mm, thus a nominal diameter equal to 12.9 mm and total strands' area $A_{p,0}$ equal to 201.06 mm^2. The upper reinforcement, $A_{s,0}$, consists of two bars with a diameter of 5 mm and no transversal reinforcement is provided. The concrete cover is equal to 50 mm. The effective depth of the two strands, d_p, and the eccentricity, e, are equal to 250 mm and 100 mm, respectively.

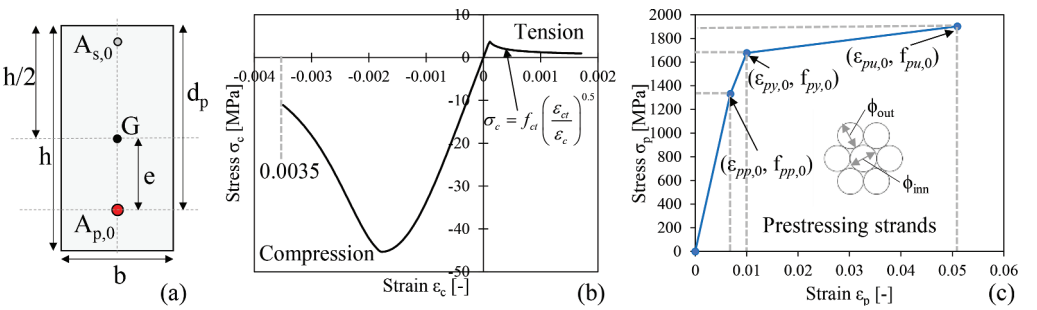

Figure 1. Reference *PC* beam section geometry and stress-strain relations for concrete and prestressing steel strands (Franceschini et al., 2022).

The random variables associated to the mechanical properties of concrete and uncorroded prestressing steel are reported in Table 1. The Thorenfeldt model was adopted for concrete in compression and the power law was used for tensile softening, Figure 1(b). A lognormal distribution was used for the uncorroded properties of concrete and a normal distribution was used for uncorroded prestressing steel (JCSS, 2001). The *SCPS* model (Franceschini et al., 2022) was used for the strands' stress-strain relation (Figure 1(c)). The stresses, $f_{pp,0}$ and $f_{py,0}$, are assumed equal to $0.7 \cdot f_{pu,0}$ and $0.882 \cdot f_{pu,0}$, respectively, while the strains, $\varepsilon_{pp,0}$ and $\varepsilon_{py,0}$, are assumed equal to $f_{pp,0} / E_p$ and 0.01, respectively. By considering only long-term effects, the uncorroded prestressing stress, $\sigma_{p,0}$ was estimated equal to 1171 MPa. The ordinary reinforcement, $A_{s,0}$, has a yield strength equal to 435 MPa. The random variability of the mechanical properties of mild rebars is not considered herein since it does not affect the overall resistance of the section. The relationships between the normal mean and standard deviation with the lognormal one is reported in the Eq. (1) and (2):

$$\lambda = \ln(\mu) - 0.5\zeta^2 \tag{1}$$

$$\zeta = \sqrt{\ln(1 + CoV^2)} \tag{2}$$

where the coefficient of variation, CoV, is the ratio between standard deviation, σ, and mean μ.

Table 1. Uncorroded materials properties random variables and distributions.

Material	Property	Normal distribution (μ, σ)	Lognormal distribution (λ, ξ)
Concrete	f_c [MPa]	45.380, 6.848	3.804, 0.150
	f_{ct} [MPa]	3.808, 0.364	1.332, 0.098
Prestressing steel	$f_{pu,0}$ [MPa]	1901.75, 40.00	-, -
	$\varepsilon_{pu,0}$ [-]	0.051, 0.0035	-, -

2.3 *Random corroded prestressing steel properties and corrosion scenarios*

Table 2 reports the results of the study on the pitting distribution of corroded strands retrieved from the *PC* beams described in the previous Section (Franceschini et al., 2022). Firstly, each corroded strand was scanned, and the distribution of pits was derived by analysing cross-sections along the overall strand every 10 mm spacing. Secondly, for each strand, the maximum pit depth was detected. In this work, as further improvement, linear correlations between the maximum pit depth P_{max}/r_{out} (or P_{max}) and mean and standard deviation values have been constructed, refer to Figure 2. The radius of the exterior wires, r_{out}, is equal to 2.13 mm for the strands. The proposed equations allow to estimate the statistical pit distribution from the knowledge of the maximum pit depth detected along a corroded strand.

Table 2. Maximum pit depth and pit distribution for the strands analysed in Franceschini et al. (2022).

Firstly, based on the *SCPS* model (Franceschini et al., 2022), a total of four corrosion scenarios (*CSs*), (*S1*, *S2*, *S3* and the uncorroded one *S0*) have been established depending on ultimate corroded strains of the most corroded wire, $\varepsilon_{pu,corr}$, (Figure 3(a) and Table 3)

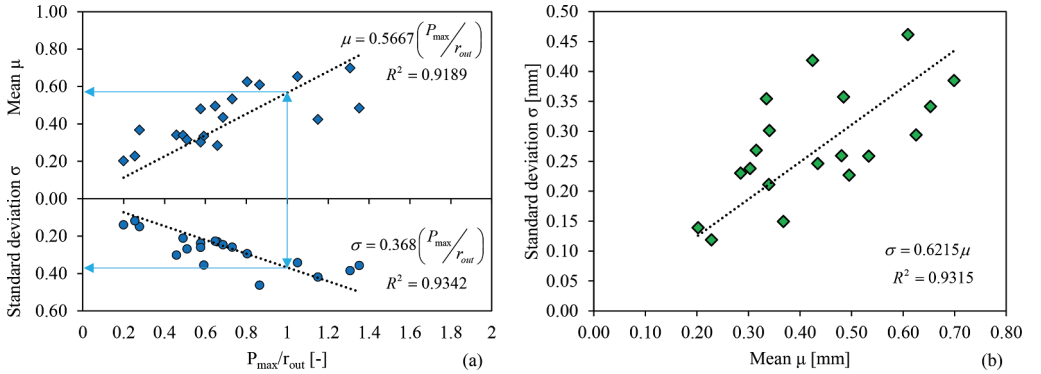

Figure 2. Correlations between P_{max}/r_{out} and mean and standard deviation.

calibrated to fall into the middle of the three ranges of the stress-strain relation. The analytical relation between the ultimate corroded strain and pit depth is reported in Eq. (3), by Franceschini et al. (2022):

$$\begin{cases} \frac{\varepsilon_{pu,corr}-\varepsilon_{py,0}}{\varepsilon_{pu,0}-\varepsilon_{py,0}} = 1 - 3.03\left(\frac{P}{r_{out}}\right) & 0 \le \frac{P}{r_{out}} < 0.33 \\ \frac{\varepsilon_{pu,corr}}{\varepsilon_{py,0}} = 1 - 0.599\left(\frac{P}{r_{out}} - 0.33\right) & 0.33 \le \frac{P}{r_{out}} \le 2.00 \end{cases} \quad (3)$$

The maximum pit depths P_{max} of each *CS* were thus calculated with Eq. (3). Secondly, from the correlations reported in Figure 2, the corresponding statistical distribution can be established, as shown in Figure 3(b) and reported in Table 3. These lognormal distributions of the pits have been adopted for the *MC* simulations as the random pits causing the failure of the most corroded wire. The prestress level decay due to corrosion is accounted for with the formula $\sigma_{p,corr} = \exp(-0.133\mu_{loss})$, where μ_{loss} is the cross-section loss (Ravasini et al., 2023). A total of 2004 simulations were run (500 random plus 1 with average values for each scenario).

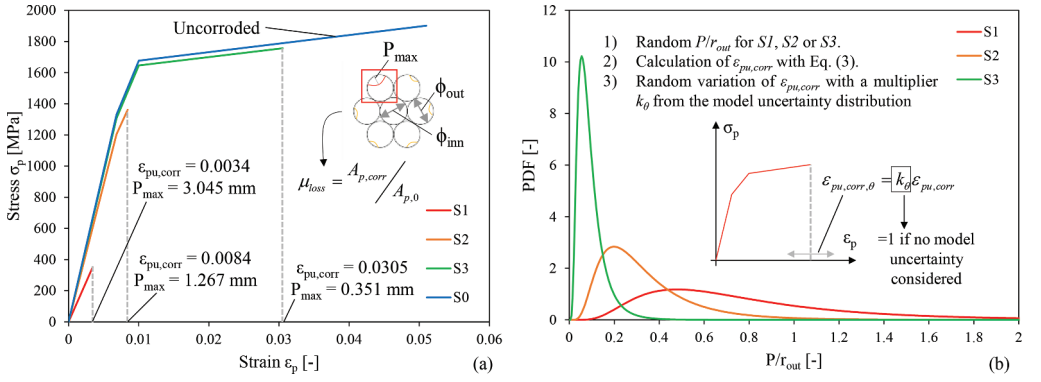

Figure 3. Corrosion scenarios: (a) stress-strain, (b) lognormal distributions of pits and model uncertainty.

The *SCPS* model uncertainty was considered by following the steps (Franceschini et al., 2023):

Table 3. Summary of corrosion scenarios and prestressing strands' random variable.

	Max. pit depth		Distributions of pits used for the *MC* simulations			
Scenario (# sim)	$\varepsilon_{pu,corr}$ [%]	P_{max} [mm]	μ [mm]	σ [mm]	λ	ζ
S1 (501)	0.340	3.045	0.810	0.526	-0.386	0.593
S2 (501)	0.840	1.267	0.337	0.219	-1.263	0.593
S3 (501)	3.050	0.351	0.094	0.061	-2.545	0.593
S0 (501)	5.100	0.000	-	-	-	-

1. For each strand "*i*", the percentile corresponding to $P_{max,i}$ is calculated with the Eq. (4):

$$\xi_{\max,i} = \Phi\left(\ln\left(P_{\max,i}\right) - \lambda_i/\zeta_i\right) \tag{4}$$

2. The average and standard deviation, $\mu_{\xi,max}$ and $\sigma_{\xi,max}$, of the percentiles are calculated.
3. The mean penetration depth for the maximum pit is estimated in a simplified way as the percentile of the distribution of the individual penetration depth measurements by using the Eq. (5):

$$\mu_{P_{\max,i}} = \exp\left(\lambda_i + \zeta_i \Phi^{-1}\left(\mu_{\xi_{\max}}\right)\right) \tag{5}$$

The value of $\varepsilon_{pu,corr,an}$, is re-calculated with Eq. (3) for each specimen and the ratio $\theta_i = \varepsilon_{pu,corr,exp}/\varepsilon_{pu,corr,an}$, is found, refer to Table 2. From the lognormal model uncertainty's distribution, (λ_θ=-0.0956 and ζ_θ=0.2840, or μ_θ=0.946 and σ_θ=0.274)), a coefficient k_θ is randomly used to multiply the ultimate corroded strain calculated with Eq. (3). Refer to Figure 3(b) for clarity.

3 RESULTS

3.1 *Moment-curvature responses and failure modes*

The moment-curvature responses corresponding to the different corrosion scenarios are plotted and shown in Figure 4. Table 4 shows the corresponding statistical parameters for the different corrosion scenarios and distributions, by considering the model uncertainty for cracking and ultimate moments. The normal, lognormal and Generalised Extreme Value (GEV) distributions have been used. For *S3* and *S0* scenarios, all the three distributions fit the numerical results well since the severity of corrosion is low. Based on R^2 value, for *S1* and *S2* scenarios, the *GEV* distribution fits the numerical results better, as observed in the previous work (Belletti et al., 2023).

The red curves in Figure 4 correspond to the analysis with the average values reported in Table 2 and Table 3. In the following, the results with the *GEV* distribution will be shown. Figure 5(a) shows the probability distribution functions (*PDFs*) of cracking and ultimate moments, while Figure 5(b) shows the decay of cracking and ultimate moments vs the normalised pit depth P/r_{out}. It can be observed that there is an increase in the dispersion of moments with increasing corrosion, with σ ranging from 1.49 to 8.18 for M_{cr} and from 1.84 to 11.77 for M_u. The average M_{cr} ranges from 47.36 (*S0*) to 32.15 kN·m (*S1*). A similar trend is observed for the average M_u, from 77.19 (*S0*) to 68.03 kN·m (*S1*). In addition, the effect of the model uncertainty is shown in Table 5 for the ultimate moment, where a higher standard deviation and a lower average value can be observed compared to the case without (k_θ fixed =1) considering the model uncertainty.

The corrosion is also recognized to affect the failure mode of a *RC* or *PC* members. In this study, the sectional failures are attributed to: (i) achieving concrete crushing in compression, (ii) achieving ultimate corroded strain of the most corroded wire of the strand. Table 6 reports the failures of the *CSs*: *S1* showed more than half simulations with strand's failure, while *S0* and *S3* are similar and show concrete crushing failure.

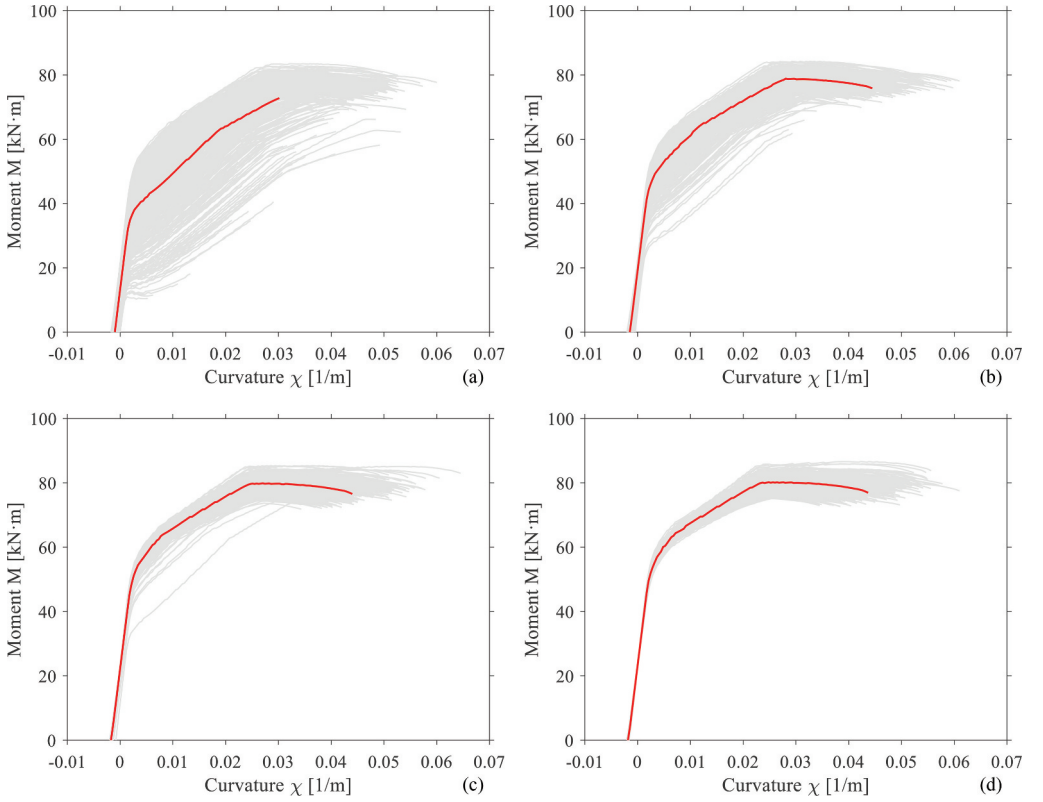

Figure 4. Moment-curvature responses: (a) *S1*, (b) *S2*, (c) *S3*, (d) *S0*.

Table 4. Summary of results for the moment-curvature response considering the model uncertainty.

		Cracking moment M_{cr} [kN·m]				Ultimate moment M_u [kN·m]			
Scenario	Distribution	R^2	μ [kN·m]	σ [kN·m]	CoV [%]	R^2	μ [kN·m]	σ [kN·m]	CoV [%]
	Normal	0.980				0.865			
S1	Lognormal	0.953	32.15	8.18	25.45	0.838	68.03	11.77	17.30
	GEV	0.998				0.950			
S2	Normal	0.976	40.93	4.30	10.51	0.942	75.31	3.53	4.69
	Lognormal	0.965				0.936			
	GEV	0.990				0.953			
S3	Normal	0.998	45.80	2.08	4.55	0.998	76.76	1.88	2.44
	Lognormal	0.997				0.998			
	GEV	0.996				0.997			
S0	Normal	0.998	47.36	1.49	3.15	0.997	77.19	1.84	2.39
	Lognormal	0.997				0.998			
	GEV	0.998				0.998			

3.2 *Design resisting moment estimation*

For practical purposes, the design resisting moment, M_d, can be estimated with the percentile:

$$p = \Phi(-\alpha_R \beta) \tag{6}$$

Table 5. Effect of the model uncertainty on the ultimate moment.

	Without model uncertainty			With model uncertainty		
	μ [kN·m]	σ [kN·m]	CoV [%]	μ [kN·m]	σ [kN·m]	CoV [%]
S1	70.97	9.11	12.83	68.03	11.77	17.30
S2	75.74	2.23	2.94	75.31	3.53	4.69
S3	76.76	1.87	2.44	76.76	1.88	2.44

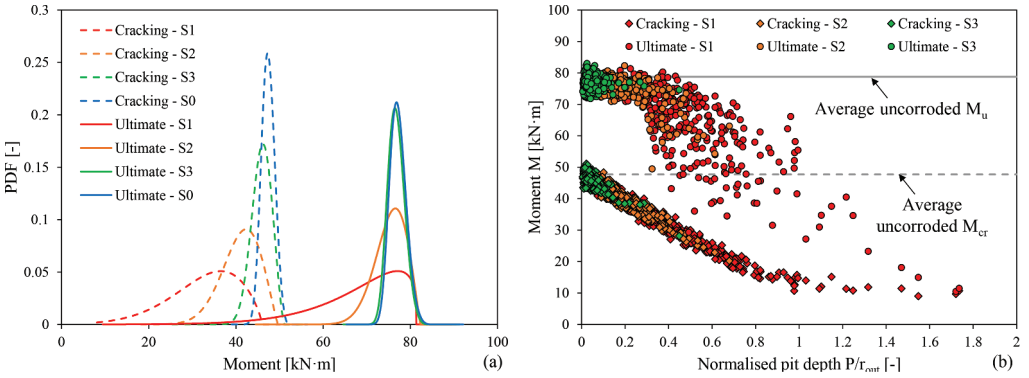

Figure 5. Corrosion scenarios: (a) *PDFs* for cracking and ultimate moments, (b) decay of cracking and ultimate moments vs normalized pit depth.

Table 6. Failure modes of the Monte-Carlo scenarios.

Scenario (# sim)	Concrete crushing [%] (# sim)	Strand failure [%] (# sim)
S1 (501)	48.90 (245)	51.10 (256)
S2 (501)	92.02 (461)	7.98 (40)
S3 (501)	99.80 (500)	0.20 (1)
S0 (501)	100.00 (501)	0.00 (0)

where Φ is the cumulative standard normal distribution. The parameter α_R is the sensitivity factor of the resistance (equal to 0.7 for a reference period of 1 year), while β is the target reliability level (ISO 2394, 2015). In this case, a large relative cost of safety measures with varying consequence classes (*CCs*) is considered to show the variability of M_d with the β value and corrosion scenarios. Figure 6(a) represents the log_{10} plot of the cumulative distribution functions (*CDFs*) and the corresponding intersections with the percentiles and Figure 6(b) represents the trend of corroded to uncorroded M_d as function of percentiles for the different corrosion scenarios.

Table 7 shows the summary for the estimation of M_d based on the different scenarios and by assuming different consequence classes with the corresponding percentiles calculated with the Eq. (6). The corroded design moment ranges from 27.47 to 46.97 kN·m for *S1* case by varying the percentile, while from 72.37 to 73.78 kN·m for *S0* case, highlighting a remarkable dependency of M_d on the severity of corrosion.

4 CONCLUSIONS

In this work, a probabilistic assessment - via Monte-Carlo simulations - of the moment-curvature response of pre-tensioned concrete beams was conducted. The main conclusions are as follows:

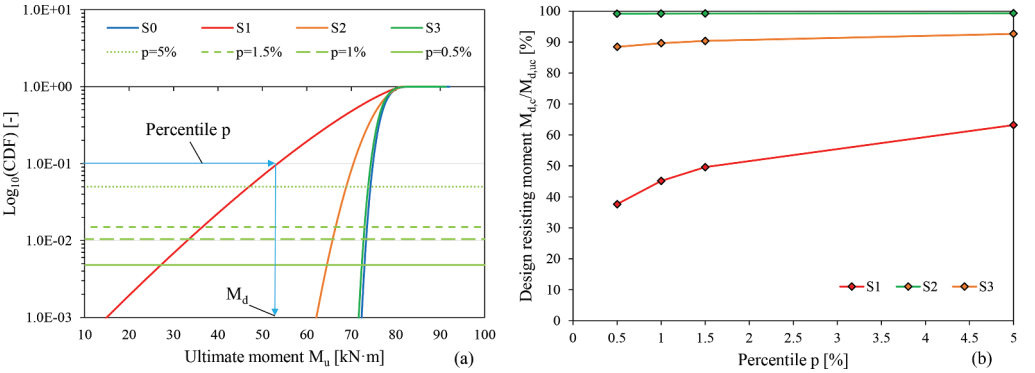

Figure 6. Corrosion scenarios: (a) *GEV CDFs* for ultimate moment and percentiles, (b) normalized corroded to uncorroded ultimate moment.

Table 7. Summary of resisting moment, M_d, for the *GEV* distribution, scenarios, and percentiles.

		Values of M_d [kN·m] for the different scenarios			
Consequence classes (α_R=0.7) (ISO 2394, 2015)	Percentile *p* [%]	S0	S1	S2	S3
CC3 (β=3.7)	0.5	72.98	27.47	64.57	72.37
CC2 (β=3.3)	1.0	73.32	33.10	65.74	72.74
CC1 (β=3.1)	1.5	73.53	36.48	66.46	72.97
-	5.0	74.30	46.97	68.86	73.78

- The *MC* approach highlighted the crucial role of the prestressing steel corrosion severity on the moment-curvature and failure modes of *PC* members. Increasing corrosion led to higher probability of brittle failure of longitudinal reinforcement instead of concrete crushing. Brittle shear failure modes will be investigated in future studies.
- The *GEV* distribution was found to better fit the resistance of corroded *PC* beams, as already stated in the previous study. The model uncertainty, assumed as a random variable with a lognormal distribution, affected the results in terms of ultimate moment M_u, by highlighting a higher dispersion in the probability distribution. Such model uncertainty distribution can be further improved based on additional experimental data.
- The calculation of the design resisting moment M_d was carried out based on the value of different percentiles for a reference period of one year and for the corrosion scenarios. An increasing sensitivity of the M_d was found with increasing corrosion severity. Such observation must be investigated more in detail in future studies.
- Additional distribution parameters for the input random variables such as corrosion of mild rebars and different geometrical features must be investigated in future works.

ACKNOWLEDGEMENTS

The presented study is part of a program of activities funded by the Italian "Consiglio Superiore dei Lavori Pubblici". The results were achieved in the national technical agreement for implementing the agreement pursuant to art. 15 law 7 August 1990, No. 241 between the Superior Council of Public Works and RELUIS. This research has also been made possible through funding from the Research Foundation Flanders (FWO) grant number S001021N (FWO-SBO project lifeMACS.

ABSTRACT: Assessing life-cycle seismic safety of aging reinforced concrete bridges is a challenging engineering task. Deterioration phenomena reduce structural capacity, exacerbating poor design choices that are typical of old bridges, while also being characterized by major uncertainties. Management of engineering systems in highly uncertain environments can be efficiently addressed through Markov decision processes, which rely on dynamic Bayesian networks to model the deteriorating system's life-cycle. However, there is still a gap in developing virtual environments that can seamlessly fit in such advanced algorithmic decision-making frameworks, especially under life-cycle seismic behavior considerations. In this study, we develop a dynamic Bayesian network capable of incorporating disparate uncertainties related to chloride-induced corrosion and seismic action, aiming at providing fragility curves over the bridge service life. The framework is applied to a prototype bridge encapsulating key risk-prone features. Using a multi-component approach, the developed network provides valuable insights into the fragility evaluation of both the system and individual components. Markovian transitions among component deterioration states are computed by combining corrosion initiation and propagation models with non-stationary Gamma processes. Subsequently, state-dependent fragilities are obtained through probabilistic seismic assessment based on non-linear dynamic analyses and multinomial logistic regression. Results show that the approach sheds light on the risk interplay mechanisms between components and the system, and on how different corrosion scenarios affect the system fragility. Discussion is finally provided on how these risk considerations can be interpreted for decision-making, allowing for better repair and retrofit strategies.

1 INTRODUCTION

Bridges, vital constituents of transport systems, must resist continuous and sudden stresses over time. Their long-term safety and resilience assessment is a challenging task, especially in the case of existing reinforced concrete (RC) bridges, owing to varied uncertainties in materials, deterioration, and design. The copresence of steel rebar corrosion and seismic actions, in particular, can pose significant risks, triggering catastrophic collapses and major network disruptions with high socio-economic impacts. Therefore, in recent years, focus on life extension and management of aging structures has intensified.

DOI: 10.1201/9781003483755-113

Steel corrosion in reinforced concrete occurs in two, largely discrete, phases: (i) initiation, where aggressive agents breach the concrete cover, and (ii) propagation, where steel rebar cross-section decreases due to material mass loss (Bertolini et al. 2004; Tuutti, 1982). Identifying chlorides as one of the most severe aggressive agents for RC structures, studies by Stewart & Rosowsky (1998) and Vu & Stewart (2000) proposed analytical models to be adopted in probabilistic assessment, taking into account both key environmental and structural factors, such as chlorides exposure, concrete cover depth and concrete water cement ratio. Eq. (1) describes initiation based on Fick's law, whereas Eq. (2) models propagation based on Faraday's law.

$$C(x,t) = \chi C_s \left[1 - \mathrm{erf}\left(\frac{x}{2\sqrt{D_c t}}\right)\right] \tag{1}$$

$$\lambda(t) = 0.37 * \frac{\left(1 - \frac{w}{c}\right)^{-1.64}}{x} (t - T_{corr})^{0.29} \tag{2}$$

where x is the concrete cover depth; C_s is the equilibrium chloride concentration at the concrete surface; erf is the Gaussian error function; χ is a factor to account for model uncertainties; t the time in years; w/c is the water cement ratio; and T_{corr} is the time for corrosion initiation in the structure's life-cycle. Corrosion initiation is postulated when the chloride content at the rebar depth $C(x,t)$ reaches a critical value C_{cr}, while $\lambda(t)$ is the uniform corrosion penetration.

Apart from chronic deterioration, extreme events like earthquakes critically impact bridge structural reliability. Knowledge from past earthquakes indicates several types of structural damage, such as deck unseating from bearing failures, column damages, and pounding between deck components (Priestley et al. 1996; Ramirez et al. 2000). Accordingly, several studies have proposed seismic risk assessment frameworks for aging RC bridges (Biondini & Frangopol 2016; Ghosh & Padgett 2010; Nielson & DesRoches 2006; Shekhar & Ghosh 2021). These probabilistic approaches predict time-based risks by merging: (i) probabilistic deterioration assessment, using Eqs. (1)-(2); and (ii) seismic fragility evaluation using nonlinear finite element analysis (NLFEA). This is accomplished initially by predicting the deterioration condition of the structure for designated time-points within the life-cycle. Subsequently, the mechanical properties of the materials are adjusted to conduct fragility analysis under the deteriorated state, aimed at quantifying the seismic risk and its rise at these specific time-points.

However, infrastructure decision-making can be more precise if joint time- and state-based models are considered. This allows for better selection of repair and retrofit actions, but also for updates of uncertainties and fragility functions based on data from monitoring and inspections. Recent advances in algorithmic decision-making reinforces the need for such models, through assimilation of probabilistic models, Bayesian updating, and stochastic optimal control algorithms (Andriotis & Papakonstantinou 2019; 2021; Andriotis et al. 2021). This approach uses partially observable Markov decision processes for inspection and maintenance planning, leveraging upon state-based formulations and dynamic Bayesian networks (DBN). Towards this, in Molaioni et al. (2023), we recently introduced a DBN approach for evaluating the seismic safety of aging bridges throughout their lifespan. This model combines non-stationary transition matrices for corrosion conditions of structural components and consistent, state-dependent seismic fragility functions for both individual components and the entire system. This provides a detailed view of how corrosion and seismic actions affect bridge safety over time. Component and system fragilities, $P_{SDS,t}$, over the life cycle, are computed as:

$$P_{SDS,t} = P(SDS_t \geq s | IM_{0:t}, CDS_{0:t}, SDS_{0:t-1}) \tag{3}$$

where s represents a damage threshold identifying the seismic damage state (SDS); IM is the intensity measure of the seismic action; CDS represents the corrosion damage state; and t is time, considering the structural life-cycle discretized in yearly time-slices.

In this paper, the effectiveness of the proposed approach is further evaluated by applying it to a case study with focus on demonstrating: (i) the method's potential to consider multiple deterioration scenarios within the life-cycle; (ii) the ability to capture how corrosion impacts the seismic safety of the case-study bridge and its components overtime; (iii) its utility in pinpointing vulnerable components and guiding retrofit strategies; (iv) its adaptability potential in incorporating real-time data and its compatibility with Markov decision processes-based decision-making.

2 METHODOLOGY

The DBN introduced by Molaioni et al. (2023) and adopted in this study to quantify aging RC bridges' seismic safety over their life cycle is shown in Figure 1. Variables of the model (blue circles in Figure 1) include: (i) the IM vector of the seismic action, assumed as the peak ground acceleration (PGA); (ii) the CDS vector of structural components, representing the corrosion intensity in a discrete space; (iii) the SDS vector of structural components, encapsulating structural damage of components based on thresholds of Engineering Demand Parameters (EDPs). Transitions among variables (red arrows in Figure 1) represent conditional probabilities among states. These include: (i) the Markovian transition for CDSs over time; and (ii) the state-dependent fragility functions for seismic damage, with the possibility of considering the carry-over effect of damage without repairs (omitted here for simplicity). This way, the adopted approach allows us to break down the problem into smaller, easier to compute segments, by independently analyzing each probabilistic dependency. The aging RC bridge is modeled as a multi-component series system, focusing on the key components, such as columns (COL), High Type Fixed Bearings (HTFB), High Type Expansion Bearings (HTEB), and Low Type Fixed Bearings (LTFB) (Mander et al. 1996; Shekhar & Ghosh 2021). SDSs for these components are classified from "Slight" to "Complete", based on FEMA (2003) definitions and quantified by thresholds from Nielson & DesRoches (2006), as shown in Table 1. CDSs range from "Sound" to "Critical", describing the corrosion intensity and its impact on structural components, as shown in Table 2. Considered corrosion intensity parameters are the average mass loss for steel rebars/bolts, M_{loss} [%], steel plate thickness reduction, PTR [mm], and bearing coefficient of friction, k_{corr} [-].

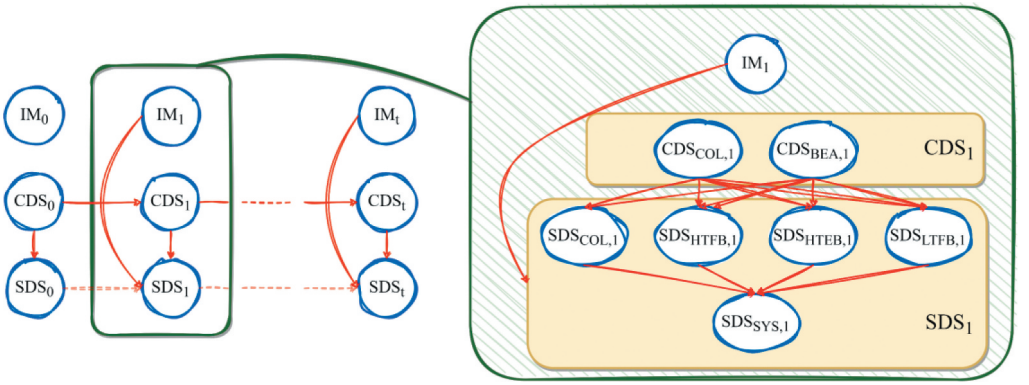

Figure 1. DBN for life-cycle seismic fragility of deteriorating bridges. Left: Model including nodes and transitions. Right: Interactions of components and system states within a single time step.

3 APPLICATION TO A CASE STUDY BRIDGE

The methodology is showcased for a 4-span bridge, typical of many pre-70s seismic-prone and deterioration-susceptible RC bridges in existing transportation networks. The bridge is characterized by poorly detailed RC columns and steel bearings, making it a relevant case study for seismic risk. For detailed information about the case study, its visual representation, and the modeling assumptions for conducting NLFEA, the interested reader is referred to Molaioni et al. (2023).

Table 1. Definition of probabilistic seismic damage states.

		Slight		Moderate		Extensive		Complete	
Component	EDP	M	D	M	D	M	D	M	D
COL	Curvature ductility [-]	1.29	0.59	2.1	0.51	3.52	0.64	5.24	0.65
BEA - Expansion	Displacement [mm]	37.4	0.6	104.2	0.55	136.1	0.59	187	0.65
BEA - Fixed	Displacement [mm]	6	0.25	20	0.25	40	0.47	187	0.65

* M = median of the lognormal distribution, D = Dispersion of the lognormal distribution.

Table 2. Definition of corrosion deterioration states.

CDS		0: Sound	1: Initial	2: Progressive	3: Critical
Component	Parameter	LB-UB	LB-UB	LB-UB	LB-UB
COL	M_{loss} [%]	0-0	0-15	15-30	30-45
BEA	M_{loss} [%]	0-0	0-15	15-30	30-45
BEA	PTR [mm]	0-0	0-3.5	3.5-5.1	5.1-6.5
BEA	k_{corr} [-]	0-0	0-0.35	0.35-0.64	0.64-0.92

* M_{loss} = rebar/bolt mass loss [%], PTR = plate thickness reduction [mm], k_{corr} = additive coefficient of friction for expansion bearings [-].

3.1 *Non-stationary transition matrix for corrosion*

Non-stationary transitions among CDSs are derived using a probabilistic analysis of the corrosion intensity, with respect to rebars/bolts mass loss, M_{loss} [%], over the structure's lifetime, applying Eqs. (1)-(2). These transitions, for initiation and propagation phases, respectively, calculate the conditional probability of moving from CDS=*i* at a given time-slice, *t*, to CDS=*j* at the next one, *t+1*. Monte Carlo simulation is conducted to propagate uncertainties in environmental conditions, material properties and geometry, thus, eventually to evaluate yearly transitions, as in Molaioni et al. (2023):

$$P(CDS_{t+1} = j | CDS_t = i) = \frac{\sum_{samples}(CDS_{t+1} = j \cap CDS_t = i)}{\sum_{samples}(CDS_t = i)} \quad (4)$$

Figure 2 illustrates the resulting non-stationary transition matrices for chloride corrosion under "splash" environmental conditions for the case study components. These matrices, showcasing Markovian probabilities of transitioning from one CDS to another over time, are upper-triangular due to the irreversible nature of damage, as long as no repair interventions are applied. In determining these, crucial is the time of corrosion initiation T_{corr}, calculated using Eq. (1). Among samples, 97.1% experienced corrosion initiation within 100 years, with a mean T_{corr} of 13.7 years and a standard deviation of 20.7 years. Assuming T_{corr} as a lognormally distributed random variable in the propagation model (Eq. (2)) significantly impacts transition probabilities, particularly from state 0 to 0 and from state 0 to 1. Sharp inflection points for these transitions are noted, as T_{corr} statistics suggest corrosion onset is more likely in the early years of the life-cycle.

3.2 *State-dependent fragility curves*

State-dependent and time-invariant fragility functions for both structural components and system have been fitted, corresponding to capacity limit state EDP thresholds, as shown in Table 1. Demand parameters have been obtained from dynamic NLFEA, developing three-dimensional finite element models in OpenSees (McKenna, 2011), incorporating non-linear

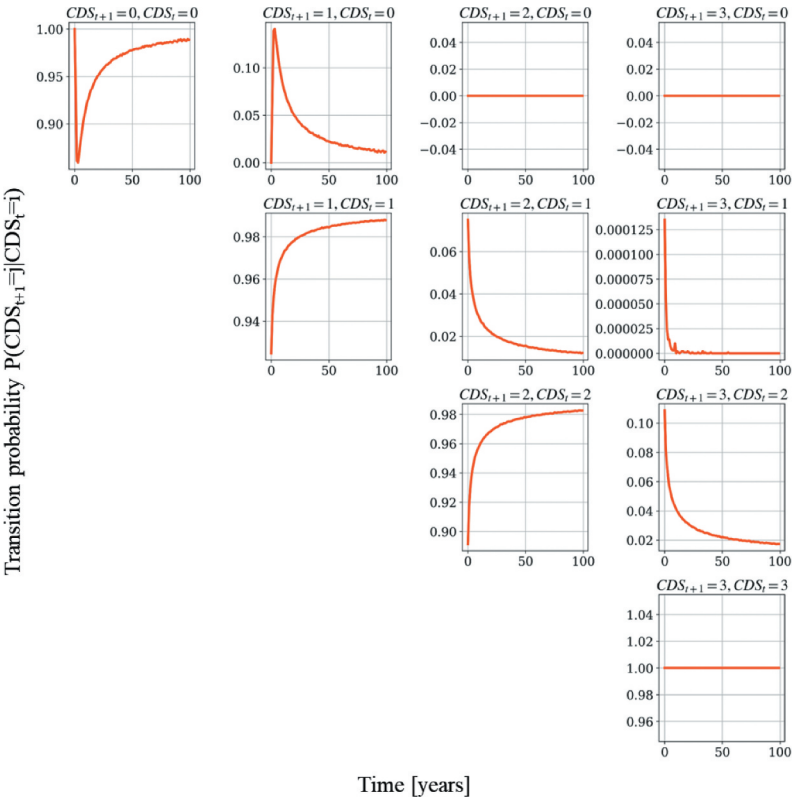

Figure 2. Non-stationary transition matrix for CDSs of components under "splash" conditions.

behavior of key components (COL, HTFB, HTEB, LTFB). A synthetic ground motion suite of 400 records has been applied on 50 statistically varied bridge models, thus propagating uncertainties related to the seismic action, the materials and geometrical properties of the bridge, as well as the corrosion deterioration of components. This way 20'000 EDPs were obtained and then compared with 50 capacity data points sampled from the distributions reported in Table 1, thus eventually creating a set of 1 million SDS labels for each component. A multinomial logistic regression model is trained on this dataset to predict the probability of exceeding a specific SDS as a function of the IM, via the softmax function as in Andriotis & Papakonstantinou, (2018).

For the sake of brevity, in this paper, results related to the "Complete" SDS and corrosion scenarios 00 (As-built), 03 ("Sound" COL, "Critical" corrosion in BEA), 30 ("Critical" corrosion in COL, "Sound" BEA), 33 ("Critical" corrosion in both COL and BEA) are presented. State-dependent fragility curves, shown in Figure 3, reveal that among bridge components, HTEB and COL exhibit the highest fragility across several SDSs and corrosion scenarios, namely, the combination of CDSs for COL and BEA components. Furthermore, a deterioration-driven increase in column fragility is observed due to their own deterioration, while this fragility slightly drops with the onset of corrosion in BEA. Conversely, HTEBs are not significantly influenced by the corrosion of COL alone and do only mildly so due to their own corrosion. This diverse impact of corrosion on the fragility of components leads to an inversion in their hierarchy of strengths. This is evident when comparing the state-dependent curves of scenarios '00' and '03', where the HTEB (dash-dot line) emerges as the most fragile component, with those of scenarios '30' and '33', where COL (thin continuous line) exhibits greater fragility. This highlights the importance of accounting for the multitude of deterioration scenarios that could arise throughout the lifespan of the structure. This understanding is

essential to grasp the potential evolution of the structural behavior, which, in turn, is fundamental in implementing effective enhancements in the bridge's seismic safety through precise retrofit interventions based on the deterioration of components.

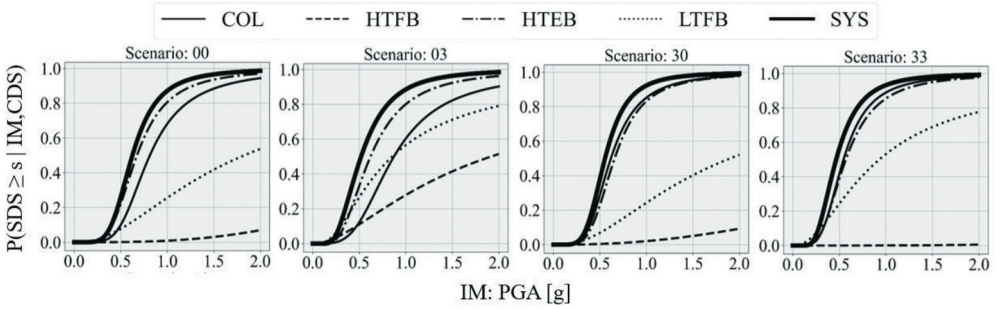

Figure 3. State-dependent fragility curves for both components and system. Corrosion scenarios '00', '03', '30', '33'.

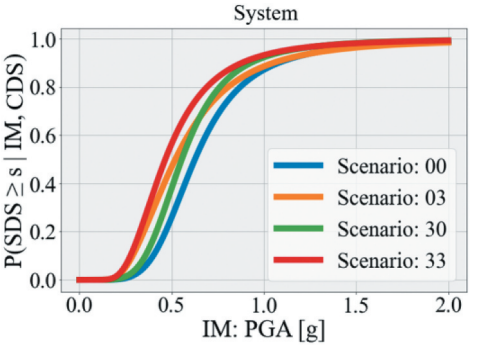

Figure 4. System's state-dependent fragility curves. Corrosion scenarios '00', '03', '30', '33'.

Focusing on the impact of corrosion at the system level, Figure 4 illustrates the system fragilities for these four scenarios. The fragility curves reveal that maximum fragility is consistently observed when corrosion is widespread across the structure (Scenario 33). Additionally, component deteriorations translate into an increase in fragility, which varies according to the deterioration scenario: the system is affected more by corrosion in bearings for PGA < 0.6, and more by the corrosion of columns for PGA > 0.6, as shown in Figure 4 (green and orange curve, respectively). These findings underscore the distinct role each component plays in influencing the system's fragility, reinforcing the utility of the adopted method in retrofit planning.

3.3 *Life-cycle fragility*

The longitudinal fragility of the bridge is determined by marginalizing out the corrosion deterioration state variables, CDSs, for all different components of the system (Figure 4 only displays scenarios 00, 30, 03, 33):

$$\mathrm{P}_t(\mathrm{SDS}{\geq}s|\mathrm{IM}) = \sum_{\mathrm{CDS_{COL}}} \sum_{\mathrm{CDS_{BEA}}} \mathrm{P}(\mathrm{SDS}{\geq}s|\mathrm{IM}, \mathrm{CDS_{COL}}, \mathrm{CDS_{BEA}})\mathrm{P}_t(\mathrm{CDS_{COL}}, \mathrm{CDS_{BEA}}) \quad (5)$$

where P_t (CDS_{COL}, CDS_{BEA}) represents the probability of having a given corrosion scenario (i.e., a combination of CDS for column and bearing components). This can be evaluated by considering the Markovian transitions among CDS and the independence of CDS_{COL} and CDS_{BEA} as:

$$P_t(CDS_{COL}, CDS_{BEA}) = [P_0(CDS_{COL}) \prod_{\tau=0}^{t-1} P(CDS_{COL,\tau+1} \mid CDS_{COL,\tau})][P_0(CDS_{BEA}) \prod_{\tau=0}^{t-1} P(CDS_{BEA,\tau+1} \mid CDS_{BEA,\tau})] \quad (6)$$

To illustrate the evolution of longitudinal fragilities, computations are performed at three time-points throughout the structural lifespan: at the as-built condition (0 years), and subsequently at the 25-, and 100-year time-points. The curves reported in Figure 5, delineating the probability of exceeding specific seismic damage states at specific years and IMs, highlight the significant impact of "splash" environmental conditions on the structural integrity over time. A salient observation is the escalation of fragility curves, notable already at year 25 since construction, a trend that reveals the inadequate component detailing and susceptibility to corrosion. Also, the influence of corrosion manifests differently across the four damage thresholds. In the case of the "Slight" SDS, the increase in fragility over time is relatively modest, in contrast to other damage states, where this increase is more significant. This is linked to the inherent seismic vulnerability of the bridge by design, predisposing the structure to readily exceed the 'Slight' threshold. On the other hand, the progression of corrosion evokes higher nonlinear demands, thereby significantly escalating the probability of exceeding more severe damage states, such as 'Moderate' and 'Extensive'. Furthermore, for all SDSs, an upward trajectory in the bridge fragility over time is evident, reflecting a growing risk of encountering more advanced damage with time. These findings demonstrate the capacity of proposed DBN to propagate corrosion deterioration effects at the component level to the global seismic system risk level over the structural lifespan.

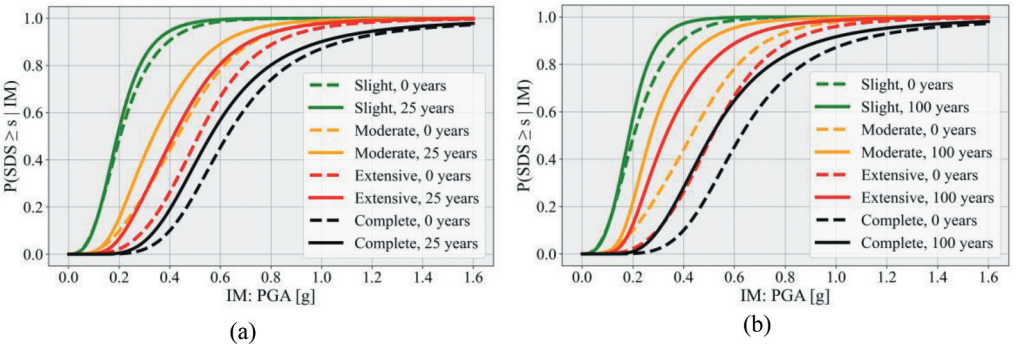

Figure 5. System System fragilities over the life-cycle under "Splash" conditions. (a) 25 years; (b) 100 years.

4 DISCUSSION

The results highlight several advantages of the proposed method. First, its potential to accommodate different deterioration scenarios over the life-cycle of the structure, allows us to define state-dependent fragility functions for possible combinations of component CDSs. This is particularly effective when applying the methodology to real-world bridge structures, which may present non-uniform deterioration distributions across components. For instance, deterioration

may concentrate more on some components than on others, either due to highly differential deterioration phenomena or partial repairs and retrofits applied at different times.

Moreover, the proposed methodology identifies the components' susceptibility to corrosion phenomena, but also how their effects act mutually on the fragilities of the components of the system. As shown by the results in Figure 3, non-uniform deterioration scenarios affect the safety of the structure in several ways. Also, the importance of modeling the bridge as a multi-component system is shown to be key for several insights. Individual component vulnerability can be evaluated through the DBN allowing us to identify the ones most at risk, such as the HTEBs and COLs for this case study. The change in hierarchy of strengths among components can thereby be tracked. This level of detail in the representation of the structural behavior can guide targeted maintenance and reinforcement interventions for the structure.

Finally, the developed DBN can be seamlessly integrated with decision-making frameworks that also involve field observations and actions. The structure of the DBN does not only allow the full description of seismic safety over time through detailed probabilistic transitions among states (i.e., CDS and SDS), but also the observation-based updating of these, which can be in turn propagated to update the fragility functions, together with changes due to repair interventions. This way, the problem can be readily defined as a partially observable Markov decision process and solved through deep reinforcement learning or other appropriate techniques to obtain a near-optimal management policy for the bridge. This has been recently considered in Metwally et al. (2024) which makes use of the realistic bridge system environment proposed here and extends it including repair actions and related costs. The study tests the applicability of multi-agent architectures in identifying dynamic component-level maintenance policies for optimizing system-level cost and reliability objectives and constraints.

5 CONCLUSION

In this paper, a dynamic Bayesian network (DBN) is developed to model the life-cycle seismic fragility of aging RC bridges, with a specific focus on encapsulating the uncertainties associated with corrosion deterioration and seismic actions as stressors to these structures. The methodology conceptualizes the bridge as a multi-component system, considering components that are crucial in determining the global seismic risk, i.e., RC columns and various types of steel bearings. The development of the DBN is facilitated by representing both deterioration and seismic damage in discrete spaces, defining corrosion deterioration states (CDSs) and seismic damage states (SDSs). This way, a structured approach to learning the evolving condition of the bridge components over time is laid out, allowing for efficient description of the complex interplay between deterioration and seismic action for the structural integrity of the bridge. Owing to the DBN properties, this complex learning task is distilled into a neat decomposition consisting of two primary sub-tasks: (i) calculating non-stationary Markovian transitions that portray the progression of CDSs; and (ii) formulating time-invariant and state-dependent fragility curves that capture the probability of exceeding SDSs given the IM and the combination of CDSs of structural components. The approach is applied to a 4-span bridge, which features characteristics typical for pre-70sRC bridges. These include inadequate RC column detailing and steel bearings. The analysis for the case study quantifies the detrimental effect of the environmental "splash" condition, which specifically instigates corrosion with an average onset time of 13.7 years, a critical factor in the structural performance overtime.

The computed time-invariant and state-dependent fragility curves for the case study underscore the high sensitivity of seismic responses to corrosion, providing valuable insights into how corrosion influences the seismic vulnerability of the bridge at various potential scenarios reachable through its life cycle. Furthermore, the approach of mechanically idealizing the bridge as a multi-component system, when combined with the DBN framework, allows us to identify the most at-risk components within the system across a spectrum of corrosion scenarios, which can lend itself to targeted inspection and retrofit intervention planning. Towards this, the capability of the approach to decipher changes in the hierarchy of strength and disentangle complex interactions among components, depending on environmental conditions, ground motion intensities and differential deterioration, provides engineers and decision-makers with insights into the structural

behavior over time. Finally, the presented DBN can be practical in enhancing fragility functions with field observations, thereby allowing for refined seismic risk inference. Due to its structure, it can be also compatible with advanced decision-support systems employing Markov decision processes that enable dynamic structural integrity management. Along these lines, current research trajectories are focused on expanding the capabilities of the DBN model with deep reinforcement learning approaches aimed at optimizing maintenance policies while ensuring structural safety and considering various performance metrics.

ABSTRACT: Concrete box culverts facilitate drainage, railway/road crossing, or subway for transportation networks. Health assessment of box-culverts when distressed, or near end of design life, is generally conducted with non-destructive and/or partially destructive tests (NDT/PDT). The selection of NDT/PDT locations for box-culverts need to consider the inherent low redundancy. In this study, the failure probability of a box-culvert is first estimated using prior knowledge, incorporating the uncertainties in design load/strength, updated later through a Bayesian pre-posterior analysis. The testing expenses and repair costs are associated with the decisions in a value of information (VoI) framework. Proposed approach to select the best possible locations is demonstrated for a square box-culvert by minimizing overall cost. A set of parametric studies have been shown to conclude upon the parameters that may influence the life cycle cost after decision making. Further, the importance of optimizing sampling location has been emphasized with respect to cost of decision making.

1 THE CHALLENGE OF SAMPLING LOCATIONS FOR STRUCTURAL HEALTH ASSESSMENT IN A STRUCTURE

Structural health assessment (SHA) and maintenance of deteriorated structures add up to a huge budget for a nation. With the increasing number of failures of old bridges/structures, SHA is of paramount importance in their life cycle management and reducing uncertainty (Biondini & Frangopol 2016). One of the key aspects of SHA is sampling locations for testing or placement of sensors. Due to lack of clear-cut guidelines, sampling may be conducted without appreciating the objectives of sampling or neglecting the concern of maximum benefit. Despite earlier research (Karmakar et al. 2023; Faroz et al. 2023) highlighting the challenges in selecting test locations in SHA, no standardized method is available till date for practical implementation. A method was proposed for this purpose by Karmakar et al. (2023) for buildings, based on the importance of the different structural elements. However, typical structures such as chimneys, retaining walls, and box culverts would demand special attention.

The concept of value of information (VoI) was used extensively in information technology (Konakli et al. 2015), economics (Willinger 1989), environmental risk management (Yokota & Thompson 2004), and healthcare (Tuffaha et al. 2014). The same has been applied for

DOI: 10.1201/9781003483755-114

structural safety assessment too in the last decade (Konakli & Faber 2014; Khan et al. 2020). A few other notable examples of the application of VoI in civil engineering are: selecting maintenance strategy (Konakli & Faber 2014); and construction management (Zhang et al. 2021). In this article, following concepts of VoI of Konakli & Faber (2014), the importance of different locations in a subway box culvert are quantified using the value of information (VoI) concept in a pre-posterior framework, later used to guide selection of optimum locations for NDT/PDT for a box culvert. This is performed for a particular sample size considering the uncertainties in concrete strength, inherent variability, and material degradation. Multiple case studies for a box culvert are considered in a pre-posterior framework for finding the VoI of different sampling options in a subway box culvert, considering stress-induced degradation.

2 PROBLEM DESCRIPTION AND SAMPLING PROPOSAL

A square box culvert was considered for the study, with sides of 4.4 m, and 7.5 m long. Typical loading considered for estimating the flexural are, a) Dead load on the top slab/ walls, b) Live load on the top slab, and c) Earth pressure from outside. Live load was considered as per Class AA (tracked and wheeled) vehicles (IRC 2017). The seismic load has not been considered during the analysis, as the culvert specified over here is less than 10 m of the span (IRC 2017). Soil weight density was considered as 18 kN/m^3. The functional design life (t_d) of the structure was considered as 50 years. The age at the first inspection was considered as 30 years according to the local municipal act (GoM 2019). Further details are listed in Table 1. Design was governed by wheeled vehicles. For this demonstration, failure probability guided by flexure was considered, but can be extended for other modes or combinations thereof. Design values were used to estimate the initial values of demand, capacity, and failure probability of the culvert.

2.1 *Load combinations and initial capacity*

Moment distribution method was employed for obtaining the bending moment profile for each component (top slab, bottom slab, side walls), the absolute value of which was normalized to the maximum value for each component, independently. Hence, values of maximum demand were kept as μ_S (mean demand) = 1 unit, σ_S (standard deviation of demand) = 0.3 unit in line with Konakli & Faber (2014).

Annual failure probability for civil structures between 10^{-4} to 10^{-3} is generally acceptable (Ghosh & Faroz 2016). Therefore, the initial failure probability is taken as 10^{-4} for the structure; and 5×10^{-5} (half of that of the structure conservatively) for each component (top slab, bottom raft, side wall). According to literature (Konakli & Faber 2014; Khan et al. 2020), taking coefficient of variation (CoV) as 0.1, the design capacity (R) of each component was assumed to be μ_R (mean) = 3.2 unit, and σ_R (standard deviation) = 0.32. Further, both capacity and demand were assigned log-normal distribution (Konakli & Faber 2014). In similar lines, the acceptable limit before maintenance is required, is taken at probability of failure of a component $\leq 5\times10^{-4}$ corresponding to the higher limit of structural failure i.e. $\leq 10^{-3}$.

2.2 *Strength degradation*

Reinforced concrete structures get non-uniformly degraded during their service life due to various factors, such as, environmental, and physical. Here the stress-induced degradation is chosen for demonstration. Higher stress in member lead to higher degradation: carbonation (Liu et al. 2023); changes in pore structure (Tanaka et al. 1999); chloride diffusion (Francois & Maso 1988). Fatigue is a predominant loading in box culverts due to vehicular load and fatigue loading leads to accelerated corrosion (Song et al. 2016). The degradation was therefore taken to be proportional to the stress level (demand/ capacity ratio) of the component. According to literature (Konakli & Faber 2014; Khan et al. 2020), the yearly degradation rate corresponding to the maximum demand/capacity ratio of components is considered 0.01/yr.

2.3 *Sampling of test locations*

In the case study for SHA with fixed sample size (demonstration with one in each component), the overall cost of decision is the sum of maintenance and remaining functional life-cycle failure costs, in addition to the cost incurred in the inspection program. To represent possible different locations on the structure, each component has been sub-divided into 20 sub-components for this study. Finally, the set of sampling locations that yields the lowest overall cost would be selected as the best one.

Table 1. Parameters considered of case studies.

Feature	Types
Prior distribution of capacity parameters	(a) Relatively non-informative, (b) Partially-informative
Age of inspection	30-49 (IS 875-3, 2015).
C_r	(a) 10 unit (Konakli and Faber, 2014), (b) 100 unit
C_{Sf}	1000 unit (Konakli and Faber, 2014)
Maximum mean demand (μ_S)	1 unit (Konakli and Faber, 2014)
The maximum standard deviation (σ_S)	0.3 unit (Konakli and Faber, 2014)
CoV of capacity	0.1 (Konakli and Faber, 2014)
Initial probability of civil structure failure	10^{-4} to 10^{-3}(Ghosh and Faroz, 2016)
Uncorrelated priors of capacity parameters	Used in Lad et al. (2020), Karmakar et al. (2023)
Maximum degradation rate	0.01/ yr (Konakli and Faber, 2014; Khan et al., 2020)
Variation of degradation across sections (Derived hypothesis)	"Highly stressed zone will have higher degradation rate". Corollary from literature (François and Maso, 1988; Tanaka et al., 1999; Song et al., 2016; Liu et al., 2023).
Same initial capacity parameter at all sections	Assumption and limitation
Consideration of Flexural failure only	Limitation

3 METHODOLOGY FOR OBTAINING OPTIMUM SAMPLING LOCATION USING A VOI FRAMEWORK

3.1 *Prior distribution of mean and standard deviation of sub-component capacity parameters*

In the present study, two different priors, (a) relatively non-informative and (b) partial informative, are chosen for the initial distribution of mean and standard deviation of capacity parameters. In the relatively non-informative case, no prior knowledge about the distribution parameters is available. Hence a comparatively wider range uniform prior $u(0.05, 6.05)$ is chosen for the capacity parameters. However, for determining parameters of partial-informative prior, existing literature is used. The value 5×10^{-5} mentioned above is considered as, 5-percentile value for defining the prior mean of component mean capacity, and one order below i.e. 5×10^{-6} is considered as a 95-percentile value. The distribution of prior mean parameters of capacity is considered to follow a normal distribution. These are used to arrive at prior parameters of mean capacity which turns out to be $\mathcal{N}(3.5, 0.182)$. In a similar line, with CoV =0.1, the prior parameter of the standard deviation of mean capacity comes to be $\mathcal{N}(0.35, 0.0182)$. The joint probability of mean and standard deviation of prior parameters can be written as given in Equation 1 considering them to be uncorrelated as used in earlier studies (Lad et al. 2020, Karmakar et al. 2023). These parameters are degraded at the average rate of degradation (of its sub-components) for each of the components of the box culvert and for the remaining life span of the structure to decide upon prior parameters at any age t. The maximum rate of degradation for any sub-component of a component is considered

as 0.01/yr of initial capacity (Konakli & Faber 2014) corresponding to highly stressed zone (lowest capacity to margin ratio) as stated in section 2.

$$f'_{\Theta}(\theta) = P\left(\mu_{R_m}, \sigma_{R_p}\right) = P\left(\mu_{R_m}\right) P\left(\sigma_{R_p}\right) \tag{1}$$

where, $P\left(\mu_{R_m}\right)$ and $P\left(\sigma_{R_p}\right)$ are prior distributions of capacity parameters of m^{th} and p^{th} populations respectively. In the absence of any inspection data cost involved in decision-making can be obtained from prior distribution as written in the form of Equation 2, where, $C(\theta)$ is the cost involved with parameter θ.

$$C' = \int_{\Omega_\Theta} C(\theta) f'_{\Theta}(\theta) d\theta \tag{2}$$

3.2 *Bayesian updating to arrive at the posterior distribution of capacity parameters from its prior distribution*

In light of the test results, the prior distribution of capacity parameters (θ) can be updated to the posterior distribution as given below.

$$f''_{\Theta/\mathrm{x}}(\theta/x) = \frac{L(x|\theta) f'_{\Theta}(\theta)}{\int_{\Omega_\Theta} L(x|\theta) f'_{\Theta}(\theta) d\theta} \tag{3}$$

Similarly, the cost (C'') based on the posterior distribution of θ is

$$C'' = \int_{\Omega_\Theta} C(\theta) f''_{\Theta/x}(\theta/x) d\theta \tag{4}$$

The difference between the costs obtained using prior distribution and posterior information is the value of information as shown below. From the equation it can be said that, these cost values can be correlated as the negative of the value of information.

$$\mathrm{VoI} = C' - C'' \tag{5}$$

3.3 *Cost analysis*

The cost function is defined based on a combination of loss due to structural failure and cost of strengthening/maintenance based on test results. The cost due to structural failure is found by multiplying the cost of structural failure with the probability of its failure (Konakli & Faber 2014). The probability of failure is obtained from the actual demand and capacity parameters of each of the sub-components for each structural component. Bayesian updating is carried out for the capacity parameter with obtained test results as described earlier. The posterior predictive distribution is obtained from the joint posterior distribution of capacity parameters. Next, for the decision-making on maintenance strategy, the strengths are assumed as follows.

1. *Non-tested locations/ sub-components*: The mean and standard deviation of the posterior predictive distribution are assigned.
2. *Tested locations/sub-components*: The actual test value obtained from the experiment at the tested locations is assigned as the mean value of capacity for that location. The standard deviation for capacity is obtained using this capacity mean and CoV is obtained from the posterior predictive distribution.

Next, the probability of failure of any sub-component is obtained using Cornell's reliability method with these assigned mean and standard deviation and actual demand. If

the failure probability values come to be more than the acceptable limit ($P_{fscj}(t_i) \geq 0.0005$) then the strengthening of those locations/ sub-components is carried out. The extent of strengthening is the difference between the desired target mean value (S_t) (Not always the actual S_{at} at that age) to the obtained/ updated capacity mean value (S_{oj}) at the year of decision-making t_i. Readers may note that this strengthening is not the actual required strengthening for all the sub-components except those where inspection/ testing is being carried out. Therefore, after the decision-making on the strengthening scheme the updated actual capacity of the sub-components will be as follows.

1. *Non-strengthened sub-components*: The mean will be the actual (S_{at}) and standard deviation is considered using S_{at} and CoV obtained from posterior predictive distribution.
2. *Strengthened sub-components*: The mean capacity will be the capacity of the sub-component (j) at that age (S_{at}) added with ($S_t - S_{oj}$). However, the CoV is again set to an initial 0.1 (assuming regaining of near initial state) for finding the standard deviation of the capacity of these sub-components.

Hence the overall cost will be the sum of the strengthening cost and the cost of failure in subsequent years, based on updated capacity values. The cost involved in maintenance for one component is calculated as,

$$C_C(t_i) = \frac{C_r}{S_c} \sum_{j=1}^{S_c} \frac{S_t - S_{oj}}{S_t}, \text{if} \left(P_{fscj}(t_i) > 0.0005\right) \tag{6}$$

where, C_r is the cost of fully replacing the component, S_c are the number of sub-components. On the other hand, the cost of failure (C_{lcf}) of the structure based on pre-posterior analysis using the testing results (x) of one component and necessary strengthening can be given by Equation 7. However, for finding the probability of failure for this time, the updated actual capacity distribution is used. This failure probability goes with the assumption that other components in the series have the reliability of 1 and in parallel have the reliability of 0. This assumption is made to simplify the problem and obtain the optimum location component-wise. The obtained optimum sampling locations for individuals can then be compiled to arrive at the optimum test of the location of the complete box culvert. The failure of one component is governed by the failure of any of the sub-components for being correlated systems and placed in series.

$$C_{lcf} = C_{Sf} \sum_{t=t_i}^{t_d-1} \max_{S_c \in all} \left[\frac{P_{fsc}(t_i)}{(1+r)^{(t-t_i)}} \right] \tag{7}$$

C_{Sf} is the cost of complete failure, r discount rate with due consideration to than inflation rate, t_d is the functional design life, t_i is the age of inspection and $P_{fsc}(t_i)$ is the probability of failure of the sub-component in year t_i as given in Equation 8.

$$P_{fsc}(t_i) = P_{fsc}(R_{i+1} < S) - P_{fsc}(R_i < S) \tag{8}$$

where, R_i and S are the capacity and demand in the year 'i'. Finally, the overall cost: $C_{ov}(t_i)$ till the functional service life for the decision in the year t_i can be written as the sum of C_{lcf} and $C_C(t_i)$ as given in Equation 9. The total cost of structural failure is assumed as 1000 units and full replacement cost 10 units in a similar line with earlier works(Konakli et al. 2015; Konakli & Faber 2014).

$$C_{ov}(t_i) = C_{lcf} + C_C(t_i) \tag{9}$$

3.4 *Optimum sampling locations*

In the present problem, capacity parameters for each of the sub-components are considered to be constant and demand is considered to be the highest value in the smallest segment. To find out the optimum sampling location, samples are chosen separately from each of the locations, and comparing the obtained cost of the decision (maintenance and failure), the optimum location is suggested. Ω_Θ is the space containing different possible samples from the overall set of locations. Hence the optimum sampling scheme will be the one giving the lowest value of cost or highest value of information (negative cost) as shown in Equation 10 and Equation 11.

$$S_o = \underset{S \in \Omega_\Theta}{\operatorname{argmax}}(VI) \tag{10}$$

$$S_o = \underset{S \in \Omega_\Theta}{\operatorname{argmin}}\left[\int_{\Omega_\Theta} C(\theta) f''_{\Theta/x}(\theta/x)\, d\theta\right] \tag{11}$$

4 ILLUSTRATION OF THE PROPOSED METHODOLOGY

4.1 *Optimum location for the uniform initial capacity parameters of individual components*

With uniform initial capacity at 3.2 unit, the varying demands at different sub-component, the resulting stress levels also vary. The cost of decision-making was obtained using Equations 6- 9 for each sampling option, and are plotted for the top slab in Figure 1(a) and Figure 1(b) for the remaining service life, respectively for relatively non-informative prior and partially informative prior cases. Similar plots for side walls are presented in Figure 2(a) and Figure 2(b). Plots for the bottom slab were almost similar to the top slab and are not reproduced for brevity. From these figures, it can be observed that: selecting a sampling location corresponding to the lowest initial safety margin would provide the lowest overall life cycle cost; or in other words yield the highest VoI. Studies of these response patterns for different initial parameters are indicated as future scope of research. However, the aspect that application of VoI in selection of sampling location is strongly recommended in optimum decision making to reduce overall life cycle cost.

4.2 *Effect of the year of decision in overall cost thereafter*

Depending on the remaining service life, the effectiveness of the sampling scheme is studied in this section with C_{Sf}=1000 units and C_r = 10 units. The variations of minimum and maximum costs obtained for different sampling schemes with respect to age of structure, for relatively informative and partial informative prior are displayed: for top slab in Figure 3(a) and Figure 3(b); for side walls in Figure 4(a) and Figure 4(b). The reduced cost for higher age arises due to the lesser number of years the structure is to serve based on t_d. Although the cost of maintenance increases in the later phase of decision-making, the total failure cost, being much higher than the maintenance cost, govern the overall cost.

4.3 *Effect of different ratio of total failure cost to replacement cost*

If decision-making happens based on samples collected from highly deteriorated locations and decision is followed based on the obtained result, more cost will be incurred in maintenance. On the other hand, decision based on information from lesser deteriorated portions will lead to higher overall failure costs. Hence, the ratio of overall failure cost to replacement cost could play a major role in the overall life-cycle cost, and decisions. Presently, two different replacement costs for components (10 units, and 100 units) are examined, keeping the overall failure cost same as 1000 units. Similar plots as above are presented: for the top slab in Figure 5(a) and Figure 5(b); for side walls in Figure 6(a) and Figure 6(b). The figures show an increase in the overall cost when samples are collected from lower-margin zones, the effect being more for relatively non-informative prior.

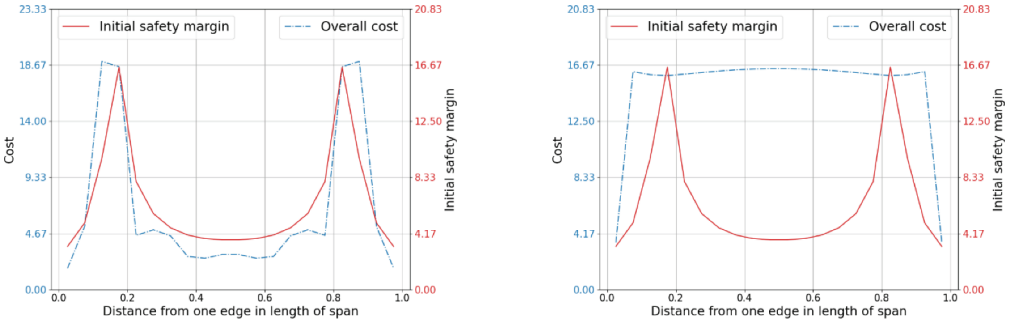

Figure 1. Overall cost and initial safety margin at different sampling location in fraction of length for (a) Relatively non-informative prior and (b) Partial informative prior for top slab.

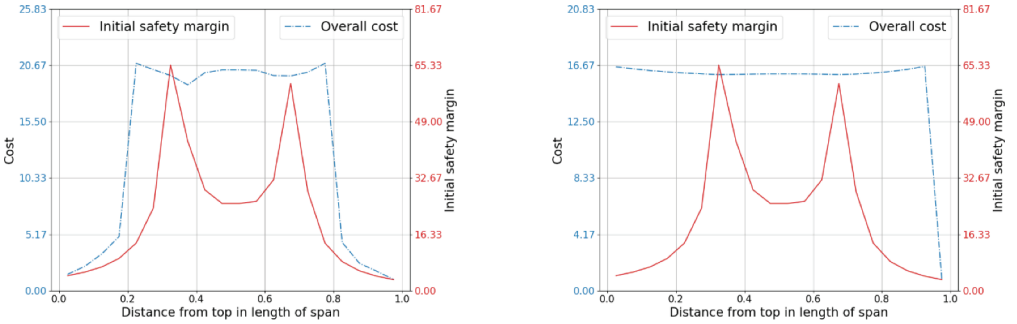

Figure 2. Overall cost and initial safety margin at different sampling location in fraction of length for (a) Relatively non-informative prior and (b) Partial informative prior for side wall.

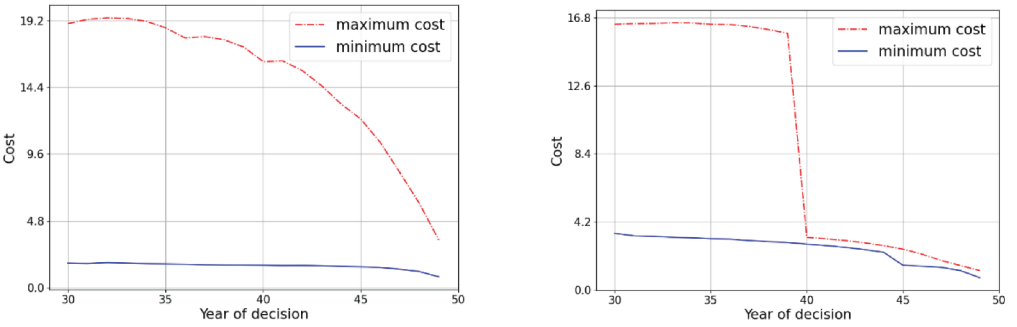

Figure 3. Maximum and minimum overall cost with respect to year of decision for all sample choices for, (a) Relatively non-informative prior and (b) Partial informative prior for top slab.

5 CONCLUSION

This work is the first-of-the-kind study, suggesting locations for NDT/PDT/monitoring for a box culvert, for SHA, in the VoI framework, considering various costs involved. The selection of test locations in the VoI framework would help to achieve overall lowest life-cycle cost for the structure. This case study does not propose a particular sampling location. Rather the work gives

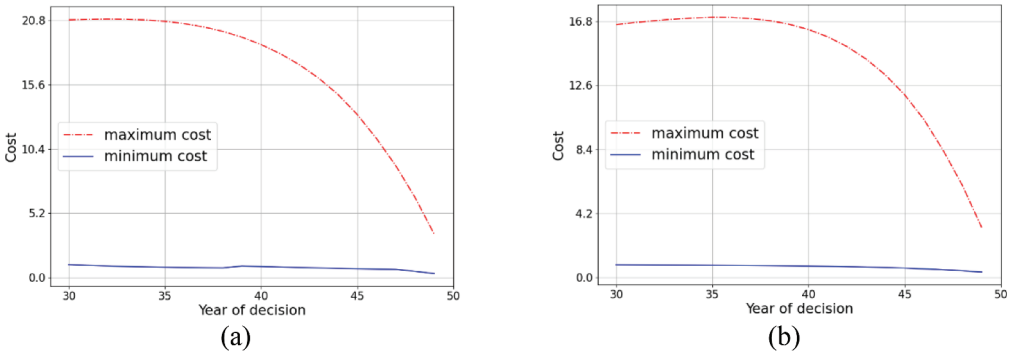

Figure 4. Maximum and minimum overall cost with respect to year of decision for all sample choices for, (a) Relatively non-informative prior and (b) Partial informative prior for side wall.

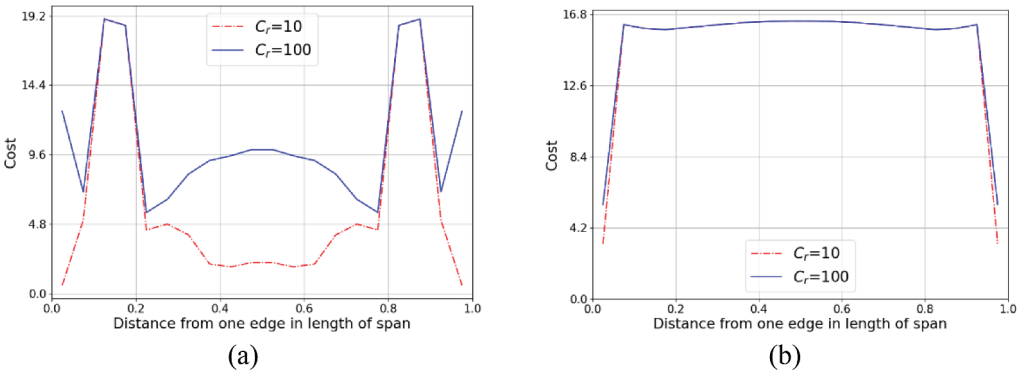

Figure 5. Overall cost at different sampling locations in fraction of length for different C_r values: (a) Relatively non-informative prior and (b) Partial informative prior for top slab.

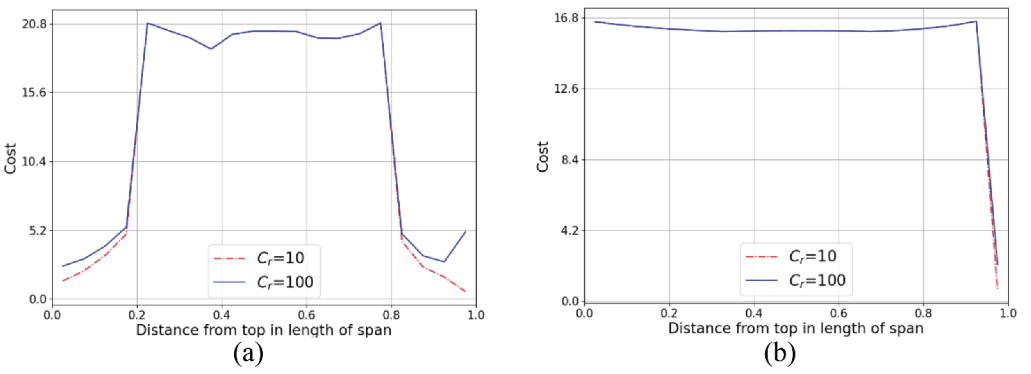

Figure 6. Overall cost at different sampling locations in fraction of length for different C_r values: (a) Relatively non-informative prior and (b) Partial informative prior for side wall.

a methodology to arrive at the optimum sampling location in VoI framework. From the example case studies considered the findings are as follows, a) In pristine conditions, the locations with higher stress would yield highest VoI for test for C_{Sf}=1000 units and C_r = 10 units. b) The age of inspection and functional design life plays role in relative efficacy of this optimization approach, c) The relative cost of repair and cost of failure is an important aspect for choice of location, and detailed rate analysis would be advocated.

The cost, degradation, initial capacity and demand parameters considered in this paper is based on certain values used in earlier literature due to lack of real field data. This is major limitation of the case study. However, the methodology is applicable for both real and normalized parametric values. Hence, obtaining the parameters used in Table 1 experimentally and carrying out the exercise will produce a more realistic picture. Incorporating the effect of imperfect information, effect of correlated prior parameters of capacity can also be examined in future. From the results of such studies, generic guideline for carrying out NDT/PDT/monitoring of box culverts may be formulated in future.

Assessment of a 60-year-old corroded concrete girder through finite-element analysis

L. Soto, M. Noël, B. Martín-Pérez & L. Sanchez
Department of Civil Engineering, University of Ottawa, Ottawa, Ontario, Canada

ABSTRACT: This study implements a two-dimensional nonlinear finite-element approach for the assessment of the shear behavior of a post-tensioned bridge girder whose tendons and reinforcement suffered severe corrosion during its service life of almost 60 years. The girder is lightly reinforced with vertical stirrups and its tendons follow a parabolic profile, with many of them anchored at the top of the girder; as such, the contribution of post-tensioning is significant to its shear capacity. The objective of the study is to understand the various aspects of the progressive damage of the girder due to increased corrosion of its prestressing steel. Through the finite-element modeling tool, different approaches have been considered to model the corrosion of post-tensioning tendons and reinforcement to assess the shear response of the girder in the degraded state.

1 INTRODUCTION

Corrosion of steel in concrete structures is one of the main durability issues that compromises their structural performance; therefore, the assessment of their structural behavior in the degraded state is of significant interest. In the past decades, nonlinear finite element analysis (NLFEA) has proven to be a useful tool in evaluating reinforced concrete (RC) and prestressed concrete (PC) elements affected by corrosion. In the case of PC, several studies may be mentioned that have been dedicated to assessing pretensioned members (Belletti et al. 2020, Huang et al. 2022, Osmolska et al. 2022), while to the knowledge of the authors, NLFEA evaluations of post-tensioned members are practically non-existent.

This study pertains to one of the typical post-tensioned girders from a 60-year-old bridge in Canada, for which detailed field inspections resulted in estimates of 40% to 47% reduction in steel cross-section due to corrosion attack. Although a detailed spatial distribution of corrosion has not been determined, the estimates for the residual capacity calculations of the girder according to current Canadian standards indicated a considerable deficiency in shear.

A numerical approach is implemented herein to incorporate degraded material constitutive models into the assessment of the girder in shear, and to that end, NLFEA have been utilized. The aim of the study is twofold: first, it is of interest to estimate the residual shear capacity and failure mode of the girder by means of an adequate methodology (NLFEA), and through the incorporation of material models that take into account corrosion attack; and second, to obtain insight pertaining to the influence of different degraded material models on the predicted response of the studied member.

2 GIRDER PROPERTIES

The girder used as the basis for this study was part of a decommissioned bridge which had a deck width of 24.08 m and a clear span of 52.43 m. Seven identical parallel girders were used for each span of the superstructure. The girder depth is 3,073 mm and is post-tensioned with 24 tendons, each consisting of 12 -7 mm diameter wires. The tendon layouts are all parabolic, with

DOI: 10.1201/9781003483755-115

13 of them anchored at girder-end and the rest at the top of the girder, as shown in Figure 1. Longitudinal reinforcement is comprised of 4 ϕ10 mm bars in the bottom flange, and 8 ϕ10 mm bars in the top flange. Stirrups at girder ends are ϕ15 mm spaced at 267 mm, while for the rest of the girder ϕ13 mm and ϕ15 mm stirrups are alternated at 800 mm. The thickness of the web varies along the length of the girder, with a maximum of 254 mm at the end of the span.

Concrete compressive strength was measured from drilled cores, and a value of 53.9 MPa was determined for evaluation purposes according to CSA S6-19. Prestressing and reinforcing steel properties were obtained from the original bridge design calculations, with the ultimate tensile strength of tendons being 1,572 MPa and a yield strength for reinforcing steel of 275 MPa.

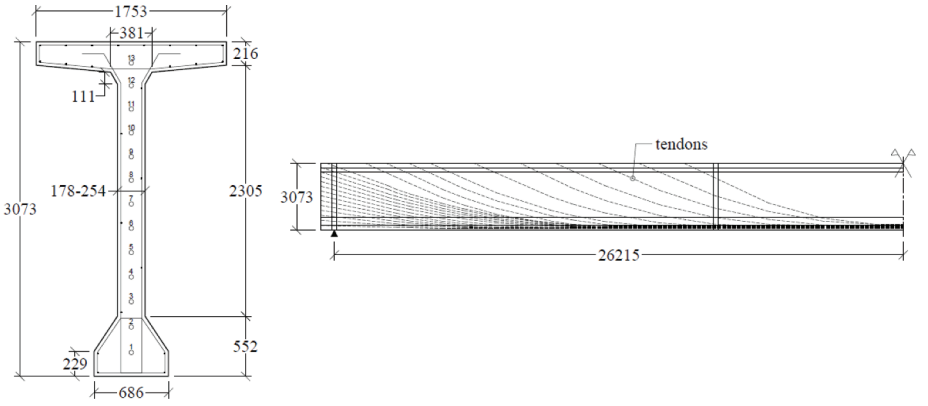

Figure 1. Girder cross-section at end of span, and elevation (dimensions in mm).

Through rigorous inspection campaigns of the bridge through the years, severe corrosion signs in the inclined tendons and bottom tendons were detected, as well as some corrosion of the vertical reinforcing steel. Although a complete assessment of the spatial degree of corrosion has not been possible, it was found that near the mid-span of the girder, the loss of the cross-sectional area of the tendons was approximately 47%. Thus, for the engineering assessment of the girders, a uniform degree of corrosion of 40% area loss was considered. Some of the defects found through the inspections are seen in Figure 2.

Figure 2. Corrosion damage of girder (left: mid-span, right: girder end).

3 FINITE ELEMENT ANALYSIS

Four different degrees of corrosion attack were studied through NLFEA, with 40% area reduction of the steel considered as the most severe scenario. The girder was analyzed considering the application of a concentrated load at a distance of 1.5d from the support.

Furthermore, different degraded material models have been implemented for separate analyses. A total of 19 analyses have been conducted for the girder. The details of the models, analyses, and constitutive models used are found in the next sections.

3.1 *Finite element modeling and analysis*

The girder has been modeled as a plane stress problem using VecTor2 software (Wong et al. 2013), which employs the Modified Compression Field Theory (MCFT) for the analysis of concrete membranes. Given the distribution of the tendons along most of the length of the girder, three-node elements have been used to model concrete and provide a better discretization along the tendons. Two-node truss elements were used to model the tendons in a discrete manner, while stirrup reinforcement has been defined in a smeared approach. Given the large number of tendons near the girder end, they have been modelled in groups of two with equivalent properties to simplify the model mesh. All the different thicknesses and reinforcement ratios in the girder have been explicitly modeled.

The constitutive models were selected from the VecTor2 material library (Wong et al. 2013): for concrete, Popovic's model for pre and post-peak behavior; for prestressing steel, a bilinear model with a transition curve from the elastic to the hardening branch; and for reinforcing steel, a nonlinear strain-hardening branch after the yield plateau. Eligehausen's model has been used for the steel-concrete bond relationship. The finite element model is presented in Figure 3; different colors are used to represent the different concrete web thicknesses ranging from 178-254 mm.

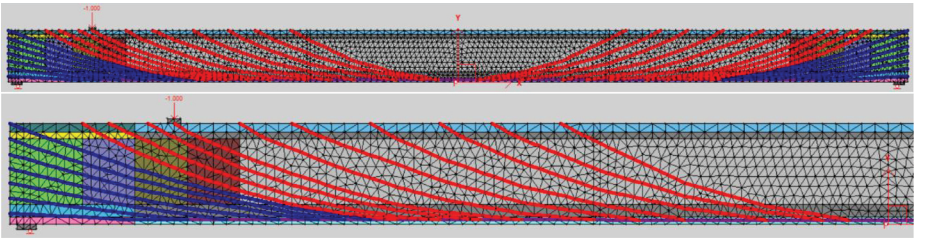

Figure 3. FE model: Complete, and close up of half the girder.

The analysis was carried out in a displacement-controlled manner in two stages: the first one where the effective prestressing forces and self-weight of the girder are applied; and the second, where a downwards displacement is enforced at a distance of 1.5d from the support. A steel plate element was placed under the applied displacement and at support points. The girder is simply supported at its ends.

3.2 *Degraded material constitutive models*

For the analysis of the girder the material models for concrete and steel were modified according to selected degradation models and corrosion degrees. To the knowledge of the authors, no models have been proposed for the degradation of prestressing steel in post-tensioned applications. Under that consideration, three different models were implemented to simulate the degradation of the steel tendons. Furthermore, one model for the degradation of bond properties was also considered.

The compressive strength of concrete has been reduced by applying the compression softening model in the MCFT as used by Coronelli & Gambarova (2004), where the average tensile strain in the transverse direction resulting from corrosion-induced cracking is estimated from the corrosion cracking width in Equation 3 proposed by Molina et al. (1993):

$$f_c^* = f'_c/(1 + K\varepsilon_1/\varepsilon_0) \tag{1}$$

$$\varepsilon_1 = n_{bars} w_{cr} / b_0 \tag{2}$$

$$w_{cr} = \sum u_{i\,corr} = 2\pi(v_{rs} - 1)X \tag{3}$$

where $f'c$ is the compressive strength of undamaged concrete, K is a roughness coefficient, ε_1 is the average strain in the cracked concrete at right angles to the direction of compression, ε_0 is the strain at peak compressive stress, b_0 is the unaffected section width of the girder, n_{bars} is the number of bars in the compression layer, and v_{rs} and X are the ratio of volumetric expansion of oxides and the depth of corrosion attack.

For reinforcing steel, a reduction of the effective area and ductility has been applied according to the degree of corrosion. For prestressing steel, three models have been implemented: 1) by Cairns & Millard (1999) as in Equation 4, 2) by Cairns et al. (2005) as in Equations 5-7, and 3) by Lu et al. (2016) as in Equations 8-10. The models are designated "C&M", "C", and "L" for further differentiations.

$$\varepsilon'_{su} = \varepsilon_{sy} + (\varepsilon_{su} - \varepsilon_{sy})\left(1 - \frac{\alpha_{pit}}{\alpha_{pit,max}}\right) \tag{4}$$

$$f_u = f_{u0}(1 - \alpha_u Q_{corr}) \tag{5}$$

$$f_y = f_{y0}(1 - \alpha_y Q_{corr}) \tag{6}$$

$$\varepsilon_u = \varepsilon_0(1 - \alpha_1 Q_{corr}) \tag{7}$$

$$f'_u = f_s(1 - 2.8\eta_s) \tag{8}$$

$$E'_s = E_s(1 - 1.8\eta_s) \tag{9}$$

$$\varepsilon'_u = \varepsilon_u\left(0.1 + 0.9e^{(-20\eta_s)}\right) \tag{10}$$

In the previous equations α_{pit} is the area reduction due to corrosion, Q_{corr} and η_s, represent the average corrosion degree, and α_u, α_y, α_1 are empirical coefficients depending on experimental conditions. The C&M model allows for a reduction of cross section up to 50%, according to several investigations, while the empirical coefficients of model C have been determined for average corrosion degrees of approximately 30%, and model L has practical application up to a degree of corrosion of approximately 15 to 20%. It is worth noting that model C was developed from experimental tests on artificially corroded strands.

Additionally, a model for bond deterioration between concrete and strands according to Wang et al. (2017) has been employed, denoted as "W". The model considers a reduction of the maximum bond strength τ_{max} as a function of the average corrosion degree η_s calculated in terms of reduction of cross-sectional area. This model may provide practical results up to a degree of corrosion of approximately 15 to 20%.

$$\tau'_{max} = \tau_{max}\left(2.03e^{(-0.118\eta_s)}\right) \tag{11}$$

3.3 *Finite element analyses*

Analyses have been performed for degrees of corrosion of 10, 20, 30, and 40% where the range of applicability of the degradation material model has so permitted according to the limits described in the previous section. The models are labeled according to the degradation models they implement; for example, "C+W" uses prestressing steel degradation by Cairns et al. (2005) and bond degradation by Wang et al. (2017). The summary of conducted analyses is presented in Table 1; where there is no applicability of a model, no analysis has been conducted, and it is denoted as "N/A".

Table 1. Girder FE analyses.

C+W	+	+	N/A	N/A
L+W	+	+	N/A	N/A

* No concrete degradation

4 RESULTS

The results regarding the variation of shear resistance for the different analyses are reported in Figure 4 as normalized shear capacity (V_{corr}/V_0) against corrosion degree, where V_0 is the girder capacity in the uncorroded state.

The load-displacement responses for a corrosion degree of 20% are presented in Figure 5; such degree of corrosion represents the limit of applicability in some of the used models, thus providing an interesting point for comparison. In the figure, the response of the undamaged girder is plotted as well.

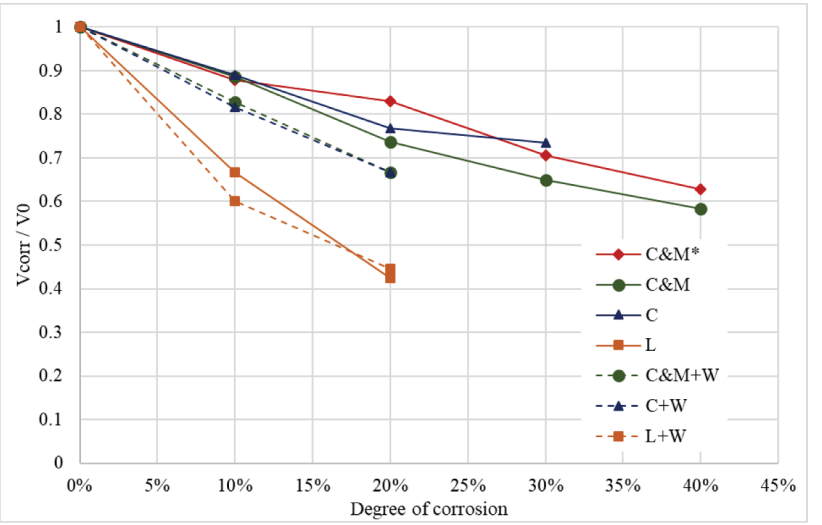

Figure 4. Normalized reduction of shear capacity vs degree of corrosion.

In general, 3 failure modes have been identified throughout the analyses: 1) a combination of wide diagonal cracking to the right of the loading point along the tendons and wide flexural cracking with rupture of some lower tendons, denoted "V-F"; 2) wide flexural cracking in the soffit of the girder in the vicinity of the loading point due to high slippage of tendons, denoted "F-B"; and 3) wide diagonal cracking to the left of the loading point extending to the top of the web where crushing occurs, denoted "V-C". The results are summarized in Table 2, and numbered according to the aforementioned description. The cracking patterns for the identified failure modes are shown in Figure 6, where for clarity only a portion of the girder is shown.

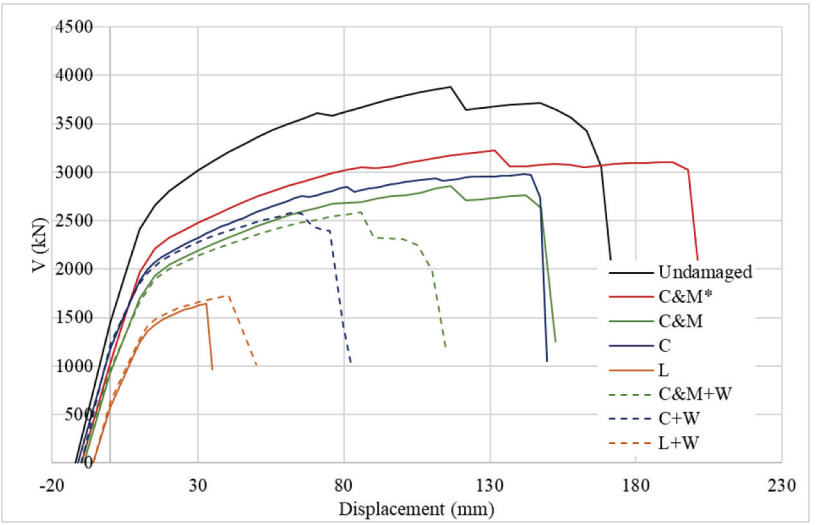

Figure 5. Load-displacement responses of models with 20% corrosion degree.

Table 2. Girder failure modes.

Model	ηs = 10%	ηs = 20%	ηs = 30%	ηs = 40%
C&M*	V-F	V-F	V-F	V-F

Figure 7 and Figure 8 show the typical stresses in the stirrups and tendons for each type of failure mode; once again, only the relevant portion of the girder is displayed.

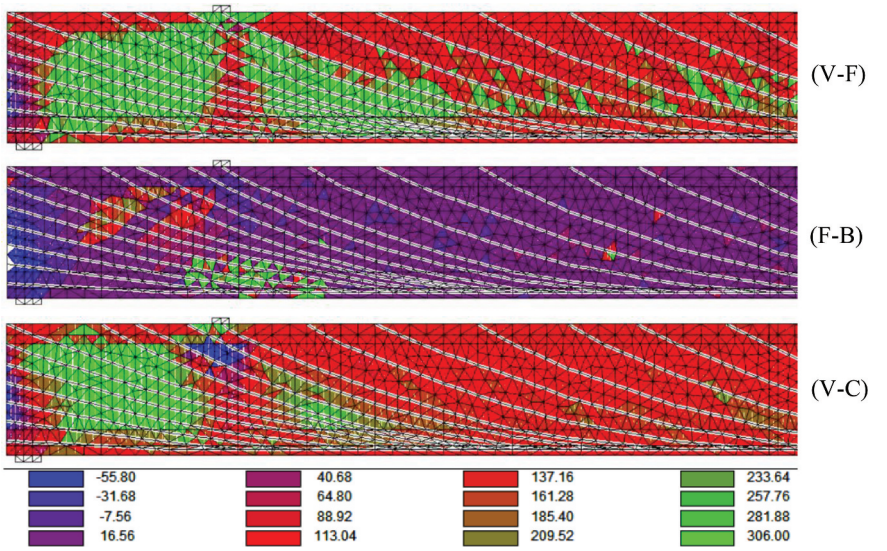

Figure 7. Stresses in stirrups (MPa).

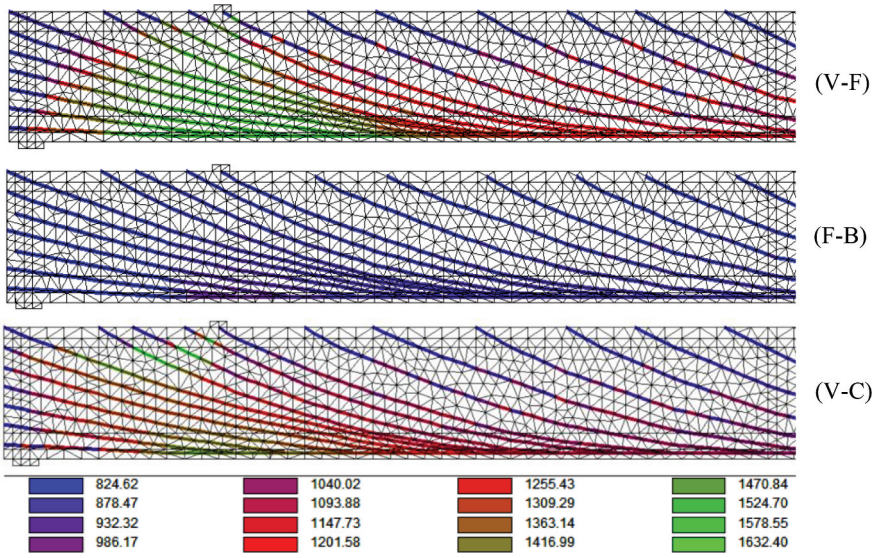

Figure 8. Stresses in tendons (MPa).

5 DISCUSSION

A range for the reduction in shear capacity of the girder has been obtained through the different analyses. By analyzing Figure 4, it is seen that models C&M and C seem to offer an upper bound for the capacity of the girder, while model L provides results on the other side of the spectrum. By comparing results at a degree of corrosion of 20%, both C&M and C models estimate a reduction in capacity of 25%, while L model estimates 55%. Also, it is evident that considering the degradation of concrete has an effect on the behavior of the girder, but it does not seem to be a marked one, perhaps due to the dominant contribution of the steel components to shear resistance. The effect of the reduction of ductility and strength of prestressing steel may be clearly

observed by means of Figure 5, emphasizing its contribution to the shear capacity. Both L and L +W models estimate failure at a much lower vertical displacement, and failure is brittle.

The following observations can be made by examination of the failure modes and stresses in the steel: 1) models C&M and C predict in most cases a failure in which the stirrups and tendons fully engage in the shear response of the girder near ultimate, and failure occurs in the location where stirrup reinforcement is at a minimum and the angle of the tendons decreases; 2) when bond degradation is taken into account, failure due to slippage occurs either at the soffit of the girder or near their anchorage points at the top; 3) when considering model L, the failure is brittle with a very early slippage and rupture of the tendons which have a considerable reduced capacity.

The most evident difference in results occurs when using L model for the reduction of steel properties, and the difference with the other models suggests that further research and experimental work to understand the degradation of post-tensioned steel strands is required.

6 CONCLUSIONS

In this study, estimates of the reduction in shear capacity of a post-tensioned girder were obtained by means of 2D NLFEA according to different degraded material models and degrees of corrosion. At 20% corrosion, shear capacity predictions ranged widely from approximately 45% to 85% that of the undamaged girder. Also, insight into the possible failure modes for each case was obtained, as well as an understanding of the contribution of prestressing steel to the shear response of the girder. NLFEA has proven to be a suitable tool for this evaluation; however, the adequacy of the results will depend on the use of proper material models. Also, it is recognized that further study is needed into the degradation models for implementation in prestressed concrete. Furthermore, it is acknowledged that this type of study would greatly benefit from accurate information pertaining the spatial distribution of corrosion; however, for the problem at hand where a relatively small portion of the member is of interest, the approach followed may prove valuable in the estimation of the shear response of post-tensioned girders.

Analysis for the bridge fatigue failure and weight limit using the probabilistic machine learning method

Wangchen Yan
College of Civil Engineering, Xiangtan University, Xiangtan, China

ABSTRACT: In this study, a probabilistic machine learning method was proposed as an alternative to the time-consuming finite element simulation method for analyzing the bridge fatigue failure probability under overloading conditions. First of all, the parameters that have great influences on the bridge fatigue failure probability were selected as input variables and the value of the limit state function of the fatigue damage was adopted to be the output variable. Moreover, the feedforward neural network integrated with the Monte Carlo method was employed to predict the bridge fatigue failure probability under different loading conditions. Finally, the influence of different weight limits on bridge fatigue life was explored. Results showed that the machine learning-based approach can serve as an efficient alternative for predicting the fatigue failure probability under different overloading conditions. In addition, the bridge weight limit had a significant impact on the performance of bridges in service for over 45 years. More importantly, it was found that reducing the vehicle gross weight limit from 55 t to 49 t could extend the bridge fatigue life by nearly 40%, indicating the positive effect of posing weight limits on prolonging the fatigue life of bridges.

1 INTRODUCTION

Traffic overloading has been very common around the world because of the quick development of the freight transportation. Truck overloading can pose a great threat to the bridge safety and may even directly result in bridge failure. Hobbacher et al. (Hobbacher et al. 2016) further pointed out that overloading and fatigue were the two main reasons for the damage of composite and steel bridges. As a result, it is of great importance to estimate the fatigue damage of composite girder bridges considering truck overloading.

Many efforts have been made to investigate the bridge fatigue damage caused by vehicular overloading using the deterministic approaches, i.e., finite element (FE) analysis, experiments, site surveys, and test. Cha et al. (Cha et al. 2014) integrated the FE analysis with actual inspection data to assess the influences of vehicular overloading on steel girder bridges. Wang et al. (Wang et al. 2016) evaluated the overloading induced fatigue damage of a new bridge based on the proposed vehicle-bridge coupled vibration system. Deng and Yan (Deng and Yan 2018) used the FE analysis to fulfill the permit checking for bridges in service.

When evaluating the vehicle-induced fatigue damage, scholars primarily focused on equivalent stress. In order to estimate the equivalent stress, a statistical truck model with deterministic parameters was proposed in AASHTO LRFD code (AASHTO 2017) to represent the actual truck traffic. However, the parameters of overloaded trucks were not considered in the AASHTO LRFD code (AASHTO 2017). Lu et al. (Lu et al. 2017) noted that the deterministic configuration of such truck model may not sufficiently capture the variability inherent in truck parameters. Moreover, the bridge fatigue failure is the result of the damage accumulation over time, which can be affected by the uncertainties stemming from truck traffic parameters (Chen et al. 2011). Therefore, probabilistic approaches may be

DOI: 10.1201/9781003483755-116

more suitable to evaluate the vehicle induced fatigue damage (Lu et al. 2017). However, it is known that the probabilistic analysis heavily relies on computation due to the necessity for a large amount of simulations, posing a significant challenge for the efficiency of fatigue damage estimation.

Recently, many advances have been made to improve the efficiency of fatigue damage assessment and machine learning methods are becoming popular owing to its unique advantages. Fathalla et al. (Fathalla et al. 2018) attempted to quickly predict the fatigue life of bridge decks using the artificial neural network (ANN), which was developed based on a large number of crack patterns of bridge deck slabs and the corresponding deck slab fatigue life. Lu et al. (Lu et al. 2017) adopted the support vector regression method to address the fatigue reliability of the bridge deck under the loading of truck models developed based on the weigh-in-motion (WIM) data. It is noted that although the bridge deck slabs directly suffered from the traffic loading, its failure does not lead to the failure of the bridge (Kayser and Nowak 1989). Moreover, despite recent achievements on the fatigue damage evaluation using machine learning, the evaluation of the fatigue failure reliability for steel girder bridges under overloading is still lacked. In this study, the fatigue failure probability of the steel girder bridge was focused on using the machine learning method.

2 TRAFFIC OVERLOADING

Vehicle-induced damage for short-to-medium-span bridges is not only influenced by gross vehicle weight, but also closely related to the vehicle axle load. In this study, the axle-load-based (AL) and gross-weight-based (GW) overloaded trucks were both considered and they were typically represented by the three- and five-axle trucks, respectively, which were shown in Figure 1. In Figure 1, the three-axle overloaded truck model was based on the AASHTO HS 20-44 fatigue design truck, which was developed statistically using the WIM data of 27,000 trucks (Snyder et al. 1985) while the five-axle overloaded truck model was based on the AASHTO type 3S2 truck, which can represent nearly half of heavy vehicles (Mason 1983). Finally, these two kinds of vehicles were used together to reflect the overloaded truck traffic considered in this study.

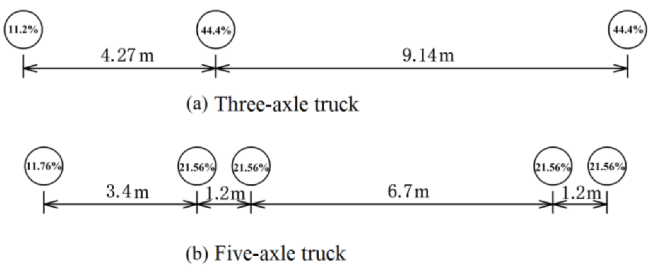

Figure 1. Truck models adopted.

According to Hwang and Nowak (Hwang and Nowak 1991), highway traffic can be typically represented by 20% three-axle trucks and 80% five-axle trucks. In this study, the original overloaded traffic considered was adopted to be the combination of 20% AL-overloaded trucks and 80% GW-overloaded trucks. Moreover, the variable traffic compositions were realized by adjusting the proportions of AL-overloaded trucks or GW-overloaded trucks in this study. Such approach was also adopted by other scholars (Laman and Nowak 1996).

In this study, vehicle weights of AL- and GW-overloaded trucks were regarded as random variables to investigate the influence of traffic overloading on the bridge fatigue failure probability. The corresponding distributions and statistics for the weight of overloaded trucks were adopted from Hwang and Nowak (Hwang and Nowak 1991), as listed in Table 1. It is noted that 320 kN

is the gross weight of both the HS 20-44 truck and type 3S2 truck as specified in AASHTO LRFD code (AASHTO 2017). In this study, in order to simulate the traffic overloading conditions, only the gross weight larger than 320 kN was generated according to Table 1. Moreover, Schilling and Klippstein (Schilling and Klippstein 1977) noted that the gross weight of vehicles larger than 512 kN only accounted for 0.09% according to the surveys for WIM sites, which were not considered in this study. Eventually, the gross weight of AL- and GW-overloaded trucks larger than 320 kN while less than 512 kN were regarded as the effective weight value in this study. Additionally, based on the generated gross weight, the corresponding axle weight of the AL- and GW-overloaded trucks can be calculated according to the distributions shown in Figure 1.

Table 1. Statistics of the gross weight for three- and five-axle trucks (data from Hwang and Nowak 1991).

Truck type	Distribution	Mean value kN	Standard deviation kN
Three-axle	Normal	178	37
Five-axle	Normal	290	76

3 FRAMEWORK

3.1 *Computational framework*

In this study, the main framework was shown in Figure 2, which was conducted according to the following steps. At the first step, the input and output variables were selected carefully. The adopted input variables were randomly generated based on the corresponding distributions, and the value of the limit state function for the accumulative fatigue damage was selected as the output. At the second step, the ANN model was developed based on the

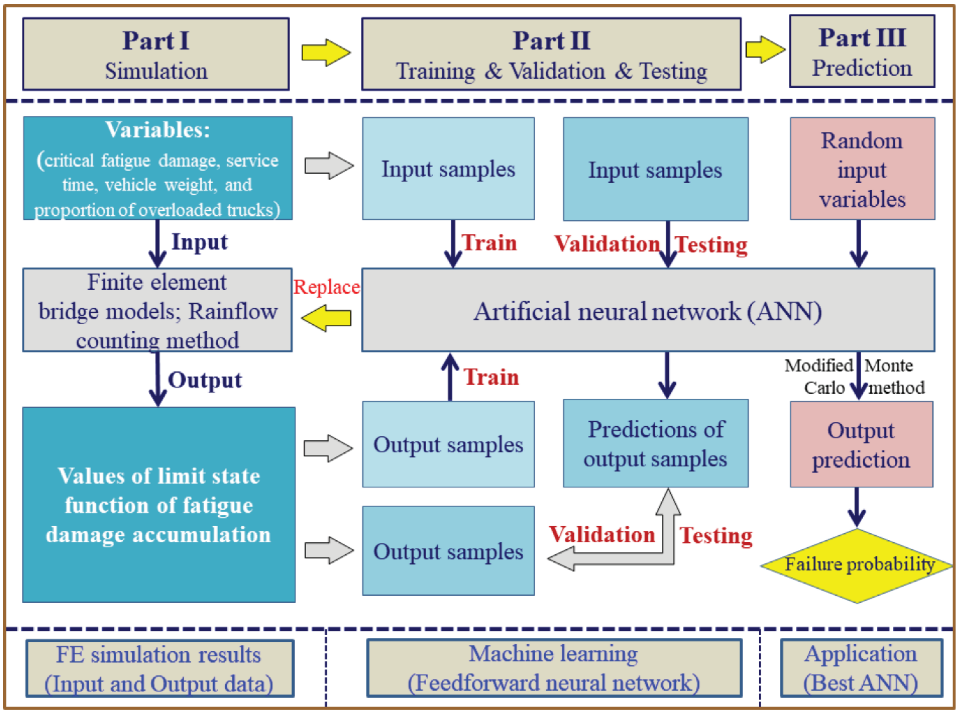

Figure 2. Flowchart for determining vehicle weight limit and making permit decision.

Matlab platform, which was trained, validated, and tested based on the generated input and output data samples. At the third step, the trained ANN model was integrated with the Monte Carlo method to predict the bridge fatigue failure probability under certain overloading conditions.

3.2 *FE bridge model*

In this study, a typical composite steel girder bridge with the concrete deck slab was adopted for illustration. The bridge is 30.48 m in length and 9.75 m in deck width. The cross-section of this bridge model is shown in Figure 3. It should be noted that the adopted bridge model was proved to be a good representative of the simply-supported composite steel girder bridges with concrete deck slabs in the United States and has been employed in many studies for the bridge fatigue damage evaluation (Wang et al. 2016; Wang et al. 2005).

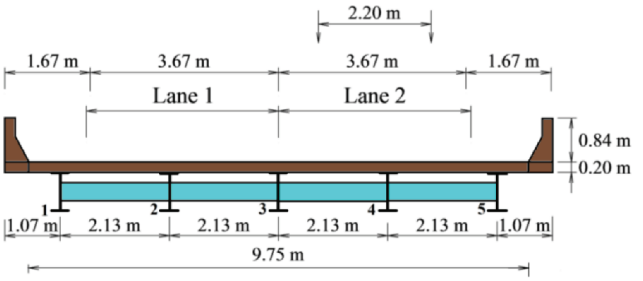

Figure 3. Cross-section of the bridge model.

In the present study, a three-dimensional (3D) FE model of this bridge was built with ANSYS framework. Five identical steel girders were uniformly placed with an interval of 2.13 m in the bridge transverse direction. Two end steel diaphragms and three steel intermediate diaphragms were arranged with a space of 7.6 m in the bridge longitudinal direction. In the FE bridge model, steel girders, the concrete bridge deck, and guardrails were all modeled by solid elements while the steel diaphragms were modeled by shell elements. More detailed bridge parameters can be found in Table 2.

Table 2. Details of the steel girders of the bridge model.

Cross-sectional area	Moment of inertia	Initial Young's modulus	
m^2	m^4	GPa	Poisson's ratio
0.02	0.0011	210	0.25

It is noted that the adopted bridge has a fast lane and a slow lane, which were denoted by Lane 1 and Lane 2 in Figure 3, respectively. Considering the statistics that more than 90% heavy trucks passed through the bridge along the slow lane (Lu et al. 2017), only overloaded trucks traveling in the slow lane were considered in this study, which was also the loading condition suggested by AASHTO LRFD code (AASHTO 2017) when evaluating the bridge fatigue damage.

3.3 *Probabilistic fatigue analysis*

Repetitive overloading can induce increased number of bridge stress cycles and therefore cause accumulated fatigue damage. Generally, the limit state function of the accumulative

fatigue damage, i.e., $g(X)$ as listed in Eq. (1), can be a good indicator of the bridge fatigue reliability, and the condition that the value of $g(X) \leq 0$ indicated the bridge fatigue failure states.

$$g(X)=FD_{\Delta}-\sum_{i=1}^{t} FD(t) \tag{1}$$

where FD_{Δ} is the critical fatigue damage in terms of fatigue resistance and was adopted as a variable in this study; $FD(t)$ denotes the overloading-induced bridge fatigue damage after t years of service.

According to Chen and Li, the critical fatigue damage (FD_{Δ}) usually ranged from 0.5 to 2.0 when the materials failed (Chen and Li 2010). In addition, the parameter FD_{Δ} was assumed to follow the lognormal distribution with a mean value of 1.0 and a coefficient of variation (COV) of 0.15 (Raju et al. 1990). Considering the condition that the overloaded truck traffic can be comprised of trucks with different weights and different proportions of AL- and GW-overloaded trucks, the updated function of $g(X)$ can be found in Eq. (2).

$$g(X)=FD_{\Delta}-Num\cdot t\cdot\left(r_{AW}\cdot\sum_{i}^{t}\frac{n_i\cdot S_i^m}{A}+r_{GW}\cdot\sum_{j}^{t}\frac{n_j\cdot S_j^m}{A}\right) \tag{2}$$

where t is the bridge service time in years, and it was assumed to follow a uniform distribution starting from 1 to any interested year, such as 225 years in this study; Num is the number of passing trucks in one year; r_{AL} and r_{GW} are the proportions of the AL- and GW-overloaded trucks in the truck traffic, respectively; S_i and S_j are the stress range induced by the AL- and GW-overloaded trucks, respectively.

It is noted that the sum of r_{AL} and r_{GW} is always 1. Moreover, it was assumed that the parameter r_{AL} followed a lognormal distribution with a mean value of 0.2 and a COV of 0.15. Regardless of traffic growth, the parameter Num can be calculated based on the average daily truck traffic (ADTT) specified in the AASHTO LRFD code (AASHTO 2017), namely, Num=365 x 2000=730,000. In addition to the distributions for variables of gross weight of AL- and GW-overloaded trucks listed in Table 1, the other distributions of aforementioned variables were listed in Table 3.

Table 3. Distributions of the variables investigated.

Par.	Distribution	Mean value	COV
FD_{Δ}	Truncated lognormal	1.0	0.15
r_{AL}	Truncated lognormal	0.2	0.15
t	Uniform	1 (Minimum)	225 (Maximum)
A	Deterministic	$3.93\text{x}10^{12}$	-
m	Deterministic	3	-

It is noted that the fatigue failure probability of bridges caused by overloaded trucks, as defined in Eq. (3), is closely related to the bridge safety reliability (Melchers and André 2018). In addition, based on the finding by Helmerich et al. (Helmerich et al. 2007), the target reliability of existing bridges usually ranges from 2.0 to 3.5, and the reliability of 2.0 corresponds to a failure probability of 2.3%. Therefore, the value of 2.3% was adopted as the target P_f in this study, which was also employed by other scholars (Lu et al. 2017; Zhu and Zhang 2018).

$$P_f=P(g(X)\leq 0) \tag{3}$$

3.4 *Probabilistic prediction of fatigue failure based on machine learning*

In this section, the feedforward neural network was developed based on the Matlab platform in order to map the relationship between the outputs, i.e., the value of g(X) and the inputs, namely, the gross weight of AL- and GW-overloaded trucks, r_{AL}, service time t, and FD_{Δ}.

The feedforward neural network has an input layer, an output layer, and multiple hidden layers. Each neuron is a basic data processing unit. The data flowed from the input layer and was processed by the neurons in hidden layer, and was finally transferred to the output layer. Each neuron in the hidden layer performed the similar data processing procedures, as shown in Figure 4, and offered the prediction eventually. Once the error between the prediction from the ANN and the actual value met the requirement, the training was complete. The ANN model providing the best predictions was regarded as the trained ANN, which was used to predict the fatigue failure probability with Monte Carlo method in the next section.

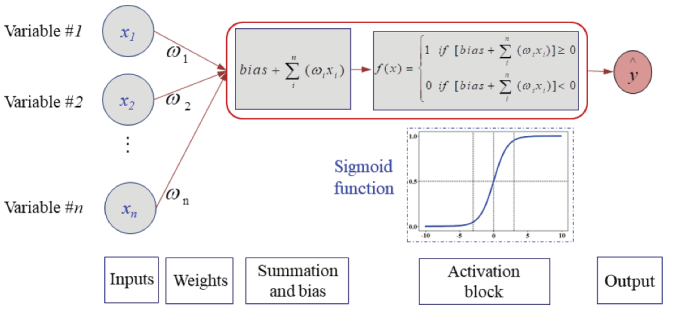

Figure 4. Processing procedure of the neuron in hidden layers.

In order to verify the accuracy of the optimized ANN in this study, differences between the values of $g(X)$ obtained from FE analysis and ANN were compared. The maximum difference was proved to be 0.35%, which demonstrated the reliability and accuracy of the trained ANN.

4 PREDICTION OF THE FATIGUE FAILURE PROBABILITY

Based on the trained ANN model, the bridge fatigue failure probability caused by overloaded truck traffic was studied using the Monte Carlo method. Specifically, a total number of 500,000 sets of input samples were firstly generated randomly according to the distributions summarized in Tables 1 and 3. Then, 500,000 outputs can be predicted using the optimized ANN model. Eventually, the ratio of the number of predicted negative outputs to the total number of outputs predicted, i.e., 500,000, was calculated to be the fatigue failure probability P_f.

In this study, several typical weight limit values were adopted to be the upper limits for *W_AL* and *W_GW*, i.e., 33 t, 41 t, 43 t, 45 t, 47 t, 49 t, 51 t, 53 t, and 55 t. Under these weight limits, the predicted fatigue failure probability was shown in Figure 5. It is necessary to mention that the target fatigue failure probability was selected as 2.3% in this study which corresponds to a target reliability of 2.0 according to Helmerich et al (Helmerich et al 2007).

It can be seen from Figure 5 that under different gross weight limits, the bridge fatigue failure probability varied slightly before the bridge reached its 45th service years. Moreover, the influence of different weight limits became apparent after 45 years of service, which indicated that posing weight limits was more important for the performance of old bridges.

In the early time when the bridge load limit value was not clarified, the vehicle design load value was often mistaken for the bridge load limit value. It was observed from Figure 5 that the fatigue life of the bridge was more than 225 years when the weight limit was adopted to be 33 t. It is noted that 33 t was slightly higher than the vehicle design load value 32 t. This

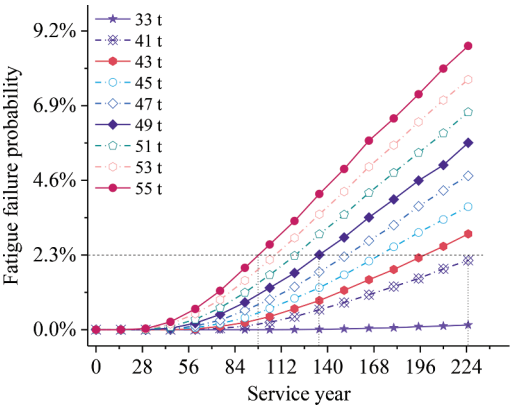

Figure 5. Fatigue failure probability of the bridge under different gross weight limits.

phenomenon clearly indicated that using the vehicle design load value as the bridge weight limit value would significantly underestimate the performance of bridges.

In addition, Under the gross weight limit specified in the "General Specifications for the Design of Highway Bridges and Culverts" (JTG D60-2015), i.e., 55 t, and the maximum allowable total mass of vehicles determined by "External Dimensions, Axle Loads and Mass Limits of Cars, Trailers and Car Trains" (GB1589-2016), i.e., 49 t, the corresponding predicted fatigue life were 98 years and 135 years, respectively. It is noted that the currently used vehicle load limit of 49 t is about 10% lower than the vehicle load limit of 55 t determined in 2015, which could result in nearly 40% extension of the bridge fatigue life. This comparison demonstrated the importance of bridge weight limits in extending the bridge service life.

It is noteworthy that based on the ordinary laptop equipped with Intel® Core™ i7-3520M, the total processing time of the trained ANN for each scenario was only several seconds, which was much less than the time required by performing the FE analysis on the workgroup with Intel® Core™ i7, i.e., 16 hours in this study.

5 CONCLUDING REMARKS

In this study, a method based on the machine learning and Monte Carlo method was proposed to predict the bridge fatigue failure probability considering the effect of overloading. A typical composite steel girder bridge was adopted to illustrate the proposed framework. Results showed that the proposed approach was capable of predicting the fatigue failure probability with high accuracy and efficiency, providing an excellent alternative for finite element analysis-based methods. Moreover, it was found that posing weight limits was more helpful for bridges servicing over 45 years. It was demonstrated that if the weight limit value was decreased from 55 t to 49 t, i.e., 10% reduction, the bridge fatigue life could nearly increase 40%, which indicated the importance of determining rational weight limit to prolong the bridge service life.

Stationary proposal importance sampling for structural reliability of aging RC bridges

L. Capacci
Politecnico di Milano, Milan, Italy

ABSTRACT: Safety assessment of aging bridges may require the modeling of complex deterioration processes, further exacerbating in time the uncertainties involved in the mechanical response of critical members. Simulation-based techniques applied to life-cycle reliability problems may rely on time-consuming structural analyses, leading to untenable computational efforts and impairing the accuracy of the numerical estimates. This paper discusses an efficient computational framework for time-variant failure probability based on Importance Sampling (IS) with Stationary Proposal (SP) distribution. This novel methodology exploits numerical approaches traditionally developed for time-invariant structural reliability problems and extends them into a life-cycle context. Specifically, the simulation density is adaptively selected by minimizing the Kullback–Leibler Cross-Entropy from a chosen family of parametric distributions. The numerical procedure is applied to lifetime structural reliability of a reinforced concrete bridge exposed to chloride-induced corrosion.

1 INTRODUCTION

Traditional simulation-based procedures for structural reliability assessment can be computationally inefficient when time-consuming analyses are required to estimate relatively small failure probabilities (Yang et al. 2017). In life-cycle reliability problems, the computational effort is also affected by factors involved in the evolution in time of physical deterioration phenomena exacerbating uncertainties in structural capacities and performance decay such as functionality and resilience (Capacci et al. 2022). In this context, the impact of environmental aggressiveness and maintenance interventions play a key role in the assessment of structural safety for aging Reinforced Concrete (RC) bridges. Incorporating complex deterioration processes as well as countermeasures adopted to mitigate their impact would further exacerbate uncertainties involved in the time-variant structural capacity assessment of critical members.

Enhancing standard methodologies for the estimation of life-cycle structural safety is an open issue in reliability assessment of structures prone to aging effects. To this purpose, the paper presents a novel numerical framework to efficiently estimate time-variant failure probabilities of deteriorating structural systems, with specific focus on RC bridge decks exposed to chloride-induced corrosion. Random variables and stochastic processes associated to the structural demand and capacity of bridge members are efficiently simulated based on Importance Sampling (IS) from a Stationary Proposal (SP) time-invariant distribution. An adaptive procedure is also implemented to select the optimal SP distribution by identifying the parameters of a prescribed distribution family that minimize the discrepancy with the target density function (Rubinstein 1981). The results in terms of near-optimal sampling distribution parameters and reliability indices highlight the potentialities of the proposed methodology to improve the accessibility of reliability-based design optimization procedures for aging structures as well as to guarantee faster reliability updating frameworks to incorporate additional information available through inspections and maintenance.

2 LIFE-CYCLE STRUCTURAL RELIABILITY ESTIMATE: THE CE-SP-IS APPROACH

2.1 *Monte Carlo Simulation (MCS) and Stationary Proposal Importance Sampling (SP-IS)*

In life-cycle reliability problems, structural capacity evolves in time and underlying uncertainties to deterioration phenomena are described by time-variant Random Variables (RVs) $\mathbf{X}(t)$ with joint Probability Density Function (PDF) $f_{\mathbf{X}(t)}(\mathbf{x})$. The failure probability is formulated based on the mathematical expectation of the indicator function $I(\mathbf{x})$ of limit state function $g(\mathbf{x})$:

$$P_f(t) = E_{f_{\mathbf{X}(t)}}[I(\mathbf{x})] = \int_x I(\mathbf{x}) \cdot f_{\mathbf{X}(t)}(\mathbf{x}) d\mathbf{x} \tag{1}$$

More specifically, the Heaviside step function $I(\mathbf{x})$ is unitary in the failure domain $\{g(\mathbf{x}) \leq 0\}$ and null in the complimentary safe domain$\{g(\mathbf{x}) > 0\}$. Simulation methods are adopted to numerically estimate the multidimensional integral formulated in the failure probability. In traditional Monte Carlo simulation (MCS) for time-variant reliability problems, samples of the indicator function are generated based on the distribution of basic RVs progressively evolving over the system lifetime, requiring one simulation per observation time t. The MCS reliability estimator is the sample mean of the indicator function:

$$p_{MCS}(t) = \frac{1}{N} \sum_{i=1}^{N} I_i(t) \tag{2}$$

where N is the sample size of a single simulation carried out at each observation time t.

Stationary Proposal Importance Sampling (SP-IS) reformulates the failure probability in terms of a *time-invariant* sampling distribution ψ relying on the weighting coefficient W:

$$W(\mathbf{x}|t) = \frac{f_{\mathbf{X}(t)}(\mathbf{x})}{\psi(\mathbf{x})} \tag{3}$$

The SP-IS failure probability refers to the mathematical expectation in terms of the proposal PDF ψ of the product between indicator function I and time-variant weighting coefficients W:

$$P_f(t) = E_{\psi}[I(\mathbf{x}) \cdot W(\mathbf{x}|t)] = \int_{\mathbf{x}} I(\mathbf{x}) \cdot W(\mathbf{x}|t) \cdot \psi(\mathbf{x}) d\mathbf{x} \tag{4}$$

The failure probability is then estimated by the weighted sample mean of the indicator function:

$$p_{IS}(t) = \frac{1}{N} \sum_{i=1}^{N} I_i \cdot w_i(t) \tag{5}$$

The main advantage of SP-IS compared to MCS is that a single simulation is required to estimate probabilities at discrete times t, rather than a single simulation per time instant. Nonetheless, designing the sampling density ψ is a critical issue to effectively retrieve accurate results.

2.2 *Cross-Entropy-based Stationary Proposal Importance Sampling (CE-SP-IS)*

Methodologies based on Cross-Entropy (CE) are conceived to minimize the variance of the reliability estimator obtained by IS, seeking for a near-optimal simulation density ψ from a family of parametric distributions (Rubinstein 1981). This is done by minimizing a discrepancy metrics between a prescribed proposal density ψ with parameters $\mathbf{v}$ and the absolute best distribution p^*. For example, the Kullback-Leibler Cross-Entropy (KL-CE) is formulated as follows:

$$D_{KL} = \int_{\mathbf{x}} p^*(\mathbf{x}) \cdot \ln p^*(\mathbf{x}) d\mathbf{x} - \int_{\mathbf{x}} p^*(\mathbf{x}) \cdot \ln \psi(\mathbf{x}; \mathbf{v}) d\mathbf{x} \tag{6}$$

The optimization problem and the related algorithm to iteratively retrieve the proposal parameters $\mathbf{v}$ minimizing KL-CE are thoroughly described in Kurtz and Song (2013) and Geyer et al. (2019) regarding time-invariant reliability analysis.

In the SP-IS approach, the best possible density $p^*(\mathbf{x})$ is defined over the n_c combinations of (1) n_t discrete times and (2) n_p hazard scenarios affecting the actual PDF $f_{\mathbf{X}}$ as well as (3) n_s investigated limit states affecting the indicator function I (Capacci and Biondini 2023):

$$p^*(\mathbf{x}) = \frac{1}{n_c}\left[\sum_{c=1}^{n_c} \frac{I(\mathbf{x}|c)\cdot f_{\mathbf{X}(c)}(\mathbf{x}|c)}{P_f(c)}\right] \tag{7}$$

where each combination $c=\{t_z,p,s\}$ collects a given pair of z-th time instant t_z, p-th hazard scenario and s-th limit state.

The Gaussian Mixture Model (GMM) is a flexible family of proposal distributions $\psi(\mathbf{x},\mathbf{v})$ and a particularly suitable candidate as proposal density. The PDF of a K-variate is defined as follows as the weighted sum of K variates:

$$\psi(\mathbf{x},\mathbf{v}) = \sum_{k=1}^{K} \pi_k \cdot N(\mathbf{x}|\boldsymbol{\mu}_k,\boldsymbol{\Sigma}_k) \tag{8}$$

where the k-th variate is described by weighting probability π_k, mean vector $\boldsymbol{\mu}_k$, and covariance matrix $\boldsymbol{\Sigma}_k$. For exponential densities such as GMMs, explicit updating rules of their descriptive parameters $\mathbf{v}$ are available (Rubinstein and Kroese 2004). The $(m+1)$-th updating rules for the k-th density are defined as follows (Capacci and Biondini 2023):

$$\pi_k^{(m+1)} = \frac{\sum_{i=1}^{N} \tilde{w}_i \cdot \gamma_{ik}^{(m)}}{\sum_{i=1}^{N} \tilde{w}_i} \tag{9}$$

$$\boldsymbol{\mu}_k^{(m+1)} = \frac{\sum_{i=1}^{N} \tilde{w}_i \cdot \gamma_{ik}^{(m)} \cdot \mathbf{x}_i}{\sum_{i=1}^{N} \tilde{w}_i \cdot \gamma_{ik}^{(m)}} \tag{10}$$

$$\boldsymbol{\Sigma}_k^{(m+1)} = \frac{\sum_{i=1}^{N} \tilde{w}_i \cdot \gamma_{ik}^{(m)} \cdot \left(\mathbf{x}_i - \boldsymbol{\mu}_k^{(m)}\right) \cdot \left(\mathbf{x}_i - \boldsymbol{\mu}_k^{(m)}\right)^{\mathrm{T}}}{\sum_{i=1}^{N} \tilde{w}_i \cdot \gamma_{ik}^{(m)}} \tag{11}$$

where the i-th weight $\tilde{w}_i$ depends on the n_c reliability problems (Capacci and Biondini 2023):

$$\tilde{w}_i = \frac{1}{n_c}\sum_{c=1}^{n_c} \frac{I_i(s)\cdot w_i(\mathbf{w}|t_z,p)}{p_{IS}(t_z,p,s)} \tag{12}$$

3 TIME-VARIANT RELIABILITY OF A STATICALLY INDETERMINATE BEAM

3.1 *Limit states and failure probabilities*

The time-variant structural reliability of a statically indeterminate beam (Capacci and Biotndini 2022) is investigated with respect to two limit states: first plastic hinge formation and collapse. Figure 1a shows the plastic hinge formation mechanism triggering collapse, which is characterized by half-length l=3m and is loaded at midspan by a concentrated force ΘQ. The bending moment diagram sketched in Figure 1b depends on the positive plastic moment M_p^+ at midspan and the negative plastic moment M_p^- at the clamped end. Due to deterioration, the plastic moments are stochastic processes with parameters evolving over the normalized $\tau\in[0,1]$.

Assuming the beam has uniform bending stiffness over its length, elastic analysis allows identifying two safety factors associated to the load multiplier associated to first plastic hinge formation at midspan (i.e., Θ_p^+) and clamped end (i.e., Θ_p^-). The first yielding safety factor is retrieved by the minimum among the safety factors for each potential plastic hinge:

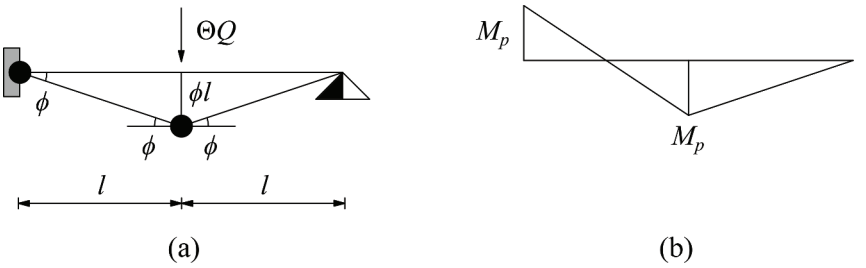

Figure 1. Collapse of a statically indeterminate beam: (a) mechanism; (b) bending moment distribution.

$$\Theta_1(\tau) = \min\left\{\Theta_p^+(\tau), \Theta_p^-(\tau)\right\} = \min\left\{\frac{M_p^+(\tau)}{\frac{5}{16}Ql}, \frac{M_p^-(\tau)}{\frac{3}{8}Ql}\right\} \tag{13}$$

Structural collapse is then evaluated by limit analysis and the related load multiplier is:

$$\Theta_2(\tau) = \frac{2M_p^+(\tau) + M_p^-(\tau)}{Ql} \tag{14}$$

The probabilities of occurrence of each event associated to limit state s=1,...,n_s with n_s=2 is expressed in terms of the related safety factors Θ_s:

$$p_s(\tau) = P[\Theta_s(\tau) \leq 1] \tag{15}$$

3.2 *Statistical dependency and environmental hazard scenarios*

Time-invariant concentrated force Q and time-dependent resisting moment $Mp^{\pm}$ are jointly lognormally distributed with linear coefficient ρ=0.7. Degradation laws in terms of the normalized time τ can be adopted to account for different scenarios for the evolution in time of the plastic moment descriptors. The statistical descriptors of Q and $Mp^{\pm}$ are listed in Table 1. Aging of plastic moments is expressed in terms of the hazard coefficients a_1 and a_2 respectively governing the linearly decaying mean value $\mu_M(\tau)$ and linearly increasing CoV $\delta_M(\tau)$.

Table 1. Statistical descriptors of concentrated force Q and resisting moment M_p.

Random Variable	Mean Value μ	Coefficient of Variation (CoV) δ
Concentrated Force Q	100 kN	0.10
Plastic Moment $M_p^{\pm}$	$(1-a_1\cdot\tau)\cdot$250 kNm	$0.15 + a_2\cdot\tau$

The SP-IS numerical framework effectively allows not only analyzing the evolution in time of multiple reliability problems, but also investigating different hazard and durability scenarios. Two scenarios characterized by "fast" and "slow" deterioration rates are considered and four hazard scenarios n_p=4 are considered by combining the deterioration rates for M_p^+ and M_p^-:

- Scenario "fast-fast": both moments are characterized by "fast" deterioration;
- Scenario "slow-slow": both moments are characterized by "slow" deterioration;
- Scenario "fast-slow": M_p^+ decays faster than M_p^-;
- Scenario "slow-fast", M_p^+ decays slower than M_p^-.

The first two cases are representative of hazard scenarios with different damage propagation rates and uniform aggressiveness over the beam span, whilst the last two scenarios simulate environmental exposure affecting differently the resisting moments at midspan and clamped end. The degradation coefficients a_1 and a_2 for each deterioration rate are collected in Table 2.

Table 2. Degradation coefficient of resisting moment $M_p^{\pm}$ descriptors.

Deterioration Rate	Coefficient a_1	Coefficient a_2
"Fast"	1/3	0.150
"Slow"	1/6	0.075

3.3 *Results of CE-SP-IS methodology*

The optimal proposal density is identified considering multiple time instants n_t, limit states n_s and parametric hazard scenarios n_p. Failure probabilities with respect to the previously discussed n_s=2 limit states are assessed for n_t=21 normalized time instants (i.e., from 0.05 to 1.00 every 0.05). All n_p=4 combinations of correlation and deterioration scenarios are considered, for a total of $\underline{n_c}=\underline{n_t}\cdot\underline{n_s}\cdot\underline{n_p}$=168 reliability problems to be solved.

The simulation is initialized with K=10 Gaussian mixtures with probability π_k=1/K with mean vectors $\boldsymbol{\mu}_k$ randomly simulated from an uncorrelated joint normal distribution standard deviation σ=0.2and centered at the mean vector associated with the final time τ=1 of the "fast-fast" hazard scenario and. Five rounds n_{iter}=5 of pre-sampling with N_{pre}=5′000 are adopted to calibrate the SP optimal density. A simulation with large sample size of N_{final}=25′000 is carried out to obtain the final reliability estimates, for a total of 50′000 structural analyses. Figure 2 shows the results for each aging scenario and time instant for first yielding (Figure 2a) and collapse (Figure 2b) limit states. Regarding first yielding, the most detrimental scenarios correspond to fast aging of end plastic moment M_p^- since scenario "fast-fast" almost overlaps with scenario "slow-fast". Faster degradation pace for midspan moment M_p^+ can lead to larger decay in collapse reliability.

4 TIME-VARIANT RELIABILITY OF A RC BRIDGE DECK

4.1 *Bridge properties and collapse probability*

Figure 3 shows the investigated two-span continuous RC bridge. Each span is l=30 m and it is subjected to both dead load G and live load Q (Figure 3a). The deck is characterized by box-girder cross-section (Figure 3b). The reinforcement layouts S1 and S2 respectively span over the outer deck segments close to the abutments and over the mid-support.

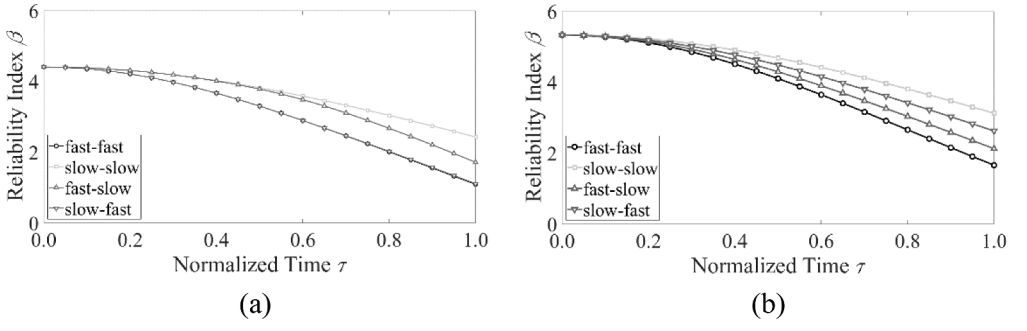

Figure 2. Time-variant reliability index for (a) first yielding and (b) collapse limit states.

The collapse load multiplier of the safety factor can be expressed in terms of the plastic hinge location along the span identified by the local abscissa $z_p \in [0,l]$. The collapse mechanism is retrieved by identifying the plastic hinge location that minimizes the load multiplier obtained by means of the kinematic theorem of limit analysis. Thus, the collapse safety factor Θ_c is:

$$\Theta_c = min_{z_p \in [0,l]} \left[\frac{M_p^- + M_p^+ \cdot \frac{l}{l-z_p}}{Q\frac{l \cdot z_p}{2}} - \frac{G}{Q} \right] \tag{16}$$

The bridge deck is exposed to a chloride diffusive attack that reduces in time the resisting moments $M_p^+(t)$ and $M_p^-(t)$ and, in turn, the collapse safety factor $\Theta_c(t)$ leading to a time-variant failure probability as follows:

$$p_c(t) = P[\Theta_c(t) \leq 1] \tag{17}$$

In pristine conditions, uncertainties are associated to loading conditions informing structural demand (i.e., dead load G and live load Q) and mechanical parameters informing structural capacity (i.e., steel yielding strength f_y and concrete compressive strength f_c). Table 3 summarizes the statistical descriptors of these four lognormally distributed and statistically independent random variables. The collapse probability in pristine conditions is evaluated with a state-of-the-art stand-alone CE-IS, leading to an initial reliability index of $\beta(t=0)=4.7057$.

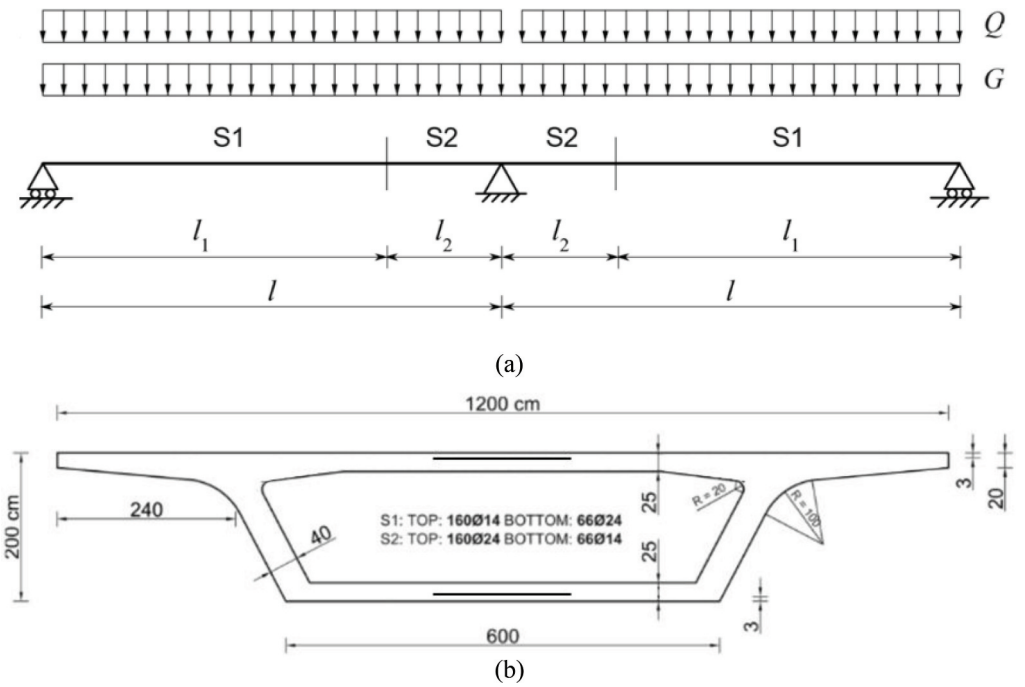

Figure 3. RC bridge: (a) deck static scheme; (b) box girder cross-section geometry and reinforcement.

Table 3. Statistical descriptors of random variables informing pristine structural demand and capacity.

Random Variable	Mean Value μ	Coefficient of Variation (CoV) δ
Dead Load G	100 kN/m	0.05
Live Load Q	150 kN/m	0.20
Steel Yielding Strength f_y	500 MPa	0.10
Concrete Compressive Strength f_c	45 MPa	0.20

4.2 *Corrosion model*

The corrosion initiation phase is governed by environmental aggressiveness and concrete properties. The 1D second Fick's law of diffusion is a suitable model to assess the evolution in time t of steel reinforcement characterized by net cover c from the external surface exposed to a constant concentration C_0:

$$C(c,t) = C_0 \cdot \left[1 - \mathrm{erf}\left(\frac{c}{2\sqrt{D(t)\cdot t}}\right)\right] \tag{18}$$

where erf(·) is the error function and $D(t)$ is concrete diffusivity defined in terms of reference diffusivity coefficient D_e, aging coefficient a, relative humidity RH and temperature T [°C] (Nava et al. 2023):

$$D(t) = D_e \cdot \left(\frac{0.076}{t}\right)^a \cdot \left[1 + \frac{(1-RH)^4}{(1-0.75)^4}\right]^{-1} \cdot e^{\left[\frac{40}{8.314\times10^{-3}}\left(\frac{1}{293}-\frac{1}{273+T}\right)\right]} \tag{19}$$

Corrosion initiates at time t_{cr} a critical concentration C_{cr} is attained at the reinforcing steel bar.

After corrosion onset, the propagation phase deals with the loss assessment of steel area A_s:

$$A_s(t) = [1 - \delta_s(t)] \cdot A_{s0} \tag{20}$$

where the damage index δ_s is the percentage of steel mass loss of a bar with pristine area A_{s0}. The corrosion penetration depth normalized by the diameter of the pristine steel bar ϕ_0 [mm] can be defined in terms of current density i_c [μA/cm^2] and pitting factor R_f (Capacci and Biondini 2022):

$$\delta(t) = \frac{0.0116 R_f}{\phi_0} \cdot \int_{t_{cr}}^{t} i_c(t)dt \quad \text{with } t \geq t_{cr} \tag{21}$$

The current density i_c is adapted from its reference value $i_{c,ref}$ based on temperature, relative humidity, chloride concentration and time from corrosion initiation (Nava et al. 2023):

$$i_c(t) = i_{c,ref} \cdot \left[\frac{0.85}{(t-t_{cr})^{0.29}}\right] \cdot [1 + K_T\ (T-20)] \cdot \left[e^{-6000(RH-0.75)^6}\right] \cdot \left[\frac{Cl(t)+Cl_{cr}}{2\ Cl_{cr}}\right] \tag{22}$$

where K_T=0.025 and 0.073 when temperature is T≤20°C and T>20°C, respectively. Finally, the damage index δ_s is then evaluated in terms of the normalized corrosion depth δ based on the hemispherical pit model proposed in Val and Melchers (1997).

In the proposed case study, the reinforcement layers at top and bottom slabs are subjected to chloride-induced corrosion and, assuming perfect correlation regarding the exposure scenario, steel mass loss of bottom slab reinforcement $\delta_{s,bot}$ and top slab reinforcement $\delta_{s,top}$ can be deterministically related. Therefore, the percentage of steel mass loss $\delta_{s,top}$=δ_s is representative of the bridge cross-section damage and, in turn, of the overall mechanical deterioration suffered by the structural system. Table 4 collects all information regarding random variables governing initiation (i.e., C_s, D_e, a, and C_{cr}) and propagation (i.e., $i_{c,20}$ and R_f). Constant temperature and relative humidity are assumed to be 20°C and 75%, respectively.

Table 4. Probabilistic model of random variables involved in the deterioration process.

Random Variable	Distribution	Mean Value μ	Std. Dev. σ
External Concentration C_0 [%wt./c]	Truncated Positive Normal	μ_C	0.30 μ_C
Reference Diffusivity D_e [10^{-12}m^2/year]	Truncated Positive Normal	μ_D	0.20 μ_D
Aging Parameter a [-]	Uniform Beta	0.30	0.12
Critical Concentration C_{cr} [%wt./c]	Bounded Beta ∈ [0.2-2.0]	0.60	0.15
Current Density at 20°C $i_{c,ref}$ [μA/cm^2]	Lognormal	2.586	1.724
Pitting Factor R_f [-]	Gumbel	7.1	0.17

4.3 *Results of CE-SP-IS methodology*

The CE-SP-IS method is applied to estimate the collapse probability every two years over 50 years of lifetime (i.e., n_t=25). Different environmental aggressiveness scenarios and design strategies for durability are investigated. Five scenarios of external chloride concentrations are investigated, with mean value μ_C increasing from 2.0%wt./c to 4.0%wt./c with steps of 0.5% wt./c and constant mean reference diffusivity μ_D=15·10^{-12}m^2/year. A similar parametric analysis is carried out considering μ_C=3.0%wt./c and five durability scenarios with mean reference diffusivity μ_D equally spaced from 10 to 20·10^{-12} m^2/year. Since one exposure scenario overlaps with one durability scenario, the total number of parametric scenarios is n_p=9 and the total number of structural reliability combinations is n_c=n_t·n_p=225.

The time-variant collapse probability can be evaluated based on the total probability theorem by superposing three components: (1) the pristine failure probability $p_c(t=0)$ scaled by the initiation time PDF $P_0(t)$, (2) the time-variant probability of full damage $P_1(t)$ characterized by certain failure, (3) and most importantly the time-variant failure probability with damage index in the interval between 0 and 1 $\tilde{p}_c(t)$ scaled by $P_\delta(t)$=1–$P_0(t)$–$P_1(t)$:

$$p_c(t) = P_0(t) \cdot p_c(t=0) + P_1(t) + P_\delta(t) \cdot \tilde{p}_c(t) \tag{23}$$

$$\tilde{p}_c(t) = [\Theta_c(t) \leq 1 | \delta_s \in (0,1)] \tag{24}$$

The numerical estimates of the collapse probabilities $\tilde{p}_c(t)$ are obtained by CE-SP-IS. Damage indices are sampled in the simulation space u_δ and transformed into their actual space δ_s as follows:

$$\delta_s = \frac{e^{u_\delta}}{1+e^{u_\delta}} \tag{25}$$

The damage indices δ_s in their actual space are necessary to evaluate the plastic moments adopted in limit analysis for the assessment of the indicator function I_i. Then, weighting coefficients w_i are computed in the simulation space exploiting the inverse transformation.

$$u_\delta = \log \frac{\delta_s}{1-\delta_s} \tag{26}$$

The time-variant actual PDFs of the damage indices in the simulation space $\psi(u_\delta)$ are estimated based on a Gaussian Kernel smoothing function calibrated by MCS involving the deterioration process. Also, $P_0(t)$, $P_1(t)$ and $P_\delta(t)$ are estimated based on such simulation, whilst the pristine failure probability $p_c(t=0)$ is estimated by CE-IS involving the time-invariant random variables (i.e., loading conditions and strength of materials).

The initial GM model constituted by K=20 densities with probability π_k=1/K. The components of mean vectors $\boldsymbol{\mu}_k$ associated to time-invariant random variables are simulated from the actual distribution with standard deviation scaled by σ=3 (Yang et al. 2017). The component of u_δ is analogously simulated from a standard normal variate with scaled standard deviation. The covariance matrices $\boldsymbol{\Sigma}_k$ are then initialized based on the same model adopted for mean vectors initiation.

Five rounds n_{iter}=10 of pre-sampling with N_{pre}=5·10^3 and final simulation with N_{final}=5·10^4, for a total of 10^5 analyses. Figure 4 shows the estimated time-variant collapse reliability indices for all investigated scenarios, spanning between 1.2 and 4.7. The structural reliability decay is more severe when the bridge is exposed to large chloride concentrations (Figure 4a) and larger concrete diffusivity (Figure 4b).

The benefit of CE-SP-IS can be measured by quantitative measures of the degree of estimate accuracy of the failure probability, such as the reliability estimator CoV (Capacci 2024). To give an idea of the accuracy improvement, estimating a reliability index β=4.7 with a CoV=20% by a single traditional MCS would require a sample size of N=(1-p_f)/(CoV^2·p_f)>10^7, which may be practically unfeasible for one out of the 225. The proposed approach leads to very accurate estimates, showing average and maximum CoV of respectively 0.6% and 4.6% over the 225 reliability problems. Therefore, the proposed methodology not only improves the accuracy for low probability estimates as other consolidated IS-based variance reduction techniques, but it also leads to such improvement for multiple reliability problems with a single simulation to explore different hazard scenarios and encompassing the structure lifetime.

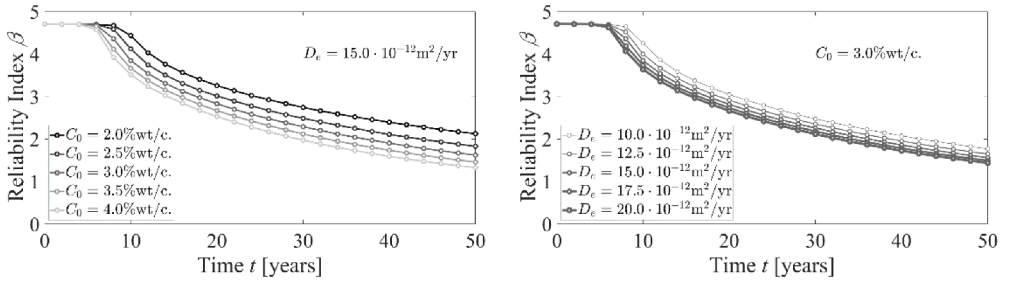

Figure 4. Time-variant collapse reliability index (a) exposure scenarios and (b) durability scenarios.

CONCLUSIONS

Stationary Proposal Importance Sampling (SP-IS) is a novel computational approach to efficiently estimate combinations of structural reliability problems for multiple hazard scenarios and limit states over the system lifetime. In this paper, SP-IS has been applied to aging structures such as a statically indeterminate beam and bridges exposed to chloride-induced corrosion under different environmental aggressiveness scenarios. The methodology is also fostered by a Cross-Entropy-based numerical approach to estimate the near-optimal simulation density to reduce the variance of the reliability estimators over the investigated combination of reliability problems.

The proposed technique is particularly suitable for problems involving time-consuming structural analyses. Typical examples are the calibration of time-variant seismic fragility curves for bridges exposed to chloride-induced corrosion (Capacci and Biondini 2022) and life-cycle seismic risk and resilience assessment of aging infrastructure lifelines such as bridge networks (Capacci 2024). Nonetheless, this approach can be adopted to aid life-cycle reliability-based optimal design of critical structures. Further insight should be devoted to addressing the effective benefit provided by the proposed methodology in comparison to traditional Monte Carlo approaches in terms of computational time and reliability estimator variance.

ABSTRACT: Assessment of hydrodynamic performance of the Submerged floating tunnel (SFT) under wave actions is one of the important factors in the design of the SFT. In this paper, an efficient and accurate theoretical hydrodynamic model is developed to analyze the global spatial dynamic response of the SFT under wave actions. The tube is treated as a more accurate BOEF model with three degrees of freedom, and the new calculation formula of cable-constraint reaction on the BOEF model is proposed. A numerical approach based on potential flow theory and a higher-order boundary element method (BEM) was developed to calculate the wave force on the SFT tube. The numerical results are successfully validated by direct comparison against published numerical data and the calculation results of the finite element model.

1 INTRODUCTION

Submerged floating tunnel (SFT), also known as Archimedes Bridge, is considered an innovative alternative to conventional bridges and underground or immersed tunnels for passing through waterways, lakes, and rivers. A typical SFT generally involves several segments of tubes, which are confined at a certain distance from the sea bed due to residual buoyancy, an anchoring system to restrain large motions of the tube, and revetment structures that act as the connecting device to the shores [1,2]. Since the concept was brought forward, exploration of theoretical methods, small-scale experimental studies and verification, and no prototype has yet been built [3].

Several researchers have performed analyses and experiments for SFT under wave actions. Examples include global performance analysis focused on cable tension and tunnel displacements carried out by Kunisu et al. [4], which disclosed direct proportionality between wave height and cable tension. Remseth et al. [5] discussed the stochastic dynamic response of an SFT to wind-driven waves and time domain earthquake analysis with particular emphasis on fluid-structure interaction. Xu et al. [6] studied the effects of structure parameters on dynamic responses of SFT based on the hydrodynamic environment of Qiandao Lake by an empirical formula called the Morison equation [7]. Xiang and Chao. [8] also applied the Morison equation to solve the fluid force acting on the cables of the SFT, and established a theoretical model for coupled tube-cable vibration to evaluate the SFT structural dynamic response to water current. Oh et al. [9] studied the dynamic response of the SFT with the vertical and inclined mooring cable under the action of regular waves through the physical experimental method. For a simple but accurate estimation of hydrodynamic forces, a theoretical method is proposed by Seo et al. [10] and the tests with physical models in a wave flume were carried out for verification. Luo et al. [11] developed a theoretical hydrodynamic model to describe the coupled dynamic response of a SFT and the cable under regular waves. In this model, wave-induced hydrodynamic loads are estimated by the Morison equation for a moving object. Computational fluid dynamics (CFD) is the analysis of systems involving fluid flow, heat transfer, and

DOI: 10.1201/9781003483755-118

associated phenomena using computer-based simulation, which has been widely used in many offshore engineering fields, such as coastal bridges and offshore platforms [12]. Zou et al. [13] simulated the oceanic internal solitary wave's generation and propagation using the CFD software FLUENT to study the mechanism of interaction between the internal solitary wave and the SFT. At the same time, the cross-section of the SFT tube is optimized by using an artificial neural network and genetic algorithm. Yang et al. [14, 29] developed the vehicle-SFT-current coupling spatial vibration equation based on the Hamilton's principle and Galerkin hybrid method, and further discussed the vehicle-SFT-current coupling vibration.

The traditional empirical formula Morison equation is usually applicable to the calculation of wave forces for small-scale structures, but it cannot guarantee the accuracy of the calculation results for large-scale structures. Although the general CFD method can guarantee the accuracy of calculation, it is difficult to guarantee the solving efficiency. So, some researchers use numerical methods based on potential flow theory to calculate wave forces on large-scale structures. Paik et al. [15] and Ge et al. [16] performed analyses on the fluid-structure interaction of the SFT in wave field by boundary element method (BEM) implementing potential flow theory and investigated dynamic response characteristics of the SFT. Kunisu [17] evaluated the wave forces based on the two-dimension diffraction theory by BEM, and the effects of the size and the shape of the SFT on the wave forces are discussed. Ti et al. [18] developed a numerical approach based on three-dimensional potential flow theory in the frequency domain to study the interaction between surface waves and a flexible bridge pier. A full time-domain two-dimensional numerical model was established by Jin et al. [19] for the coupled dynamic analysis of the SFT structures and a higher-order BEM was applied to discretize the body boundary and the free surface boundary. Huang et al. [20] proposed an analytical method to estimate random wave forces on the box-girder superstructure based on the potential flow theory and the correction parameters, and explore the influence of the peak frequency of the incident wave spectra and the structural configuration on the hydrodynamic performance of the submerged box-girder superstructure.

The finite element method (FEM) or classical dynamics theory is usually used to calculate the tube motion of the SFT under external load. Xiang et al. [21,22] and Lin et al. [23,24] simplified the model of the SFT by using the mathematical analogy method as a beam on an elastic foundation (BOEF) and investigated the global dynamic response of the SFT subjected to external impact, cable break, and vehicle passage. However, the BOEF model proposed by Xiang et al. [21,22] does not consider the wave actions, and the coupling relationship between horizontal displacement and torsional displacement of the SFT tube is not fully considered for the cable-constraint reaction in the BOEF model. Thus, it may not be suitable for the case of large horizontal and torsional displacement of the SFT tube, and needs to be further improved under the wave actions.

Based on the previous research, this paper presents an efficient and accurate theoretical hydrodynamic model in the frequency domain to analyze the global spatial dynamic response of the SFT under linear waves. The new calculation formula of cable-constraint reaction on the BOEF model is proposed, which fully takes into account the coupling relationship between horizontal displacement and torsional angle of the SFT tube due to the constraint effect of the cable, and more suitable for the case where the SFT tube has relatively obvious horizontal displacement or torsional angle. A numerical approach based on potential flow theory and a higher-order BEM was developed to calculate the wave force on the SFT tube. The numerical results are successfully validated by comparisons against published numerical data and the calculation results of the FEM model. On this basis, the effects of the environment and structural parameters on the dynamic response of the SFT under linear waves are studied.

2 THEORETICAL ANALYSIS METHOD

2.1 *Basic assumption and simplified model*

Figure 1 shows a typical SFT structure and the coordinate system. In a global analysis, the cables can be generally regarded as discrete elastic supports with a certain stiffness. To

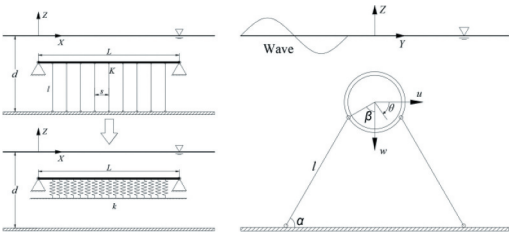

Figure 1. A simplified model of the SFT and the coordinate system.

simplify the SFT model, the cable is assumed to be of the same length, arrangement, material, and spacing, and the SFT tube is considered a BOEF model when the stiffness of the anchoring system and the rigidity of the tube meet the relation of Eq. (1) [25,26].

$$\frac{Ks^3}{24EI} \leq 0.05 \tag{1}$$

Where K is the anchoring stiffness of a pair of cables; s is the longitudinal interval of cable, and the rigidity of the elastic foundation after transforming is uniformly distributed within the interval; EI is the flexural rigidity of the tube. To analyze the tube coupling spatial vibration due to periodic wave action, three further assumptions are given as follows: (a) The tube is a simply-supported Euler-Bernoulli beam with constant sections and equal stiffness. The displacements in the Y and Z directions and the torsion with respect to the X axis are considered. (b) Only the elastic vibration of the SFT tube is considered and assumed that the vibration is small relative to the length of the SFT tube [21]. (c) The incident wave is linear and propagates toward the positive Y-axis. The steady-state wave motion and the structural responses are all harmonic with the same frequency ω under the linear approximation [27].

2.2 *Governing equation of the wave motion in the frequency domain*

In order to obtain an accurate and efficient analysis method for the dynamic response of the SFT, the wave forces on the SFT tube are calculated using the potential flow theory, and the wave forces of the cable are ignored. From the perspective of potential flow theory, the fluid is assumed as an ideal, incompressible, and irrotational material. In addition, the size of the tube length direction of the SFT is much larger than the size of the SFT cross-section, and the vibration of the SFT tube is small compared with the length of the SFT tube. Therefore, two-dimensional linear potential flow theory can be used to solve the wave forces. There is a velocity potential Φ(y, z, t; x) that satisfies the Laplace equation.

The spatial complex velocity potential $\varphi(y, z; x)$ also satisfies the Laplace equation and is subjected to the boundary conditions applied on the seabed, the still water surface, the mean body surface, and far-field, respectively, as:

$$\begin{aligned} &\nabla^2\varphi(y,z;x) = 0 \\ &\begin{cases} \frac{\partial\varphi}{\partial z} = 0 \ (z=-d), \ \text{seabed boundary} \\ \frac{\partial\varphi}{\partial \boldsymbol{n}} = v(y,z;x) \ (\boldsymbol{r}=\partial\Omega_o), \ \text{mean body surface boundary} \\ \frac{\partial\varphi}{\partial z} - \frac{\omega^2}{g}\varphi = 0 \ (z=0), \ \text{still water surface boundary} \\ |\nabla\varphi| < \infty \ (y\to\infty), \ \text{far}-\text{field boundary} \end{cases} \end{aligned} \tag{2}$$

Where d is water depth; $\boldsymbol{n}$ is the normal unit vector of the mean body surface pointing out of the fluid; Ω is all flow field area; $\partial\Omega_o$ represents mean body surface; $\boldsymbol{r}$ is radius vector (x, y, z); v $(y, z; x)$ is the spatial complex velocity of fluid particles in the $\boldsymbol{n}$ direction on the mean body surface; g is the gravitational acceleration. According to the linear characteristics of the above definite solution problem, The spatial complex velocity potential of the wave around the flexible SFT tube is the combination of incident potential (φ_i), diffraction potential (φ_d), and radiation potential (φ_r).

2.3 *Solving the velocity potential and calculating the wave forces of the SFT tube*

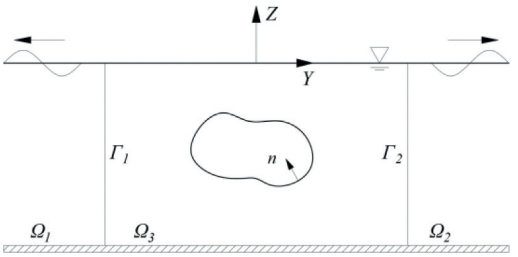

Figure 2. The schematic diagram of calculation of diffraction potential and radiation potential.

Before calculating the wave forces on the SFT tube, the definite solution problems satisfied by φ_d, φ_{u1}, φ_{w1}, and $\varphi_{\theta 1}$ should be solved first. However, due to the irregular shape of the boundary, it is difficult to find analytical solutions for the above velocity potentials. By discretizing the body surface into a finite number of panels, the BEMs provide numerical alternatives to approximate the hydrodynamic solutions for structures with arbitrary geometry [28]. The computational area of the numerical approximation method must be finite, thus the flow field is divided into three regions as shown in Figure 2. Region 3 (Ω_3) is the calculation region, and Region 1 (Ω_1) and Region 2 (Ω_2) are the far-field regions, respectively. Γ_1 and Γ_2 are the interfaces between the calculation region and the far-field region. According to the linear potential flow theory, when the interface is far away from the object surface, the non-propagating term in the potential function can be ignored.

$$\begin{cases} \frac{\partial \varphi_3}{\partial x} + ik\varphi_3 = 0, & (\boldsymbol{r} = \Gamma_1) \\ \frac{\partial \varphi_3}{\partial x} + ik\varphi_3 = 0 & (\boldsymbol{r} = \Gamma_2) \end{cases} \tag{3}$$

Where φ_3 represents one of φ_d, φ_{u1}, $\varphi_{w1,}$ or $\varphi_{\theta 1}$ in the Ω_3. The higher-order BEM associated with Green's function is employed as the solution algorithm to solve the unknown potential function in the Ω_3. Then, The dynamic pressure can be obtained by using the linearized Bernoulli's equation:

$$-\frac{1}{\rho}P(y,z,t;x) = \frac{\partial \Phi}{\partial t} = \frac{\partial}{\partial t}\mathrm{Re}\left[\varphi(y,z;x)e^{-i\omega t}\right] = \mathrm{Re}\left[-i\omega\varphi(y,z;x)e^{-i\omega t}\right] \tag{4}$$

Where $P(y, z, t; x)$ is dynamic pressure in local point (x, y, z) at time t; ρ is the fluid density. Then the wave forces can be expressed as:

$$\begin{cases} F_{fu}(x,t) = \int\limits_{\partial\Omega_o} P \cdot n_y \mathrm{d}s = \mathrm{Re}\left[\int\limits_{\partial\Omega_o} i\omega\rho\varphi n_y \mathrm{d}s \cdot e^{-i\omega t}\right] \\ F_{fw}(x,t) = \int\limits_{\partial\Omega_o} -P \cdot n_z \mathrm{d}s = \mathrm{Re}\left[-\int\limits_{\partial\Omega_o} i\omega\rho\varphi n_z \mathrm{d}s \cdot e^{-i\omega t}\right] \\ F_{f\theta}(x,t) = \int\limits_{\partial\Omega_o} P \cdot (zn_y - yn_z)\mathrm{d}s = \mathrm{Re}\left[\int\limits_{\partial\Omega_o} i\omega\rho\varphi(zn_y - yn_z)\mathrm{d}s \cdot e^{-i\omega t}\right] \end{cases} \tag{5}$$

Where $F_{fu}(x, t)$, $F_{fw}(x, t)$, and $F_{f\theta}(x, t)$ are the horizontal, vertical, and torsional wave forces per unit length of the tube, respectively. According to the assumption in the above section, the wave forces on the structure are also harmonic, and they can also be denoted as:

$$\begin{cases} F_{fu}(x,t) = \mathrm{Re}[f_u(x)e^{-i\omega t}] \\ F_{fw}(x,t) = \mathrm{Re}[f_w(x)e^{-i\omega t}] \\ F_{f\theta}(x,t) = \mathrm{Re}[f_\theta(x)e^{-i\omega t}] \end{cases} \tag{6}$$

Since the curve integral in the above equation can be calculated as a definite number, for convenience, the above equation can be denoted as:

$$\begin{cases} f_u(x) = A_u + v_u B_u + v_w C_u + v_\theta D_u \\ f_w(x) = A_w + v_u B_w + v_w C_w + v_\theta D_w \\ f_\theta(x) = A_\theta + v_u B_\theta + v_w C_\theta + v_\theta D_\theta \end{cases} \tag{7}$$

The wave forces at each point of the SFT tube can be calculated by using Eqs. (6) and (7) according to the vibration amplitude of the SFT tube, v_u, v_w, and v_θ.

2.4 *The cable stiffness of the BOEF model*

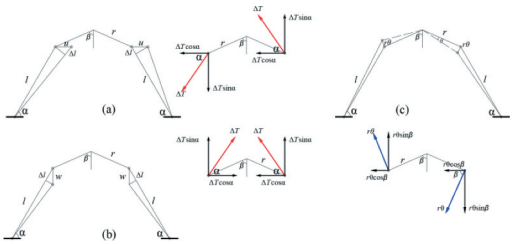

Figure 3. Constraint reaction of the cable due to tube displacement. (a) horizontal displacement; (b) vertical displacement; (c) Torsional displacement.

For discrete elastic supports, the constraint reaction of the cable due to tube displacement with three directions is shown in Figure 3. According to the geometric relation, the stress-strain relation of axial force, Hooke's law, and the symmetric principle, the cable-constraint reaction generated by the horizontal displacement of the SFT tube can be obtained:

$$\Delta T = \frac{E_c A_c \cos\alpha}{l} u \tag{8}$$

For the BOEF model, the constraint reaction of the cable can be evenly distributed in the direction of the SFT tube axis. Thus, the constraint reaction of the cable for the BOEF model due to tube displacement can be expressed as follow:

$$\begin{pmatrix} F_{eu} \\ F_{ew} \\ F_{e\theta} \end{pmatrix} = \begin{bmatrix} k_u & 0 & k_u r(\tan\alpha \sin\beta - \cos\beta) \\ 0 & k_w & 0 \\ k_u r(\tan\alpha \sin\beta - \cos\beta) & 0 & k_\theta - 2k_u r^2 \tan\alpha \sin\beta \cos\beta \end{bmatrix} \begin{pmatrix} u \\ w \\ \theta \end{pmatrix} \tag{9}$$

Where F_{eu}, F_{ew}, and $F_{e\theta}$ are the constraint reaction of the cable of the BOEF model in the horizontal, vertical, and torsional directions per unit length of the SFT tube, respectively.

2.5 *Governing equation of the SFT tube and its solution*

Based on the simplified calculation model in the previous sections, Hamilton Principle is applied to establish the tube-wave coupling spatial vibration equations of the SFT:

$$\delta \int_{t_1}^{t_2} (T - V + W) \mathrm{d}t = 0 \tag{10}$$

The kinetic energy of the tube while moving and twisting can be written as Eq. (11), and a schematic diagram for the positive displacements in three directions of the tube is displayed in Figure 1.

$$T = \frac{1}{2} m_0 \int_0^L \left[\left(\frac{\partial u(x,t)}{\partial t} \right)^2 + \left(\frac{\partial w(x,t)}{\partial t} \right)^2 + a^2 \left(\frac{\partial \theta(x,t)}{\partial t} \right)^2 \right] \mathrm{d}x \tag{11}$$

Where m_0 is the mass per unit length of the tube; L is the span of the SFT; a is the radius of gyration of the tube section. The strain energy of the tube can be represented as Eq. (12).

$$V = \frac{1}{2} \int_0^L \left[EI_w \left(\frac{\partial^2 u(x,t)}{\partial x^2} \right)^2 + EI_u \left(\frac{\partial^2 w(x,t)}{\partial x^2} \right)^2 + GI_p \left(\frac{\partial \theta(x,t)}{\partial x} \right)^2 \right] \tag{12}$$

Where E and G are the elastic modulus and shear modulus of the tube, respectively; I_u and I_w are the moments of inertia of the tube section around the Y axis and Z axis; I_p is the torsional moment of inertia of the tube section. The work of external forces, W, consists of the elastic foundation constraint reaction force, structural damping effect, and wave force, denoted by W_1, W_2, and W_3 respectively as follows:

$$\begin{cases} W_1 = \int_0^L \left[-F_{eu} u(x,t) - F_{ew} w(x,t) - F_{e\theta} \theta(x,t) \right] \mathrm{d}x \\ W_2 = \int_0^L \left[-c_u \frac{\partial u}{\partial t} u(x,t) - c_w \frac{\partial w}{\partial t} w(x,t) - c_\theta \frac{\partial \theta}{\partial t} \theta(x,t) \right] \mathrm{d}x \\ W_3 = \int_0^L \left[F_{fu} u(x,t) + F_{fw} w(x,t) + F_{f\theta} \theta(x,t) \right] \mathrm{d}x \end{cases} \tag{13}$$

Where c_u, c_w, and c_θ are the damping coefficients of the tube in three directions based on the structural material parameter; F_{fu}, F_{fw}, and $F_{f\theta}$ are the horizontal, vertical, and torsional wave forces per unit length of the tube, respectively. The differential equations for three motion components of the SFT tube under wave forces can be obtained. The natural vibration mode can be further simplified as follows:

$$\begin{cases} u(x,t) = \mathrm{Re} \left[\sum_{n=1}^{\infty} U_n \sin \frac{n\pi x}{L} e^{-i\omega t} \right] \\ w(x,t) = \mathrm{Re} \left[\sum_{n=1}^{\infty} W_n \sin \frac{n\pi x}{L} e^{-i\omega t} \right] \\ \theta(x,t) = \mathrm{Re} \left[\sum_{n=1}^{\infty} \Theta_n \sin \frac{n\pi x}{L} e^{-i\omega t} \right] \end{cases} \tag{14}$$

3 NUMERICAL EXAMPLE AND MODEL VERIFICATION

3.1 *Convergence analysis of the proposed method*

The feasibility of the proposed theoretical method depends on the number of vibration modes used in the analysis. Lower modes cannot reflect the vibration characteristics of the structure, but higher modes tend to be less reliable in the vibration. Figure 4(a) shows the horizontal displacements at each point of the SFT tube with a different number of vibration modes. The results obtained by the proposed method with the first nine modes and the first eleven modes are almost the same. Therefore, the first eleven modes of the SFT are adopted in the analysis to ensure computational efficiency and reasonable results. At the same time, as discussed above, the accuracy of solving the velocity potential also depends on the division of the calculation region. For a small computing region, the influence of non-propagating terms cannot be eliminated at the boundary of the region interface, and the calculation accuracy cannot be guaranteed. However, computing resources will be seriously wasted if the computing region is too large. Figure 4(b) shows the horizontal displacements at the position of the longitudinal direction of the SFT tube with different distances (Rc) of from the center of the tube. It's not hard to see that Rc=40 m gives almost the same result as Rc=48 m. Therefore, when Rc is

greater than 48 m, the influence of non-propagating terms on the calculation results can be eliminated to ensure the accuracy of the results.

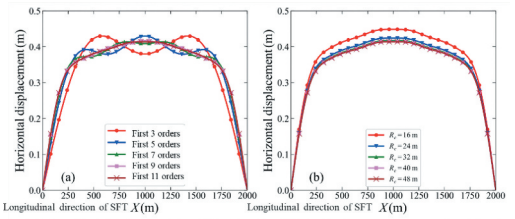

Figure 4. The convergence of the analysis results with the number of modal order terms (series terms) or the convergence of the analysis results.

Accurate calculation of the wave force is the key to obtaining the precise dynamic response of the SFT tube using the proposed method. The proposed method based on the potential flow theory and BEM approximation is validated firstly by the classical problem conducted by Mei and Black [30], and they investigated the transmission coefficient, reflection coefficient, and horizontal and vertical linear wave forces on the rectangular structure. Based on the calculating wave forces part of the proposed method, the dimensionless horizontal, vertical linear wave forces and dimensionless wave moment on the rectangular structure are calculated and compared with the research results conducted by Mei and Black [30] and Li and Teng [31], which is shown in Figure 5. It shows that the wave forces and wave moment based on the proposed BEM approximation method agree very well with the analytical results from Mei and Black [30], which indicates that the estimation of the wave forces and wave torque on the structure using the BEM approximation method is accurate and reliable.

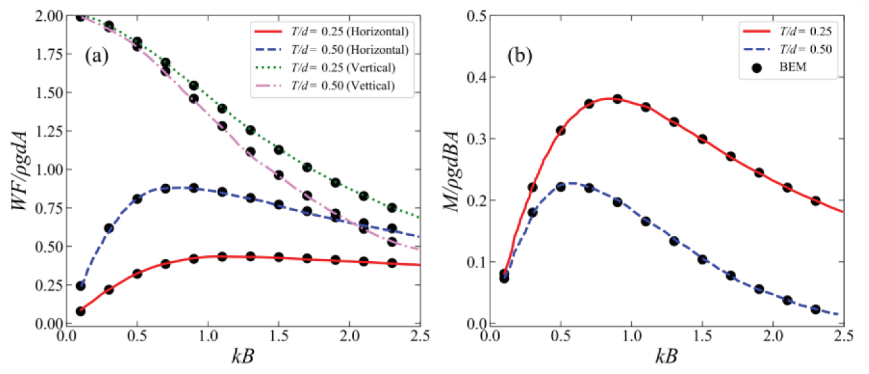

Figure 5. Comparison of nondimensional horizontal and vertical wave forces (a) and dimensionless wave torque (b). The line represents the analytical result conducted by Mei and Black (1969), and the solid point represents the BEM approximate calculation result in this paper.

A finite element analysis (FEA) is conducted to verify the accuracy and applicability of the BOEF model of the theoretical method in this paper. The commercial FEA software, ABAQUS 2020, is used to simulate the vibration process of the SFT, and the dynamic analysis is performed within ABAQUS/Modal dynamics. The basic parameters of the FEA model are the same as the theoretical method, as given in the study conducted by Huang et al. [32]. In the model, the tube of the SFT is modeled with the beam element B31, and the cables are modeled with the truss element T3D2. The connection between the installation point of the cable and the centroid of the SFT section is the MPC/beam. The FEA model is divided into 2,077 nodes and 2,038 elements. When the vibration of the SFT tube reaches a steady state, the wave forces calculated by theoretical methods will be extracted and loaded onto the FEA model in the form of

distributed loads. The maximum horizontal, vertical and torsional displacements at each point of the SFT tube using the BOEF and FEA method are shown in Figure 6.

The SFT tube will produce obvious horizontal displacement under the wave forces. For the wave environments, this study presents a new equation (Eq. (22)) for calculating the constraint reaction of the cable of the BOEF model (called the improved cable-constraint reaction), which is improved from Xiang and Yang [21]. Therefore, Figure 6 also shows the comparison of the calculation results between using the improved cable-constraint reaction and the cable-constraint reaction given by Xiang and Yang [21]. As can be seen from Figure 6, the results calculated by using the improved cable-constraint reaction are in good agreement with those calculated by the FEA model. However, the horizontal and torsional displacements that calculated by using the cable-constraint reaction of Xiang and Yang [21]. are quite different from those calculated by the FEA model. This is because the coupling effect of the horizontal and torsional displacements of the SFT tube under the constraint of the cable increases the displacements in the two directions. Therefore, when the SFT tube appears obvious horizontal or torsional displacement under the action of external wave force, the dynamic response of the SFT tube in the horizontal and torsional directions calculated by using the cable-constraint reaction of Xiang and Yang [21] may be smaller than the actual situation. The calculation results show that the BOEF model using the improved cable-constraint reaction proposed in this paper is accurate and effective, and can be applied to the case of large horizontal and torsional displacement, such as wave environment, horizontal impact, large eccentric vehicle load, and so on.

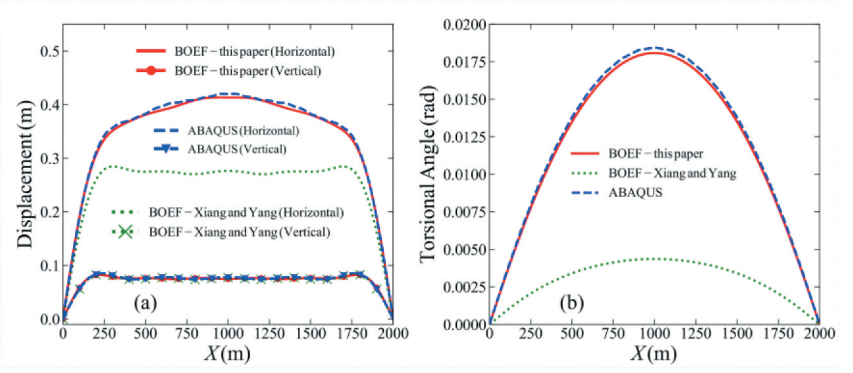

Figure 6. Maximum horizontal, vertical (a), and torsional (b) displacements at each point of the SFT tube.

4 CONCLUSIONS

In this study, an efficient and accurate theoretical hydrodynamic model in the frequency domain is proposed to analyze the global spatial dynamic response of the SFT under linear waves. The calculation results are successfully validated by direct comparison against published numerical data and the calculation results of the FEM model. The main conclusions are as follows:

(1) The proposed theoretical hydrodynamic model based on the BOEF model, potential flow theory, and BEM is efficient and accurate in calculating the dynamic response of the SFT tube under wave actions.
(2) Under the action of periodic wave forces, the peak bending moment and vertical displacement of the SFT tube generally appear near the two ends of the SFT tube, while the peak torsional angle and horizontal displacement generally appear in the midspan position after the SFT tube vibration is stabilized.

Dynamic substructuring technique for submerged floating tunnels

S. Corazza, F. Foti & L. Martinelli
Department of Civil and Environmental Engineering, Politecnico di Milano, Italy

ABSTRACT: Seabed-anchored Submerged Floating Tunnels (SFTs) are structures made of watertight tubular segments, assembled, and kept floating under the water table by a spread system of anchoring elements connected to the seabed. Due to their inherent flexibility, SFTs are prone to the effect of dynamic loads such as seismic and hydrodynamic loads. These peculiar features have since long lead to the assessment of the SFTs' dynamic response by resorting to the simplified model of a beam on an elastic foundation. This amounts to totally neglect the mass of the anchoring elements and, therefore, their local vibration modes. In this work, the mooring system is modeled as a discrete series of taut-strings possessing axial extensibility, while the tunnel is considered as a continuous Euler-Bernoulli beam. Within this modeling choices, a dynamic substructuring technique is presented and used to obtain both the natural circular frequencies and the mode shapes of the coupled system.

1 INTRODUCTION

Submerged Floating Tunnels (SFTs) are an interesting alternative to long-span bridges and immersed tunnels for crossing deep waterways. Their origin can be traced back to the first patents granted in Norway in 1923-1947 (see (Jacobsen 2010)). Even though a first realization is still missing, preliminary design proposals have been developed for sea straits, fjords and lakes (see, e.g. (Ahrens 1997), (Bruschi et al. 1990)). A distinctive feature of the dynamic behavior of SFTs is the presence of both global vibration modes, that involve significant displacements of the tunnel and quasi-static displacements of the anchoring elements, and local modes, that mainly involve transverse vibrations of the anchors. Dominant global and local modes of the structure are typically associated to well-separated values of the natural frequencies. However, computationally efficient Finite Element (FE) models able to simultaneously capture the main features of both global and local vibration modes with the same degree of accuracy, are inherently hard to set up. To overcome this difficulty, a dynamic substructuring technique for SFTs is here presented. A separate modeling of the two main substructures (i.e. the tunnel and the mooring system) is employed, involving (1) a Reduced Order Model (ROM) of the anchoring elements, which accounts for a generic form of support motion, and (2) a continuous model of the tunnel, which relies on the well-known Euler-Bernoulli beam theory. Within this context, undamped free vibrations of the coupled system are studied, evidencing the influence of a variable mooring stiffness profile on the mode shapes of the SFT, and shedding light on the effect of the mooring system's mass on the global response of the structure. As an illustrative example, the aforementioned approach is applied to the SFT proposal for the Messina's strait crossing, in Italy. On this behalf, the classification of the SFT motion regimes is investigated with regards to the spectral description of hydrodynamic loads, that are assumed to be representative of both service life conditions of the structure and extreme events. The paper is organized as follows: the modeling of the two substructures is presented in Section 2, then the global equations of motion of the SFT are derived in Section 3.

DOI: 10.1201/9781003483755-119

An application example regarding the proposal for the Messina's strait SFT is presented in Section 4, while the conclusions of the work are drawn in Section 5.

2 SUBSTRUCTURES MODELING

2.1 *Preliminaries*

Let us refer to Figure 1a, and consider a tether inclined with an angle θ with respect to the horizontal plane, having initial chord length L_0, external diameter D_o, mass per unit of length γ_s, axial stiffness EA_0 and subject to a static tension $T_0 > 0$ (i.e. a pretension). It is also convenient for the following developments to introduce the non-dimensional load parameter as $\eta_0 = T_0/T_y$, where $T_y = f_y A_0$ is the yielding tensile force and f_y is the yielding stress of the material. The non-dimensional load parameter is directly proportional to the Buoyancy-to-Weight Ratio (BWR) of the tunnel. Moreover, in the case of the vibrations of submerged anchoring elements, the structural linear mass should be modified to account for the mass of the fluid which is moved due to the presence of the anchoring element itself (i.e. the so-called added mass), resulting in "virtual" mass per unit of length given by:

$$\gamma_v = \gamma_s + C_A \gamma_w \tag{1}$$

where γ_w denotes the linear mass of the water moved by a "section" of the tether (i.e. $\gamma_w = \rho_w \pi D_o^2/4$) and C_A denotes the added-mass coefficient, which depends on the cable cross-section. In the case of a circular cross-section, the unit value is usually adopted (i.e. $C_A = 1$) (see, e.g. (Chakrabarti 1987)).

2.2 *Reduced-order model of the anchoring elements*

the anchoring elements of the mooring system are described according to a slightly modified version of the classical taut-string model. Indeed, sag effects and geometrical nonlinearities are neglected, while axial extensibility is accounted for in the present work. It is worth noticing that the well-known elasto-geometric Irvine's parameter (often denoted as λ^2), which is introduced when dealing with the small-sag cable theory, is strictly equal to zero for the present modeling choice, being the initial static configuration coincident with the reference (undeformed) configuration, i.e. the chord of the tether. Let us denote with u_a and w_a the interface-degrees of freedom associated to the top support motion of the anchoring element, according to a classical dynamic substructuring framework, and collect them in a vector $\boldsymbol{r}^k = [u^k{}_a,\ w^k{}_a]^{\mathrm{T}}$, where the superscript k denotes the generic k-th anchoring element. The work-conjugated quantities to the support displacements are the interface forces Fu_a and Fw_a, which can be casted in the following vector: $\boldsymbol{R}^k = [Fu_a{}^k,\ Fw_a{}^k]^{\mathrm{T}}$. In this work, the bottom support is kept fixed to the seabed; however, generalization of the proposed approach to account for soil-structure interaction phenomena is straightforward.

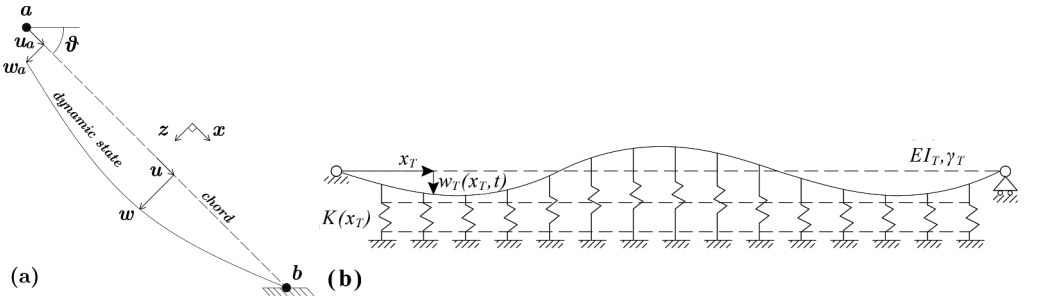

Figure 1. Schematic representation of a generic anchoring element (a), schematic representation of the SFT modeled as an Euler-Bernoulli beam on a Winkler's bed (b).

By following the approach proposed by (Warnitchai et al. 1995), the total motion of the anchoring element is decomposed in a quasi-static component (superscript q) and a modal component (superscript m). The longitudinal and transverse displacement respectively reads:

$$u(x,t) = u^q(x,t) + u^m(x,t) \tag{2}$$

$$w(x,t) = w^q(x,t) + w^m(x,t) \tag{3}$$

At this stage, the quasi-static component of the motion can be related to the support displacements by means of suitable shape functions, whereas the modal part can be expressed as a function of time-varying modal coordinates. Moreover, the axial modal motion can be neglected, being the frequencies of such motion much higher than the ones associated to the flexural motion, i.e.: $u^m(x,t) \ll w^m(x,t)$. One then has:

$$w(x,t) = \sum\nolimits_{s=1}^{N_r} \psi_{w,s}(x) r_s(t) + \sum\nolimits_{m=1}^{M} \phi_m(x) z_m(t) \tag{4}$$

$$u(x,t) = \sum\nolimits_{s=1}^{N_r} \psi_{u,s}(x) r_s(t) \tag{5}$$

The shape functions of the quasi-static component of the motion (i.e. $\psi_{w,s}$ and $\psi_{u,s}$) are linear functions of the interface degrees of freedom r_s, i.e. the entries of the vector $\boldsymbol{r}^k$ (being N_r the total number of interface degrees of freedom. In this case $N_r = 2$), while the modal shape functions are selected as the fixed-base eigenmodes of the taut-string (see e.g. (Irvine 1981)):

$$\phi_m(x) = \sin\frac{m\pi x}{L_0} \tag{6}$$

According to a classical lagrangian approach, the kinetic and potential energy of the generic anchoring element can be respectively expressed as:

$$\mathrm{K}(t) = \frac{1}{2}\gamma_v \int_0^{L_0} \left[\left(\frac{\partial u}{\partial t}\right)^2 + \left(\frac{\partial w}{\partial t}\right)^2 \right] dx \tag{7}$$

$$V(t) = \frac{1}{2} EA_0 \int_0^{L_0} \varepsilon^2(x) dx + \frac{1}{2} T_0 \int_0^{L_0} \left[\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial w}{\partial x}\right)^2 \right] dx \tag{8}$$

where, by denoting with an apex the total derivative operator, the axial strain reads:

$$\varepsilon(x) = \frac{\partial u(x,t)}{\partial x} = \sum\nolimits_{s=1}^{N_r} \psi'_{u,s}(x) r_s(t) \tag{9}$$

Substitution of Equations (4), (5) and (9) into Equations (7) and (8) straightforwardly leads to the identification of the entries of both mass and stiffness matrices. The undamped equation of motion (in partitioned form) of the k-th anchoring element simply reads:

$$\begin{bmatrix} \boldsymbol{M}^k{}_{rr} & \boldsymbol{M}^k{}_{rz} \\ \boldsymbol{M}^k{}_{zr} & \boldsymbol{M}^k{}_{zz} \end{bmatrix} \begin{bmatrix} \ddot{\boldsymbol{r}}^k \\ \ddot{\boldsymbol{z}}^k \end{bmatrix} + \begin{bmatrix} \boldsymbol{K}^k{}_{rr} & \boldsymbol{K}^k{}_{rz} \\ \boldsymbol{K}^k{}_{zr} & \boldsymbol{K}^k{}_{zz} \end{bmatrix} \begin{bmatrix} \boldsymbol{r}^k \\ \boldsymbol{z}^k \end{bmatrix} = \begin{bmatrix} \boldsymbol{R}^k \\ \boldsymbol{F}^k{}_z \end{bmatrix} \tag{10}$$

where $\boldsymbol{z}^k$ is vector containing the modal coordinates of the k-th anchoring element, i.e.: $\boldsymbol{z}^k = [z_1,\ldots,z_m,\ldots,z_M]^{\mathrm{T}}$ and $\boldsymbol{F}^k{}_z = [F_1,\ldots,F_m,\ldots,F_M]^{\mathrm{T}}$ is the vector of modal generalized loads, whose components can be obtained through a direct projection on the modal basis of the external forces (e.g. hydrodynamic loads) acting on the k-th element.

2.3 *Tunnel modeling strategy*

The tunnel is modeled as a Euler-Bernoulli beam. Let us denote with L_T and D_T, respectively, the total length of the tunnel and its external diameter, with EI_T its flexural stiffness, and with γ_T its mass per unit of length, which is comprehensive of the added mass of the water moved by the tunnel itself (i.e. $\gamma_T = \gamma_{sT} + \rho_w \pi D_T^2/4$). Then, the vertical (i.e. in-plane, w_T) and horizontal (i.e. out-of-plane, v_T) displacements can be expanded in the modal basis of the decoupled tunnel (free-interface modes):

$$w_T(x_T, t) = \sum_{n=1}^{N_{in}} \phi_n(x_T) q_n(t) \tag{11}$$

$$v_T(x_T, t) = \sum_{n=1}^{N_{out}} \phi_n(x_T) p_n(t) \tag{12}$$

where q_n and p_n denote, respectively, the in-plane and out-of-plane generalized displacements, N_{in} and N_{out} denote, respectively, the in-plane and out-of-plane number of retained basis functions, and:

$$\phi_n = \sin \frac{n\pi x_T}{L_T} \tag{13}$$

being $x_T \in [0, L_T]$ an abscissa spanning the longitudinal dimension of the tunnel (see Figure 1(b)). Entries of both mass and stiffness matrices of the bare tunnel can be easily computed by resorting to classical expressions (see e.g. (Foti et al. 2023)). The undamped equation of motion of the tunnel reads:

$$\boldsymbol{M_T}\ddot{\boldsymbol{q}}_T + \boldsymbol{K_T}\boldsymbol{q}_T = \boldsymbol{F_T} - \sum_{k=1}^{N_A} \boldsymbol{\Phi}_A^k \boldsymbol{F_k} \tag{14}$$

where $\boldsymbol{q}_T = [\boldsymbol{p}, \boldsymbol{q}]^{\mathrm{T}}$ is the vector which collects the out-of-plane and in-plane generalized displacements of the tunnel, $\boldsymbol{F_T}$ is the vector of modal generalized dynamic loads which is obtained by direct projection of the external forces (e.g. hydrodynamic loads), on the modal basis of the tunnel, N_A is the total number of anchoring elements, $\boldsymbol{F_k} = [H_k, V_k]^{\mathrm{T}}$ is the vector containing the horizontal (H_k) and vertical (V_k) forces acting on the tunnel (exchanged by the k-th anchoring element) and $\boldsymbol{\Phi}_A^k$ is the matrix whose entries are defined as follows:

$$\boldsymbol{\Phi}_A^k = \begin{bmatrix} \sin\frac{\pi x_{A,k}}{L_T} & \dots & \sin\frac{n\pi x_{A,k}}{L_T} & \dots & \sin\frac{N_{out}\pi x_{A,k}}{L_T} & 0 & \dots & 0 & \dots & 0 \\ 0 & \dots & 0 & \dots & 0 & \sin\frac{\pi x_{A,k}}{L_T} & \dots & \sin\frac{n\pi x_{A,k}}{L_T} & \dots & \sin\frac{N_{in}\pi x_{A,k}}{L_T} \end{bmatrix} \tag{15}$$

being $x_{A,k}$ the abscissa of the k-th anchoring element in the reference system of the tunnel.

3 EQUATIONS OF MOTION OF THE SFT

In order to couple the equations of motion of the anchoring elements (see section 2.2) and those of the tunnel (see section 2.3), some further advancements are necessary. The interface forces exchanged between the anchoring elements and the tunnel can be expressed in a vectorial form as:

$$\boldsymbol{F^k} = \boldsymbol{T_k}\boldsymbol{R^k} \tag{16}$$

where $\boldsymbol{T_k}$ is the transformation matrix, which permits to pass from the local reference frame of the k-th anchoring element, to the global reference frame of the tunnel, which simply reads:

$$\boldsymbol{T_k} = \begin{bmatrix} \cos\theta_k & -\sin\theta_k \\ \sin\theta_k & \cos\theta_k \end{bmatrix} \tag{17}$$

It is noteworthy that in many SFT design proposals, the angle of inclination $\theta_k = \theta$ is constant for each anchoring element, resulting in a constant transformation matrix $\boldsymbol{T_k} = \boldsymbol{T}$ as well.

By resorting to the description of the displacement field of the tunnel, one can express the vector of interface displacements of the k-th anchoring element according to the following relationship:

$$\boldsymbol{r^k} = \boldsymbol{T}^T \boldsymbol{\Phi}_A^k \boldsymbol{q}_T \tag{18}$$

At this stage, Equation (18) is substituted into the system of Equations (10), and the vector of interface forces acting on the k-th anchor $\boldsymbol{R^k}$ is expressed from the first row. Direct substitution of $\boldsymbol{R^k}$ into Equation (16) allows to obtain the vector of interface forces acting on the tunnel, i.e. $\boldsymbol{F^k}$, which can be finally inserted into Equation (14). The undamped equations of motion of the SFT are then obtained by direct assembling the contributions stemming from all the (N_A) anchoring elements. The system of equations finally reads:

$$\begin{bmatrix} \boldsymbol{M}_T + \boldsymbol{\Phi}_A^T \boldsymbol{T} \boldsymbol{M}_{rr} \boldsymbol{T}^T \boldsymbol{\Phi}_A & \boldsymbol{\Phi}_A^T \boldsymbol{T} \boldsymbol{M}_{rz} \\ \boldsymbol{M}_{zr} \boldsymbol{T}^T \boldsymbol{\Phi}_A & \boldsymbol{M}_{zz} \end{bmatrix} \begin{bmatrix} \ddot{\boldsymbol{q}}_T \\ \ddot{\boldsymbol{z}} \end{bmatrix} + \begin{bmatrix} \boldsymbol{K}_T + \boldsymbol{\Phi}_A^T \boldsymbol{T} \boldsymbol{K}_{rr} \boldsymbol{T}^T \boldsymbol{\Phi}_A & 0 \\ 0 & \boldsymbol{K}_{zz} \end{bmatrix} \begin{bmatrix} \boldsymbol{q}_T \\ \boldsymbol{z} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F}_T \\ \boldsymbol{F}_z \end{bmatrix} \tag{19}$$

where the matrices $\boldsymbol{\Phi_A}$, $\boldsymbol{T}$, $\boldsymbol{M_{rr}}$, $\boldsymbol{K_{rr}}$, $\boldsymbol{M_{zz}}$, $\boldsymbol{K_{zz}}$ and $\boldsymbol{M_{rz}}$ and the vectors $\boldsymbol{F_T}$ and $\boldsymbol{F_z}$ have been assembled by blocks, according to standard procedures (see e.g. (Clough and Penzien 2003)) and $\boldsymbol{z}$ is the vector obtained by queueing the vectors of modal coordinates $\boldsymbol{z_k}$ of each anchoring element. Circular frequencies and mode shapes of the SFT are then found from the following undamped eigenproblem:

$$\left(\boldsymbol{K}_G - \omega^2 \boldsymbol{M}_G\right)\varphi = 0 \tag{20}$$

where the global mass ($\boldsymbol{M_G}$) and stiffness ($\boldsymbol{K_G}$) matrices have been implicitly defined in Equation (19).

4 APPLICATION EXAMPLE

The present section considers an application example regarding the SFT which was proposed for the crossing of the Messina's strait, in Italy (see e.g. (Bruschi et al. 1990), (Perotti et al. 2018)). The considered SFT is designed to connect Sicily to the mainland, crossing a strait characterized by a maximum seabed depth of 325 m (see Figure 2). The total length of the SFT is L_T = 4680 m and the tunnel axis is placed 40 m below the water table. The cross section of the tunnel is defined by the following parameters: D_T = 15.95 m, $EI = 4.383 \cdot 10^{10}$ kNm^2 and γ_T = 368.41 ton/m. The mooring system is made of inclined hollow core circular cross-section tethers, located along 65 mooring stations, with uniform spacing equal to 72 m. For the sake of simplicity, in the present work, the mooring system is considered composed of one hollow circular cross-section only (Type B), leading to a mooring stiffness variability which is only induced by the variation of the seabed depth along the tunnel's abscissa. The cross-section type B is defined by the following parameters: D_o = 1.950 m, s = 0.065 m, A_0 = 0.3849 m^2, γ_v = 6005 kg/m, where s denotes the thickness of the hollow circular profile. The angle of inclination and the non-dimensional loading parameter of the anchoring elements are set respectively to θ= 45° and η_0 = 5%.

In the present work, only in-plane motion of the tunnel is considered, and 100 terms are retained in the series expansion of Equation (11) (i.e. N_{in} =100 and N_{out} = 0). The mooring system is modeled by considering 65 "equivalent" anchoring elements, i.e. characterized by values of both axial stiffness and virtual mass which are representative of the real configuration

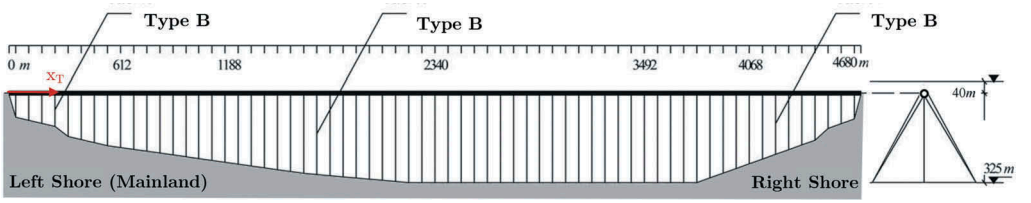

Figure 2. Side view and cross-section of the proposal for the Messina's strait SFT, in Italy.

(which is composed of 4 inclined tethers per mooring section, see again Figure 2). Each "equivalent" tether is then modeled by retaining the first in-plane mode only (i.e. M=1).

Hydrodynamic loads acting on the structure have been modeled starting from the spectral representation of the wave elevation for a certain return period. A general analytical form of the surface wave energy spectrum is (see e.g. (Wilson 1984)):

$$S_\eta(\omega) = C_0 \omega^{-m} e^{-B\omega^{-n}} \tag{21}$$

in which the empirical coefficients C_0, B, m and n define the spectrum. In the most widely used forms, m = 5 and n = 4. Several empirical expressions for the C_0 and B coefficients have been proposed in the literature. In the following, reference is made to the so-called Bretschneider Spectrum, for which C_0 and B coefficients become:

$$C_0 = 0.0081 g^2$$
$$B = 3.11/H_s^2 \tag{22}$$

where g is the gravity acceleration and H_s is the significant wave height. The latter is an important statistical parameter defined as the arithmetic average of the highest one-third of the waves in a wave record (Wilson 1984). Two significant wave heights are considered for the following developments, namely H_s = 5 m and H_s = 16 m, which are tentatively assumed to represent the "operational" wave conditions and extreme hydrodynamic events, respectively.

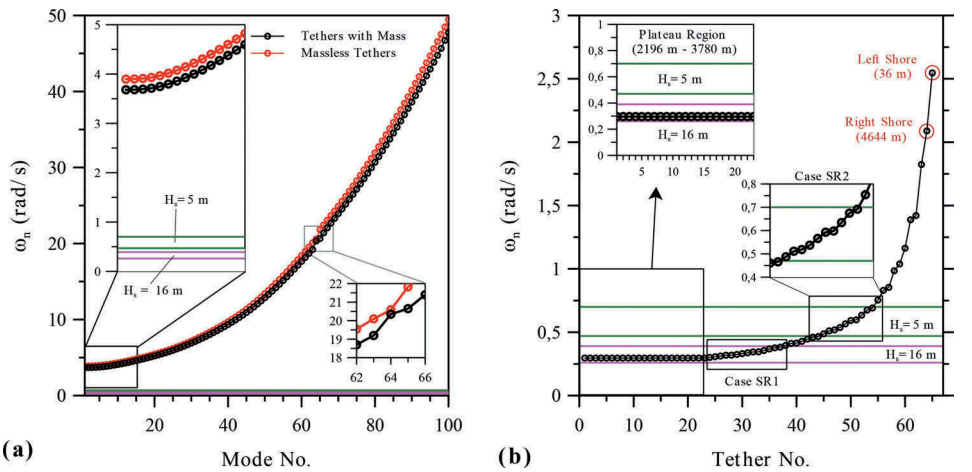

Figure 3. Natural circular frequencies of the tunnel (a) and of the anchoring elements (b) compared to the band of circular frequencies associated to the highest wave elevation spectral ordinates, for two significant wave heights (H_s = 5 m and H_s = 16 m).

Figure 3a depicts the tunnel circular frequencies obtained from the solution of the eigenvalue problem (see Equation (21)) compared to the ones corresponding to the highest spectral ordinates

of the wave elevation spectrum S_η. As a first important comment, it is evident that the response of the tunnel to hydrodynamic excitation can be regarded as quasi-static, being the first natural frequency of the tunnel much higher than the frequency interval associated to the highest spectral ordinates of the wave spectra. Additionally, it is noted that accounting for the anchoring elements' mass, leads to a variation of about 5.5% in the tunnel's circular frequencies, compared to the massless tethers modeling choice. Moreover, around mode 65, an abrupt change in the frequency can be observed. This phenomenon is due to the matching of the wavelength of such mode and the spacing of the anchoring elements, resulting in an activation of the quasi-static motion of the whole mooring system, with a consequent increased global stiffness of the structure.

Figure 3b shows the plot of the anchoring elements circular frequencies, ordered in an ascendent way. The anchoring elements located in the "plateau region" of the seabed (see Figure 2) are characterized by the lowest circular frequencies, being their chord length the longest of the whole mooring system. These anchors might encounter high level of vibrations induced by the motion of the tunnel both for the case of simple resonance, occurring for "extreme" hydrodynamic events, and for the case of parametric resonance, which may arise if "ordinary" waves associated to the service life of the structure are considered. In fact, the frequencies corresponding to the highest spectral ordinates in the wave elevation spectrum (for H_s = 5 m) are close to two times the first natural frequency of these tethers. Proceeding towards the right direction of the abscissa axis, one may find two sets of circular frequencies, respectively denoted as SR1 and SR2. These sets of tethers might be susceptible of simple resonance phenomenon induced respectively by the hydrodynamic motion of the tunnel, whenever "extreme" waves and "ordinary" waves are considered. Finally, the last two circular frequencies correspond to the stiffest anchoring elements, having shortest chord length, which are located very close to the right and left shore, respectively. However, no significant dynamic amplification phenomena are expected in this case, since the natural circular frequencies of these tethers are sufficiently far from the first one of the tunnel. Additionally, it is worth noticing that the first mode of the tunnel is always expected to have a node very close to the position of these two tethers (see Figure 4b).

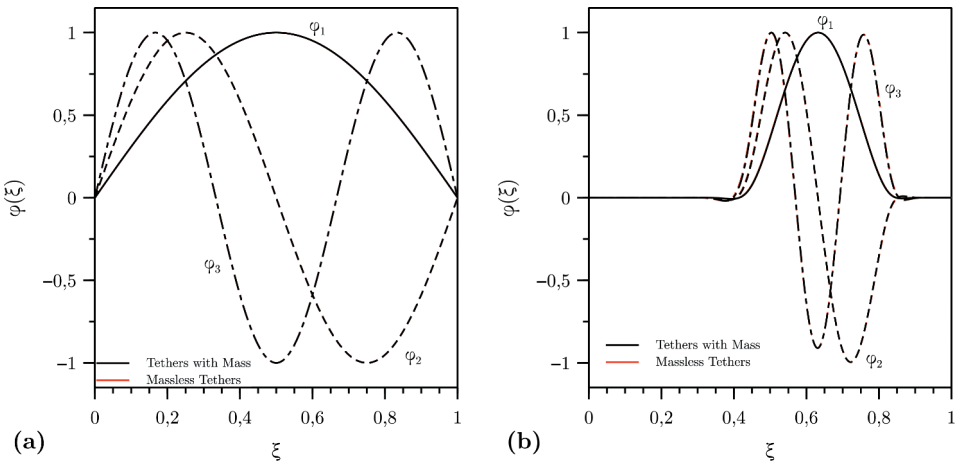

Figure 4. First three mode shapes of the tunnel for a constant (a) and variable (b) seabed depth profile. The non-dimensional abscissa of the tunnel is denoted as $\xi = x_T/L_T$.

Figure 4a and 4b shows the first three global modes of the SFT for a constant and variable seabed depth profile, respectively. As already evidenced in (Foti et al. 2023), the variable seabed profile (which consequently induces a spatially variable mooring stiffness profile) is responsible for the mode localization phenomena, around the region of highest flexibility of the mooring system. As long as the mooring stiffness is constant, localization phenomena do not occur and the mode shapes of the SFT preserve a global character (see Figure 4a). On the contrary, if the mooring stiffness is variable, the mode shapes localize in the range of lowest

stiffness, which is not located symmetrically with respect to the midspan but coincides with the "plateau" region (see Figure 4b – cf. Figure 2).

Moreover, it is noted that the influence of the anchoring elements' mass on the mode shapes is practically negligible for both seabed profiles. This evidence, together with results obtained in Figure 3, permits to conclude that it is feasible to assess the global dynamic response of the SFT by resorting to the simplified model of Euler-Bernoulli beam on a Winkler's bed (possessing a non-homogenous stiffness of the springs), and therefore, neglecting the mass of the tethers (see also (Foti et al. 2022) and Figure 1b).

5 CONCLUSIONS

In this paper, a dynamic substrucuring technique for Submerged Floating Tunnels (SFTs) was presented. The mooring system was modeled as a discrete series of anchoring elements individually described by a taut-string possessing axial extensibility, while the tunnel was modeled as a Euler-Bernoulli beam. The degrees of freedom at the interface between the tunnel and the anchors were evidenced, by expressing their value through the displacements of the tunnel. The inertially-coupled system was assembled and undamped free vibrations of the global structure were studied. The results showed the influence of both the variable mooring stiffness and the anchoring elements' mass on the global modes of the SFT. The classification of the motion regimes for the proposal of the Messina's strait SFT highlighted that the response of the tunnel to hydrodynamic loading conditions can be regarded as quasi-static. For this reason, it is feasible to address the global response of the system by relying on the simplified assumption of mass-less elastic tendon for the anchoring elements, which amounts to consider the tunnel as a Euler-Bernoulli beam resting on a non-homogenous Winkler-type soil. As per the anchoring elements, classification of the motion regimes has revealed the possibility of different resonance phenomena (both simple and parametric) under hydrodynamic loading conditions. Further research is currently ongoing to assess the role of geometrical nonlinearities of the anchoring elements on the global response on the SFT, and to include system coupling due to hydrodynamic loading of the tunnel itself, which may cause parametric excitation (and possibly, parametric resonance) of some tethers.

Forming guidelines for software evaluation in bridge structural health monitoring systems

T.A. Bayda, H.W. Shenton & M. Chajes
University of Delaware, Newark, DE, USA

ABSTRACT: With increasing costs of constructing and maintaining infrastructure systems, structural health monitoring (SHM) has seen increased use because it enables owners to evaluate the performance of their systems in real time. To do this, robust, reliable, and intuitive software platforms that can collect, store, manage, process, visualize, and report SHM data are critical. In this study, an evaluation of various existing commercial software platforms was performed using a decision matrix that was developed and used to evaluate the functionality and useability of each platform. Areas evaluated included cost structure, data interpretation, data calculation, software visualization, alarm and report creation, and project management. Ten plus years of experience with the Indian River Inlet Bridge, a fully instrumented cable-stayed bridge, was utilized in developing the decision matrix and evaluating various commercial software platforms.

1 INTRODUCTION

The Charles W. Cullen Bridge, commonly referred to as the Indian River Inlet Bridge (IRIB), is a 533-meter-long reinforced concrete cable-stayed bridge located in Delaware, USA. The IRIB has two 122-meter back spans and a main span of 290 meters to allow for potential future widening of the inlet channel that the bridge spans. Due to its proximity to the Atlantic Ocean, reinforced concrete was chosen as the most durable material to withstand the constant chloride presence in the area. An elevation view looking east towards the IRIB is shown in Figure 1.

Figure 1. Elevation view of the IRIB looking east toward the Atlantic Ocean.

Construction of the bridge was completed in 2012 and included a permanent structural health monitoring (SHM) system with seven different types of sensors to measure strain, tilt, displacement, acceleration, wind speed and direction, chloride content, and temperature. There are over 120 sensors of all types installed at various locations on the bridge (Shenton *et al*, 2017a).

Because of the cooperative efforts between the University of Delaware (UD) and the owner, the Delaware Department of Transportation (DelDOT), the IRIB and the data from its SHM system has been used for multiple research projects. Numerous research papers on the SHM

DOI: 10.1201/9781003483755-120

system and monitoring results have been published (Shenton *et* al, 2017b, Al-Khateeb *et al*, 2018, Al-Khateeb *et al*, 2019). DelDOT also uses the SHM data to catalog and evaluate the performance of the bridge over time.

This paper will provide a methodology to address DelDOT's need for a new SHM data management software platform by describing the creation of a decision matrix that was used to compare the features of platforms from various commercial software vendors.

2 CURRENT SHM SYSTEM STATUS

When the SHM system was installed on the IRIB, SHM was still in its infancy. To meet DelDOT's requirements, a custom software platform was sourced from a commercial vendor. To ensure future reliability and support, DelDOT coordinated with UD to identify and evaluate new software platforms that can perform tasks beyond what the initial platform can do.

Despite some sensors going offline and some limitations of the original software platform, the original SHM system continues to run reliably. The IRIB SHM system has a fiber optic design allowing for fewer cables and corrosion resistance. Located on-site, the raw sensor data is processed by the local computer and then stored on its hard drive. The SHM system regularly

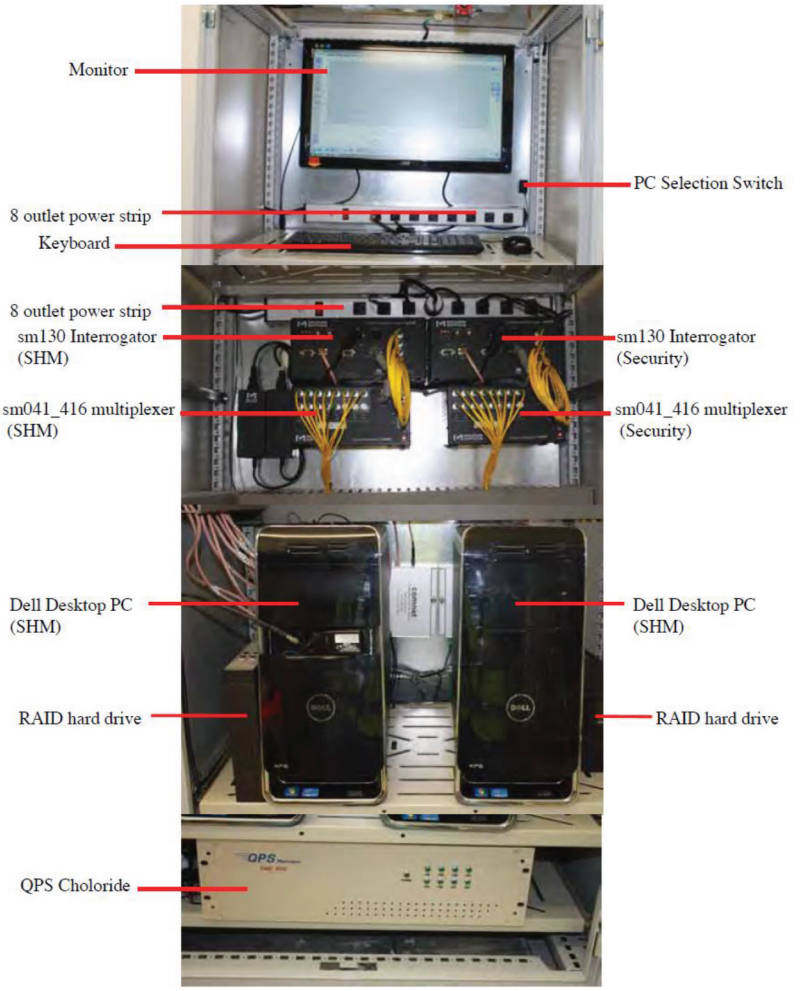

Figure 2. Central processing unit for the IRIB SHM system.

collects data from all sensors at 12.5 Hz and averages 10-minute intervals for strain and temperature data. DelDOT receives the averaged data via file transfer protocol (FTP) that is stored on its secure servers. A depiction of the SHM system's main unit is shown in Figure 2.

3 SOFTWARE PLATFORM EVALUATION METHOD

The IRIB requires a robust and specialized software platform to effectively manage and communicate the substantial data captured by its SHM system. Currently, multiple reputable software companies offer data management software similar to, but more advanced than, the current IRIB SHM system. An initial study evaluated 10 vendors and their respective software platforms to quantify available features and company capabilities. Public documentation and inquiry into each vendor allowed for the development of a feature compatibility checklist. One primary requirement was that a vendor had to have enough staff to have full-time dedication to customer support, usually meaning a staff of 25 or more personnel. Because DelDOT has strict requirements with companies it can do business with on a large scale, only vendors that were based in, or had data servers in, the USA could be selected. Another primary requirement was to source a vendor with at least 20 years of experience in data management software. As was often the case in the early years of SHM, the current software platform was custom-made. Vendors that met the primary requirements were then evaluated based on the features they had available which is outlined in the following section. The 10 vendors were reduced to four who had the most compatibility with DelDOT's requirements. Each of those four vendors were then interviewed and asked to provide a demonstration of their product. After the interviews, three of the vendors were selected, and trial testing of their software was conducted by the UD research team.

The trial testing involved using a simple data logger setup since the actual IRIB SHM data is so extensive. The data logger chosen for this setup was a Campbell Scientific CR6 because of its simplicity and cross-platform compatibility. Three strain gauges were used along with a thermocouple to feed data into the trial software platforms.

All strain gauges were attached to easily bendable objects that allowed for noticeable levels of strain. A thermocouple was positioned in the open air so that the ambient room temperature could be collected easily. Since little energy was required to change any of the readings from the sensors, it was easy to test different features within the software platforms.

The easiest way to get data into the different software platforms was to use FTP. This setup allowed the data logger to automatically send the data files over the Internet to the vendors' respective servers.

Campbell Scientific's programming language for the CR6 data logger is relatively intuitive. The data logger was set to export data via FTP every 10 minutes. Each sensor could be set to sample at rates between every 30 seconds to every two minutes. Ultimately, data was logged every minute for each sensor and then the accumulated data was exported every 10 minutes.

4 THE SOFTWARE DECISION MATRIX

4.1 *Existing decision methods*

After reviewing existing work, three decision-making methods were identified to be most applicable to the IRIB software selection task. Analytical Hierarchy Process (AHP) and Analytical Network Process (ANP) are two similar methods that allow multiple criteria-related problems to be solved using a systematic mathematical theory with weights. ANP differs from AHP in that it allows the evaluator to integrate relationships for relevance and feedback of criteria. ANP has been used to evaluate enterprise risk management and internal auditing software (Lin and Wang, 2011).

Due to the stringent requirements set by DelDOT, however, neither AHP nor ANP could identify the best software platform. All criteria provided by DelDOT would be weighted equally, defeating the purpose of AHP and ANP.

Another option found in the review uses an International Organization for Standardization and International Electrotechnical Commission (ISO/IEC) quality standard. Using ISO/IEC 9126-1 quality standard, the evaluator can compare user requirements and software capabilities (Franch and Carvallo, 2003).

The ISO/IEC 9126-1 quality standard methodology is much more applicable to the IRIB SHM software platform replacement task. A multitude of features present in each vendor's platform can be generalized and then refined to specific attributes. These attributes are then given a metric that can be used to compare between platforms. The IRIB SHM software platform decision matrix primarily uses this methodology as its design template.

4.2 *Understanding DELDOT'S requirements*

From years of using the current software platform, DelDOT was able to determine multiple key features and upgrades that they wanted for the new software platform. Features that were of the highest priority revolved around reporting and figure creation. Of all the desired requirements, the ability of the replacement software to receive full-speed data was the most challenging to accomplish. It is virtually impossible to stream, process, and display the volume of data from the bridge at 12.5Hz with the technology currently available.

In terms of reporting, DelDOT relies on scheduled reports to observe the overall short- and long-term structural health of the IRIB. These reports need to contain text, graphs, and tables that can concisely describe the performance of the bridge. In addition to scheduled reports, DelDOT wants the capability to quickly create a report "on the fly" that may include only certain elements or periods of data.

Bridge safety and data monitoring are also critical aspects that DelDOT requires. The ability to set thresholds on sensor values that could trigger alarms is another invaluable feature. These thresholds can be used to determine both real and error values that could help determine if a sensor is malfunctioning. Any time a threshold is exceeded, an alarm is sent out through multiple channels, such as a text, email, and/or internal software notification, to the key personnel.

The new software graphical user interface (GUI) needed to be able to visualize data in real-time via graphs, tables, dials, and real-time numerical values. All visualized data needs to be able to be created, edited, and/or deleted whenever necessary, allowing the user to see exactly what they want to see. These values, as displayed by the GUI, should be able to recall data for an effective time range that can be changed depending on the situation. DelDOT also specified that the ability to perform basic statistical evaluation on the data is important so that averages and standard deviations, for example, can be quickly calculated.

A feature currently not available in the present system is the ability to create a "virtual variable." This virtual variable allows a new sensor to be created by using raw data from "real" sensors located on the bridge that can then be used to calculate a new variable from one or multiple sensors. This virtual variable does not replace the real sensors on the bridge but compliments them as all data remains real-time and is just funneled through additional calculations to an additional data point on the GUI. If possible, DelDOT and the UD would also like the ability to develop more advanced scripts in programming languages like MATLAB and Python that could be integrated into the software platform.

Since DelDOT wants to have the autonomy to archive its own data outside of the software program, they want to be able to both export and import files and data to and from the software platform. Any charts and reports should be able to be easily exported to common standard formats that can then be manipulated, if necessary, via programs like Microsoft Excel or Word. The likelihood of one employee monitoring and using the software for the entirety of their career at DelDOT is small which is why DelDOT wants to be able to import documentation and other reports to the platform so that anyone that has access can quickly read the necessary materials.

Finally, to avoid some of the current longevity issues that are apparent with the present software solution, DelDOT wants the new platform to be scalable so that it is easy to add additional bridges and personnel to the project. This would involve the software being able to handle many projects and distinguish between each one but house them in the same program. DelDOT wants to be able to have designated login credentials for each user that allows the

user to track changes to the GUI or data, such as addressing alarms from the data. Each user should have individual permissions or be put into groups that have set permissions so that each party has set technical involvement in the software.

4.3 *Development of the software decision matrix*

After evaluating each software platform, a decision matrix was created by combining the similarities of each platform's capabilities and the requirements provided by DelDOT. The following main categories were created to summarize each software platform's features: Cost, Data Management, Calculation, Visualization, Alarms, System Administration, Reporting, and Additional Features.

Each category was then broken down into multiple sub-categories that outlined the platform's capability within a certain feature. For each sub-category, a visual dot rating system was used to distinguish which platforms performed better. The system went from four dots to one dot, with four dots exceeding requirements, three dots meeting requirements, two dots only partially meeting requirements, and one dot failing to meet DelDOT's requirements. The dots served as a quick visual representation of each platform's capabilities and allowed for a quantitative comparison. The average of all sub-categories became the category average. An additional comparative measure was chosen which used the sum of individual sub-category performances to determine a total score for each platform.

Table 1 outlines each sub-category description grouped into each category. By establishing objective sub-categories, the evaluator can consistently describe different features of each platform and how they contribute to the overall requirements of the client, in this case, DelDOT. Since each sub-category is relatively specific, tying each one to an overall category allows the client to see where compromises might need to be made to achieve the highest overall satisfaction with any platform.

Combining this method with the dot rating system allows the client to easily see in which areas each platform excels. Incorporating the actual performance of each sub-category for each platform based on the descriptions listed allows the client to gain a better understanding of why the dot rating was chosen. This can also provide the client with insight into how the evaluator prioritized the requirements provided for each category. Figure 3 provides an example section of the final decision matrix for the IRIB.

5 RESULTS

After evaluating each software platform for a few months, the decision matrix was completed by assigning a metric to each subcategory. A meeting with DelDOT was held in which UD provided quick demonstrations of each software platform and presented the completed software decision matrix. A discussion of the sub-categories which showed the widest range of ratings was presented at the end of the meeting. This greatly helped DelDOT narrow the decision to two vendors. The main differences of each vendor are shown in Figure 4. The decision matrix scored the two vendors selected by DelDOT highest both in terms of total score and average total score.

In addition to selecting two final vendors, DelDOT wanted to see an extended demonstration of each platform. The DelDOT engineer who primarily works with the software platform met with the first author to review the entire list of features available for both platforms. During the meeting, the first author walked through each step of creating and editing features as well as showing any limitations of each feature. Multiple additional questions were generated during these two meetings (one for each software platform) that were then asked to the software vendor to help DelDOT make the best decision.

6 CONCLUSIONS

Critically important to the functionality of any SHM system is having a robust data management software platform. DelDOT's requirement for a new software platform for the IRIB

Table 1. Sub-category descriptions in software decision matrix.

Category	Sub-Category	Description
Cost	Cost	Annual cost structure or total cost as well as alternative costs
Data Management	Data Import	Methods to bring data into platform
	Data Location	Where data can be housed for platform
	Data Export	Ability to export raw data and description of how it's done
	Data Tables	Ability to sort custom sensors into predetermined tables for easy export
	Historic Data	Allows for distinctions in time between data sets
	Data Frequency	How quickly the system can realistically visualize and import data
Calculation	Data Calculations	Calculations that can be per real data sensor
	Virtual Variables	Ability to create additional sensors not physically present and supported calculations available
	Ease of Virtual Variable Creation	Difficulty of creating virtual variable
Visualization	Screen Visualization	Main GUI present in default view of platform and ability to change view
	Dashboard	Ability to see multiple figures at the same time
Alarms	Alarms & Thresholds	Ability to set thresholds for sensors and then assign alarms to each sensor
	Ease of Alarm Setting	Difficulty of creating alarms and alarm types available
	Automatic Alarm Notification	Options for how personnel are notified of alarms
System Administration	User System	Describes the administrative hierarchy of users and permissions
	Multiple Job Sites	Ability of platform to house multiple bridges in one common application and distinguish between them
	General Ease of Use	Qualitative analysis of overall simplicity of platform
	Customer Support	Available customer support present for each platform
Reporting	Reporting Capabilities	Ability of platform to generate reports and any automation capabilities
	Automated Reports	Describes how automation occurs within each platform if possible
	Report Customization	Describes the level of customization allowed by each platform for report development
	Ease of Report Creation	Difficulty of creating a report and ability to change reports once developed
	Figure Development	Ability to create custom figures like charts and tables within the software to then be put in reports or exported
	Document Import	Ability for the system to assign imported documents to sensors or created reports
	Figure Export	Ability to selectively export created figures without creating a report
Additional Features	Custom Scripts	Ability of the platform to interface with advanced coding languages

bridge was investigated by assessing various commercially available software platforms. An initial set of platforms was chosen due to their ability to satisfy most of the features required by DelDOT. A decision matrix based on existing decision-making methodology was then created to evaluate the various platforms. After scoring each element in the decision matrix, DelDOT was given the final scores and showed a demonstration of each platform. The top two platforms were then extensively evaluated by the DelDOT engineer who interacts with the system the most, and DelDOT is currently making their final decision as to which platform to adopt.

ABSTRACT: Seismic safety of submerged floating tunnel (SFT) is one of the important factors of influencing application of the new structure, so it has important significance to investigate the seismic behaviour of SFTs. In this paper, SFT cable-tube coupling system nonlinear seismic model is established by simplifying the structure of SFT, and the seismic wave propagation mode in cable is constructed. Then, taking the coupling effect between cable vertical vibration and tube lateral vibration into account, the differential equations of the cable and tube coupled motion are derived by using Hamilton principle. In order to evaluate the SFT structural response to seismic events, the time domain dynamic response analysis is carried out by using variable separation approach and modal superposition method. The seismic behaviour of SFT in four cases are analyzed. The result shows that SFT seismic safety needs adequate reserves to ensure the structural safety and the cable vibration can inhibit tube vibration to some extent. The water resistance or damping can effectively weaken the cable vibration, and make the vibration energy of the SFT to be dissipated quickly. The cable maximum displacement tends to decrease with the increase of initial tension and the reasonable tilt angle of anchor cable is about 60°.

1 INTRODUCTION

Submerged Floating Tunnel, is simply called for as "SFT". In Italy, SFT is also known as "Ponte Di Archimede"(PDA) or "Archimede Bridge". It is a new type of transportation structure across the long and deep waterways and straits. It is generally composed of a tubular structure which is submerged in a certain depth of water, a mooring line (or floating tank on the water) anchored in the underwater foundation (it can prevent excessive displacement of the tunnel) and revetment structures connected to the bank in the ends of the waterways and straits Some relevant conceptual designs and application prospects were discussed and analyzed (AHRENS D. 1997, Xiang Y.Q. & Xue J.P. 2002.). Based on this, the application of SFT across straits and bays along the coast of China and the problems that need to be solved were discussed and related problems were studied (Xiang Y.Q. & Chao C.F. 2013, Xiang Y.Q. et al. 2013). Although experts and scholars from all over the world have done a lot of research on the design and analysis of SFT, but so far, no real SFT in the world has been built The reason for this is that there are still many key technical questions that need to be

DOI: 10.1201/9781003483755-121

addressed about how to analyze and design the SFT reasonably for ensuring the safety of the structure.

During the life cycle operation and service of SFT, it is subjected to complex action of the environments and loads around SFT, and the behavior and mechanism of SFT are very complex. Therefore, Xiang Y.Q. et al. (2022) summarized that many scholars from different countries have conducted a series of research related to SFTs from different perspectives in the past more than 20 years. Based on relevant research on bridge and tunnel engineering, Xiang Y.Q. et al. (2020a) also proposed a theoretical framework for the life cycle design of SFT from structural life cycle point of view, and conducted relevant theoretical analysis methods and experimental research, such as the response of SFT to impact loads (Xiang Y.Q. & Yang Y. 2017), the vibration response of SFT due to local anchor cable breakage (Xiang Y.Q. et al. 2020), the vehicle-SFT-fluid coupling vibration response (Xiang Y. Q. et al. 2021), the health monitoring system of SFT (Xiang Y. Q. 2015) and so on.

Due to the fact that earthquakes are one of the important threats to the safety of civil engineering structures, studying the dynamic performance of SFTs under earthquake action is of great significance. Sun S.N. et al. (2006) studied the hydrodynamic pressure acting on a suspended tunnel under seismic shear waves. Di Pilato M. et al. (2008a, b) conducted numerical simulations on the spatial dynamic response of SFT under seismic loads and hydrodynamic excitation. Martinelli L. et al. (2010, 2011), Martinea G. et al. (2010), Chen W.J. & Huang G.J. (2010), Xiao J. & Huang G.J. (2010), Perotti F. et al. (2013), Su Z. etc. (2013), Xiang Y.Q. & Chao C.F. (2015), Lee J.H. (2016), Martinelli L. et al. (2016), Dong M. & Li M.(2016), Mirzapour J. (2017) et al. experts and scholars have also done a lot of research in this area.

Martinelli L. et al. (2010, 2011) proposed a new seismic response spectrum method and a multi support seismic response analysis model for SFT structures, by taking into account the geometric nonlinearity and comprehensive damping effects of anchor cables. Martiera G. et al. (2010) analyzed the seismic dynamic response of SFT scheme in the Messina Strait. Chen W. et al. (2010) analyzed the dynamic response mechanism of SFT under non-uniform seismic excitation. Xiao J. et al. (2010) studied the seismic response of SFT under different forms of revetment connections. Su et al. (2013) established a seismic response model for underwater SFT tethers. Xiang et al. (2015) studied the lateral seismic response analysis considering boundary soil properties based on numerical models. Lee et al. (2016) discussed the impact on the seismic performance of SFTs with rectangular cross-section, including factors such as fluid compressibility, depth of seawater, and position of tunnel structures in water. Dong et al. (2016) studied the influence of SFT span and vertical equivalent stiffness of anchor cables on the dynamic response characteristics of SFT under seismic effect. Martinelli et al. (2016) summarized the dynamic behavior of SFT under seismic motion and emphasized the possibility of mitigating dynamic response through structural control. Mirzapour et al. (2017) studied the seismic response of SFT under support excitation and mainly discussed the influence of model size and anchor stiffness factors on its seismic response characteristics.

In recent years, Chen J.Y.et al. (2021) proposed a vibration control scheme based on plastic deformation dampers arranged side by side with anchor cables, and optimized the number of dampers. Xie J.et al. (2021) proposed a mathematical model, which considered the effect of canyon water transport and analyzed the seismic response of SFT systems. Akbarzadeh et al. (2021) discussed the effects of SFTs under asynchronous support excitation. It takes into account the impact of seismic input non-uniformity due to site differences in the positions of the SFT bank revetments at both ends. Shekari et al. (2022) discussed the impact of seismic wave period and intensity characteristics on the seismic safety performance evaluation of SFT.

Jin & Kim (2021) used a finite element line model to model the SFTs and mooring cables, by taking into account the dynamic/structural deformation capacity of the entire SFT and using the virtual connection mass method and constraint boundary conditions, and the hydrodynamic forces caused by waves and earthquakes were evaluated at the instantaneous node position using the Morison equation. Jin C. et al. (2021, 2022) proposed a new method of installing tuned mass dampers in tunnel pipes to control SFT vibration, carried out the

damper optimization method, and further proposed a passive tuned mass damper by establishing a time-domain dynamic simulation model of SFT and a tuned mass damper (TMD) and considering the interaction of SFT-TMD to slow down and control the resonant motion of SFT in waves and earthquakes.

Xie J. et al. (2023) established a non-uniform input model for seismic motion caused by multi-point excitation (including SFT end revetment points and SFT bottom anchorage points), and used spring elements to simulate the stiffness of joints between pipe segments. Based on harmonic superposition method, the influence of different seismic input modes on the dynamic response of SFT were studied, which improved the universality of problem discussion (Xie, J. 2023).

However, in the above studies, most studies are based on numerical simulations using general programs, while there are relatively few studies using classical analytical methods. The influence of anchor cable on vibration response of SFT under earthquake action is rarely mentioned. In this paper, based on the previous studies, a nonlinear dynamic model of the cable-body coupling system of the SFT is established, and the corresponding dynamic equation is derived. Considering the influence of the cable vibration, the dynamic response of SFTs under seismic action is studied by using time-history analysis method.

2 MATHEMATICAL MODEL

2.1 *Simplification and assumption of the model*

There is a big difference between the dynamic characteristics of the tube body and the cable of the SFT. In order to study the vibration characteristics of the mooring cable-type SFT under earthquake action, the long SFT pipe body is simplified into a beam with simple support at both ends, and the pipe body and the underwater foundation are hinged with mooring anchor cables. Figure 1 shows the simplified calculation model. In the vibration process of SFT, the top of the anchor cable generally moves with the pipe body, and the vertical displacement or strain should be coordinated, while the pipe body can rotate freely at the hinged point, and the bottom end of the anchor cable is fixed. The cross section of the pipe body is to be axially symmetric. At the same time, it is assumed that:

1) The tube body is Bernoulli-Euler beam with equal section and stiffness, and the tube body has no rotational displacement;
2) The pair of cables are equal section, length, stiffness and inclination angle, but the cross section, length, stiffness and inclination angle between the different pairs of cables can be different, and the flexural stiffness of the cables and geometric nonlinearity are ignored, so it can be simplified as a standard string in the model;
3) The earthquake wave input only consider lateral and horizontal seismic acceleration, it is directly acting on the axis line of tube body along the X direction of tube body, that is, is in Y direction of the over-all coordinate is, as shown in Figure 1;
4) Regardless of the traveling wave effect, the two end supports excitation is considered as the consistent excitation;

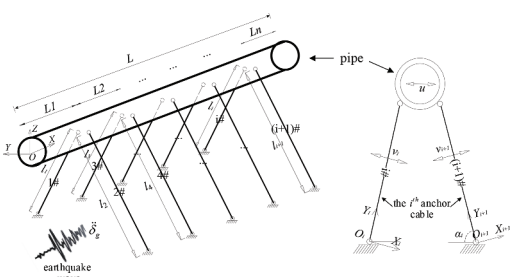

Figure 1. The simplified calculation model of seismic response of submerged floating tunnel.

5) The tube body moves only in the lateral direction (in Y direction). The i^{th} anchor cable moves only in the Xi direction of the local coordinate system.

2.2 *Basic differential equations of motion*

The global coordinate system of the tube body is O-XYZ, and the axis line of the tube body is X-axis. The local coordinate system of the i^{th} anchor cable is $X_iO_iY_i$, located in the inclined plane of anchor cable, and the anchor cable axis line is Y_i axis. Since the space distance between any two anchor cables is generally far, the water flow driven by the anchor cable vibration has basically no influence on the water body at a distance, so the anchor cable vibration cannot affect each other through the water body. Therefore, based on the coordinate system established in Figure 1 and Hamilton's principle, differential equations of the combined structure of anchor cable-tube with respect to u and v_i motion can be obtained:

$$\begin{cases} m_{ci}\ddot{v}_i + c_i\dot{v}_i - (T_i + \Delta T_i)\frac{\partial^2 v_i}{\partial y^2} = -F_{iD} - m_{ci}\ddot{\delta}_{ci} \\ m_{ci+1}\ddot{v}_{i+1} + c_{i+1}\dot{v}_{i+1} - (T_{i+1} + \Delta T_{i+1})\frac{\partial^2 v_{i+1}}{\partial y^2} = -F_{i+1D} - m_{ci+1}\ddot{\delta}_{ci+1} \\ m_b\ddot{u} + c_b\dot{u} + E_bI_b\frac{\partial^4 u}{\partial x^4} + \sum_{i=1}^{(n+1)/2}(\Delta T_i - \Delta T_{i+1})\cos\alpha_i \cdot \delta(x - x_i) = -F_{bD} - m_b\ddot{\delta}_g \\ i = 1, 3, 5, \cdots, n(n\ is\ \text{oddnumber}) \end{cases} \tag{1}$$

Where v_i is the longitudinal displacement of the i^{th} anchor cable perpendicular to the anchor cable axis; u is the lateral displacement at any position x of the pipe body; and m_{ci} is the mass per unit length of the i^{th} anchor cable; c_i is the viscous damping coefficient of the i^{th} anchor cable; $m_b$is the tube body mass per unit length; c_b is the viscous damping coefficient of the tube body; T_i is the initial tension of the i^{th} anchor cable at static equilibrium; ΔT_i is the tension increment of the i^{th} anchor cable during vibration, $\Delta T_i = \frac{E_{ci}A_{ci}}{l_i}\int_0^{l_i}\varepsilon_i \mathrm{d}y$; E_{ci} is the equivalent elastic modulus of the i^{th} anchor cable; A_{ci} is the cross-sectional area of the i^{th} anchor cable; l_i is the actual length of the i^{th} anchor cable; ε_i is the dynamic strain of the i^{th} anchor cable; x_i is the horizontal coordinate of the articulation point between the pipe body and the top of the i^{th} anchor cable; α_i is the tilt angle of the i^{th} anchor cable; E_b is the elastic modulus of the tube body; I_b is the bending stiffness of pipe section; F_{iD} is the sum of the unit length drag force and additional inertial force caused by the longitudinal vibration of the i^{th} anchor cable; F_{bD} is the sum of the unit length drag force and additional inertial force caused by the lateral vibration of the pipe body; $\ddot{\delta}_g$ is the horizontal and lateral acceleration of the earthquake wave; $\delta(x - x_i)$ is the Dirac function.

The dynamic axial strain of anchor cable can be obtained from Green strain:

$$\begin{cases} \varepsilon_i = \frac{u(x=x_i).\cos\alpha_i}{l_i} + \frac{1}{2}\left(\frac{\partial v_i}{\partial y}\right)^2 \\ \varepsilon_{i+1} = -\frac{u(x=x_i).\cos\alpha_i}{l_{i+1}} + \frac{1}{2}\left(\frac{\partial v_{i+1}}{\partial y}\right)^2 \\ i = 1, 3, \ldots n(n\ is\ \text{odd number}) \end{cases} \tag{2}$$

Where $u(x{=}x_i)$ is the displacement of the transverse vibration of the tube body at the articulation point of the i^{th} pair anchor cables.

According to Morison's formula, the dragging force and additional inertial force of water body on the vibrating tube body or anchor cable can be expressed as:

$$F_D = \frac{1}{2}\rho_w D C_D \dot{U}\left|\dot{U}\right| + \frac{\pi D^2}{4}\rho_w C_m \ddot{U} \tag{3}$$

Where C_D is the drag force coefficient; C_m is the additional mass coefficient; U is the displacement of the tube segments relative to the water body; ρ_w is the density of water; D is the

diameter of tube body or anchor cable. For both the pipe body and the anchor cable $C_D = 0.7$ and $C_m = 1.0$.

2.3 *Seismic wave propagation mode in anchor cable*

The propagation of seismic waves in the anchor cable is approximated here as a plane amplitude-varying harmonic shear wave propagating along the anchor cable axis Y axis with velocity V, without considering the reflection of seismic waves. By referring to the wave equation of mechanical waves and considering the effect of viscous resistance on the vibration system, the wave equation of seismic waves in the anchor cable and pipe body can be obtained as follows:

$$\begin{cases} \ddot{\delta}_{ci}(y,t) = \ddot{\delta}_g e^{-\frac{\gamma_i}{2m_{ci}}t}[\sin\omega(t-\frac{y}{V}) + \sin\omega(t-\frac{l_i-y}{V})] \cdot \sin\alpha_i \\ \ddot{\delta}_b(x,t) = \ddot{\delta}_g \\ i = 1,2,\cdots,n \end{cases} \tag{4}$$

Where $\ddot{\delta}_g$ is the seismic acceleration; ω is the seismic wave vibration frequency; $V = \sqrt{\frac{G}{\rho}}$ is the seismic wave propagation speed in the anchor cables; $\gamma = \sqrt{4\beta^2 m_{ci} k_{ci}}$ is the resistance coefficient; G is the shear modulus of the anchor cable material; ρ is the density of the anchor cable material; k_{ci} is the anchor cable stiffness; β is the dimensionless coefficient.

2.4 *Solution of equations*

According to equation (1), for the pipe body and anchor cable with simple support at both ends, the mode superposition method of variable separation can be used to solve the problem, so that:

$$\begin{cases} v_i(y,t) = \sum_{j=1}^{m_i} v_{i,j}(t)\sin(\frac{j\pi y}{l_i}) \\ u(x,t) = \sum_{j=1}^{m} u_j(t)\sin(\frac{j\pi x}{L}) \\ i = 1,3,\cdots,n(n \text{ is odd number}) \end{cases} \tag{5}$$

$$\begin{cases} \ddot{v}_{i,1} + \left[\omega_{i,1}^2 + \frac{E_{ci}A_{ci}\pi^2}{\bar{m}_{ci}{l_i}^3}\cdot u(x=x_i)\cdot\cos\alpha_i\right]\cdot v_{i,1} + 2\xi_{i,1}\omega_{i,1}\dot{v}_{i,1} + \frac{E_{ci}A_{ci}\pi^4}{4{l_i}^4\bar{m}_{ci}}\cdot v_{i,1}^3 = \\ \qquad -\frac{4}{3\bar{m}_{ci}\pi}\rho_w D_i C_{Di}\dot{v}_{i,1}\left|\dot{v}_{i,1}\right| - \frac{m_{ci}}{\bar{m}_{ci}}\cdot e^{-\frac{\gamma_i}{2m_{ci}}t}(B_{1i}\sin\omega t + B_{2i}\cos\omega t)\cdot\ddot{\delta}_g\cdot\sin\alpha_i \\ \ddot{v}_{i+1,1} + \left[\omega_{i+1,1}^2 - \frac{E_{ci+1}A_{ci+1}\pi^2}{\bar{m}_{ci+1}{l_{i+1}}^3}\cdot u(x=x_i)\cdot\cos\alpha_i\right]\cdot v_{i+1,1} + 2\xi_{i+1,1}\omega_{i+1,1}\dot{v}_{i+1,1} + \frac{E_{ci+1}A_{ci+1}\pi^4}{4l_{i+1}^4\bar{m}_{ci+1}}\cdot v_{i+1,1}^3 = \\ -\frac{4}{3\bar{m}_{ci+1}\pi}\rho_w D_{i+1}C_{Di+1}\dot{v}_{i+1,1}\left|\dot{v}_{i+1,1}\right| - \frac{m_{ci+1}}{\bar{m}_{ci+1}}\cdot e^{-\frac{\gamma_{i+1}}{2m_{ci+1}}t}(B_{1i+1}\sin\omega t + B_{2i+1}\cos\omega t)\cdot\ddot{\delta}_g\cdot\sin\alpha_i \\ \ddot{u}_1 + \omega_b^2 u_1 + 2\xi_2\omega_b\dot{u}_1 = -\sum_{i}^{(n+1)/2}\frac{2}{\bar{m}_b L}\left[\frac{2E_{ci}A_{ci}}{l_i}\cdot u(x=x_i)\cdot\cos\alpha_i + \frac{E_{ci}A_{ci}\pi^2}{4{l_i}^2}\cdot v_{i,1}^2 - \frac{E_{ci+1}A_{ci+1}\pi^2}{4{l_{i+1}}^2}\cdot v_{i+1,1}^2\right] \\ \cdot\sin(\frac{x_i\pi}{L})\cdot\cos\alpha_i - \frac{4}{3\bar{m}_b\pi}\rho_w D_{tube}C_D\dot{u}_1|\dot{u}_1| - \frac{4m_b}{\pi\bar{m}_b}\ddot{\delta}_g \\ i = 1,3,5,\cdots,n(n \text{ is odd number}) \end{cases} \tag{6}$$

Where $\omega_{i,1}$ is the first order natural frequency of the i^{th} anchor cable; ${\omega_{i,1}}^2 = \frac{T_i}{\bar{m}_{ci}}\left(\frac{\pi}{l_i}\right)^2$, $\bar{m}_{ci} = m_{ci} + \frac{\pi {D_i}^2}{4}\rho_w C_{mi}$; $\xi_{i,1}$ is the first damping ratio of the i^{th} anchor cable; $B_{1i} = \frac{4\pi V^2(\cos\frac{\omega l_i}{V}+1)}{\pi^2 V^2 - \omega^2 l_i^2}$, $B_{2i} = \frac{4\pi V^2\sin\frac{\omega l_i}{V}}{\pi^2 V^2 - \omega^2 l_i^2}$; ω_b is the first order natural frequency when the tube body is connected without anchor cable; $\omega_b^2 = \frac{E_b I_b}{\bar{m}_b}\left(\frac{\pi}{L}\right)^4$, $\bar{m}_b = m_b + \frac{\pi {D_{tube}}^2}{4}\rho_w C_{mi}$; ξ_2 is the first damping ratio of the tube body.

Tagata G.(1997) pointed out from the test that the basic modes of the tensioned-anchor cable vibration under the end excitation play a dominant role, that is, the displacement response caused by the first-order resonance is the largest. Some research shows that the first mode of the SFT tube body contributes the most to the displacement response, while the higher mode contributes little to the displacement. Therefore, the first-order vibration mode is only taken for both the anchor cable and the tube body in this paper, thus, the differential equations of the motion of the combined structure of the anchor cable-tube body are simplified as equation (6).

Some of studies have shown that when the natural vibration frequency of the pipe body is close to twice the frequency of a certain order vibration of the anchor cable, the structure may produce self-excited resonance phenomenon, also known as parametric vibration (Wang Z.G.& Sun B.N. 2001), and the seismic response of the anchor cables will be amplified several times. The vibration equation of the SFT under earthquake excitation is a nonlinear equation, and there is a nonlinear term of pipe body and anchor cable displacement coupling. Therefore, the vibration of the SFT under earthquake action is nonlinear vibration.

3 NUMERICAL EXAMPLE

3.1 *Numerical examples and benchmark model*

This calculation example is partly taken from the design parameters of SFTs studied in literature (Chen J.Y., Sun S.N. & Su Z.B. 2008). In order to explore the most unfavorable situation under earthquake action, some of structural parameters were artificially changed according to actual possibilities so that the first-order vibration frequency of the pipe body was twice that of the first-order vibration frequency of the anchor cables to generate parametric resonance.

Table 1. Basic model parameters of numerical example.

Structure and medium, Mass or earthquake	Parameter name	symbol	unit	values
1st and 2nd anchor cable	Length	l	m	228.62
	Diameter	D	m	0.489
	Mass per unit length	m_c	kg/m	1474.23
	Density	ρ_c	kg/m^3	7850
	Modulus of elasticity	E_c	MPa	2.1×10^5
	Initial tension	T	kN	6.5×10^4
	Tilt Angle	α	—	45º
Tube body	Length	L	m	90
	Tube diameter	D_{tube}	m	10
	Mass per unit length	m_b	kg/m	1.5×10^5
	Flexural stiffness	I_b	m^4	58
	Modulus of elasticity	E_b	MPa	3.45×10^4
	Density	ρ_b	kg/m^3	2500
Water	Density	ρ_w	kg/m^3	1000
El Centro	Vibration frequency	ω	rad^{-1}	8.98
	Velocity of propagation	V	m/s	3281
	Resistance coefficient	γ	kg/s	150

Here, only a pair of anchor cables is arranged on the pipe body, and the connection point between the pipe body and the pair of anchor cables is located at L/2. The length, cross-sectional area, material and stiffness of two anchor cables are the same. The cable inclination angle α is 45º. The specific values of system parameters are listed in Table 1 and are used as the benchmark model. Newmark method is used for numerical calculation, the parameter

analysis of the seismic response of the SFT based on the benchmark model is realized by Matlab programming.

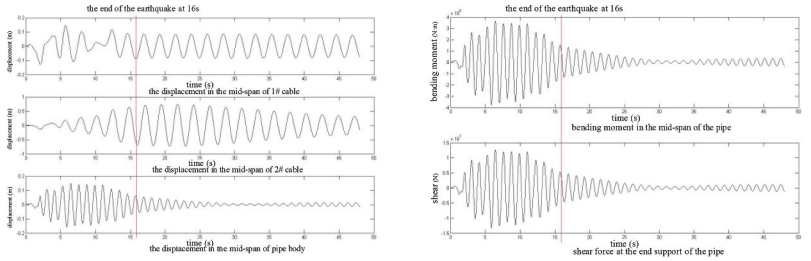
3.2 *The selection of seismic waves*

Because the structural response of SFT under earthquake is closely related to the time-history characteristics of the input ground motion, the representative El Centro wave occurred in 1940 in the United States is selected in this paper, which is suitable for class III sites. The peak acceleration recorded in the actual ground motion of the seismic wave is converted into the basic intensity, and the single parameter relationship between seismic intensity and ground motion proposed by Hershlcrger is adopted, and the seismic intensity is VIII degree. In the actual calculation of this example, the seismic action adopts the case of laterally acting on the axis line of tube body along the X direction of tube body.

3.3 *Calculation working condition setting*

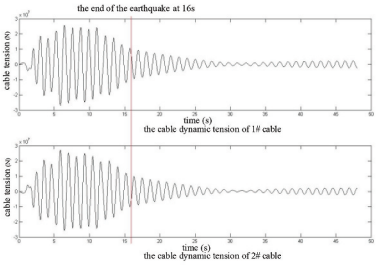
The four typical working conditions and corresponding parameter settings are selected to use the calculation analysis. The $\xi_{1,1}$ and $\xi_{2,1}$ are the first order damping ratio of 1st, 2nd anchor cables respectively, and ξ_b is the first order damping ratio of tube body, The detailed specific values is seen in Table 2.

Table 2. Work conditions and parameters set.



Cases	$\xi_{1,1}$	$\xi_{2,1}$	ξ_b	Remark
1	0.0018	0.0018	0.01	El Centro wave excitation
2	0.0018	0.0018	0.01	El Centro wave excitation, without cable vibration
3	0.0018	0.0018	0.01	El Centro wave excitation, without water damping
4	0.0018	0.0018	0.01	El Centro wave excitation with change of cable inclination

Using dynamic time history analysis method, the displacement time history curves at the center position of anchor cable and mid-span position of tube body were calculated in five different working conditions.



4 NUMERICAL RESULTS AND ANALYSIS

In order to explore the nonlinear seismic response characteristics of the SFT under uniform excitation, the parameters of the SFT are analyzed from the following five cases: (1) The seismic response of the benchmark SFT model; (2) The seismic response of SFT without cable vibration under El Centro wave excitation; (3) The seismic response of SFT without water damping under El Centro wave excitation; (4) The seismic response of SFT with different cable inclination angle under El Centro wave excitation.

It can be seen from Figure 2 that in case 1, under the excitation of El Centro wave, the maximum mid-span displacement of the SFT reaches 0.156m, the maximum mid-span bending moment of the SFT is 3.81×10^5kN.m, and the maximum shear force of the SFT at the end support is 1.33×10^4kN. The maximum displacement of cable span is 0.737m, and the maximum dynamic tension of cable is 2.69×10^4kN, which is 41% of the initial tension. It can be seen that the SFT must reserve enough safety margin to meet the requirements of the SFT safety under the action of earthquake. Under earthquake excitation, due to the large stiffness of the tube body, the seismic response is more significant, so the response of the tube body is the most sensitive, the change of displacement and internal force is basically consistent with the change trend of seismic wave acceleration, and the vibration rapidly attenuates after the earthquake. The vibration response of the anchor cable has a hysteresis effect, and the amplitude continues to increase to the maximum after the earthquake, and then slowly attenuates.

(a) Displacement time history curve (b) The bending moment and shear time history curve of tube

(c) Cable dynamic tension time history curve

Figure 2. Seismic time-response curve of SFT in case one.

Figure 3 shows that in case 2 the maximum displacement in the span of the pipe body reaches 0.167m, which increases by 7.1% compared with the displacement in Figure 3(a). Meanwhile, the vibration attenuation of the pipe body is relatively slow after the earthquake. It can be seen that the cable vibration has a certain inhibition effect on the pipe body, that is, the cable vibration has an "additional damping" effect on the pipe body. This function of the anchor cables are mainly due to the non-synchronous vibration and different direction characteristics of the anchor cables.

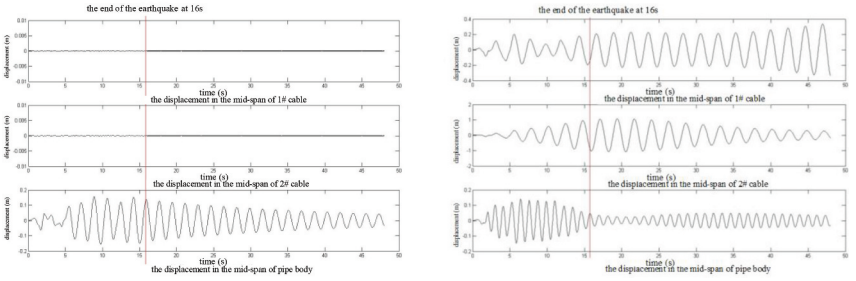


Figure 3. Disp. time-response curve of SFT in case 2 Figure 4. Disp. time-response curve of SFT in case3.

As shown in Figure 4, in case 3, when the effect of water damping on pipe body and anchor cable is not considered, the maximum mid-span displacement of anchor cables reach 1.08m and the maximum mid-span displacement of pipe body is 0.157m. After the end of the earthquake, the pipe body and anchor cable have parametric vibration, and the structural vibration attenuation is slow. Compared with case 1, it can be seen that water damping has a significant effect on inhibiting the maximum vibration displacement of the anchor cable, but cannot inhibit the maximum displacement peak of the pipe body. The vibration energy is consumed by water damping, and the vibration amplitude of the structure is attenuated rapidly.

Cable inclination angle is also one of important parameters in SFT design. Through parameter research, it is found that with the increase of the inclination angle, the maximum vibration

displacement in the span of the cable also tends to decrease on the whole. But at the base inclination angle $\alpha = 45^{\circ}$, that is, when the pipe body and anchor cable have parametric vibration, the peak displacement of 2nd anchor cable reaches the maximum. In addition, when the cable tilts angle $\alpha = 60^{\circ}$, the pipe displacement appears a minimum value, while the cable displacement value is also small. Comprehensive consideration of the cable length, structural vibration and other factors, the reasonable value of the cable tilt angle is about 60°.

5 CONCLUSIONS

This paper only studies the dynamic response of the SFT under the uniform transverse earthquake excitation. By simplifying the SFT structure into a model of simple support at both ends, in which the pipe body of SFT is fixed with the underwater foundation by the anchor cables, the Hamilton principle is used to establish the combined structure model of the anchor cable-pipe body under the earthquake action. The differential equation considering the coupling between the lateral vibration of anchor cables and the transverse vibration of pipe body is derived, and the solution of the equation is given. Based on the above, the vibration response of the cable and pipe body of a SFT is analyzed and studied by setting different design parameters and working conditions of the SFT under uniform transverse seismic excitation. The result shows that SFT seismic safety needs adequate reserves to ensure the structural safety and the cable vibration can inhibit tube vibration to some extent. The water resistance or damping can effectively weaken the cable vibration, and make the vibration energy of the SFT to be dissipated quickly. The cable maximum displacement tends to decrease with the increase of initial tension and the reasonable tilt angle of anchor cable is about 60°.

Experimental investigation for dynamic behavior of the scaled segment model of submerged floating tunnels under waves

H. Ding, L. Cheng, K. Li, D. Zhong & X. Hu
China Merchants Chongqing Communications Technology Research & Design Institute Co., Ltd., Chongqing, China
National Engineering Research Center of Road Tunnel, Chongqing, China

ABSTRACT: Understanding the hydrodynamic behavior of structure under wave loads is essential to improve the safety and stability of the Submerged Floating Tunnel (SFT). Based on the Qiongzhou Strait SFT scheme, the dynamic characteristics of SFT subjected to regular wave were investigated deeply and thoroughly employing experimental tests with a scale of 1:60. The impacts of wave parameters on the dynamic response of the scaled segment model of SFT were discussed in detail. Further prospects for developing experimental research on SFT were given as well. The results show that the acceleration and displacement of the scaled segment model tend to increase nonlinearly with the increase of wave height. The ratio of wavelength to structure size has a significant effect on the dynamic response of the segment model. And the bottom anchor cable provides most of the restraining force for the segment model.

1 INTRODUCTION

Submerged floating tunnel (SFT) is an innovative transportation scheme for crossing deep and large fjord, with prominent advantages in waters with poor geological conditions and high environmental protection requirements. SFTs are surrounded by complex marine conditions, the dynamic response of the structure under multiple external loads is an essential basis for the design of SFT, which has become the research emphasis of many scholars. Tariverdilo et al. (2011) derived an expression for the fluid force acting on the tube based on the potential function of the flow field. Seo et al. (2015) calculated the forces acting on the tube utilizing linear wave theory and Morrison's equations and verified the reliability through a small wave-flume test. Hong et al. (2010), Kang et al. (2016) investigated the vibration characteristics of tube and anchor cables of SFT under the action of wave and current. Martire et al. (2010) and Yuan et al. (2016), Xiang et al. (2018) investigated the influence of traffic inside the tunnel on the dynamic response of SFT by simplifying the traffic loads into homogeneous loads and moving concentrated forces, respectively. Kunisu et al. (1994) and Oh et al. (2013) studied the hydrodynamic characteristics of SFT under the action of regular waves by wave flume tests. Chao et al. (2016) analyzed the effect of impact loading on the structure, and Sun et al. (2008) pioneered the experimental study of the seismic response of SFT. Iovane et al. (2023) summarized the status of experimental research on SFT in detail.

The present research mainly adopted theoretical and numerical analysis to investigate the dynamic response characteristics of SFT under the effects of wave, current and seismic loads, etc. For the model test, the small-scale two-dimensional flume test and pool test were mainly used, and the tube section was primarily modeled by circular. There are fewer studies on large-scale hydrodynamic tests considering three-dimensional effects and the dynamic response characteristics of elliptical section SFT, which lack the support of experimental data.

DOI: 10.1201/9781003483755-122

A hydrodynamic modeling test with geometric scale of 1:60 was conducted in the present study. Section 2 introduced in detail the device of the test, the measuring instruments, and the wave parameters of the regular waves. Section 3 mainly discussed the effects of wave parameters on acceleration, displacement, wave pressure on the surface of the model and anchor cable force. The conclusions and the prospects of the experimental study were presented in Section 4.

2 EXPERIMENTAL SETUP

2.1 *Experimental facility*

The tests were conducted in a wave-current basin at the Underwater Tunnel Laboratory, China Merchants Chongqing Communications Technology Research and Design Institute Co., Ltd., China (CMCT). The wave-current basin is 36 m long, 31 m wide, and 3 m deep. A piston-type wave-making system is equipped at the one side of the basin, generating waves with height ranges from 0.025 to 0.2 m and period ranges from 0.50 to 2.00 s. At the other end of the basin, a series of wave absorbers are installed to reduce the influence of the reflection of incident waves. A large truss truck is mounted above the basin to assist in the installation of SFT scaled segment model (Hereafter referred to as the model) and to provide a platform for testing operations on the water.

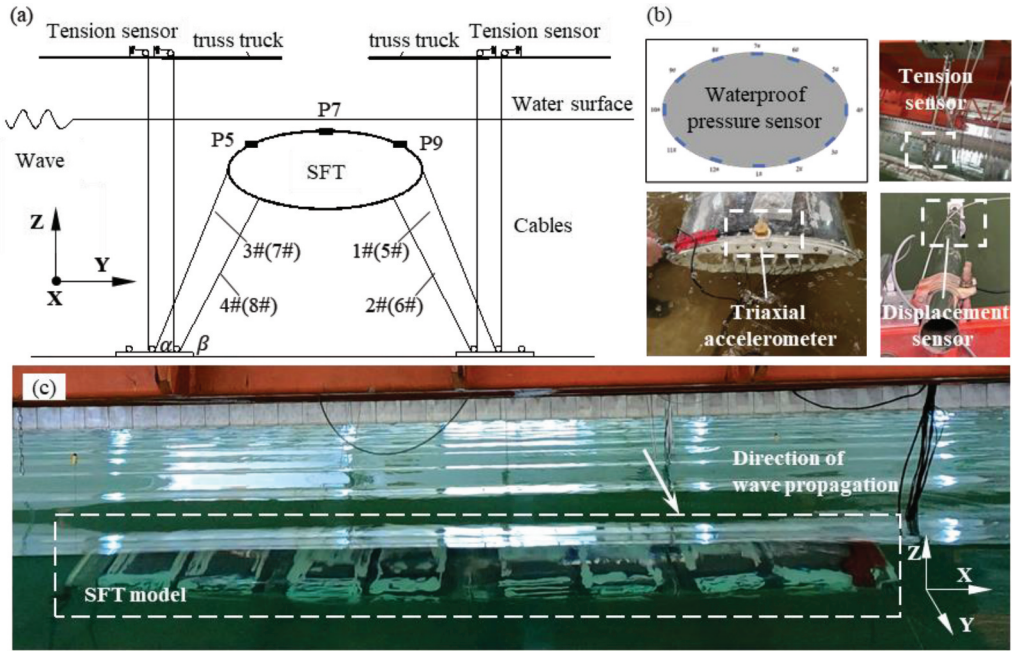

Figure 1. Layout of the test set-up and the submerged floating tunnel model.

2.2 *Model and layout*

The SFT model prototyped from the design plan of Qiongzhou strait passageway proposed by CMCT, and the scale ratio of 1:60 and Froude similarity were used for experiment design. The section of test model is elliptic with a long axis (D_L) of 0.75 m and a short axis (D_S) of 0.317 m, the length is 2 m. The test model was made of polymethyl methacrylate with a thickness of 0.008 m. The buoyancy to weight ratio (BWR) is 1.3. The interior of the model

is padded with lead plates as counterweights according to the center of gravity of the prototype. The coordinate system is illustrated in Figure 1(a), the X-axis (longitudinal direction) aligned with the longitudinal axis of tube, the Y-axis (transverse direction) aligned with wave propagation direction, the Z-axis (vertical direction) aligned with gravity acceleration.

Two pairs of inclined anchor cables symmetrically arranged at each end of the tube, one pair mounted below the tube (bottom cables) and one pair mounted on the transverse side of the tube (side cables). For the sake of distinction, the cables on one side are numbered 1# to 4# and on the other side are numbered 5# to 8#. A series of pulley devices were installed at the bottom of the wave-current basin to fix the cables. The angles between the two pairs cables and the ground are $\alpha = 56^\circ$ and $\beta = 65^\circ$, respectively. The cables were made of stainless-steel wire rope with a diameter of 5 mm. More details on the experimental setup and model can be found in literature written by Ding et al. (2024).

The model was installed at the center of the wave-current basin. The distance separating the model from the wave-generator and wave-absorber is about 12 m and 14 m, respectively. The waves could propagate and develop sufficiently before reaching the model. The three-dimensional effects of waves were considered in this experiment.

2.3 *Measurement*

The time history of model acceleration response was measured by a triaxial accelerometer. This accelerometer was installed above one end of the tube, and its orientation was calibrated to align with the coordinate system illustrated in Figure 1(a) by means of an internal levelling device. The maximum range and accuracy of the accelerometer are 2.0 g and 0.3% respectively. The pull rope displacement sensor with a maximum range of 1000 mm and a sampling rate of 200 Hz was selected to measure the horizontal and vertical displacement. The 4 displacement sensors were grouped into two sets mounted on the two diagonal corners of the model. The circumferential wave pressure of the tube was obtained by 12 waterproof pressure sensors. The measurable pressure ranges from 0 to 20 kPa, the resolution accuracy is 1%, and the sampling rate is 200 Hz. The 12 pressure sensors were evenly installed in the middle of the SFT model as shown in Figure 1(b). Furthermore, the tension sensor with a maximum range of 30 kg was connected to anchor cable through stainless steel collet to monitor cable forces.

2.4 *Test conditions*

The present experimental test focuses on the dynamic response characteristics of SFT model under regular waves. The wave height and period in testing were determined based on long-term observation data of the east coast of China (Huang et al., 2021). Wave heights ranged from 0.05 to 0.1 m, while the wave period varied from 0.8 to 1.10 s. Water depth was kept constant at 2.2 m during the test, which means that the model was 0.4 m below the water surface. The incident wave propagation direction was perpendicular to the longitudinal axis of the SFT model.

The actual wave generated by the wave-making system during the test may be affected by control system errors, basin boundaries or other unknown factors. The reliability of the generated wave field should be examined first before formal test. The actual wave surface without the SFT model was measured by 2 capacitance-type wave gauges installed in the central test area of the wave-current basin. Several wave-generation experimental tests under different wave parameters were conducted, and Figure 2 illustrates the results for typical tests. The measured wave heights showed a relatively good agreement with the calculated values of linear wave theory, with an overall error of less than 3%. The two cases shown above essentially cover the wave condition in tests, including large wave heights as well as large period conditions. Consequently, the wave-current basin can generate a stable and accurate wave field satisfying the requirements of experimental test. All the regular wave parameters are detailed in Table 1.

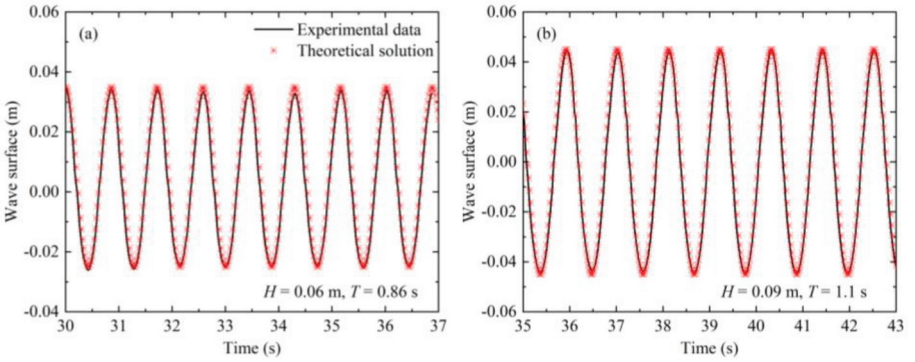

Figure 2. Comparison of regular wave between experimental data and theoretical solution.

Table 1. Regular wave parameters in the tests.

Number	H (m)	T (s)

D36 - D42	0.10	0.8, 0.86, 0.9, 0.96, 1.0, 1.06, 1.10

3 RESULTS AND DISCUSSION

3.1 *Acceleration response*

Figure 3 illustrates the time history of acceleration response in the X, Y, and Z directions (presented in Figure 1(a)) under the wave period of 0.9 s. The longitudinal acceleration of the tube is relatively small, caused mainly by the interaction of the waves with the structure. The transverse acceleration is significantly much greater than the longitudinal acceleration and shows a cyclical pattern consistent with waves. This is primarily due to the wave propagating in the transverse direction, the transverse movement of the water points driving the movement of model. However, when the wave height is small, the curve exhibits a multi-peak phenomenon at the crest. This phenomenon is mainly caused by a combination of wave-reflected wave interactions and wave-structure interactions, indicating a typical nonlinear trend. Compared with the longitudinal and transverse directions, the variation of vertical acceleration response is more complicated. The vertical acceleration shows a multi-periodic variation pattern across the zero point in one wave period, which also indicates that the response frequency of the model in the vertical direction is greater than that in the lateral direction. The multi-peak phenomenon of transverse acceleration becomes attenuated after the wave height greater than 0.07 m, which is because the interaction between the wave and the model strengthened obviously, and it becomes the main influence on the dynamic response of the structure.

Figure 4 shows the time history of the acceleration response under the wave height of 0.08 m with different periods. Under a certain wave height, the multi-peak phenomenon of lateral acceleration weakens as increasing of period and the periodicity of vertical acceleration becomes more significant as well. The reason for this is that the wavelength

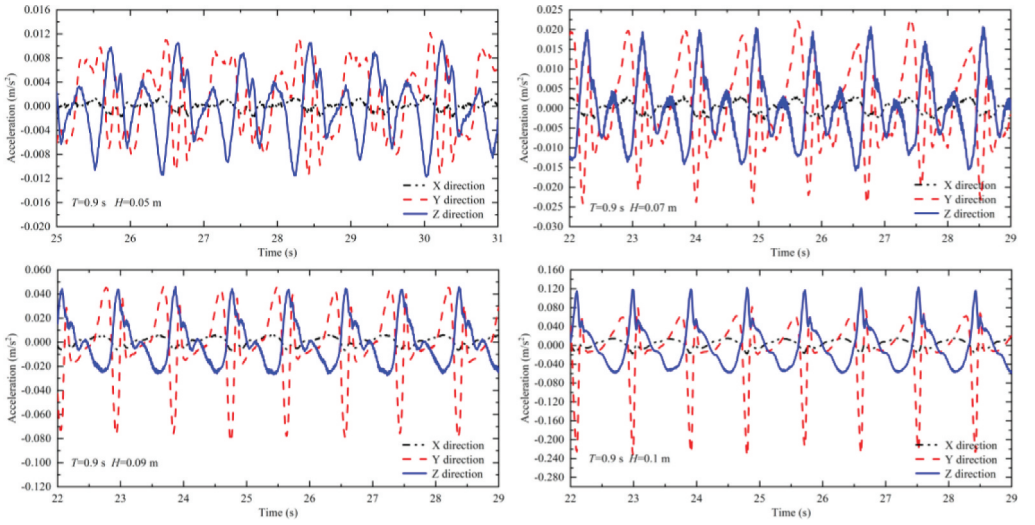

Figure 3. The time history of acceleration response for STF with different wave heights.

increases with increased period, leading to a decrease in wave steepness, which attenuates the energy dissipation of wave breaking. With the increase of wave height and wave period, the amplitude of the negative acceleration in the transverse and vertical directions gradually increases and is much larger than the positive acceleration, and the curve peak of the negative acceleration is also "sharper", which indicates that the speed of the tube changes considerably in a transient time. This is since the transverse and vertical upward movement of the tube is constrained by mooring cable. When the movement of the tube exceeds the permissible range of mooring system, the tube is subjected to a large mooring tension, and the corresponding velocity of the movement will decrease rapidly. It's worth noting that this phenomenon is consistent with the variation of anchor cable tension, which will be further discussed later in Section 3.4.

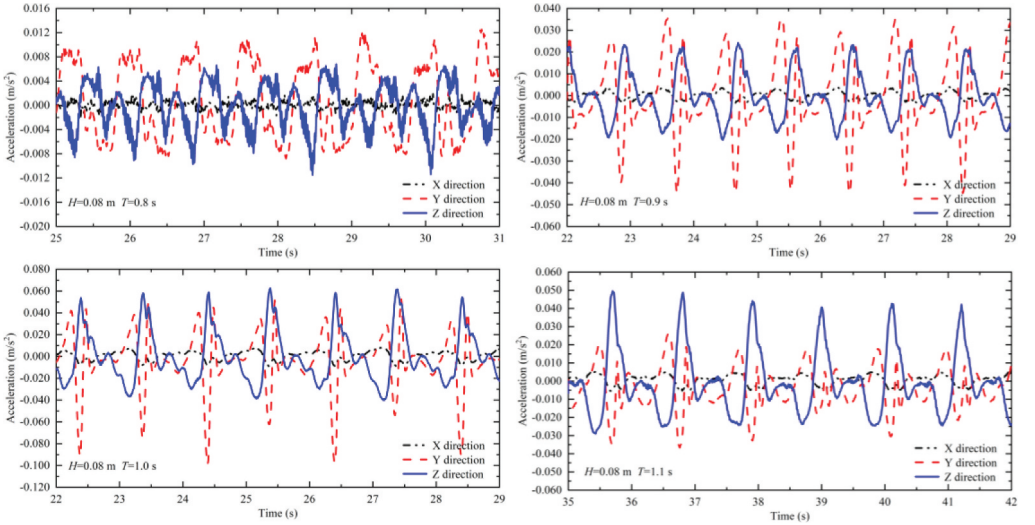

Figure 4. The time history of acceleration response for STF with different wave periods.

To further investigate the influence of wave height as well as wave period on the acceleration response, the extreme values of acceleration response for the model in X, Y and Z directions were extracted. Transverse acceleration is discussed as an example in Figure 5. As the wave height increases, the acceleration responses show a nonlinear increasing trend, indicating that the influence of wave height on the dynamic response of the model is nonlinear. Figure 5 (b) illustrates the variation of acceleration response of tube with wave period. As the period increases, the absolute value of acceleration response increases firstly and then decreases, and reaches the maximum when the wave period is of 1.0 s. The wave period indicates the relative relationship between wavelength and the lateral dimensions of the SFT model. In this test, the wave has the greatest effect on the acceleration response of the tube when the ratio of wavelength to the lateral structure dimensions is approximately 2. Among the different series of data points in Figure 5 (b), the variation of acceleration response with wave period is different in magnitude, indicating that the wave height and wave period play a reciprocal role on the motion response of the structure.

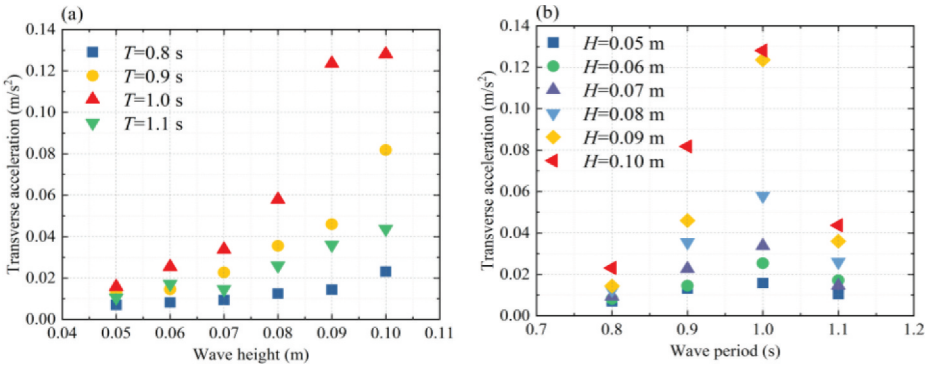

Figure 5. Variation of transverse acceleration maximum with wave height and wave period.

3.2 *Displacement response*

Figure 6 presents the variations of transverse and vertical displacement extremes of the tube with wave height under different wave periods. When the wave period is of 0.8 s, the transverse displacement roughly increases with the increasing of wave height, while the variation regularity of the vertical displacement is relatively weak. Both the vertical and transverse displacements of the tube increase with increasing wave height at wave periods of 0.9, 1.0 and 1.1 s. Meanwhile, it can be found that the vertical and transverse displacements are closer at small wave heights, and the vertical displacement is significantly larger than transverse displacement at large wave heights, indicating the wave height is more significant in influencing the vertical displacement. When the wave period is of 1.0s, i.e., the ratio of wavelength to the transverse structure dimensions is 2, the increase of the displacement for the model increases significantly. It indicates that the wave exerts a significant influence on the kinematic response of the SFT model when the ratio of the wavelength to the structural dimensions is in a certain range. To investigate the effect of wave period on transverse and vertical displacements for the tube, Figure 5 presents the variation of displacement extremes for the tube with wave period. It was found that the displacement of the tube increases firstly and then decreases as the wave period increases (except for wave heights is of 0.05 m). The variation amplitude of the displacement increases significantly when the wave height changes from 0.06 m to 0.1 m. This indicates that the effect of the ratio of wavelength to the structure size on the kinematic response of SFT is more significant at large wave heights.

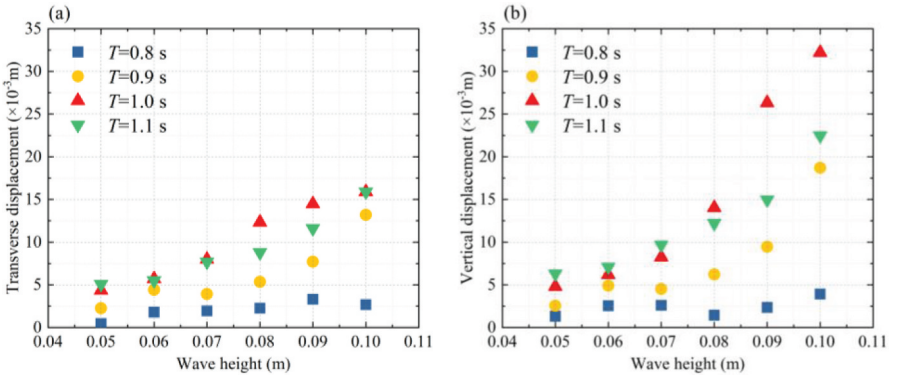

Figure 6. Variations of the displacement extremes of the SFT model with wave height.

3.3 *Wave pressure on the tube*

Taking the case of wave period of 0.8 s as an example, Figure 7 shows the variation of the point pressure at the positions P5, P7 and P9 on the surface of the tube under different wave heights. As presented in Figure 1(b), 5#, 7# and 9# are the midpoint of the wave front, the upper midpoint, and the midpoint of the back wave surface on the SFT model, respectively. As can be seen, the point pressure histories of the three positions show a relatively regular fluctuation phenomenon. Due to the difference in the pressure measurement position, resulting in the wave action time in a sequential order, there is a phase difference in the pressure time histories. The wave pressure is maximum at P5 on the wave front side of the SFT model and minimum at P9 on the leeward side, the former being influenced by both the transverse and vertical movements of the water points. The pressure of P7 at the top of the SFT model is mainly caused by the wave-induced vertical motion of the water points. As the wave height increasing, the energy of the water points increases, it enhances the wave action on the model, and the wave pressures at the three positions show a nonlinear increasing trend, as well as the pressure difference between the three positions decreases progressively. This is distinct from the linear growth trend of the theoretical values calculated using the linearization assumption, indicating the wave-structure interaction has an important effect on the wave force.

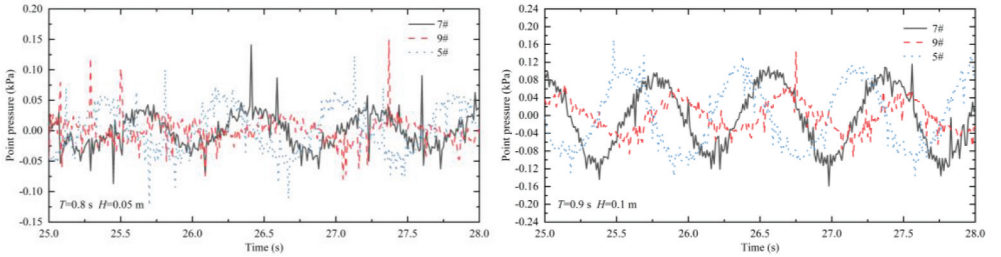

Figure 7. Variation of the point pressure at positions 5#, 7# and 9# on the surface of SFT model.

3.4 *Tension force of cables*

In this test, the anchor cables were symmetrically arranged, and the variations of cable force were comparable. In this section, the 3#~6# anchor cables (see Figure 1(a) for details) were taken as specific examples to discuss the response pattern of the cable force under regular wave. Figure 8 presents the time history of the anchor cable force when the wave height varies from 0.5 to 0.1 m at a wave period of 0.9 s. For small wave heights cases, the four anchor cables' force shows a periodic variation consistent with the wave period, and the order of magnitude for the cable

force is congruent, indicating a uniform distribution of the cable force under the cable arrangement scheme in this test. The variations of the maximum of the cable force with the wave height are given as an example for 3# and 5# anchor cables, which are shown in Figure 9. It should be noted that the measurement equipment failure in the wave height of 0.08m case, so the cable force data is missing. As the increasing of wave height, the cable force of 5# cable (side cables) increased slightly, while the cable force of 3# cable (bottom cables) increased significantly (increased about 6~8 times), and their time history exhibits obvious sharp peaks. As discussed above, with the increase of wave height, the vertical displacement of the tube increases significantly, and the transverse and vertical direction acceleration response curves exhibit obvious "sharp" peaks, when the acceleration response of the tube reaches the maximum, the force of the cables also reaches the maximum at the same time. It is revealed that the anchor cables located below the center of the tube provide most of the restraining force for the structure under large wave height, and more safety allowance is required in the design. The anchor cables located at the side of the tube also play an important role in distributing the force, although the force is smaller. This finding provides an important reference for the selection and design of anchor cable scheme and the safety design of the structure under extreme wave conditions.

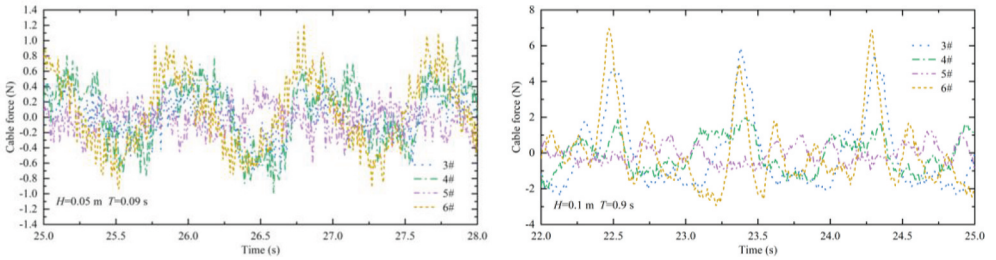

Figure 8. Time history of the anchor cable force with different the wave height.

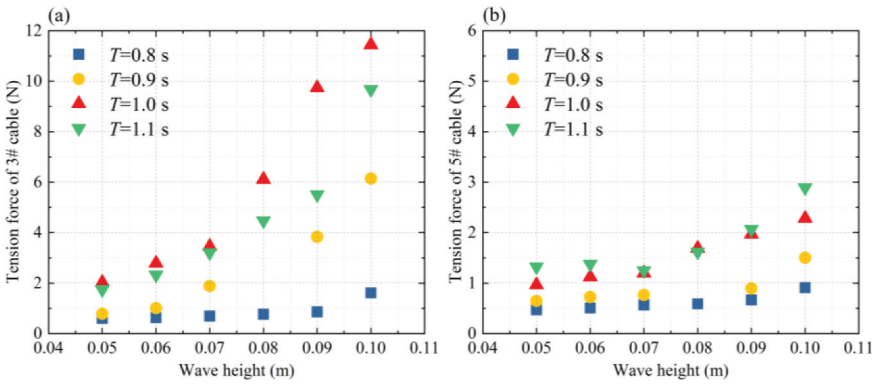

Figure 9. Variations of the maximum of the cable force for 3# and 5# anchor cables.

4 CONCLUSION

In this study, a hydrodynamic experiment of single segment SFT with a geometric scale of 1:60 was conducted based on the Qiongzhou Strait passageway SFT scheme proposed by CMCT. The influence of regular waves on the acceleration, displacement, wave pressure of tube and force of cables were investigated. The results show that:

(1) The acceleration, displacement, wave pressure of the tube and tension force of the cable exhibit a nonlinear increasing trend with the increase of wave height. The acceleration and displacement of the tube firstly increases and then decreases with the increase of wave

period. Wave height and wave period have a reciprocal effect on the kinematic response of the SFT scaled segment model.

(2) The ratio of wavelength to structure size has a significant effect on the dynamic response of SFT. In this test, the wave has a significant effect on the kinematic response of segment model when this ratio is about 2.

(3) With the increase of wave height and wave period, the tension force of the cables below the tube increases significantly and is about twice as much as that of the side anchor cables. The bottom anchor cable provides most of the restraining force for segment model, and the safety allowance for the bottom cable should be increased appropriately in design.

This study can provide an important reference for the structural selection and design of SFT. Further study should be carried out purposely for multi-segment SFT under actual oceanic conditions.

(1) In terms of structure, the influence of neighboring tube sections and boundary constraints should be considered. Special boundary devices should be used in the test to simulate the constraint stiffness. Meanwhile, the characteristics of the joints between tube sections are important factors that reflect and influence the flexible structure characteristics of multiple-segment SFT, which should be emphasized.

(2) In terms of loading conditions, numerical and experimental studies mostly focus on regular waves. However, the actual marine environment is complex, the effects of irregular waves, wave-current coupling, and the coupling of wave-current loads with other loads (impact loads, seismic loads, etc.) on the dynamic response and safety of SFT should be considered as well.

ABSTRACT: This paper presents the numerical simulation of the dynamic response of a long-span submerged floating tunnel under wave action. A numerical model for solving the motion of an elliptical cross-section tunnel is established using the commercial software Ansys. The tunnel structure is simulated using multi-point constrained beam elements, and the wave loads are computed using the Morison equation. The hydrodynamic coefficients of the elliptical cross-section are determined using a three-dimensional FDM-VBF-VOF hydrodynamic model that captures the effects of cross-sectional shape. The numerical calculations were conducted to analyze the motion response characteristics of the submerged floating tunnel under the action of different incident wave periods and wave heights. The numerical results indicate a significant correlation between the amplitude of tunnel motion and the structural natural frequency: the closer the incident wave frequency to the structural natural frequency, the greater the amplitude of structural motion.

1 INTRODUCTION

The Submerged Floating Tunnel (SFT) is an innovative marine transport facility characterized by its low environmental impact, stable operation, and consistent costs that remain relatively unaffected by variations in water width and depth. It is suitable for crossing deep and long straits. However, owing to the unique characteristics of its environment, boundary conditions, load capacity, and structural dynamics, the dynamic response of the SFT is very complex, involving the nonlinear interactions of waves, currents, the tunnel structure, anchors, and boundaries. The associated research encompasses nonlinear wave mechanics, vortex dynamics, fluid-structure coupling mechanics, and structural dynamics, among other multidisciplinary fields, so it has become a research hotspot in recent years. (Zhang et al., 2021; Iovane et al., 2023; Xu et al., 2023).

Limited by the development of technology, present model experiments and CFD research of SFT mainly focus on short-span or truncated models. Chen et al. (2023) experimentally studied the motion characteristics of a twin-circular SFT under wave actions. They found when the incident wave frequency was close to twice the natural frequency of the structure, the resonant sway motion with half of the incident wave frequency and a large amplitude would be excited, so they suggested that this resonance phenomenon should be avoided in the design of the structure. The hydrodynamic characteristics of SFT are closely related to its cross-section shape (Li et al., 2018;

DOI: 10.1201/9781003483755-123

Zou et al., 2020). Mandara et al. (2016) compared the dynamic response characteristics of circular and elliptical cross-section SFT for different flow velocities using the Abaqus FSI co-simulation tool. The results show that the elliptical cross-section has better hydrodynamic characteristics. Therefore, this manuscript focuses on the study of SFT with elliptical cross-section.

It is difficult to study the dynamic response characteristics of large-span SFT by experiment and three-dimensional CFD simulation. Therefore, to study the motion response of a large-span elliptical cross-section SFT under the action of regular waves, the Ansys mechanical module is used for structural mechanical analysis and finite element analysis, and the Morrison equation is used to simulate the wave action. The hydrodynamic coefficients of the elliptical cross-section are determined using a three-dimensional FDM-VBF-VOF hydrodynamic model that captures the effects of cross-section shape.

2 NUMERICAL MODEL

2.1 *Ansys numerical model*

The governing equations of dynamics for the structure are described as:

$$[\mathbf{M}]\{\ddot{\boldsymbol{\xi}}\} + [\mathbf{C}]\{\dot{\boldsymbol{\xi}}\} + [\mathbf{K}]\{\xi\} = \{\mathbf{F}\} \tag{1}$$

where [**M**] is the mass matrix; [**C**] is the Rayleigh damping matrix; [**K**] is the stiffness matrix; $\{\ddot{\xi}\}$is the acceleration vector; $\{\dot{\xi}\}$is the velocity vector; [**ξ**] is the displacement vector; {**F**}is the hydrodynamic load vector.

The Newmark-β scheme is used for the time advancements of Equation (1) and the Newton–Raphson technique is adopted for the sub-iteration at each incremental step. The incremental equations for the n+1th incremental step are given as:

$$\begin{aligned} \dot{\xi}_i^{n+1} &= \dot{\xi}_i^{n} + (1-\gamma)\ddot{\xi}_i^{n}\Delta t + \gamma\ddot{\xi}_i^{n+1}\Delta t \\ \xi_i^{n+1} &= \xi_i^{n} + \dot{\xi}_i^{n}\Delta t + \left(\frac{1}{2}-\beta\right)\ddot{\xi}_i^{n}\Delta t^2 + \beta\ddot{\xi}_i^{n+1}\Delta t^2 \end{aligned} \tag{2}$$

where n denotes the time step, the coefficient γ denotes the weight of the effect of the initial and final accelerations on the change in velocity, and the coefficient β denotes the weight of the contribution of the initial and final accelerations to the change in displacement.

2.2 *The FDM-VBF-VOF numerical model*

Based on the fluid-structure interaction model proposed by Wang et al. (2022) and Wang et al. (2023), the incompressible Navier-Stokes equations are adopted as the governing equations for the fluid flow, which are numerically discretized by the finite difference method (FDM). The virtual boundary force (VBF) method proposed by Lin et al. (2016) is used to deal with the boundary conditions at the fluid-solid interface. The volume of fluid (VOF) method is used to capture the water-air interface. The numerical model has been used to investigate the vortex-induced vibration of a circular cylinder with two degrees of freedom (Zhao et al., 2023). The relevant formulas are given as follows:

$$\begin{aligned} \frac{\partial u_i}{\partial x_i} &= 0 \\ \frac{\partial u_i}{\partial t} + u_j\frac{\partial u_i}{\partial x_j} &= -\frac{1}{\rho_f}\frac{\partial p}{\partial x_i} + \nu\frac{\partial^2 u_i}{\partial x_j \partial x_j} + f_{\mathrm{VBF}} \end{aligned} \tag{3}$$

$$\frac{\partial F}{\partial t} + \frac{\partial (u_i F)}{\partial x_i} = 0 \tag{4}$$

where u_i is the fluid velocity in the x_i direction (i, j=1,2 for the x and y directions in the Cartesian coordinate system), t is time, p is pressure, f_{VBF} denotes the momentum forcing term when imposing the no-slip boundary condition on the immersed boundary, and F represents the volumetric fraction between the air and water, which equals to 0 in air and 1 in water.

2.3 *The Morison equation*

The wave force, calculated by Morison's equation, consists of two components: the drag force and the inertia force. Considering the relative motion of the structure to the water, the expression is as follows:

$$f_i = C_d \frac{\rho_w}{2} D(u_i - \dot{\xi}_i)\left|u_i - \dot{\xi}_i\right| + \rho_w \frac{\pi D^2}{4}\frac{\partial u_i}{\partial t} + C_{m0}\rho_w \frac{\pi D^2}{4}\left(\frac{\partial u_i}{\partial t} - \ddot{\xi}_i\right) \tag{5}$$

where f_i is the wave force acting on the cylinder with unit length; ρ_w is the density of water; D is the diameter of the cylinder; u_i is the velocity of the water parcel; C_d is the drag coefficient, C_{m0} is the additional mass coefficient, and C_m=1+C_{m0} is the coefficient of inertia force coefficient. There are no suitable reference specifications and formulas yet for hydrodynamic coefficients of elliptical cross-sections, so C_d and C_m are calculated by a three-dimensional FDM-VBF-VOF hydrodynamic model that captures the effects of cross-sectional shape.

3 NUMERICAL SIMULATION SETUP

Considering the influence of wave nonlinearity and structural nonlinearity, the numerical calculations were conducted to analyze the motion response characteristics of the SFT under the action of different incident wave periods and wave heights (T=6s-26s, H=9m). The main simulation parameters are listed in Table 1. The damping ratio of the structure is set to 0.8%.

Since Ansys does not provide elliptical pipe elements, and the hollow beam elements are unable to differentiate between internal and external media (which leads to a change in the buoyancy/weight ratio and hydrodynamic force), we propose a composite beam modeling method in which the interior of an elliptical cross-section hollow beam is filled with another elliptical cross-section beam without mass and stiffness, as shown in Figure 1.

Give the structure an initial displacement, and let it vibrate freely in the water, after the free decay test, we can get the horizontal first-order natural frequency is 0.154 Hz, and vertical first-order natural frequency is 0.295 Hz. The vertical natural frequency is about 2 times the horizontal natural frequency.

Table 1. Test parameters.

Parameter	Symbols	Value	Unit
Water depth	h	100	m
Submergence depth	d_m	45	m
Buoyancy to weight ratio	BWR	1.3	/
Length	l	13000	m
Cross-section dimension of external beam	$a_1 \times b_1$	40×15	m
Density of the external beam	ρ_1	4354	kg/m^3
Young's modulus of external beam	E_1	4.20E+10	Pa
Cross-section dimension of internal beam	$a_2 \times b_2$	38×13	m
Density of the internal beam	ρ_2	0	kg/m^3
Young's modulus of internal beam	E_2	10	Pa
Inclination angle of mooring line	α	60	°
Installation angle of mooring line	β	60	°
Stiffness of mooring line	k	3.5E+8	N/m
Spacing of mooring lines	s	100	m

4 RESULTS AND DISCUSSION

4.1 *The hydrodynamic coefficient*

The hydrodynamic coefficient is calculated as follows:

(1) When the structure is fixed, the Equation (5) is simplified as:

$$f_i = C_d \frac{\rho_w}{2} D u_i |u_i| + C_m \rho_w \frac{\pi D^2}{4} \frac{\partial u_i}{\partial t} \tag{6}$$

(2) The theoretical wave force $f_c(i)$ is obtained by the Morrison equation, where the expressions for velocity and acceleration are from linear wave theory. The equations for velocity and acceleration in the horizontal and vertical directions are given below:

$$\begin{aligned} u_y &= \frac{\partial \phi}{\partial y} = \frac{gkA}{\omega} \frac{\cosh k(z+d)}{\cosh kd} \text{ and } \frac{\partial u_y}{\partial t} = gkA \frac{\cosh k(z+d)}{\cosh kd} \\ u_z &= \frac{\partial \phi}{\partial z} = \frac{gkA}{\omega} \frac{\sinh k(z+d)}{\cosh kd} \text{ and } \frac{\partial u_z}{\partial t} = gkA \frac{\sinh k(z+d)}{\cosh kd} \end{aligned} \tag{7}$$

(3) The sum of error squares between the wave force $f_m(i)$ and $f_c(i)$ calculated by the FDM-VBF-VOF numerical model is:

$$Q = \sum_{i=1}^{n} [f_c(i) - f_m(i)]^2 \tag{8}$$

(4) By the least square method, the hydrodynamic coefficients C_d and C_m can be obtained from $\frac{\partial Q}{\partial C_d} = \frac{\partial Q}{\partial C_m} = 0$.

Using the above method, the hydrodynamic coefficients of the elliptical cross-section under two wave conditions in this study are obtained, as shown in Table 2. It can be seen that the vertical inertia force coefficient is about 2.7 times that of the horizontal inertia force coefficient, which is consistent with the ratio of the elliptical long axis to short axis; the inertia force coefficients increase slightly with the increase of the period, C_{my}=1.2~1.3 and C_{mz}=3.2~3.5; Since the drag force accounts for the small percentage of the total wave force, the drag coefficient solution is poorly accurate, as shown in Figure 2. According to Kunisu (2010), inertial forces play a dominant role when the K_C number is less than 15 (K_C=$u_m T/D$, where u_m is the maximum velocity of the water parcel at the center of the model). The range of K_C numbers involved in this study is 0.012-2.17, so the effect of drag force is ignored in the subsequent study, and C_{my} took a mean value of 1.25 and C_{mz} took a mean value of 3.35.

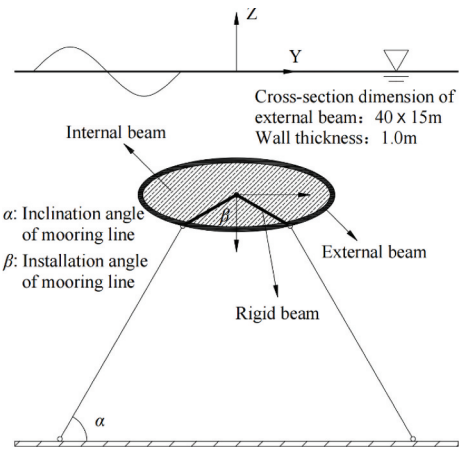

Figure 1. Schematic diagram of composite ellipse section.

Table 2. The hydrodynamic coefficient.

Wave condition	C_{my}	C_{mz}	C_{dy}	C_{dz}
H=9m, T=9s	1.2	3.2	/	19.8
H=9m, T=12s	1.3	3.5	/	7.7

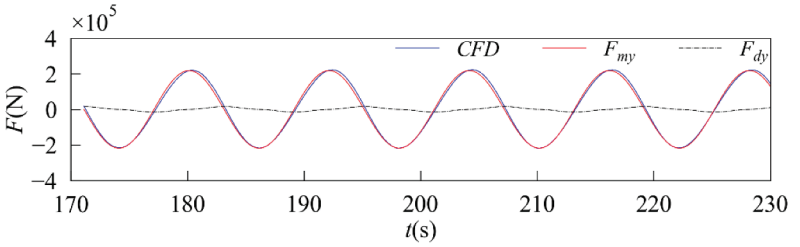

Figure 2. Comparison of total wave force, drag force and the inertia force at H=9m, T=12s.

4.2 *Response amplitude of the SFT*

Figure 3 and Figure 4 show the horizontal and vertical displacement distribution of the tunnel at H=9m, T=7.3s, respectively. It can be seen that the tunnel vibrates in a first order mode in both the horizontal and vertical directions, with the maximum displacement in the midspan.

Figure 5 and Figure 6 depict the time histories of horizontal and vertical displacement in the quarter span and midspan of the tunnel at H=9m, T=7.3s, respectively. It can be seen that the horizontal and vertical displacement amplitudes gradually increase to a fixed value with time. In addition, all other cases in this study also vibrate in first order mode, so in the following analysis, we focus on the displacement in the midspan of the tunnel.

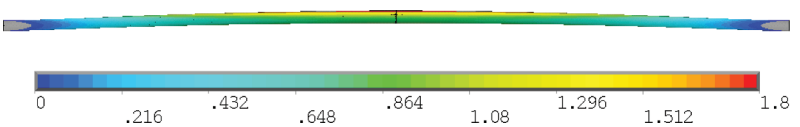

Figure 3. Horizontal displacement distribution of the tunnel at H=9m, T=7.3s (magnified 20 times).

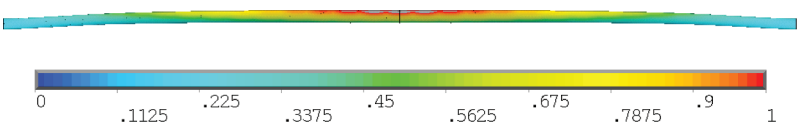

Figure 4. Vertical displacement distribution of the tunnel at H=9m, T=7.3s (magnified 100 times).

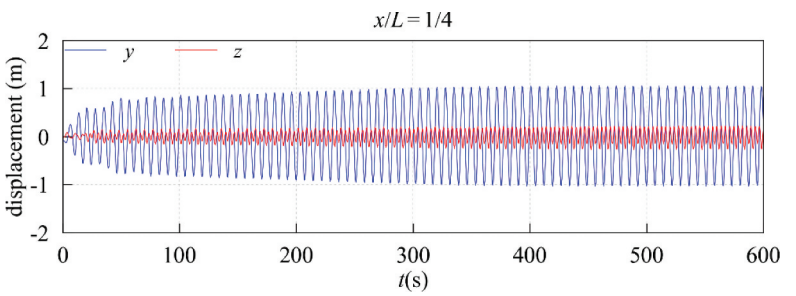

Figure 5. Time history of horizontal and vertical displacement in the quarter span of the tunnel at H=9m, T=7.3s.

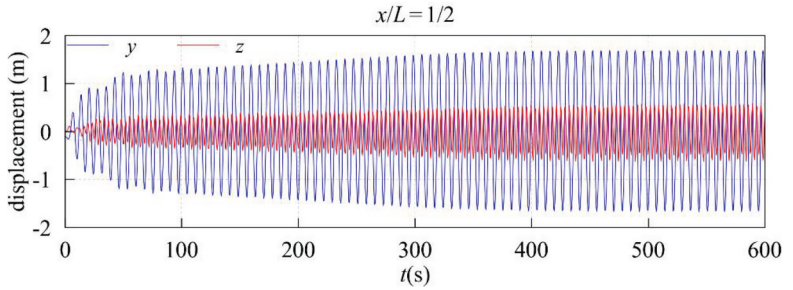

Figure 6. Time history of horizontal and vertical displacement in the midspan of the tunnel at H=9m, T=7.3s.

Figure 7 shows the variation of maximum horizontal and vertical displacements of the SFT with dimensionless wave frequency. It can be found that when the incident wave frequency is close to the horizontal natural frequency of the SFT, the horizontal resonance motion of the tunnel is excited, and the horizontal and vertical displacements of the SFT reach the maximum values of 1.68m and 0.6m, respectively; when the incident wave frequency is close to half of the horizontal natural frequency of the SFT, the parametric resonance of the tunnel is excited, and the horizontal and vertical displacements of the SFT reach the peak values of 0.93m and 0.2m, respectively.

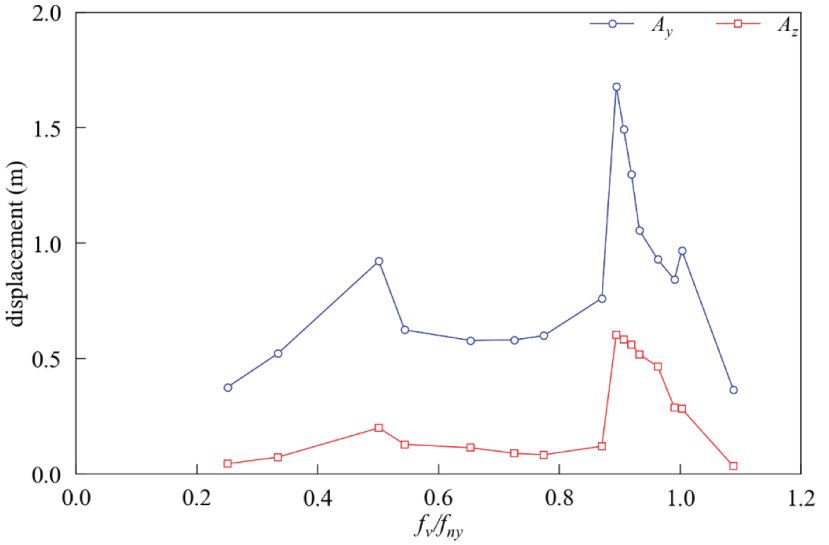

Figure 7. Variation of maximum horizontal and vertical displacements of the SFT with wave frequency.

4.3 *Response frequency of SFT*

Figure 8 demonstrates the variation of the horizontal and vertical response frequencies of the SFT with dimensionless wave frequency. It can be seen that the main horizontal response frequency of the SFT is consistent with the wave frequency. The vertical response frequency of the SFT is twice the wave frequency in the range of f_v/f_{ny}=0.87-1.0 (T=6.5s-7.5), while outside of this range, the main vertical response frequency of the SFT is consistent with the wave frequency. It is also worth noting that the structure does not have a single response frequency and that only the frequency with the largest amplitude is shown in the figure.

Figure 9 shows the horizontal and vertical response frequency amplitude spectrum at two cases. It can be seen that the movement of the structure has many frequency components, including wave frequency and multiple wave frequency. This is because both the nonlinearity of waves and the nonlinearity of structures are considered.

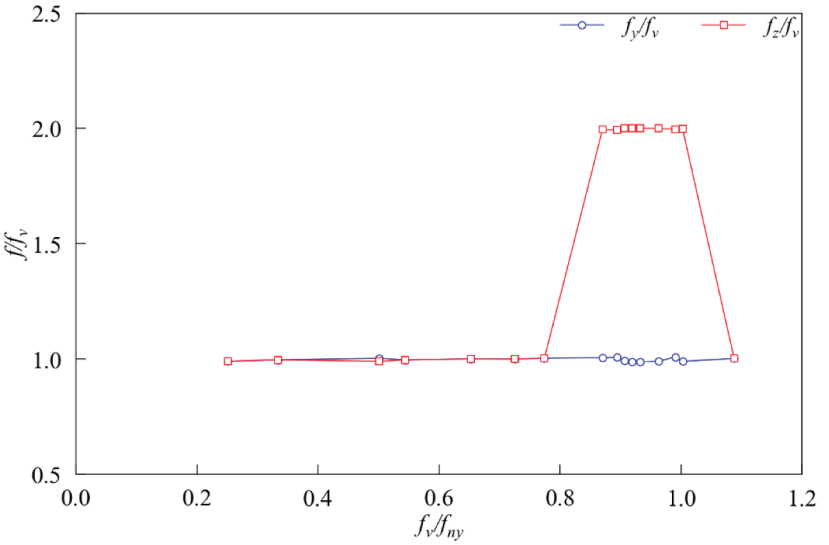

Figure 8. Variation of SFT response frequency with wave frequency.

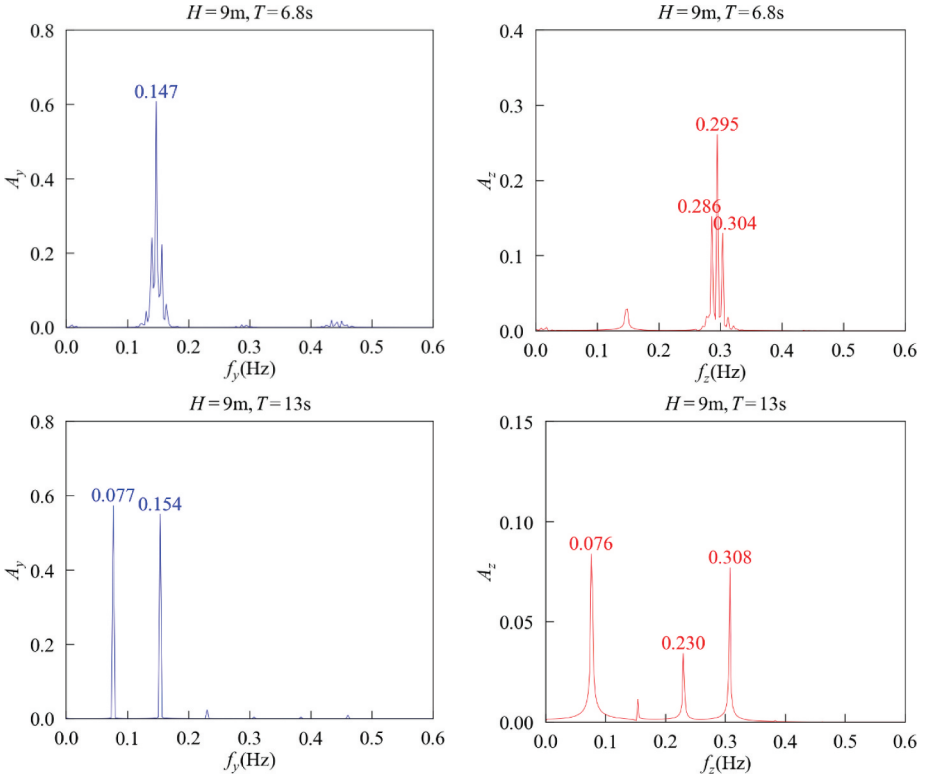

Figure 9. Horizontal and vertical response frequency amplitude spectrum.

5 CONCLUSION

Considering the influence of wave nonlinearity and structural nonlinearity, numerical calculations were conducted to analyze the motion response characteristics of the SFT under the action of different incident wave periods and wave heights. The main findings are summarized as follows:

(1) When the incident wave frequency is close to the horizontal natural frequency of the SFT, the horizontal resonance motion of the SFT is excited, and the horizontal and vertical displacements of the SFT reach the maximum values of 1.68m and 0.6m, respectively.
(2) When the incident wave frequency is close to half of the horizontal natural frequency of the SFT, the parametric resonance of the SFT is excited, and the horizontal and vertical displacements of the SFT reach the peak values of 0.93m and 0.2m, respectively.
(3) The main horizontal response frequency of the SFT is consistent with the wave frequency. The vertical response frequency of the SFT is twice the wave frequency in the range of f_v/f_{ny}=0.87-1.0 (T=6.5s-7.5), while outside of this range, the main frequency of the vertical response of the SFT is consistent with the wave frequency.

Modeling of two-dimensional water motion field during a seaquake

V. Maugeri, L. Martinelli & F. Perotti
Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: This study investigates seaquake phenomena, analyzing the role of P-waves in generating seismic waves in water. Different modeling approaches for understanding the dynamic water motion during seaquake are addressed and one-dimensional P-wave propagation in the frequency domain is compared to two dimensional propagation models in frequency and time domain. The comparison is specifically carried out for structures like Submerged Floating Tunnels focusing on the effect of water depth, self-damping and resonance on the water motion field. The two dimensional propagation model in frequency domain is extended to account for a non-flat seabed. The results obtained are critically compared to the ones delivered by a time domain approach utilizing a Finite Element discretization and exploiting the Domain Reduction Method for soil-structure interaction analysis.

1 INTRODUCTION

Seaquake phenomena are associated to seismic events that occur beneath the oceanic Earth's crust. These can generate significant energy release, resulting in the propagation of seismic waves throughout the surrounding water.

Among the various types of seismic waves, P-waves (primary, or compressional, waves) play an essential role in seawater propagation. Understanding their behavior and characteristics is crucial for various applications, since the derived motion field is fundamental to assess the potential impact on submerged and floating structures.

The present work aims to offer a first contribution concerning the knowledge of the dynamic water motion field during a seaquake, comparing different modelling methodologies. The problem is tackled in two dimensions, both in time and frequency domain, and compared to one-dimensional vertical propagation of P waves in frequency domain, i.e. to the most frequent approach adopted in practical applications. This comparison is of great interest for long structures, as Submerged Floating Tunnels are.

The frequency domain solution is further updated by removing the hypothesis of flat seabed, assuming that the soil-water interface follows a piece-wise constant profile.

The resulting water motion field is first examined for resonance phenomena, observing the dependence on water depth and self damping. Then, the results are critically compared against those coming from the time domain approach, which are based on the use of Finite Elements and implementation in ABAQUS (Dassault Systèmes Simulia Corp. 2022) of the soil-structure interaction analysis technique called Domain Reduction Method (Bielak et al. 2003).

2 TWO DIMENSIONAL FREQUENCY-DOMAIN MODEL

The model developed in this chapter aims to reproduce, in two dimensions, the water motion field due to seaquake events. The equations used to represent compressive waves propagation are based on (Wang et al 2004) theory; this model is here used to analyze the effects of porous seabed on dynamic pressures of ideal fluid under the action of P waves, deriving the water motion field in terms of a displacement potential. In the present study, the porous medium

DOI: 10.1201/9781003483755-124

(which represents the overlying sediment to the seabed) considered by (Wang et al. 2004) is neglected and an ideal fluid (water) is directly in contact with the underlying elastic bedrock.

The model accounts for both the inclination of the incident wave at the water-bedrock interface, and the contribution provided by S waves propagation into the soil medium. The ground motion is expressed through its vertical and horizontal components.

The formulation can address the case of multiple layers, each with its own governing equations.

The first layer, representing the linear elastic bedrock, uses Lamé-Navier's equation derived from elastodynamics equilibrium. The second layer, ideal compressible water, assumes compressible seismic wave propagation, neglecting S-waves due to an ideal fluid assumption. Water damping, crucial for realistic motion outcomes, is assumed as linear hysteretic damping; in such model dissipation is independent of excitation frequency and affects the P-wave velocity in seawater by introducing an imaginary part proportional to the non-dimensional damping coefficient.

2.1 *Flat seabed model*

In the simplest case, the water is directly in contact with the flat semi-infinite elastic bedrock. A plane P-wave hits the interface between the bedrock and the water with an incidence angle θ and an angular frequency ω. A transmitted P wave propagates initially upward through water, while reflected P and S wave propagate downward in the elastic half-space. The P waves which propagate upward are then reflected on the free surface, generating a downward propagating P wave.

The wave number k_x in x direction is the same due to Snell's Law in all layers, while k_{wz}, in z direction, changes depending on the layer properties.

Starting from the scalar and vector displacement potentials, φ_s and ψ_s, for the elastic bedrock ($z<0$), and the scalar displacement potential φ_w for the water ($z>0$) defined as in Wang et al., the following vertical and horizontal components of the water motion field are obtained:

$$\xi_{wz}(x,z,t,\omega) = ik_{wz}\left[-A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} + A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{1}$$

$$v_{wz}(x,z,t,\omega) = \omega k_{wz}\left[A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} - A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{2}$$

$$a_{wz}(x,z,t,\omega) = i\omega^2 k_{wz}\left[A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} - A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{3}$$

$$\xi_{wx}(x,z,t,\omega) = -ik_x\left[A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} + A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{4}$$

$$v_{wx}(x,z,t,\omega) = \omega k_x\left[A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} + A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{5}$$

$$a_{wx}(x,z,t,\omega) = i\omega^2 k_x\left[A_{lP1}e^{i(\omega t-k_x x-k_{wz}z)} + A_{lP2}e^{i(\omega t-k_x x+k_{wz}z)}\right] \tag{6}$$

In Equations 1-6 ξ_w, v_w, a_w denote the displacement, velocity and acceleration in water, ω is the angular frequency of the incident wave, i is the imaginary unit, t is the time, while A_{lP1}, A_{lP2} are unknown constant coefficients representing waves amplitude, respectively related to transmitted and reflected P waves in the water. Wave numbers k, with their components along x and z directions, depend on wave propagation velocities in each medium. The unknown amplitudes are determined through the imposition of the following boundary conditions: equilibrium of fluid pressure at the water free surface, compatibility of normal displacements at bedrock-water interface, equilibrium of normal and tangential stresses at the bedrock-water interface.

2.2 *Rising bedrock model*

The model can be further improved, varying the water depth through a piece-wise constant function, which approximates the water depth to a constant value in each finite length in which the domain is subdivided. In this way, the system is solved for each portion of the

domain, calculating the contribution of that portion to the adjacent water columns, which can show different depths.

In this case, the unknown amplitudes A_{lP1}, A_{lP2} are functions of the global coordinate x, defining the location of P-wave source along the longitudinal domain of the bedrock. In fact, these parameters are evaluated by solving the system for each water depth in which the specific ground portion is defined, leading to different results.

2.3 *Two-dimensional development of the problem*

Integration of the results in Equation 1-6 along the entire longitudinal dimension x of the problem is necessary to recover the overall motion field across the entire water domain, considering that each portion of the water-seabed interface represents a source of spherically propagating P-waves, which gives its contribution in terms of motion field in a generic point P of the water domain.

At each seabed point the earthquake motion can be expressed starting from the direct PSD of the ground motion components. The spatial variability of the ground motion is introduced through a coherency function, allowing to define the Cross Power Spectral Densities (CPSD). Once the ground motion is known at each ground site in terms of PSDs and CPSDs, it is possible to superimpose the results. The contributions in the generic point P provided by each infinitesimal source having x_p and z_p as horizontal and vertical distance respectively from the point P is obtained, simplifying the problem, subdividing the horizontal domain into N_P portions having δ_x length. In addition, each portion is assumed to be characterized by a constant value in x of the PSDs and CPSDs (the average value). For example, the overall water vertical velocity is given by

$$v_{wz,tot}(x_P, z_P, \omega) = \sum_{i=1}^{N_P} \left\{ \omega k_{wz} \left[A_{lP1} e^{i\left(-k_x x_P^i - k_{wz} z_P\right)} - A_{lP2} e^{i\left(-k_x x_P^i + k_{wz} z_P\right)} \right] \right\} \delta_x \tag{7}$$

3 2D TIME-DOMAIN MODEL

As explained in Chapter 2.2, introducing a varying water depth by means of a frequency-domain formulation results to be a complex task. An alternative way to model the wave propagation phenomenon in a two-dimensional domain is to study it in time-domain. In the following a two-dimensional seaquake model developed in the ABAQUS Finite Element (Dassault Systèmes Simulia Corp. 2022) code is proposed, characterized by the implementation of a state-of-the-art method to perform soil-structure interaction analyses. A comparison with the results coming from frequency-domain model is then performed.

3.1 *Semi-unbounded medium and seismic force definition*

Two main aspects need to be investigated to well represent wave propagation in Finite Elements in a semi-unbounded medium: the identification of the domain in which the soil-structure interaction (SSI) analysis has to be performed, and the selection of proper boundary conditions for the selected domain. Wave propagation between soil and seawater is a fluid-structure interaction problem, in which the soil must be elsewhere truncated. In fact, the model should be able to simulate the dissipation of energy occurring when an outgoing wave approaches the infinitely extending boundaries of the modeled domain, preventing any spurious reflection towards the domain of interest. This fluid-structure interaction system can be interpreted as a soil-structure-interaction problem, in which the water behaves like a structure.

There are different methodologies to perform soil-structure interaction analyses. In general terms, these methods differ for the extension of the modeled domain, the necessity of employing specific boundary conditions, and the way in which input forces are included in the model.

In (Lysmer and Kuhlemeyer 1969) viscous boundaries are introduced to absorb outgoing incident waves. This boundary condition is the one selected to develop the following analyses. Note that, on practical grounds, the required elements are already implemented in ABAQUS under the name of infinite elements (4 nodes CINPE4). It is also worth noting that many studies, such as the one of (Kontoe et al. 2007), demonstrated that their functionality highly depends on the SSI

technique used for the analysis. In fact, when they are used alone on the side boundaries of a simple direct method, they fail to reproduce free-field response and lead to serious inaccuracy of the response in the near field. By contrast, the same study shows that, when these standard viscous boundaries are combined with an innovative SSI scheme such as the Domain Reduction Method (DRM), originally formulated in (Bielak et al. 2003), and implemented in the present work, their efficiency significantly improves. This is because the DRM procedure allows the dashpots to be located at a sufficient distance from the excitation source, thus reducing the energy to be transmitted to the scattered energy only, deriving from the structure.

The DRM allows to define the seismic forces in the model through a set of effective nodal forces P^{eff}. These forces are defined in two layers of nodes: ${P_b}^{eff}$ corresponds to nodal forces on an inner boundary Γ, while ${P_e}^{eff}$ are defined in Γ_e, which is the surface (boundary) externally adjacent to Γ:

$$P^{eff} = \begin{bmatrix} {P_i}^{eff} \\ {P_b}^{eff} \\ {P_e}^{eff} \end{bmatrix} = \begin{bmatrix} 0 \\ -M_{be}^{\Omega^+} \ddot{u}_e^0 - K_{be}^{\Omega^+} u_e^0 \\ M_{eb}^{\Omega^+} \ddot{u}_b^0 - K_{eb}^{\Omega^+} u_b^0 \end{bmatrix} \tag{8}$$

where M and K denote mass and stiffness matrices, the subscripts e, and b, refer to nodes in either the exterior boundary Γ_e or on the inner boundary Γ, respectively. The superscripts Ω and Ω^+ refer to the domains over which the various matrices are defined. Specifically, Ω is the inner domain containing the geological feature of interest (i.e. water), which is separated by Γ from Ω^+ that represents the truncated semi-infinite exterior domain. Finally, u^0 and $\ddot{u}^0$ represent the free-field within motion in terms of displacement and acceleration respectively.

The developed time-domain model relies on a fully automated implementation of the DRM in ABAQUS. This implementation technique relies on an additional hypothesis on the evaluation of free-field motion, that is evaluated assuming vertical propagating waves. Thanks to this assumption, free-field motion determination is performed by a deconvolution analysis, which is provided by the software STRATA (Kottke et al 2009). These motion components are automatically extracted, read, and manipulated through a MATLAB (The MathWorks, Inc. 2022) preprocessing module, where effective nodal forces are evaluated through Equations 8, using structural matrices directly exported from ABAQUS. Once the effective earthquake forces are evaluated, they are included in the ABAQUS main model through a further manipulation of the input file, where parts of the input script, defining amplitude and location of each nodal force, are directly written by another MATLAB code.

3.2 *Soil modeling*

The soil part is defined as a 2D planar deformable body, and the material is modeled as homogeneous, isotropic, linear elastic and composed by only one infinite layer, extending in vertical and horizontal directions. The identified parameters to model the soil are listed in Table 1:

Table 1. Mechanical parameters of soil in ABAQUS.

E	ν	λ	μ	ρ	v_p	v_S
Pa	-	*Pa*	*Pa*	*kg/m³*	*m/s*	*m/s*
1.1489e+09	0.3	6.6283e+08	4.4189e+08	1000	902.25	482.26

Regarding the criteria for meshing the domain, two types of elements are used in the model. The ones inside the domain's boundaries are linear plane strain elements with reduced integration (CPE4R), belonging to the family of solid continuum elements. The elements on the boundaries are 4-node infinite elements (CINPE4) reproducing the unlimited extension of the domain. Regarding the interaction between soil and fluid, the applied modeling technique is the surface-based tie constraint, which links the relative motion between the two parts by simply defining a master-slave surface pair.

3.3 *Water modeling*

In general, to model water material, two requirements are necessary: first, the material must have zero or negligible shear stiffness, such that the propagation of shear waves is prevented; second, the material must be characterized by a volumetric module such that the propagation speed of compressive waves is comparable to the real one. In this model, two options are employed and compared. The first alternative is represented by equation of state (EOS) materials, which are specific type of materials available in Abaqus/Explicit (Dassault Systèmes Simulia Corp. 2006a). They provide a hydrodynamic material in which the pressure is defined as a function of the density and the internal energy, whereas its volumetric strength is determined by an equation of state. The parameters s, c_0, and Γ_0 are the input constants to define the material behavior in ABAQUS. The literature offers enough information about the selection of these parameters. In ABAQUS benchmarks (Dassault Systèmes Simulia Corp. 2006b, 2006c) the constants s and Γ_0 are set to zero whereas c_0 is selected such that the elastic bulk modulus ($K = \rho_0 c_0^2$) is reduced to well represent sloshing phenomenon, with a value c_0 = 30 ÷ 50 *m/s*. However, since the task of this study is to properly represent the wave propagation problem, the elastic wave velocity is set to the real one (c_0 = 1483 *m/s*), therefore the volumetric stiffness is 2.2 *GPa*. Concerning the dynamic shear viscosity, a value of $\eta_v = 13e^{-4}$ $Pa \cdot s$ is chosen to be consistent with the values suggested in ABAQUS benchmarks. Finally, the mass density is set to 1000 kg/m^3.

The second method arises from Kuznetsov works (Shugan et al 2021), in which the author proposes to model water by quasi-elastic medium with small Young's modulus and large Poisson's ratio. In fact, by setting a very high value for the Poisson's ratio close to the limit 0.5, and accordingly reducing the Young's modulus, it is possible to obtain a material with the same volumetric stiffness of the water and a negligible shear modulus.

Regarding the identification of meshing elements, in all the mentioned modeling techniques, the water is composed by first order plain strain elements CPE4R, as the soil. However, as suggested by ABAQUS Manual (Dassault Systèmes Simulia Corp. 2006b, 2006c), the hourglass scaling factor is set to 25.

3.4 *Meshing techniques and mesh size selection*

To properly capture the wave propagation behavior in a discretized domain, the domain discretization must comply with the Courant-Friedrichs-Lewy (CFL) (Moura et al 2013) limitation. In the present case, assuming a maximum excitation frequency of 25 *Hz*, and considering the maximum and minimum wave velocities associated to water and soil respectively, the largest allowed mesh size is about 2.4 m. However, to be conservative and to guarantee a proper resolution even when higher frequencies occur, the mesh size is furtherly reduced to have a uniform value of Δx = 1 m.

Finally, it is important to mention that the techniques used to model the water material must be supported by a specific ABAQUS remeshing function called Arbitrary Lagrangian-Eulerian adaptive meshing (ALE) in order to maintaining a high-quality mesh throughout an analysis, even when large deformation or loss of material occur. The developed FE model follows the indications coming from Abaqus manual (Dassault Systèmes Simulia Corp. 2006b, 2006c) and Buccino's work (Buccino 2019) in this respect.

4 NUMERICAL RESULTS

Numerical results are first analyzed for the frequency-domain models, where the flat seabed and the rising bedrock models are compared with the one-dimensional analytical model provided by Hamamoto (Hamamoto 1995). Eventually, the proposed frequency-domain flat seabed model is then compared to the time-domain ones for both water modeling techniques, under the simplifying assumption of vertical propagating waves, which actually makes the frequency-domain model one-dimensional ($\theta = 0°$).

The bedrock depth assumed in this analysis starts from 40 *m* for x = 0 *m*, it increases by 28.5 *m* every δ_x = 100 *m*, reaching the maximum value of 325 *m* in correspondence of x =

1000 m, and it remains constant along the following 3000 m; finally, the seabed arises symmetrically to the other bank for the remaining kilometer. Overall, the horizontal length is 5000 m. The geometry is schematically represented in Figure 1.

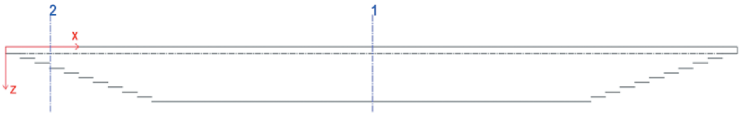

Figure 1. Reference sections for the comparison of frequency-domain models.

Bedrock elastic parameters are defined by Lamè constants λ = 76 983.35 $10^6 Pa$ and μ = 51 750 $10^6 Pa$, whereas material density is ρ = 2200 kg/m^3. To define the earthquake motion at a single point, Kanai-Tajimi PSD modified by Clough and Penzien (Clough and Penzien 1995) has been adopted. In addition, the parameters characterizing the PSD are the ones evaluated by Martinelli (Martinelli et al 2011) to minimize the difference between the consequent pseudo-acceleration response spectrum RS_a and the one prescribed by Eurocodes . The adopted coherency function is the one by Luco and Wong one (Luco and Wong 1987).

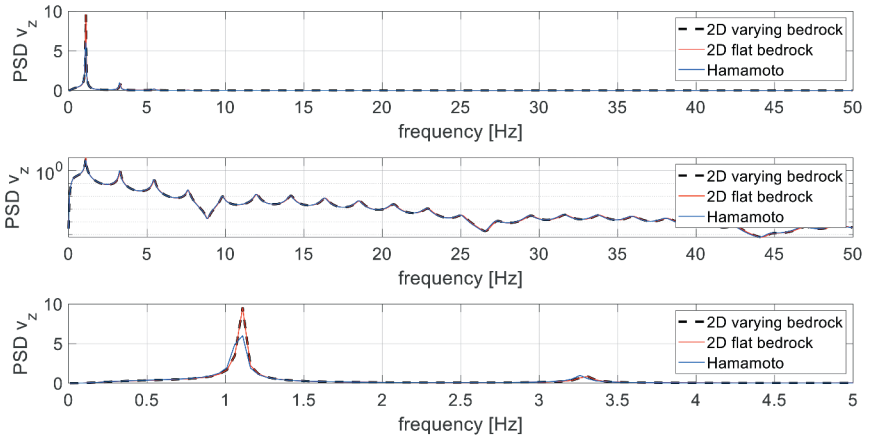

Figure 2. Section 1, 40m depth from water free surface. Comparison of the three frequency-domain models, in terms of vertical velocity PSD.

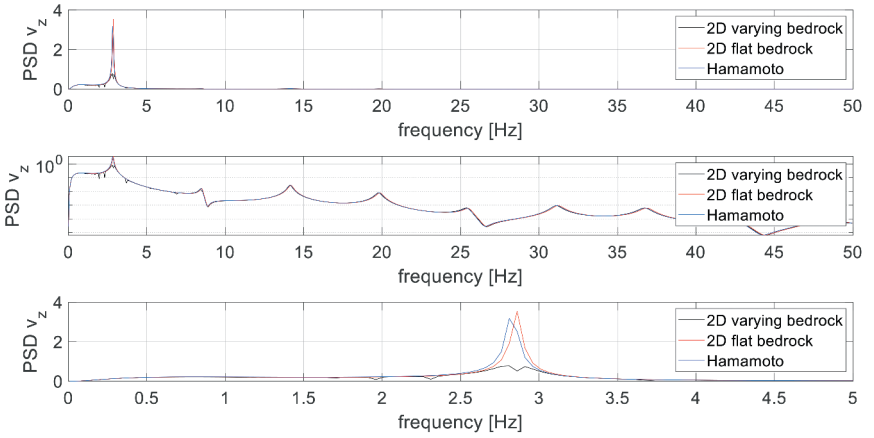

Figure 3. Section 2, 40m depth from water free surface. Comparison of the three frequency-domain models, in terms of vertical velocity PSD.

The results are reported in terms of vertical velocity power spectral densities at 40 m below the water free surface, for two sample sections (Figure 2 and Figure 3).

As it can be observed, for Section 1 both the two-dimensional models are characterized by a slightly amplified response with respect to the one-dimensional Hamamoto model, especially at the water resonance frequency 1.1 *Hz*. Furthermore, as it was expected in this case, flat-seabed and varying-seabed cases lead to the same results, since the Section 1 is located on the symmetry axis of the system, which is characterized by a large portion of flat seabed.

By contrast, for Section 2 the two-dimensional models diverge in their outcomes, especially at frequencies below 5 *Hz*. In fact, while the flat-seabed model is characterized by a slightly amplified response with respect to the one-dimensional Hamamoto model at the first water resonance frequency, the varying-seabed model leads to much less pronounced amplitudes, with relevant reduction of the response at the first water resonance frequency. This kind of destructive interference occurring in the varying seabed case can be appreciated by looking at the small-scale plot of Figure 3. This behavior can be attributed to the space discretization of the system. In fact, by analyzing the frequencies at which those rifts occur, it can be recognized that they correspond to the natural frequencies of the adjacent discretized water columns.

Concerning the horizontal velocity component, which is not reported in the figures, it is characterized by the same resonance frequencies of the vertical component, with an amplitude that is about 20% of the vertical one.

For models in time domain, the reference ground motion supplied to STRATA for obtaining the "within" free-field motion is an outcrop sinusoidal vertical acceleration with an amplitude of 1 m/s^2, frequency of 7.5 *Hz* and duration of 20 *s*. Furthermore, a baseline correction is performed throughout the whole 20 seconds of simulation, to guarantee null residual displacements at the end of the analysis. The geometry is the one depicted in Figure 4 with $\beta = 45°$, and the resulting vertical acceleration is reported for the set D of nodes above the inclined seabed portion in Figure 5.

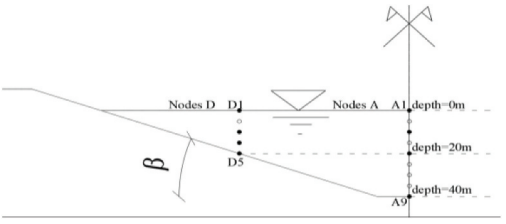

Figure 4. Nodes for motion evaluation in time-domain models.

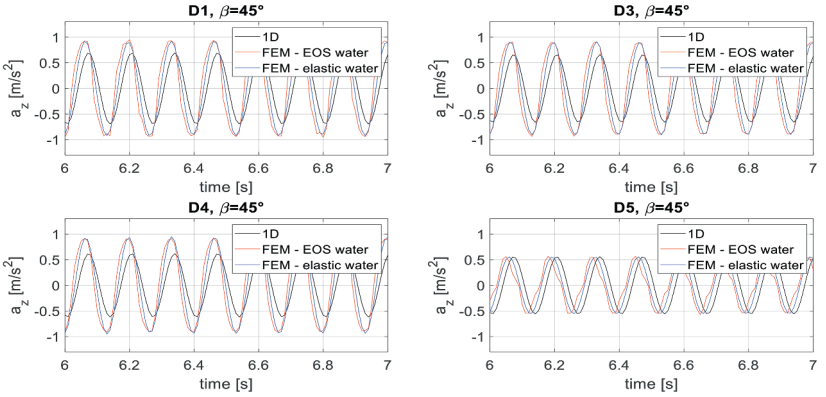

Figure 5. Nodes D: vertical acceleration from t=6s to t=7s, seismic force at 7.5Hz, β=45°.

As it can be noticed, results provided by frequency-domain analysis at corresponding depths have some common aspects to the ones given by ABAQUS models. When the water is

modeled as EOS material, small scale plots highlight high frequency components appearing in the solution, while large scale plots show modulation in time. Nodes located above the inclined portion of the seabed, present some relevant differences in the results with respect to the one-dimensional case, for both water modelling techniques. Nodes located above the flat portion of the seabed (not shown in this work), present results very similar to the frequency-domain case for both water modelling techniques. Regarding horizontal components, which are not reported in the figures, they present the same high frequency components and modulation in time; in addition, higher horizontal accelerations are observed in the vicinity of the coast.

5 CONCLUSIONS

The present research work analyzes the dynamic water motion field during a seaquake using different modelling methodologies. The problem is tackled in two dimensions, both in time and frequency domain, and compared to one-dimensional vertical propagation of P waves in frequency domain.

The results presented show the effect of using a 2D propagation model versus a 1D one and of removing the hypothesis of flat seabed, assuming that the soil-water interface follows a piece-wise constant function.

Comparison of results obtained in time domain from a FE model point out how all the frequency domain models can be used for prediction of the water motion if the seabed is substantially flat; the results, however, substantially differ near the shore where the FE modeling approach highlights the occurrence of higher horizontal accelerations.

ABSTRACT: SFT is a super large floating structure with huge horizontal scale and low structural stiffness, the dynamic response of which can not be calculated according to the rigid body hypothesis. Under the framework of the Discrete-Module-Beam (DMB) method, the hydroelastic behavior of a fixed horizontal hollow tube body that is completely submerged under the action of different regular waves is investigated. In the DMB method, the floating elastic structure is divided into a sufficient number of rigid bodies connected by beam elements. These bodies are equivalent to mass nodes with mass concentrated at the center of gravity and bearing all the loads acting on the submodules. The hydroelastic response of the SFT is obtained based on the potential flow theory and the Morison equation, respectively. The results show that the two modeling methods can both accurately calculate the hydroelastic response of the underwater suspended tunnel in their applicable ranges.

1 INTRODUCTION

Submerged floating tunnels (SFTs), also known as Archimedes Bridges, are new structures designed to cross long distances in deep water. Compared with bridges or immersed tube tunnels, SFTs have better environmental adaptability, greater crossing capacity, lower construction costs, and do not block water traffic. For this reason, they are attractive to academic and engineering circles. SFT is one type of very large floating structure, whose horizontal size is on the order of kilometers, and is much larger than the vertical size, therefore the deformation of the tunnel under wave excitation cannot be ignored. Therefore, the hydroelastic method, which takes into account the coupling effect of fluid and structural deformation, is used to analyze the dynamic response of SFTs under the action of waves (Price et al, 1985).

Several methods were proposed for the hydroelastic analysis of very large floating structures, among which the mode superposition method (Newman, 1994) and the direct coupling method (Das et al, 2012) are the most widely used. The mode superposition method analyzes all necessary elastic modes and superimposes all modes together to obtain the hydroelastic response (Fu et al, 2007). The three-dimensional finite element (FEM) method is usually used to determine the mode and natural frequency. When the structure has complex geometry and connection features, it is slightly difficult to determine the best mode combination. Another method is to combine finite element structural dynamics simulation with 3D hydrodynamic time-domain tools, called the direct coupling method. Its advantages are that it does not need to calculate mode characteristics in advance, can introduce nonlinearity in the time domain, and can simulate complex structural shapes. However, this method is very time-consuming.

DOI: 10.1201/9781003483755-125

In recent years, Lu et al. have proposed a simpler hydroelastic theory called the Discrete Module Beam (DMB) method (Lu et al, 2019). The method divides the elastic body into multiple rigid bodies connected by beam elements. With a sufficient number of elastic-connected rigid bodies being divided, the DMB method can solve the hydroelastic problem without predetermining the elastic mode of the structure and is more suitable for solving the dynamic response of very large floating structures with complex connection forms. Compared with the direct coupling method, the computational efficiency of the DMB method is greatly improved. In addition, Zhang et al. extended its application to complex structural shapes through finite element simulation, where the stiffness of the complex structure is converted to the stiffness of the equivalent beam (Zhang et al, 2019). Jin et al. established a time-domain coupled simulation model to study the hydroelastic behavior of SFT under the random wave and earthquake excitation (Jin et al, 2021).

The purpose of this paper is to extend the DMB method to the hydroelastic analysis of SFTs and to verify this method by comparing it with Jin's research work (Jin, 2022). In the framework of the DMB method, potential flow theory and the Morison method are used respectively to solve the hydroelastic response of an underwater suspended tunnel with fixed ends.

2 BASIC THEORY

2.1 *Potential flow theory*

The DMB method is used to predict the hydroelastic response of the suspended tunnel model, as shown in Figure 1. First, the whole structure is simplified into a hollow cylinder structure and divided into several sub-modules along the length direction. The mass matrix $\mathbf{M}$, the hydrostatic restoring force matrix $\mathbf{C}$, the additional mass matrix $A(\omega)$, the damping matrix $\mathbf{B}(\omega)$, and the wave exciting force matrix $\mathbf{F}_E$ of the multi-body structure are further solved. With the finite element method, the stiffness matrix of the whole structure is assembled according to the structural stiffness matrix of each beam element, and the external load is fully defined on the center of mass of each submodule. Euler-Bernoulli beams and Saint-Venant distortion theory interpret the elastic behavior of beam elements. According to the force balance of nodes, the motion equation in the frequency domain is constructed to calculate the displacement of each mass node:

$$\left[-\omega^2(\mathbf{M}+\mathbf{A}(\omega))-i\omega\mathbf{B}(\omega)+(\mathbf{C}+\mathbf{K}_{st})\right]\xi=\mathbf{F}_E \tag{1}$$

where $\mathbf{M}$ is the mass matrix of concentrated masses, $\mathbf{K}_{st}$ is the stiffness matrix of the total structure and ξ is the displacement matrix of concentrated masses.

The two ends of the SFT model are set as fixed boundary conditions by modifying the stiffness matrix of the beam elements at both ends. If both ends of beam element e are connected to the concentrated mass i and j, then the relationship between the structural deformation forces $\mathbf{F}_{st}^{i}$ and $\mathbf{F}_{st}^{j}$ at both ends of the beam element and the displacements ξ_i and ξ_j of the two concentrated masses is:

$$\begin{bmatrix}\mathbf{F}_{st}^{i}\\ \mathbf{F}_{st}^{j}\end{bmatrix}=-\begin{bmatrix}\mathbf{k}_e^{(i,i)} & \mathbf{k}_e^{(i,j)}\\ \mathbf{k}_e^{(j,i)} & \mathbf{k}_e^{(j,j)}\end{bmatrix}\begin{bmatrix}\xi_i\\ \xi_j\end{bmatrix} \tag{2}$$

where $\mathbf{k}_e^{(i,i)}$, $\mathbf{k}_e^{(i,j)}$, $\mathbf{k}_e^{(j,i)}$and $\mathbf{k}_e^{(j,j)}$ are the submatrices of the structural stiffness matrix $\mathbf{k}_e$ of beam element e. It is worth noting that for the beam elements located at both ends, the structural deformation force at the endpoints is zero.

After restoring the displacement of the mass node, a subelement f between the node r at any position and its adjacent concentrated mass node i is established on each beam element, and the stiffness matrix of the subelement is solved. The structural force and displacement of any node are restored by solving equations (3)-(5):

$$\begin{bmatrix} \mathbf{F}_{st}^{i} \\ \mathbf{F}_{st}^{j} \end{bmatrix} = -\begin{bmatrix} \mathbf{k}_{e,f}^{(i,i)} & \mathbf{k}_{e,f}^{(i,r)} \\ \mathbf{k}_{e,f}^{(r,i)} & \mathbf{k}_{e,f}^{(r,r)} \end{bmatrix} \begin{bmatrix} \xi_i \\ \xi_r \end{bmatrix} \tag{3}$$

$$\xi_r = \left(\mathbf{k}_{e,f}^{(i,r)}\right)^{-1} (\mathbf{F}_{st}^{i} - \mathbf{k}_{e,f}^{(i,i)} \xi_i) \tag{4}$$

$$\mathbf{F}_{st}^{r} = \mathbf{k}_{e,f}^{(r,i)} \xi_i + \mathbf{k}_{e,f}^{(r,r)} \left(\mathbf{k}_{e,f}^{(i,r)}\right)^{-1} (\mathbf{F}_{st}^{i} - \mathbf{k}_{e,f}^{(i,i)} \xi_i) \tag{5}$$

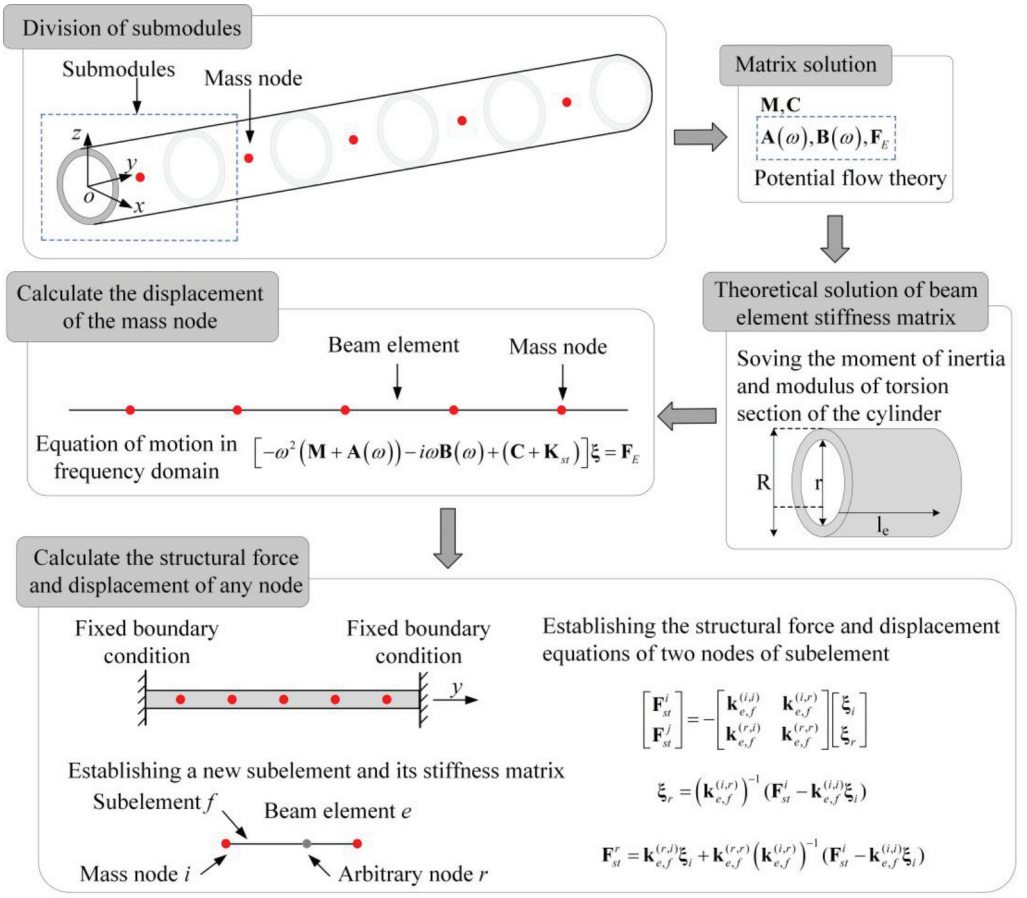

Figure 1. The steps of calculating the hydroelastic response by the DMB-potential flow method.

2.2 *Morison method*

The diameter D of the tube body of SFTs is generally not more than 25m, and the wavelength L of the design wave is about 160 m. When D/L is less than 0.2, the effect of wave diffraction can be ignored and the Morison equation, which only considers the viscosity and inertia of water, is adopted. In this paper, the method combined with DMB and Morison formula is used to predict the hydroelastic response of the suspended tunnel model, as shown in Figure 2:

The velocity of water particle in the horizontal and vertical directions:

$$u = \frac{\pi H}{T}\frac{\cosh(k(z+d))}{\sinh(kd)}\cos(kx-\omega t)$$
$$v = \frac{\pi H}{T}\frac{\sinh(k(z+d))}{\sinh(kd)}\sin(kx-\omega t) \tag{6}$$

Acceleration of water particle in horizontal and vertical directions:

$$\dot{u} = \frac{2\pi^2 H}{T^2}\frac{\cosh(k(z+d))}{\sinh(kd)}\sin(kx-\omega t)$$
$$\dot{v} = \frac{2\pi^2 H}{T^2}\frac{\sinh(k(z+d))}{\sinh(kd)}\cos(kx-\omega t) \tag{7}$$

where H is the wave height, T is the wave period, d is the water depth, k is the wave number, ω is the wave frequency and y is the coordinate of SFT along the axis.

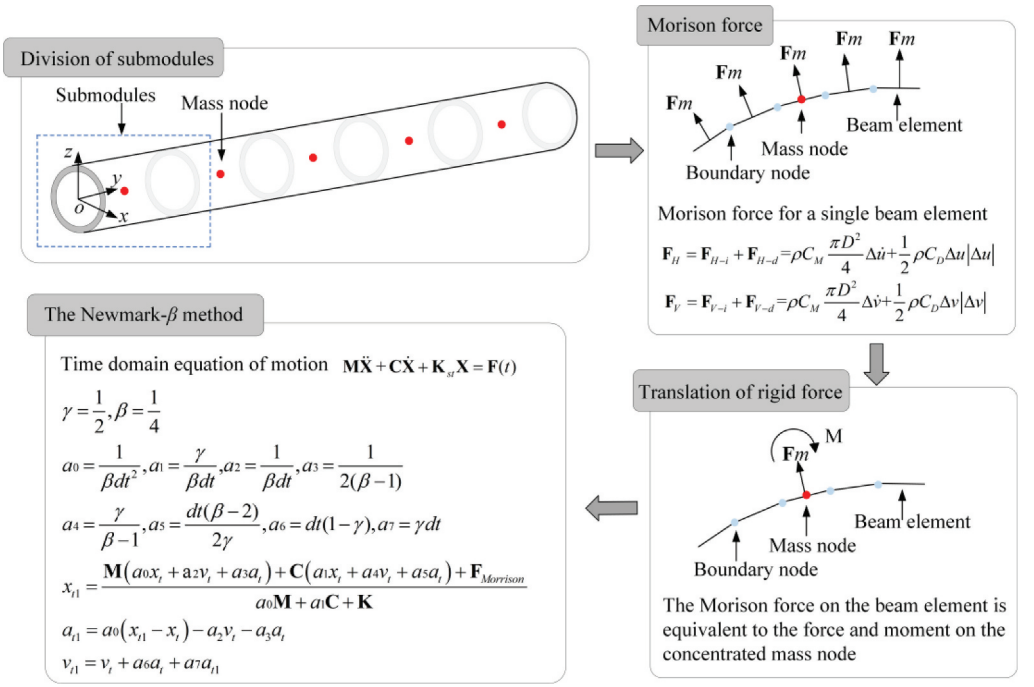

Figure 2. The steps of calculating the hydroelastic response by the DMB-Morison method.

The Morison force on the beam element is calculated by the velocity and acceleration of the water quality point at the midpoint of the axis of each beam element:

$$\mathbf{F}_{H-d} = \frac{1}{2}\rho C_D D u|u| = \frac{\rho C_D D\pi^2 H^2}{2T^2} e^{\frac{4\pi z}{L}}\left(\frac{\cosh(k(z+d))}{\sinh(kd)}\right)^2 \cos(kx-\omega t)|\cos(kx-\omega t)| \tag{8}$$

$$\mathbf{F}_{H-i} = \rho C_M \frac{\pi D^2}{4}\dot{u} = \frac{\rho C_M D^2\pi^3 H}{2T^2} e^{\frac{2\pi z}{L}}\left(\frac{\cosh(k(z+d))}{\sinh(kd)}\right)\sin(kx-\omega t) \tag{9}$$

$$\mathbf{F}_H = \mathbf{F}_{H-i} + \mathbf{F}_{H-d} \tag{10}$$

$$\mathbf{F}_{V-d} = \frac{1}{2}\rho C_D D v|v| = \frac{\rho C_D D\pi^2 H^2}{2T^2} e^{\frac{4\pi z}{L}}\left(\frac{\cosh(k(z+d))}{\sinh(kd)}\right)^2 \sin(kx-\omega t)|\sin(kx-\omega t)| \tag{11}$$

$$\mathbf{F}_{V-i} = \rho C_M \frac{\pi D^2}{4} \dot{v} = \frac{\rho C_M D^2 \pi^3 H}{2T^2} e^{\frac{2\pi z}{L}} \left(\frac{\cosh(k(z+d))}{\sinh(kd)}\right) \cos(kx - \omega t) \tag{12}$$

$$\mathbf{F}_V = \mathbf{F}_{V-i} + \mathbf{F}_{V-d} \tag{13}$$

Each submodule is divided into several beam elements and the force and moment of each are calculated by the Morison equation, which are equivalent to those on the concentrated mass of the corresponding submodule according to the translation theorem of rigid force.

The dynamic response of the structure is calculated by solving the structural dynamic balance differential equation:

$$\mathbf{M}\ddot{\boldsymbol{X}} + C\dot{\boldsymbol{X}} + \mathbf{K}_{st}\mathbf{X} = \mathbf{F}(t) \tag{14}$$

The Newmark-β method was used to iteratively solve displacement, velocity and acceleration, as shown in Figure 2.

3 MODEL LAYOUT AND VALIDATION

3.1 *Model layout*

Jin (2022) explored the hydroelastic characteristics of a completely submerged horizontal hollow cylinder under different regular waves with the DMB method and compared the settlement results of the potential flow theory method with the frequency domain and the Morison method based on the time domain.

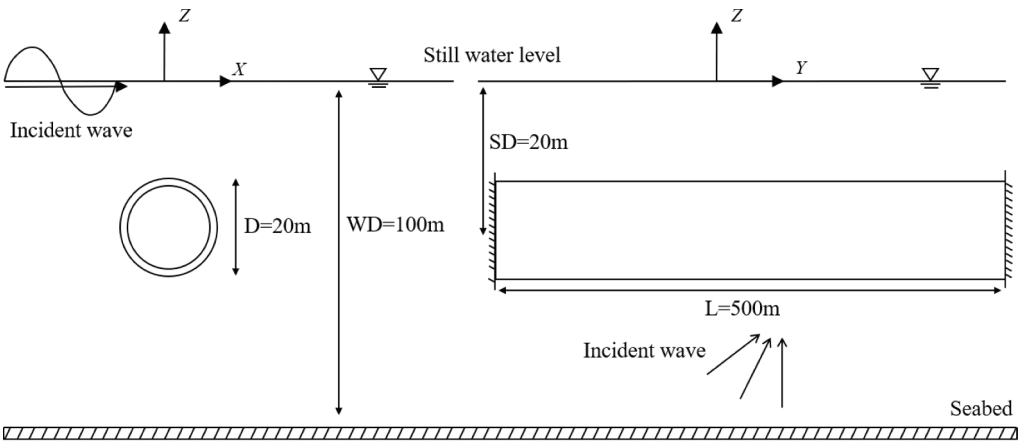

Figure 3. Configuration of a hollow cylinder with fixed-fixed boundary condition.

The same calculation model is established in this paper, and the model configuration and the dimensions of the hollow cylinder are shown in Figure 3 and Table 1. The model is a concrete structure with a density and Young's modulus of 2300 kg/m^3 and 30GPa, respectively. The length of the concrete cylinder is fixed at 500m, the outer diameter is 20m, the submerged depth is 20m, the water depth is 100m, and the angles between the wave incident direction and the length direction of the cylinder are 30°, 60°, and 90°. The two ends of the cylinder are set as fixed boundary conditions, that is, the displacement and angles remain unchanged. The buoyant weight ratio of the cylinder is set to 1.0, that is, the buoyancy of the cylinder is the same as the dry weight. The wave height is 1m.

Table 1. Geometric dimensions and mechanical properties of the hollow cylinder.

Parameter	Unit	Value
Length	m	500
Diameter	m	20
Density	kg/m^3	2300
Submerged depth	m	20
Young's modulus	Pa	3e10
Buoyancy-weight ratio		1

3.2 *Validation*

The vertical displacement response of the center position of the model when regular waves are vertically incident and inclined incident at different frequencies is shown in Figures 4-6. It can be seen that the calculated results of of Morison equation in this paper are in good agreement with those calculated by Orcaflex and Jin, which proves the accuracy of this method.

In the high-frequency range of waves, the calculated results with the Morison equation have a large deviation compared with those by Orcaflex, which may be because the wavelength decreases and the influence of wave diffraction cannot be ignored, so the Morison equation is no longer applicable.

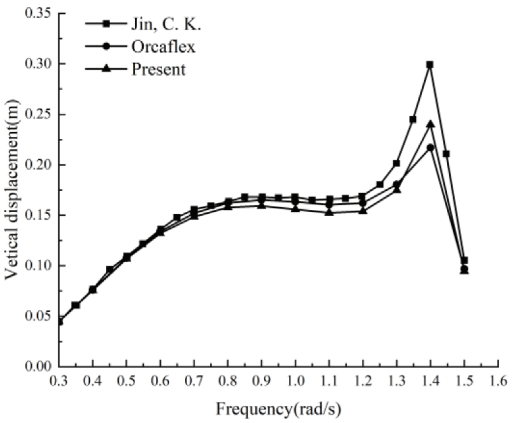

Figure 4. The vertical displacement response of the center position of the model when the regular wave is vertically incident.

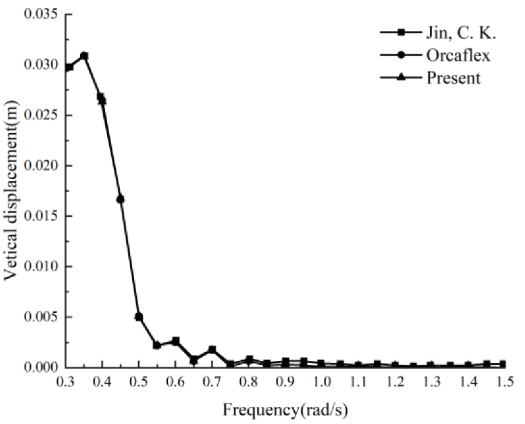

Figure 5. The vertical displacement response of the center position of the model when the regular wave is incident along 30°.

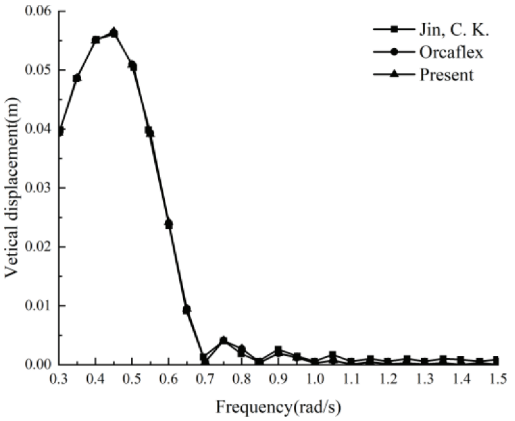

Figure 6. The vertical displacement response of the center position of the model when the regular wave is incident along 60°.

The bending moment along the length direction of the model under the action of the vertically incident regular wave (ω=1rad/s) is shown in Figure 7. It can be seen that the calculated result of the DMB method are in good agreement with that of Orcaflex.

At present, the bending moment is restored by cubic spline curve interpolation, that is, the bending moment value at the adjacent node is used for interpolation. This method is only suitable for structures with simple shapes. Complex geometrics requires a new interpolation method to reduce structural forces.

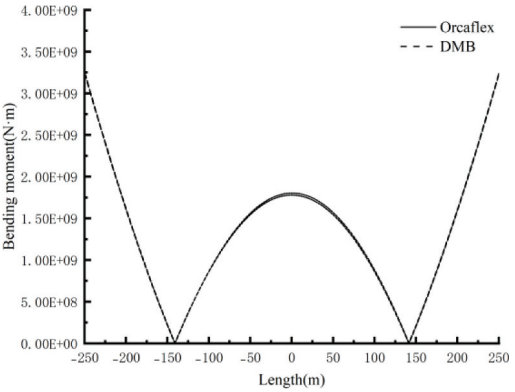

Figure 7. Bending moment along tunnel length when ω=1rad/s.

4 CONCLUSIONS

Under the framework of the DMB hydroelasticity theory, this paper proposes a method to calculate the elastic response of SFTs under wave action in both frequency and time domains, and the numerical model was validated by comparing the numerical results with those of related paper and commercial software.

The results show that the DMB method can accurately calculate the displacement response and structural force response of the fixed suspension tunnel at both ends, and the Morison method can accurately estimate the displacement response of the submerged hollow cylinder within its applicable frequency range. The application range of the DMB method is expanded.

It is worth mentioning that the equivalent displacement response of the tunnel can be calculated by equivalent hydrodynamic pressure distribution along the length direction of the tunnel through the DMB method. Still, it cannot be considered that the equivalent

displacement is the same as the displacement under the real hydrodynamic pressure distribution. In the future, it is necessary to find a new method to restore the pressure distribution by equivalent displacement, that is, to find a hydrodynamic distribution under which the displacement response is consistent with that calculated by the DMB method. In addition, the problem of coupling response between the mooring lines and tube body will be solved in future research, and the influence of different buoyancy-weight ratios (BWRs) on the overall motion response of the SFT will be further considered.

Main issues of the structural analysis of SFT against environmental loads

G. Iovane, F.M. Mazzolani, R. Landolfo, E. Begovic, E. Bilotta & B. Faggiano
University of Naples Federico II, Napoli, Italy

ABSTRACT: The Submerged Floating Tunnel (SFT) is an innovative concept for crossing waterways. It is a tube, submerged at a specific depth, fixed in position through anchorage systems, providing opportune restraints and stiffness against service and environmental loads. Numerous feasibility studies and preliminary designs have been carried out up to today, but no SFT has been realized yet. However the SFT solution attracts more and more attention, having several advantages with respect to traditional structures. The focus of this paper is on the fundamental aspects related to the structural analysis of the behavior of SFT against environmental loads, such as hydrodynamic and seismic actions, based on a literature review. In particular, theoretical evaluations and numerical analyses on SFTs solutions adopting different cross-sections, structural materials, support systems, joints, under diverse imposed loads, are presented and discussed.

1 INTRODUCTION

The Submerged Floating Tunnel (SFT) consists of a tubular structure immersed in the water at an appropriate depth, compatible with the free navigation at the surface, fixed in position through anchoring cables systems. The structure should be designed to achieve a positive residual buoyancy (i.e. the buoyancy overcomes the weight of the tunnel), so that anchorages are always in tension, providing an effective restraint condition both in vertical and horizontal planes.

Even though not yet exploited in engineering applications, the concept of SFT has gained interest in recent years from both theoretical and practical points of view. As a demonstration of this, a great amount of proposals have been presented all around the world, like in China, Indonesia, Italy, Japan, Mexico, Norway, South Korea, Switzerland, USA, concerning a number of possible implementations of the SFT concept (Iovane et al., 2023).

Compared to traditional structural systems for long span waterway crossings, such as suspension and stayed bridges, as well as immersed and underground tunnels, the SFT shows many advantages, among others low influence of weather conditions, great adaptability to site morphology, low environmental impact. Research studies extensively deal with the analysis of the SFT structural response against wave, current and seism-induced dynamic loads in combination with the residual buoyancy, giving rise to an hydrodynamic interaction between water and structure (Mazzolani et al., 2008; Martire et al., 2010; Faggiano et al., 2019). Researches are also devoted to catch and model the state of the water, as well as the kinematics of water particles due to currents and waves, since it is crucial for the safety of offshore structures. Thus, a wealth of observed data and theories exists (Sorensen, 1993; Hedges, 1995).

In this context, the main purpose of the paper is to collate and summarize the research achievements on the hydrodynamic behaviour of tethered SFT under environmental and seismic actions, highlighting the main issues of the analytical formulations, the physical and numerical models, as well as of the structural response.

2 HYDRODYNAMIC ACTION MODEL

The determination of the hydrodynamic forces generated by the relative motion between the water and the SFT structure is a complex problem since it involves many variables. When an immersed body is invested by a fluid flow, it is subjected by a force, which depends on the fluid-structure acceleration and velocity. The contribution due to velocity can be split in two components: the drag and the lift forces, which are parallel and perpendicular to the flow direction.

The most used methods to model hydrodynamic actions are: Morison equation, Diffraction theory by boundary element method (or potential theory) and Navier–Stokes (N–S) models.

In the field of the design of offshore structures, the Morison equation (Morison et al, 1950) is the most widespread and simple way to calculate the hydrodynamic forces F_h per unit length. It was developed for slender cylindrical components. Based on an empirical approach, it considers the effects of water viscosity and inertia through the following equation (1), where ρ_w is the water density, D is the external diameter of the structural element (i.e. tunnel or cable), C_I is the inertial coefficient, C_M is the added mass coefficient, C_D is the drag coefficient, a_w, a_s and v_w, v_s are the water and structure acceleration and velocity, respectively:

$$F_h = \rho_w \frac{\pi D^2}{4} [(C_I - C_M)(a_w - a_s) + C_M a_w] + \frac{1}{2}\rho_w C_D D(v_w - v_s)|v_w - v_s| \quad (1)$$

The first addend is the inertial contribution, given by the sum of the diffraction effects, due to the presence of the structure, proportional to the relative acceleration between the water and the structure (the motion of the water particles is deviated by the presence of the marine structure), and the Froude-Krilov force, related to the undisturbed flow of water. The first contribution is the additional inertia force needed to accelerate a structure immersed in a fluid. The second contribution is due to the dynamic pressure field that accelerates the amount of water moved by the body.

The second addend is the drag force or resistance, produced by the separation of the water flow from the body surface due to the viscosity of the fluid. The separation of the fluid generates a turbulent wake, occurring mainly below the downstream portion of the body, thus entailing a difference between the pressures acting on the upstream and downstream part of the body, whose resultant is the drag force. Flow separation and resulting turbulence is the key phenomenon influencing the dynamic pressure field occurring at the water structure interface. It strongly depends on the Reynolds number, which is defined as the ratio between the product of the water velocity V and the cylinder diameter D (or the cross-section projection of the body in a direction orthogonal to the flow) and the kinematic viscosity of the water ν (equal to approximately 10-6 m^2/s).

Note that the lift force, perpendicular to the flow direction, is not covered by the Morison equation, which is only for the inline forces in an oscillatory flow (inertia and drag). Therefore the lift force has been addressed separately by Strouhal (1878) similarly to the drag force, by using the following equation (2), in function of the water density ρ_w, the external diameter of the tunnel D, the lift coefficient C_L and the water velocity v_w:

$$F_L = \frac{1}{2}\rho_w C_L D v_w^2 \quad (2)$$

Many authors have used Morison equation in SFT studies (i.e.Faggiano et al., 2001; Di Pilato et al., 2008; Martire et al., 2010; Wahyuni et al., 2009; Kunisu et al., 2010; Cantero et al., 2016; Jin and Kim, 2018; Won et al., 2019). The equation can be used also to roughly estimate hydrodynamic loadings during seismic events, once the water velocities and accelerations due to seaquake are determined (Martire et al., 2010).

The Diffraction Theory proposed by MacCamy and Fuchs (1954) can be also used for hydrodynamic force computation. This method assumes that the fluid is inviscid and incompressible, with an irrotational motion. The velocity potential generated by wave field and SFT is assumed to be divided into the incident and the diffraction potentials. The velocity potential can be evaluated through the boundary element method (BEM), then the pressure distribution acting on the

tunnel surface can be obtained using the Bernoulli's equation. Based on the pressure distribution, the force and moment acting on the tunnel can be determined. Jin et al. (2020) calculated the wave force of SFT based on the diffraction theory through the BEM, while Guerber et al. (2012), Hannan et al. (2014), Bai et al. (2014), Teng et al. (2019) through the Fully Non-Linear Potential Flow Theory (FNPT), demonstrating the accuracy and convergence. Nevertheless, since the convection potential flow method assumes an irrotational flow, the nonlinear interactions of waves with submerged constructions, the flow separation, the vortex generation and shedding are difficult to be evaluated satisfactorily. Besides, this type of model is not able to predict the pitch motion of an SFT structure caused by viscous damping around the structure.

In general, the diffraction theory is mostly used when the wave force acts on a large size structure, such as ships and floating platforms, for which the inertial force is dominant for the wave force evaluation, while the Morison equation is used when the structural size is rather small, for which both the inertial and drag forces are non-negligible. Comparison of these two methods by Kunisu (2010) for the hydrodynamic computation of SFTs highlighted that for common construction conditions (like water depth 100m, submerged water depth 30m, tube diameter 23m), both drag and inertial forces are significant. When larger tube diameters are considered, the inertial force would dominate. Moreover, both Morison equation and diffraction theory was found to provide accurate hydrodynamic calculations.

With the development of computer technology, it has been possible to carry out a direct numerical simulation of the wave-structure interaction based on the *Navier-Stokes (N-S) models*, by implementing different theoretical relationships. Long (2009) used simultaneously fifth-order Stokes wave theory and Morison formula to evaluate the dynamic response of an SFT. Many other researchers have applied high-precision numerical models in addition to empirical formulas (Muhammad et al., 2017; Chen et al., 2020). With regards to the numerical modelling techniques to solve Reynolds Averaged Navier-Stokes (RANS) equation, Marker-And-Cell (MAC) and Volume Of Fluid (VOF) (Hirt and Nichols, 1981) are often used for the simulation of the free surface wave generation. The MAC method calculates the free surface by recording movement of each of the fluid particles, requiring huge amount of both computational space for storage and time for computation. The VOF method overcomes this shortcoming (Rahman et al., 2006). Peng et al. (2013) applied the Immersed Boundary Method (IBM) to deal with the movable SFT under waves, with a numerical model based on Eulerian grid methods (fluid Eulerian and Lagrangian domain). Ren et al. (2017) applied a Smoothed Particle Hydrodynamics (SPH) model, a meshless method with simple mathematical formulation and high computational efficiency, to simulate the nonlinear interaction between waves and the SFT, gaining a good agreement between numerical results and experimental data.

3 STRUCTURAL MODEL

In the last decades, several studies have focused on the analyses of the structural performance of SFT under real environmental conditions through numerical semi-empirical models (Chen et al., 2018) and experimental investigations (Iovane et al., 2023).

From the analysis of the scientific literature, it is possible to distinguish three different structural modeling approaches: (1) cables and tunnel are studied separately; (2) simplified coupled tunnel-cable model with one-dimensional elements (beam elements); (3) advanced coupled tunnel-cable model with 2D elements (shell elements) or 3D elements (solid elements).

With regards to the first approach, Kunisu (2010) analyzed an SFT with elliptical cross-section for investigating the influence of diameter and installation depth on the hydrodynamic force. The model considered only the tube with hinge end restraints. The hydrodynamic force was evaluated based on the diffraction theory by Boundary Element Method (Figure 1). Zou et al. (2021), Xu et al. (2022) and Liu et al. (2023) modeled two tunnels as separate cylinders, restrained through springs with specific stiffness, with the purpose to evaluate the effects of Vortex Induced Vibration (VIV) as a function of distance and diameter between tubes. Other authors (Lin et al., 2016; Cantero et al., 2016; Wu and Mei, 2017; Figure 1) studied the behavior of the only anchor-cable under parametric axial excitation, modeling the cable as beam element

in tension with the base end hinge restraint, while the tunnel as a simple lumped mass block equipped with springs having stiffness, damping and vibration directions along the cable-axes.

With regards to the simplified coupled tunnel-cable model (Figure 2), Xie et al. (2023) modelled both the tunnel and the anchor-cables as one-dimensional beam elements with bending and axial stiffnesses equivalent to those of the SFT and anchor cables, respectively, opportunely supported at the ends, where either transverse displacements or torsional rotations are restrained. Similarly, Di Pilato et al. (2008) modelled the tunnel by means of geometrically non-linear beam finite elements, neglecting axial deformation and torsional behavior, with a cross section having area and moment of inertia equivalent to the studied SFT. The tube masse is lumped at each connection-to-anchoring section. As the same the anchoring system is modelled by beam elements having equivalent total area and slenderness of the real cables. The soil–structure interaction effects are taken into account by considering three springs at the bottom of each anchor element and at the tunnel end sections.

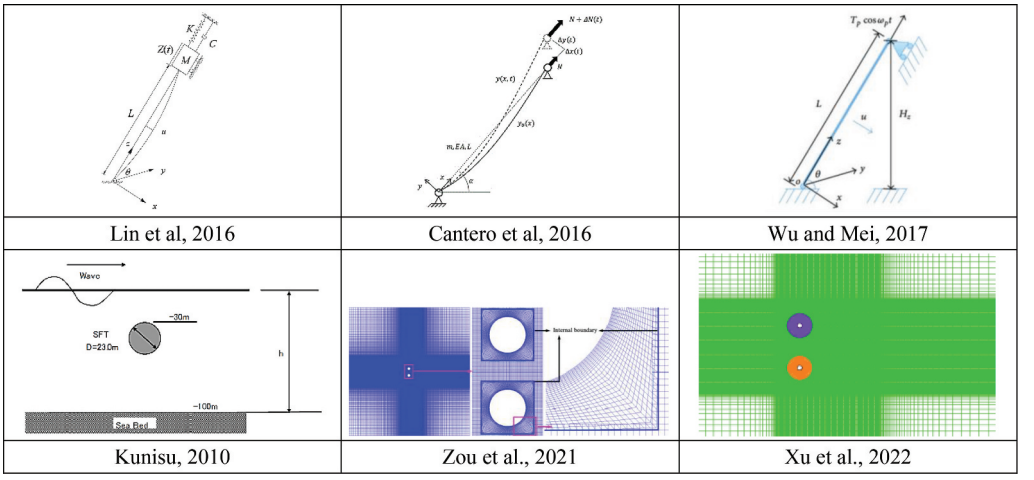

Figure 1. Literature review of the SFT structural models: Separate tunnel and cable system.

Also Martire et al. (2010) set up a FE numerical model of a SFT structure with an elliptical cross section, by varying either the cable system configurations in the transversal plane or the crossing lengths, corresponding to pedestrian crossings, railway and motorway crossings. The tunnel is modeled by means of quadratic beam elements, with masses lumped at the connection-to-anchoring sections, while cables through quadratic beam hybrid elements, with predominant axial stiffness, geometric non-linearity, negligible inertia moments of the cross-section. The connection between the cable anchoring systems and the tunnel is modelled through a rigid body constraint, so that the actual dimensions of SFT cross-sections are taken into account. Spherical hinge are considered at both ends of each cables.

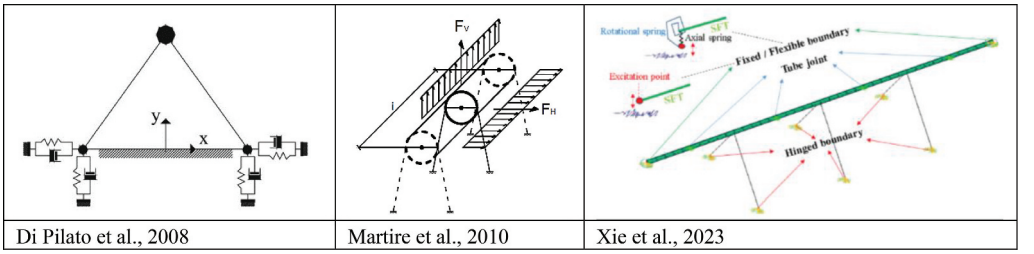

Figure 2. Literature review of the SFT structural models: Simplified coupled tunnel-cable model.

In the context of advanced coupled tube-anchoring system modelling, the global vibration behavior of the SFT tube and the local oscillations of the cables are coupled under realistic environmental conditions. The tunnel and cables are modeled in a more refined way, considering the real geometry and shape of the cross-section with 2D or 3D elements appropriately scaled (Figure 3).

In particular, the SFT end restraints are usually modeled through springs in both vertical and horizontal transverse directions that prevent rotations. Axial displacements are prevented too. The anchoring cables are connected to the tunnel and at the foundation through spherical hinges. In more refined models, the tunnel is characterized by a sandwich cross-section, so that the contacts between the layers are modeled through a simple contact interaction, defining a friction coefficient, while the tunnel-water contact is modeled through a general interaction, in which all relative displacements and rotations are allowed (Wahyuni et al., 2009; Long et al., 2009; Muhammad et al., 2017; Won et al., 2019; Chen et al., 2020; Kim and Kwak, 2021). Moreover, to simulate the response of solids and fluids in high dynamic conditions, as in case of explosions and impacts, the coupled Eulerian-Lagrangian (CEL) hydro code is used (Faggiano et al., 2019). The global behavior, the vibrations induced by the hydrodynamic loads, the influence of the oscillation of the cables on the tunnel behavior, the corresponding pressures and stresses of the coupled tunnel-anchor cable system are thus evaluated with higher accuracy, however at the expense of high computational time of analysis (Figure 3).

Lastly, it is worth noticing that experimental investigations play a key role for the insight of the SFT structural behavior and for the development of the construction technologies, with the special task to calibrate numerical models aimed at the parametric study of the hydrodynamic response of SFTs. During the last 10 years, several scale model tests of SFTs under wave loads have been carried out for several different purposes by different authors. Details can be found in Iovane et al. (2023).

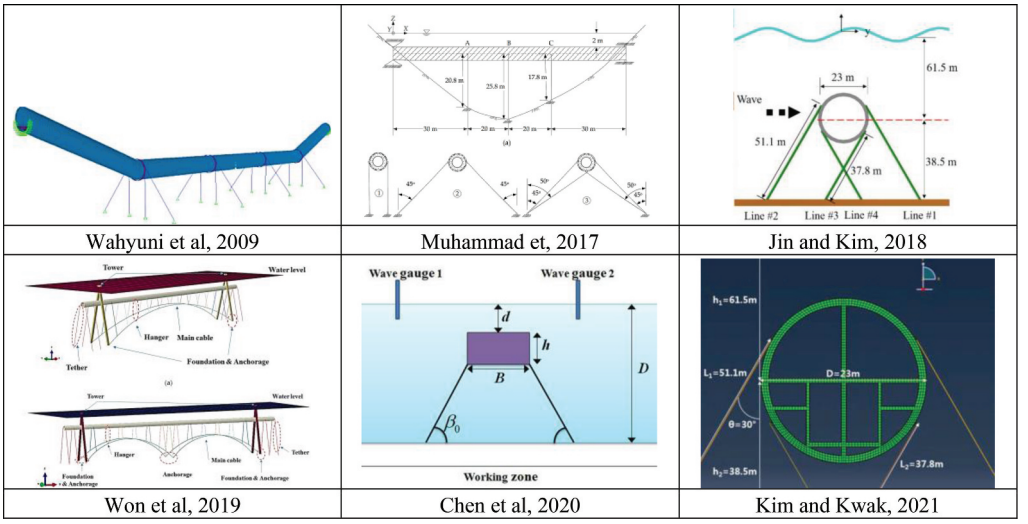

Figure 3. Literature review of the SFT structural models: Advanced coupled tunnel-cable model.

4 COMMON TYPE OF ANALYSIS AND GENERAL OUTPUTS

With regards to the evaluation of the hydrodynamic behavior of SFT models in terms of internal forces, deformation and displacements, most studies concern numerical analysis with regular and irregular wave-induced dynamic loads, by varying the conditions of wave, such as height and period. Moreover, the influences of several structural factors, like the mooring lines configuration, the immersion depth of the SFT, the shape of the tunnel cross-section, the SFT configuration with single cylinder or two cylinders (tandem configuration), the buoyancy

to weight ratio (BWR), on the global dynamic response of SFTs are investigated, in order to provide suitable and reliable criteria for the structural design.

Generally, dynamic time history analyses are carried out. Among these, many authors (Martire et al., 2010; Wahyuni et al., 2009; Muhammad et al., 2017; Jin and Kim, 2018; Won et al., 2019; Chen et al., 2020; Kim and Kwak, 2021) studied SFT with a single tube and different cable system configurations, through non-linear dynamic analyses, by using advanced structural calculation programs. The numerical results show that the mooring systems type and inclination play a significant role on either the tunnel deformation and displacement or on the tensile forces in the anchoring cables under hydrodynamic loads. Specifically, the vertical cables counteract the buoyancy induced by the water, while the inclined cables stabilize the tunnel under hydrodynamic actions. Moreover, by increasing the inclination of the anchoring system, the tension in the cables and the transversal displacements of the tube are reduced.

As concerns the shape of the tube cross section, it greatly affects the fluid-structure interaction (Kunisu, 2010). Elliptical and circular cross-section shapes provide smaller oscillations of the tube as respect to rectangular and polygonal cross-section shapes, resulting in lower anchor cables tension, in a more uniform distribution of pressure on the tunnel, as well as minimizing the drag force due to hydrodynamic forces and the vortex shedding induced vibrations (Jin and Kim, 2018). With this regards, the spacing between two tubes in a tandem configuration has important effects on the vortex shedding induced vibrations, which decreases by increasing the spacing (Zou et al., 2021; Xu et al., 2022).

Also the immersion depth of tunnel and the BWR affect the global response of SFT, with particular reference to the stress in the cables and along the tube. In fact, as the immersion depth increases, the drag and lift forces decrease, wave effects are damped, the effects of hydrodynamic actions due to the currents increase, while effects induced by the seism remain almost unchanged (Faggiano et al., 2001). Furthermore, the length of the mooring lines decreases, leading to greater lateral stiffness under transverse loads and lower vibration of the mooring lines. These results were also confirmed by studies conducted on only anchor cables by Lin et al. (2016) and Cantero et al. (2016), who specifically analyzed the tension in the mooring lines during a dynamic cyclic parametric axial excitation. Moreover they highlighted that as the BWR increases, the cable axial force also increases, leading to a reduction of the probability of tethers slacking, ensuring permanent tension in the tethers and reducing the displacement amplitudes. However, this implies higher bending moments on the tube that can be critical at the landfalls (Iovane et al., 2023).

With regards to analysis of the seismic behaviour of SFT, Martire et al. (2010) proved that the multi-support excitation due the seism significantly influence the SFT response. This is specially true in case of long SFT, for which a large number of vibration modes is involved in the oscillations, being higher modes contribution being more relevant. Moreover when the vertical water motion is considered, it strongly affects the frequency content of vertical vibrations, moving it in the high frequency range. It is also shown that short SFTs are subjected to great bending moments in the tunnel, with maximum values close to the middle section, while in long SFTs the critical issue is related to the axial force stressing the anchorages, mainly near the shore where cables are shorter and therefore more rigid. The performed analyses show that stresses induced in the tunnel and in the anchorages generally reduce due to vertical water motion.

5 CONCLUSIVE REMARKS

In this paper, the state of the art on scientific literature focused on the evaluation of the response of the SFT under hydrodynamic loads is summarized. In particular, the models of the actions and of the structure, most frequently adopted, as well as the common type of analysis and the main general outputs are presented.

With regards to the environmental actions, wave and currents are defined according to consolidated models, taking into account the specificities of the site of construction, as well as the ensuing hydrodynamic forces can be generally determined by means of the consolidated Morison equation. As concerns the seismic actions, the seismic input energy

can be transferred to the tunnel through the shore connections and anchoring foundations, but the vertical seismic component can be also transferred through the layer of water. Moreover, for short-span SFT it is reasonable to consider a single excitation of the ground motion, but for long and large-span structures connected to the seabed with multi-supports, the spatial features of the ground motion are significant for the seismic response of the system and the ground motion of multi-supports are often different. Therefore the most suitable model for the seismic actions is a set of time histories of the ground motion, which adequately take into account the spatial variability, introduced in a three-dimensional dynamic analysis. The effect on the SFT structure of the vertical seismic component through the water should be accounted for.

The structural models used for the analysis of the SFT behaviour can be mainly of three types, depending on the degree of the numerical approximation: separate models for the anchoring systems and the tunnel, when the local response is to be studied, or the coupled model for anchor cable-tunnel system, when the global response is to be studied. In the latter case, the FE model can be simplified, using one-dimensional beam elements for cables and tunnel, or it can be advanced, using 2D or 3D elements, with opportune interaction models between parts. The use of advanced models allows to deepen the fluid-structure interaction and provide the complete pressure and stress distribution within the tube cross-section, at the cost of longer computational times of structural analysis.

Main general outcomes evidence that design criteria should include the shape of the tunnel cross section, the inclination of the anchoring system, the SFT immersion depth, taking into account that tunnel rectangular and polygonal cross-section shapes involve greater water flows turbulence and thus larger oscillations of the tube as respect to elliptical and circular cross-section shapes, larger inclination of the anchor cables result in lower tension in the cables and greater transversal stiffness of the tube, larger SFT immersion depth entails shorter anchor cables, therefore greater cable axial stiffness and tunnel lateral stiffness.

It is worth noticing that the number of studies and the involved countries on the SFT technology has increased in recent years, also evidencing the sustainability of the structural solution. Further to numerical investigations also experimental campaigns in tanks on small scale specimens have been carried out, especially in Europe and in Asia. Outcomes demonstrate the suitability of the SFT. The preparation of SFT design guidelines, collecting the requirements ensuing from the acquired knowledge is compulsory. Nevertheless in order to overcome the mistrust of a new technology, the construction of a full scale SFT will be surely encouraging.

A. Strauss
University of Natural Resources and Life Sciences, Vienna, Austria

ABSTRACT: Infrastructure systems, such as bridges, are a driver for economic growth and development of countries. Similarly, development of operation and maintenance strategies for infrastructure systems may aim at optimal management using Key Performance Indicators (KPIs) such as reliability, redundancy, availability, safety, economy, environmental performance, and resilience. With a background in Danish consultancy and Austrian research this paper discusses how KPIs are accounted for in current bridge management. New technologies, such as structural health monitoring, artificial intelligence supported virtual/immersive inspections and reliability-based structural assessments, push for quantitative rather than qualitative decisions regarding interventions on element or structural level. Combined with risk-based decision-making based on multiple KPIs should allow bridge managers to make more objective, transparent and better decisions. This paper provides examples of some of the gaps between research-based decision-making models and technologies and thereby also the gap between current and future decision-making practice in Denmark and Austria.

1 INTRODUCTION

Infrastructure systems, such as bridges, are a driver for economic growth and development of countries. Every single day infrastructure operators and owners strive to make decisions that allow for optimal operation and maintenance (O&M) whether on bridge element, system or portfolio level. Decision-making is made on all levels within an owner/operator organization and often many years before the interventions. As a basis for decision making, infrastructure managers rely on data as well as systems/tools developed and operated internally within their organization or by external companies. The quality of information and the knowledge of the structures with their local peculiarities, damage processes as well as associated intervention costs and methods are crucial for good decision-making.

The project COST TU1402 on quantifying the Value of structural health Information (VoI) for decision support prepared a Guide for practicing engineers (COST TU1402, 2019) that summarized that the knowledge about the decision context is the fundamental factor for optimal decision-making and is generally in association with:

- decision maker (private or public authority),
- decision scenario (future use of the structure)
- decision time horizon and other time constraints,
- technical constraints such as code requirements or safety targets,
- complexity of the 'case study',
- socio-economic or political preferences,

DOI: 10.1201/9781003483755-127

Decisions are made using one or several Key Performance Indicators (KPIs) such as reliability, redundancy, availability, safety, economy, environmental performance, and resilience. Top level or executive asset management policies often address some or all the KPIs. How these policies are translated within the owner/operator organization into daily operation is not always transparent, and for a good reason - because this translation is not straightforward. However, decisions need to be transparent as infrastructure operators and owners are accountable towards various stakeholders (public at large, government, concession contract provider etc.). With a background in Danish consultancy and Austrian research this paper discusses how KPIs are accounted for in current bridge management.

New technologies, such as structural health monitoring, artificial intelligence supported virtual/immersive inspections and reliability-based structural assessments, push for quantitative rather than qualitative decisions regarding interventions on element, structural or portfolio level. Combined with risk-based decision-making based on multiple KPIs should allow bridge managers to make more objective, transparent and better decisions.

Based on experience from consultancy and research this paper discussed scope, ambitions and prioritization incl. KPIs related to bridge management in Denmark and Austria. Likewise, new trends in Danish and Austrian bridge management such as UAV-based immersive inspections and the revival of proof-loading for existing structures is debated. Last, gaps between current and future decision-making in bridge management whether technical (e.g. lack of data), educational (e.g. communication and training) and/or economic/contractual are also debated.

The paper is structured to present Key Performance Indicators (KPIs) in bridge management (chapter 2), supporting technologies (chapter 3) followed by a discussion of the general status, new trends and gap between current and future decision-making in bridge management in Denmark (chapter 4) and Austria (chapter 5). The conclusion provides a comparison and an outlook for the future.

2 KEY PERFORMANCE INDICATORS (KPI) IN BRIDGE MANAGEMENT

The performance-based evaluation of engineering structures is becoming increasingly important and allows maintenance management and long-term planning to be carried out according to the needs of the user and owner. Often, performance evaluations make use of the term Performance Indicator (PI), which stems from economics and measures the success of an organization or of a particular activity (such as projects) with which it engages. The application of this term to physical objects is coupled to their fitness for purpose. The PI measures the fitness for purpose of a physical object such as a route (portfolio of bridges), a bridge or one of its elements.

Since the fitness for purpose can change over time, so does the value of a PI. Maintenance interventions can also change the value of PI. Generally, there is no clear distinction between PIs and KPIs. In this article, like the COST TU1406 project WG3 report (COST TU1406, 2018), KPIs relate to a whole bridge and are in terms of Reliability, Availability, Safety, Economy, and Environment (RASEE) defined as follows:

Reliability is the probability that abridge will be fit for purpose during its service life. It is the complement of the probability of structural failure (structural safety), operational failure (serviceability) or any other failure mode chosen by the infrastructure manager or required by other stakeholders.

Availability is the proportion of time a structure is open for service. It does not include failure-related service outages, but those due to expected maintenance interventions. Alternatively, Availability can for instance include additional travel time due to an imposed traffic regime on a bridge.

Safety is the situation of life and limb being protected from harm during the service life of a bridge. Loss of life and limb due to structural failure is not included by this definition (since it would overlap with the Reliability).

Economy is related to minimizing the long-term cost of maintenance activities over the service life of a structure. Herein the user costs for instance for bridges incurred due to detours and delays are not included.

Environment is related to minimizing the harm to environment during the service life of a structure.

Furthermore, in recent years, *Resilience* as a KPI has been addressed by some infrastructure managers. Resilience is associated with the ability of a structural system to deliver a certain service level even after the occurrence of an extreme event or series of events, and to recover the desired functionality as fast as possible. One can see that Resilience may be seen as a combination of the above listed KPIs as a function of time.

Often the KPIs will be evaluated for different maintenance scenarios looking for the most feasible one. Here, it must be underlined that the KPIs Reliability and Safety can be evaluated based on inspection and/or investigation at a point in time (i.e. static quality assessment) but can also be predicted over time (i.e. dynamic quality assessment). The KPIs Availability, Economy and Environment can only be reasonably applied as a function of time and are very strongly linked to political and social constraints and needs.

3 SUPPORTING TECHNOLOGIES

In order to evaluate KPI's and subsequent for the infrastructure managers to make decisions, detailed information on structural performance is required. In recent years several supporting technologies have been applied in the field of bridge management.

Structural Heath Monitoring (SHM) of bridges using sensor technologies and Bayesian updating has gained significant momentum. One application is loading response versification often applied to major bridges. Loads could be environmental as well as traffic. Such monitoring is often launched as campaigns which is beneficial for the bridge operator as sensors have a limited service life compared to the service life of the bridge. Another 'campaign' monitoring example is proof -loading of 'ordinary bridges', which has also gained momentum during recent years, see section 4.2. Most bridge degradation processes are slow under 'normal' environmental exposure. This is part of the motivation for launching long term monitoring related to bridge resistance such as monitoring the level of corrosion in different depths within a concrete structure to provide data for service life updating. Long term monitoring comes with a (semi-)continuous O&M cost that needs to be considered. Furthermore, it must be acknowledged that SHM provide data that must be processed to provide information. This information needs to be visualized and possibly integrated into existing management systems. In addition, the infrastructure manager also needs to decide where to store, process and visualize data and information for decision-making.

Immersive (virtual) inspection is another technology that has made it possible to have a better view and understanding of existing conditions. The use of Unmanned Aircraft Systems (UAS) and Photogrammetry to create photorealistic reality models have yielded significant benefits by allowing inspectors, bridge maintenance personnel, and engineers to have a clearer view of what is happening on critical infrastructure and to also perform many of the tasks virtually that would have previously required expensive travel, access equipment, and manual labor. Not to mention the impact on the normal operations of a transportation infrastructure asset (reduced availability and safety). Infrastructure owners and engineering firms are starting to apply them on projects to see tangible benefits in terms of costs, time, environmental impact, and safety. Artificial Intelligence can also aid the inspectors. Some examples have appeared with machine vision technology that lets inspectors get a more consistent and objective understanding of issues, such as cracking, spalling, or corrosion. The AI-ML detector can go through all the 2D images to detect and then mark the cracks in the photos and display the result in the 3D reality model. A post-processing cleaning step can find and remove known false positives.

Reliability-based assessment of existing bridges started many decades ago. In Denmark the Danish Road Directorate published their first guideline on this matter in 2004, ref. (DRD,

2004). In 2023 effort have been made in order to update the 2004 version which is soon to be published. It is fair to say that the guideline has not been used extensively in practice but when it has been used significant repair and replacement savings have been obtained. It is expected that the sustainability agenda promote refined analysis for prolonged service lives and hence reliability-based methods. In popular terms money should be spend on calculations rather than materials.

Reliability-based assessment pave the way for detailed quantitative rather than qualitative decisions on element and structure level. Combined with assessment of consequences the infrastructure manager can make quantitative risk-based decisions based on one or multiple KPI's. Today, many infrastructure owners make qualitative risk-based decisions as an individual or within a sector, a department, or an asset type but if they want to align decisions across asset types as a start, they need to be quantitative. Infrastructure managers strive to make objective and transparent decisions – and risk-based methods could support this process. Similarly, risk-based methodologies also pave the way for portfolio management in a network related context.

4 BRIDGE MANAGEMENT IN DENMARK

The following sections provide a general status and highlight some new trends from bridge management in Denmark with special focus on roadway bridges on the state network. Furthermore, gaps between current and future decision-making have been summarized – all seen from the perspective of a consultant.

4.1 *General status*

According to [Ebbesen, 2022] asset management at the Danish Road Directorate (DRD) is defined as "...Asset Management includes methods, processes, procedures, data and IT systems that together ensure the implementation and documentation of the long-term economically most optimum operation and maintenance or reinvestment of the non-current assets with the given economic framework and the expectations of the society".

Asset management support the objective of providing safe, functional and economic optimized maintained roads (incl. bridges) in conformity with the politically defined needs and priorities including sustainability. Economic optimized maintained roads is controlled using Net Present Value Life Cycle Costs (LCC) benchmark of maintenance strategies. In case of scarce financial resources, the owner must be able to prioritize safety and functionality and account for the consequences for condition as technical KPI and financial aspects of omitting economic optimum (minimal LCC) operation and maintenance, ref. [Ebbesen, 20222].

According to [Ebbesen, 2022] the ambition of the DRD is "By means of transverse Asset Management for the operation and maintenance of the roads, the Danish Road Directorate will achieve high quality and transparency in the underlying data for decisions, execution and implementation as well as reporting. At the same time, the given resources and skills are utilized optimally across the Danish Road Directorate. Within the given framework, the aim is to minimize the total life cycle cost of the road network, while agreed service level is maintained."

According to the above, the following list of decision-making objectives can be highlighted:

- Safety and functionality are always given highest priority,
- Condition assessment provides the basis for the estimation of maintenance needs,
- Operational activities (cleaning, minor repair jobs etc.) are linked to service level which is balanced politically in line with the appropriate funds,
- Prioritization of O&M tasks is based on technical and economic assessment of likelihood and consequences. This assessment is most often conducted as an implicit risk assessment, where technical and economic KPIs, ref. section 2, incl. social and traffic-related importance are evaluated and quantified to an extend where unambiguous and transparent

decisions on maintenance or reinvestment strategy can be made. It is clear that data are in demand in order to be quantitative rather than qualitative in this assessment,
- The above decisions are logged on an ongoing basis in order to be able to explain development of grants spending, technical progress and actual production.

4.2 *New trends*

In Denmark it is common to use of a traditional hierarchy of inspections, comprising routine, principal, and special inspections. In recent years, the Danish Road Directorate has with success implemented a UAV-based immersive inspection workflow on some of their major bridges.

Major bridges are often difficult to reach (at arms-length), typically because they span from coast to coast. This implies that inspections shall be performed by rope access and/or moveable underbridge inspection gantries on trucks. Performing such inspections comes with a risk to the bridge users (due to traffic restrictions) as well as the inspection personnel working at heights and/or near water. Furthermore, this inspection type is labor-intensive and costly. The immersive inspection workflow comprises a drone flight where RGB and often also thermal pictures are obtained with 70-80% overlay. From these pictures a reality model is established. Thermal images obtained during e.g. temperature rise provides excellent data on delamination of concrete structures that otherwise only could be obtained using hammer tapping or by use of NDT equipment at the concrete surface.

Using the reality capture model an immersive inspection can be performed at the office. This allows for collaboration between the inspector and various experts, the inspector can be well rested and go back-and forth between locations of interest. Defects and be annotated on the reality capture model for easy communication between consultant, owner and contractor and all data are stored for easy reuse – maybe in connection with defect prognosis at the next principal inspection.

Furthermore, several trained artificial intelligence (AI) models for defect detection are being used. They assist the inspector during virtual inspection especially at vulnerable zones (could be that a crack-overlay highlight flow of forces at half-joints or beneath bearings).

The use of proof-load testing for documentation of allowable traffic load on roadway bridges are performed by the Danish Road Directorate (DRD) during recent years. This is an example, where the DRD as owner has been very active with interaction and financial support to research. Proof-loading in Denmark has proven technical and economic attractive. Furthermore, it supports the sustainability agenda – keeping the portfolio of bridges fit for society demands regarding traffic loads. As highlighted by [Straus et al, 2022], it is important that owners and consultants are in close contact with universities, so that decision-support models developed by research are easy to implement and respond to the exact needs of the owner. This owner-interaction also motivates standardization and development of guidelines, so that the research-outcome can be used by the industry at large.

Maintenance activities in Denmark are preventive rather than reactive. With the increased use of Artificial Intelligence throughout the industry the concept of cognitive learning or cognitive maintenance activities has also found the way to selected Danish owners. It seems to be an area where the technology needs to mature or prove itself robust for a portfolio of O&M scenarios. Again, interaction between owners, consultants and research is needed for easy implementation and exploration of the full potential of this interesting area of research.

4.3 *Gaps between current and future decision-making*

Seen from the perspective of Danish consultancy, some gaps between current and future decision-making has been divided into the following clusters: technical, educational and economic/contractual:

Technical

- With increased complexity of quantitative decision-models, valid data are in demand. Research, owners and consultants should work close together, so that decision-models are based on data that can be obtain with reasonable efforts.
- Owners strive to digitalize existing data and make these readily available. This should allow for better prognosis, pattern recognition not yet known utilizing AI, attaching data to digital twins incl. reality capture models.
- 'Alignment' of asset management across asset types. Owners would like to make objective and transparent decisions across asset type incl. aligned budget allocation.
- Transition from a defragmented IT landscape to integrated IT solutions is a constant strive.
- Asset management is often based on implicit risk-based assessment. There is a strive to make these decisions more quantitative. One such initiative is to perform reliability-based load capacity assessment of existing bridge.
- Sustainability is high on the owner agenda. This fosters new materials, new technologies and new ways of working.

Educational:

- O&M is a broad technical area comprising many different technical disciplines. This may be part of the reason why universities struggle to make tailormade courses in asset management.
- Danish owners support and run industry courses such as 'principal bridge inspection'. Such courses, where hands on experience is required, are better suited as industry courses rather than university courses.

Economic/contractual:

- Contracts shall support innovation. This is one of the most powerful instruments to make industry ready research.

5 BRIDGE MANAGEMENT IN AUSTRIA

5.1 *General status*

All the relevant infrastructure operators in Austria have built up valuable database systems. The common understanding is that database maintenance is essential for inventory evaluation and for work with the inventory. On the one hand, an accurately maintained database is necessary; on the other hand, the effort required for data maintenance must not be neglected. Operators of infrastructure assets have clearly defined data fields which must be updated after every bridge inspection, ref. (RVS 13.04.11).

With regard to condition assessment and evaluation, the operators have established clearly defined processes based on experience and expert knowledge. The regular survey of the state of maintenance serves to identify and rectify defects and possible damage in a timely manner. Condition is determined by three types of inspection (surveillance, control and main inspection) which differ in terms of effort and time intervals.

The guidelines for carrying out a Surveillance and/or Controlling represent the minimum standard in accordance with RVS and operator internal standards. The aim is to ensure a uniform and efficient procedure. This should ensure the best possible availability and traffic safety, the utilization of life cycles and thus an economical approach, ref. RVS 13.03.11.

The procedure for the Main Inspections (RVS 13.03.11) is also regulated in RVS 13.03.11 and is to be regarded as a minimum standard. The examination is associated with 5 condition classes and inspection intervals of up to 5 years, in which a condition grade and a maintenance measure are determined with a near-hand examination. Most operators also have additional standards to raise the level of quality and ensure a uniform approach to asset management.

Monitoring, in particular Structural Health Monitoring (SHM), is to be seen as a special case in Austria and does not replace conventional inspections such as ongoing surveillance, controlling or main inspections. The data collected in this way are provided for both the action side and the resistance side. Sensors are installed temporarily or permanently on the structures. Depending on the task, the sensors can be used to measure different physical parameters statically and/or dynamically. In Austria there is a distinction made between global and local monitoring methods. According to RVS 13.03.01, the following objectives can be pursued with monitoring of engineering structures: (a) Measurement-based documentation of construction conditions, (b) Monitoring of condition development during operation, (c) Early detection of critical structural conditions, (d) Comparative values for structural calculations, (e) Influence of boundary conditions (e.g. temperature) on load-bearing behavior, (f) Recording of real variables on the action and resistance side as a basis for updating, (g) Monitoring of structural areas that cannot be visually inspected, (h) Recording of the real behavior of structures even under exceptional loads (e.g. special transports) or test loads. The monitoring must be adapted to the existing situation and the importance of the structure as well as the hazard potential and the complexity of the task.

For the component Assessment, condition grades from 1 to 5 are assigned for the individual elements in accordance with Annex 5 of RVS 13.03.11 and, based on this, for the overall structure. The condition classes in accordance with RVS 13.03.11 essentially assess the urgency of the rehabilitation based on the structural condition. Structures with relevant deficits on element level would therefore not necessarily be classified as being in a structurally defective condition. In order to prevent misunderstandings in management about the urgency of measures, it is standard practice that for bridges with relevant deficits according to the standards on which the planning is based, these deficits should be included in the overall assessment of the structural condition. Depending on the engineering assessment and requirements, special inspections can be initiated in accordance with RVS 13.03.11 due to the prevailing state of preservation or if the extent of damage cannot be determined with sufficient accuracy using simple testing equipment. In addition to the triggering measure, all other assets that match the main measure (e.g. Intervention on a bridge in urgent need of repair) in terms of space and time are also reported. This already considers what the next measure in this area will be. The outcome may be that components have to be repaired before the theoretical standard life cycle expires in order to ensure that the section in question remains free of construction sites for the following years. The aim is to move from a purely condition-based maintenance of the individual assets to an overall maintenance project.

Measures are prioritized in the following order: Structural capacity, Road safety, Availability. If the above-mentioned characteristics cannot be used to adequately prioritize measures, a robustness index can be used as defined in internal guidelines of the infrastructure operators. If it is also not possible to prioritize the measures using this, the impact on the customer must be taken into account.

Based on the historical component classifications maintained in the database, an ageing model of the individual components is determined using Markov chains. These ageing models are also the basis for the prognosis calculations of the condition development that will be calculated using the dTIMS software tool. It is worth noting that this is a standard deterioration model, which may deviate from the actual deterioration of the individual components of the asset. A grade of 3 indicates that the structure can still be used to its full extent, but also creates a certain awareness that this structure will need to be repaired in the foreseeable future. Up to a score of 3, the data is very valid; from a grade less than 3, there is a lack of available data due to the relatively good condition of the bridge structures in the network, which means that a greater variation must be assumed here.

A probabilistic life cycle model is used to determine the long-term budget requirements for the bridge structures of some operators. Based on the year of construction of the structure, the standard life cycle with the corresponding cost estimates is used to determine the theoretical maintenance requirements. This procedure provides an estimate of the resources to be expected if the portfolio behaves in accordance with the previous pre-scribed assumptions made. The current condition is only taken into account indirectly by adjusting the Markov chain models.

5.2 *New trends*

As described in 5.1, a clearly defined inspection and assessment procedure has also been established in Austria, which comprising routine, principal, and special inspections and allows to include innovative monitoring concepts.

For special cases, such as structures with high piers, but also for very long and inaccessible structures, video and innovative monitoring systems (UAV or Satellite Systems) have also been trialled and used as a supplement for some time. In connection with this, there are also developments as to how such monitoring information can be made available to maintenance managers and decisions makers in the future in the form of BIM concepts, for example, and in what form this BIM information can possibly supplement the established databases in a data-based assessment strategy.

In Austria, there are similar developments and considerations for reality capture models on certain structures, although the implementation incl. AI technology has not yet found its way into daily practice. However, a number of research projects supported by infrastructure operators are being conducted on the topics of BIM, AI and IoT as well as reality capture models and digital twin topics.

5.3 *Gaps between current and future decision-making*

On the basis of the above-mentioned gaps between the current and future decision-making of our Danish partners, the following can be mentioned for the Austrian side in addition to the above-mentioned gaps

Technical

- Data safety/security and also the verifiability of the data and decision processes by engineering experts
- Transparency of the decision-making processes, which refers not only to a structure but also to the network level
- Avoidance of small errors with major consequences in the decision-making processes and the associated automation
- Implementation of scientific methods in practical processes and their verifiability - the impossibility of installing a living laboratory due to large economic effects

Educational:

- The professions in the field of infrastructure inspection and asset management require a high level of expertise in engineering, digitalization techniques, understanding of time-dependent processes and economic as well as political and environmental processes.

Economic/contractual:

- Digitalization, especially the digital transformation of inspections and asset management, will require investments in digital systems and their maintenance and servicing, as well as the training of personnel on these media, in addition to investments in the classic maintenance of structures. These investments must be accepted

6 CONCLUSION

Many of the issues presented in this article were also investigated and discussed as part of IABSE TG5.4 (Strauss et al, 2022) and can be summarised as follows:

- Most of the infrastructure operators have very well-developed systems for assessing the condition of their infrastructure assets.
- Inventory and asset management databases and their importance for an objective assessment as well as future planning of refurbishments and interventions is indisputable

- The use of monitoring systems and SHM concepts for the performance assessment is only commissioned for specific reasons in the countries analysed and must not replace traditional engineering-based inspections, however, a freer interpretation can already be seen, e.g. in areas that are difficult to access or for very long-span structures.
- The methods, some of which are highly digitalised by scientists, are only used to a limited extent in daily practice, as their validation and plausibility checks are only possible to a limited extent in short periods of time and long-term planning is usually also influenced by many unforeseeable factors.
- With increasing academic training at universities and in praxis in the areas of asset management, confidence in scientific methods is growing and the number of experts and methods are finding more and more their way into practice.
- AI and IoT techniques are increasingly being used by some of the operators and owners combined with engineering survey methods.
- Data-driven assessment or risk-based assessment in general is only partially implemented in daily practice, as it is often limited by political barriers and regulations.
- The merging of asset management systems with performance indicator systems paired with testing procedures is still in its beginnings and requires more communication and training.

Overall, the survey results of TG5.4, especially for the two countries presented in this article, show that operators are taking powerful steps towards digitalization and digital transformation, while maintaining proven, reliable engineering methods.

ABSTRACT: Hydraulic actions resulting in scour are a major cause of bridge failures worldwide. The development of scour is affected by various factors including structural geometry, river morphology and weather conditions. Detection of scour is often carried out using visual inspection-based methods. Visual inspection requires the expertise of divers which incurs high levels of risk, especially during times of high-water flow. Therefore, sensing technologies are becoming increasingly popular with the aim to supplement or replace higher risk visual inspection approaches. Specification of Structural Health Monitoring (SHM) systems is an important activity for bridge engineers and asset managers. This activity can be assisted by SHM rating frameworks, the use of which gives evidence to support specification of monitoring systems for individual bridges. In this paper, three previously published scour rating frameworks are compared using a bridge case study database.

1 INTRODUCTION

1.1 *Background*

Bridge scour is the erosion of material around bridge piers, abutments, and foundations (e.g. Kirby *et al.* 2015). Scour accounts for approximately 60% of bridge failures, including pier scour incidents (Lagasse *et al.* 1997). As a result of scouring actions, the foundations of a bridge may become unstable potentially resulting in collapse (e.g. Maddison 2012). About 60,000 highway and railway bridges span watercourses in the UK, many of which are over 150 years old with unknown foundations (especially unknown foundation depths) (e.g. Clubley *et al.* 2015).

Scour is a challenge for engineers due to the complex soil-water-structure interactions (cf. Kirby *et al.* 2015, Pregnolato *et al.* 2022). Empirical scour depth prediction methods show considerable scatter (cf. Gavriel *et al*. 2023, Shahriar *et al*. 2023). Hence it is important to monitor scour in the field and if possible, employ real time monitoring (cf. Prendergast & Gavin 2014, Vardanega *et al.* 2021). It is also desirable to develop efficient and durable scour monitoring systems (e.g. Pizarro *et al.* 2020, Vardanega *et al.* 2021). These systems are important for evaluating the scour process and for providing early warnings for hazard mitigation (Prendergast & Gavin 2014). Scour monitoring systems should possess key characteristics such as accuracy, longevity, ease of installation, non-obstructiveness to bridge owners or users, cost-effectiveness, and the ability to withstand a range of environmental conditions (cf. Vardanega *et al.* 2021, Pregnolato *et al.* 2022).

The impact of scour on bridges is becoming more serious every year due to climate change (Sasidharan *et al.* 2023). The increase in frequency and severity of flood incidents

DOI: 10.1201/9781003483755-128

(due to the effects of climate change) heightens the risk of scour to bridges (Foley 2021). A bridge collapse is considered a socio economical problem as it is associated with loss of life, high economic losses, and disruptions to traffic (Pregnolato *et al.* 2021, Dawson *et al*. 2018). It is therefore necessary for engineers to ensure that the effects of scour are mitigated and managed.

1.2 *Scour monitoring*

Prendergast & Gavin (2014) and Vardanega *et al.* (2021) present reviews on various scour monitoring devices. Numerous monitoring techniques have been developed which are able to detect scour occurrence: these techniques can be broadly categorized into 'direct' and 'indirect' technologies (see Pregnolato *et al.* 2022). Direct technologies involve the use of sensors near the bridge foundations, while indirect technologies rely on approaches such as remote sensing or modelling (Pregnolato *et al.* 2022). For instance, two direct technologies are the mechanical sounding rod and the sliding magnetic collar (SMC); devices that are simple to install and produce data which are easy to interpret (cf. Lu *et al.* 2008). Sonar, another direct technology, although easy to use, is prone to the effects of turbulent flow, turbidity, and debris (cf. Fisher *et al.* 2013, Hong *et al.* 2016).

Indirect technologies usually measure the structural response and performance over time to estimate scour depth (Pregnolato *et al.* 2022). These technologies include float-out devices which have high operational capacity in harsh flow conditions enabling their use during times of flooding when scour holes are more likely to develop (Prendergast & Gavin 2014, Pregnolato *et al.* 2022). One downside of float-out devices is that their power supply and reliability cannot be checked once deployed (Prendergast & Gavin 2014). Float out devices are placed in the riverbed and will activate when released during scouring, by floating above the surface (Prendergast & Gavin 2014, Tola *et al.* 2023). Numbered bricks are robust during flood events and are useful for measuring scour (Lu *et al*. 2008). Smart magnetic rocks can monitor scour depth, but they are also susceptible to being washed away during high flows (Jiang *et al.* 2022).

Visual inspection, which is typically carried out by divers, is still a common scour monitoring technique (e.g. Clubley *et al.* 2015, Kirby *et al.* 2015, Selvakumaran *et al.* 2018). Operations cannot however take place during flood events due to the high risk involved for the divers. Divers are only able to inspect a bridge for scour holes after the flood event is over (e.g. Larrarte *et al.* 2020). Visual inspection sometimes may give inaccurate information about the current scour situation due to the presence of debris and lack of clear visibility (e.g. Clubley *et al.* 2015). An example of false inspection is the collapse of the Mayou bridge in France back in 2009 (Larrarte *et al.* 2020). Despite a visual inspection carried out two years prior to the incident, the inspectors failed to detect any scour hole (Larrarte *et al.* 2020). The use of scour monitoring devices can result in less reliance on visual inspections. To decide on the best combination of scour devices for the monitoring of a specific bridge SHM scour assessment frameworks may be used.

1.3 *Study aims*

In this paper, three scour assessment frameworks (Vardanega *et al*. 2021, Pregnolato *et al*. 2022, Lueker *et al*. 2010a, b) are applied to nine bridge case studies reported in the literature (Hayden & Puleo 2011, Wang *et al.* 2012, Zarafshan *et al.* 2012, Topczewski *et al.* 2016, Peng 2020, Lin *et al.* 2021, Weissmann *et al.* 2021, Zhan *et al.* 2022, San Martin *et al.* 2023). This paper aims to provide guidance for those seeking to select an appropriate framework for use during the specification of scour monitoring systems. This aim is accomplished by: (a) applying nine case studies to the three aforementioned frameworks (b) comparing the results from the nine case studies and (c) evaluating the capabilities of each framework to provide guidance as to which is the most suitable framework depending on the situation.

2 SCOUR RATING FRAMEWORKS

2.1 *Framework 1 - Vardanega et al. (2021)*

Framework 1 has been developed by Vardanega *et al.* (2021) based on preliminary work by Gavriel (2019). Framework 1 evaluates the suitability of scour monitoring devices based on five criteria given in Table 1. For each of the five criteria a device can score between 1 to 5 (5 being the highest). The score from each category is summed up to give the total score. This process is repeated for all devices under consideration. The devices are then ranked from highest to lowest score. Framework 1 also provides an indication of the relative applicability of each device depending on the score ranges given in Table 2.

Table 1. Criteria for sensor-rating methodology (taken from Vardanega *et al.* 2021).

Criterion	Description
Q1	Ease of installation
Q2	Ease of operation
Q3	Ease of data logging/capture
Q4	Ease of data interpretation
Q5	Measurement frequency

Table 2. Sensor-rating category (taken from Vardanega *et al.* 2021).

Total score	Applicability for scour detection and monitoring
23-25	Very high applicability
18-22	High applicability
13-17	Moderate applicability
8-12	Low applicability
5-7	Very low applicability

2.2 *Framework 2 - Pregnolato et al. (2022)*

Framework 2 by Pregnolato *et al.* (2022) is a further development of the approach by Vardanega *et al.* (2021). This approach was used to evaluate the feasibility of various monitoring technologies for scour detection and monitoring on three railway bridges in the UK (Pregnolato *et al.* 2022). The study follows a three-stage evaluation process. In Stage 1, available technologies are assessed against the requirements of the CIRIA manual (Kirby *et al.* 2015) and those of Network Rail (see Table 3 for the Stage 1 criteria). Technologies that do not satisfy all the requirements of Table 3 are disregarded and do not pass to Stage 2. In Stage 2, sensors are assessed over nine criteria listed in Table 4. The main difference to Framework 1 is the introduction of heuristically assigned weights on each category. The category score is between 1 to 5 as in Vardanega *et al.* (2021). In the final stage the scores from each category are multiplied by the weight of that category and they are then summed up. The devices are then ranked from highest to lowest score and assessed in a similar way to that shown in Table 2 (see Pregnolato *et al.* 2022 for further details).

2.3 *Framework 3 – Scour Monitoring Decision Framework (SMDF) Lueker et al. (2010a, b)*

Framework 3 is the Scour Monitoring Decision Framework (SMDF) proposed by Lueker *et al.* (2010a, b). Framework 3 was developed for the evaluation and selection of scour monitoring devices on river bridges in Minnesota (USA). Framework 3 can evaluate one bridge at a time and can consider multiple piers or abutments of that bridge. Framework 3 requires

site-specific information about the assessed bridge. The required information includes details about the bridge location and dimensions, flow conditions, bridge conditions, structural elements, and environmental factors. Based on these inputs the framework compares the various types of fixed scour monitoring equipment. By entering sufficient information about the site and the bridge, Framework 3 can rank instruments by suitability for the specific bridge site. Framework 3 is also able to show the effect each of the site/bridge characteristics inputted has on each score for each device. A data file for each bridge containing the structural and environmental information about the specific site is prepared i.e. the input data. The workbook compares the structural and environmental information inputted to the ideal structural and environmental conditions as indicated by the worksheet. The two are illustrated on a bar chart for which a score in the form of a percentage is shown (see Lueker *et al.* 2010a, b for further details). In this framework, each case study can only be assessed against the devices available in the SMDF.

Table 3. Mandatory criteria for Stage 1 (based on Pregnolato *et al*. 2022).

Criteria	Description
R1	Suitability for use at a remote site
R2	Capability of installation on or near a bridge pier or abutment
R3	Capability of obtaining readings from above the water surface (transmitting data without need for underwater access)
R4	Operation capability during storm and flood conditions
R5	Ability to operate from battery, solar power or fuel cell
R6	Ability to operate without the need to mobilize personnel during flood condition
R7	Industry-ready in a related application and/or laboratory-proof for scour assessment

Table 4. Stage 2 Criteria (Q) and Weights for Framework 2 (based on Pregnolato *et al.* 2022).

Criteria	Description	Weight
Q1	Purchase Cost	0.8
Q2	Expected Lifespan	1.1
Q3	Environmental Limitations	1.2
Q4	Robustness	1.2
Q5	Maintenance Requirements	1
Q6	Whole-life Cost	0.8
Q7	Accuracy, Repeatability, Reliability	1
Q8	Ease of Installation (access)	0.7
Q9	Power Consumption	0.8

3 CASE STUDIES

In this section, an assessment is conducted using Frameworks 1 to 3 which are applied to nine different case studies. Table 5 shows the results of the scour rating framework comparison conducted. When using Framework 3 if additional information concerning the location and dimension of the bridge was not available and required, Google Earth was used to estimate this information.

4 DISCUSSION

The comparison of the frameworks as applied to the nine-case studies are given in Table 5. For CS1 from Lin *et al.* (2021), MEMS sensor (which is the device installed on the bridge at

the time of the case study) scored very high for both Frameworks 1 and 2. For Framework 3, evaluating MEMS was not an option as this device is not included in Framework 3. Nevertheless, the case study was tested over the nine already available SHM devices which showed that TA/V device (79%) was the best option followed by the FO device (66%). Framework 1 and 2 can be easily used on already reported case studies to test the suitability of a known device but this may not be an option when using Framework 3 unless the device of interest is available in Framework 3. In the case of a bridge where the user wants a recommendation of a monitoring approach Framework 3 is more suitable.

For CS2, from Zarafshan *et al.* (2012), FBG device (which is the device installed on the bridge at the time of the case study) was ranked as more suitable by Framework 1 (19/25, High Applicability) compared to Framework 2 (27.6/43, Moderate Applicability). The device (which is similar to that reported in the case study of Lin *et al.* 2021) was not one of the nine available devices. However, Framework 3 shows that the TA/V device scored the highest (69%) followed by the FO device (68%). For CS2 the FO device although ranked second, scored higher compared to CS1. The TA/V device only scored 1% more than the FO device.

For CS3, PF was available as one of the nine devices in Framework 3. The PF device scored higher in Framework 1 (20/25, High Applicability) compared to Framework 2 (27.9/43, Moderate Applicability). Framework 3 listed the device fifth best, indicating that there may be more suitable devices. The device scored 59% according to Framework 3, providing similar results to Framework 2.

For CS4, from Zhan *et al.* (2022), the device installed on the bridge at the time of the case study was an accelerometer. Framework 1 scored the device as being of low applicability (11/25, Low Applicability) compared to Framework 2 for which the device did not pass to Stage 2 as it did not meet the criteria in Table 3. For Framework 3 the TA/V device (70%) scored the highest followed by the FO device (67%).

For CS5, from Weissmann *et al.* (2021), the approaches evaluated were US (sonar) and MSC. The US and MSC are highly applicable according to Framework 1 (21/25) and moderately applicable (32.1/43) according to Framework 2. Framework 3, once again, lists TA/V (78%) and FO (67%) as the top two devices. The MSC scored 48% while SN scored 49% according to Framework 3.

CS6, 7 and 8 all test a version of sonar (SN) which is also one of the nine devices available in Framework 3. SN was ranked as Moderately Applicable for CS6 (17/25) and Highly Applicable for CS7 (20/25) and CS8 (21/25). The device was ranked as Moderately Applicable for all three case studies when Framework 2 is applied. When Framework 3 was applied, SN scored 56%, 48% and 52% for case studies 6,7 and 8 respectively. The top two devices according to Framework 3 are the TA/V and FO device for all three case studies. Frameworks 1 and 2 give similar results for SN in all three case studies. For case studies 6 and 8, the score of SN by Framework 3 is slightly higher than 50%.

For CS9, the Limnimeter (LNM), the device installed on the bridge at the time of the case study (San Martin *et al.* 2023), scored very low with Framework 1 (9/25) and did not pass to the next stage for Framework 2. The LNM requires the intervention of a human operator during times of high flow to take the reading, making it a riskier device to deploy. The LNM is not one of the nine available devices in Framework 3. The results from Framework 3 show TA/V (68%) and FO (64%) as the top two devices for CS9 followed by ASC (62%).

5 SUMMARY AND CONCLUSIONS

Frameworks 1 and 2 provide similar results for the reviewed case studies with Framework 2 generally indicating lower applicability. According to Framework 3, the most suitable devices, for the nine case studies, are the TA/V and FO devices. In the cases where comparison between all three Frameworks could be done, the three Frameworks tended to agree. To allow a better comparison between the three Frameworks, as a next step, the nine devices available in Framework 3 should be tested for the nine case studies and ranked. A larger database could also be assembled for future calibration efforts of these (and possibly other) frameworks.

Table 5. The application of Frameworks 1 to 3 to previously published case studies.

CS	Bridge Name	Location	References	Device(s)	Framework 1	Framework 2	Framework 3

[Note: Case Study = CS; MEMS = Vibration based Micro Electro Mechanical Accelerometer System Sensor; FBG = Fiber-optic Bragg Grating; ACC = Accelerometer; US = Ultrasonic Sensors (sonar); DS = Dual-axis Sonar; PS = Profiling Sonar; LNM = Limnimeter; TA/V = Tilt Angle/Vibration; ASC = Automatic Sliding Collar; PF = Piezoelectric Film; SR = Sounding Rod; SN = Sonar; TDR = Time Domain Reflectometry; MSC = Magnetic Sliding Collar; PSDS = Pneumatic Scour Detection System and FO = Float Out].

This paper has compared three scour rating frameworks using a selection of case studies from the literature. Frameworks 1 and 2 can evaluate monitoring devices and their accompanying instruments, offering insights into their applicability for specific scenarios. However, a-priori knowledge of possible sensing technologies is needed to effectively employ these frameworks. Framework 3 can yield results for nine monitoring devices, but it does require some updating especially with respect to the cost information.

Next generation risks challenge bridge maintenance and management in Finland

J. Wuorenjuuri
Sweco Finland Oy

ABSTRACT: The Finnish bridges have been traditionally well kept. However, there are many significant findings of new types of technical challenges in bridge maintenance that will cause significant funding and innovative needs soon in the future. The environment, load management and aging of structures have been in focus earlier, but traditional bridge inspections are not sufficient to find these new structural risks. New generations of risks cannot be managed by only traditional inspections. Also, a new generation of bridge management is needed. Finland is not alone with these challenges.

1 INTRODUCTION

The merger of the road, railway and maritime authorities and the establishment of the Finnish Transport Infrastructure Agency in 2011 was a significant step forward in bridge management and maintenance in Finland. In the case of bridges, this has been significant in the improvement of resources and the quality and coverage of design, construction, and maintenance procedures. Although railway bridges and road bridges differ in many ways in terms of maintenance, there are also similarities. In particular, the procedures were unified by comparing and selecting the best operating methods from the practices of all engineering structures.

In Finland, the national road network is divided into 79 maintenance areas and the rail network is divided into maintenance areas. The basic maintenance actions are given to private companies that are supervised by the Agency officials. The maintenance company performs the basic maintenance and annual inspections. The Finnish Transport Infrastructure Agency conducts research, repair programing and commissions bridge inspections. Repairs are separate tasks for companies specialized in the field of bridge repairs. The repair debt program has increased bridge repairs in recent years.

2 THE TRADITIONAL CHALLENGES

In addition to aging, the traditional challenges of bridges in Finland have been related to heavier traffic, changes in load conditions and identifying special structural solutions. These challenges have been well managed, but there has also been development of new challenges in the recent years. Repair activities have often been not only slowing the aging process or modernizing the bridge, but also new innovations.

The starting point of all bridge management and maintenance is safety everywhere. Maintenance tasks must be planned and performed under the conditions of road and train traffic. Safety always involves both work and train/vehicle safety aspects, and often also electrical safety near electrified tracks. During repair and maintenance measures, it is usually not possible to interrupt traffic for a very long time, so work methods in the infra environment are

DOI: 10.1201/9781003483755-129

always chosen according to how traffic can be organized. There has been an improvement in this planning in Finland in recent years.

In Finland, the actual loads on bridges have developed significantly over the years. Older bridges are designed for much lower loads than the traffic that crosses them now. Old railway bridges also have many load accumulations, which is a fatigue issue. Although today's bridges are designed for fatigue, older bridges are usually not designed for fatigue at all. Older bridges may have fatigue-related damage, although these are not always recognized as fatigue-related problems.

Railroad bridges often also have special structures that must be considered in maintenance and upkeep. These include for example riveted steel structures in significant joints, different edge structure solutions, fall protection deficiencies of old bridges and diverse track structures. Road bridges have joints that need attention. Old railings on bridges do not meet the requirements of safety, especially when aged and damaged.

Of course, railway bridges have also practical challenges compared to road bridges. Access to structures is often difficult in Finland or at least requires special arrangements. Railroad bridges may be at the end of non-road access routes, and the transport of repair materials or equipment to the site sometimes requires ingenuity. The electric track makes lifting work more difficult, limits the use of large work tools in treatment procedures. There is a great number of large road bridges that need special arrangements just to get to get access to details.

3 THE TRADITIONAL CHALLENGES

3.1 *Riveted bridges*

In 2009, serious damage was found in the riveted steel bridge joints. It was found that the joints of the beams supporting the tracks were swaying under the traffic. In worst cases the rail had suffered serious local wear. When the rivets were examined, it was possible to find with ultrasound that some of the rivets were broken and the movement in the joint was at worst visible with the naked eye. In this case, the 60-meter span steel truss bridge was repaired by strengthening the joints. The following years, similar joint damage was observed in many bridges, which also needed to be urgently repaired.

The Finnish Transport Agency carried out a risk mapping based on the calculation of the bearing capacity of all steel bridges and the assessment of the consequences, based on which joint inspections of steel bridges were systematically carried out. 91 bridges were selected for the steel bridge program. In addition to the special inspections, the maintenance companies were given instructions for an enhanced inspection. Especially significant were the cases where track measurement errors cannot be explained on the track itself in the track structure. In on-going projects, it was re-evaluated whether risky bridges should be replaced instead of repaired.

Today, most of the steel bridges of main line tracks have been renovated into modern bridges. In addition, quick joint repairs have been made to a dozen bridges on other track sections to extend their life cycle. All riveted bridges are examined with ultrasound every 10 years. Monitoring of these structures has been tested, but it has been a challenge to monitor all joints. Also, studies have been made how critical these movements are. A new question is whether a fixed bolted joint has the same behavior than the original riveted joint.

Several studies of joints and rivets have been carried out, and repair methods of these joints have been introduced in a way that does not disturb traffic. Most of the costs of the repair work are scaffolding costs when the scaffolding is hung from the bridge. There are probably several reasons for the damage, but the most damaged joints have been found in those bridges where the load accumulations have been the greatest. In certain cases, it has been possible to show that the secondary structures participate in carrying the load more than what was considered in the old calculations. The dimensional accuracy of the joints and manufacturing defects have also been a factor in the progression of damage.

Old railways bridges of steel without a without the ballast layers also have other maintenance challenges. Wooden sleepers, track structures, rail movement joints and transition zones are special structures, for which special expertise should also be focused on. Since most bridge

maintenance activities focus on concrete bridges, the number of available experts of these structures has been minimized. The experts need and understanding of these structures and is essential for any old structure. The challenges and problems are so diverse that the owners have not been able to highlight the problems in the contracts, and so the maintenance companies have not been able to offer the expertise. This leads to the maintenance of steel bridges being only light actions and running after possible faults.

3.2 *Aesthetics or lifetime durability*

In the design and construction of bridges, the 1960s-70s seemed to be a period in which wonderful slender bridge structures were designed, built, and admired. It was seen professionally talented if all capacity of materials could be used in design. Some of the bridges were new innovations, where the lifetime of the bridge was not prioritized very highly. Not all bridges were made this way, but many significant bridges were. However, this design approach has had its downside, as many bridges from that era now have problems that require constant maintenance and monitoring. A traditional special inspection does not necessarily provide an answer to problems. The problems cannot be detected in one inspection. With these bridges, it is important to know how to maintain and understand the history of the bridge structure and the overall behavior.

Bridges, which are still aesthetically stunning, are the most valuable structures in the rail and road network. The aging network and its structures are a challenge for maintenance anyway. It's good that life cycle aspects and easy maintainability in the design of new bridges have increased the value in the railway bridge industry.

3.3 *Post-tensioned structures*

In 2012, a water tower collapsed in Jyväskylä early in the morning. Fortunately, there were no personal injuries, but the collapse has had significant effects. One of the main reasons for the collapse of the prefabricated and tensioned water tower was the corrosion of the tension cables. The steel of post tensioning was rusted on the surface, but the most important were the cracks, which had significantly weakened some of the steels. According to the research, it was a so-called delayed hydrogen fracture, which is possible with older, stronger permanently stressed steels.

The Finnish Transport Infrastructure Agency immediately studied whether road and railway bridges have been made with excessively strong post tension steel of the same type and from the same era. Several bridges were found. Completely similar cases and a dozen other suspicious cases were found on bridges. Special inspections were targeted at all these bridges with risk spans. There were some closures to road bridges, and they were built again. On the railways it was not possible close train traffic, so these bridges are also heavily monitored and managed. Perhaps the most significant bridge that was renewed because of this is the long road bridge crossing the Ilmala railway yard rails in Helsinki, which was found to be tensioned with corresponding steels. The bridge was closed to car traffic almost immediately. The bridge has since been rebuilt.

Bridge structures under tension also have other challenges. Tensioned trough bridges, which were built before frost-resistant concrete was developed, are challenging due to frost cracking. Large concrete surfaces are susceptible to weathering. Although they can be coated and processed afterwards, the weather stress is so severe that the concrete has already been found to be deeply damaged on several bridges. This requires a very extensive special inspection program for bridges and, of course, the repair measures are technically more difficult than just repairing the surface. Of course, worst case scenario is the aging that influences load bearing capacity and the functioning of the tendons.

3.4 *Quality of concrete*

Defects in the quality of concrete occur in other bridges as well. Of course, most of the concrete damage in concrete structures is caused by aging, but in recent years, because of special

inspection efforts, it has also been possible to find other types of concrete quality problems, both in new and older railway bridges. In surprisingly many bridges, there is reason to suspect the presence of alkaline aggregate in the concrete.

In newer bridges, strength deficiencies have now been observed in the concrete, which are thought to be due to over-optimization of the concrete manufacturing processes. Concrete and cement quality issues have come up. In some cases, concrete has had too much air, and this causes losses in strength and lifetime behavior. Transporting concrete from longer distances has been aided by adding air to it. New codes and testing of concrete have been introduced.

3.5 *Consequences*

In Finland, there has been a situation for a long time where the number of bridges in poor condition has been growing. Thanks go to a good management system and the efficient and successful allocation of repair funds. But these new generations problems also have meant that many of these bridges are rebuilt well before their planned design life is over.

The funding needs greater estimates for repairs. Unfortunately, there are still large bridges in the repair programs, which are both technically challenging and expensive to renew or repair. In addition, the repair works are difficult to coordinate in terms of road and train traffic, and exceptional arrangements for train traffic must be agreed upon several years in advance. Even though the number of bridge repairs is under control; it can be argued that all the easy bridge repairs have been done and the difficult and expensive bridge repairs remain.

When the speeds of traffic and the weight of freight vehicles have increased, it has been necessary to think about installing speed and weight limits on older bridges, if there is a doubt that the behavior of the bridge is no longer controllable due to damage or otherwise. The Finnish Transport Infrastructure Agency maintains information about traffic restrictions caused by bridges in the management systems. The number of traffic restrictions has increased significantly in the past years.

Some of the bridges are clearly weight-restricted as old bridges, when calculations do not make the bridge withstand the new load requirements. But there are also cases where the damage to the bridge has progressed so far that the installation of a traffic limitations has been a necessary measure. In addition, these bridges cause pressure on daily maintenance. They must be monitored daily and possibly organized monitoring so that safety can be guaranteed.

Aging and deteriorating infrastructure, including bridges, are an even bigger challenge for basic maintenance. At its most effective, daily maintenance is the best medicine to ensure the safety and condition of bridges. The maintenance person must have enough activity and understanding to take care of the condition of the bridges. It is very valuable information for the owner of the bridge and the owner's experts when the maintenance personnel reports that he does not understand why there is a problem on a certain bridge that the problem cannot be removed by his own efforts. This automatically leads to additional studies of bridge experts.

Daily maintenance is also the most cost-effective way to maintain bridges. By making small repairs in maintenance, the owner can extend the repair interval of bridges by up to several tens of years. Active maintenance personnel should be given better opportunities to take care of the bridges. It would also reduce the owners work by reducing the bureaucracy associated with the tendering of repair works and the collection of initial data. If the owner does not know how to define bridge maintenance in tender documents and contracts, it also leads to the fact that contractors do not know how to resource enough skilled personnel for bridge maintenance.

4 MEETING THE CHALLENGES

4.1 *Bridge management system*

At the beginning of 2017, the Finnish Transport Agency introduced a register of engineering structures, which includes bridges and all other structures related to roads, railway, and maritime infrastructure. The register has been developed for several years and almost the entire

industry has been involved in doing this in some way. This is a big step towards more effective maintenance management. There is a lot of information on repairs related to bridge repairs in the register. All bridges decisions are now in the same process of making decisions as other engineering structures.

Of course, data maintenance processes play an important role in ensuring that the register contains high quality information in the future. The Finnish Transport Infrastructure Agency has great goals that all data from maintenance and inspections to planning and construction is gathered into the system. The challenge is to get all implementation information up to date in the register, especially when the processes and delays in the delivery of implementation information vary almost from contract to contract. The delivery and collection of register data is also expert work, which is not so simple for all operators who come to infrastructure projects as new designers or contractors.

4.2 *Bridge inspections*

Since the beginning of the Finnish Transport Infrastructure Agency, a lot has been invested in bridge inspections, and the information and benefits obtained from them are great. All bridges undergo a general expert inspection every five years. Carrying out general inspections requires a bridge inspection qualification. Bridges with known faults, are listed and inspected more thoroughly.

The number of special inspections of bridges has been increased considerably. The number of special inspections in a year has doubled or tripled. Also, most of the repair design is now based on special inspections. With the special inspections, maintenance programming has become more detailed, and repairs have been able to be optimized even better. There has been better starting information for repair planning than before.

Bridge monitoring has also been increased. In 2016, the Finnish Transport Agency completed a Monitoring Guide to improve the operations of subscribers and a Monitoring Handbook as a tool for planners. As the possibilities of monitoring increase and the costs become more reasonable, it is important that the clients know how to define the contents and requirements of the monitoring assignments well. Different monitoring projects, monitoring project phases and actors are identified in the instructions, and the instructions have already been used successfully in several orders.

The Finnish Transport Infrastructure Agency also renewed the annual maintenance inspections for railway bridges. With the new instruction, the inspections involved not only renewing the forms, but also defining the reporting requirements. The maintenance person is now also required to have an annual inspection qualification. This has been reflected in the improvement of the quality of the inspections and in the improvement of the possibilities of utilizing the inspection results.

4.3 *Knowing the weak points*

As mentioned above, there are numerous new challenges in the bridges that cannot be detected by traditional inspections. In Finland a continuous improvement in inspection methods and data quality in the database are crucial. Of course, there will be new challenges in the future also, but it is a success story how these problems of bridges have been handled in the management systems.

It is known, where the week points are, why they are named as monitored structures and how to manage them, keeping the bridges safe for the users. These hidden defects are part of the complete management and maintenance systems.

5 CONCLUSIONS

Although the maintenance of bridges in Finland has always been done very professionally, there has been a significant shift in bridge maintenance. More resources have been obtained both in terms of know-how and money. Road and track projects and bridge repairs are better

defined, which can be seen in the fact that bridge repairs are better included and managed in large road and rail projects. Competent people are needed now and certainly more in the future, but the development of railway bridges is now of interest to a wide range of professionals, from professionals to decision-makers. And even though bridges are replaced with new bridges, old bridges are still valued by keeping them in good condition.

The effect of conceptualization on bridge maintenance prioritization

K. Zangpo, A. Amir & M. Henry
Shibaura Institute of Technology, Tokyo, Japan

ABSTRACT: The safety and operability of bridges are key elements for ensuring the functionality of highway networks. However, in Bhutan, road bridges are aging and deteriorating faster than they are maintained. This may be due to the current practice of bridge prioritization for periodic maintenance by ranking based on bridge inventory data and bridge structure condition data, as the ranking is affected not only by the actual condition of the bridges but also by bridge characteristics unrelated to the condition. Therefore, the statistical effect of indicator selection on the ranking of bridges for maintenance prioritization needs to be examined. This research explores the effect of different conceptualizations of maintenance prioritizations by analyzing how the rankings of the bridges change depending on what combination of bridge data are used for calculating the maintenance priority. This study will clarify how uncertainties in the subjective choice of conceptualization affects the bridge ranking for maintenance prioritization.

1 INTRODUCTION

Bridges are a crucial component of road infrastructure. While they are constructed to serve the purpose of connecting roads, inadequate maintenance can impose a significant burden on a country's economy (Mansour et al., 2019). This is particularly evident in Bhutan, where many bridges are ageing and need prioritization for maintenance. However, in Bhutan, due to budget constraints in the road sector, funds have often been reallocated to constructing new bridges, neglecting the maintenance of existing ones. This lack of attention to bridge maintenance is partly attributed to the absence of a systematic maintenance strategy within the Department of Surface Transport (DoST) and the lack of a decisive tool for prioritizing bridge maintenance.

The Japan International Cooperation Agency (JICA) supported the "Construction and Maintenance of Bridge" (CAMBRIDGE) project in Bhutan from 2016 to 2022. This project aimed to develop a comprehensive Bridge Management System (BMS) to facilitate decision-making in prioritizing bridge maintenance within the country. The BMS in Bhutan prioritizes maintenance by ranking bridges based on inventory data and their structural condition. Ranking and prioritizing provide the insight needed for the decision-making process (Dabous & Alkass, UK). Different departments of transportation widely employ various ranking and prioritization procedures to evaluate and select bridge projects. However, the conceptualization behind ranking bridges for maintenance prioritization is an essential aspect of bridge management. Conceptualization is the source of uncertainty (Henry & Opon, 2022) and in the BMS, it can potentially lead to alterations in the prioritization ranks of bridges depending on the chosen conceptualizations. Various approaches or models based on different conceptualizations have been developed to prioritize bridge maintenance, with each approach emphasizing distinct factors. Zhang & Wang (2017) underscore the importance of considering bridges' rankings at the network level, the condition of structural elements, and conducting risk analyses for selected maintenance strategies to effectively prioritize within budget constraints. Similarly, Contreras et al. (2019) focused on factors like aggregated ratings, average daily traffic, safety, resilience, serviceability, and comfort, determining

DOI: 10.1201/9781003483755-130

weights for these factors to enable systematic maintenance prioritization under budget constraints. Echaveguren & Dechent (2019) proposed a prioritization index considering structural condition, hydraulic vulnerability, seismic risk, and the bridge's significance in the road network to prioritize maintenance at the network level. Correspondingly, Whealan et al. (2019) introduced an approach that assesses factors such as bridge condition, maintenance urgency, traffic impact, costs associated with failure, and natural disaster risk to rank bridges for maintenance. While the development of these objective and transparent prioritization formulas is crucial for effective bridge maintenance management, it is also important to assess and understand the impact of various conceptualizations on bridge ranking, as conceptualization can introduce uncertainty into the prioritization of bridges for maintenance planning.

Hence, this study explores the effect of different conceptualizations on bridge maintenance prioritization by analyzing data obtained from the DoST. This data includes bridge inventory (characteristics of the bridges), condition data of the entire bridge, superstructure, and substructure, as well as the condition of secondary facilities such as bearings, ancillary facilities, expansion joints, and drainages. Three conceptualization scenarios were analyzed: firstly, ranking bridges based solely on bridge structure condition data; secondly, considering both bridge structure and secondary facilities condition data; and thirdly, a comprehensive approach that includes all data combinations, namely bridge inventory, structure condition, and secondary facilities condition. The results of these scenarios were compared with the baseline scenario to determine the impact of different conceptualization approaches on bridge ranking for maintenance prioritization. Comprehending the impact of conceptualization on prioritization is crucial for the roads department in any country facing similar uncertainties in the prioritization process. This understanding helps in carefully defining a strategy for ranking bridges and facilitates the development of an effective maintenance plan.

2 RESEARCH METHODOLOGY

2.1 *Data acquisition*

The Bridge Management System (BMS) data were obtained from the Department of Surface Transport (DoST) under the Ministry of Infrastructure and Transport in Bhutan. The BMS data included inventory data for 235 bridges, along with bridge inspection data for the year 2023. These bridges are located along national highways, Dzongkhag Roads (connecting each district to the Local Government Centre), and Access Roads under the administration of DoST. During the data cleaning process, it was noted that the construction year for 9 bridges (approximately 3.8% of the total) was missing. Consequently, the analysis was conducted on the remaining 226 bridges. The BMS database, developed as part of the JICA Project "CAMBRIDGE," comprises both inventory and inspection data for each bridge. It's important to note that the inventory data, which includes detailed bridge characteristics as illustrated in Table 1 below, is collected and updated only for newly constructed bridges and is not updated unless there is a change in the bridge characteristics.

Table 1. Bridge inventory data.

Inventory	Type
Bridge classification	Concrete, steel, composite, bailey bridge
Road classification	Primary NH*, Secondary NH, Dzongkhag Road, Access Road
Loading capacity of bridge (tonne)	8, 12, 18, 24, 40, 70
Average Daily Traffic (ADT)	<50, 50-100, 100<
Age of bridge (years)	0-10, 11-20, 21-30, 31-40, 41-50, 50<
Abutment type	Reinforced Cement Concrete, Random Rubble Masonry
Rainfall conditions	Light, Moderate, High
Alternate route	Yes, No

* NH: National Highway

The bridges are usually inspected twice a year, and, for maintenance prioritization, the bridges are ranked based on the scores calculated from bridge inventory data and the inspection data. The bridge inspection data consists of damage rating criteria for individual bridge elements such as the overall condition of the bridge, superstructure (deck and girder), and the substructure of the bridge. Each damage rating criterion has its respective damage score points. This damage rating criteria and distribution of damage score points for each bridge element were framed during the CAMBRIDGE project. Table 2 shows the sum of the maximum damage scores for each bridge element.

Table 2. Bridge damage criteria with the sum of the maximum score for each bridge element.

Bridge elements	Maximum score
Overall condition	60
Superstructure (concrete deck)	55
Superstructure (steel deck)	25
Superstructure (concrete girder)	70
Superstructure (Steel girder)	65
Substructure (Masonry)	40
Substructure (Masonry)	10

2.2 *Conceptualizations of maintenance prioritization*

In the present context, the bridges are ranked based on the calculated scores from the inventory data and the inspection data, and based on this rank the bridges are prioritized for periodic maintenance. However, it is important to note that the inclusion of inventory data, such as road categories, bridge types, and other factors, may lead to changes in ranks even though they may not directly impact the structural condition of the bridge. This leads to the exploration of the effect of different conceptualization scenarios on the prioritization of bridges to see the effect of choice in the conceptualization approach by analyzing how the rank of the bridge changes depending on each method of conceptualization scenario. In this research, the current

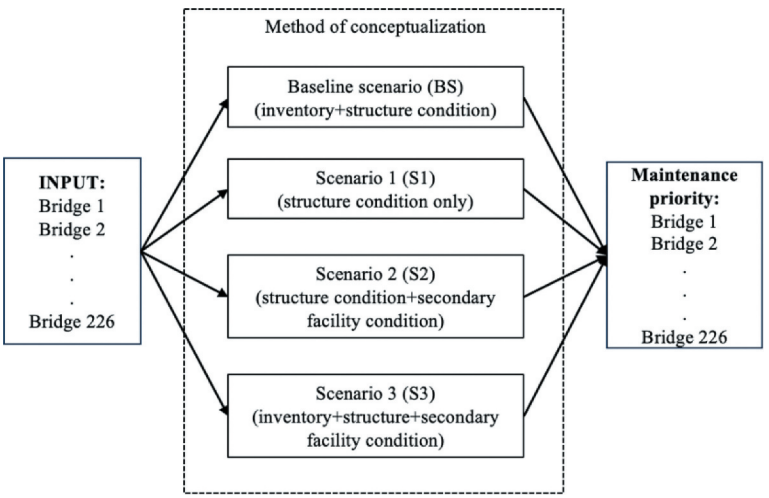

Figure 1. Analytical framework for examining the effect of conceptualization on maintenance prioritization.

practice of bridge prioritization by ranking based on inventory data and structure condition data was considered as the baseline scenario (BS) and further explored three different conceptualizations to study the statistical effect on the conceptualizations for bridge ranking. The first scenario (S1) considered only the structural condition of the bridge, the second scenario (S2) considers the structure condition, as well as the secondary facility condition of the bridge, and the third scenario (S3), includes not only the structure and secondary facility condition but also the inventory of the bridge. The analytical framework used for this study is shown in Figure 1.

The difference in each conceptualization scenario is reflected based on the inclusion or exclusion of either bridge inventory or the secondary facility condition while computing the prioritization ranking. The baseline scenario includes inventory data and the structure condition data whereas scenario S1 excludes the inventory data. Scenario S2 differentiates from S1 with the inclusion of the secondary facility condition of the bridge. While S3 and baseline scenarios have common inventory and structure conditions, S3 has an additional secondary facility condition that distinguishes it from the baseline scenarios as shown in Table 3.

Table 3. Distinguishing feature of each conceptualization scenario.

	Are secondary facility conditions included?		
		Yes	No
Inventory included?	Yes	S3	Baseline
	No	S2	S1

The propagation of uncertainty from the choice of conceptualization can be analyzed using sensitivity analysis to quantify the average rank and standard deviation of the ranks of all bridges across the four conceptualization scenarios. This shift in the rank of a particular bridge will infer the sensitivity of the bridge rank concerning the choice of the conceptualizations for maintenance prioritization.

2.3 *Assigning damage score points for the secondary facility conditions*

The secondary facility conditions of the bridges, such as bearing, railing, expansion joints, and drainage facilities, are also inspected together with the structural condition of the bridge. Since they are not considered in the prioritization of the bridge in the current prioritization method, they do not have any distribution of scores against their damage scales. However, based on the importance of the facility members and the similar point allocations from existing bridge elements, suitable scores were also assigned to the secondary facility conditions. The score of zero applies to the excellent condition without any defect to the secondary facilities and higher scores denote the high level of defects/damages observed. These scores were assigned specifically for this research to analyze the role of conceptualizations in ranking the bridges for prioritization.

2.4 *Data normalization and priority ranking*

The bridges with different abutment types get different scores from the observed damage criterion during the inspection. The Reinforced Cement Concrete (RCC) abutment bridges get a maximum score of 40 while Random Rubble Masonry (RRM) abutment bridges get only 10 points. Therefore, the RCC bridge scores were normalized from 40 to a maximum of 10 points so that the ranking comparisons can be done regardless of abutment type.

The total score for each bridge was then computed based on the damage criterion and the distributed scores for each damage scale observed in the bridge elements and with these scores, the rank of the bridge was generated for all the bridges in all four scenarios. However, due to the different calculation processes used during the conceptualizations, the rank of the bridges was inconsistent within these four scenarios and the range of the ranks is also different

for each scenario. Hence, the ranks in all four scenarios were normalized from 0 to 1 with the highest normalized priority of 1.0 for the highest rank bridge and similarly, lowest rank bridges get the normalized priority of 0.0, and the normalized priority of the bridges falling between the highest and lowest ranks is linearly calculated between 0.0 and 1.0. This process was repeated for all scenarios and each bridge obtained four priority ranks based on the four different conceptualization scenarios adopted. The correlation matrix was also developed to check the relationship between different conceptualization approaches to see how the introduction of different categories of criteria influences the prioritization ranking of bridges. The normalized priority ranks of BS, S1, S2, and S3 were used to calculate the average normalized priority rank to represent the average priority across the four different scenarios. The standard deviation was also calculated, which shows the variability in the priority of the bridges due to the choice of conceptualizations.

3 RESULT AND DISCUSSION

3.1 *Priority ranks in each scenario*

Table 4 shows the five highest, and five lowest normalized priority ranks of the bridges obtained in each conceptual scenario. Since there are 226 bridges in total, all the bridges' rankings are not displayed, rather the top and bottom five are to see the consistency in the ranking for these bridges regarding the choice of conceptualization methods. For baseline and Scenario 3, bridge B151 exhibits the highest priority rank whereas Bridge B129 is the highest for Scenario 1 and Scenario 2. While the baseline scenario and Scenario 3 maintain a consistent priority rank for up to the second highest priority rank, Scenario 1 and Scenario 2 are consistent up to the third highest priority rank. Similar patterns are observed for the bottom 3 priority rank for the baseline scenario and Scenario 3. However, Scenario 1 and Scenario 2 have 100 bridges with the same rank at the bottom of the prioritization.

Table 4. Priority rank in each scenario.

	Baseline Scenario		Scenario 1		Scenario 2		Scenario 3	
Rank	Bridge No.	Priority rank	Bridge No.	Priority rank	Bridge No	Priority rank	Bridge No	Priority rank
1	B151	1.000	B129	1.000	B129	1.000	B151	1000
2	B184	0.996	B151	0.988	B151.	0.992	B184	0.996
3	B136	0.991	B136	0.975	B136	0.984	B129	0.991
4	B135	0.987	B127	0.963	B115	0.976	B136	0.987
5	B18	0.982	B115	0.950	B184	0.968	B115	0.982
222	B134	0.022	B222	0.000	B222	0.000	B8	0.022
223	B1	0.013	B223	0.000	B223	0.000	B138	0.022
224	B6	0.009	B224	0.000	B224	0.000	B6	0.009
225	B180	0.004	B225	0.000	B225	0.000	B180	0.004
226	B14	0.000	B226	0.000	B226	0.000	B1	0.000

Overall, the rank of the bridges is inconsistent across each scenario, but some scenarios exhibit a similar rank of the bridges when they have common categories of criteria for prioritization used for the conceptualization. The correlation matrix in Table 5 shows how the introduction of different categories of criteria for prioritization influences the ranking for prioritization. In a correlation matrix, variables with correlation coefficient values close to −1.0 or 1.0 are highly correlated, whereas variables having correlation values close to 0 are regarded as non-correlated (Amir & Henry, 2023). It was observed that the correlation coefficient of the baseline scenario and S3 was found to be 0.97, highly showing a correlation between these two

scenarios. While this strong correlation is due to the common inventory data, the inclusion of secondary facility condition data in scenario 3 does not affect the overall ranking of the bridge compared to the baseline scenario. Similarly, the correlation coefficient between S1 and S2 was found to be 0.87 showing these two scenarios also correlated due to common structure condition data. Correspondingly, the inclusion of secondary facility condition data in scenario 2 does not affect much the overall rank of the bridges compared to scenario 1.

Table 5. Correlation matrix in each conceptualization scenario.

	Baseline	S1	S2
S1	0.55		
S2	0.47	0.87	
S3	0.97	0.58	0.58

3.2 *Relationship between the average priorities and their standard deviations*

The normalized priority ranks from the four scenarios were used to compute the average normalized priority rank of each bridge to represent a single priority rank across all four scenarios. The standard deviation of the four normalized priority ranks was also calculated for each bridge to quantify the variability in the bridge's ranks, which indicates the sensitivity in the rank of the bridge due to the uncertainty that arises from the choice of conceptualization.

From Figure 2 which shows variability in the rank of 226 bridges against their average normalized priority, it can be observed that certain bridges are highly sensitive to the choice of conceptualization while certain bridges are not regardless of what prioritization

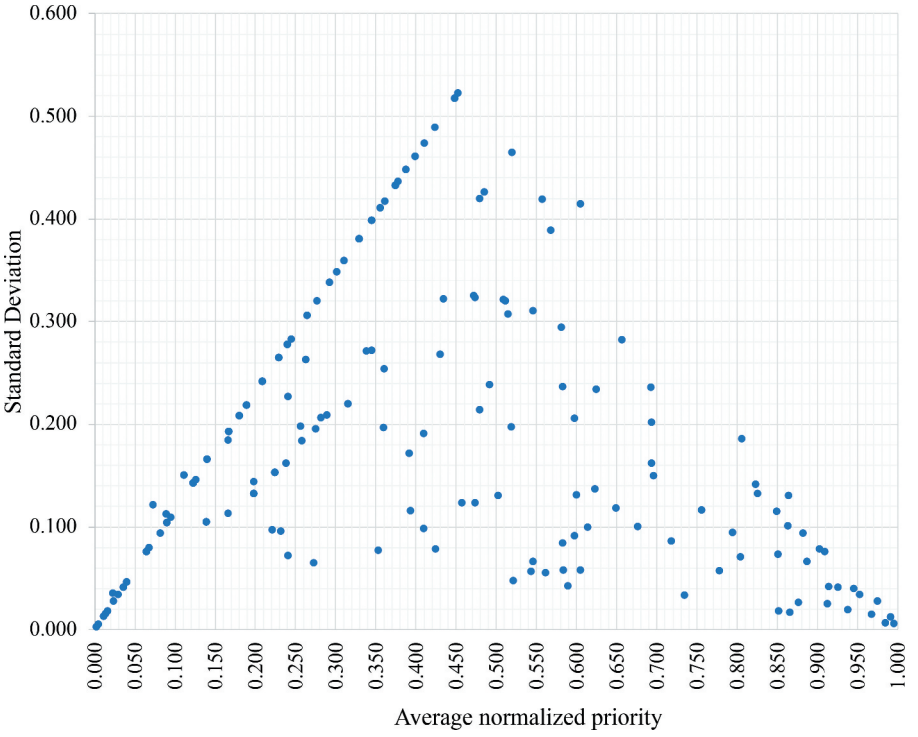

Figure 2. Average normalized priority of bridges against standard deviation.

conceptualizations are used. Bridges with extreme (very high or very low) average priority are consistent in their rank regardless of what conceptualization is used. The bridges with high average priority tend to have a low standard deviation, which suggests that regardless of what conceptualization is used these bridges have high normalized priority. It can be ascertained that there is little uncertainty about their priority and their rank is not very affected by the choice of conceptualization. The bridges with the low average priority also tend to have low standard deviation, so it can be surmised that they are consistently a low priority regardless of how the priority is conceptualized.

It is observed that the high-average priority bridges have a higher level of damage in the bridge structure conditions and thus they have high scores in the structure conditions. These bridges are located along higher classifications of road, have medium to high loading capacity of bridge, and have high average daily traffic volume, and the older age of the bridge contributes higher to the inventory scores. With these two high scores, the average score remains high with a less standard deviation. On the other hand, low-average priority bridges have lower levels of damage, and they score the least in the bridge structure conditions. These bridges are located along the lower classifications of roads with less average daily traffic and younger ages of the bridge which contributes least to the inventory scores. With these two low scores, the average score remains low with less standard deviation. Hence, the bridges with both high and low average normalized priority are insensitive to the selection of conceptualizations.

In Scenario 1 and Scenario 2, many bridges have the same normalized priority of 0. However, normalized priority in the baseline scenario and Scenario 3 are highly linearly correlated with almost the same value. With the same normalized priority in the two scenarios in S1 and S2, their average normalized priority is a linear function of a change of just one variable since the normalized priority of baseline and S3 are almost the same. This results in the linear change of the standard deviation with the average normalized priority, which can be observed on the left side of Figure 2. Since the average normalized priority will be just the function of the baseline scenario and Scenario 3, and when those values increase, the average normalized priority will also increase. Similarly, the standard deviation also increases at an equivalent rate. When these average normalized priority increases, the standard deviation shifts by the same amount since standard deviation is a function of how far the values in baseline and S3 are from S1 and S2. Hence, a linear straight line is observed for the standard deviation with the increase in average normalized priority.

The bridges in the middle range of average normalized priority exhibit absolute more uncertainty since they have low priority in one or two conceptualization scenarios but have high priority in the remaining scenarios. These bridges are highly sensitive to the choice of conceptualizations due to zero scores in the structure condition of the bridge, but the inventory scores are higher. These bridges have good structural condition but their location in a higher classification of roads, high traffic volume, classification of bridge types, and the age of the bridge contributes to high scores in conceptualizations that include inventory, which creates a large gap from the structure conditions. The average of these two scores depends entirely upon the inventory condition of the bridge and accordingly, the standard deviation varies. There arises an ambiguous situation as to whether they can be low priority or high priority. These bridges are highly sensitive to the choice of conceptualization which can result in the alteration of its priority ranking depending upon the choice of conceptualizations.

4 CONCLUSION

This paper examined the statistical effect of conceptualization on the maintenance prioritization of bridges based on four different conceptual scenarios. The bridges were ranked in each scenario and these ranks were compared with the average normalized rank to see how the ranks change depending on the choice of conceptualizations.

The introduction of different categories of criteria for the prioritizations in different conceptualizations influences the ranking of the bridges for prioritizations. Two categories of criteria such as inventory data and secondary facility condition data were introduced in two scenarios to see how the rank changes. The baseline scenario and Scenario 3 show a strong correlation

due to the common inventory data, whereas the baseline scenario and Scenario 1 show a high difference in rank due to the difference in inventory data. However, the introduction of secondary facility condition data in Scenario 2 does not influence much the prioritization ranks from Scenario 1. This concludes that, even if the secondary facility condition data are included in the prioritization, the prioritization ranks are not sensitive to the inclusion of this data.

The bridges with high average normalized priority are consistently high priority regardless of the conceptualizations. There is little uncertainty in the fact that they are high-priority bridges. Similarly, the bridges with low average normalized priority are consistently low priority regardless of the conceptualizations for they don't need prioritizations. The high and low average normalized priority bridges have low certainty in the context of decision-making and can be confident in terms of budget allocations that high-priority bridges are always higher priority regardless of how the prioritization is conceptualized. However, the bridges in the middle range of the average normalized priority are highly sensitive to the choice of conceptualization. While these bridges are low priority when considering only the structure condition of the bridge, the same bridges are high priority when the inventory condition data is introduced. This leads to ambiguity in setting the priority into either low or high priority for those bridges.

This study delved into the understanding of how conceptualization can impact the prioritization of bridges for maintenance planning. Therefore, the road department should carefully define strategies for effective prioritization in bridge maintenance planning.

ACKNOWLEDGMENTS

The authors would like to thank the Japan International Cooperation Agency (JICA) for the support through the Road Asset Management Platform (RAMP) at Shibaura Institute of Technology (SIT) and the Department of Surface Transport (DoST) for providing the BMS data without which this research would not be possible.

Bridge condition index: A review of methodologies used in Bridge Management Systems

A. Agredo Chávez, J. Gonzalez-Libreros, C. Wang & G. Sas
Luleå University of Technology, Luleå, Sweden

ABSTRACT: The transport infrastructure consists of roads, bridges, and tunnel networks. Among these, bridges, viaducts, and tunnels are particularly vulnerable due to structural degradation caused by environmental conditions, overloading, and other factors. Ensuring the safety of these assets, especially at the network level, is a significant challenge. The emergence of Bridge Management Systems (BMS) addresses the need for comprehensive information in managing inspections, condition assessments, and optimizing investments in bridge maintenance. Despite the benefits, many countries face challenges in identifying high-risk bridges. Issues include the lack of high-quality data, mixed ownership of assets, diverse management system platforms, varying condition rating schemes, and the absence of a risk-based assessment. This review aims to highlight current practices and research efforts in evaluating bridge condition indices/ratings (BCI) for existing bridges. The identified knowledge gaps emphasize the need for national authorities to develop policies leading to a unified and functional approach for condition rating.

1 INTRODUCTION

Since the late 1980s the structural health assessment and monitoring of bridges represented a critical topic in the field of civil infrastructure management (Thompson et al., 1998). Transportation agencies face the challenge of balancing limited resources with the growing demands of an aging highway system, particularly in addressing the diverse needs of numerous bridges. While deciding what is more optimal for each bridge is crucial, it is important to realize that the ideal choice for one bridge may not match the overall priorities of the entire bridge system, especially when dealing with financial limitations.(Rashidi and Gibson, 2012). Acknowledging this complexity, bridge engineers, bridge managers and owners, and public officials understand the necessity for established methods and procedures. These methods are essential not only to assess the current and future conditions of bridges but also to determine the most effective allocation of funds within a broader system of bridges. The objective is to make informed choices regarding various types of bridge maintenance, repair, rehabilitation, and replacement options. Currently, municipalities face considerable financial strain due to their underperforming aging infrastructure. This escalates the risk of service disruptions compelling decision-makers to undertake immediate interventions (Soliman and Frangopol, 2015)

The emergence of Bridge Management Systems (BMS) addresses the growing demand for effective management of bridge-related information. BMS employs a comprehensive set of methodologies and procedures to oversee data throughout a bridge's entire life cycle, encompassing project design, construction, monitoring, maintenance, and eventual decommissioning as defined by Rogulj and Kilić Pamuković (2023). BMS is a response to the heightened awareness of bridge collapse incidents (Arismendi et al., 2020) particularly in forecasting the degradation of bridges influenced by changing climate conditions (Nasr et al., 2020). Some countries, such as The United States, France, and Italy (AASHTO, 2018, CEREMA, 2019, CSLP, 2020), have introduced national guidelines to provide detailed instructions for the

DOI: 10.1201/9781003483755-131

development and adoption of multi-risk BMS, aiming to optimize the management of bridges at both national and regional levels.

Within the complex framework that encompasses BMS, condition assessment and bridge health rating stand out as one of the most critical parts in assessing bridge damage for future allocation of budget. Currently, national authorities address the condition rating scales in the guidelines with different approaches, which makes them not easily comparable (Iacovino et al., 2022). These differences in approaches could yield to different conclusions related to the management of the target asset within the road network. Establishing a standardized rating system offers numerous benefits, notably facilitating an objective comparison of the health status of infrastructures. This contributes to the allocation of economic funds for the rehabilitation and modernization of these infrastructural assets (Matos et al., 2023).

This study compares how different countries rate the condition of existing bridges and their methodologies used. A review was conducted on their standards, guidelines, and practices. The objectives of the study are: (1) to examine different ways countries evaluate bridge condition index (BCI), (2) to identify variations in the factors influencing these condition ratings, and (3) to explore emerging trends that could lead to a more comprehensive approach in evaluating and scoring bridges for budget allocation.

2 BRIDGE MANAGEMENT SYSTEMS

2.1 *Components*

According to (Omar and Nehdi, 2018), a fully developed BMS should include four main components for the implementation of a functional BMS.

2.1.1 *Data inventory*

Information related to each stage in the life cycle of bridges must be gathered and stored. Typically, the inventory comprises technical drawings of the initial project design and as built condition, written reports from regular on-site inspections, data series obtained from monitoring sensors, and geographically referenced information pertaining to the structure's location (FHA, 2022).

2.1.2 *Bridge condition rating*

Bridge condition rating (BCR) consists of condition assessment and a rating system. The efficacy of a bridge management system relies on the precision and on the extent of the condition data collected. Condition assessment involves comparing the as-designed, as-built, and as-is states of structures, alongside an evaluation of their current load-bearing capacity. The evaluation of the as-is state involves various tools for field and site inspections. While various bridge owners and managers employ distinct strategies for condition rating (see Table 1 and Table 2), the element-based inspection is widely recognized as the most commonly used technique for assessing conditions (Rashidi and Gibson, 2012). Given that bridge inspection involves inherent imprecision, the bridge condition rating naturally incorporates uncertainty, especially when local authorities lack specific guidelines for damage assessment and condition rating (Dabous, 2017).

2.1.3 *Deterioration prediction and cost models.*

A deterioration model (usually Markov-chain theory for bridge deterioration (Liu and Frangopol, 2006)) is used to predict the future condition of the bridge and its components by means of mathematical models and numerical simulations using finite element method. This scenario becomes particularly beneficial when detailed data from in-depth inspections or load tests are accessible. Cost models associated with maintenance, rehabilitation and replacement is also presented.

2.1.4 *Maintenance planning*

The outputs from condition rating and simulations, collectively function as input for executing intervention prioritization, a pivotal element within the maintenance planning component of a BMS framework. The prioritization of interventions, whether on individual elements or the entire structure, is determined through a multi-criteria approach that considers the risk of

defects or collapse. Specialized methods, such as the Analytic Hierarchy Process (AHP), have been developed to streamline and automate this type of management (Santarsiero et al., 2021).

Current Bridge Management Systems (BMS) vary in terms of the number of modules they possess. Some function solely as data management systems without the capability to forecast deterioration. Meanwhile, other systems allow for deterioration predictions, employing either deterministic or more or less complex probabilistic deterioration models (Lukas and Borrmann, 2012). Some BMS apply multi-risk methodologies for prioritization of maintenance and/or rehabilitation of a bridge within a given network, which can provide information of the likelihood of occurrence of adverse events and their associated consequences (Saydam et al., 2013). Nevertheless, current literature on applying probabilistic risk methodologies to BMS is limited. Many transportation agencies predominantly use only the risk towards structural deficiency to allocate funding for deficient bridges (Yang and Frangopol, 2018). Therefore, the respective practices of BMS's modules vary from agency to agency.

3 REVIEW OF EXISTING BRIDGE CONDITION INDICES

Current practices in BMS are reviewed with the aim to map out the main parameters involved in the assessment of bridge health condition rating worldwide. BCI, also known as: Bridge Health Index (BHI), Bridge Condition Rating (BCR), or Attention Class (CdA), between others, is the term used in literature to define rating systems for bridges. These performance ratings serve to show how vulnerable bridges are to structural or operational hazards, such as hurricanes, earthquakes, or overloaded trucks, and to assess their effectiveness in handling these scenarios (Adu-Gyamfi et al., 2016).

Table 1 displays the BCI employed by BMS in different countries along with the corresponding guidelines applied for the calculation of condition ratings within the BMS. Additionally, it is shown if the guidelines consider a multi-risk assessment in the calculation of the condition rating and the frequency of inspection dictated by the standard.

Table 1. Bridge Management System's BCI and guidelines per country.

Country	BMS	Guidelines	Multi-risk	Risk type	Inspection freq. R* /D**
Slovenia	MOST	MOST guidelines			5 y.
USA	AASHTOware	NBI AASHTO	✓	Seismic, Floods, scour	2 y.
Sweden	BaTMan	BaTMan Teknisk Handbok			6 months 6 years
Finland	HiBris, HankeSiha	Finnra Guidelines			1 year 6 years
Norway	BRUTUS	HB129, HB136,147			1 year. 5 years
Italy	INBEE	MIT 2020	✓	Str.-found, Seismic, Hydraulic, Landslide	2 years
Portugal	GOA	IP			6 years
Slovakia	-	SSC			1 year. 4 years.
France	LAGORA	IQOA	✓	Scour	1 year 6 years
Denmark	DANBRO+				6 months 6 years
UK	SMIS	CS469 2021	✓	Scour Hydraulic	1 year 6 years

* Regular inspection
** Detailed inspection

In Table 1, it is possible to identify significant variations in condition ratings depending on the country. Ranging from qualitative to quantitative approaches and featuring a considerable gap between BCI values, the assessment considers the worst condition in either an ascending or descending manner. Nevertheless, when there is an increase in the number of levels or categories within a system used to rate the condition of bridges, it becomes more difficult to express clear differences between the various states of structural condition (Matos et al., 2023). The challenge arises because the boundaries that separate one level from another become less distinct or harder to define. As the complexity of the rating system increases, it becomes harder to clearly distinguish between the different conditions or states of the structure being assessed.

Moreover, it is possible to notice how new guidelines are incorporating the use of multi-risk assessment. For instance, after the events of the collapse of the Morandi Bridge, Italian Ministry of Transport and Infrastructure worked on improvements in the reliability of existing Italian bridges (Sano et al., 2023). The new Guidelines for the classification and management of risk, the evaluation of safety and the monitoring of existing bridges was published in 2020 (CSLP, 2020), determining risk classification based on hazard, exposure, and vulnerability (see Figure 1).

The concept of risk in BMS comprises two key elements: the probability of failure and the consequences. The probability of failure is associated with the forces acting on the structure

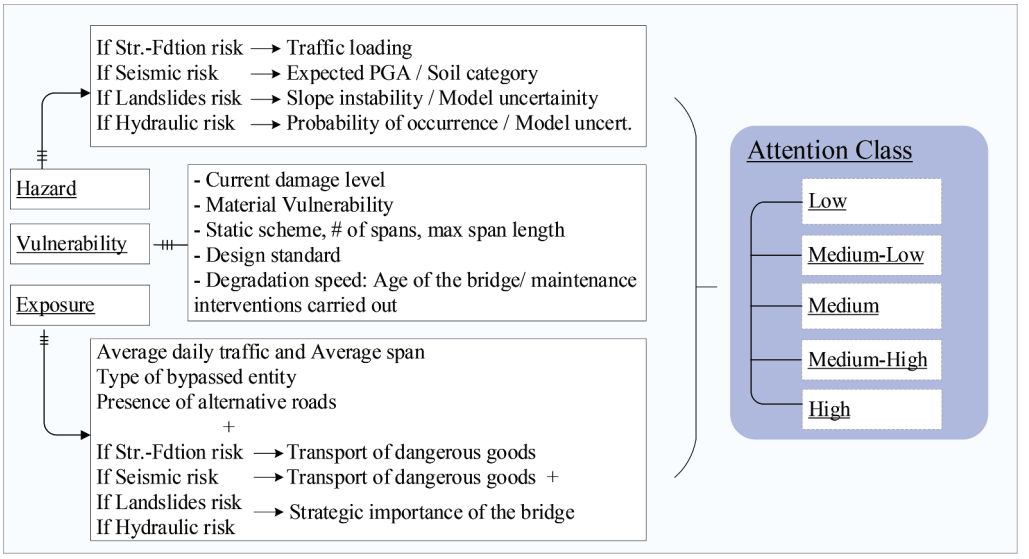

Figure 1. Scheme for Italian guidelines for attention class (CdA) classification (CSLP, 2020).

due to specific events. The consequences encompass user costs, social costs, and the expenses associated with repairs or reconstruction. In this regard, in the context of seismic assessment, the probability of failure is linked to seismic forces, while the consequences are tied to the damage incurred by the bridge (Valenzuela et al., 2009). The assessment of risk depends on the specific hazards associated with each country. For example, seismic activity is a significant consideration in Italy and the USA, but not as much in England or France. This distinction becomes crucial if European codes aim for unification, as certain hazards, like earthquakes, would carry greater weight in calculations compared to others, such as hurricanes.

On this matter, it is important to analyze how BCI is calculated in every country. By doing this, it is possible to capture the parameters of influence that govern the rating of bridges. Currently, most BMSs rely on element-level information for calculating BCIs, indices vary primarily based on the type of information and the quantity of data used in their calculation. According to literature (Adu-Gyamfi et al., 2016, Casas and Bien, 2007, Iacovino et al., 2022, Pregnolato et al., 2024), the different approaches used by the guidelines to calculate the condition index are:

- Ratio-Based Methods: These methods involve assigning a Bridge Condition Number (BCN) based on the ratio of the current condition to the condition when the bridge was new.
- Weighted Averaging Approach: This approach is suitable for planning maintenance and rehabilitation activities. It estimates the overall structure condition by combining condition ratings of individual bridge elements identified during inspection, with weights based on their significance or contribution to structural integrity. The urgency of intervention depends on the probability of structure or element failure.
- Worst-Conditioned Component Approach: Common in systems inspecting key bridge components, this method identifies critical defects by approximating the BCI to the rating of the worst-conditioned component. The German and Japanese BCIs are the examples of this approach.
- Qualitative Methods: Qualitative methods describe a bridge's condition as "Poor," "Fair," or "Good" capturing information about the critical defects in bridge components. For example, in Sweden, repair priorities are scheduled based on severity, functional, and economic condition (related to the extent of damage).
- Risk-based Prioritization: Thie method is focus on prioritization of bridge repair and replacement works in a system. The aim of the proposed method is to offer bridge owners and managers, a transparent and objective scheme for bridge evaluation and project prioritization through a risk-based strategy.

Table 2 depicts a summary of the approaches utilized by the previously mentioned countries.

Table 2. Bridge Management System's BCI approach.

Country	Condition Definition	Original Language	BCR approach	BCI	Worst condition
Slovenia	Condition Rating	(R)	Weighted average	0-40	>25
USA	BHI	Bridge Health Index	Ratio-based /Risk-based	0-9	0
Sweden	Alllowed Classes	Tillståndsklasser (TK)	Qualatitive/ Weighted average	Good (0) Bad (3)	Bad (3)
Finland	Condition Index	KTI	Weighted average	0-4	4
Norway	Condition Number	Skadegrad	Qualitative	1-4	4
Italy	Attention Class	Classe di Attenzione (CdA)	Weighted average/ Risk-based	Low-High	high
Portugal	Condition State	(EC)	Qualitative	0-5	5
Slovakia	Condition Index	Index stavebno-technického stavu	Weighted average	I-VII	VII
France	Condition Class	Classe d'état	Qualitative	1-3U	3U
Denmark	Condition Rating	Tilstandskarakter	Qualitative	0-5	5
UK	BCI	Bridge Condition Index	Weighted average	0-100	(<65)

Some agencies could incorporate two methods to evaluate a BCI, for instance, BaTMan in Sweden incorporates the qualitative method only if specified important structural elements (such as supports, primary load-bearing elements, foundation, etc.) are assigned to a condition class 3. If they are assigned a lower condition class, the determination of the overall condition class relies on the weighting factors outlined in the guidelines. Certain organizations that have adopted risk-based methodologies still depend on the inspector's judgment to determine severity of deterioration elements. For example, the Italian guidelines (CSLP, 2020) use an attention class to assess the structure's vulnerability through visual inspection. In this approach, the inspector assigns defect severity and extent, and the process involves a weighted average.

A significant drawback of the examined methods for calculating the BCI is the absence of entirely objective data. This limitation stems from the prevalent use of visual inspection, which relies on the inspector's expertise and judgment. Consequently, the assignment of weights can vary, resulting in different ratings for the same bridge by different inspectors. Autonomous damage detection is arising as a tool to overcome this problem. Some road agencies (i.e., New Jersey Department of Transportation) incorporate a value of uncertainty in the calculation of the perceived risk to account for a factor to account for the level of uncertainty associated with the selected assessment approach, including the quality control measures employed. Table 3 describes a summary the advantages and limitations associated with each approach aimed to estimate the BCI.

Table 3. Advantages and limitation for the calculation approach of Bridge Condition Indices (BCI).

Ratio-based approach	Weighted Average approach	Worst-Conditioned approach	Qualitative Approach	Risk-based approach
Advantages				
Useful in resource allocation for bridge networks.	Index combines all defects identified at the element level.	Correlates the bridge condition to the weakest link in the structure.	Straightforward and representation of the bridge condition without relying on a numerical scale.	More transparent and objective method for assessing bridges and prioritizing projects.
Can be integrated into prioritization models for allocating funds.		Useful for assessing the vulnerability of a bridge in case of extreme events.		
Limitations				
Could be inconsistent if no standardized guidelines for bridge element inspection are available.	Difficulties in assessing how the condition of an element impacts the overall structure of the bridge	Does not provide a comprehensive view of the distribution of deterioration across the bridge.	Inefficient for prioritizing and planning maintenance as it lacks a quantitative scale for ranking bridges in a network.	The ranking is frequently determined by individual owner/agency-defined criteria or perceptions of risk.

4 IDENTIFICATION OF PARAMETERS OF INFLUENCE

Apart from the variation in the calculation methods, most of the parameters used in determining the BCI are similar. Each country considers various damage characteristics: extent (how widespread the damage is), severity (intensity of the damage), and intervention urgency (recommended repair time for safety, usability, and durability). Additionally, structural type, material vulnerabilities, degradation level, the structural element under assessment, traffic load, environmental exposure, and the type of bypassed entity (if a bridge spans over a river, a major highway, a railway line, etc.) are other parameter commonly found within the methodologies assessed. However, certain parameters are not frequently considered in these calculations.

4.1 *Design standard*

Numerous bridges constructed during the '50s and '60s exhibit structural and technological shortcomings inherently associated with the construction era. These deficiencies stem from the absence of seismic design codes and limitations tied to the technologies and materials available during that period, rendering them "afflicted by design" (Cutrone et al., 2022). Furthermore, in order to be able to estimate the level of vulnerability of the works, it is important to know the hypotheses underlying their creation and, among these, the loads foreseen in the design phases.

4.2 *Static scheme*

The vulnerability of structures is closely tied to their structural characteristics, encompassing static scheme and response to external forces. Parameters such as redundancy in the static scheme (greater hyperstaticity indicates lower vulnerability), susceptibility to brittle failures (e.g., shear failures for Gerber beams), are important factors when assessing vulnerability in structures with varying static schemes, materials, and spans.

4.3 *Age of the structure/Last inspection performed*

Comparing bridges based on their year of construction is particularly relevant when there have not been significant maintenance interventions. However, if well-documented maintenance has effectively reduced degradation, returning the structure to its initial condition, the focus should shift to the year of the last maintenance intervention. In such cases, a special concern should be assigned to bridges with more recent interventions, even if their current degradation level matches that of structures with less recent maintenance.

4.4 *Environmental exposure*

Climate influences on the rate of bridge deterioration. A study lead by (Šelih, 2014) found that structural decay is slowest in the Mediterranean climate, moderately slow in the Alpine climate (likely due to fewer annual freeze-thaw cycles), and notably faster in the continental climate, characterized by numerous freeze/thaw cycles during winter.

4.5 *Road alternatives*

In areas with insufficient infrastructure, the collapse of a road bridge could have catastrophic consequences for road traffic, particularly in emergency situations, as there may be a lack of alternative routes. Some agencies, like the North Carolina Department of Transportation (NCDOT) consider this on the calculation of the ranking criteria for Priority Replacement Index (PRI).

Some guidelines include additional factors like the transportation of dangerous goods, military significance, or serving as an evacuation route for nuclear incidents. Assessing exposure involves analyzing traffic data, including vehicle frequency, and considering the network's resilience to unexpected situations.

5 CONCLUSIONS

The aim of this paper was to provide an overview of different methodologies within the field of bridge condition rating. The methodologies employed for bridge condition rating differ from country to country, and the parameters considered in the assessment could also vary. The variations in these approaches may lead to different conclusions regarding the management of the specific asset within the road network, especially when analyzing the road infrastructure at border crossings. In essence, the methods used to assess or address issues at these border-related road structures may differ, potentially leading to divergent recommendations or management decisions. A comprehensive approach for bridge condition index is essential, it should not only evaluate bridge health by identifying its degree of degradation but also all potential hazards to encompass risks. New guidelines incorporate concepts of risk and bridge prioritization indexes to account for hazards, societal, environmental, political, and military consequences to provide a more objective classification of the bridge when funds for maintenance need to be allocated.

Recommendations for a unified condition rating system is imperative. This system should address the diverse needs and challenges, including those posed by climate changes. However, to limit the number of such levels to ensure that engineers can easily classify bridges without encountering unnecessary complications.

ABSTRACT: When analyzing the impact of vehicle braking on a bridge, it becomes evident that the bridge's deflection increases significantly compared to when a vehicle is in constant motion. The magnitude of this deflection is influenced by the Vehicle-Bridge Interaction (VBI) phenomena, which is significantly activated by road roughness. This road roughness instigates specific dynamics in the vehicle, accentuating the VBI. Our study introduces a probabilistic model to quantify this amplification factor due to a vehicle's hard braking at the bridge's mid-span across various road roughness categories. The amplification factor is defined as the ratio between maximum deflections during vehicle braking and those when the vehicle is at a consistent speed. It's estimated considering parameters like the vehicle's mass, velocity, natural frequency, and damping. For our VBI model, we utilized the finite difference method to discretize the coupled governing equations. Here, the vehicle is represented as a two-degree-of-freedom system, accounting for both its bouncing and pitching motions. The model's computational efficiency facilitated extensive analyses where parameters were chosen via the Latin Hypercube sampling method. Ultimately, we validated our model outputs against real-world bridge displacement measurements under varied conditions.

1 INTRODUCTION

The displacement impact factor IF is commonly considered in order to quantify the effects of braking on bridge dynamics under traffic loads. It is defined as follows:

$$\mathrm{IF} = \frac{w_{b,braking}}{w_{b,constant}}, \tag{1}$$

where $w_{b,braking}$ and $w_{b,constant}$ are the maximum bridge deflection under braking conditions and the value corresponding to a vehicle that moves at a constant speed, respectively.

The thorough examination of vehicle-bridge dynamic interactions necessitates considering a multitude of factors. However, many research works employ analogous, oversimplified models. This trend, coupled with the paucity of studies comparing these various modeling techniques, hinders understanding the significance of all elements and parameters related to braking in estimating its impact on bridge dynamics. It's pivotal not only to assess alternative

DOI: 10.1201/9781003483755-132

modeling methodologies based on their intricacy, precision, and computational implications but also to gauge their utility in real-world applications, including sensitivity and reliability assessments. Consequently, this research delves into two distinct modeling strategies to explore the dynamics of vehicle-bridge interactions during braking scenarios. The initial category encompasses models rooted in foundational physics principles. Notably, six such models, distinguished by varying degrees of complexity and precision, are incorporated into this study. A detailed outline of these models, along with their inherent assumptions, is presented in Table 1.

Table 1. Considered physics-based models of the vehicle-bridge interaction in braking conditions.

Model assumptions					
Model label	IF label	Roughness	Vehicle model	Inertial effects	Braking friction
1dof-hb-st	$IF_{1,hb,st}$	Stationary	1 degree-of-freedom	No	No
1dof-hb-st	$IF_{1,bl,st}$	Stationary	1 degree-of-freedom	No	Yes
1dof-sb-nst	$IF_{1,bl,nst}$	Nonstationary	1 degree-of-freedom	No	Yes
2dof-hb-st	$IF_{2,hb,st}$	Stationary	2 degrees-of-freedom	Yes	No
2dof-sb-st	$IF_{2,bl,st}$	Stationary	2 degrees-of-freedom	Yes	Yes
2dof-sb-nst	$IF_{2,bl,nst}$	Nonstationary	2 degrees-of-freedom	Yes	Yes

Physics-based models, governed by differential equations, can be computationally intensive when executed repeatedly. Metamodels present an effective solution for such computational demands. The objective is to craft an efficient, data-driven model of vehicle-bridge dynamics during braking to swiftly estimate outcomes, such as the bridge's IF response, based on key parameters. Crafting these metamodels demands both the identification of an apt function and its numeric coefficients. Machine learning has emerged as a potent tool for this purpose across various domains. This research delves into the potential of two primary supervised learning methods:

1. Neural Networks: They are utilized due to their renowned capability as comprehensive function approximators for vehicle-bridge dynamics.
2. Genetic Programming: This evolutionary computing technique searches for an optimal symbolic model function that closely mirrors the intended outcome.

2 METHODS

2.1 *Road roughness model*

The randomness of the road surface roughness can be represented by means of a periodic modulated random process. Within the ISO 8608 specifications (ISO/TC, 1995), the road surface roughness depends on the vehicle Fspeed through a formulation that relates the velocity power spectral density (PSD) and the displacement PSD. The general expression for the displacement PSD of the road surface roughness S_d is the following:

$$S_d(n) = S_d(n_0) \cdot \left(\frac{n}{n_0}\right)^{-a}, \tag{2}$$

where n is the spatial frequency (cycles/m), $n_0 = 0.1$ cycles/m is the reference value of the spatial frequency, and a is a suitable exponent. Equation 2 gives an estimate of the actual road roughness level $S_d(n)$ as function of the corresponding reference value $S_d(n_0)$. Note that the classification of the road roughness according to the ISO 8608 specifications is based on a constant vehicle velocity PSD by taking $a = 2$. The road roughness r can be generated as function of the spatial coordinate x through the following equation:

$$r(x) = \sum_{p=1}^{Q} d_p \cos(n_p x + \varphi_p), \tag{3}$$

where n_p is the pth spatial frequency and φ_p is the pth random phase angle, being Q the total number of harmonics assumed to generate the road roughness profile. Moreover, d_p is the pth amplitude, which is computed as follows:

$$d_p = \sqrt{2S_d(n)\Delta n}, \tag{4}$$

where Δn denotes the sampling interval of the spatial frequency. The nonstationary road roughess has been defined based on the paper by (Yin, Fang, Cai, & Deng, 2010).

2.2 *Vehicle-bridge interaction model*

Translation and rotational dynamic equilibrium equations of the vehicle mass can be written as follows:

$$m_v\left[\ddot{w}_v + \left(\frac{\ddot{r}(x_r) + \ddot{r}(x_f)}{2}\right) + \left(\frac{\ddot{w}_b(x_r,t) + \ddot{w}_b(x_f,t)}{2}\right)\right] + 2c_v\dot{w}_v + 2k_v w_v = 0, \tag{5}$$

$$I_v\left[\ddot{\theta}_v + \left(\frac{\ddot{r}(x_r) - \ddot{r}(x_f)}{B}\right) + \left(\frac{\ddot{w}_b(x_r,t) - \ddot{w}_b(x_f,t)}{B}\right)\right] + m_v h\ddot{x}_v + \frac{B^2}{2}c_v\dot{\theta}_v + \frac{B^2}{2}k_v\theta_v = 0, \tag{6}$$

where m_v, I_v, c_v,k_v are mass, inertia, damping coefficient and sprung stiffness of the vehicle, respectively. Moreover, h is the height of the vehicle centre of mass distance from the road surface and B is the distance between the contact points of the two wheels. The absolute vertical displacement of the vehicle mass is given by three terms, namely w_v (i.e., relative displacement between the road surface and the center of gravity of the vehicle mass), r (i.e., road roughness, that is the distance between the road surface and the averaged road surface), and w_b (i.e., deflection measured from the line axis of the bridge). Similarly, the absolute rotation of the vehicle is given by three contributions, namely θ_v (i.e., relative rotation between the vehicle and road surface), r, and w_b. The coupling between the bridge and the vehicle is due to the inertial terms in Eq. 5 and Eq. 6, whereas damping and elastic term are only affected by the relative displacement between the vehicle and the road surface. The contact force of the rear wheel $f_{c,\,r}$ can be derived from the equilibrium equation:

$$m_w[\ddot{r}(x_r) + \ddot{w}_b(x_r,t)] + f_{c,r} - c_v\left(\dot{w}_v + \dot{\theta}_v\frac{B}{2}\right) - k_v\left(w_v + \theta_v\frac{B}{2}\right) = 0, \tag{7}$$

where m_w is the mass of the wheel. So doing, it is obtained:

$$f_{c,r} = -m_w[\ddot{r}(x_r) + \ddot{w}_b(x_r,t)] + c_v\left(\dot{w}_v + \dot{\theta}_v\frac{B}{2}\right) + k_v\left(w_v + \theta_v\frac{B}{2}\right). \tag{8}$$

Similarly, the contact force for the front wheel $f_{c,\,f}$ is:

$$f_{c,f} = -m_w\left[\ddot{r}(x_f) + \ddot{w}_b(x_f,t)\right] + c_v\left(\dot{w}_v - \dot{\theta}_v\frac{B}{2}\right) + k_v\left(w_v - \theta_v\frac{B}{2}\right). \tag{9}$$

The contact force due to the vehicle oscillation does not include the weight of the sprung-mass system $m_w g$ + $m_v g$. Horizontal friction forces arise between the tyres and the bridge

surface during braking. If the width of the contact area between the tyre and the bridge is T, then the bending moment induced by the friction forces is:

$$\begin{aligned} m(x) &= \frac{\mu m_v y_s}{T}\left[H\left(x_r - \dot{x}_v t - \frac{T}{2}\right) - H\left(x_r - \dot{x}_v t + \frac{T}{2}\right)\right] + \\ &+ \frac{\mu m_v y_s}{T}\left[H\left(x_f - \dot{x}_v t - \frac{T}{2}\right) - H\left(x_f - \dot{x}_v t + \frac{T}{2}\right)\right] \approx \\ &\approx \frac{\mu m_v y_s}{B}\left[H\left(x_v - \dot{x}_v t - \frac{B}{2}\right) - H\left(x_v - \dot{x}_v t + \frac{B}{2}\right)\right], \end{aligned} \tag{10}$$

where y_s is the distance between the beam center of mass and the road surface while H is the Heaviside step function. Equation 10 approximates the two distributed bending moments induced by friction forces corresponding to the two tyres with a single distributed bending moment that extends over the wheelbase.

The partial derivative of the approximated expression for the distributed bending moment can be written as:

$$\begin{aligned} \frac{\partial m(x)}{\partial x} &= \frac{\mu m_v y_s}{B}\left[\delta_r\left(x_v - \dot{x}_v t - \frac{B}{2}\right) - \delta_f\left(x_v - \dot{x}_v t + \frac{B}{2}\right)\right] = \\ &= F\left[\delta_r\left(x_v - \dot{x}_v t - \frac{B}{2}\right) - \delta_f\left(x_v - \dot{x}_v t + \frac{B}{2}\right)\right], \end{aligned} \tag{11}$$

where δ_r and δ_f are the Dirac delta corresponding to the rear and front wheels, respectively.

The bridge is modeled as linear elastic Euler–Bernoulli beam with constant mass per unit length ρA (where ρ is the specific mass and A is the cross-section area of the beam) and constant bending stiffness EJ (where E is the elastic modulus and J the cross-section inertia of the beam). The continuous vertical displacement $w_b(x, t)$ of the bridge is governed by the following partial differential equation (Fryba, 2013):

$$\begin{aligned} &\rho A \ddot{w}_b(x,t) + EJ w_{r,xxxx}(x,t) = \delta_r(x_r - \dot{x}_v t)\left(f_{c,r} + m_w g + \frac{1}{2} m_v g\right) + \\ &\delta_f(x_f - \dot{x}_v t)\left(f_{c,f} + m_w g + \frac{1}{2} m_v g\right) + \frac{(x)}{\partial x}, \end{aligned} \tag{12}$$

The following boundary conditions apply on the left and on the right for a pinned-pinned beam:

$$w_b(0,t) = 0,\ w_{b,xx}(0,t) = 0, \tag{13}$$

$$w_b(L,t) = 0,\ w_{b,xx}(L,t) = 0, \tag{14}$$

respectively.

2.3 *Machine-learning*

This study employs a layered feed-forward neural network. Optimizing the design of the neural network is vital for enhancing its precision and forecasting abilities for fresh data. While various methods exist for network layout optimization (Quaranta, Lacarbonara, & Masri, 2020), this research adopts a method rooted in genetic algorithms (Azimi, Khoshrou, & Osanloo, 2019). These algorithms use a computational model that symbolically integrates variables, constants, and operators. Beginning with an arbitrary set of potential solutions, the model undergoes modifications via genetic processes until specific criteria are met. To address

the issue of bloat in genetic programming, our approach views model precision and intricacy as competing factors, aligning with the insights of Ekart & Nemeth, 2001.

3 RESULTS

The study focuses on a pre-stressed concrete girder bridge with simple support, part of Italy's highway system (Aloisio, Pasca, Alaggio, & Fragiacomo, 2020). The section is trapezoidal, 2.3 m tall, and features two cantilevered extensions each 3.85 m in width, strengthened with bonded post-tensioned cables. Every bridge section rests on a pair of pillars spaced roughly 40 m apart. Montecarlo analyses indicate that braking effects largely hinge on road conditions and vehicle's starting speed (Aloisio, Contento, Alaggio, & Quaranta, 2023). Figure 1 illustrates the IF against starting speed, drawing from experimental findings and both physics-based and surrogate models.

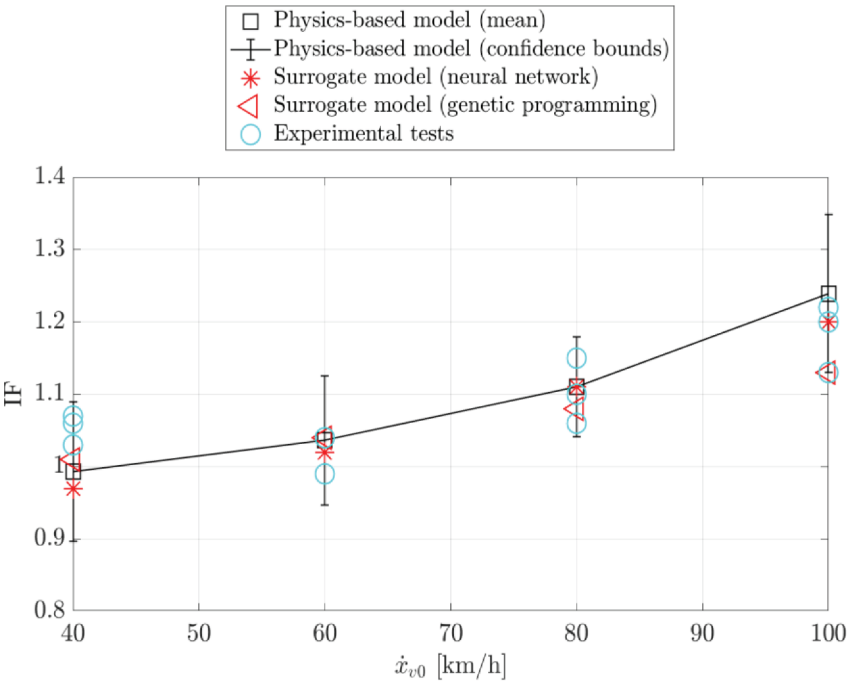

Figure 1. Variation of the IF as a function of the vehicle velocity: confidence bounds estimated using the physics-based model, nominal values carried out through surrogate modelling, and experimental data.

The symbolic form of the final surrogate models for IF and $w_{b,braking}$ obtained via genetic programming is the following:

$$\begin{aligned} \mathrm{IF} = \theta_{IF1} + \theta_{IF2} f_{v,p} h^2 + \theta_{IF3} B \dot{x}_{v0}^2 + \theta_{IF4} B f_{v,p} h + \\ \frac{1}{m_v}\left(\theta_{IF5} \dot{x}_{v0}^2 f_{v,p} h + \theta_{IF6} B f_{v,p} h + \theta_{IF7} B^2 h\right), \end{aligned} \tag{15}$$

$$\begin{aligned} w_{b,braking} = \theta_{w_b 1} + \theta_{w_b 2} B + \theta_{w_b 3} \dot{x}_{v0} + \frac{\theta_{w_b 4} h + \theta_{w_b 5} m_v}{f_{v,b}} + \\ \frac{\theta_{w_b 6} f_{v,p} + \theta_{w_b 7} h + \theta_{w_b 8} m_v}{B^{\theta_{w_b 9}}} (in[m]), \end{aligned} \tag{16}$$

respectively. The involved sets of coefficients, $\boldsymbol{\Theta}_{IF}$ and $\boldsymbol{\Theta}_{w_b}$, are listed in Tab 2.

Table 2. Coefficients of the genetic programming-derived surrogate models for IF and $w_{braking}$ in Eq. 15 and Eq. 16, respectively.

IF (Θ_{IF})	$w_{braking}$ (Θ_{w_b})
$\theta_{IF1} = 1.009$	$\theta_{w_b1} = 2.8268\text{E} - 04$
$\theta_{IF2} = 0.0024$	$\theta_{w_b2} = 9.9309\text{E} - 06$
$\theta_{IF3} = -1.6712\text{E} - 07$	$\theta_{w_b3} = -2.4731\text{E} - 06$
$\theta_{IF4} = -0.0013$	$\theta_{w_b4} = -4.9481\text{E} - 07$
$\theta_{IF5} = 2.0845\text{E} - 05$	$\theta_{w_b5} = -7.2693\text{E} - 06$
$\theta_{IF6} = -0.0042$	$\theta_{w_b6} = -8.9722\text{E} - 05$
$\theta_{IF7} = -6.7429\text{E} - 04$	$\theta_{w_b7} = -6.7173\text{E} - 05$

	$\theta_{w_b9} = 0.0833$

These surrogate models for IF and $w_{b,braking}$ involve the same parameters except for $f_{v,b}$, which is missing within the symbolic expression for IF. The results demonstrate that genetic programming is also able to produce good surrogate models. Considering the compact form of the final symbolic expressions, the accuracy of the genetic programming is still deemed satisfactory. However, the surrogate model for the IF carried out via genetic programming is slightly less accurate than those produced via artificial neural networks, being R^2 between 80% and 85%. The surrogate models for $w_{b,braking}$ obtained by means of genetic programming and artificial neural networks display almost the same accuracy level, being R^2 around 99% for both machine learning techniques.

4 CONCLUSIONS

This paper's primary conclusions include:

- The most intense dynamic load arises from hard braking, which typically produces Impact Factor (IF) values at or above one. To get the most conservative bridge response estimates during this condition, a precise two degree-of-freedom vehicle model is crucial.
- For hard braking, a two degrees-of-freedom model results in higher IF values. However, for softer braking, a single degree-of-freedom model often provides more conservative bridge movement estimations.
- Soft braking effects on bridge behavior vary based on the road's surface quality model. Using a nonstationary model generally results in higher IFs than a stationary one. This relationship shifts with increased surface irregularity. For intense braking, greater road roughness leads to decreased average IFs.
- IF value variability mainly arises from braking types and the vehicle model. Soft braking with a two degrees-of-freedom model shows notable IF dispersion. IF variability also has some dependence on surface quality during hard braking, with smoother roads causing greater IF dispersion.

Distributed fiber optic sensing during static and dynamic bridge loading

L. Strasser & W. Lienhart
Institute of Engineering Geodesy and Measurement Systems, Graz University of Technology

ABSTRACT: In order to ensure a safe operation of bridges and other civil infrastructure, efficient methods for condition assessment are necessary. Distributed Fiber Optic Sensing (DFOS) offers highly accurate monitoring and provides significant advantages over point-wise sensors.

In order to assess the condition of an Austrian highway bridge, static and dynamic load tests have been performed. Two spans have been equipped with fiber optic cables and point-wise sensors. Through the use of Optical Backscatter Reflectometry (OBR), the strain distribution of the bridge spans under static load was measured. Additionally, the use of Distributed Acoustic Sensing (DAS) enabled the measurement of vibrations along the bridge spans under dynamic load.

In this paper we demonstrate that through the use of complementary DFOS techniques, a more comprehensive analysis of the bridge's behavior can be achieved. The resulting measurements are verified not only by the bridge's numerical model, but also by co-located point-wise reference sensors.

1 INTRODUCTION

In order to assure a safe operation of bridges, many of them have to be placed under observation. This applies especially to bridges which by now are coming to the end of their design lifetime. As shown in Figure 1, this affects the majority of bridges, since the main construction activity in many parts of the world has taken place during the 1960s and 1970s.

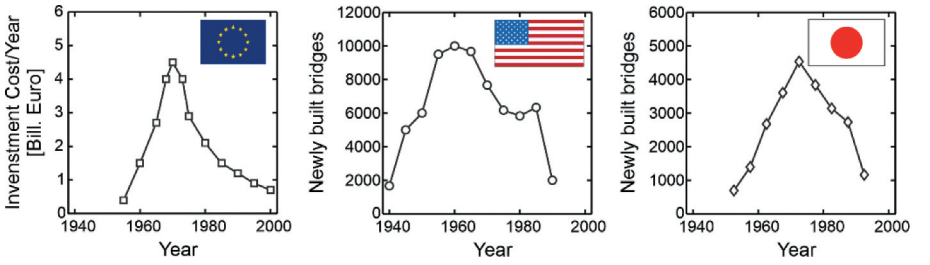

Figure 1. Investment costs in Europe (Geier & Wenzel 2002) and bridge construction activity in USA (Chase & Washer 1997) and Japan (Fujino & Abe 2004).

Different monitoring techniques can be applied for bridge monitoring to assess the current health state of the bridge, to enable condition-based and predictive maintenance and to extend the lifetime of the structure. Generally, monitoring systems can be classified into surface mounted/embeddable sensors and remote sensing techniques, where a line of sight to the object is required. Another distinction can be made between point-wise and distributed

DOI: 10.1201/9781003483755-133

sensors. Point-wise sensors suitable for bridge monitoring are e.g. accelerometers (Xu & Xia 2012), which can give an insight into the bridge's vibrations and provide data for point-wise frequency analysis. Furthermore, modern Robotic Total Stations (RTS) can also serve for the determination of point-wise frequency behavior as they can measure absolute displacements in 3 directions, although with a limited frequency range (Psimoulis & Stiros 2013, Lienhart et al. 2023). Another possibility is the usage of tilt sensors, which can –when placed correctly – give an insight into the temperature- and load-induced deformation of the bridge. Additionally, GNSS sensors (Schönberger et al. 2022) and high-speed cameras (Ehrhart & Lienhart 2015, Yoneyama & Ueda 2012) have successfully been applied for bridge monitoring. The drawback of all these sensors is that they only provide information related to the designated position. In order to obtain a bigger picture, multiple sensors would be needed. This is where distributed sensors show their potential. Ranging from profile laser scanners (Schill et al. 2022) and interferometric radars to Distributed Fiber Optic Sensing (DFOS), these methods enable the seamless monitoring of entire bridge spans. Whereas laser scanners and radars can deliver only line-of-sight measurements, DFOS can give an insight into the bridge's behavior at any time with the use of only a single sensing fiber. Different DFOS techniques enable the measurement of long- and short-term deformations and can even be used for frequency analysis (Strasser et al. 2023). The methods are described in more detail in the following section.

2 BRIDGE MONITORING WITH DFOS

In recent years, civil infrastructure monitoring with DFOS has become more popular, especially for bridges (Pannese et al. 2020, Barker et al. 2022). The principle of DFOS is light coupled into a glass fiber, in which the entire fiber serves as a sensing element. By propagating through the fiber, the light captures information along it. Due to natural impurities inside the fiber, parts of the light are backscattered to the interrogation unit from every point along the fiber. Figure 2 schematically demonstrates the generic working principle of DFOS.

If temperature and/or strain changes affect the fiber, the backscatter also changes and the information can be measured with high accuracy. As the velocity of the light inside the glass fiber is known, the impact position along the fiber can be determined. The accuracy of this position can reach from µm to several meters and is dependent on the gauge length, which describes the length considered for the calculation of the strain along the fiber (Hartog 2017).

Different DFOS techniques make use of different backscattering effects. These are depicted in Figure 2 and are dependent on strain and temperature changes.

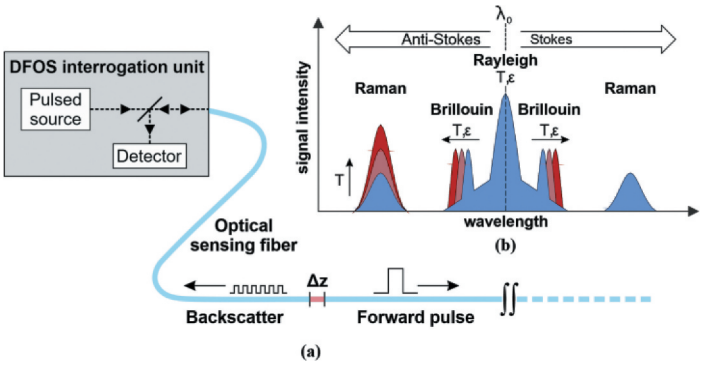

Figure 2. Schematic representation of distributed fiber optic sensors (a) and different backscattering effects (b). (Monsberger & Lienhart 2021).

This article focuses on the use of Optical Backscatter Reflectometry (OBR) and Distributed Acoustic Sensing (DAS) measurements, both of which make use of the Rayleigh backscatter,

although they deliver different results. OBR provides highly accurate strain information along the entire fiber with a local resolution in the range of a few millimeters. The measurement principle utilizes the unique 'fingerprint' of each fiber, caused by the production process. Every subsequent measurement is compared to a zero-measurement from which long-term changes can be derived. In principle, in OBR measurements the scatter amplitude is a random but static property and can be modelled as a continuous weak Fiber Bragg Grating (FBG) with a random period (Luna 2013). In contrast, DAS is able to deliver a seamless frequency profile along the entire fiber by sending high frequency light pulses into it (Owen et al. 2012). Vibrations can be measured and even single vehicles crossing the bridge can be identified. The combination of both techniques can give a valuable insight in the short- and long-term behavior of the bridge. Table 1 demonstrates the main characteristics of both measurement techniques.

Table 1. Overview on used DFOS techniques.

	DAS (Febus 2021)	OBR (Luna 2013)
Backscatter component	Rayleigh	Rayleigh
Absolute measurements	No	Yes
Measurand	Strain (rate)	Strain, Temperature
Spatial resolution	≥ 1 m	≥20 µm
Sensing range	Up to 50 km	Up to 2 km
Measurement rate	Up to several kHz	Static (<1Hz)

3 LOAD TEST OF A HIGHWAY BRIDGE

The results shown in this paper are derived from measurements on a highway bridge in the Austrian Alps (Figure 3). The steel-concrete composite bridge was built in the late 1960s and consists of 7 spans with a total length of 560 m. Although they share the same pillars with heights up to 80 m, the two carriageways are vibration-decoupled from each other. The bridge is exposed to high traffic volume, since it is the main route crossing the Alps from northern Europe to southern Europe. Therefore, its operability is of high interest and a safe operation has to be ensured.

In order to assess the condition of the bridge and perform regular monitoring, two out of the seven spans have been equipped with different monitoring systems. For DFOS measurements, two fiber loops have been installed along the steel bridge beam on the top and the bottom. Additionally, several prisms for Robotic Total Station measurements have been installed, as well as accelerometers in the middle of span 7. Laser scans have additionally been performed on this span. The different monitoring techniques complement one another and although this paper focuses only on the DFOS measurements, the point-wise sensors can be used as a reference. More information on the RTS measurements can be found in Lienhart et al. (2023). Figure 4 demonstrates the installed monitoring systems on the bridge spans.

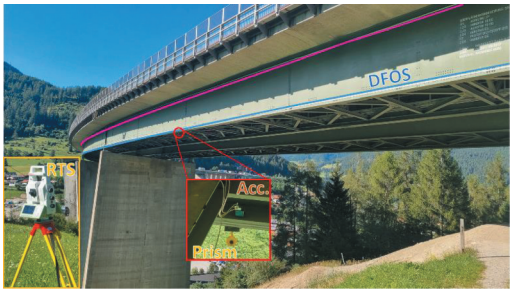

Figure 3. Monitored highway bridge in the Austrian Alps.

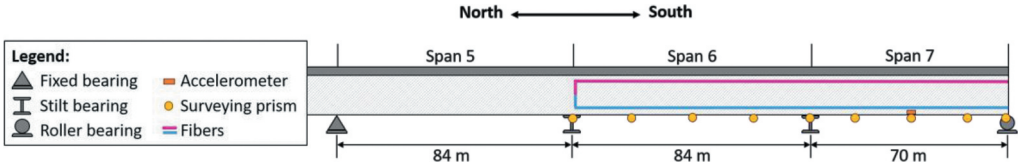

Figure 4. Schematic representation of installed monitoring systems.

In addition to epoch-wise monitoring, a load test was carried out in order to assess the condition of the bridge and to compare it to numerical models calculated in advance. For the load test, one carriageway was closed for normal traffic. Two trucks with a weight of 55 tons each were used for the load test. Several runs of the trucks crossing the bridge at a defined distance and a defined speed were carried out. Additionally, the trucks stopped at several predefined positions on the bridge in order to carry out static measurements. The following sections show the results of the static and dynamic load scenarios.

4 STATIC LOAD TEST

For a complete assessment of the bridge condition, both the behavior under static and dynamic load are of interest. First, the results of the static OBR measurements are discussed. As previously mentioned, there have been different scenarios on where the trucks stopped at the bridge. Either both trucks stop in the middle of span 6, or both in the middle of span 7, or one each. In order to measure the absolute displacements of the bridge deck, RTS measurements were carried out. Figure 5 (left) shows the displacement of the deck on several positions for the load scenario of both trucks being placed in the middle of span 6. The downward movement of span 6 results in a simultaneous uplift in span 7. These absolute displacement measurements can also be converted into strain readings between those few points, since the load causes not only a sag but also a length change between those points. This result can be compared to the strain distribution obtained by the OBR measurements. In order to compare displacement to strain, it has to be mentioned that the downward movement of the deck caused by a vertical load leads to positive strain on the lower part and negative strain on the upper part, as depicted in Figure 5 (right).

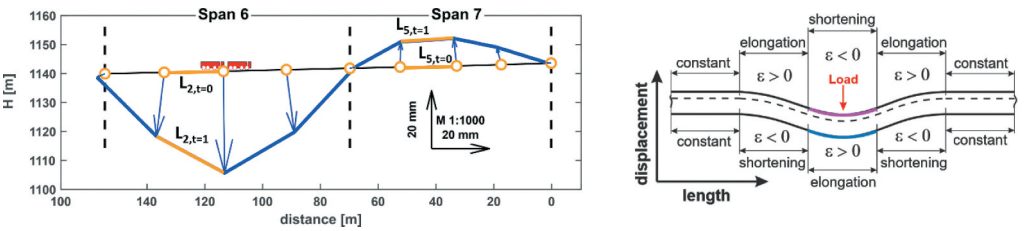

Figure 5. Left: Displacement and strain measured with RTS. Right: Schematic representation of the relation between displacement and strain.

The comparison with the OBR measurements shown in Figure 6 (left) shows a very good agreement for both data series. The low level of detail for the RTS measurements due to the small amount of measurement points outlines the main benefit of the DFOS measurements, which provide a seamless strain profile along the entire fiber for the upper and lower bridge beam. The high spatial resolution strain measurements show a sawtooth pattern with peaks along the bridge spans.

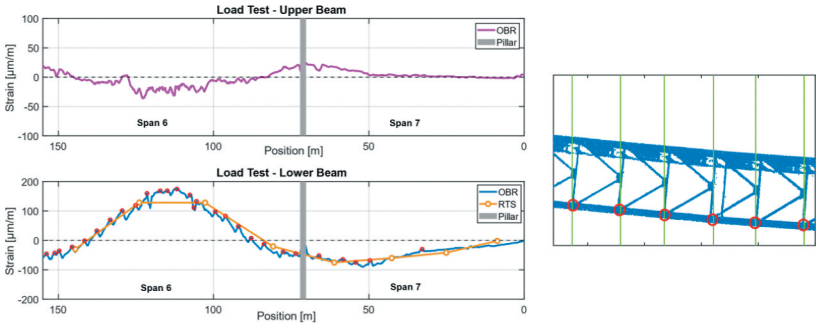

Figure 6. Left: Comparison of RTS and OBR measurements. Right: Comparison of peak locations with laser scan data.

After comparing the peak locations to the laser scan of span 7, it was discovered that the positions of the peaks match the locations of the girder connectors (Figure 6, right). Figure 7 shows the measured strain for all load scenarios for both the upper and lower fiber at the beam. The strain behavior of the upper and lower part differs significantly, which can be explained by the high vertical location of the neutral axis of the bridge beam (Figure 5, right). Furthermore, the same load results in less strain in span 7, which can be explained by its shorter length.

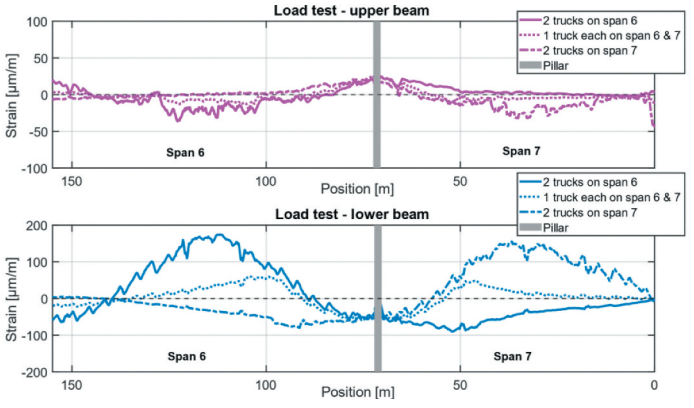

Figure 7. OBR measurements for all load scenarios for upper and lower fiber.

For all load scenarios, numerical models have been used to predict the absolute displacements and strain, which were then compared with the actual measurement. Figure 8 shows the comparison for the load scenario of both trucks being positioned in span 6. The data shows a very good agreement with a little higher strain in the numerical model, caused by more pessimistic assumptions made in its calculation. Furthermore, it should be noticed that the peaks in the strain distribution are also present in the numerical model.

5 DYNAMIC LOAD TEST

As described in the previous sections, the OBR measurements can only be used for the determination of a static load scenario. To also analyze the dynamic behavior of the bridge through the passing of the trucks, DAS measurements can be performed. Although the spatial resolution amounts to only a few meters, the measurements benefit from the high temporal

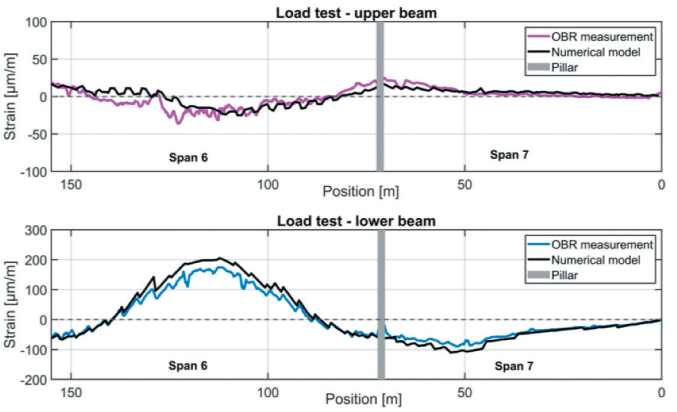

Figure 8. Comparison of OBR measurements and the numerical model.

resolution with a sampling rate of 1 kHz. This enables a seamless frequency analysis along the entire bridge spans. Furthermore, the passing of the trucks can be visualized in the data, and even their velocity can be estimated. Figure 9 shows a waterfall plot of the trucks passing on the bridge and after that driving back to position themselves on span 6.

In order to obtain the frequency behavior of the bridge at the time the trucks are passing, a frequency analysis can be performed. Figure 10 shows the frequency distribution for a location in the middle of span 7. At the same position, an accelerometer was additionally mounted, which can be used as a reference. The data series show very good agreement, both displaying a peak at 2.5 Hz.

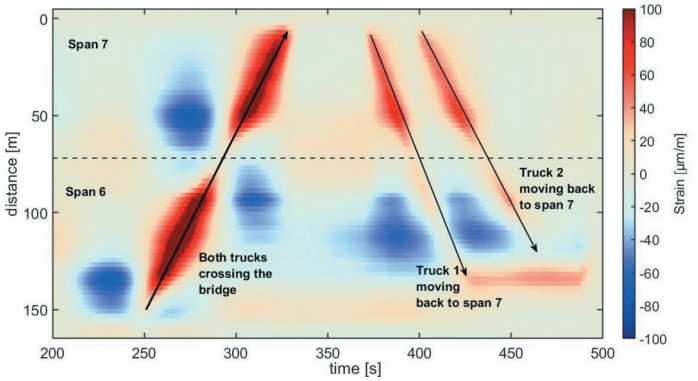

Figure 9. Waterfall plot of DAS measurements showing the movement of the trucks.

As previously mentioned, the main advantage of DFOS is the seamless monitoring along the entire fiber. Therefore, the frequency behavior can be evaluated on several points along the bridge spans. Figure 11 shows the frequency analysis on different points along span 7 for the upper and lower fiber line. First, a difference between locations along span 7 can be noticed with the peak frequency components decreasing at the end of span 7, which is also the end of the entire bridge. The amplitudes derived from the upper fiber are much lower, although the main frequencies remain unchanged, staying between 2 and 3 Hz. The lower amplitudes can once more be explained by the high neutral axis and consequently less movement in the upper part. Taking a look at the frequency behavior above the pillar between the spans, the amplitudes are rather low compared to the spans (Figure 12). Furthermore, the frequencies show a wider range by decreasing under 2 Hz.

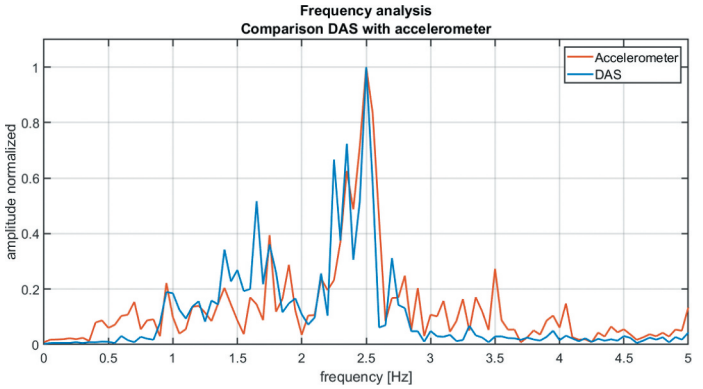

Figure 10. Comparison of frequency spectra from DAS and accelerometer measurements at the same location.

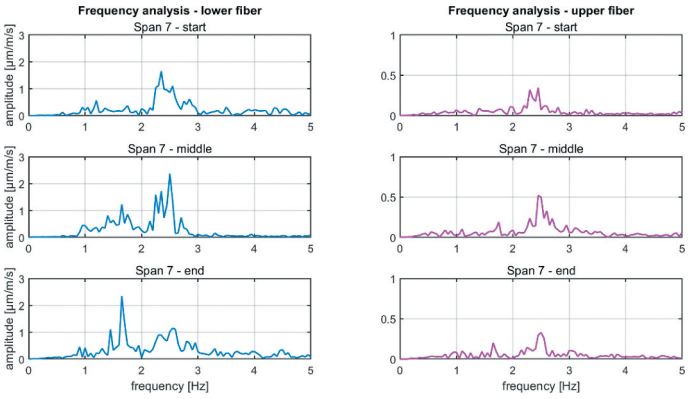

Figure 11. Frequency analysis at different fiber locations for upper and lower fiber on the bridge beam.

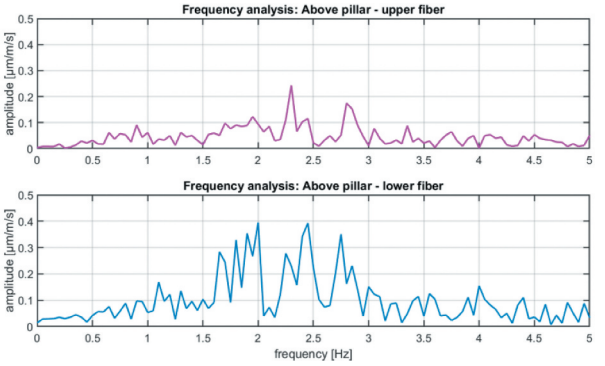

Figure 12. Frequency analysis above pillar for upper and lower fiber on the bridge beam.

6 SUMMARY AND OUTLOOK

This analysis outlines the advantages of using DFOS for bridge monitoring. The one-time installation of a fiber at the bridge enables the usage of different DFOS techniques, each providing different information. The same fiber can be used for both static and dynamic

measurements by connecting different interrogation units to it. The information obtained includes not only a detailed and highly accurate strain distribution, but also a seamless frequency analysis along the entire bridge spans. The gapless information has significant advantages compared to point-wise techniques. Nevertheless, the simultaneous point-wise measurements are a reasonable complement and can also serve as a reference to DFOS measurements. The comparison with the precalculated numerical model of the bridge showed very positive results with high agreement. The small difference in the strain values proves a better condition of the bridge than indicated by the numerical model.

ACKNOWLEDGEMENTS

We want to acknowledge the support of the Austrian Highway Agency (ASFINAG), especially Peter Augschöll for the possibility of performing a load test on the bridge. Further, we want to appreciate the cooperation with Patrick Huber from Fritsch, Chiari & Partner (FCP) and acknowledge the calculation of the numerical models.

ABSTRACT: In recent years, research on human-induced vibrations has developed several advanced modelling approaches aimed at achieving a more accurate description of human-structure interaction (HSI). The prevailing method involves using the load function from walking individuals on rigid ground as a starting point, considering the deviation when walking on vibrating structures, and incorporating the person as a single degree of freedom (SDOF) model coupled with the structure. However, this approach suffers from the need for case-by-case consideration, as the load model parameters are not universally applicable for each HSI model. To overcome these limitations, this study presents a modelling approach that strives to capture the HSI by accounting for the gait cycle dependency of the SDOF parameters. To apply the proposed model, measurement data collected on an experimental pedestrian bridge were analysed. The results show that further analyses and more data processing are required to evaluate whether the model is a good approach to account for human-induced vibrations including HSI.

1 INTRODUCTION

Various load models have been developed in recent years to describe the interaction between humans and structures (HSI) caused by pedestrians walking on vibration-prone structures Caprani & Ahmadi (2016). These models vary in complexity, with some approaches assuming the human-induced load by using a moving force (MF), a moving mass (MM), and a single-degree-of-freedom oscillator (SDOF) model. Most studies to date have focused on numerical analysis, assuming lumped biomechanical parameters based on existing literature (Archbold (2004), Caprani et al. (2011), da Silva et al. (2013), Qin et al. (2013), Shahabpoor et. al. (2013)) or using optimized model parameters (Czwikla & Kasperski (2017), Fanning et al. (2005), Zhang et al. (2015), Zivanović (2015)). In most cases, however, there is still a lack of experimental validation of these models.

It should be noted that all previously published models calculate new parameters for each human-structure interaction case, meaning that the values cannot be generally applied. Therefore, this paper proposes a modelling approach that differs slightly but essentially from previous SDOF models. The main difference lies in the consideration of changes in spring-damper values of the SDOF model that are dependent on both gait cycle, as shown by Firus et al. (2017), and vibration, as shown by Zivanović (2015).

DOI: 10.1201/9781003483755-134

First, the experimental setup is described briefly, including the measurement technology used to determine the load model parameters based on real test runs with walking pedestrians. The new load modelling approach and the methodology used to calculate the SDOF model parameters are then presented. Finally, exemplary calculation results of a single run of a walking individual emphasise the need for further analyses.

2 METHODS

2.1 *Experimental setup*

The experimental investigations were carried out on the HUMVIB bridge, which was developed and built on the Lichtwiese campus of TU Darmstadt to investigate the vertical HSI effects (see Figure 1). The bridge consists of two longitudinal, load-bearing steel girders HEA 240 (structural steel S235JR), on which 13 concrete slabs form the bridge deck. Without a movable centre support, the bridge is a single-span system with a span of 13.24 m and a natural frequency of 2.02 Hz. As the natural frequency of the structure is in the typical human cadence range, the system is susceptible to human-induced vibrations. By adding the optional centre column, the single-span beam system becomes a much stiffer double-span system, increasing the natural frequency to 7.71 Hz and making the system no longer susceptible to human-induced vibrations. For further details regarding the HUMVIB bridge, it is referred to Fritzsche et al. (2023).

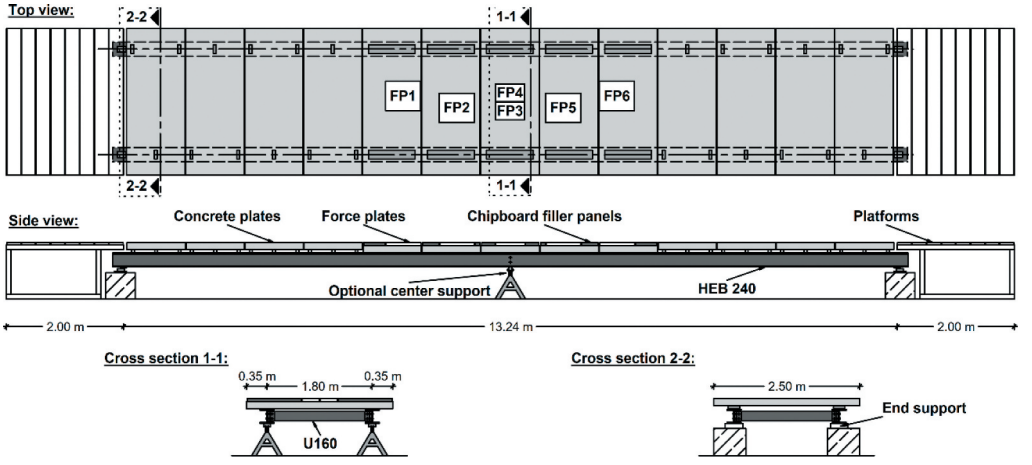

Figure 1. HUMVIB bridge with six portable 3D force plates (FP) mounted on the bridge deck.

To measure the structural response due to human-induced vibrations, the steel girders of the HUMVIB bridge have been equipped with acceleration, displacement, and strain sensors arranged according to the positions shown in Figure 2. Using the structural response measured at discrete points, the bridge response is estimated at each time t for discrete locations x in the longitudinal direction of the bridge. The accelerations of the bridge can thus be used

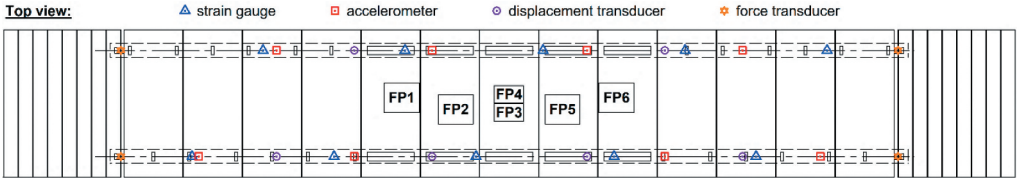

Figure 2. Sensor setup for the structural response measurement.

to extract the inertial forces from the measured ground reaction forces (GRF) of the force plates and to determine the relative displacement of the pedestrian with respect to the bridge deck. The GRF of the participants are measured using six mobile force plates type 9260AA6/AA3 from Kistler Instrumente AG. The force plates are arranged in such a way that five individual steps are recorded for each run. The force plates measure at a sampling rate of 1,000 Hz and can determine the centre of pressure in addition to horizontal and vertical GRF.

2.2 *Load model approach*

Figure 3 shows the proposed modelling approach for a structural load model of walking individuals. The key aspect of this model compared to other SDOF modelling approaches is the structural independence of the model parameters. Therefore, the unknown model parameters k_p and d_p are determined on a rigid ground as shown in Figure 3a assuming that they are not constant but variable over the gait cycle T. The mass of the person is given as M_p and corresponds to the dead load of the pedestrian.

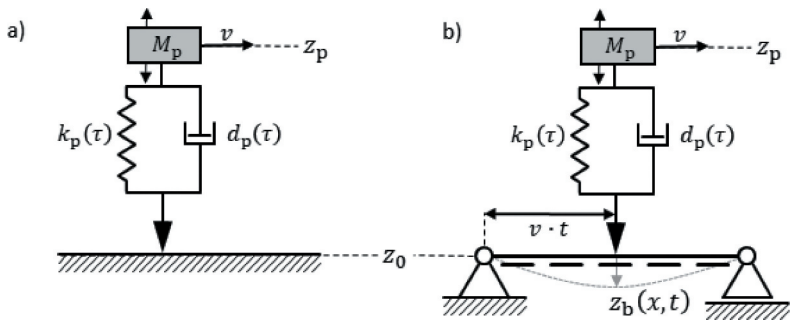

Figure 3. SDOF model for walking persons with model parameters depending on the gait cycle.

The normal gait cycle is shown in Table 1 and consists of a stance phase (STP) and swing phase (SWP) of each leg. Since we measured the total GRF of both legs, as we assume that the walking person is an SDOF, the model parameters reflect the combined behaviour of both legs and not the behaviour of the walking person for each individual leg. The process of walking can be divided in several subphases of the gait cycle. In most cases and according to Hartmann et al. (2010) we have eight phases within a gait cycle with the loading response phase covering the first 10% of the gait cycle.

Table 1. Normal gait cycle with approximated event timings (according to Hartmann et al. (2010)).

gait cycle 100%							
stance phase (STP) ≈ 60 %					swing phase (SWP) ≈ 40 %		
initial contact	loading response	Mid STP	terminal STP	pre-SWP	initial SWP	Mid SWP	terminal SWP
0 %	0 to 10 %	10 to 30 %	30 to 50 %	50 to 60 %	60 to 73 %	73 to 87 %	87 to 100 %

$$F_z(t) = -M_p \cdot \left(g + \ddot{z}_p(t)\right) = k_p(\tau) \cdot (z_0 + z_{rel}(t)) + d_p(\tau) \cdot \dot{z}_{rel}(t) \tag{1}$$

$$z_{rel}(t) = z_p(t) - z_b(t) \tag{2}$$

To determine the unknown and time-variant load model parameters k_p and d_p, we first consider the dynamic equilibrium for Figure 3. The measured vertical ground reaction force (GRF) F_z results from the acceleration of the point mass. This must be equal to the sum of the

spring and damper force on the ground. The static component of the acceleration due to gravity or the mass displacement z_0 of the spring as a static component are reduced, which means that only the dynamic force can be used to determine the spring-damper parameters k_p and d_p over time. Motion capture (MoCap) data are used to calculate the centre of mass (COM) and determine the coordinate z_p. For a more detailed description of the COM calculation, see Section 2.3.

The velocity $\dot{z}_{\mathrm{rel}}$ and acceleration $\ddot{z}_{rel}$ at any time t are obtained by single or double derivation of the displacement z_{rel}. Assuming rigid ground conditions, z_{b} and its derivatives are zero, so that $z_{\mathrm{p}} = z_{\mathrm{rel}}$. Hence, the unknowns are reduced to the model parameters k_p and d_{p}. Since there are two unknowns per time step, the equation system is underdetermined for each time step. By setting up several systems of equations for several time steps t_{n}, a definite or, for more than two equations, an overdetermined linear system of equations can be created for time intervals t_1 to t_{n}. Within the selected time interval, the SDOF parameters are constant and the more equations or time steps in the time interval are used to determine them, the more robust they are. For the overdetermined system of equations, the unconstrained least-squares method is used to identify the corresponding stiffness k_{p} and damping coefficient d_{p}.

Once the model parameters are calculated on rigid ground, the load model can be applied to a structure as shown in Figure 3b, resulting in a combined HSI model. If the displacement z_{b} of a structure is not zero, the calculation of z_{rel} must take this into account. This can be done using structural response sensors and is explained in more detail within Section 2.4.

It should be noted that the spring-damper values are not related to the time t but to the gait cycle of each double step of the period T or time step in the gait cycle τ. The model considers the influence of the spring-damper mass of the SDOF of the pedestrians on the structural response but defined independently of the structural model. In this case, the HSI is considered solely through the interaction of the person's point mass with the gait cycle depending on the spring/damper values with the structure.

2.3 *Calculation of the centre of mass*

The COM of the test person is calculated according to Equation 3, in which the COM of the total body is calculated depending on the COM of the individual body segments. Here, m_i is the segment mass, z_{i} is the COM coordinate of segment i, which results in the COM coordinate z_{p} in z-direction. For the other spatial directions in x- and y-direction the calculation is identical using x_i and y_i to calculate x_{p} and y_{p} respectively. The segmentation was limited to 14 segments (segments of arms/hands and legs/feet double, head and trunk single) with segment masses and COM according to Table 2.

$$z_{\mathrm{p}} = \frac{\sum_{i=1}^{14} m_i \cdot z_i}{\sum_{i=1}^{14} m_i} \tag{3}$$

The segment lengths of the legs, arms and torso are calculated directly from the relative marker positions of the motion capture system. The joint node of the elbow is formed from the mean value of markers 12 and 13, as shown in Figure 4. In this way, the segment lengths, labelled A to E according to Figure 4, can be clearly determined. The other segment lengths for hands, feet, head, and neck are calculated according to Winter (2009). The reason for this is the fact that the marker set used does not allow a direct calculation of the segment lengths, as the segment length does not have a start or end point for the calculation.

2.4 *Determination of bridge displacement*

To form the dynamic equilibrium according to Equation 1, considering the displacement of the bridge, local sensors for the structural response can be used. In this case, a signal z_1 from a displacement sensor attached to one of the main beams of the HUMVIB bridge is used (see Figure 2). For all time steps t, the corresponding displacement for any location x on the bridge with the bridge length L can be determined based on the value of x_1 according to

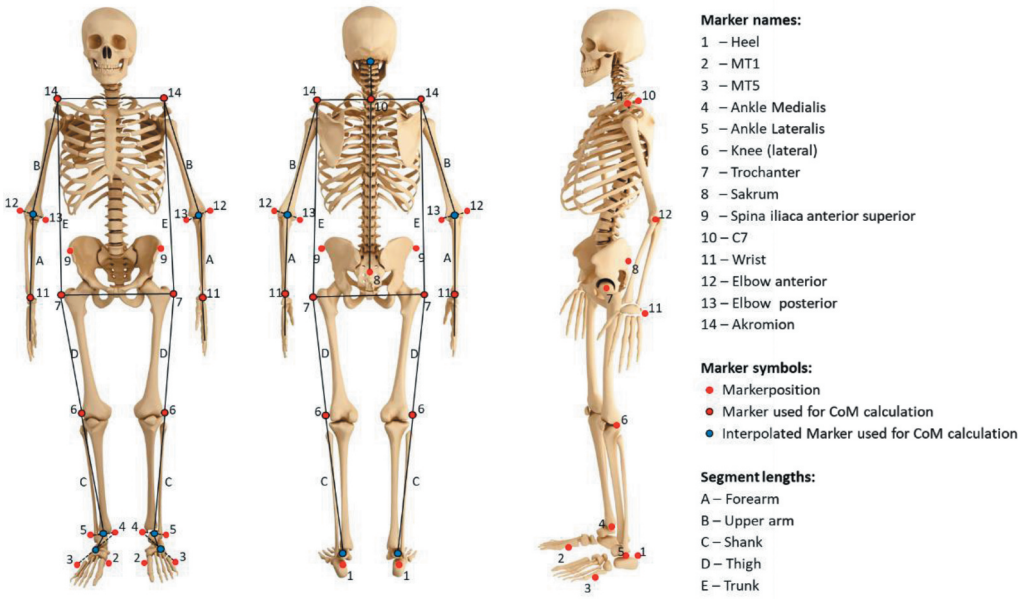

Figure 4. Positions of the passive markers on the participants and visualization of the segment lengths.

Table 2. Segment weights according to Winter (2009).

Index	Segment	Segment weight/ Total weight	COM/segment length (proximal)
1	Hand	0.006	0.506
2	Forearm	0.016	0.430
3	Upper arm	0.028	0.436
4	Foot	0.0145	0.500
5	Shank	0.0465	0.433
6	Thigh	0.100	0.433
7	Trunk	0.497	0.500
8	Head and neck	0.081	1.000

Equation 4. Here, the similarity of the bending curve to the main vibration is considered. Accordingly, higher natural modes or lateral and torsional vibrations are neglected.

$$z_b(t) = z_1(t) \cdot \frac{\sin\left(\frac{\pi}{\mathrm{L}} \cdot x(t)\right)}{\sin\left(\frac{\pi}{\mathrm{L}} \cdot x_1\right)} = z_1(t) \cdot \frac{\sin\left(\frac{\pi}{\mathrm{L}} \cdot l_s \cdot f_p \cdot t\right)}{\sin\left(\frac{\pi}{\mathrm{L}} \cdot x_1\right)} \tag{4}$$

The position x of the walking pedestrian can either be tracked by the MoCap or calculated by deriving the step length l_s and the cadence f_p from the force plate (FP) data, assuming a constant velocity v_p during the run. Since the MoCap data are also used to calculate the vertical displacement of the SDOF model, these are also favoured here.

In Figure 5, the displacement assumed from the bending curve affinity of the vibration at the position x_2=2.65 m of the displacement sensor D_01 has been calculated on the basis of the displacement sensor D02 at the position x_1=5.30 m of the 13.24 m long HUMVIB bridge. The dotted line shows the residual of the measurement signal of sensor D01 compared to the calculated values of the virtual sensor at the same position, which is approximately zero. Thus, the displacement at each time step can be calculated for each location x_i at which the walking pedestrian is located so that the dynamic equilibrium of the SDOF model can be calculated according to Equation 1 for the relative displacement z_{rel}.

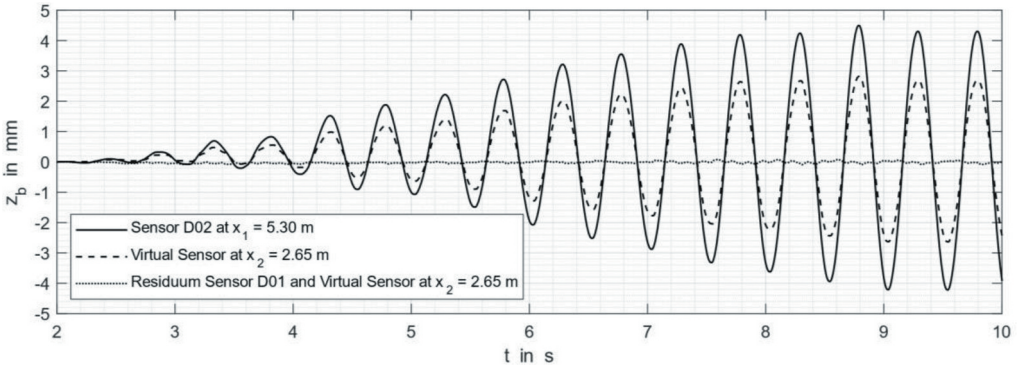

Figure 5. Measured displacement of the HUMVIB Bridge for sensor D02 at location x_1 = 5.30 m (solid line) compared to the approximated displacement of a virtual sensor at location x_2 = 2.65 m (dashed line) and the difference curve between the virtual sensor and a physical sensor D01 at the same location (dotted line) under pedestrian load with approx. 2.0 Hz walking frequency.

3 RESULTS

Figure 6 shows the application of the load model approach mentioned in Section 2.2 exemplarily on one single run of one pedestrian walking across the HUMVIB bridge. Since the spring-damper values of the SDOF model are to be determined for rigid ground, the overruns are carried out on the two-span system configuration. The processed sum curve of the vertical GRFs F_z of the subject is shown at the very top graph followed by the COM displacement z_p below. The signals from the MoCap and the force plates were filtered with a low-pass filter (Butterworth 4th order) with a cut-off frequency of 10 Hz.

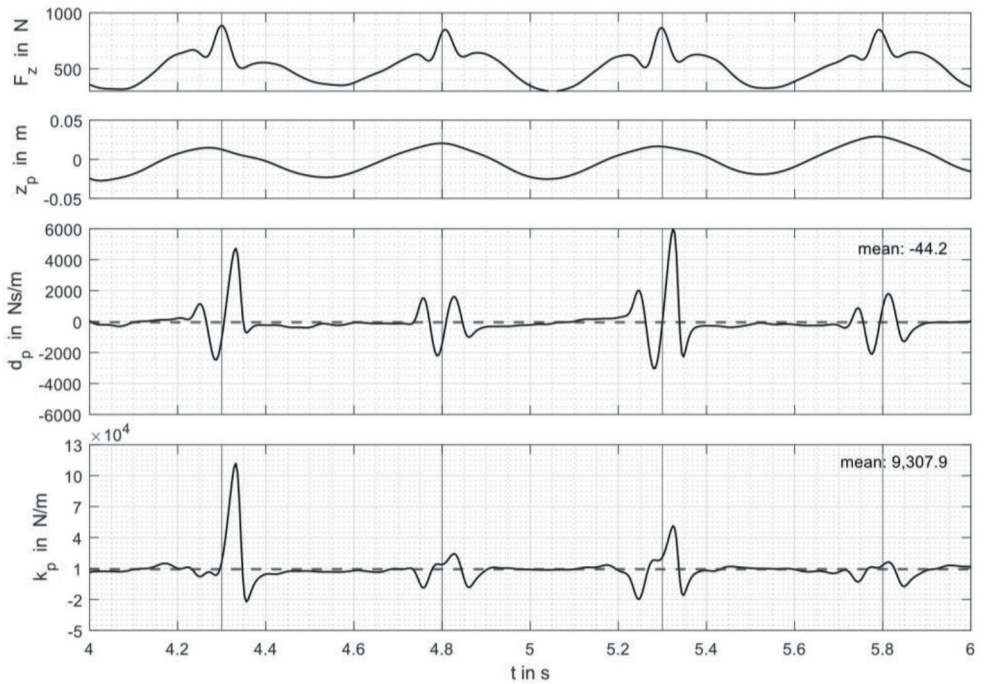

Figure 6. Vertical GRF F_z (top) and the vertical COM coordinates z_p (second graph) at walking with 2 Hz for rigid ground conditions. The lower two graphs show the calculated model parameters d_p and k_p (solid line) and the mean values for the time range between 4 and 6 seconds (dashed line).

The least squares optimisation problem was then solved for each time window, which was chosen here with four samples and thus two times overdetermined linear systems of equations. The window size was chosen small to emphasise the change in spring-damper values depending on the gait cycle. Further investigation regarding optimal time window sizes are definitely necessary. While a clear harmonic progression can be derived for the COM displacement, this is not a justified simplification for the SDOF model parameters. However, the extreme variations in the SDOF model parameters only occur in the area after the initial contact phase of the gait cycle according to Figure 4, which is caused by the sudden change in vertical GRF. Before and after the loading response phase, the spring-damper values are almost constant relative to the extreme change within this phase.

The four consecutive gait cycles shown in Figure 6 clearly demonstrate the intra-variability even within a single overrun. Accordingly, it is necessary to analyse many different steps to determine the subject dependency of the spring-damper values. Similarly, only the curves for walking on a rigid surface with a cadence of 2.0 Hz are shown here. The influence of the cadence on the SDOF model parameters must be analysed.

In Figure 7, the vertical GRF for one of double steps of Figure 6 is focused. In addition to the reference measurement of the 3D force plate, the vertical GRFs were calculated based on the COM for a moving mass (MM) without taking spring-damper values into account. Since in this case the force results solely from the COM acceleration and the mass of the person, the same forces should result for both curves (MM and 3D force plate).

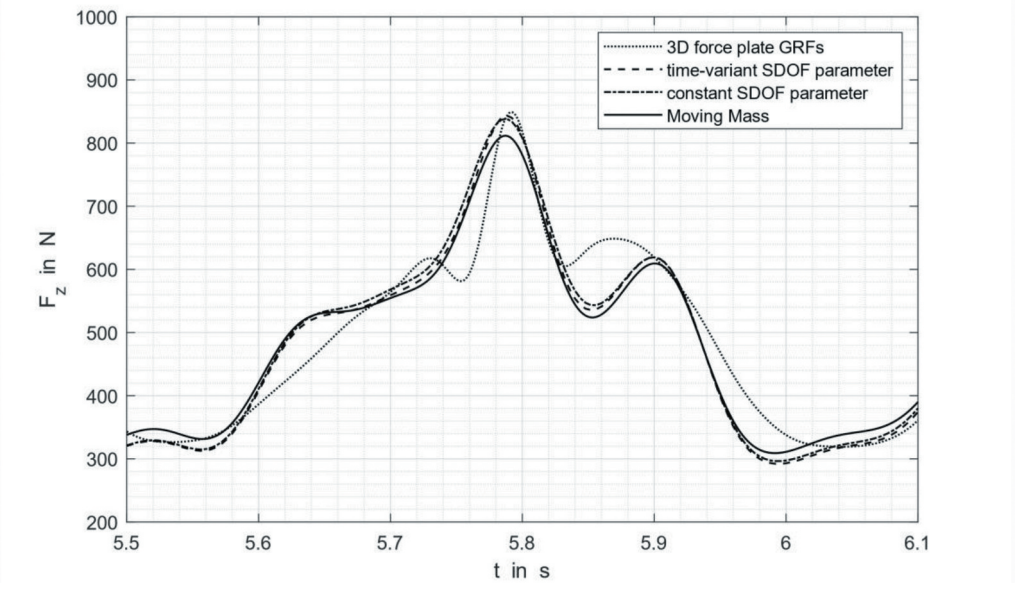

Figure 7. Vertical GRF for double step three of Figure 6.

However, there are clear differences, which are due to uncertainties in the calculation of the COM, errors in the coordinate transformation and orientation of the local coordinate systems transferred to the global coordinate system of the HUMVIB bridge, as well as measurement deviations (due to measurement technology, weight of the person, distribution of the segment masses, etc.). Further optimisation of the post-processing of MoCap data and COM calculation should reduce this deviation. However, as the deviations are quite high, the vertical GRF calculated according to Newton's second law of motion and not the 3D force plate GRFs is used as a reference value for comparison with the results of the SDOF model.

In addition, the vertical GRFs calculated with the SDOF model are shown in Figure 7. The previously determined SDOF model parameters are shown once with the time-variant (dashed line) and the time-invariant mean value (dashed-dotted line). Both approaches show

deviations compared to the MM model. In comparison, the reference values of the MM model are very close to the two SDOF model parameter assumptions. It can be observed that the time variant SDOF parameters map better than for constant values.

4 CONCLUSION

Within this contribution, a new load model approach was presented, which introduces the modelling of walking individuals as an SDOF model with gait cycle-dependent model parameters. The advantage of this modelling approach is the independence of the HSI model parameters regarding the explicit human structure configuration. However, the results presented so far only show the model used for the HUMVIB bridge as the only structure and only the application for the two-span configuration.

The processing of the measurement data required to solve the dynamic equilibrium was presented to determine the initially unknown SDOF model parameters (spring-damper values). The time-varying spring-damper values determined using the method of least squares exhibit fewer errors than those determined using the assumption of constant model parameters, as assumed in existing modelling approaches.

The results show that the methodology must first be improved before the transfer to other structures or the single-span configuration as a vibration-prone structure and thus the consideration of HSI effects on the spring-damper values. Due to the intra-variability of the individual stages, the deviations from the GRF calculated with the MM model are many times greater than the change caused by the different system configurations or HSI effects. Without analysing many individual steps, no significant deviation or well-founded statement can therefore be made.

By analysing many individual steps, the SDOF parameters for individuals as well as for a large sample of people are to be considered in further investigations. This will reduce the scattering due to inter- and intra-variability of the gait data and provide more robust SDOF model parameters. The cadence dependence and HSI-effect-related influences for other system configurations and structures on the SDOF parameters must also be determined. Furthermore, additional post-processing of the data is required to minimise the deviations of the calculation using COM compared to directly measured GRFs using force plates.

CFD analyses for wind load assessment of the new Bomarsund arch bridge

F. El Azrak, S. Sadrizadeh, J. Leander & R. Karoumi
K.T.H. Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: The trend in recent years to build longer and slender bridges has created new challenges in terms of safety and structural integrity. This study focuses on the effects of wind-induced vibrations on the hangers of the Bomarsund Bridge in Åland, Finland. Those close to the mid-span have exhibited significant vibrations, requiring a thorough investigation to understand the response of the bridge to wind action. Computational Fluid Dynamics (CFD) simulations were performed using ANSYS Fluent to calculate the aerodynamic coefficients characterizing the given section (i.e. Strouhal number, drag, shedding frequencies, etc.) and to investigate the vortex-induced vibration (VIV) phenomena at different wind speeds. The results showed inconsistent drag coefficients at varying wind speeds and lower drag for geometries with rounded edges. The study highlighted the significant dependence of the Strouhal number on wind speed, challenging traditional geometry-based estimations. These findings can be used to implement effective measures to mitigate wind-induced vibrations.

1 INTRODUCTION

The examination of vortex-induced vibrations (VIV) is essential when analyzing components of slender metal bridges exposed to significant gusts of wind. This aeroelastic phenomenon arises due to a complex interaction between the wind flow and the structure and can lead to a compromise of the structural integrity of the whole system. In-depth analyses and comprehensive explorations of various aspects related to VIV have been studied by, e.g., William and Roshko (1988), Dahl et al. (2006), Mao et al. (2016), and Wang et al. (2017). Bluff bodies with rectangular sections in particular, as for the bridge hangers, have been studied by Dey and Das (2015) and Yuce and Kareem (2016). The loss of streamlined flow significantly increases the body's resistance to the impact. These VIVs result from the development of a shedding street wake behind the bluff body. The oscillations are characterized by two fundamental frequencies, one in the direction of the wind and one perpendicular to it. The latter is the one that is consequential as it defines a fundamental dimensionless parameter such as the Strouhal number. This parameter categorizes the type of vortex shedding, ranging from viscous to quasi-steady state dominancy.

2 CASE STUDY

The Bomarsund Bridge, Figure 1, is a newly built bridge connecting Bomarsund and the island of Prästö in the municipality of Sund, in Åland, an area affected by strong wind gusts. Its main load-bearing structure is of steel designed by the Swedish company WSP in 2023. This bridge has attracted a lot of attention, particularly for its interesting structural and dynamic challenges, such as the high vibrations of the hangers, especially the longer ones close to the midspan of the bridge. These excessive vibrations are of critical importance because of their potential to cause structural fatigue problems, particularly in the hanger section, thus threatening the overall integrity of the bridge. Using the Abaqus software, the first two

DOI: 10.1201/9781003483755-135

natural frequencies of the hanger were defined: the first natural frequency of transverse vibration at 6.6 Hz and the first in the longitudinal direction at 14.1 Hz. These vibrations are compared with the lift and drag frequencies for the model implemented in ANSYS Fluent.

Figure 1. New constructed Bomarsund Bridge.

3 METHODOLOGY

Using ANSYS Fluent for CFD, it was possible to simulate the airflow around the hanger section and study the flow patterns, velocity distributions, pressure profiles and extract the aerodynamic quantities. The simulations were performed in two-dimensional (2D) space, which allows efficient yet accurate representation of the primary aerodynamic characteristics while minimizing computational cost. Both steady and transient state analyses were performed, the latter was required for this study to capture the shedding frequency and calculate the Strouhal number. For the steady analysis the solution was run for 6000-12000 iterations, while for the transient solution the convergence was reached with a time step of 0.01s for a total of 60s of flow simulation Convergence criteria, including absolute thresholds set at 0.001 for continuity, related to mass balance, x-y velocity components for a stabilized velocity distribution, k (turbulence kinetic energy) and ϵ (dissipation rate of kinetic energy) to ensure that the turbulence model has reached a stable solution. The processing workflow used in ANSYS is presented in Figure 2.

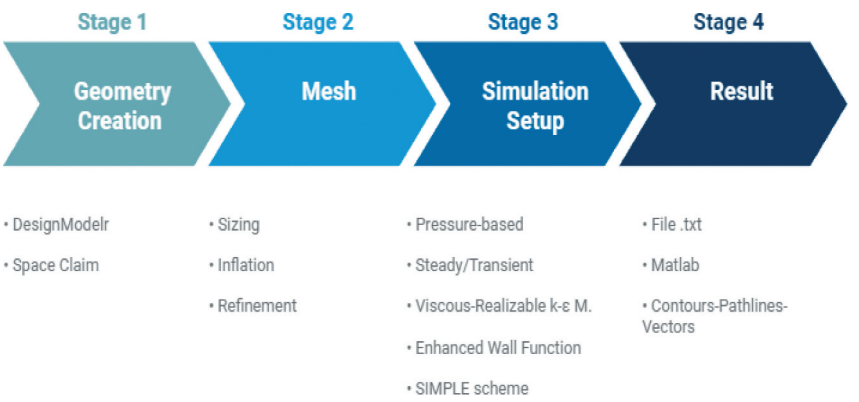

Figure 2. Processing workflow for ANSYS fluent simulations.

3.1 *Computational wind domain and mesh*

The wind domain was sized based on the characteristic dimension of the hanger d = 25.38 cm, see Figure 3. The final size of the wind domain was set to 20d from the inlet and far-field, and 40d from the outlet. The mesh was generated based on the need to find a compromise between cell fineness and computational cost. Local meshing refinements were used to obtain a denser cell zone around the cross-section and a high mesh quality. There are several parameters to evaluate, the most important being skewness, minimum orthogonal quality, and aspect ratio. The skewness is the percentage difference between the optimal cell size and the actual cell size (<1), the average value was kept below or at a maximum of 0.33. A good orthogonal quality (≈1) was maintained for a high percentage of cells, with an average value above 0.2. While the aspect ratio is the ratio of the base to the height of the cell, a value less than 35 indicates a good mesh, for the current model it was kept below 10.

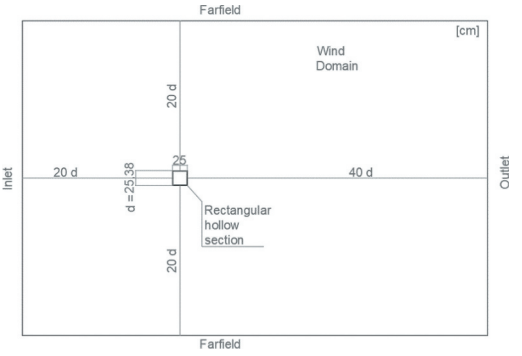

Figure 3. Computational wind domain.

3.2 *Simulation settings*

To accurately model the turbulent flow pattern around the steel section, the Realisable k- ϵ model was chosen with Enhanced Wall Treatments. These allow to model near-wall flow with higher accuracy by considering the effects of turbulence and resolving boundary layer phenomena. All the simulations were performed using a Pressure-Based Solver with a SIMPLE coupled algorithm. This is the most widely used algorithm, both for transient and steady solutions, and uses a relationship between velocity and pressure correction to enforce the conservation of mass and obtain the pressure field.

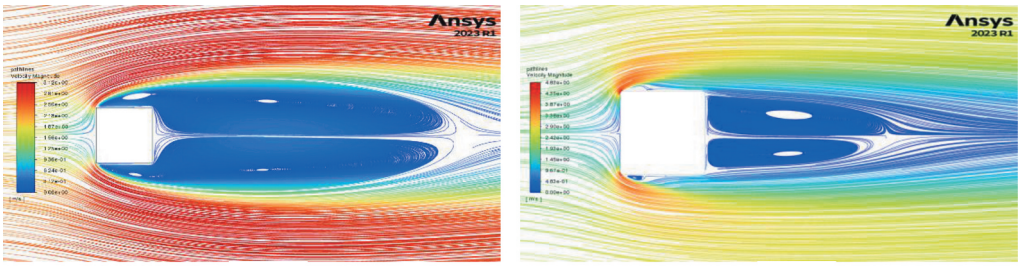
4 RESULTS

The following results summarize the extracted data of several simulations, each designed to meet a specific purpose. There is a macro division between steady-state and transient simulations, the difference between the two being that the latter allows time-dependent data to be obtained and is essential to capture the shedding frequency, which is of considerable importance for the purpose of the research.

4.1 *Steady-state solution*

The steady-state simulations were carried out primarily to verify the model on which to run a transient simulation, but also to assess the differences between the aerodynamic values in the two different state analyses. The range of wind speeds investigated for steady-state analysis varies between 2.5 m/s and 10 m/s, and two different geometries were considered, one of rectangular cross-section with no rounded edges, and the other with rounded edges.

Table 1. Aerodynamic coefficients for the steady solution: no rounded edges.



Wind speed [m/s]	2.5	5.0	7.5	10
Drag Coeff. C_D	1.379	1.397	1.398	1.402
Lift Coeff. C_L	0.000	0.002	0.001	0.001
Moment Coeff. C_M	-5.345	-5.410	-5.414	-5.432

The drag coefficient, denoted by C_D, represents the resistance of a cross-section in the direction of the wind flow. The increasing CD with wind speed, as shown in Table 1, is consistent with the fact that the drag force is proportional to the square of the flow velocity. However, it should be noted that this relationship cannot be extended to all speeds, as the drag force also depends on other factors. This issue will be covered in the following sections. An intriguing outcome is achieved for the lift coefficient C_L, which gauges the force perpendicular to the flow. Since the wind force acts without any angle of attack, it is expected that the coefficient fluctuates around zero. This implies that, on average, the hanger division undergoes negligible lift, suggesting that the structure does not create considerable transversal forces, a desirable trait for maintaining the structural stability. The moment coefficient C_M denotes the hanger section's inclination to rotate in response to fluid forces. Negative values signify the section's orientation of rotation. As with the C_D, C_M increases with wind speed, denoting that the section encounters amplified rotational forces at higher wind speeds.

Table 2. Aerodynamic coefficients for the steady solution: rounded edges r = 1 cm.

Wind speed [m/s]	2.5	5.0	7.5	10
Drag Coeff. C_D	0.889	1.096	1.144	1.145
Lift Coeff. C_L	0.059	0.019	0.000	-0.011
Moment Coeff. C_M	-3.249	-4.155	-4.390	-4.426

Table 2 displays the outcomes of the model with rounded edges. The presence of the radius in the wall section undoubtedly affects the aerodynamic coefficients. As the edge radius is introduced, the drag coefficient is reduced. A notable decline in C_D was evident. Smoothing and increasing the size of the radii of the edges generally decreases drag, following a common principle of aerodynamics. The reduction in drag is linked to an improvement in the flow characteristics around the section. The edge that was not rounded generated a significant negative moment, demonstrating a strong inclination to rotate under the influence of fluid forces. The negative moment magnitude decreased with rounded edges, which implies a reduced tendency to rotate. Rounded shapes generally result in greater stability due to the reduction of moments that might cause rotation. By analyzing the pathlines shown in Figure 4, of the two different sections, it becomes clear that the radius significantly influences the fluid flow behavior. In particular, the streamlines and vortexes are notably impacted by the presence of a radius. Sections with radii exhibit significantly shorter vortices waves compared to the sections without rounded edges. This phenomenon suggests that the vortexes generated by rounded sections are more confined and compact. The velocity of the fluid flow near the rounded section is significantly lower. The presence of radii seems to reduce the turbulence effects with a consequent increase in the velocity of the fluid flow. These observations lead to an important conclusion: the resistance encountered by the wind flow is reduced when a section contains radii. The formation of two perfectly symmetrical vortexes behind the section. It is a peculiarity of a steady flow simulation. The introduction of rounded edges alters the flow patterns, limiting the development of vortices and reducing the flow velocities in the vicinity of the section. In practical terms, this means that it is essential to consider the actual radii of the section edges to achieve accurate and realistic simulations. However, for a conservative approach, it may be advantageous to ignore the radius in the simulation.

(a) (b)

Figure 4. Velocity magnitude pathlines for not rounded (a) vs rounded (b) edges of rectangular cross section.

This effectively overestimates the drag of the section and provides a safety margin. This conservative approach ensures that the verification process accounts for higher aerodynamic forces, thereby increasing the safety and reliability of the structure.

4.2 *Transient-state solution*

The transient simulation brings to a solution that allows the extraction of time-dependent data, capturing aerodynamic effects over different temporal scales. Shedding frequencies and related parameters, including the Strouhal number, can be obtained through this process. This type of analysis provides a possibility to investigate the phenomenon of Vortex Induced Vibrations (VIV). The range of wind speeds investigated, ranging from 2.5 m/s to 30 m/s, is wider than the one for the steady solution, as the focus is shifted towards high speeds and Reynold number. The graphs in Figure 5 depict aerodynamic coefficients for a rectangular cross-section that was derived from a transient state solution at varying wind speeds. There is a tendency for the drag coefficient (C_D) to decrease as wind speed increases, reaching a minimum at v = 30 m/s. However, until a speed of 10 m/s is reached, the drag coefficient increases, following the same trend as observed in the steady solution. Nevertheless, for the remaining speed range, the behavior aligns as expected with the results reported from the literature, (Hoerner, 1965; Yuce & Kareem, 2016) see Figure 6, in which the drag coefficient values are plotted as a function of the Reynold number instead of the wind speed.

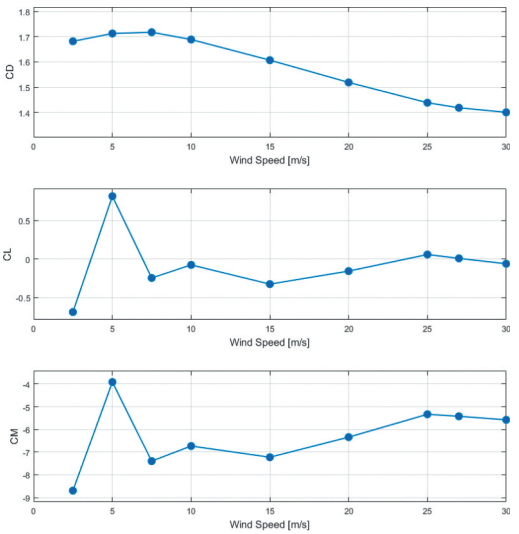


Figure 5. Aerodynamic coefficients at different wind speeds.

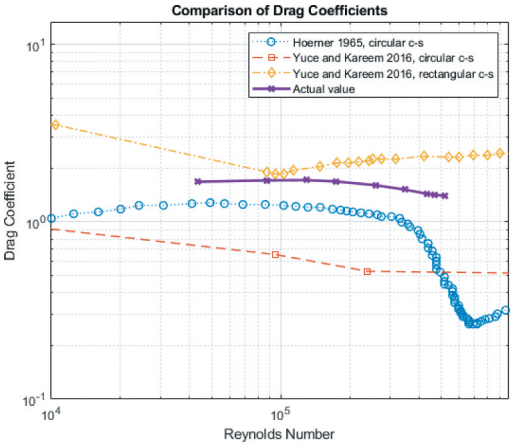

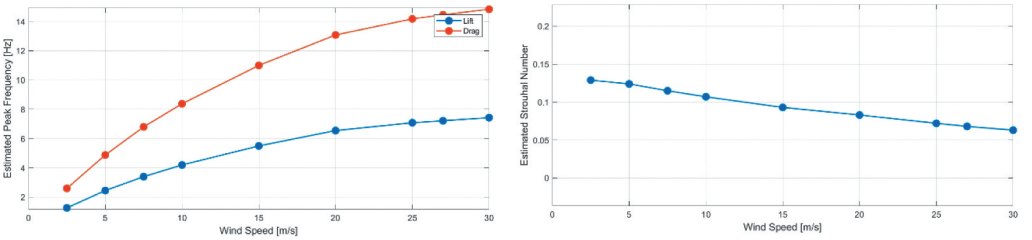

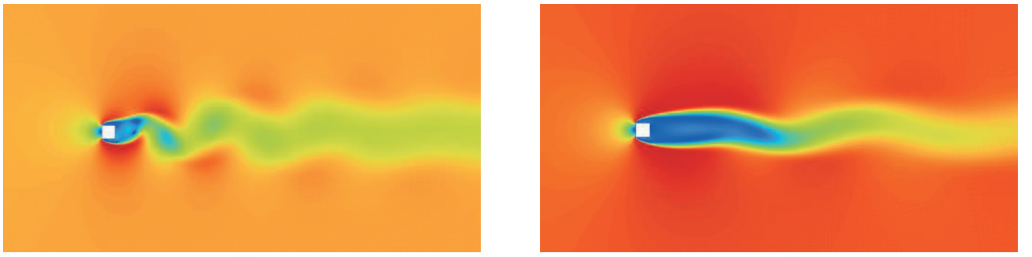

Figure 6. Aerodynamic coefficients vs Reynolds.

This is since at a higher Reynold number, flow around the structure becomes more streamlined, due to the high wind speed intensity, thereby reducing drag. For 2D simulations, the coefficient of lift (C_L) is of little significance as its value is small and oscillates around zero. Therefore, it is not possible to define a specific trend for the lift, which changes randomly in magnitude and sign due to the oscillating value around zero. The moment coefficient gradually decreases at higher speeds, following the trend of the drag coefficient. The values in Figure 5 are punctual values at time t = 60 s, which represents the end of the simulated time. The peak value in the lift at 5 m/s is not relevant because the mean value of the lift for the simulation at 5 m/s and all other simulations tends to zero. The estimated peak frequencies of drag and lift, Figure 7, were calculated using Fast Fourier Transformation (FFT) of their respective signals, and related amplitudes were subsequently extrapolated. This allowed for the calculation of the Strouhal number S_t, based on the estimated peak frequency of lift. An intriguing observation pertains to the drag frequency magnitude, which fluctuates between 5.5 Hz and 8 Hz for wind speeds ranging from 5 m/s to 10 m/s. According to the Abaqus frequency analysis, the first natural frequency of the structure is approximately 6 Hz, while the others vary within a range of up to 14 Hz. The fundamental natural frequency's vibration is out of plane. As a result, it can be concluded that the critical wind speed for the hangar ranges from 5 to 8 m/s. This wind speed range falls within reasonable values for the geographical location of the Bomarsund Bridge. The calculation of the Strouhal number, a significant parameter that signifies the shedding of vortexes surrounding the structure, considers the lift peak frequency. A decreasing trend of Strouhal numbers with increasing wind speed is observed, indicating that a shift from regular to more irregular vortex shedding patterns is occurring. A characteristic phenomenon of vortex shedding was observed, with the peak frequency of drag being twice the one for lift in the frequency domain spectra. Two vortexes of equal strength and opposite signs are shed during each oscillation period in the wake of a structure, such as a rectangular cross-section. It is important to note that the sign of the vortex has no impact on the experienced drag force. This distinctive feature results in a period-doubling effect. Regarding the wind flow configuration, it is interesting to observe how it changes above the range of wind speed simulated. At low speeds behind the bluff body, the Von Karman vortex street forms, allowing the identification of zones where the flow changes direction and local eddies form. As wind speeds increase, the vortex shedding tail becomes more elongated and less turbulent, resulting in a more streamlined flow. This explains the reduction in the magnitude of the drag coefficient. In Figure 8, two contour images are presented as examples of the vortex shedding tail for low and high wind speeds - one at 7.5 m/s and the other at 27 m/s.

(a) (b)

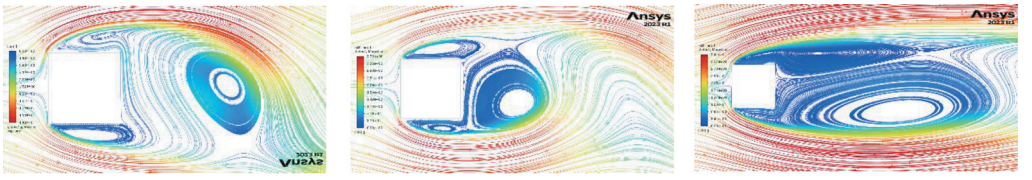

Figure 7. Lift and drag frequencies (a) and Strouhal number (b) at different wind speeds.

(a) (b)

Figure 8. Transient solution: Velocity contour at different wind speeds at t = 60 s.

It is also noteworthy to examine the form of the shedding vortex located at the rear of the cross-section. For the steady solution, the two vortexes were symmetric, but with a transient state analysis representing the effect of turbulence over time, it is apparent that this symmetry is lost. Additionally, lower wind speeds result in larger eddies that are also distributed laterally to the section. At high velocities, the vortex tail becomes more streamlined, and a second vortex forms above the first one. Some examples are reported in Figure 9, for different speeds that cover the whole range of wind speeds simulated.

(a) v = 2.5 m/s (b) v = 10 m/s (c) v = 27 m/s

Figure 9. Transient solution: Velocity pathlines at different wind speeds at t = 60 s.

5 CONCLUSIONS

The aerodynamic performance of a bridge hanger was investigated using CFD analysis. The distinction between steady-state and transient simulations allowed the detection of time-dependent phenomena such as shedding frequencies and related parameters. However, the steady-state solution overestimates the magnitude of the aerodynamic coefficients compared to the transient analyses and does not provide information on the shedding frequency and the time-dependent response of the cross-section. This type of simulation remains a valid

technique for obtaining an overview of the aerodynamic properties of the fluid around a bluff body and for investigating different factors that could influence the dynamic behavior of the structure, such as geometry influences. By increasing the wind speed from 2.5 m/s to 10 m/s for both geometries analysed, the drag coefficient increases, but the presence of rounded edges results in lower values compared to the rectangular cross-section with sharp edges, highlighting an improvement in vortex shedding stability for more rounded geometries. Moving to transient solutions, it was accurately characterized VIV by investigating a single rectangular cross-section with sharp edges at varying wind speeds. The aerodynamic coefficients, such as drag and Strouhal number (St), showed significant variability within the wind velocity range of 2.5 m/s to 30 m/s. This emphasizes the sensitivity of aerodynamic parameters to different magnitudes of wind speeds. For wind speeds below 7.5 m/s, an increasing trend in drag was observed, while for wind speeds above 30 m/s, drag coefficients decreased, indicating the effect of vortex street confinement due to high-speed flow. Additionally, the Strouhal number (S_t) shows a decreased trend across the investigated wind speed range, revealing its dependence on wind speed rather than solely on the geometry of the bluff body analyzed. The S_t value is typically determined based on the geometry, as per the Eurocode Standards. Specifically, for a rectangular cross-section without rounded edges, the S_t value is 0.12. However, this simulation has shown that the S_t value varies with wind speed, ranging from 0.129 for a wind speed of 2.5 m/s to 0.063 for a wind speed of 30 m/s. The comparison of the aerodynamic frequencies and the fundamental frequencies of the structure demonstrates the significance of assessing both crosswind and headwind response in identifying the direction that is more susceptible to resonance phenomena under vortex shedding phenomena.

ABSTRACT: To realize rapid damage assessment of old bridges in remote areas, this paper proposes a rapid damage evaluation platform based on the combination of dynamic response of bridges and Machine Learning (ML). Selecting several typical old bridges, the acceleration signals of these superstructures under different vehicle loads were collected. The damage indicator defines the health status of superstructure, which is developed from the wavelet packet theory. Finally, a set of damage recognition models with universal applicability is established according to the optimized algorithms derived from ML training. The results shows that the proposed approach provides a rapid and economic damage identification of bridges. The approach is a prospective solution for rapid structural evaluation of similar girder bridges.

Keywords: Old bridge, Structural health, Wavelet packet, Machine learning

1 INTRODUCTION

Bridge structures are prone to damage during the operational stage due to vehicle overloads and performance degradation. Structural damage can significantly influence the safety of bridges, which makes the Structural Health Monitoring (SHM) of great significance (He et al 2022, Svendsen et al 2022). Considerable progress has been made in the field of damage identification, which serves as a core role in bridge SHM (Bao & Li 2021, Malekloo et al 2022). In this regard, the accuracy of damage identification methods has been extensively validated on bridge structures (Wang & Shi 2018; Pan et al 2019; Machorro-Lopez et al 2021). These methods involve constructing various damage indicators to identify structural damage. With the continued advancement of research in the field of ML, the integration of ML techniques into structural damage identification has gained significant attention. Khodabandehlou et al. (2019) proposed a structural damage identification method based on Convolution Neural Network (CNN). Mousavi et al. (2021) combined Empirical Wavelet Transforms (EWT) and Artificial Neural Network (ANN) to identify the damage of steel truss bridge models. The damage identification method combining wavelet packet theory and machine learning has been verified on bridges in remote region (She et al 2023; Liang et al 2023).

For the numerous small and medium-span bridges in remote region, it is challenging to conduct or to install individual inspections due to remote geographical locations and tight maintenance cost. In this paper, wavelet packet analysis of SHM methods based on vehicle excitation together with optimized ML algorithm, the damage database was established. A fast identification platform was developed.

2 CONSTRUCTION OF DAMAGE IDENTIFICATION INDEX BASED ON WAVELET PACKET ANALYSIS

The wavelet packet is a set of wavelet basis functions, which has the advantage of characterizing the local features of the signal in the time-frequency domain and overcomes the disadvantage of poor high-frequency resolution in the decomposition of the low-frequency part due to the fixed sub band taken by the resolution of each layer. By using wavelet packet analysis, the response signal of bridge structure under vehicle excitation is decomposed into different frequency bands, and the energy characteristic values of each frequency band are obtained. In the response signal of the damaged structure, the energy of different nodes contains the damage information of the structure, and the damage information can be extracted by wavelet packet decomposition to obtain the damage state of the structure.

For the dynamic response signal x(t), the total energy under the J-layer decomposition can be defined as:

$$E_\chi = \int_{-\infty}^{\infty} \chi^2(t)dt = \sum_{m=0}^{2^j-1}\sum_{n=0}^{2^j-1}\int_{-\infty}^{+\infty} \chi_j^m(t)\chi_j^n(t)dt \tag{1}$$

By using the orthogonality relationship, the total signal energy of each frequency band can be obtained:

$$E_\chi = \sum_{i=0}^{2^j-1} E_{\chi_j^i} \tag{2}$$

In the above equation, $E_{x_j^i} = \int_{-\infty}^{+\infty} [X_j^i(t)]^2 dt$ is the signal energy in band *i*.

When bridge is damaged, the dynamic response signal of the bridge will fluctuate, and the energy of the corresponding frequency band will increase or decrease after the wavelet packet is decomposed. Based on the above principle, the response signal of the superstructure under vehicle excitation and the wavelet packet analysis are adopted. The Wavelet Packet Energy change Rate Sum Square (WPERSS) is defined as (Zhu & Sun 2015.):

$$WPERSS = \sum_{j=0}^{2^i-1}\left[\frac{(E_{f_i^j})_b - (E_{f_i^j})_a}{(E_{f_i^j})_a}\right]^2 = \sum_{i=1}^{m}\left[\frac{(E_{f_i^j})_b}{(E_{f_i^j})_a} - 1\right]^2 \tag{3}$$

Among them, $(E_{f_j^i})_b$ represents the signal energy of the response of the healthy bridge structure, $(E_{f_j^i})_a$ represents the signal energy of the response of the damaged bridge structure, *i* represents the scale, which is the number of decomposition layers, $m=2^i-1$ represents the total number of wavelet packet decomposition frequency bands.

3 PROJECT OVERVIEW

3.1 *Profile of Hou River Bridge*

The Hou River Bridge was completed and opened to traffic in 1997. With a total length of 15 meters, the bridge has a span arrangement of (3x5) meters and a width of 6 meters. The bridge deck is designed to accommodate a net width of 0.25 meters for guardrails, 5.5 meters for the driving lane, and an additional 0.25 meters for guardrails. The superstructure of the bridge consists of reinforced concrete beams, with each span comprised of six beams and each beam having a width of 1.0 meter. The hollow concrete slab and the cast-in-place deck, which are key components of the bridge, are constructed using C40 concrete. The overall arrangement of the bridge is shown in Figure 1

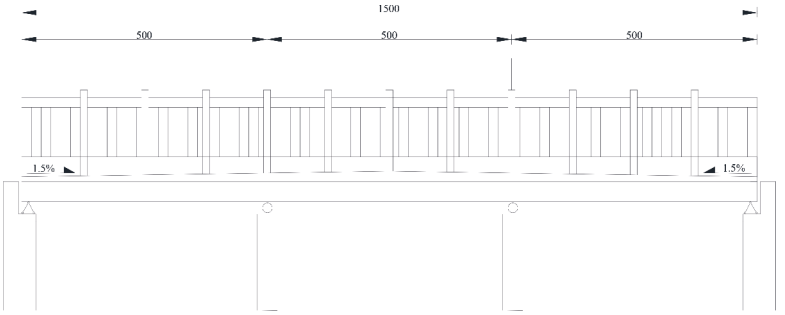

Figure 1. Bridge elevation view.

3.2 *Numerical modelling*

The engineering structure is discretized into 43,656 C3D8R elements using the finite element software Abaqus. The elastic modulus of each span of concrete is obtained using interpolation as follows: 29.8 GPa, 30.84 GPa, and 30.48 GPa. The density of the entire bridge is uniformly set at 2460 kg/m³, and the Poisson's ratio is uniformly set at 0.2. Based on the actual construction conditions, the structure is a continuous simply supported structure with the bridge deck cast as a whole. Therefore, tie contacts are established between the decks of each span. Fixed constraints are applied at both ends of the bridge abutments and the bottom of the bridge piers.

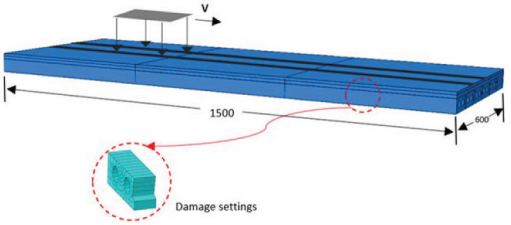

Figure 2. FE model.

3.3 *Identification of damage case*

Selecting the Hou River Bridge in Figure 2 as a case, the damage position is accurately simulated by setting the damage on different beams, and there are 9 measuring points with an equal distance of 0.5m on each beam. The local damage conditions of the structure are corresponded to by stiffness reduction, and there are three damage conditions of 10%, 20%, and 30%. There are six beams in the whole span, and the cross-section and load are symmetrical. It is assumed to be sufficient to analyze the three beams in the structure. The damage settings are shown in Figure 3.

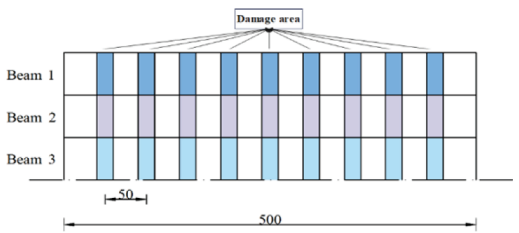

Figure 3. The damage cases of the structure.

Based on previous research (Liang et al 2023), we have selected the db20 wavelet basis function with a decomposition level of 5 to decompose the unit acceleration signal's free attenuation segment. This decomposition evenly divides the signal frequency band into 32 frequency bands. Additionally, at the same measuring point, three deliberate damage conditions of 10%, 20%, and 30% were introduced. The obtained WPERSS values, as shown in Figure 4, clearly indicate that the WPERSS value accurately identifies the location of damage while maintaining a positive correlation with the severity of damage at the measuring point.

Furthermore, three different levels of damage reduction were applied to each measuring point, as depicted in Figure 3. The corresponding damage index values were then derived, as displayed in Figures 5, 6, and 7. It was observed that the WPERSS value increased as the reduction degree of measuring points intensified. This observation confirms the excellent quantification capability of the WPERSS value as a damage indicator.

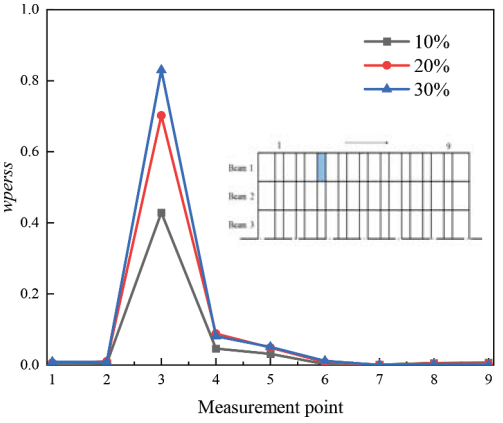

Figure 4. WPERSS values of different damage degrees at the same measurement point.

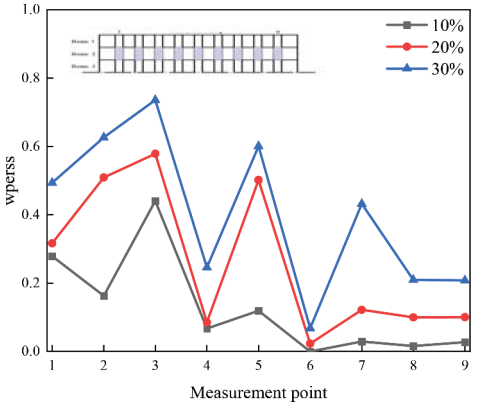

Figure 6. WPERSS values of different damage degrees at each measurement point of Beam2.

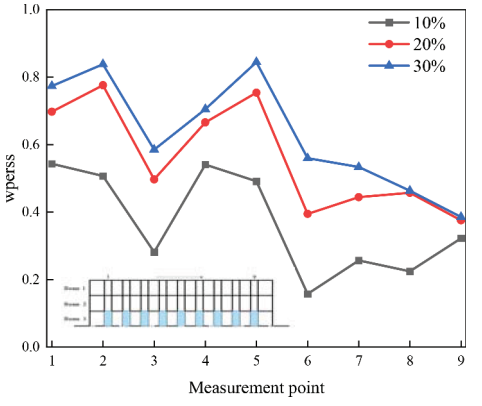

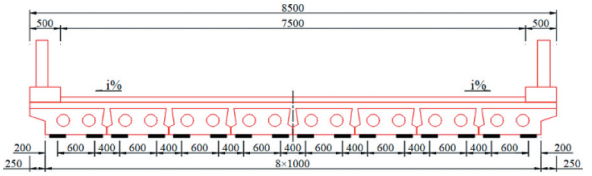

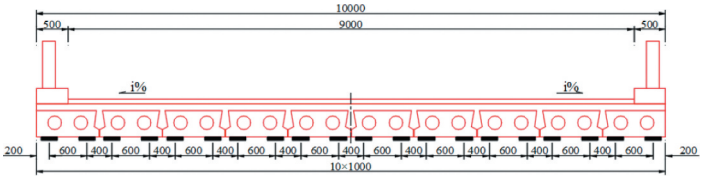

Figure 7. WPERSS values of different damage degrees at each measurement point of Beam3.

4 DEVELOPMENT OF RAPID EVALUATION PLATFORM

Various bridge numeric models with different width-to-span ratios were developed through on-site investigations, reflecting actual bridge in remote region. The prototype of bridges utilized general hollow slab bridge drawings issued by the Transportation authorities. The cross-

Table 1. Basic information of the bridge.

Model	Span lengh (m)	Bridge width (m)	Section
1	6.0	8.5	
2	8.0		
3	6.0	10.0	
4	8.0		

sectional arrangements and bridge span designs for single-span bridges are summarized in Table 1.

According to the cross-sectional arrangements and span of bridge, acceleration measurement points were spaced at equidistance on each beam. Parametric analysis was then conducted to calculate the corresponding damage index values for each damage scenario.

4.1 *BPNN optimization algorithm selection*

Back Propagation Neural Network (BPNN) has a strong ability to perform nonlinear mapping and self-learning, allowing it to accurately predict outputs based on input data (Ma et al. 2023). However, due to improper selection of initial weights and thresholds, BPNN may suffer from local convergence and slow convergence speed. To address this issue, this study utilizes Particle Swarm Optimization (PSO) algorithm to optimize BPNN.

For the BP neural network damage identification model, a three-layer BP neural network structure is selected in this study, as shown in Figure 8. The model consists of an output layer that represents the output event (bridge damage index denoted as y), a hidden layer, and an input layer that includes four input variables: lateral displacement $x1$, longitudinal displacement $x2$, damage identification index value $x3$, and aspect ratio $x4$.

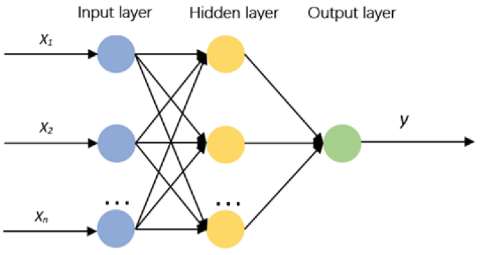

Figure 8. 3-Layer BPNN model.

To determine the optimal number of nodes in the hidden layer, this study utilized multiple simulation data sets as the training set and 9 sets of data from 9 measuring points in field tests

as the prediction set. The entire dataset was divided into 70% for training and 30% for testing. Multiple machine learning models were constructed when n=3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, and the model with the smallest error was selected as the optimal machine learning model to evaluate the extent of damage in the target bridge. To demonstrate the training accuracy of the machine learning model, two metrics were introduced: Root Mean Square Error (RMSE) and Pearson correlation coefficient (R).

In Figure 9, it can be concluded that when the number of nodes in the hidden layer is set to 8, the PSO-BPNN algorithm achieves the smallest RMSE and the maximum correlation coefficient R. This indicates that the training effect is the best with this configuration. Consequently, a BPNN neural network model with 8 hidden layer nodes and PSO optimization was selected to evaluate the damage degree of the target bridge.

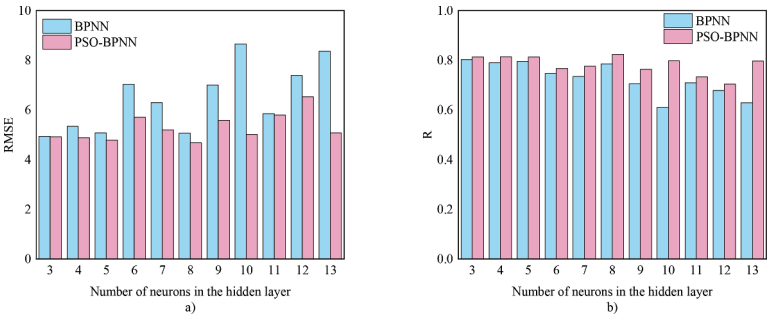

Figure 9. a) RMSE of BPNN models. b) R of BPNN models.

4.2 *Rapid identification platform development*

The structural signals collected from bridge dynamic loading experiments may not directly reflect the structural damage of the bridge. To address this, a bridge state rapid assessment software package was developed using a Python code editor, it is named RAAB, RAAB integrates evaluation methods to quickly process the collected structural signals and derive information about the bridge damage. RAAB consists of three modules: bridge basic information, bridge mechanics information, and bridge assessment and maintenance. The interface is shown in Figure 10. Figure 11 is the software flow diagram.

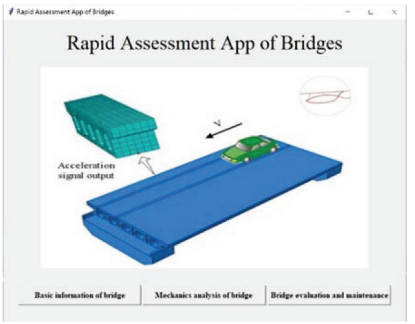

Figure 10. RAAB interface.

4.3 *Verification of RAAB*

To verify the function of RAAB, a bridge model with a length of 6.0 m and a width of 8.5 m was created as shown in Figure 12. Single-damage and multi-damage conditions were set respectively, as shown in Table 2. By inputting the acceleration signal into RAAB, we obtained the specific damage degree index value of each measuring point. The final damage

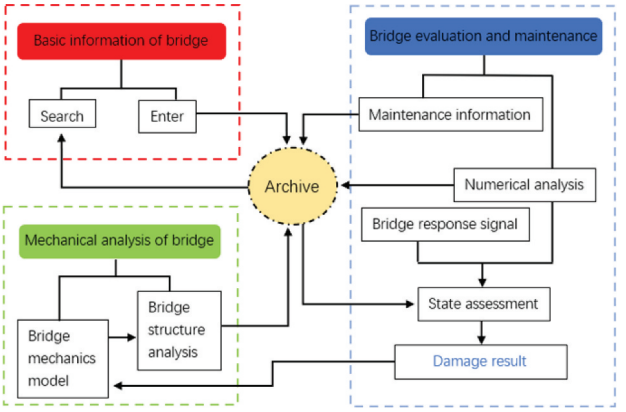

Figure 11. Flowchart of RAAB.

degree prediction results are shown in Figure 13. The results show that the damage results generated by RAAB are highly consistent with the actual model damage setting.

5 CONCLUSIONS

In this paper, a fast and feasible detection method is proposed to identify the damage of old bridges in remote areas. Comparing the two BP neural network algorithms, the error results show that the prediction accuracy of PSO-BP algorithm is better than BP. At the same time, the damage database is established, and the software platform RAAB is developed. Through the actual engineering verification matched with the database, RAAB can accurately identify the damage location, and the error of the damage quantization value is less than 5%. The platform could hopefully provide a solution for bridge structural evaluation in remote areas.

Experimental determination of trough bridges pressure distribution

S. Sarmiento, J. González-Libreros & G. Sas
Luleå University of Technology, Sweden

O. Enoksson & T. Höjsten
Trafikverket, Sweden

ABSTRACT: The IronOre line between Narvik in Norway and Luleå in Sweden faces challenges with aging bridges and an increase in allowable axle loads. In this line, reinforced concrete trough bridges constitute about 50% of the bridge population; therefore, they are crucial for the country's economy. An essential factor of trough bridge design is how traffic loads are distributed on the concrete surface. Thus, in this study, a laboratory campaign was implemented by monitoring the pressure on the slab and beams of a new full-scale trough bridge. The monitoring was made using load cells placed on the slab and beam surfaces at points of interest. The pressure was measured for different axle load levels and static and cycling loads. This study belongs to a more extensive experimental campaign where further tests on load distribution are planned. The results show how the loads are distributed among the sleepers and the final transversal and longitudinal distribution shapes on the bridge.

1 INTRODUCTION

In Sweden, there are approximately 21,000 bridges connected to the rail and road network, with 4,000 dedicated to railways (Trafikverket 2022). Among these, roughly 83% are reinforced concrete bridges (BaTMan 2021). Specifically, of the 4,000 railway bridges, 1,000 (23%) fall into the category of trough bridges (Sarmiento Nova et al. 2021). A typical reinforced concrete trough bridge is constituted by two longitudinal beams that support a slab forming a U-shape, which functions as a container for the ballast and railway track.

Many of the trough bridges in Sweden are approaching their intended lifespans, raising concerns about their current capacity and safety. Despite their age, previous studies (Elfgren et al. 1996) have shown that these bridges do not exhibit visible damage, suggesting a potentially hidden capacity that should be accounted for when assessing their current performance. Previous bridge designs were grounded in conventional assumptions, potentially leading to a conservative estimation of their strength capacity.

Understanding the stresses transferred through the track and support is crucial for developing design practices that ensure adequate track performance, especially for railway trough bridges (Unluoglu et al. 2023). Significant differences exist in pressure distribution when comparing various codes and experimental studies. Eurocode 1 (CEN-1991 2003) and the Swedish standard, TDOK 2013:0267 (Trafikverket 2019), assume a uniform distribution, contrary to experimental tests revealing a double parabolic shape (Andersson 2020, Sadeghi 2005, Navaratnarajah et al. 2018, Piaxâo et al. 2018). Multiple factors contribute to these differences, including sleeper seating, ballast compaction, sleeper spacing, rail bending stiffness, and the presence of additional layers for load distribution (Esen et al. 2022).

Current literature emphasizes the need for more experimental investigation into sleeper-ballast contact pressure and stress distribution along and across the ballast (Sadeghi 2005). Therefore, this paper aims to contribute to research on traffic load distribution for typical

DOI: 10.1201/9781003483755-137

concrete trough bridges in Sweden. The goal is to enhance our understanding of their actual load-bearing capacity and behavior. To achieve this, an experimental study on a full-scale reinforced concrete trough bridge was conducted, measuring load distribution in a laboratory setting. Load plates were fabricated and strategically placed on the concrete slab surface to measure load magnitudes. The study involved static and cyclic loading, and the obtained pressure profiles were compared with current standards.

2 BACKGROUND

Determining and field-testing the stress distribution pattern along and across the ballast has proven to be a complex task. Through both experimental and numerical analyses, existing literature has revealed that the assumption of uniformly distributed pressures does not accurately reflect reality.

Early investigations into this matter were conducted by Talbot (1980), who proposed various hypothetical distributions of the bearing pressure at the ballast-tie interface. These hypotheses were formulated based on the variability of the contact area from one tie to another. Given the inherent difficulty in precisely predicting pressure distribution between the sleeper and the ballast, Sadeghi (2005) further presented hypothetical contact pressure data gathered from various theoretical and field test studies, illustrating at least six distribution types.

In contrast to these findings, Eurocode 1 (CEN-1991 2003) assumes a transversally uniformly distributed load on the slab. It employs a trapezoidal transition from the sleeper's bottom through the ballast to the slab's surface, with an inclined ratio of 4:1 (Figure 1a). The Swedish administration's TRV (Trafikverket 2019) also assumes a uniform distribution but with a steeper slope of 2:1 (Figure 1b). Additionally, from Figure 1, it is possible to observe that the Swedish standard assumes a shorter distance under the sleeper (2.25m), whereas the CEN-1991 2003 considers the entire length of the sleeper.

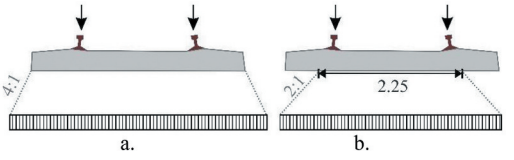

Figure 1. Load distribution through the ballast according to a. Eurocode 1 (CEN-1991 2003) and b. the Swedish standard (Trafikverket 2019). measurements in meters. (measures in meters).

The American Railway Engineering Maintenance-of-way Association (AREMA) assumes a pressure distribution according to Figure 2a (AREMA 2010). The pressure distribution has a double parabolic shape simplified with a uniformly distributed load with the length L_{eff}. L_{eff} is calculated as 1/3 of the length of the sleeper and is acting at the ends of the sleeper, where the load is assumed to be the largest. Standards Australia (2003) takes a load that is partially uniformly distributed under the rail seats of the sleeper and no load in the middle of the sleeper, as presented in Figure 2b.

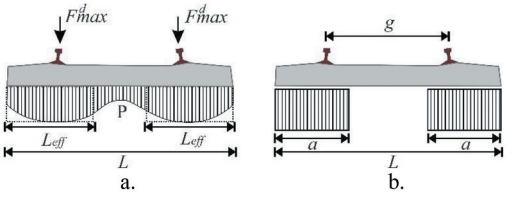

Figure 2. Load distribution assumption according to a. AREMA (2010), where F^d_{max} Is the load from the rails on the sleeper and b. the australian standards (Standard Australia 2003).

The load distribution in the longitudinal direction for one axle load can, according CEN-1991 (2003), can be assumed to be distributed between the three sleepers, according to Figure 3a. Half of the axle load is considered to be distributed to the sleeper directly below the axle load and one-quarter of the load to the two adjacent sleepers. The distance 'a' in the figure is between sleepers, 'b' is the length distribution of the load, and Q_{vi} is the load from one axle load. The slope for the transmission of the load to the slab is 4:1. The TDOK 2013:0267 makes the same assumptions; however, the slope is the same as the transversal (2:1) and establishes two additional cases for the distribution of loads among sleepers (see Figure 3b).

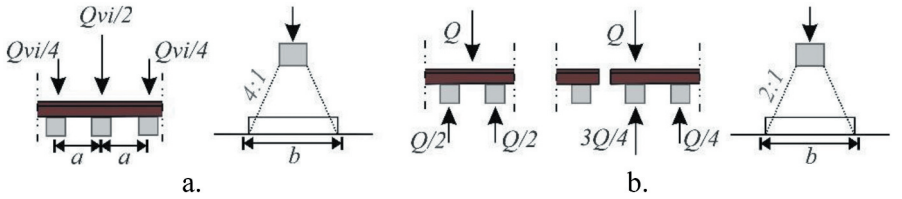

Figure 3. Longitudinal aoad distribution according to a. Eurocode 1 (CEN-1991, 2003) and b. TDOK 2013:0267 with additional cases of axle load (Q) distribution between sleepers. (Trafikverket, 2019).

According to the U.S. Army Corps of Engineers (2000), the longitudinal load between sleepers can be assumed to be distributed according to Figure 4a. This case is valid when the axle load is placed directly on top of a sleeper. U.S. Army Corps of Engineers (2000) underlined some essential aspects that affect the load distribution, such as the size of the axle load, track design, and track condition. Profillidis (2006) suggests that the load can instead be assumed to be distributed across five sleepers, with the distribution being 7 %, 23 %, 40 %, 23 %, and 7 % of the total axle load according to Figure 4b. Lichtberger (2005) suggested a load distribution that is very close to this and a distribution according to Figure 4c.

Experimental tests have shown that the load distribution is more of a double parabolic shape instead, where the stresses are more concentrated directly under the section in which the train wheels are in contact with the rails and underlying sleepers (rail seating) (Esmaeili et al. 2019, Andersson 2020, Sadeghi 2005, Zakeri & Sadeghi 2007, Navaratnarajah et al. 2018, Piaxâo et al. 2018).

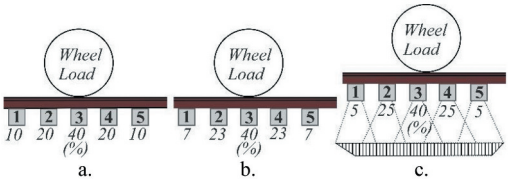

Figure 4. Pressure distribution according to a. (U.S. Army Corps of Engineers, 2000) b. Profillidis (2006) and c. Lichrberger (2005).

Finite Element (FE) modeling has been broadly implemented to understand the behavior of railway track structures. Sadeghi (2005), for instance, employed FE modeling to analyze track structure responses under static and transient loads. In this investigation, the deflection was considered proportional to the pressure beneath the sleeper, resulting in a deflection pattern composed of two parabolas—a model akin to that proposed by Talbot (1980) and ORE (1968). Zakeri & Sadeghi (2007) and Aursudkij (2007) further affirmed the existence of non-uniform contact pressure between the ballast and the sleeper, describing a parabolic pressure distribution diminishing with depth.

Navaratnarajah et al. (2018) explored the impact of Under Sleeper Pads (USPs) on track behavior, revealing higher stresses in the ballast directly under the rail seat where the wheel load is applied, with pressure decreasing on average with ballast depth.

Andersson (2020) conducted an FE analysis investigating load distribution through the ballast on a 4.0 m reinforced concrete trough bridge. Results indicated a more uniform distribution for a thicker ballast layer, affirming a double parabolic shape for a 0.6 m ballast layer. Conversely, load distribution peaks were lower for a 1.0 m thick ballast layer, reflecting a more even load distribution.

Sarmiento et al. (2021) developed an FE model of a trough bridge employing different pressure distributions to assess their impact on bridge performance. A parametric study and reliability analysis were conducted under various boundary conditions, revealing that assumptions about support conditions and pressure patterns significantly influence this type of structure's capacity, failure mode, and probability of failure. Failure modes could range from flexure at the support to shear, depending on the pressure pattern.

Other numerical approaches have been presented, such as Kaewunruen & Mirza (2017), who used a combination of Discrete Element (DEM) and Finite Element Methodology (FEM) to analyze ballast behavior under dynamic loading. They reported high ballast stresses directly below the outer rail during yielding. Additionally, Eriksson et al. (2023) compared FEM and DEM results on load distribution, noting that FEM exhibits a smoother and more even load distribution compared to the unique patterns observed in the DE model.

3 DESCRIPTION CASE STUDY

An analysis of the bridge population in Sweden concluded that a typical single-span trough bridge has, on average, a span length of 6.8 m and a width of 5.4 m. Therefore, the geometry and available design of a trough bridge close to the average was used as a base for building two reinforced concrete trough bridges at the Luleå University of Technology. The geometry is displayed in Figure 5. It used a concrete quality C40 and reinforcement bars class Ks40. The railway track used rails type UIC60, a ballast class I with a height of 27 cm from the concrete slab top surface to the bottom sleeper surface, and sleepers with fast clippers.

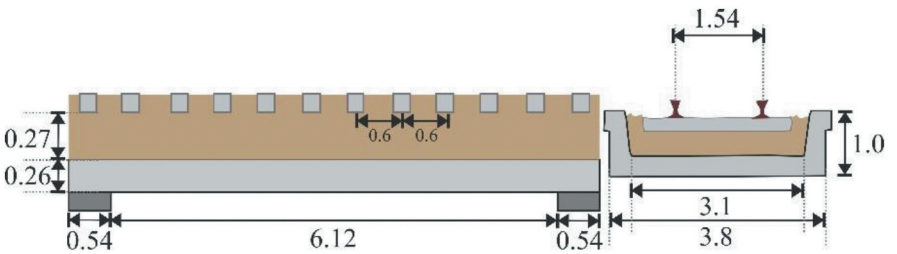

Figure 5. Geometry of the two casted trough bridges at LTU.

4 DESCRIPTION EXPERIMENTS

4.1 *Instrumentation*

To measure how the pressure is distributed on the concrete surface, 12 load plates consisting of two steel plates and four (4) force transducers were built. A force transducer, also known as a load cell, is a sensor that measures the force or load applied to it. These devices are widely used in various applications, from industrial settings to scientific research, where the accurate measurement of force or weight is necessary. The range of applications includes load testing, materials testing, industrial weighing scales, and force feedback in robotics and haptic devices.

A force transducer typically operates on the principle of strain gauges. When a force is applied to the transducer, it deforms slightly, causing the strain gauge to stretch or compress. This change in strain causes a difference in the gauge's electrical resistance. Force transducers need to be carefully calibrated to ensure accurate and consistent measurements. Calibration involves applying known forces to the transducer and recording the corresponding output signals.

For this study, force transducer type C9C, which is a compact design compressive force transducer with accuracy class 0.2, was chosen. The force transducers can measure forces from 50 N to 50 kN, and they are considered to have high rigidity and are particularly suited for dynamic measurement tasks. Figure 6a shows an example of a force transducer C9C.

The steel plates were designed to support the expected load during the test and serve as a box for the force transducers. Therefore, the steel plates have an area of 25x25 cm and thickness of 2.1 and 1.1 for the bottom and top plates, respectively. Once the steel plates were designed and fabricated, the force transducers were placed on the bottom steel plate and then closed with the top steel plate, as shown in Figure 6b-c.

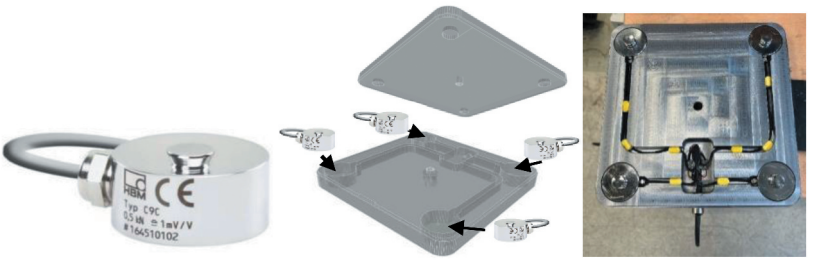

Figure 6. A. Example of a force transducer type C9C steel plates of pressure cells b. 3D model of steel plates and transducers' position and b. picture of the assembling.

4.2 *Test protocol and set-up*

The test protocol consisted of two main stages: static and cyclic loads. A load rate of 0.6 kN/s was used for the static stage, and for the cycles, a frequency of 1 Hz was used. The load ranges and the number of cycles is illustrated in Figure 7. The test set-up consisted of one load applied with a hydraulic jack, equally distributed into two beams (see Figure 8a). During the test, stops were established to inspect the bridge for crack development control and to perform photogrammetry. The moments of inspection are also illustrated in Figure 7.

It was considered the test set-up to position the load plates, which consisted of one axle load at 0.9 meters from the mid-span. Therefore, the plates were distributed transversally and longitudinally above the axle position (see Figure 8a-b). Also, two plates were located on the surface of the longitudinal beam to control the transference of pressure to the beam.

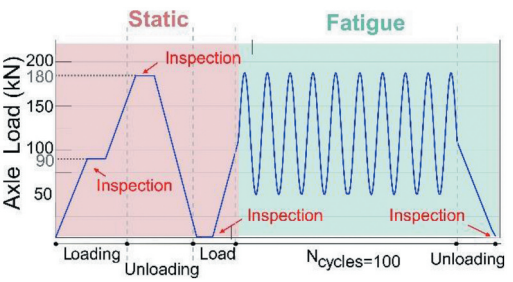

Figure 7. Sketch of the test protocol.

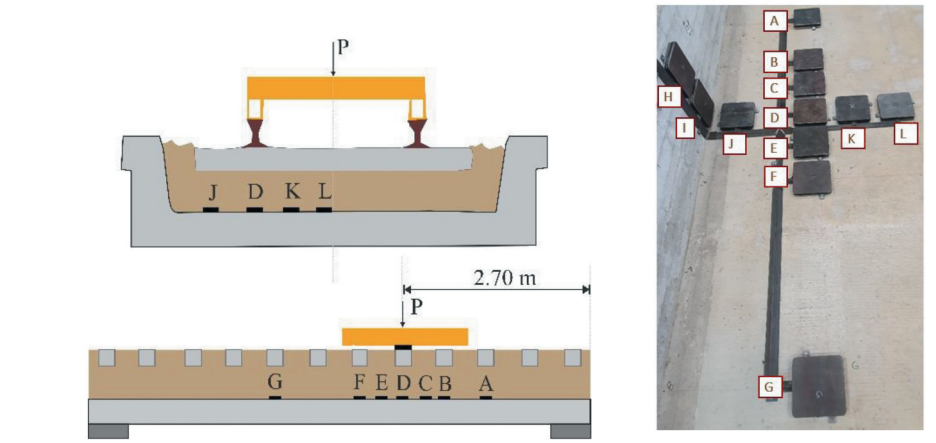

Figure 8. A. Position of the load plates and test set-up and b. picture after instalation.

Plates A-G were placed to obtain the pressure profiles of the force along one of the axle longitudinal edges. The idea was to capture the load transmitted above the closest sleepers and in between them. Transversally, plates D, J, K, and L provide the shape of the wheel load distribution. It is assumed that because of symmetry in load position and structure, the distribution is symmetric as well.

5 RESULTS AND DISCUSSION

The transversal and longitudinal pressure profiles obtained for different load levels (90, 120, 150, and 180 kN) are displayed in Figure 9, which show the applied load, the position of the plates, and the respective load value.

The transversal pressure profile displays a higher load on Plate K, a similar load magnitude on Plates D and L, and a lower magnitude on Plate J. The obtained pressure pattern describes a parabola with a peak at 32.25 cm from the rail edge. The bridge's symmetrical behavior was checked by measuring the displacements under the load application in each railway position. Therefore, it can be affirmed that the pressure in the transversal direction describes a double-parabola shape (or w-shape).

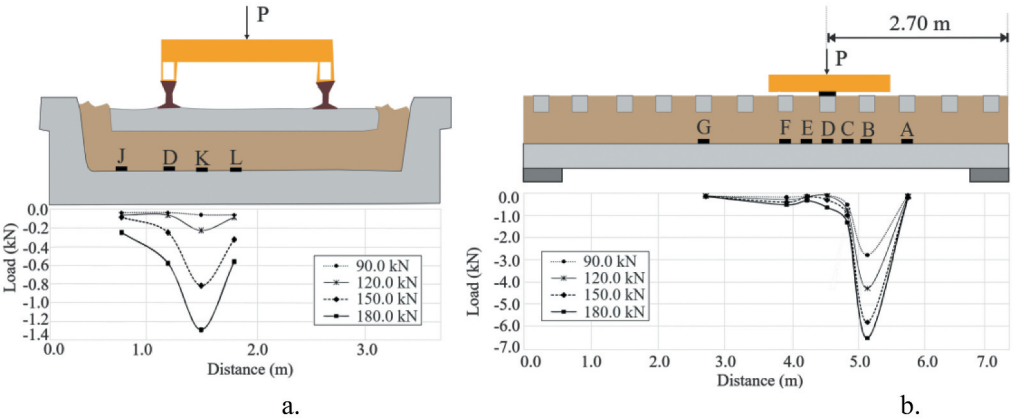

Figure 9. a. transversal pressure profile b. longitudinal pressure profile.

The longitudinal pressure distribution obtained exhibits a high peak on Plate B, which significantly drops on Plate C, continues to decrease on Plate D-E, and experiences a slight increase on Plate F compared with Plate E (0.19 kN for an axle load of 180 kN). Given the position of the axle load, Plate G did not receive any load, and Plate A only received a small percentage.

The obtained results show that the axle load was highly concentrated at the sleeper behind the axle load application. This result might be the influence of parameters such as the level of compaction of the ballast and how the sleepers were sitting. When the ballast was placed, it was carefully sorted and leveled so that all the sleepers were aligned; however, there still exists the possibility of existing voids underneath some sleepers, such as the sleeper above Plate D, where the load was applied. This made the load to be transferred to the sleeper behind. Also, since the compaction after a few cycles has been shown to affect the distribution of loads, it can be affirmed that it is necessary to have a stage of 'compaction' before applying the static load. Nevertheless, the results showed that the pressure is not uniformly distributed on the entire concrete surface, as design standards assume, in any of the directions (transversal and longitudinal).

The pressure profile was also calculated following TRV and Eurocode standards (based on Figs. 2-3), and the values were compared with the experimental results presented above. Figure 11a-b compare transversal and longitudinal profiles, respectively. The peak load was higher in the experiments than the standards, which can be because the ballast was not compacted, and a small number of cycles was applied. However, the pressure on the remaining points of the slabs was much smaller in the tests than in the standards, indicating a smaller load spread (load distribution length). The Eurocode shows the same distribution as TRV, transversally and longitudinally; however, Eurocode showed more pronounced peaks and higher-pressure values given that the distribution length was shorter, and the loads were more concentrated near the load application.

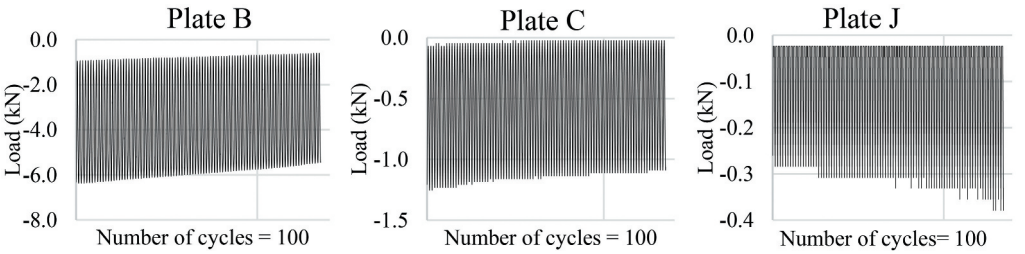

Figure 10. Loads in plates B, C, and J during the fatigue test.

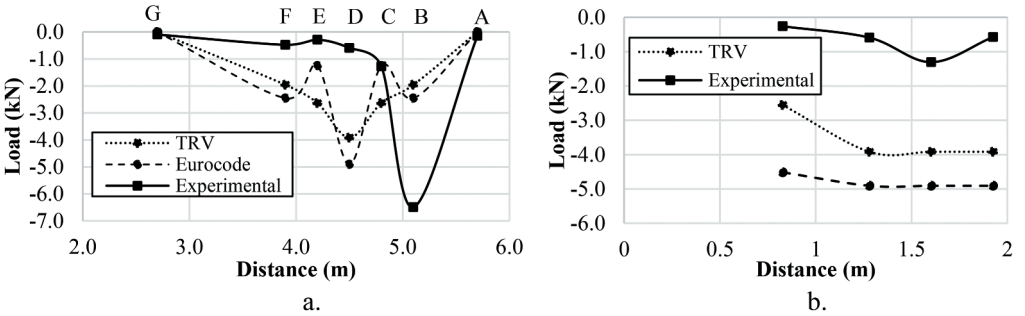

Figure 11. Comparison of load distribution among TRV, Eurocode (CEN-1991 2003), and Experimental results a. longitudinally and b. transversally.

6 CONCLUSIONS

Given the results obtained and analysis carried out, the following conclusions can be drawn:

- Experimental results showed that the transversal pressure distribution of loads on the concrete slab is not uniform for the entire surface, but it follows a w-shape distribution. The results showed that given the configuration of ballast particles, some concentration of loads would be expected near the load application.
- The ballast compaction influences the pressure distribution. A non-compacted ballast, such as the one used in the test, tends to concentrate the loads in smaller slab areas. For a total of 100 cycles applied, a re-distribution of loads was observed.
- It is necessary to check the sleeper's contact area to certify that the highest load is transmitted to the sleeper where the axle load is applied. Techniques such as tamping can ensure a more uniform contact area between ballast-sleepers.
- Significant differences in pressure profiles between the experiments and Eurocode and TRV standards were obtained. The assumption of a more uniformly distributed load might lead to either an underestimation or overestimation of the concentration of stresses in different critical points of the structure.
- Further experiments should be conducted by considering more compacted ballast and additional load plates that can eliminate the uncertainties regarding contact between the sleeper-ballast and uniform distribution of ballast aggregates.

ABSTRACT: This study aims at the development of digital twin that consists of two parts. One is data storage of inspection data. The other is numerical model to evaluate the performance of the structure. The objective of the numerical model is to predict the influence of the deterioration, when the deterioration gets worse. A bridge was picked up and the finite element model was built. Reproduction of the actual behavior is very important to estimate the influence of deterioration. The field loading test was conducted for the verification. A heavy vehicle of 40 tons was loaded. By considering the reinforced concrete sidewalk and steel fences of sidewalks, the agreement between the actual structure and numerical model could be improved up to 92 %. After the loading test, continuous monitoring of bridge weigh-in-motion was carried out. The result showed that the traffic condition of the bridge was not serious very much.

1 INTRODUCTION

Deterioration of infrastructure has become one of the most serious problems. Appropriate maintenance works are necessary. From 2014 in Japan, periodical inspections have been started. The inspection should be a close visual inspection, for example, within 1m. The results of inspection are open to the public on the web by the administrator of infrastructure such as bridges and tunnels. Because the period of the inspection is 5 years, the second cycle is coming to the end in the fiscal year of 2023.

Even though the guideline of the inspection was published, the results are not always consistent by the administrators. This problem usually comes from the recordability of the inspection data. In order to improve the recordability, some studies have investigated the application of a bridge in a computer space with data storage.

In recent years, digital twin has been applied in many fields (Nakabo 2022, Thelen 2023, Zhang 2022). Digital twin is a counterpart usually in the computer space and plays important roles such as simulation, monitoring, data storage, and maintenance. This study aims at developing a digital twin, as shown in Figure 1. We will develop two types of digital models in a computer space. One is used for data storage of periodical maintenance work in every five years. The model can also work as a simulator of inspection prior to the actual work. The other model is related to structural behavior (Fujikubo 2021). It

DOI: 10.1201/9781003483755-138

is easy to accelerate a deterioration such as corrosion in the virtual space, while it actually takes long time to reduce the thickness of the member. The numerical model predicts the performance of the structure such as ultimate strength. Based on the results of the numerical analyses, it is possible to know the weak point in advance. In the next maintenance works, inspection of the weak points can avoid the fatal failure of the structure (Sugisaki 2023).

In this study, as a prototype of modeling the digital twin of a structural behavior, an existing bridge was chosen and the verification was conducted by the field test. This paper describes the details of the field test.

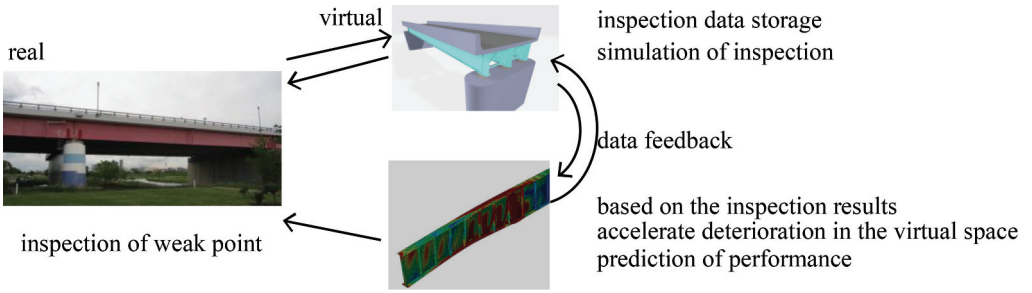

Figure 1. Concept of digital twin in this study.

2 BRIDGE OF INVESTIGATION

A real bridge in Tokyo area was chosen. Figure 2 shows the bridge. The bridge is a three span continuous bridge of 150 m long. The bridge is about 15 m wide and consists of two lanes of two ways and pedestrian deck on both sides. It consists of two steel box girders. An orthotropic steel deck system was applied. The bridge was completed in the late 1980s.

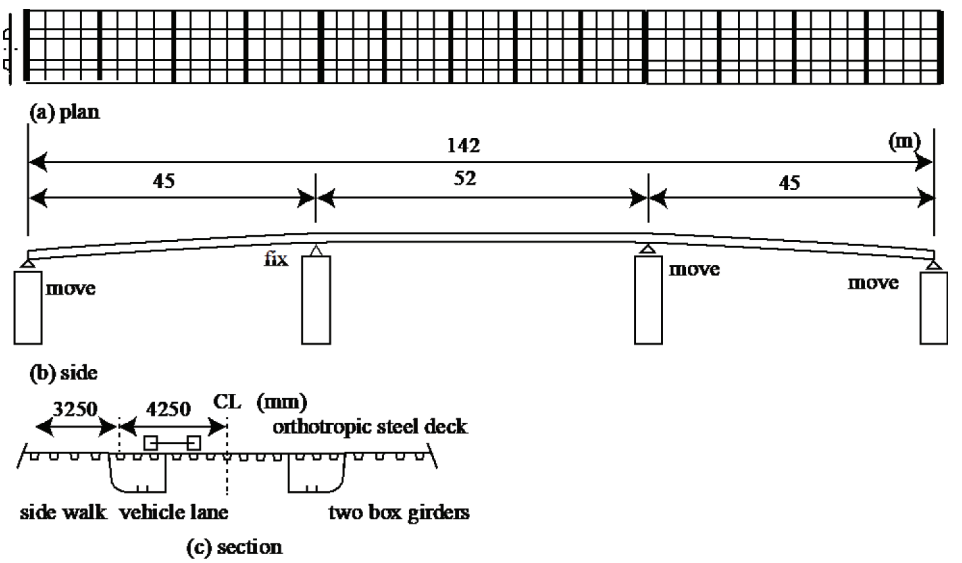

Figure 2. Bridge of investigation.

2.1 *Finite element model*

Prior to the field measurement, numerical model by the finite element method was constructed. It was possible to find the complete drawings of the bridge. Based on the drawings, the numerical model could be established. Shell elements were employed for the box girder and deck system. Solid elements were applied for the pavement, asphalt concrete. At first, reinforced concrete of pedestrian deck, to cover the side block, and fences were not modeled.

The size of the elements was not bigger than 20 cm by 20 cm. A commercial software of Marc was used. As the pre- and post- processor, Mentat was used. The total number of nodes and elements were 435000 and 455000, respectively.

2.2 *Field measurement*

Field loading test was carried out. Figure 3 summarizes the items of measurements. There were five items. One was strains at the center of each span. The second was displacement of roller bearings. The third was temperature at the center of the bridge both inside and outside of the girder.

Figure 4(a) shows the placement of strain gauges. Dots in Figure 4 correspond to nodes of finite element analysis. Strains were measured almost at the center of the three spans about 60 cm away from the diaphragm.

Figure 4(b) shows the details of bearings. A spherical type was used. At each bearing location, two laser sensors were used in the bridge axis and lateral directions.

Figure 4(c) shows the placement of thermo sensor around the center of the bridge. Two thermo sensors were put inside of the girder at the upper and lower flanges, respectively. One thermo sensor was also put outside of the girder.

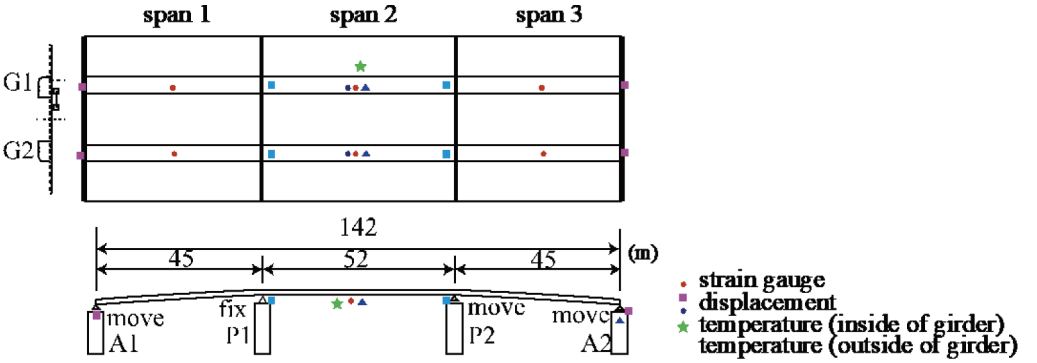

Figure 3. Items of measurement of field load test.

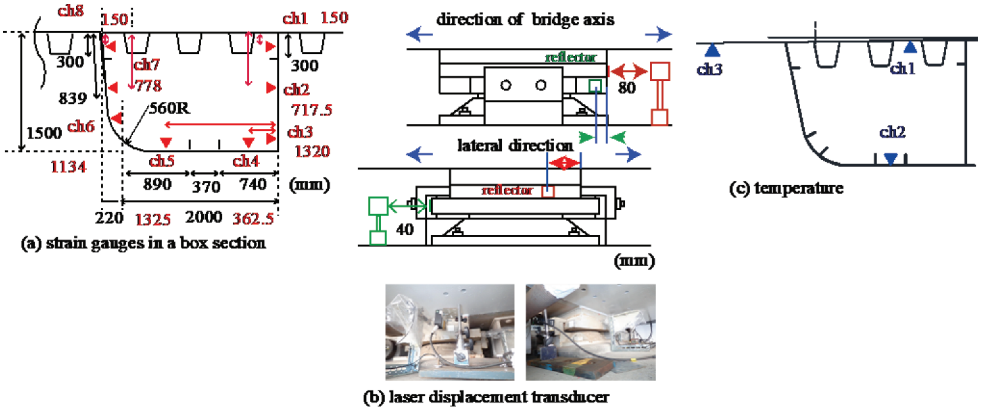

Figure 4. Strain gauges in a box girder section.

3 FIELD LOADING TEST

3.1 *Vehicle*

A truck of about 45 tons were used by the field loading test as shown in Figure 5. The truck consists of 5 axles and the axial loads are shown in Figure 6. Generally, in Japan, a truck of over 25 tons requires the permission for driving.

Two types of loading were performed. One was static and the other was dynamic. In case of static loading, the vehicle took positions along the bridge axis as many as 30 patterns. Considering the probable local maximum strains at axle position and the vehicle had 5 axles, strain data was recorded at 5 axle positions adding to the center of the vehicle. At each location of strain gauge, the vehicle was placed corresponding to axles 1 through 5 and the center. Especially in the center span, at two more points of quarter of the center span length, the vehicle was placed. Regarding the lateral direction, the center of the vehicle was the same as the center of the lane.

In case of dynamic loading, vehicle moved at the speed of about 30 km/hour. The driver tried to keep the center of the lane.

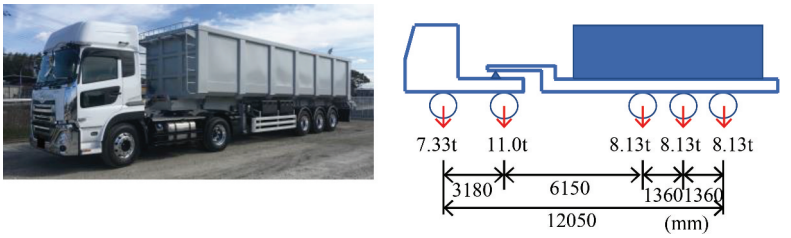

Figure 5. Truck ofcfield loading test.

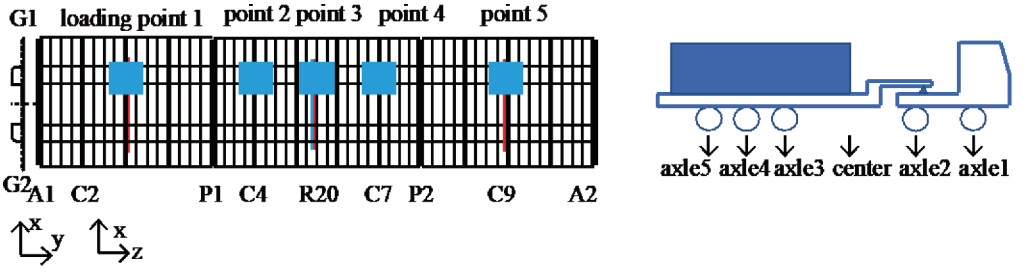

Figure 6. Main five loading points and axles.

3.2 *Verification of the numerical model*

Influence line of the bridge was obtained. The boundary conditions were applied by the analyses, considering the loading points by the field test. By comparing between the analysis and field test, the results of analyses were verified.

Strains were compared at the maximum point that is the center of the second span. The results are shown in Table 1. The strain was 66 μ by the field measurement. Only steel girder and pavement were modeled in the first numerical model. The value was 87.2 μ. This result implies that the stiffness of other components was not negligible. As shown in Table 1, the influences of sidewalk made by reinforced concrete (RC), steel plate covering the RC sidewalk,

and fences on the curb and between sidewalk and traffic lane. Finally, the strain was reduced up to 71.6 μ that was 92.7 % of the actual measurement.

There still existed the error. The possible reason was the stiffness of the asphalt pavement. The field test was carried out in the winter night. The stiff ness used was the highest value of 2000 MPa. That still could be higher. Another reason could be the low functionality of the moving bearings. That would be shown later. Hereafter, the results of numerical analyses were shown by the stiffest case.

3.3 *Results of numerical analyses and loading test*

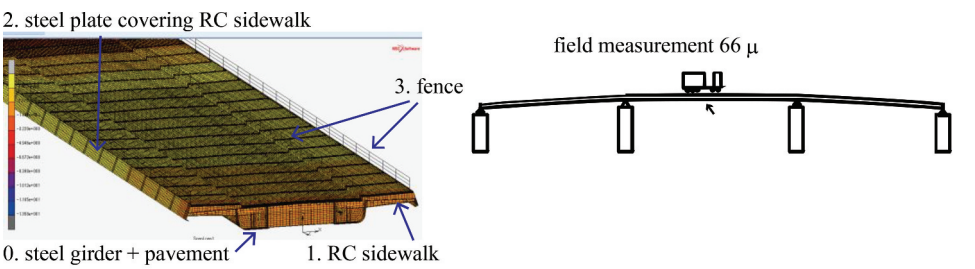

Figure 7 shows the comparison between the numerical analyses and the loading test. These are the influence lines of strain at the center of the bridge. Figures 7 (a) through (h) represent channels 1 through 8, respectively. Strains of bottom flange were almost the same by comparison between channels 4 and 5. Strain of channel 8 did not change very much. Neutral axis should be located around the channel. All of the strains were not completely the same, but relatively good agreement could be seen.

Figure 8 shows the influence lines of displacement of the bearings. Figures 8 (a), (b) and (c) show those of G1 girder A1 support G1 girder A2 support, and G2 girder A1 support, respectively. All of the influence lines correspond to the displacement in the axis direction. As shown in Figure 8 (a), the maximum dis- placement could be seen in span 1. Result by numerical analysis was about 1.5 mm, in contrast, that by field test was 0.6 mm. Field test result also shows almost no displacement in span 2. It is possible that the bearing does not work as a movable support.

To reproduce the behavior precisely, agreement of 100 % is preferable. Except for the functionality of the movable bearing, the field test and numerical analysis were in good agreement. However, at the same time, simplicity of linear calculation is also important. Although the nonlinearity of the numerical model is still the subject to be resolved, linear analyses would be done in this study.

In addition to the static loading test described previously, dynamic loading test was also carried out. The main objective was to confirm the movement of bearing even under dynamic loading. The result is shown in Figure 9. The vehicle was traveling on girder 1 (G1) from span 1 through 3. Displacement of lateral direction did not change very much. Displacement in the axis direction showed smooth move. However, the maximum displacement was about 0.33 mm that was much smaller than the numerical analysis of about 1.5 mm. For both static and dynamic loading tests, the bearing did not move smoothly.

Table 1. Accuracy of models.

model	strain (μ)	ratio (field/analysis)
girder + pavement	87.2	76.1%
girder + pavement + RC pedestrian deck	79.4	83.6%
girder + pavement + RC ped. deck + steel plate for RC ped. deck	73.7	90.1%
girder + pavement + RC ped. deck + steel plate for RC ped. deck + fence	71.6	92.7%

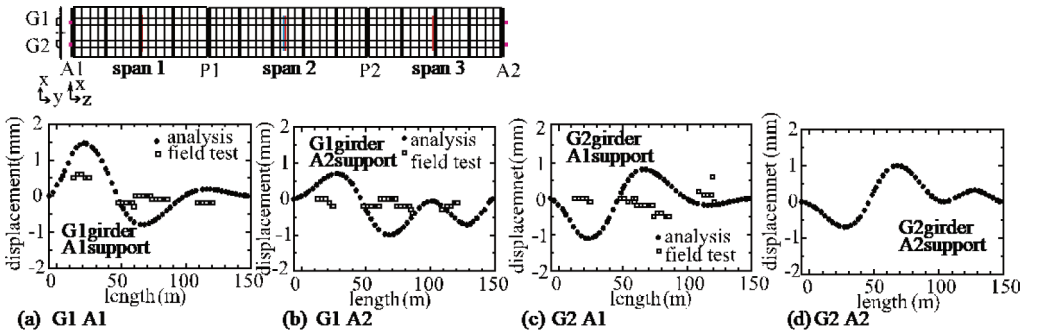

Figure 8. Displacement of bearings.

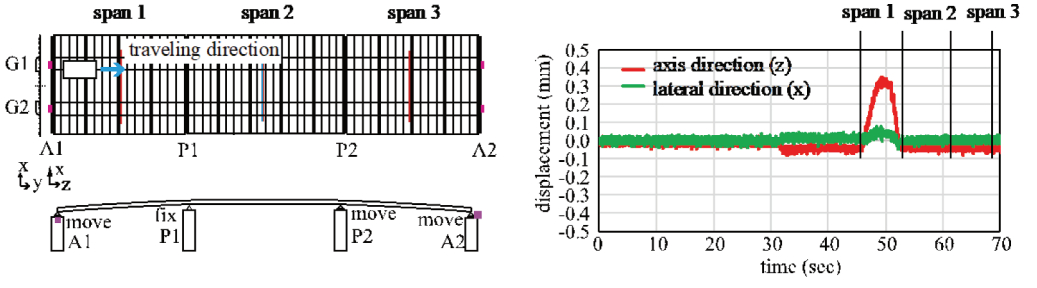

Figure 9. Displacement of bearing by the field loading test (dynamic).

4 BRIDGE WEIGH IN MOTION

Bridge weigh in motion (BWIM) was conducted (Zolghadri 2016). BWIM has been applied to estimate axle loads of vehicles with relatively simple instrumentation such as strain gauge, displacement transducer, or accelerometer (Sekiya 2018). Figure 10 shows the items measured in the BWIM. Those were almost the same as the field test, including strain, temperature, and displacement. The test was carried out in a week of February, 2022.

Figure 11 shows an example of daily transition. Figures 11 (a), (b), (c), and (d) show strain of the bot- tom flange, displacements of bearings of support A1 and A2, and temperature, respectively. The date was 15th February. It was a fine day.

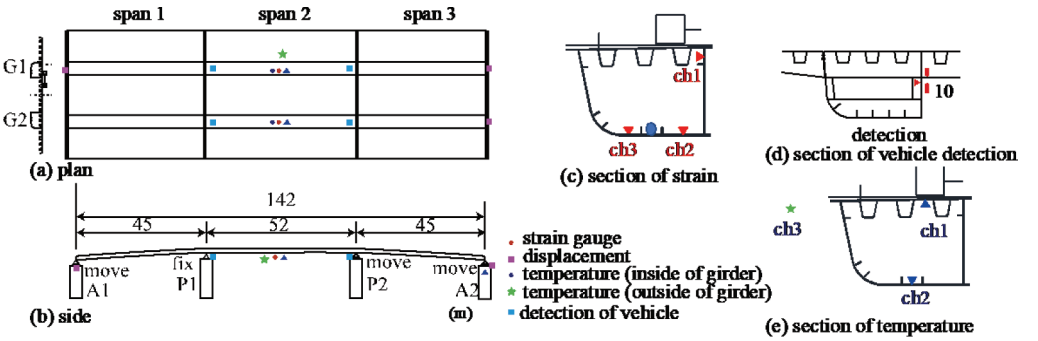

Figure 10. Setup of Bridge-Weigh-In-Motion (BWIM).

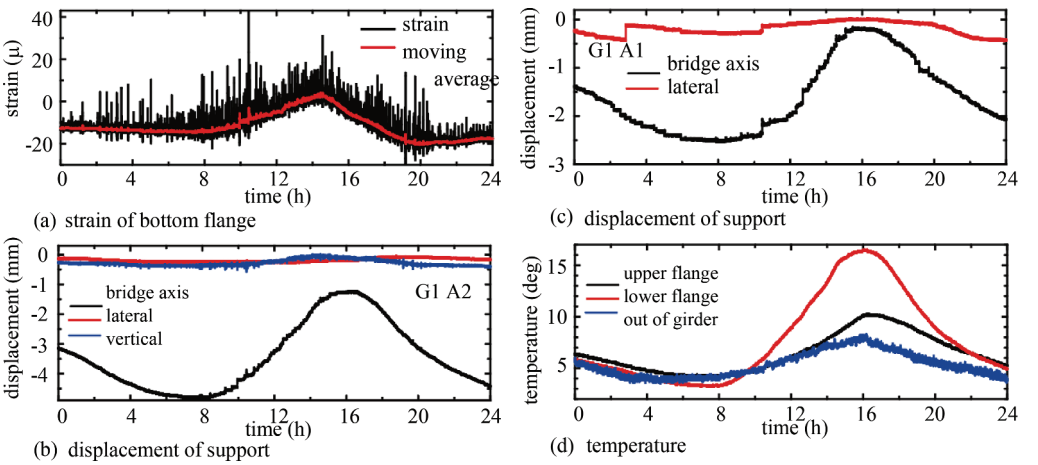

Figure 11. Data by BWIM.

Many spikes can be seen in Figure 11 (a). That rep- resents passage of vehicles. All of the items showed similar tendency as the temperature, higher values in daytime and lower values in night. As shown in Figure 11 (d), temperatures of the upper flange and out of girder took almost the same values. In contrast, that of the lower flange got much higher value. The upper flange was underneath of the deck system of which heat capacity is much higher.

As shown in Figures 11 (b) and (c), displacements in lateral and vertical directions did not change in comparison with the bridge axis direction. Displacements in the axis direction also showed the trend of daily temperature. Some step wise behaviors could be seen. That came from the nonlinearity of the bridge bearings.

For the estimation of axle loads, acquisition of influence lines is necessary. The dynamic response was decomposed by the known axle loads in the loading test described in the previous section.

Usually, dynamic response of a bridge $w(x,t)$ can be represented by equation (1).

$$w(x,t) = \sum_{i=1}^{n} p_i h(t-\tau_i) \tag{1}$$

where, p_i is the axle load of the i-th axle. $h(t)$ is an influence line. τ_i is a time when the axle gets in the bridge, n is the number of axles.

By the Fourier transformation, we obtain equation (2).

$$F(w(\omega)) = \int_{-\infty}^{\infty} e^{-i\omega t} w(x,t)dt \tag{2}$$

Substituting equation (2) into (1).

$$\begin{aligned} F(w(\omega)) &= F\left(\sum_{i=1}^{n} p_i h(t-\tau_i)\right) \\ &= \sum_{i=1}^{n} \left(p_i F(h(t-\tau_i))\right) \\ &= \sum_{i=1}^{n} \left(p_i e^{i\omega t_i} F(h(t))\right) \end{aligned} \tag{3}$$

By Fourier transformation of $w(x,t)$ of the loading test, equations with respect to $F(h(t))$ are obtained. After solving the equations about $F(h(t))$, inverse Fourier transformation gives the influence line of $h(t)$.

In case of BWIM, axle load p_i is unknown variable. Assume that $w^m(x,t)$ is an obtained waveform by BWIM. Error E can be represented by equation (4). Where T is the total time, k is the number of time steps. For the optimization of axle loads, error E should be minimized.

$$E = \sum_{k=1}^{T} (w^m - w)^2 \tag{4}$$

$$\frac{\partial E}{\partial p_i} = 2\sum_{k=1}^{T} (w^m - w)\frac{\partial (w^m - w)}{\partial p_i} \tag{5}$$

Table 2. Results of BWIM of one week.

Load(kN)	Tue	Wed	Thu	Fri	Sat	Sun	Mon	Totla
400~	0	0	1	0	0	0	1	2
300~400	0	1	2	1	1	0	1	6
250~300	0	0	1	1	0	0	1	3
200~250	3	4	6	2	4	0	7	26
150~200	13	13	6	15	11	11	12	81
120~150	25	25	24	19	18	16	15	142
100~120	20	19	24	17	5	0	25	110
90~100	34	36	30	35	6	1	34	176
80~90	46	32	31	29	12	8	29	187
70~80	21	27	20	25	8	6	18	125
60~70	64	54	64	64	25	28	56	355
50~60	71	84	73	72	57	54	70	481
40~50	112	99	108	99	59	55	98	630
30~40	117	127	126	13264	43	11	27	21
20~30	462	464	414	464	328	282	44	52859
10~20	515	512	541	518	329	314	52	03249

Equation (5) is a simultaneous equation about p_i. We can obtain unknown p_i.

Table 2 shows the traffic volume of vehicle weights of one week. The heaviest vehicle was as much as 400 kN. A video camera was installed at the site. Al- though the camera was not always working during the week, the results of BWIM and the camera showed good agreement.

5 SUMMARY AND FUTURE WORK

Conclusions obtained in this study are as follows.

A numerical model of a bridge was established in the computer space. As structural point of view, this model was used as the digital twin. Field measurement was carried out to verify the numerical model. The stiffness of the secondary component such as covering plate of side-walk, fence was not negligible to achieve actual behavior. In comparison with the strain at the bottom flange of the center span, 96% of agreement was obtained.

Monitoring by bridge-weigh-in-motion was con- ducted. Comparison with the video camera, the number of vehicles could be estimated relatively precisely. Phenomenon caused by the nonlinearity of movable supports were observed. It is necessary to con- sider the nonlinearity and get in the model. As the second step of the infrastructure management, we will find the weak points of the structure, in particular, seismic behavior.

ABSTRACT: The aim of this study is to evaluate the vertical vibrational response of simply-supported (SS) highly-skewed railway bridges. Configurations of interest are pre-stressed concrete girder deck bridges with and without end transverse diaphragms from conventional and High-Speed (HS) lines. Two detailed 3D Finite Element (FE) numerical models including the ballast track are implemented and updated from experimental modal data from two real bridges of approximately 15 and 25 m of span lengths. The evolution of modal parameters and maximum acceleration under passing trains is investigated for several variants of the reference models. Conclusions regarding the effect of skewness correlated with the execution procedure of the transverse diaphragms are finally extracted.

1 INTRODUCTION

The accurate assessment of train running safety on railway bridges has become an issue of major importance in the last decades. The European Union Agency for Railways (ERA) recently published a technical note on the investigations needed for closing the Technical Specifications for Interoperability open points on railway bridge dynamics (ERA 2022). Therefore, the train-track-bridge interaction problem is a matter of concern and investigation, still up-to-date, and far to be closed.

Since the opening of the first HS railway lines worldwide it has become clear that, at certain speeds, railway bridges may experience excessive vertical accelerations at the platform, leading to premature deconsolidation of the ballast layer, the consequent loss of track stability, fatigue problems in steel bridges or strand breakage in pre-stressed concrete ones in the long term, an increase in the operating costs of the lines, deterioration of passenger comfort, etc. (Ishibashi 2004) Research in the past showed that single-track bridges composed of SS short-to-medium spans (12-25 m) are especially critical, due to their low mass and typical natural frequencies (Frýba 2008) The problem of the excessive vibrations of railway bridges and viaducts is aggravated by resonance (Yang et al. 1997). A convoy causes resonance of a bridge when the passing time between groups of axles with a certain repetition pattern is a multiple of one of the natural periods of the structure. Because of the problems detected in several HS railway bridges, and to ensure traffic safety, the maximum vertical acceleration in these structures is limited to 3.5 m/s^2 in ballast tracks, and to 5 m/s^2 in slab tracks (CEN 2002). This constitutes one of the most restrictive Serviceability Limit States (SLS) in the design of new structures.

This work is devoted to oblique SS girder bridges, as those shown in Figure 1. In Spain, in the 80's several bridges were built with pre-stressed concrete double-T girders and upper slabs for spans in the range 10-25 m, both in HS and in conventional lines, despite their low torsional stiffness, some of them being oblique in plan. Oblique or skewed bridges are built

DOI: 10.1201/9781003483755-139

when, for topographical reasons, the superstructure cannot be perpendicular to the abutments and piers. Skewed bridges experience an inherently coupled 3D dynamic response when traversed by trains (Nguyen et al. 2014), especially in multi-track decks due to the eccentricity of the track, different from that of straight bridges, for which the dynamic response under moving trains may be assimilated to that of a beam-type structure mostly deforming under longitudinal bending. Several methods in the design codes for dynamic analysis of railway bridges are based on this premise. The actual relevance of the participation of 3D modes in the case of skewed bridges when traversed by trains at high speeds is still not well known.

The aim of this work is to analyse the influence of skewness on the dynamic response of railway bridges composed by SS pre-stressed concrete multi-girder decks. The correlation with the stiffening effect of transverse diaphragms for different span lengths will be evaluated through a sensitivity analysis over a wide catalogue of bridges. Conclusions regarding the evolution of the maximum vertical acceleration and its distribution over the platform depending on the actual speed window considered will be finally presented.

2 GIRDER BRIDGES UNDER STUDY

Two existing railway bridges, constitute the starting point for this investigation: the bridges over Arroyo Bracea and Jabalón watercourses, from now on Arroyo Bracea and Jabalón bridges (see Figure 1). Both belong to the Madrid-Sevilla High-Speed railway line, which in 2022 completed 30 years of service, and are approximately 100 km separated along the track.

Arroyo Bracea Bridge is composed by two identical 15.25 m SS spans and presents a skew angle of β=135º. The deck is composed by a 25 cm thick, 11.6 m wide cast-in-place concrete slab resting over five 1.05 m high pre-stressed concrete I girders. The girders lean on two external abutments and an intermediate pier through laminated rubber bearings. Two transverse concrete diaphragms link the girders at the supports. The slab carries two ballast tracks with an equal eccentricity of 2.15 m, two sidewalks and handrails. The rails present a UIC60 cross section and are continuously welded. The rails are supported by rail pads and fixed with clips on monoblock concrete sleepers with a regular spacing d=0.60 m.

Jabalón Bridge, is also a SS bridge with three equal spans of 24.9 m and crosses Jabalón River with similar obliqueness. The longer spans justify the difference in the girders height and slab thickness but, apart from this, both bridges are of the same typology. The ballast track layout and components are identical in both cases.

Figure 1. (a) Jabalón HS railway Bridge; (ii) detail of transverse diaphragm at the support.

In July 2016 and in May 2019 two experimental programs were carried out by the authors to identify Arroyo Bracea and Jabalón bridges dynamic properties. On the bridges the vertical response underneath the longitudinal girders was measured under ambient vibration and under operating conditions, for several train passages in both directions. The natural frequencies and corresponding mode-shapes were identified from ambient vibration by Stochastic Subspace Identification (Reynders 2012). Modal damping was obtained from the free vibrations left by the train passages, as it is considered to be more representative of the structures response under moving trains than that associated to ambient excitation. In Figure 2 the natural frequencies, mode-shapes and modal damping ratios identified for the first four modes are included for both

(a)-(d) Arroyo Bracea and (e)-(h) Jabalón bridges. This information is used in what follows to update 3D finite element (FE) numerical models from both structures.

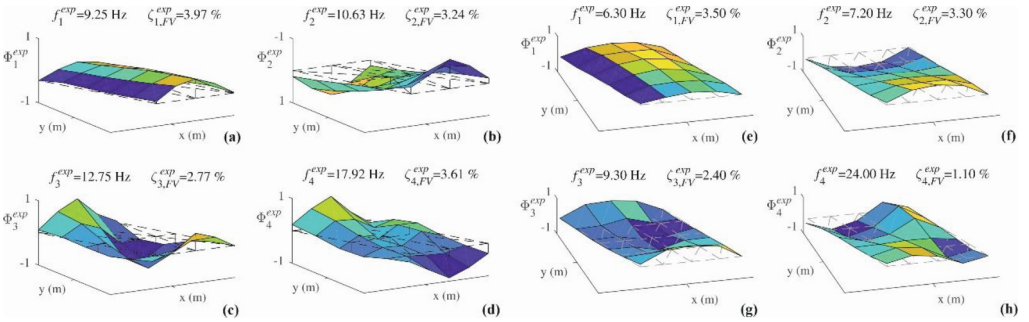

Figure 2. Natural frequencies, mode-shapes and modal damping ratios identified experimentally in (a)-(d) Arroyo Bracea and (e)-(h) Jabalón bridges.

3 NUMERICAL MODELS AND MODAL UPDATING

A 3D FE model is implemented in ANSYS(R)2020R2 for dynamic analysis of the track-bridge systems of interest (Figure 3). As for the deck, the longitudinal girders, the slab, and the transverse diaphragms are meshed with isotropic Kirchoff shell FE (SHELL181) with 6 degrees of freedom (DOFs) per node. The laminated rubber bearings, located under each girder at the supports, are modelled with solid elements (SOLID185) with 3 DOFs per node, considering their real dimensions. The vertical displacement of all the nodes at the bottom surface of the bearings is restrained, therefore ideal fixed boundary conditions are assumed and the flexibility of the piers, abutments and any interaction with the soil is neglected. Transverse bearings restraining the horizontal movement of the girders with respect to the pier cap lateral walls, present in Jabalón Bridge, are modelled as discrete elastic springs (COMBIN14).

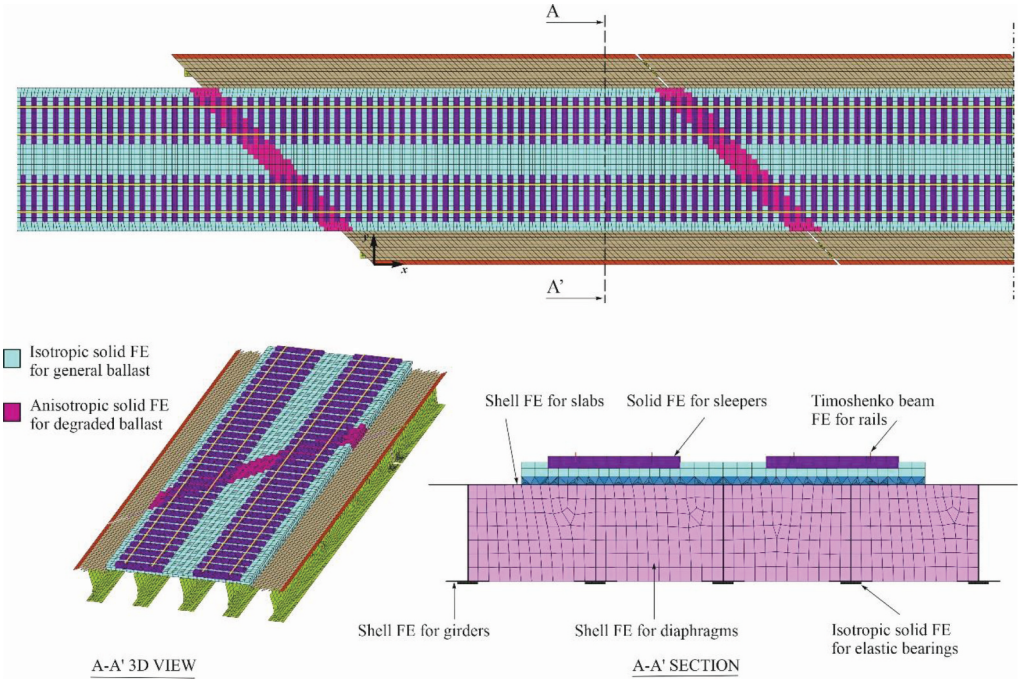

Figure 3. FE numerical model.

The ballast bed is discretised with solid FE (SOLID185). Two constitutive models are adopted over the platform: the volume of ballast along the transverse joint between adjacent spans or degraded ballast, shaded in purple in Figure 2, is represented as transversely isotropic, to consider the possible loss of stiffness due to the relative movement caused by passing trains. This effect is accomplished by reducing the vertical elastic modulus with respect to that associated to the remaining ballast, an approach also adopted in previous research works (Ticona Melo 2020). Additionally, this type of material permits the representation of different interlocking mechanisms of the ballast granules in the out-of-plane (vertical) and in the in-plane (horizontal) directions. For the non-degraded ballast region (marked in blue in Figure 3), a linear isotropic material behaviour is considered. The sleepers are meshed into SOLID185 elements with elastic isotropic behaviour, while Timoshenko beam elements with 6 DOFs per node (BEAM188) are adopted for the rails. Finally, the rail-pads are simulated as discrete spring-dashpot elements (COMBIN14) with constant vertical stiffness and viscous damping connecting the relative vertical displacements and velocities between the rails and the sleepers through kinematic constraints applied over the contact area between both elements.

To simulate the continuity of the railway track along the adjacent embankment, the ballast track model is extended 15 m from the abutments on both sides, which is equivalent to 25 times the sleeper spacing and adequate according to convergence tests performed on the modal parameters. At these extensions, the ballast mesh rests on a subgrade layer, also discretised with SOLID185 isotropic elastic elements. The three translations of the nodes at the horizontal lower plane of this layer are fully restrained. The self-weight of non-structural elements such as the handrails is included as additional lumped masses (MASS21) uniformly distributed along the two external borders. Additional density is also considered in the sidewalks areas.

The FE model is first updated to accurately reproduce the modal parameters experimentally identified of Arroyo Bracea and Jabalón bridges. The calibration procedure comprises two steps: a sensitivity analysis and an optimisation by means of a Genetic Algorithm, involving the use of ANSYS(R)2020R2 and MATLAB.2018b. The purpose of the first step is the selection of the model parameters that influence the most the prediction of the natural frequencies and mode shapes to be included in the optimisation procedure.

The correspondence between the first four experimentally identified modal parameters and those predicted by the calibrated numerical models is provided in Table 1, in terms of frequency differences and MAC numbers.

Table 1. Natural frequencies, frequency differences and MAC values between experimental and numerical first four paired modes.

Structure	Arroyo Bracea Bridge				Jabalón Bridge

4 SENSITIVITY ANALYSES

In this section a sensitivity analysis on the bridges modal parameters and maximum dynamic response under passing trains is presented. The main goal is to evaluate the influence of the deck obliqueness and diaphragm configuration on the modal properties (section 4.1) and dynamic response under moving loads (section 4.2) of the bridge typology of study. For the aforementioned tasks, variations of Arroyo Bracea and Jabalón bridge models are considered. Arroyo Bracea derived models represent girder bridges with a span length of approximately 15 m while Jabalón derived models present a longer span in the vicinity of 25 m. In what follows all the bridge models are limited to just one span and include the track extensions.

4.1 *Evolution of the modal parameters*

In Figure 4 the evolution of the first, second and third natural frequencies, which correspond to the first longitudinal bending, first torsion and first transverse bending modes, is represented for variations of the deck obliquity β and for three diaphragm realistic configurations. FD stands for full diaphragms. This implies that the diaphragms are connected to the girders web, the upper flange and the slab between adjacent girders. In the numerical model both displacements and rotations of the diaphragms, girders and slab shell elements are fully connected in this case. PD stands for partially connected diaphragms. In this case the diaphragms are connected only to the girders vertical web, as it happens in some bridges to simplify the construction process. Finally, ND stands for no diaphragms or total absence of these elements. 12 levels of obliquity are considered for each length and diaphragm configuration. Therefore, modal analyses are performed over 72 different bridges.

In the first row of plots in Figure 4 the evolution of the natural frequencies is represented vs. the skewness of the deck. Notice that the natural frequency is expressed relative to the straight (not-skewed) case for the same diaphragm configuration (FD, PD or ND). Solid and dashed traces distinguish Arroyo Bracea and Jabalón bridges derived models, respectively. In general, the obliqueness of the deck leads to a raise of the natural frequencies. The fundamental frequency is especially affected, increasing approximately 10% for the shortest bridges and highest obliquity considered. The effect of the skewness on the bridges with spans close to 25 m is lower, with a maximum increase of approximately 6%. The first torsion natural frequency also increases with the skew angle but to a lesser extent. In this case, the difference between shorter and longer bridges is smaller. The third frequency is almost unaffected by the skew angle, at least for moderate skew levels. In the second row of plots the natural frequencies are expressed relative to decks with full diaphragms and the same obliqueness, to highlight the influence of the diaphragm configuration. The second and third frequencies reduce when the diaphragms are not fully connected (PD) and further reduce in the total absence of these stiffening elements. This does not happen for the fundamental frequency, which makes sense as the deformation of the cross-section is negligible in this case, and it is especially visible in the case of the third transverse bending mode, with an important transverse deformation of the cross-section. This reduction is in general higher for shorter bridges and is approximately constant with the level of skewness.

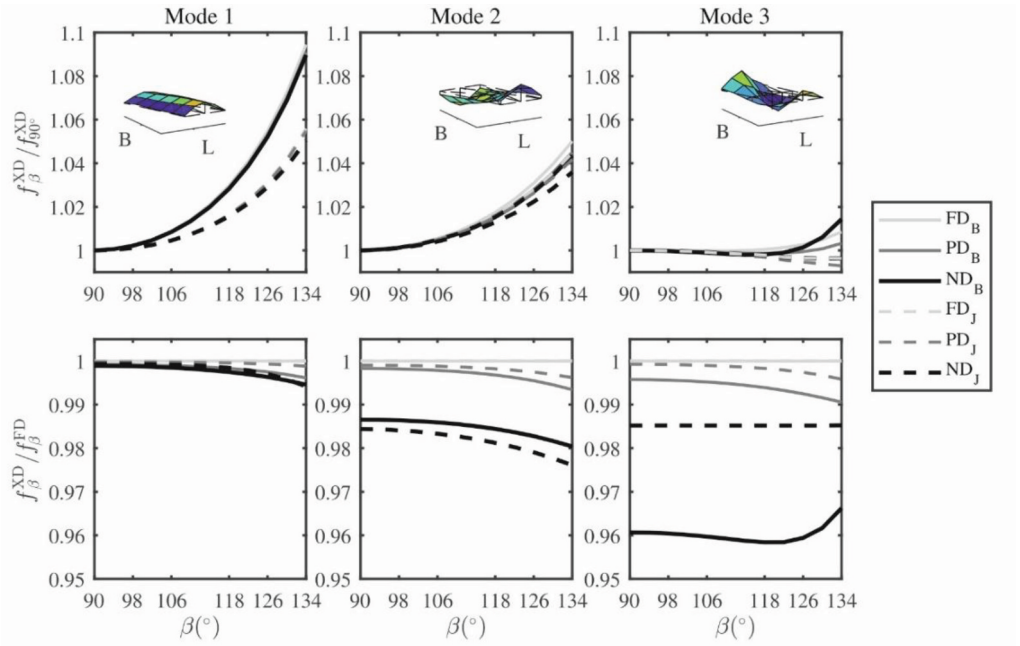

Figure 4. Frequency evolution with skew angle for different diaphragm configurations (FD, PD and ND) for Arroyo Bracea (B) and Jabalón (J) bridges derived models.

4.2 *Evolution of the maximum acceleration under moving trains*

In this section the vertical acceleration over the platform for the same catalogue of bridges is evaluated in terms of the bridge obliqueness and diaphragm configuration. To this end, the bridge acceleration is obtained at the 25 points of post-process shown in Figure 4 where Ai, Bi, Ci, Di and E_i are points under the girders lower flange along the left support, one quarter, mid-span, three-quarters of the span and right support, respectively.

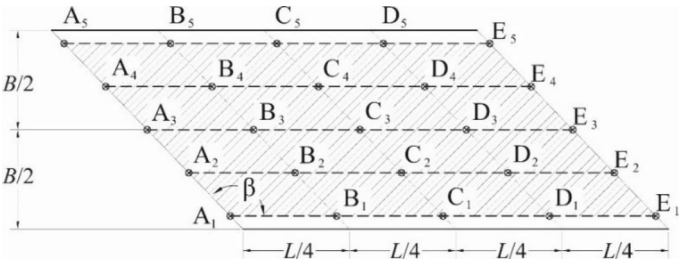

Figure 5. Post-process points.

The vertical response of the bridges is obtained under the circulation of the ten trains from the moving load model HSLM-A from Eurocode 1 (CEN 2022) in the speed range [144, V_{lim}] km/h every 3.6 km/h. The equations are solved in the time domain admitting modal superposition of the normal modes, including the contributions of modes with natural frequency lower than 30 Hz. In Figure 6 envelopes of maximum acceleration for the ten trains are represented at each postprocess point considering a progressively increasing upper limit V_{lim} from 200 km/h to 420 km/h. Only acceleration values higher than 3.5 m/s^2 are shown in colour in Figure 6. Each representation corresponds to the 90º straight case with full diaphragms for the Arroyo Bracea (left) and the Jabalón (right) bridges, respectively.

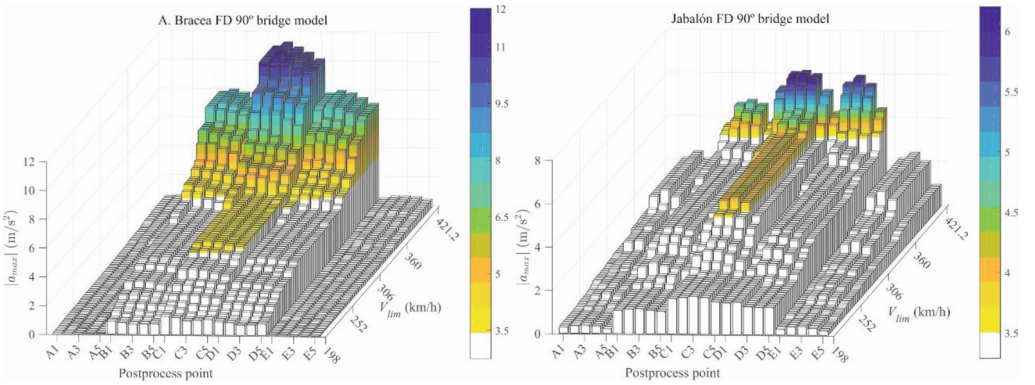

Figure 6. Maximum vertical acceleration at the 25 post-process points for different speed windows [200, V_{lim}] km/h for Arroyo Bracea and Jabalón bridges derived models (β=90º and FD configuration).

From the figures it can be observed that in Arroyo Bracea Bridge the maximum response takes place at the central section and at point C2, which corresponds to the second girder, underneath to the loaded track. In the case of Jabalón Bridge something similar happens but the acceleration at three-quarters of the span is more relevant. In both cases the maximum response increases as the upper speed limit considered does, following a stepped pattern as the speed window progressively accommodates the appearance of new resonances associated to the characteristic distances of the HSLM-A model. The maximum acceleration starts to exceed 3.5 m/s^2 for speeds higher than 255.60 km/h in the case or Arroyo Bracea and higher than 270 km/h in the case of Jabalón Bridge.

Next, in Figures 7 and 8 plan views of the previous 3D representations are shown, for Arroyo Bracea and for Jabalón derived models, for three levels of obliqueness and the three diaphragm configurations envisaged. In general, the maximum acceleration reduces with the skew angle. This is due to the increase of the fundamental frequency and associated resonant speeds, and their exceedance of the upper speed limit in the most skewed cases. On the other hand, there is not significant difference in the response between the FD and PD models. This implies that the effect fully connecting the transverse diaphragms is negligible, both in the shortest and longest bridges. The total absence of diaphragms does lead to moderately higher accelerations in the case of prominent skewness, especially in the shortest bridges.

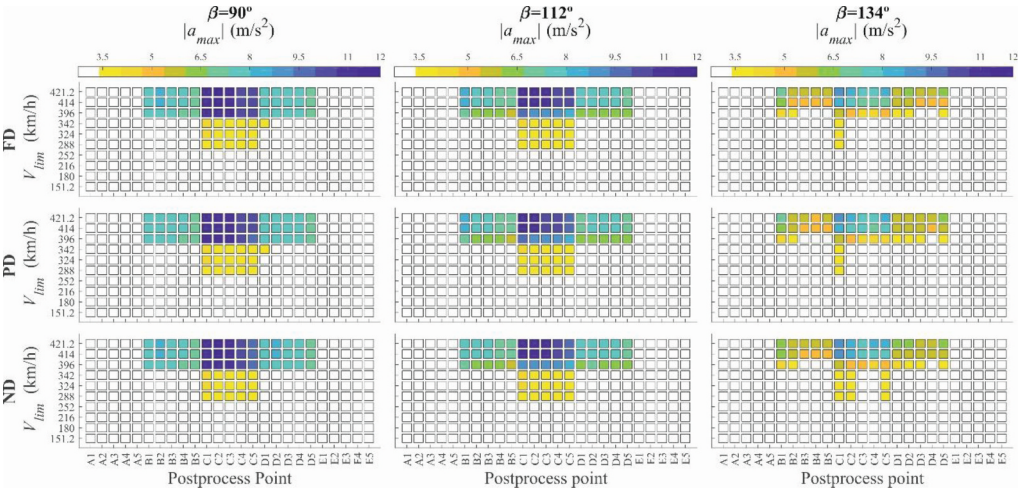

Figure 7. a_{max} at the 25 post-process points for different speed windows [200, V_{lim}] km/h for Arroyo Bracea Bridge derived models for β=[90º,112º,134º] and three diaphragm configurations.

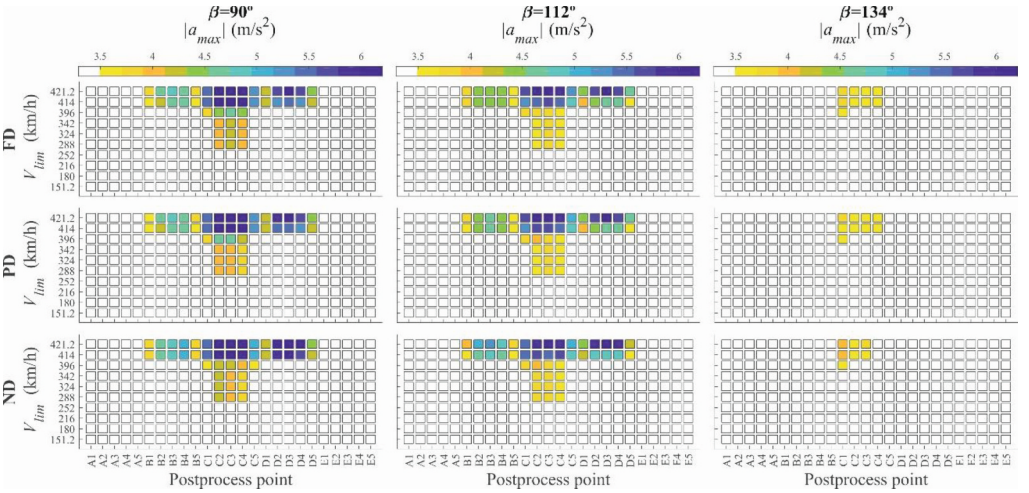

Figure 8. a_{max} at the 25 post-process points for different speed windows [200, V_{lim}] km/h for Jabalón Bridge derived models for β=[90º,112º,134º] and three diaphragm configurations.

5 CONCLUSIONS

Oblique girder railway bridges present a complex dynamic behaviour under railway traffic, due to the contribution to the vertical response of 3D modes of vibration. Transverse diaphragms at the end sections of SS girder decks are generally installed to

stiffen the cross-section, but on some occasions these elements are poorly built or do not exist. In this investigation the evolution of the lowest modal properties is investigated with the level of deck obliqueness for different diaphragm configurations and span lengths. Regarding the evolution of the first natural frequencies, the following is concluded:

- The fundamental frequency increases approximately 10% with obliqueness for the shortest bridges and highest obliquities considered. The effect of the skewness on the bridges with spans close to 25 m is lower (6%). The first torsion natural frequency also increases with the skew angle but to a lesser extent, the difference between shorter and longer bridges being smaller. The third frequency is almost unaffected by skewness.
- The second and third frequencies reduce when the diaphragms are not fully connected and further reduce in the total absence of these elements. This does not happen for the fundamental frequency, and it is especially visible in the case of the third transverse bending mode. This reduction is in general higher for shorter bridges and is approximately constant with the level of skewness.

Also, the maximum response in terms of vertical accelerations over the platform area is analysed in terms of these same parameters. The main conclusions extracted are the following:

- The maximum response increases as the upper speed limit considered does, following a stepped pattern as the speed window progressively accommodates the appearance of new resonances associated to the characteristic distances of the HSLM-A trains.
- The maximum acceleration reduces with the skew angle. This is due to the increase of the fundamental frequency and associated resonant speeds, and their exceedance of the upper speed limit in the most skewed cases.
- There is not significant difference in the response between the FD and PD models. This implies that the effect of fully connecting the transverse diaphragms to the slab is negligible, both in the shortest and longest bridges. The total absence of diaphragms does lead to a higher response in the case of prominent skewness in the shortest bridges.

ABSTRACT: The dynamic response of portal frame bridges is influenced by soil-structure interaction. Due to the complexity of the phenomenon, predicting its dynamic behaviour is difficult and time-consuming. For this reason, this interaction is rarely considered in the numerical analyses. However, recent research is providing further evidence about the importance of considering it to avoid discrepancies between numerical and experimental results. In this contribution, a study on an existing portal frame railway bridge is carried out. First, the determination of its modal parameters is addressed. Then, a 3D finite-element numerical model of the bridge is implemented considering the track, track-bridge-soil system. Perfectly matched layers are considered at the model boundaries. The results obtained with this model are employed to implement a simplified version on which the soil is substituted by a series of spring-dashpots. After calibration, a comparison is carried out with the experimental and numerical modes of the bridge.

1 INTRODUCTION

The need of transition to a more sustainable means of transportation is leading to an expansion in railway networks in a number of European countries. As part of the rail infrastructure, a typical solution to allow its adequate implementation are the portal frame underpasses. This type of bridge consists of a reinforced concrete rigid frame flanked by integral wing walls surrounded by an embankment. As could be expected, due to their integration within the soil, the dynamic response of portal frame bridges is strongly influenced by Soil-Structure Interaction (SSI) (Zangeneh 2018). However, simulating this complex interaction mechanism entails a high computational cost. For this reason, SSI is not always included in the numerical analyses dedicated to predicting the dynamic behaviour of railway bridges (Galvín 2022). In the case of portal frames, the large soil-structure contact area provides the bridge an additional capacity to dissipate energy that affects in a significant way its modal characteristics and response under passing trains. Therefore, neglecting the dynamic stiffness of the surrounding soil in the numerical models may be the source of the divergences found between numerical and experimentally measured modal parameters (Zangeneh 2021). This could lead to incoherencies in the optimisation design process and misinterpretations of the Serviceability Limit States of such structures, given that the mathematical modelling is not performed with sufficient precision. As including the effect of SSI tends to reduce the fundamental frequency (Martínez-Rodrigo 2018) and increase the modal damping, the corresponding resonant train velocity could be also minor than expected without SSI. Besides, due to the additional damping, the dynamic response of the bridges in resonance could be overestimated, leading to inefficient structural solutions (Salcher 2020). It is then essential to consider SSI in the dynamic analyses of portal frame bridges to predict their dynamic behaviour in an accurate manner. In this matter, as previous research has found, the effects of SSI on portal frames are not yet well

DOI: 10.1201/9781003483755-140

known. A key factor contributing to this aspect might be the lack of reliable simple models to simulate the SSI. In consequence, experimental-numerical validation of results on portal frames are seldom found in the literature (Zangeneh 2018).

In this contribution, a study on an existing portal frame is carried out with the following objectives: (i) to experimentally identify the modal parameters of the bridge and (ii) to implement a numerical model to simulate the modal behaviour of the structure with a reasonable computational cost. To this end, a 3D Finite Element (FE) model of the structure considering the track, the bridge and the surrounding soil is implemented and padded with Perfectly Matched Layers (PML) acting as absorbing boundaries to reduce the extension of the soil domain and reproduce the radiation of incident waves through the soil layers. This model is used to obtain impedance functions that will simulate the soil-bridge interaction in a subsequent simplified model. Finally, the calibration of the track and bridge parameters is carried out and a numerical-experimental comparison of the bridge modes is conducted. The work herein presented is organised as follows. In Section 2, the portal frame under study and the modal identification process are described in detail. In Section 3, the implementation of the numerical models of the bridge is explained. Section 4 addresses how SSI is implemented on the simplified model. In Section 5, the performance of this model is assessed, and in Section 6, the main conclusions of the contribution are summarised.

2 BRIDGE UNDER STUDY AND MODAL IDENTIFICATION

2.1 *The bridge*

The portal frame under study is located on the high-speed (HS) line Madrid-Sevilla, in the section between Ciudad Real and Brazatortas. A total number of three tracks pass over the bridge: two for HS traffic and one for conventional services. The underpass consists of a reinforced concrete rectangular box integral section. The most distinctive characteristic of this bridge is that it is divided along its width in two sections by means of a longitudinal joint. In this way, two coupled structures are found: one under the HS tracks, and another under the conventional traffic track. Figure 1 shows an image of the bridge. The dimensions of the structure can be found on Figure 2, where L = 8 m, H = 5.7 m, W_1 = 13.3 m, W_2 = 8.8 m, S_1 = 1.1 m and S_2 = 1 m. The dashed line represents the longitudinal joint.

Figure 1. The underpass object of study.

2.2 *Modal identification*

An experimental campaign was carried out in September 2022 with the intention to characterise the modal parameters of the bridge. The dynamic response of the structure was recorded using 27 piezoelectric accelerometers with a nominal sensitivity of 10V/g. The sensors were distributed on the inner face of the bridge slab as indicated in Figure 3: 18 on the top slab (shown in red); 6 at the walls at a height of 2.6 m (shown in yellow); and 3 on the floor (shown in blue). The dynamic response of the structure was recorded under the passage of 27 trains

and from the ambient vibration. This latter recording, acquired at a sampling frequency of 4096 Hz and of 3600 s of duration, was then used to determine the modal parameters of the bridge. The signal was decimated to 256 Hz and a high-pass Chebyshev filter of 1 Hz was applied. Then, an Operational Modal Analysis (OMA) was carried out.

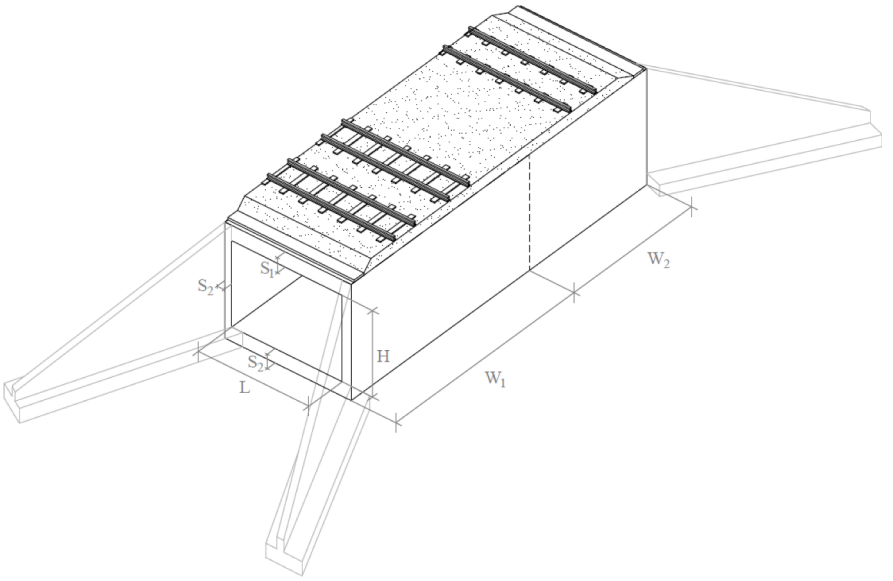

Figure 2. General view of the portal frame.

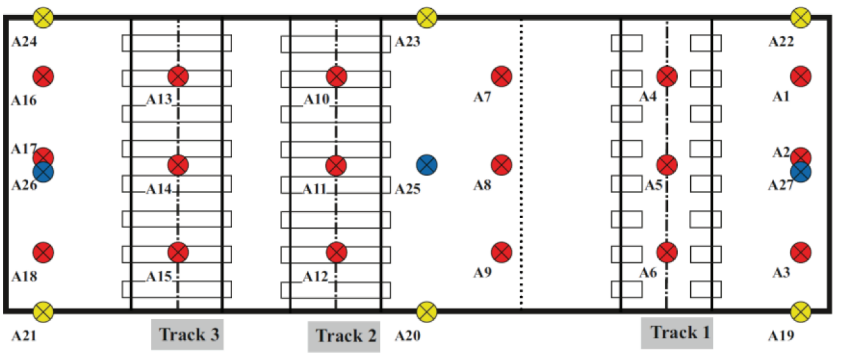

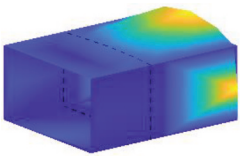

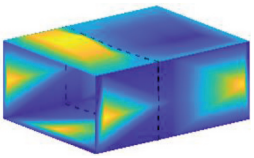

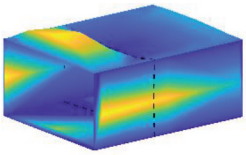

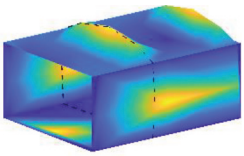

Figure 3. Schematic representation of the accelerometer layout.

The Enhanced Frequency Domain Decomposition (EFDD) method was used to identify the modes of the structure. The identification process presented several difficulties because of two factors. In the first place, the Singular Value Decomposition (SVD) plot generated with the ambient vibration data from the underpass led to unclear results, as the graphic representation lacked prominent discernible peaks that would typically indicate the presence of a structural mode of vibration in certain frequency ranges, notably in the interval between 20 and 30 Hz. For this reason, the bridge response recorded under the passage of 27 trains was also analysed. After a careful study of the Frequency Response Functions (FRF) from each accelerometer, two different trends were detected among the sensors on the top slab of the HS

section (A7 to A18) and those on top of the conventional one (A1 to A6). Specifically, the data drawn a clear pattern on which maximum acceleration peaks on the range from 20 to 30 Hz tended to occur near 24 Hz on the accelerometers located in the HS section, whereas maximum peaks were mostly detected around 27 Hz on the accelerometers on the conventional one. This confirmed what was previously obtained in the OMA. The reasons why this analysis was at first unclear were: (i) the soil interference in the measures probably incremented the noise captured by the sensors, and (ii) the partially uncoupled response of the two structures resulted into an unequal participation of the bridge sections in several modes. Due to this circumstance, the bridge has coupled or mixed modes, on which both the HS and the conventional sections have a noticeable deformation. However, in some cases, uncoupled modes, on which the participation of a single of the bridge sections (HS or conventional) is predominant are also detected. For that reason, the ambient vibration signals were also subjected to OMA and postprocess from three points of view, considering: (i) all the accelerometers (A1 to A27); (ii) those on the HS section (A7 to A18, A20, A21 and A23 to A26); and (iii) those on the conventional section (A1 to A6, A19, A22 and A27). This procedure allowed to ensure the identification of several uncoupled modes that were also noticeable when considering the signal with all the accelerometers. Table 1 lists the identified modes of the bridge. The first mode corresponds to the longitudinal bending of the HS section. In this case, the participation of the conventional part is negligible. In the second and third modes, the deformation on the conventional section is predominant. This situation is more accentuated in the third mode that, properly speaking, constitutes the fundamental bending mode of this bridge section. The fourth mode represents a transverse bending mode of the structure, on which both sections of the bridge participate.

Table 1. Modes identified with the OMA.

Mode 1	Mode 2	Mode 3	Mode 4
			
f_1 = 22.407 Hz	f_2 = 25.440 Hz	f_3 = 26.802 Hz	f_4 = 44.266 Hz

3 NUMERICAL PROCEDURE

The numerical procedure proposed is intended to assess the viability of reproducing the modal behaviour of the bridge with an admissible computational cost. To achieve this, first, a numerical model considering the track, bridge and the surrounding soil is implemented. In this step, the SSI is analysed and the results are used to configure a simplified version of the previous model.

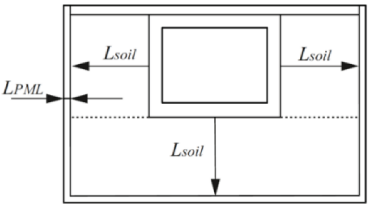

Figure 4. Dimensions of the soil and PML domains in the complete numerical model.

3.1 *Complete soil-bridge-track numerical model*

To begin with, a 3D numerical model of the bridge is implemented considering the tracks, the bridge, and the surrounding soil by means of the FE method. To avoid spurious wave reflections at the boundaries of the model, solid PML elements are implemented to absorb propagating waves. This allows the reduction of the soil domain and enables a faster computation. Sufficient soil and PML dimensions have been determined to ensure the adequacy and stability of the results, as L_{soil} = 6 m and L_{PML} = 0.5 m. Figure 4 shows the layout of the model.

Three layers of PML elements are considered. The mesh sizing in the PML region is discretised based on the frequency, as it is generally recommended to fit between 5 and 20 elements per wave length $\lambda = 2\pi \cdot c_s/\omega$ (Coronado 2016) being ω the highest detected natural frequency of the bridge. A homogeneous soil stratum is considered with C_s = 350 m/s, as at that propagation speed, the experimental modes were numerically predicted at their corresponding frequencies. The main characteristics of the model are listed on Table 2. A view of the model is available on Figure 6 (left). The soil volume under the bridge and the backfill forms a rectangular prism of dimensions 24 m × 49.1 m × 7.5 m. This model has 1,340,132 Degrees of Freedom (DOF).

Table 2. Mechanical properties of the model.

Entity	Part	Property	Symbol	Value	Unit
Track	Rail	Elastic modulus	E_r	$2.10 \cdot 10^{11}$	Pa
		Moment of inertia	I_r	$3\,038 \cdot 10^{-8}$	m^4
		Linear mass	m_r	60.34	kg/m
	Rail pad	Stiffness	K_d	$1.00 \cdot 10^8$	N/m

		Poisson's ratio	v_s	0.2	[–]
		Density	ρ_s	1950	kg/m^3

3.2 *Simplified model*

A simplified version of the previously described model is implemented. The key point of this approach is the inertial decoupling of the bridge-track system from the surrounding soil. Thus, in the simplified model, the soil is substituted by a series of linear spring-dashpots that simulate the dynamic interaction of the soil with the portal frame. A total number of 65 spring-dashpots are uniformly distributed over the whole area of the bridge-soil interface at the bridge walls and the bottom face of the box slab. At each point, they are arranged in the three spatial directions (X, Y and Z): one perpendicular and two tangential to the contact surface, as shown in Figure 5. Below, an image of the simplified model is shown in Figure 6 (right). This model has a total of 175,904 DOF, which is an important reduction in comparison with the complete version.

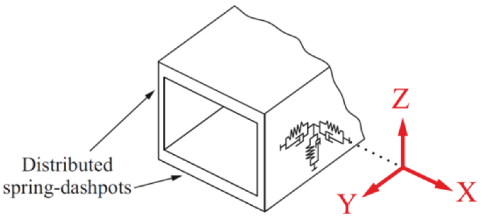

Figure 5. Distribution and orientation of the spring-dashpots.

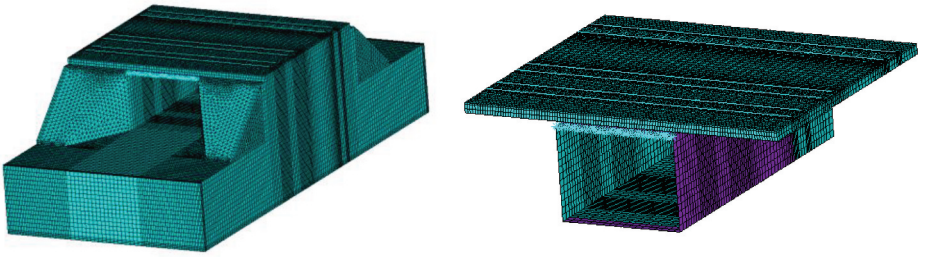

Figure 6. Views of the complete model (left) and the simplified one (right).

4 SSI ON THE SIMPLIFIED MODEL

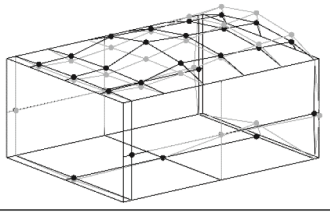
The calibration process herein described is aimed to configure the simplified model to reproduce the experimental modes of vibration of the portal frame seen in Section 2. With this objective, the first point to consider is to determine the properties of the spring-dashpots. Based on that, two different approaches are defined. The first one combines the SSI results obtained with the complete model with mathematical formulation provided in the literature to obtain the values for different sets of spring-dashpots. Instead, in the second approach, the totality of these elements are calibrated from the SSI data extracted from the complete model. In both cases, a final calibration is carried out on the mechanical properties of the portal frame to ensure a good approximation to the real modal bridge behaviour. Later in Section 5, an experimental-numerical comparison of the bridge modes is shown.

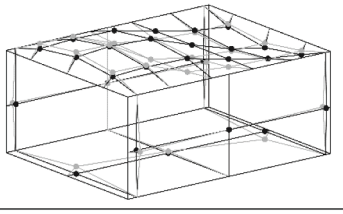
4.1 *Two different approaches*

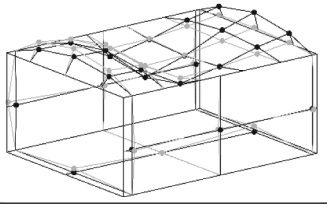
The first approach follows a similar methodology to that described in (Zangeneh 2018). Accordingly, the procedure required to assign values to the spring-dashpots varies depending on the zone of the bridge in question. Hence, for the elements at the bridge walls, stiffness and damping properties are calculated with the expressions provided in the previous reference. Still, a different method is used for the spring-dashpots located at the soil-bridge interface of the bottom slab. As it is well known, it is possible to model the interaction between a plate and the surrounding soil by means of frequency-dependent lumped impedances. Thus, the dynamic stiffness can be obtained based on a harmonic analysis performed on the complete model. In this line, a continuous distributed vertical harmonic force $F_s\ (\omega)$ is applied covering the span length of the frame on both rails of Track 2 (the centre track on Figure 3). Then, the displacement at each spring-dashpot location in the three spatial directions is obtained. Subsequently, the dynamic stiffness can be defined according to (Galvín 2022) as $K_{v,d}\ (\omega) = F_s\ (\omega)/U_s(\omega)$, where $U_s\ (\omega)$ is the displacement of the slab at each point, yielding the following properties of stiffness $K_v\ (\omega) = \mathrm{Re}\{K_{v,d}\ (\omega)\}$ and damping $C_v\ (\omega) = \mathrm{Im}\{K_{v,d}\ (\omega)\}/\omega$ on the system.

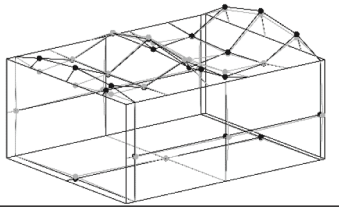
In the second approach, the method described above consisting in the harmonic analysis on the complete model is used to assign the properties to all the spring-dashpots, regardless of their location. In both approaches, the spring-dashpots are tuned to the fundamental frequency of the bridge (f_1, see Table 1).

5 RESULTS









A final calibration is conducted on the mechanical properties of the simplified model, particularly, on the ballast density and on the elastic modulus of the bridge slab. However, as previously seen, the structure presents an asymmetric modal behaviour: the participation of both bridge sections (HS and conventional) is unequal, leading to a predominant deformation of a section with respect to the other in certain modes. In light of that, the authors have found that differentiating the main properties of the slab and the ballast from both bridge sections is necessary to replicate in an accurate manner the experimental modal parameters of the structure. Thus, the final calibration is performed based on the two approaches proposed: the first one, that combines mathematical expressions and the SSI results of the complete model to assign the values to the spring-dashpots and the second one, that it is based entirely on the SSI results. The calibration process led to the results given in Table 3.

Table 3. Mechanical properties of the bridge before and after calibration.

Approach	Parameter	Bridge section	Nominal	Updated	Variation
Approach 1	Ballast density (kg/m^3)	Conventional	1950	1560	-20%
		High Speed	1950	1950	0%
	Slab elastic modulus (GPa)	Conventional	35.71	35.71	0%
		High Speed	35.71	27.50	-23%
Approach 2	Ballast density (kg/m^3)	Conventional	1950	1560	-20%
		High Speed	1950	2340	20%
	Slab elastic modulus (GPa)	Conventional	35.71	30.35	-15%
		High Speed	35.71	26.07	-27%

A modal analysis is performed to compare the modes calculated numerically and those identified experimentally. Table 4 shows the modal shapes in both cases. The numerical modes are represented in black, whereas the experimental ones are depicted in grey. For the sake of brevity, the images correspond only to the Approach 2, as the results from Approach 1 are similar.

Table 4. Comparison of the numerical and experimental modes of the frame, considering Approach 2.

Mode 1	Mode 2
	
Mode 3	**Mode 4**
	

The complete results regarding the frequency obtained with the two approaches are listed on Table 5. The Modal Assurance Criterion (MAC) calculated considering the accelerometers on the top slab (A1 to A18) is used to assess the relationship between the numerical and the experimental modes.

Table 5. Frequencies and MACs of the numerical modes computed with the two approaches considered.

Results	f_1	f_2	f_3	f_4	MAC_1	MAC_2	MAC_3	MAC_4
Experimental	22.407	25.440	26.802	44.266	-	-	-	-
Approach 1	22.459	25.561	27.490	39.445	0.675	0.716	0.455	0.778
Approach 2	22.492	25.432	27.011	37.515	0.629	0.563	0.628	0.767

6 CONCLUSIONS

In this work, the modal identification of an existing portal frame railway bridge is carried out. Then, a 3D FE numerical model is implemented considering the track, the bridge, and the soil. The complete model is padded with PML layers to reduce the computational cost. The SSI data obtained with this model is later used to configure a simplified version of it, in which the effect of the soil is simulated with distributed linear frequency-dependent spring-dashpots at the bridge-soil interfaces. Two alternative approaches are conducted to determine the properties of the spring-dashpots. In the first one, those located at the walls are calculated according to expressions given in the literature, and those located on the lower slab are computed from the SSI data obtained numerically with the complete model. In the second approach, the properties of the totality of the spring-dashpots are computed with this last method. Finally, a modal analysis is carried out on the simplified model considering both approaches. In summary, the next can be concluded:

- The combined analysis of the OMA results with the FRF data of the train passages led to a better understanding of the modal behaviour of the structure, heavily influenced by the effect of the soil and the division on two separated structures.
- The use of the simplified model led to satisfactory results, as, after final calibration, the numerical-experimental comparison resulted in a good approximation of the experimental modes of the bridge based on the two approaches considered.

These outcomes could be useful in future research devoted to predicting the dynamic behaviour of partially buried structures such as portal frames, and to assess the integrity, safety and sustainability of the railway infrastructure.

C. Caprani
Associate Professor, Department of Civil Engineering, Monash University, Melbourne, Australia

ABSTRACT: Finite-Element (FE) models, crucial for predicting structural responses, often rely on oversimplified assumptions, contrasting sharply with real-world data obtained through Structural Health Monitoring (SHM). To enhance the accuracy of these predictions, Bayesian updating techniques are employed, underscoring the significance of integrating comprehensive knowledge, including uncertainties in load and speed. These techniques refine structural models by merging prior engineering insights with SHM data. This paper delves into the latest advancements in Bayesian updating and their practical application for engineers. A case study featuring a simple beam model under a moving load showcases these methods' applicability, highlighting the importance of updating structural parameters by incorporating all available prior knowledge, especially regarding load and speed conditions. Our findings bolster ongoing efforts to ensure the reliability and safety of bridge structures amid evolving transportation demands.

1 INTRODUCTION

1.1 *Overview*

Bridges are integral to transportation networks, functioning as critical links that support communities and economies. Ensuring their safety and efficient operation is a paramount concern, particularly in light of the dynamic and often unpredictable nature of transportation demands. Traditional FE models, commonly employed for predicting structural responses, are often based on oversimplified assumptions about structural behavior. This discrepancy between theoretical models and real-world performance highlights the importance of SHM, which provides empirical data that often significantly deviates from FE model predictions (Ni & Chen, 2021).

1.2 *State-of-the-art in Bayesian updating*

SHM data is utilized to improve numerical models through the use of Bayesian model updating, which is becoming more and more common in structural engineering (Fang et al., 2022; Zhou et al., 2022). Although bridge designs can be effectively assessed using conventional techniques such as conjugate priors (Ni et al., 2020), the field is currently shifting towards more flexible methods that combine engineering knowledge with empirical data. Overcoming the drawbacks of the Metropolis-Hastings (MH) algorithm, the Hamiltonian Monte Carlo (HMC) approach has proven to be more effective for high-dimensional spaces and intricate parameter connections in structural models (Betancourt, 2019). The application of HMC in structural engineering has to be enhanced, according to recent research, which also emphasizes the significance of using suitable sampling techniques and taking parameter correlations and prior knowledge into account (Bouzas et al., 2022).

DOI: 10.1201/9781003483755-141

1.3 *Considering load uncertainties*

A critical aspect of this investigation is the consideration of parameter correlations and external factors that significantly influence structural performance. Bridge infrastructure deterioration modeling using Bayesian methods, as discussed in works by Mueller & Stewart (2011) often assumes independence between model parameters. However, as identified by Enright & Frangopol (1998) significant correlations between bridge deterioration parameters exist and should be addressed (Mueller & Stewart, 2011; Enright & Frangopol, 1998).

Research on bridge deterioration has also explored the impact of external factors such as traffic loading and environmental conditions on the deterioration process, highlighted the influence of external factors on bridge deterioration (Calvert et al., 2020). Moreover, efforts have been made to integrate these factors into deterioration modeling through multivariate regression modeling and seismic fragility methods. While the existing literature has made significant strides in understanding the multivariate dependencies and deterioration modeling of bridges, there is still a need for comprehensive studies that address the combined impacts of inherent and external correlations on Bayesian updating performance (Al-Rashed et al., 2023; Fujiu et al., 2022).

Studies show that vehicle loads, especially heavy vehicles, significantly accelerate pavement deterioration. This highlights the importance of accounting for these effects in predictive models (Bhandari et al., 2023). In addition, traffic loads influence the time-dependent bridge reliability, as evidenced by research on prestressed row box girder bridges (Biondini & Frangopol, 2016). Complex interactions of load, mass, construction type, materials, and environmental conditions all contribute to the overall structural integrity and performance of bridges, necessitating a comprehensive approach to modeling and analysis (Yang et al., 2018). Thus, when Bayesian updating is used for infrastructure modeling, an appropriate representation of load and speed uncertainty is needed to increase model accuracy and reliability. Considering these key factors, the updating process can enhance prediction accuracy.

1.4 *Contribution*

This study aims to fill the gaps in Bayesian updating of structural models by using non-conjugate priors to better represent multivariate correlations, as well as adding key explanatory variables such as load and speed to account for externalities and effects well. We illustrate the practical application of these techniques by performing a case study on a basic beam model under a moving point load, and highlight the importance of a thorough understanding of prior knowledge, especially for load and velocity conditions. Diving deeper into state-of-the-art Bayesian models, this review focuses primarily on HMC methods to address uncertainties in structural modeling. These uncertainties, when incorporated into Bayesian models, not only lead to an increase in the accuracy and applicability of predictions but also facilitate an investigation into the capacity of the HMC method to span complex parameter spaces. The complexity posed by this uncertainty is effectively navigated, providing valuable insights into the usefulness and effectiveness of advanced Bayesian sampling techniques in real-world design situations.

2 METHOD

2.1 *Bayes' theorem*

Finite element model updating (FEMU) can be considered a statistical problem. Using Bayes' theorem, measured data (D) are used to update the prior knowledge of parameters that take uncertainty into account:

$$P(\theta|D) = \frac{P(D|\theta)P(\theta)}{P(D)} \tag{1}$$

where, θ and $P(\theta)$ represent uncertain parameters, and the prior PDF for θ, respectively. D is the measurement or data, and the term $P(D|\theta)$ is the likelihood function that introduces the probability of the observed data (D) for specified model parameters (θ). $P(\theta|D)$ represents the posterior function. $P(D)$ is the normalization factor.

To gather prior information, experts can provide assessments and conduct experiments on a smaller scale in laboratories. This helps to quantify uncertainties associated with relevant parameters before any data is collected. To establish the likelihood function, we consider the equation that governs probabilistic model measurements and accounts for errors in model outputs. The focus on determining the likelihood function highlights the importance of accurately modeling the chances of observing the data given the model parameters, including how errors in the model's outputs are accounted for. This process is crucial for effectively updating the model parameters based on new data. Sampling methods are used to calculate the PDF of the posterior distribution (Ereiz et al., 2022). It can be difficult to obtain analytical solutions that accurately characterize the PDF of uncertain parameters. Thus, sampling methods are frequently employed in Bayesian model updating.

2.2 *Sampling method*

The HMC algorithm is a technique within the Markov Chain Monte Carlo (MCMC) framework, designed to improve sampling efficiency compared to methods like the MH algorithm. HMC uses gradient information to navigate the parameter space, allowing for informed steps and a higher acceptance rate with larger step sizes. This leads to samples with reduced interdependence and hence fewer samples are needed for accurate approximations. HMC is particularly effective in Bayesian analysis due to its ability to cover long distances in parameter space smoothly, despite requiring careful tuning of steps and step size for accurate approximations. (Duane et al., 1987; Baisthakur & Chakraborty, 2020).

The No-U-Turn Sampler (NUTS) addresses hyperparameter tuning challenges in HMC by dynamically selecting the number of leapfrog steps for each sample, enhancing the flexibility and efficiency of Bayesian model updating. As just one of the modern Probabilistic Programming Languages, *PyMC* facilitates the development of probabilistic models that incorporate real-world data from SHM. (Hoffman & Gelman, 2014; Fang et al., 2022).

2.3 *Convergence test and effective sample size*

In this study, the Gelman-Rubin statistic ($\hat{R}$) was employed to evaluate the convergence of the Markov chain algorithm (Gelman & Rubin, 1992). When the value of $\hat{R}$ approaches 1, it indicates convergence. Values greater than 1 suggest a lack of convergence (Gelman & Rubin, 1992).

The effective sample size (ESS) is a measure of the number of independent samples that provide information equivalent to truly correlated samples. An increased ESS denotes a more accurate and efficient parameter estimate. The effective sample size is influenced by the correlation between samples. When the samples in the MCMC series are correlated, the effective sample size is smaller.

In a system modeled using the MCMC method, introducing more uncertainties and complex relationships between priors can affect $\hat{R}$ and ESS. When more uncertain parameters are incorporated into a system that has been MCMC modeled, it introduces more complexity and variability into the simulation, which could lead to correlated samples in the MCMC chain.

In the context of the present study, the inclusion of load and speed uncertainty results in a higher correlation between subsequent samples because random variations in system

parameters make the subsequent state more reliant on the previous one. Despite the introduction of more complexity and variability into the simulation, we leverage state-of-the-art NUTS techniques to achieve high ESS and acceptable $\hat{R}$ values. This demonstrates the robustness of the approach in handling increased uncertainty while maintaining reliable parameter estimates. We thus provide a meaningful comparison between traditional MCMC and HMC for a typical structural engineering problem.

3 APPLICATION

We focus on a practical example in structural engineering with a beam being subjected to a moving point load, the goal is to assess how considering load uncertainties can affect updating uncertain parameters. Consider a 20 m long beam that is exposed to a moving point load (P = 100 kN) and has a flexural rigidity (EI = 200 MNm^2), shown in Figure 1. A closed-form function (Equation 2) using Macaulay's method calculates deflection at each desired point when the point load crosses the beam.

$$\delta = \frac{P\,L^3}{6EI}\left[a^3(1-x) - \langle a-x\rangle^3 + a(1-x)^3 - a(1-x)\right] \tag{2}$$

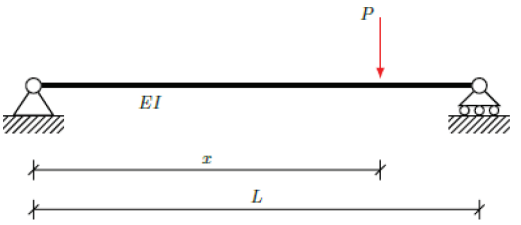

Figure 1. Beam and moving point load.

The Macaulay bracket symbol is represented by the notation $\langle a-x\rangle$. This mathematical notation is made to produce particular results depending on the sign of the phrase included within it. The term enclosed in the Macaulay bracket evaluates to zero when it is negative and to its true value when it is positive (Caprani, 2009). P stands for the point load's magnitude, a for the point on the beam where the deflection is important, and x for the place where the point load is traveling along
the length of the beam.

3.1 *Incorporating load magnitude and speed as uncertain parameters*

To understand how the beam behaves structurally, two additional factors that introduce uncertainty will be considered - the load's magnitude (P) and its speed (v). To model the deflection (δ), we use Equation 3 that takes into account these uncertain parameters:

In this equation, we use t to represent the time points when the deflection is measured. P stands
for the uncertain magnitude of the load, and v represents the uncertain speed at which the load is applied.

$$\delta = \frac{PL^3}{6EI}\left[a^3\left(1-\frac{vt}{L}\right) - \left\langle a-\frac{vt}{L}\right\rangle^3 + a\left(1-\frac{vt}{L}\right)^3 - a\left(1-\frac{vt}{L}\right)\right] \tag{3}$$

We acknowledge the importance of considering both the uncertainty in load and speed when analyzing how prior parameters correlate with sampling techniques. By incorporating these uncertainties into our analysis, we can thoroughly examine the structural behavior across various scenarios and provide a more precise representation of real-world conditions. We consider the uncertainty in P and v and compare the efficiency and accuracy of HMC sampling technique.

3.2 *Generating data*

For this application, simulated deflection data will be generated for five virtual sensors positioned along the beam from the known model. These virtual sensors are located at $0.25L$, $0.4L$, $0.5L$, $0.6L$, and $0.75L$ on the beam. At specific time intervals of 0.05 seconds, these sensors record the deflection (δ_m) of the beam. Artificial Gaussian noise was added to the deflections to reflect realistic measurement conditions as follows:

$$\delta_m = \delta + \varepsilon \tag{4}$$

where $\varepsilon \sim \mathcal{N}(0.0, 0.005)$ is a random variable with a normal distribution, indicating unbiased noise with a standard deviation of 5 mm.

To generate the simulated data, a point load is applied to move along the beam completely. During the traverse, 200 deflection values are simulated and recorded. This controlled virtual sensing provides the necessary data to accurately update the uncertain parameters of the beam using HMC-NUTS sampling. Figure 2 illustrates the theoretical and simulated measurements.

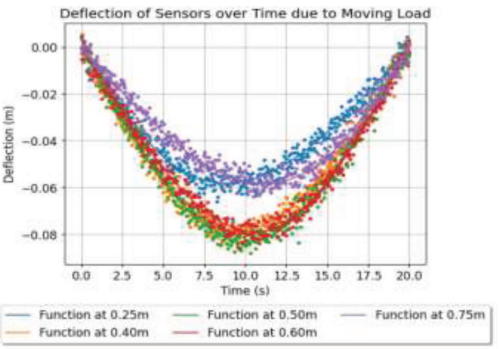

Figure 2. Function and data results plot.

3.3 *Priors and likelihood*

In engineering problems, using previous knowledge helps in establishing reasonable assumptions for uncertain parameters.

The case study models uncertain variables, EI and L, using a Beta distribution and a Normal distribution respectively. A non-conjugate prior for EI is used to account for engineering bounds. Reasonable limits are established through a Beta-distributed parameter, η. In the second phase, two additional load parameters, P and v, are introduced. P is modeled as a Normal distribution, while v is modeled as a Uniform distribution.

Table 1 summarizes prior distributions, including parameters, modes, and support. The likelihood function is a Normal distribution with a mean of zero and a Half-Normal distribution for modeling the standard deviation, ensuring non-negative values.

Table 1. The prior distributions.

Parameter	Distribution	Parameters	Mode	Support
EI (kNm^2)	Beta	$\alpha = 2$, $\beta = 3$	183300	(150000, 250000)
L (m)	Normal	$\mu = 20$, $\sigma = 0.01$	20	$(-\infty, +\infty)$
P (kN)	Normal	$\mu = 100$, $\sigma = 20$	100	$(-\infty, +\infty)$
v (m/s)	Uniform	$v_{min} = 0.75$, $v_{max} = 1.25$		(0.75, 0.125)

4 RESULTS

4.1 *Statistical results*

When load and speed uncertainty are introduced into the Bayesian updating process through NUTS, the convergence metrics $\hat{R}$ and ESS should be considered to make sure that the model works effectively. Parameter estimates are provided in Table 2. The $\hat{R}$ values are consistently close to 1 when load and speed uncertainty are taken into account. This suggests that even with these extra complications, NUTS is still able to successfully attain convergence. The durability of NUTS in managing complex scenarios with extra uncertain factors is demonstrated by the stability of $\hat{R}$ values, even with the increasing complexity of the model.

When load and speed uncertainties are taken into account, the effective sample size metrics, ESS-bulk and ESS-tail continue to have high values. This implies that NUTS can explore the parameter space efficiently. The preservation of high ESS values highlights the effectiveness of NUTS in sampling a wide range of the posterior distribution, even in a more complex model because of load and speed uncertainties.

Table 2. Comparison of parameter estimates without and with load uncertainties.

Parameter	Method	Mean	ESS Bulk	ESS Tail	$\hat{R}$
EI (kNm^2)	Phase 1*	200081.931	1759.0	2176.0	1.0
EI (kNm^2)	Phase 2**	190274.286	1589.0	2133.0	1.0
L (m)	Phase 1	20.009	1763.0	2279.0	1.0
L (m)	Phase 2	20.000	2503.0	2456.0	1.0
P (kN)	Phase 2	95.041	1635.0	2029.0	1.0
v (m/s)	Phase 2	1.000	2107.0	2327.0	1.0

* Without load uncertainties. ** With load uncertainties.

4.2 *Pair plots*

Pair plots of the NUTS sampling points offer a powerful visual depiction of the posterior distributions for important structural parameters, highlighting the effects of different situations. As shown in Figure 3, The data points for EI and L are closely clustered when load uncertainty is absent, demonstrating NUTS's ability to effectively sample from high probability density regions and provide accurate parameter estimations. Nevertheless, the data distribution within the pair plots noticeably widens with the introduction of load and speed uncertainty. The wider distribution of sample points that characterizes the phenomena does not imply a decline in sampling efficiency. Rather, it emphasizes how flexible the algorithm is in accommodating the growing unpredictability of the system, encompassing a broader range of potential results. This broader scope is especially important for structural engineering, where

it is crucial to evaluate the performance of structures realistically under a variety of unpredictable circumstances in order to guarantee resilience and safety.

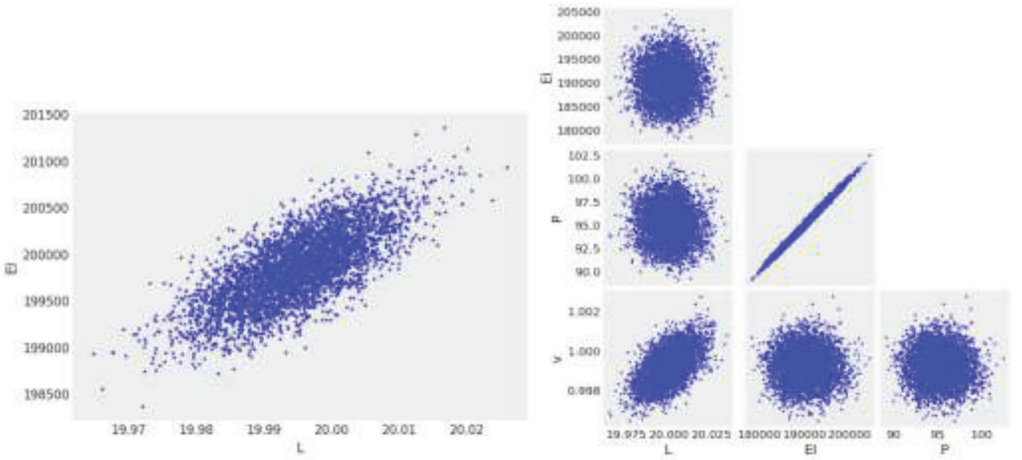

Figure 3. Pair Plots: (a) Without; (b) With load uncertainties.

4.3 *Posterior probability density functions*

Figure 4 shows the resulting posterior density and trace plots for uncertain prior parameters. The dotted or dashed lines in the trace plots represent individual traces of the sampling chains. In the presence of uncertain loads, NUTS has shown stability and strong convergence properties in producing reliable chains. All the trace plots show good convergence. This consistency suggests that the NUTS method is capable of managing the complexities inherent in these posterior distributions. The model updates that take into account deeper knowledge of load dynamics and actual condition are well-founded, and the resulting parameter estimations are reliable and representative of the underlying physical processes.

In our Bayesian analysis, as depicted in Figure 5, the findings underscore a broader methodological insight: sometimes, more complex models can yield better sampling results. This is exemplified in the posterior distributions for parameters such as L and EI. The observed variations in these distributions, particularly for EI are not so much about the specifics of load and speed uncertainties, but rather about how increased model complexity can lead to significant changes in parameter estimations. For instance, the noticeable broadening in the posterior distribution of EI, which implies a larger standard deviation and the shift in its mean value from 190,274 kNm² to 200,082 kNm² suggest a heightened sensitivity to model nuances and indicates increased uncertainty or variability in EI. This could imply a broader range of plausible stiffness characteristics than previously considered, a finding that is crucial for understanding the robustness of structural designs. The long tails of the distribution, indicating a non-negligible likelihood of extreme values, further exemplify how complex Bayesian models can reveal crucial insights into parameter behaviors that simpler models might not capture. Due to the function within the structural system under study, L has less sensitive to changes in load, as indicated by the relative stability of the mean. The HDI's wider distribution, however, highlights the necessity of taking a wider range of possible outcomes into consideration even for parameters that seem to be stable. This is especially relevant for structural engineering applications, where accurate load-bearing capacity calculations are critical to guaranteeing safety and adhering to design guidelines.

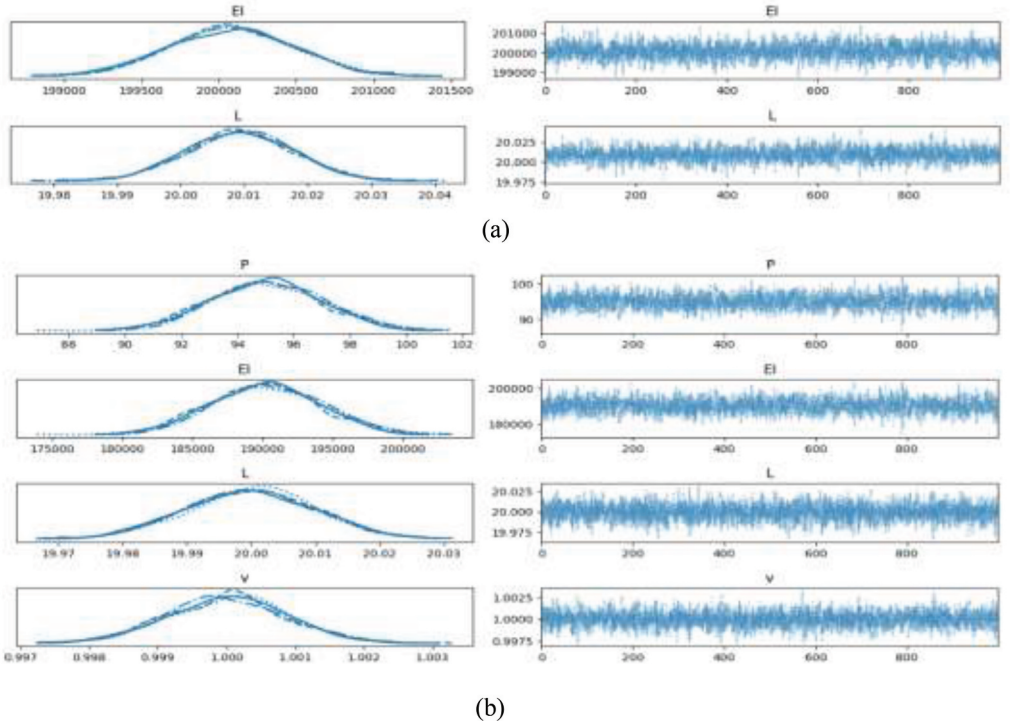

Figure 4. Comparison of posterior density and trace plots: (a) without, and; (b) with load uncertainties.

5 CONCLUSION

This study demonstrates the effectiveness of updating Bayesian models in bridge infrastructure evaluation by combining engineering ideas with data from structural health monitoring in a sophisticated way. By employing sophisticated MCMC methods, such as the NUTS, it enhances Bayesian inference by providing adaptable uncertainty representations via non-conjugate priors.

Our results demonstrate the importance of considering a wide range of uncertainties and complexities in the evaluation of structural parameters. The impact of various uncertain

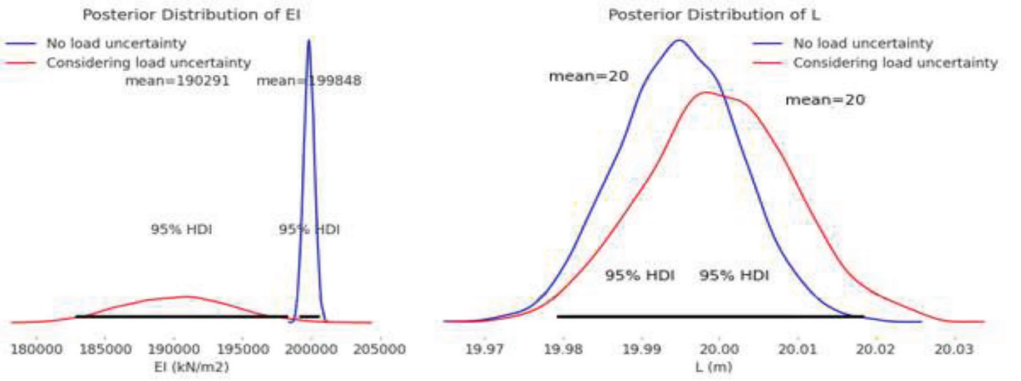

Figure 5. Posterior results comparison.

factors on the posterior distributions of key parameters illustrates the necessity of a comprehensive approach in modeling. This inclusive modeling strategy not only provides a more accurate representation of real-world conditions but also enhances the reliability of our predictions and assessments in structural engineering.

We illustrate how these Bayesian approaches improve uncertainty quantification and preserve strong convergence diagnostics using a case study of a beam subject to varying stresses. This emphasizes the necessity of contemporary, cohesive analytical frameworks in structural engineering that combine theoretical concepts, empirical data, and prior knowledge.

J. Qvisen
Proxion Oy, Finland

A. O'Connor
Department of Civil, Structural & Environmental Engineering Trinity College, Ireland

ABSTRACT: This study introduces an innovative methodology for calibrating road traffic load models on embankments using bridge weigh-in-motion (bWIM) data, focusing on developing a rapid and reproducible calibration technique, targeting the calibration of new geotechnical load models introduced in the second generation of the Eurocode standard prEN 1991-2. While the study does not aim for final model calibration, it lays the foundation for future extensive calibrations using a broader dataset and advanced reliability-based data analysis. The study is a part of the ongoing efforts of the IABSE Task Group 1.10, established in January 2023, to integrate road traffic data into bridge research, design, and assessment.

1 INTRODUCTION

This article presents a novel methodology utilizing Bridge Weigh-in-Motion (bWIM) measurements to evaluate and assess load levels on road embankments. This approach facilitates the initial calibration of newly proposed load models for geotechnical structures as outlined in the second generation of the Eurocode standard, prEN 1991-2.

While this study does not aim to achieve the final calibration of the load models, it introduces a rapid and reproducible method for preliminary calibration. Comprehensive and final calibrations will incorporate a broader data selection and employ more sophisticated, reliability-based data analysis techniques.

This publication is the inaugural article in a series representing the work of IABSE Task Group 1.10, established in January 2023. The project's primary goal is to foster a platform for exchanging knowledge and enhancing the understanding of the benefits of applying road traffic data in bridge research, design, and evaluation.

2 TRAFFIC LOAD MODELS IN 1ST GENERATION OF EUROCODE

2.1 *Traffic load model for bridge design*

The primary road traffic load model for bridge design in the Eurocode is Load Model 1 (LM1), comprising tandem loads (TS) and uniformly distributed loads (UDL). Specifically, the tandem load is 600 kN on lane one and 400 kN on lane two, while the UDL is 9 kPa for lane one and 2.5 kPa for lane two, as specified in EN 1991-2.

Additionally, the Eurocode introduces a frequent load model with a one-week return period. This model is derived by adjusting tandem loads with a factor of α_Q = 0,75 and ULD with α_q = 0,4., given in EN 1990 Annex A.2.

DOI: 10.1201/9781003483755-142

Initially calibrated using beam elements for bridge structures, LM1 has, over a decade of application, shown to represent actual traffic loads effectively, particularly when values are tailored in the National Annex to reflect local traffic conditions. However, LM1 might overestimate static traffic loads for short influence lines, offset by greater dynamic amplification under traffic flow. Conversely, it may underestimate the negative moments in small to medium-length continuous bridges under heavy special transportations. These limitations can be addressed by Load Model 3 (LM3), as delineated in Annex A of EN 1991-2. LM1 tends to be overly conservative for very long spans compared to simulated traffic flows.

2.2 *Traffic load model for geotechnical structures*

The same LM1 is currently employed for geotechnical structures, such as embankments and retaining walls, as per the Eurocode. The highly concentrated nature of this load model, characterized by two 300 kN axles with 1.2 m axle spacing, has drawn criticism, particularly in regions with soft soil conditions. Additionally, some member nations have opted not to apply LM1 for embankments, choosing instead to retain their national load models.

3 TRAFFIC LOAD MODELS IN 2ND GENERATION OF EUROCODES

3.1 *Traffic load model for bridge design*

In the second generation of the Eurocodes, the Load Model 1 (LM1) remains unchanged for bridge design. This decision reflects the consensus on LM1's adequacy and flexibility to accommodate national calibrations through the National Annex, ensuring it meets specific local requirements.

3.2 *Traffic load model for geotechnical structures*

The second generation of the Eurocode, specifically prEN 1991-2, introduces two new load models for geotechnical structures. The first model, designated for the area behind bridge abutments, applies a patch load of 600 kN over a 5m x 3m area (mirroring the Tandem System of LM1 on lane 1) combined with a uniform load of 9 kPa on the remaining embankment areas.

A simplified load model is proposed for geotechnical structures capable of redistributing loads, such as retaining walls. This model comprises a 20 kPa load on one lane (3m wide) and 9 kPa on the additional lanes. Both models offer the flexibility of adjustment in the National Annex of prEN 1991-2, allowing customization to local conditions.

This study analyses these new geotechnical load models against traffic loads measured on select Finnish roads. The analysis utilizes three sets of week-long traffic data collected via Bridge Weigh-in-Motion (bWIM) systems. The datasets represent diverse traffic scenarios: Traffic 1 embodies one of the heaviest traffic flows observed in the Finnish road network, Traffic 2 represents typical traffic conditions, and Traffic 3 highlights a road section regularly used by special transportation vehicles. Traffic 1 was measured in the year 2018, and Traffic 2 and Traffic 3 were measured in the year 2014.

4 MEASURED TRAFFIC LOADS

4.1 *The program developed for the study*

This study employs a novel program to analyze two-lane traffic over influence lines of varying lengths. This analysis method effectively captures the weight-time history of traffic over specific lane lengths. Utilizing this approach, the program determines and records the maximum weights observed during the measurement period for single-lane and simultaneous two-lane scenarios. These data points are documented in an Excel file for detailed subsequent analysis.

Additionally, the program tracks and records the axle configurations of vehicles that contribute to the most significant loading effects. This feature is precious in identifying the impact of various vehicle types on traffic load patterns.

The traffic data are imported into the program in a standardized format, which makes it easier to analyze and compare different datasets. The development of this standardized data format is a collaborative effort led by IABSE TG1.10, which is committed to creating tools that utilize WIM data effectively in the design and assessment of bridges.

4.2 *Limitations of the study*

The authors recognize that further work is essential to refine the calibration of load models for inclusion in the National Annex. This study provides only a snapshot of traffic load scenarios, capturing the most extreme loading conditions observed during the one-week measurement period. These results must be extrapolated using probabilistic methods for a more extended return period to achieve a comprehensive understanding.

In this analysis, real-time traffic data were utilized for both lanes. Future studies are planned to introduce elements of randomness into the one-week bWIM data to simulate varied traffic conditions more accurately. It is important to note that this study does not encompass exceptional design scenarios, such as those involving accidents leading to stationary heavy vehicles on a lane. Such scenarios require separate consideration due to their unique impact on load distributions.

4.3 *Hidden safety in the load models*

This study reveals that the heaviest measured loads typically originate from vehicles operating under special permits, a trend particularly noticeable in the Traffic 3 dataset. It is essential to recognize that the load variation from special transportation is generally limited, as these vehicles tend to adhere strictly to the load limits specified in their permits. Additionally, the routes for the heaviest special transportations are often carefully planned, avoiding the most adversely impacted travel lines on roads and bridges. In design load models, the load is uniformly spread across the entire width of the carriageway and hard shoulders, enhancing the model's reliability.

4.4 *Results for the example data*

Figures 1 to 3 illustrate the highest, mean, and 20th highest measured weights for Traffic 1, Traffic 2, and Traffic 3, respectively. The measurement period for the traffics were one week and only heavy vehicles weighing over 10 tons were included in the measurements. In these graphs, red represents data for lane A, blue for lane B, and black indicates the weights for both lanes combined. Figures 4, 5, and 6 focus on the highest 20 loads for loaded lengths up to 30 meters.

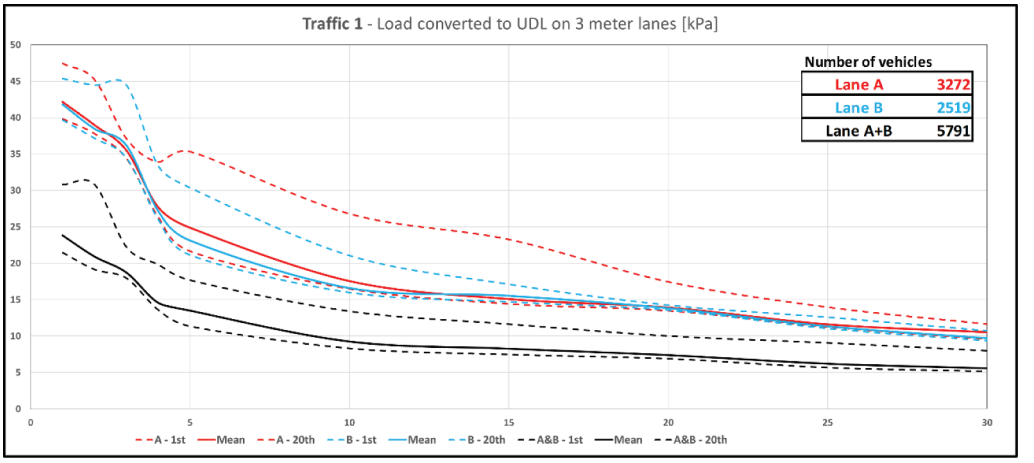

Figure 1. Traffic 1: Measured loads [kN/m^2] for 1 m. . .30 m loaded length.

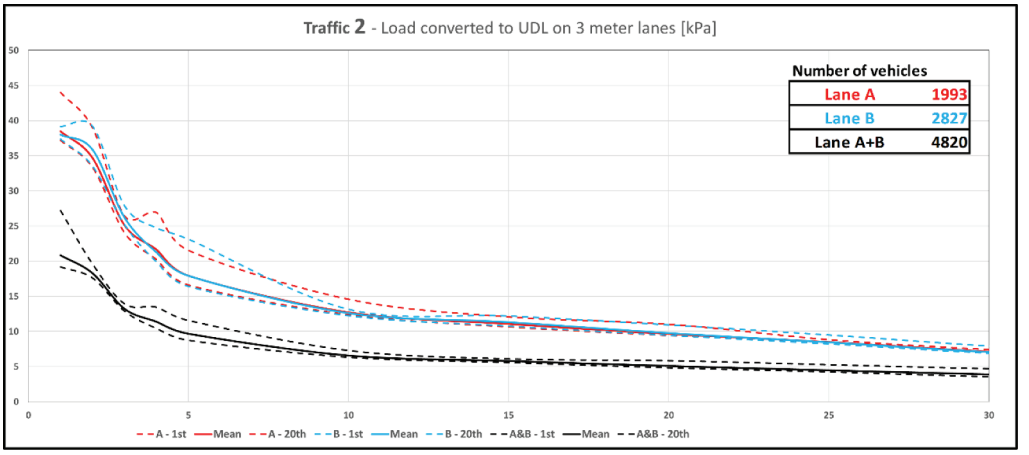

Figure 2. Traffic 2: Measured loads [kN/m^2] for up to 1 m. . .30 m loaded length.

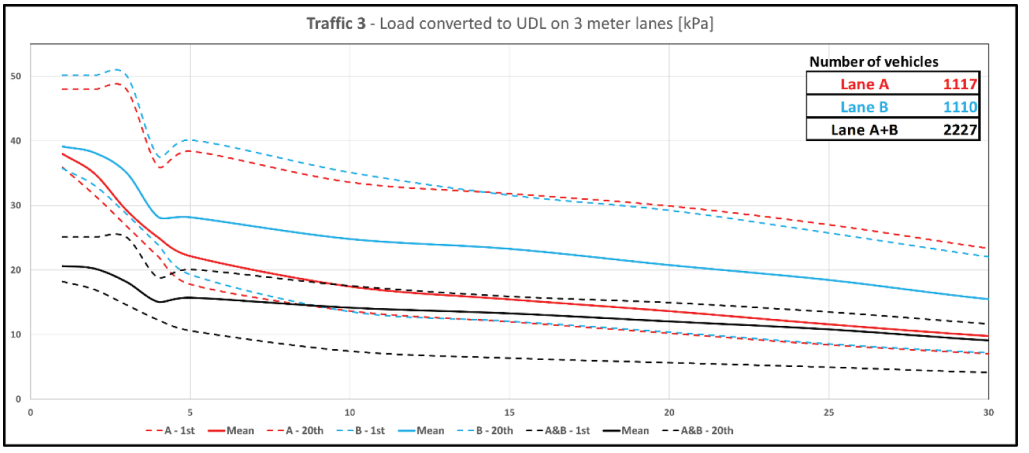

Figure 3. Traffic 3: Measured loads [kN/m^2] for up to 1 m. . .30 m loaded length.

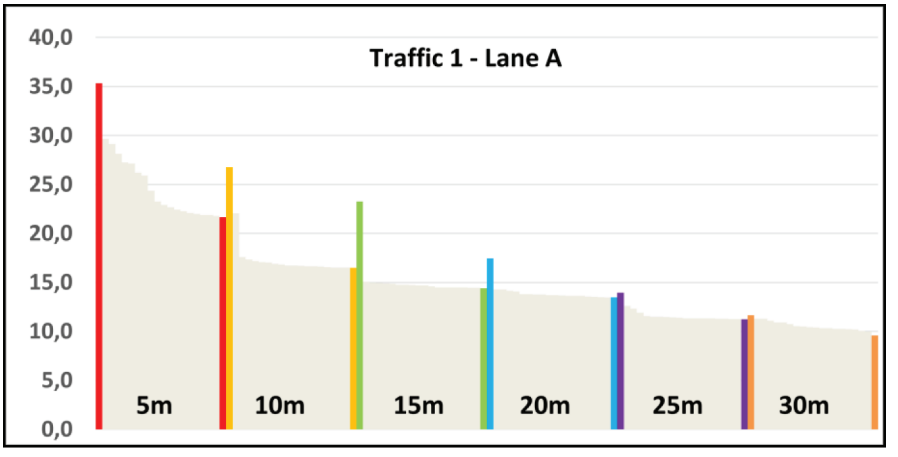

Figure 4. Traffic 1 (lane A): Top 20 measured loads [kN/m^2] for loaded lengths 5 to 30m.

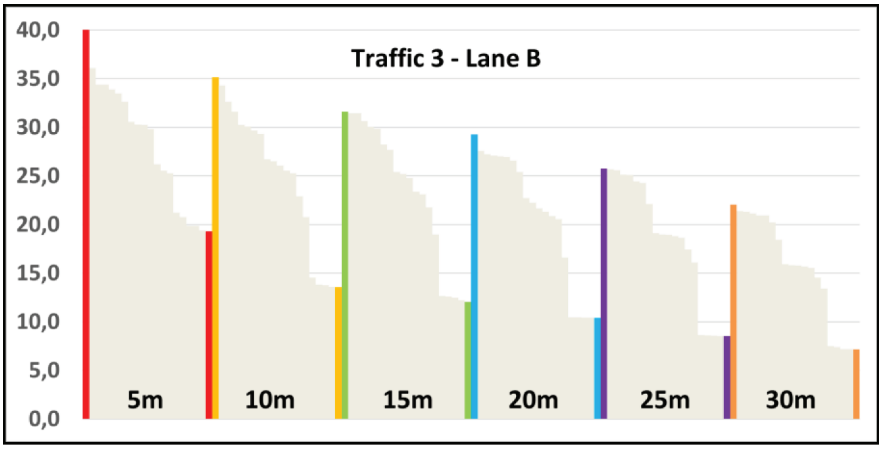

Figure 5. Traffic 2 (lane B): Top 20 measured loads [kN/m^2] for loaded lengths 5 to 30m.

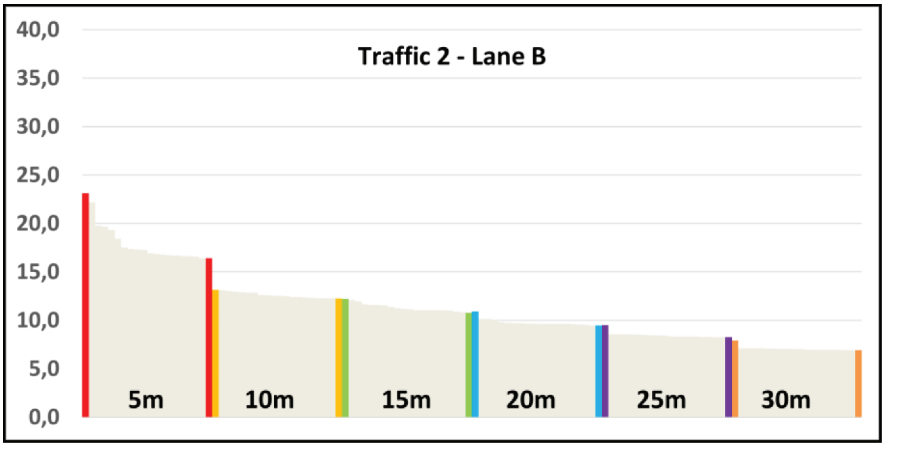

Figure 6. Traffic 3 (lane B): Top 20 measured loads [kN/m^2] for loaded lengths 5 to 30m.

Figures 7, 8, and 9 are included to draw a direct comparison between bWIM data and the Eurocode's frequent load model, which plays a significant role in the serviceability design of bridges. This comparison is beneficial because the time frame of our measurements matches the expected return period of this frequent load model. The axle configurations of vehicles that result in the highest loads are illustrated in Table 1, giving insights into vehicles that produce the most significant load impacts.

4.5 *Notes from the preliminary results*

4.5.1 *Figures 1 to 3*

The new 40 kPa load model for a 5-meter lane section in geotechnical structures is likely sufficient for even the most severe special transportation conditions. This assessment is based on the stable load magnitude and relatively consistent axle variation in these transportations. An increase in the load magnitude is not currently projected, as the existing bridges' load capacities tend to dictate these limits.

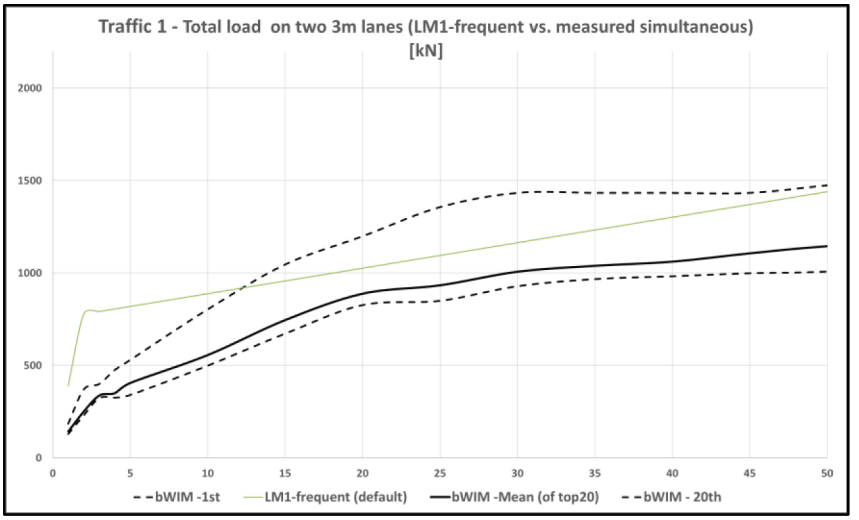

Figure 7. Traffic 1 (two lanes): comparison to LM1-frequent.

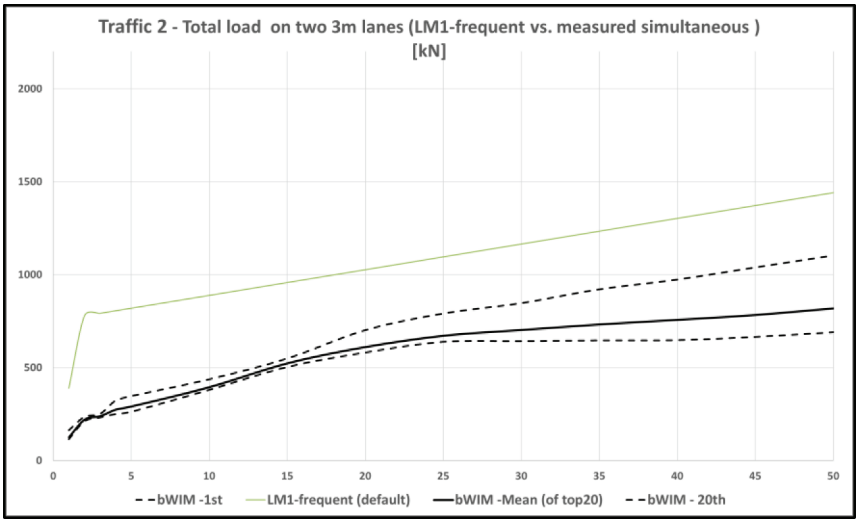

Figure 8. Traffic 2 (two lanes): comparison to LM1-frequent.

The simplified 20 kPa (one lane) and 9 kPa (other lanes) model appears appropriate for regular traffic. However, it may need adjustment for special transportations depending on the severity of their line of travel.

4.5.2 *Figures 4 to 6*

Traffic 1 reveals several high-load occurrences, yet they remain below the 40 kPa level (for 5 meters) of the newly introduced geotechnical load model, suggesting its adequacy. In contrast, Traffic 2 exhibits lighter loads, easily accommodated by the new models. Traffic 3, however, with its significant special transportation presence, frequently exceeds the bounds of the simplified model over distances up to 30 meters.

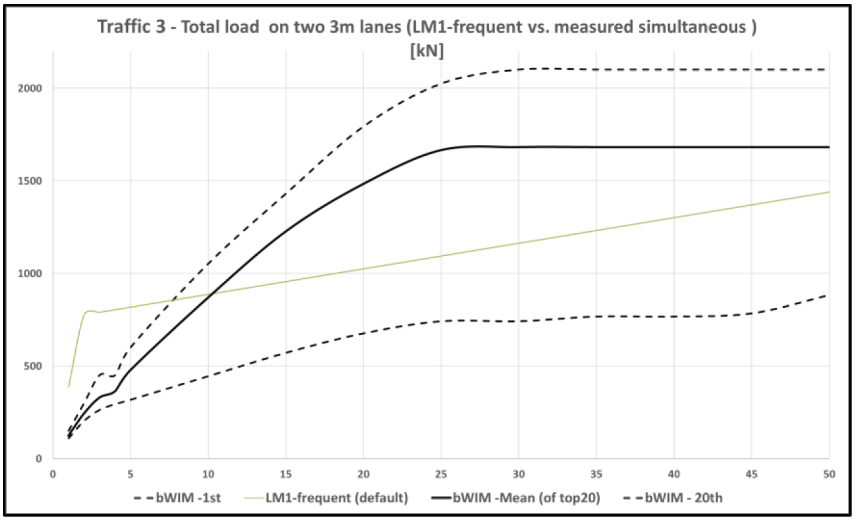

Figure 9. Traffic 3 (two lanes): comparison to LM1-frequent.

Table 1. Axle configurations causing the most adverse loads.

140-190	ooo--oo--oo--o	140-200	o--oo--oo--oo		
	o--ooo--oo--oo		o--oo--oo--o--o		
200	o--ooo--oo--o--oo--ooo		o--oo--ooo--o--o		
	o--o--o--o				
	o--ooo--oo--ooo				

4.5.3 *Figures 7 to 9*

These figures compare measured traffic weights with the Eurocodes' frequent load model based on a one-week return period. For regular traffic flows (Traffic 1 and 2), the measured peak loads may occasionally be slightly above the usual design load model with specific measured lengths but without significant cause for alarm. Special transportation, however, might require additional measures, such as integrating special vehicle types mentioned in Annex A of EN 1991-2.

4.5.4 *Table 1*

As shown in Table 1, Traffic 1 and Traffic 2 mainly comprise standard vehicles commonly used in Finland, known for being heavier than those in Central Europe. Traffic 3, however, is

marked by a range of special transports, including extremely heavy vehicles with up to 16 axles and weights surpassing 200 tons.

4.5.5 *Final calibration of new load models*

For the calibration of the new load models to be accurate, a broader array of bWIM data should be examined. The introduction of suitable probabilistic methods is also necessary to ensure the models align with the return periods of the structures being designed.

Given that Finnish traffic presented in this study is often heavier than in other European countries, some countries might need to modify the default values in the National Annexes to suit their specific traffic profiles.

5 OTHER USE CASES FOR THE WIM-DATA

The developed program can be tailored to examine more complex influence lines, which is crucial for accurately calibrating the static load model LM1, facilitating comparisons between bridge responses and the LM1 bridge design load model across a diverse range of bridge types and spans.

Additionally, the program can be expanded to perform comprehensive fatigue assessments, incorporating methods like the reservoir technique and Miner's linear summarization, which would allow the calibration of fatigue load models as per Eurocode and the development of fatigue models based on measured traffic data (FLM 5 in EN 1991-2).

6 IABSE TG 1.10

The initiatives of IABSE TG1.10 are expected to make substantial contributions to bridge engineering. While part of this effort involves enhancing load models, the broader goal is to create advanced tools for quick and accurate calibration of bridge loads using WIM data. This advancement will undoubtedly enrich the practice of bridge engineering, making WIM measurements a more integral part of the process.

7 CONCLUSIONS

The study outlined in this article gives a good starting point for more comprehensive research aiming to calibrate the new load models in prEN 1991-2.

It is important to note that Eurocode load models are specifically derived with certain traffic conditions, such as the heavy traffic in Auxerre, which influenced the ENV models. These models may not be entirely suitable for other road networks, possibly too conservative or not conservative enough in some (rare) instances. Proper calibration of these models is crucial for improving the reliability of bridges and the sustainability of infrastructure projects. The 2nd generation Eurocodes, replacing the 1st generation by 2028, provide a good opportunity for this calibration.

ACKNOWLEDGEMENTS

This research project was carried out under the funding of the Finnish Transport Infrastructure Agency. The Bridge weight in motion – monitoring and data extraction – was performed by Trafikia Ab and the Finnish Transport Infrastructure Agency.

Torsion effects in Super-T girder grillage analysis

J.W. Ngan & C.C. Caprani
Monash University, Clayton, Melbourne, Australia

M. Melhem
The Department of Transport and Planning, Melbourne, Australia

ABSTRACT: In a grillage analysis of Super-T girder bridge decks, linear-elastic analysis considering full torsion stiffness may not be appropriate for ultimate limit states. For members subjected to compatibility torsion, typically in Super-T girder bridge decks, the onset of cracking at the torsion cracking moment (T_{cr}) results in reduced stiffness as loads increase towards the ultimate limit case. Consequently, the section experiences lower torsion moments (non-linear behavior) that redistribute through greater bending moments. Therefore, as an alternative, a linear-elastic grillage analysis model considering a reduced proportion of torsion stiffness can help avoid this phenomenon of overestimating torsion and underestimating moments in grillage models. This study evaluates the effect of varying torsion considerations in grillage analysis. To represent the complete range of designs possible for a Super-T PSC member, it is necessary to analyze bridge decks with feasible lower and upper spans of a standard Super-T section. For the range of feasible spans, the section cracking torsion moment is first quantified, noting the amount of beneficial prestress force present. Following, grillage analysis is performed - each with increasing proportions of torsion stiffness from 0 to 100% of torsion constant, J for longitudinal members (Super-T girders). Torsion cracking resistance is then quantified for each feasible span. The results showed that most proportions of torsion stiffness did not lead to the torsion moment exceeding the torsion cracking moment. Overall, the results show that a range of 10 - 40 % of torsion constant J would allow bridge designers a good balance between the need for torsion design - minimizing conservatism in longitudinal bending moments.

1 INTRODUCTION

Torsion in structural members can redistribute when torsional stiffness of members is reduced from onset of excessive torsion cracking. This phenomenon is typically described as torsion compatibility where the torsion can be distributed to moments in the longitudinal direction of structural members (Wyche, 2000). Like many bridge decks, Super-T girder bridge decks are subjected to torsion compatibility and must consider torsion designs.

In a grillage analysis of Super-T girder bridge decks, linear elasticity considering full torsion stiffness may not be appropriate for ultimate limit states. For members subjected to compatibility torsion, typical in Super-T girder bridge decks, the onset of cracking at the torsion cracking moment T_{cr} results in a reducing stiffness as loads increase towards ultimate (Collins and Mitchell, 1997). Consequently, the section experiences lower torsion moments (non-linear behavior) that redistribute through greater bending moments.

As an alternative, linear elasticity considering a reduced proportion of torsion stiffness could be done in a grillage analysis to emulate this phenomenon shown in Figure 1. Previous work of Wyche (2000) suggests that 20% of the torsion constant, J could replicate a torsional moment of $0.25\phi T_{cr}$. However, this work considered the results from only one 34 m spanning

DOI: 10.1201/9781003483755-143

bridge with 1.5 m deep Super-T girders designed for T44 and HLP320 loading (Austroads, 1992). Therefore, it remains to find the appropriate proportion of torsion stiffness that achieves this goal for the entire suite of Super-T girders designs to M1600 loading for ultimate limit state.

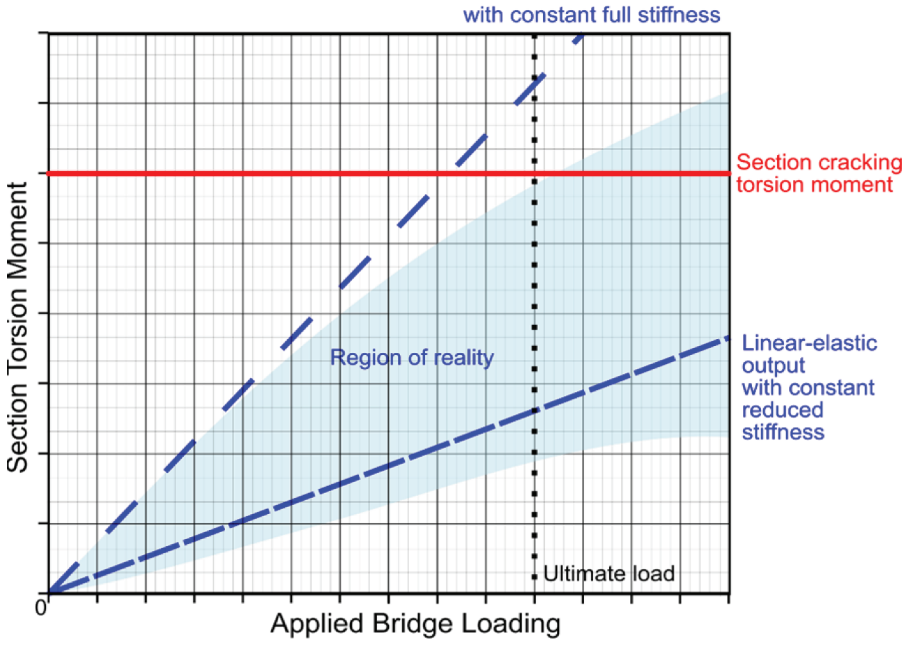

Figure 1. Section torsion moment vs. applied bridge loading in concrete bridge decks is a non-linear phenomenon at ultimate loads (adapted from Collins & Mitchell, 1997).

2 METHODOLOGY

To represent the complete range of designs possible for a standard Super-T girder section, it is necessary to analyze bridge decks with the feasible lower and upper spans of a standard section (Melhem et al., 2019). To investigate the maximum appropriate proportion of torsion stiffness that emulates the non-linear behavior (Figure 1), for each of these $5 \times 2 = 10$ spans:

- Quantify the section cracking torsion moment, T_{cr}, noting the amount of beneficial prestress present.
- Run multiple grillage analysis, each with increasing proportions of torsion stiffness from 0 to 100% of J for the longitudinal members (Super-T girders), for a representative bridge deck and ultimate design loading.

For this, the use of scripting languages (Python) and packages enabled the grillage analysis to be completed quickly and efficiently. The work of this paper feeds of existing freely available open-source packages such as *OpenSeesPy* (Zhu et al., 2018) and *sectionproperties*.

2.1 *Super-T properties*

The Super-T girder properties were directly obtained using *sectionproperties* package. An example stress analysis (principal stresses) output using the packages is shown in Figure 2. The geometry of Super-T sections was chosen as per designations (T1 to T5) with 2.1 m flange width, 75 mm flange depth, and 180 mm overlay slab. The materials chosen for concrete of beam and slab are 65 MPa and 40 MPa respectively.

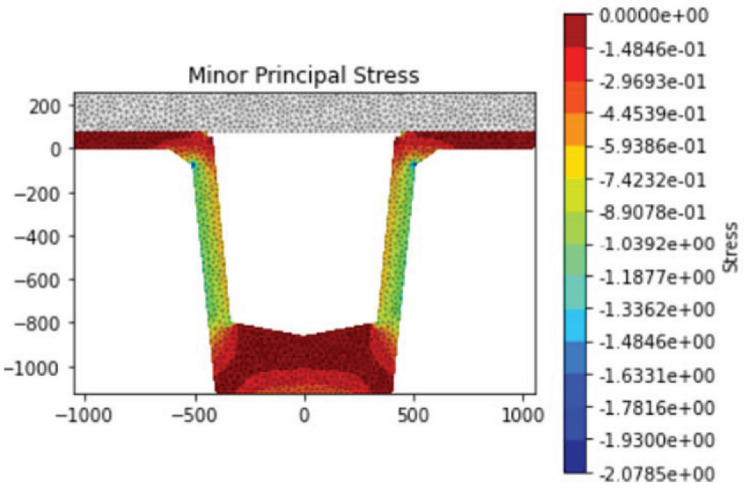

Figure 2. Example output of principal tensile stresses in Super-T girders. (Units in mm and MPa).

2.2 *Torsion cracking resistance*

To quantify the section cracking torsion moment, T_{cr}, an axial load is applied representing prestress following designs by Melhem et al. (2019). 15.2 mm diameter strands are used. Both cases of no debonding and an extreme of 50 % debonding are considered.

Optimization problem is solved to determine the maximum torsion that can be applied to the section under the prestress forces before principal tensile (minor) stresses in the beam reaches the limit of 0.33 $\sqrt{f'_c}$. A total of 10 sections (5 × 2) section cracking torsion moments were calculated.

2.3 *Grillage analysis*

The bridge deck is modelled typically with one carriageway of a dual carriageway road bridge as shown in Figure 3. The bridge deck has zero support skew angle. Super-T girders properties are considered in Section 2.1. The ultimate loading includes dead load – self weight of beams; superimposed dead loads – barrier and asphalt surfacing; and live load of M1600 with dynamic load amplification (DLA) on three design lanes arranged transversely such that Beam 1 (Figure 3) is the most heavily loaded lane.

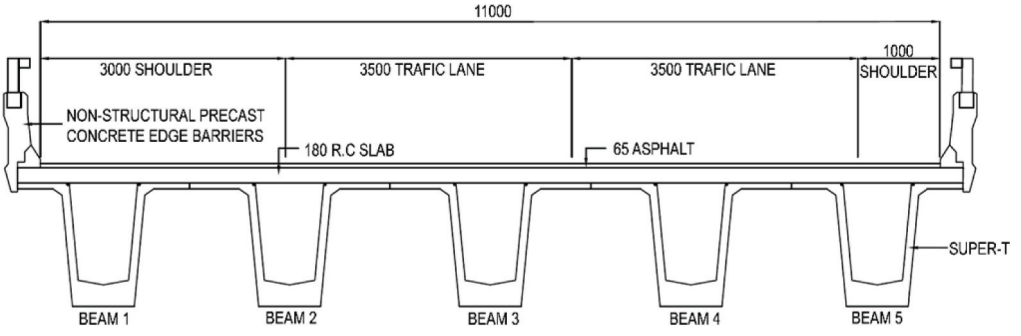

Figure 3. Section torsion moment vs. applied bridge loading in concrete bridge decks is a non-linear phenomenon at ultimate loads (adapted from Collins & Mitchell, 1997).

The torsion constants for the Super-T girders are increased from 0 to 100% at 10% increments – which in turn gives 11 grillage analysis for each of the 10 grillage models. For all grillage analysis, the maximum torsion moment from ultimate loading, T^*, is extracted.

3 RESULTS AND DISCUSSIONS

3.1 *Torsion cracking moments*

Figure 4 and Figure 5 show the torsion moment identified from the grillage analysis of Section 2.3, with the y-axis as ratio of torsion moment, T, for the different torsion constant proportions with the factored cracking torsion moment (ϕ = 0.7). Each figure represents different reductions (extreme cases) in prestress to mimic the likely debonding present in the cracked section. These figures also highlight the suggested locations according to different codes and references where torsion moment should be limited to the cracking moment. These locations are:

- $0.25\phi T_{cr}$ (seen in AS5100.5,2017)
- $0.67\phi T_{cr}$ (seen in Collins & Mitchell, 1997 and Canadian Standards)
- $1.0\phi Tcr$ (seen in ACI Report 445.1R-12)

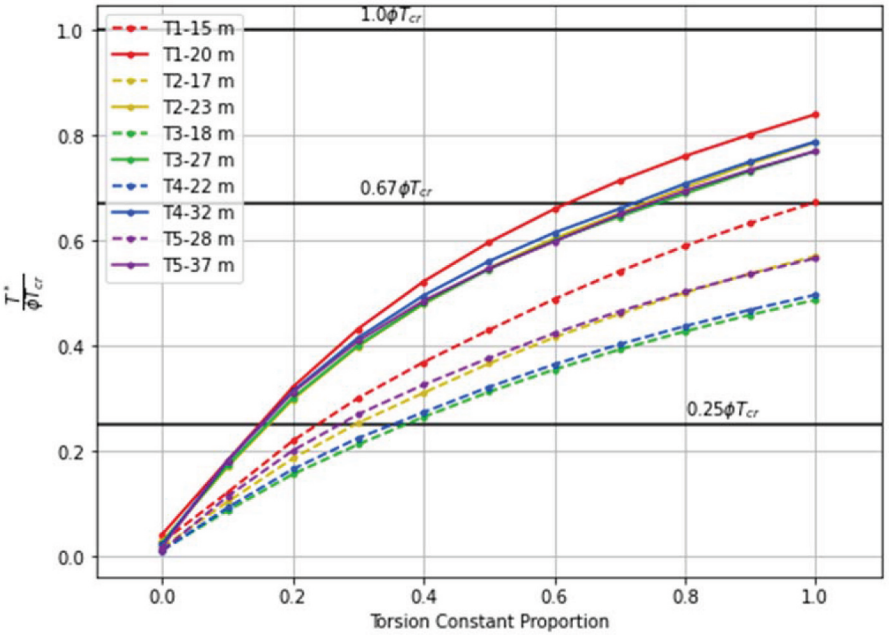

Figure 4. Effect of torsion constant on resulting torsion moments, the full design prestress is applied.

Lastly, the effect of torsion constant variation on maximum bending moment and shear forces are shown in Figure 6 and Figure 7 respectively. The increase in both load effect due to proportional torsion constant, J, is evident and expected since lower torsion constants result in redistribution of torsion moments to longitudinal bending moments and subsequently increases in shear forces.

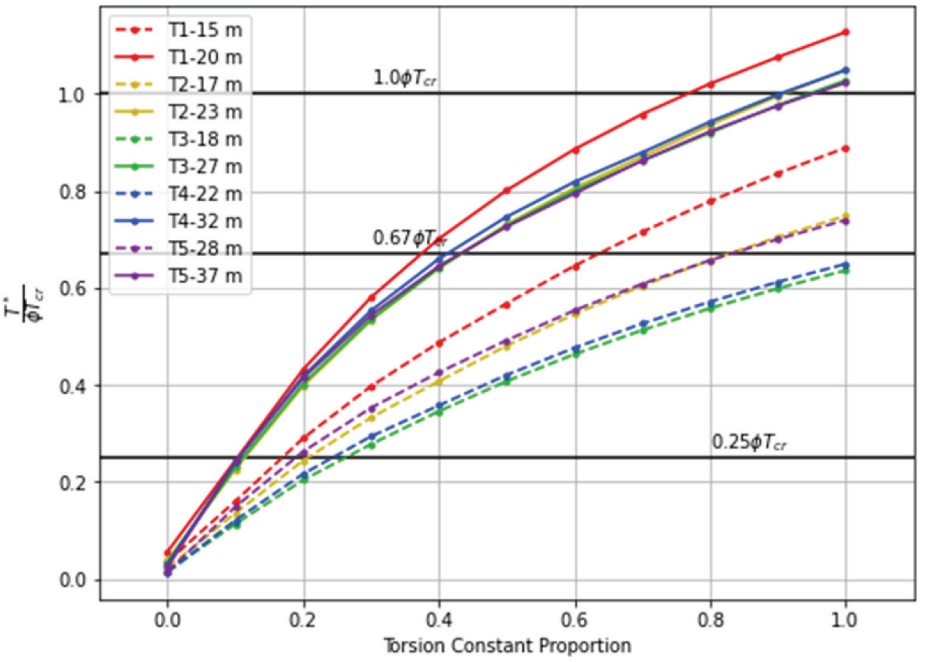

Figure 5. Effect of torsion constant on resulting torsion moments, using an extreme case of 50% prestress debonding.

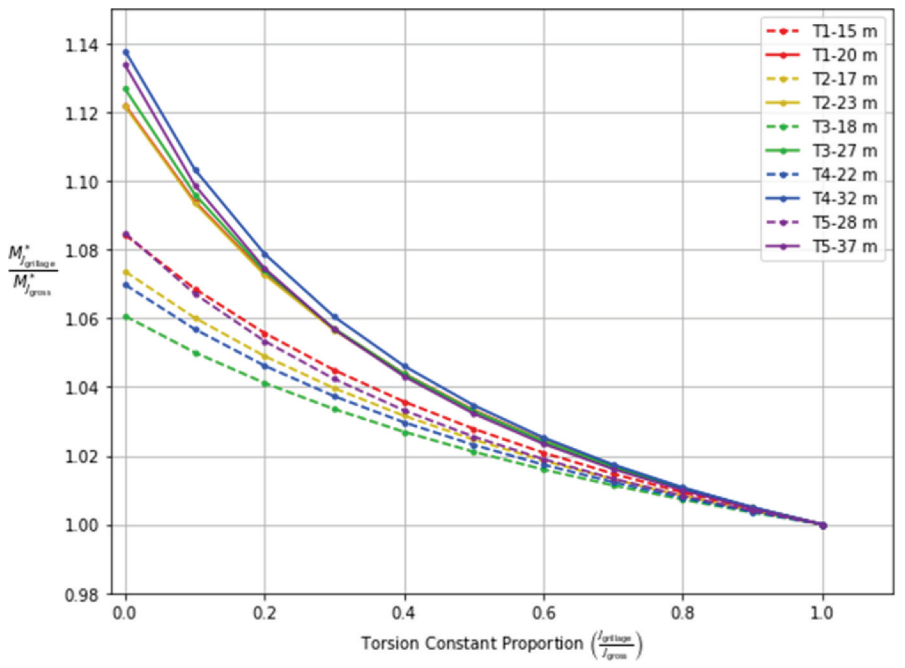

Figure 6. Effect of torsion constant on resulting bending moments.

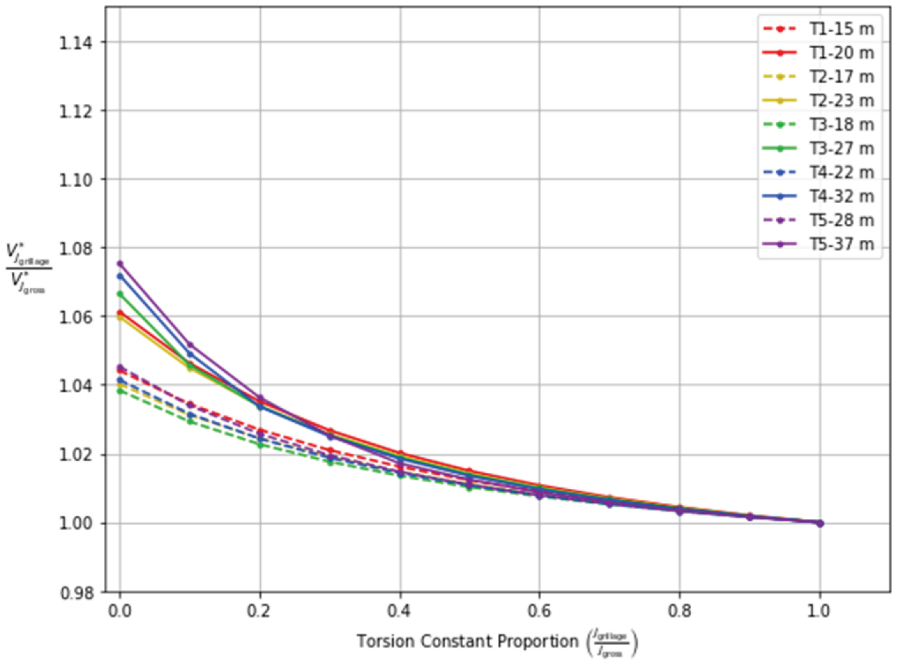

Figure 7. Effect of torsion constant on resulting shear forces.

3.2 *Discussion*

The selection of the appropriate fraction of ϕT_{cr} that should be targeted in selection the proportion of J is not clear. Indeed, the current code seems to target $0.67\phi T_{cr}$, which is simply an empirical limit below which torsion effects can be neglected. It was developed from a study on spandrel beams ultimate (Collins and Mitchell, 1997) and although it has found its way into several codes of practice, its applicability to bridge decks is questionable.

As can be seen from the results, most combinations do not exceed the ϕT_{cr} even for the extreme case of prestress debonding and so redistribution will not occur in most cases. For the 50% prestress debonding case, the limit of $0.67\phi T_{cr}$ is another recommendation that appears, and again the justification is unclear.

If the goal of the torsion constant recommendation is to reduce the need for designers to consider torsion, and the 0.25 limit remains, then a range of 10-40% torsion constant, J, would allow designers find a good balance between the need to design for torsion (based on the redistribution of loads), and minimizing conservatism in longitudinal bending moments. Indeed, as shown in Figure 6, the increases in bending moment for the recommended range of torsion constant proportions is reasonable with a maximum of 10 % increase bending moments.

4 CONCLUSIONS

The onset of cracking at the torsion cracking moment (T_{cr}) limit in Super-T girder bridge decks results in reduced stiffness as loads increase towards the ultimate limit case. In most cases, linear elastic analysis considering full torsion stiffness may not be appropriate for ultimate limit state. In this work, linear-elastic grillage analysis considering a reduced proportion of torsion stiffness is considered to evaluate this phenomenon of overestimating torsion and underestimating moments in grillage models. Based on extensive grillage analysis and Super-T girder combinations, the torsion moment in most Super-T girders considered do not exceed

the torsion cracking moment limit of ϕT_{cr} with $\phi = 0.7$. The results also highlight the questionability of current code limits for torsion cracking moment – future work in needed to re-evaluate these limits. A recommendation of 10-40% proportion of torsion constant, J, will allow designers freedom in torsion design as well as minimizing conservatism in longitudinal bending moments.

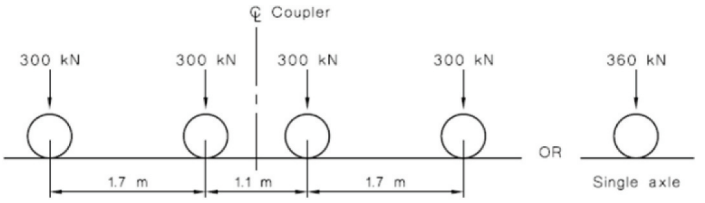
Reliability calibration of load factors for the Australian rail traffic load model

Colin C. Caprani & M. Shihabuddin Khan
Monash University, Melbourne, Australia

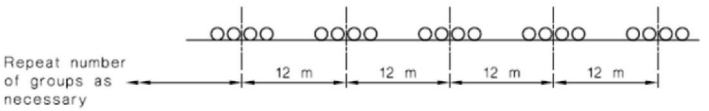
ABSTRACT: Rail traffic loads in Australia are based on AS5100 Part 2, which stipulates a number of simulated axle groups, including a simulated locomotive, called the 300LA load model. The nominal axle loads and spacings are intended to replicate a heavy-haul rail line. As a result, for light rail, metro rail, and other forms of rail, the nominal axle loads are scaled, e.g. 150LA for light rail. However, the live load factor applied to these different load models remains 1.6 for all cases. It is hypothesized that the application of the same load factor to these different forms of rail live loading will result in inconsistent reliabilities being achieved by designs to AS5100. Therefore this paper examines the achieved reliabilities under current design practice for precast concrete bridges. From these results a revised set of load factors for the different forms of loading will be determined using reliability calibration. These load factors will ensure a more consistent reliability is achieved for designs using scaled versions of the 300LA load model. As such, this work should find use in the next revision of AS5100.

1 INTRODUCTION



1.1 *Background*

The Australian rail bridge live load model over recent decades is briefly reviewed. From 1974 until 1996, the Cooper M250 load was used. However, in 1996 a Railway Supplement was added to the 1992 Australian Bridge Design Code, developed by the Australasian Railway Association. This addition specified the 300-A-12 rail live load model, shown in Figure 1.



O'Connor and Shaw (2000) outline the background to the development of the 300-A-12 load. In particular it is worth noting that a study by Brameld (1995) examined heavy haul data from major mines in Queensland which had wagons of 90 tonne nominal gross mass. The data shows that the axle loads have a mean of 225 kN and 2% coefficient of variation. From this, Brameld examined the structural reliability of 3 bridges of spans 10, 15, and 25 m in order to determine a suitable live load factor. Three cases were considered, in which the capacity reduction factors and dead load factors were set at 0.8 and 1.2 respectively. The superimposed dead load factor was varied as 2.0, 1.2, and 1.2, and the live load factor varied as 1.6, 1.6, and 1.4, for each of the three cases respectively. In all cases the reliability incidences exceed 6.00, and so Brameld concludes that the live load factor can be 1.4. Indeed, Appendix C of the Stage 4 Final Report By Selby-Smith and Bowman recommends that the 1.4 factor is adequate and even conservative. However, inexplicably, a live load factor of 1.6 was adopted for the 1996 Railway Supplement.

A further development of the 300-A-12 live load model was proposed by Marcer (2002) in recognition that the loading was inadequate for spans around 20 m. In particular, it was proposed to add the 360 kN to simulate coupled six axle locomotives on spans around 15-22 m. The resulting bending moment envelope is stated to better match existing trains. Interestingly, Marcer (2002) notes that this proposal maintains a "20% reserve" to existing trains. That is, it is recognized that the live load model is 20% more onerous than the heaviest (NSW) train. Nevertheless, this model

Figure 2. The current AS51100.2 300LA load model.

was adopted into the 2004 edition of AS5100 – the Australasian bridge design code, and termed the 300LA load model, shown in Figure 2.

1.2 *Motivation, contribution, and limitations*

Although not included in the 2004 edition of AS5100 Part 2, the 2017 edition added a 150LA load model for light rail, obtained by scaling all axle weights in the 300LA load model by a factor of 0.5. Further, in mid-2023, Amendment 1 of AS5100.2 was published for Public Comment, and also included a 200LA load model for passenger lines. Indeed, the 300LA load model is routinely scaled to achieve designs for railway lines other than heavy haul. For example:

- Metropolitan Trains Melbourne (MTM) specify a 245LA load model for some sections of the broad gauge network in Melbourne (Salandanan et al 2023).
- Metronet in Perth specify a 220LA load model, as suggested by a public comment in response to the proposed Amendment 1 of AS5100.2.

In spite of this scaling of the load model, the live load partial factor remains 1.6 in all cases between 150LA and 300LA. Thus, the question arises as to whether or not consistent safety is achieved for all designs to a scaled version of the 300LA load model.

It is worth noting here an intriguing observation by Brameld (1995): he notes that the live load factor has been established for the heaviest rail loadings but which have much less variability than lighter rail loadings. Consequently he suggests that a sliding load which increases as the basic design load decreases could be suitable. Thus, this work examines the current level of safety achieved by the current Australian railway live lode model specified in AS5100.2. More recent material statistics and probabilistic models are adopted. Based on this, partial factors to achieve a more consistent level of safety are proposed.

In this paper we consider just the ultimate limit states for bending and shear. Furthermore, we consider only precast concrete quality resistance models, as this is a very common form of bridge construction in Australia.

2 METHODOLOGY

2.1 *Design model*

A generic design equation is defined. The equation is normalized, and includes adjustments for the relative contributions of self-weight, G, to total self weight and permanent loads, P, $a_g = G/(G+P)$, and the relative contribution of live, Q, to total load, $a_q = Q/(G+P+Q)$. In particular, $a_g = 1$ means there is no permanent load, and $a_q = 1$ represents the extreme case where there is only live load.

The generic normalized design equation is:

$$\phi z r_k = \left(1 - a_q\right)\left[a_g \gamma_g g_k + \left(1 - a_g\right)\gamma_p p_k\right] + a_q \gamma_q q_k \tag{1}$$

from which the design variable z is found as a multiplier of the normalized characteristic resistance, r_k, for the normalized characteristic self-weight g_k, other permanent loads, p_k, and variable loads, q_k, using the set of partial factors under examination, ϕ for resistance, γ_g for self-weight, γ_p for other permanent loads, and γ_q for variable loads. The partial factors used in the design are taken from those in AS5100 and are shown in Table 1 below.

Table 1. Partial factors used in the designs from AS5100.

Variable	Symbol	Partial Factor
Self-weight	γ_g	1.2
Permanent loads	γ_p	1.7
Variable loads	γ_q	1.6

2.2 *Limit state function*

The limit state function from which the reliability index of the generic design conducted in accordance with Equation (1) can be determined is given by:

$$g(z) = \omega_R z R - \omega_S\left[\left(1 - a_q\right)\left(a_g G + \left(1 - a_g\right)P\right) + a_q Q\right] \tag{2}$$

in which ω_R and ω_S are the model uncertainties for resistance and load effects respectively, and the random variables R, G, P, and Q, correspond to their characteristic values in Equation (1). The First Order Reliability Method (FORM) is used to establish the reliability indices.

2.3 *Probabilistic models*

The probabilistic models used in this work as shown in Table 2. Each of the probabilistic models is described as follows, by their index:

1. As recommended for structural frameworks by JCSS (2000), and so is somewhat conservative for simpler structural forms like simply-supported or continuous beams.
2. As used in Rakoczy and Nowak (2013) for precast components.
3. Per Köhler et al (2023) for low COV permanent load forms (e.g. services).
4. From Brameld (1995): based on a mean axle load of 225 kN and a CoV of 2%.
5. Per Tb. 10 of Foster et al (2016) for the AS3600 moment capacity model.
6. Conservatively based on the relative difference between the "old" and "new" material data in Tb. 6 of Stewart et al (2016) (about 0.03 for bias and 0.05 for CoV) as applied to the results from Melhem et al (2022).
7. Using the Super-T results from Tb. 1-2 of Melhem et al (2020) which used response surfaces from the MCFT software Response2000 to compare with the predictions from the simplified MCFT in AS5100 and AS3600.
8. Based on the AS3600 model but adapted for the relative difference between the "old" and "new" material. data as described in Stewart et al (2016); these are far lower (conservative) than those reported in Agarwal et al (2021).

Table 2. Probabilistic models of the normalized variables parametrized by the bias and coefficient of variation. Note that values are based on a normalized mean of 1.0 for the random variables; i.e. $x_k = 1.0/\lambda$.

No.	Random Variable	Symbol	Distribution	Bias, λ	COV, V	Char. Value, x_k
	Load Models					
1	Actions model	ω_S	Lognormal	1.00	0.10	-
2	Self-weight (precast)	G	Normal	1.03	0.08	0.97
3	Permanent	P	Normal	1.00	0.10	1.00
4	Rail (300LA)	Q	Normal	0.75	0.02	1.33
	Bending					
5	Resistance model	ω_R	Normal	1.06	0.05	-
6	AS5100 Precast	R	Lognormal	1.08	0.08	0.93
	Shear					
7	Resistance model	ω_R	Normal	1.06	0.07	-
8	AS5100	R	Lognormal	1.08	0.07	0.93

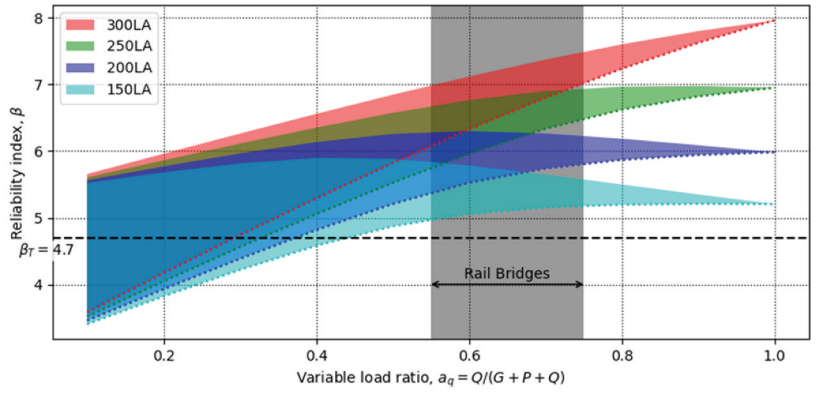
2.4 *Models for scaled 300LA loading*

Table 2 (No. 4) shows the statistics for the 300LA model derived from Brameld's background work. However, for scaled versions of the load model, these statistics ought to be amended to reflect that lighter loadings have both more variability (i.e. higher COV) and actual values closer to the nominal (i.e. a small bias). In lieu of more detailed data, the values assumed for this work as shown in Table 3.

Table 3. Probabilistic models of scaled 300LA load models.

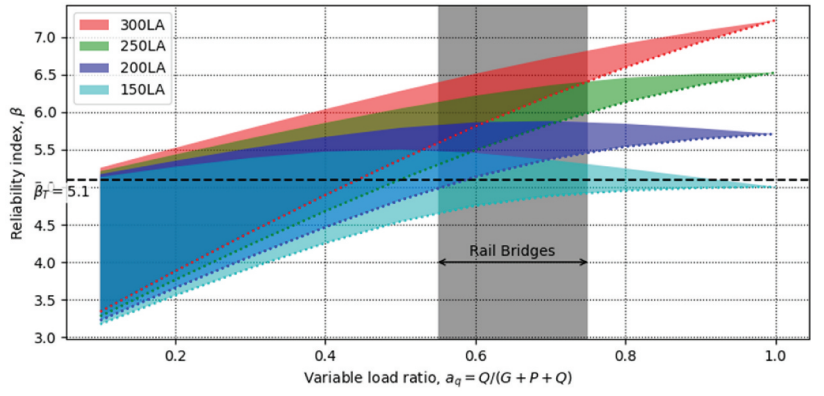
Load model	Bias	COV
300LA	0.75	2%
250LA	0.80	4%
200LA	0.85	6%
150LA	0.90	8%

3 RESULTS



3.1 *Overview*

The actions bending, shear, and axial compression are examined under different load cases across the full range of a_g, and the feasible range of a_q. The typical range of a_q for some bridge types are indicated. The value of a_g = 1 is indicated by a dotted line, and typically occurs at the bottom of the region due to the added safety from the permanent load partial factor.



The reliability indices shown are for an annual basis. The targets shown are β_T = 4.7 for ductile failures and β_T = 5.1 for brittle failures. These values were used in the calibration of AS3600 (Foster et al 2016, Stewart et al 2016) and are high by international standards (ISO2394).

3.2 *Current safety*

The current levels of safety achieved by designs to AS5100 for different scalings of the 300LA load model are shown in Figure 3.

(a) Bending;

(b) Shear

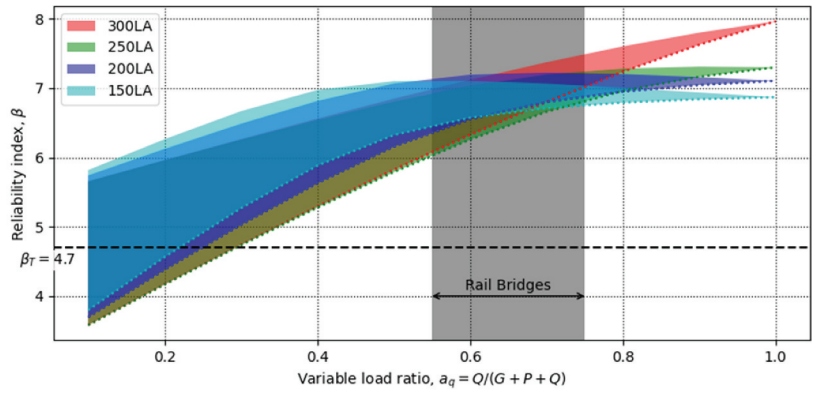


Figure 3. Current levels of safety achieved by precast concrete rail bridge designs to AS5100.

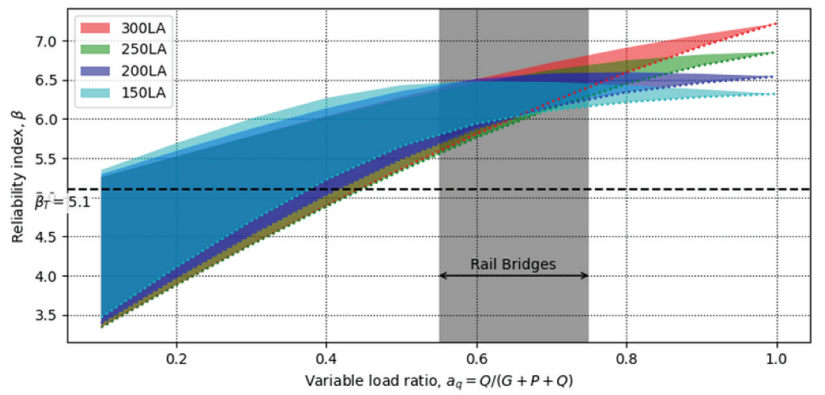
It can be seen from the figure that the different load models achieve very different levels of safety. Notably the safety achieved under ULS bending is extremely high, while that for shear is mostly high. However, there is a proportion of 150LA bridges with relatively low live and dead load ratios ($a_q \approx 0.5$, $a_g > 0.5$) for which the shear design safety is less than the highest international target.



From these results, it is clear that precast concrete rail bridge designs to AS5100 achieve inconsistent levels of safety, depending on the scaling of the 300LA load model.

3.3 *Safety consistent with 300LA*

Considering the results from Figure 3, we postulate that the level of safety achieved by 300LA designs is the implicit target (or acceptable) level of safety for AS5100. Consequently, alternative partial factors are considered to achieve safety consistent with designs to 300LA for the other scaled versions of the load model. These alternative partial factors are given later. This presumes that the 300LA safety is the level sought in the specification of AS5100. The partial factors are adjusted such that in the typical variable load ratio region for rail bridges, each load model mostly exceeds that of the target region. The results are shown in Figure 4.

(a) Bending;

(b) Shear;

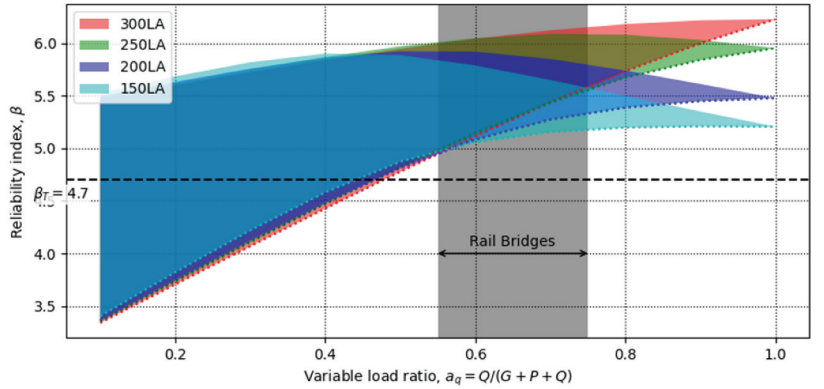


Figure 4. Levels of safety achieved by designs with adjusted partial factors to match 300LA safety.

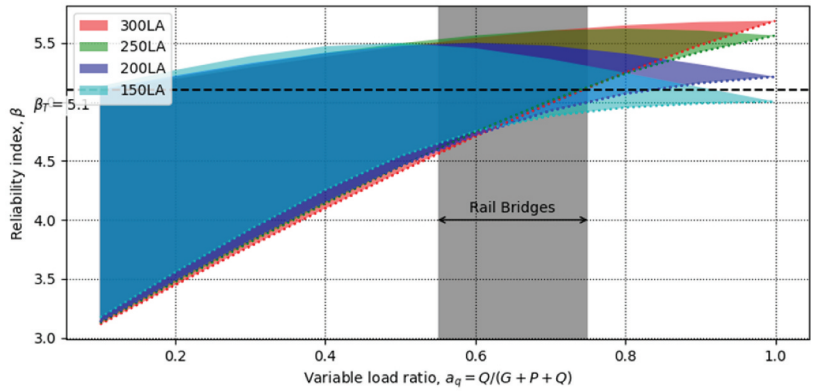
3.4 *Safety consistent wth 150LA*



In contrast to Figure 4, and referring to Figure 3 we postulate that alternatively the 150LA safety is that which is implicitly deemed satisfactory by AS5100 (even though there is a portion of shear designs with low permanent load are lower than $\beta_T = 5.1$ as mentioned earlier). Thus, proposing another set of partial factors to match this level of safety yields the results shown in Figure 5.

3.5 *Adjusted partial factors*

The adjusted partial factors found to achieve consistent safety in Figures 4 and 5 are shown in Table 4. The match was achieved through trial and error and visual assessment, ensuring that achieved safeties were typically at least that of the 300LA or 150LA target region.

(a) Bending;

(b) Shear;

Figure 5. Levels of safety achieved by designs with adjusted partial factors to match 150LA safety.

Table 4. Live load partial factors for consistent safety.

	Safety to 300LA		Safety to 150LA	
Load model	Bending	Shear	Bending	Shear
300LA	1.60	1.60	1.25	1.25
250LA	1.70	1.70	1.35	1.35
200LA	2.00	1.90	1.45	1.45
150LA	2.30	2.15	1.60	1.60

4 DISCUSSION AND CONCLUSIONS

4.1 *Discussion*

Although current practice for the design of rail bridges in Australia scales the 300LA load model, the results here show that this results in inconsistent safety being achieved. Indeed, the levels of safety being achieved are extraordinarily high against international standards, but this is to be somewhat expected, as was noted in the background studies to the load model in 1995. Nevertheless, it is not reasonable that public safety should differ depending on the load model, and so a set of partial factors to achieve consistent safety for bending and shear designs are explored. However, the target level of safety could be international practice, the safety achieved

by designs to 300LA, or those for 150LA. Presuming Australasian societal acceptance is that of 300LA or 150LA, these are examined in detail. Perversely, the resulting partial factors for 300LA-consistent safety are either very high (indicating that 300LA safety is too high); or 150LA-consistent safety are too low (indicating that 150LA designs are relatively less safe and more in line with international practice, save for designs with low permanent load, $a_g > 0.5$).

4.2 *Conclusions*

Precast concrete designs to AS5100 achieve very high levels of safety for ULS bending and shear. These designs are not consistent, depending on the scaling of the 300LA load model. The live load partial factor is more reasonably described as a linear scaling akin to:

$$\gamma_q = 1.25 + 0.35(300 - Q)/150 \tag{3}$$

based on the shear and bending results for 150LA-consistent safety in Table 4 and where 300LA ≥ Q ≥ 150LA is the scaled magnitude of the 300LA load model. Nevertheless, more work is required to confirmed this finding for other actions and bridge forms.

ABSTRACT: This contribution aims to present the application of a probabilistic methodology to update the characteristic train load for the Little Belt Bridge (Lillebæltsbroen), constructed in 1935, in Denmark. On the basis of measurements near the bridge between March 2016 and December 2021 the characteristic train load is updated based upon actual train passages on the structure. This paper presents the basis for this probabilistic analysis which concluded that (i) the theoretical train load determined in 1996 based on the background studies carried out in the 1980s for the Great Belt fixed link was still appropriate and (ii) that the load reduction factor which reflects the joint probability of occurrence of two heavy trains on the bridge also still is appropriate and might even be reduced slightly. The paper presents the basis for the analysis of characteristic loads for an existing structure where recorded loading data is available. It serves as a valuable contribution for bridge owners tasked with the management of existing landmark structures.

1 INTRODUCTION

The Little Belt Bridge, or Lillebæltsbroen in Danish, is a renowned landmark in Denmark, elegantly spanning the Little Belt strait to connect the mainland of Jutland with the island of Funen. The bridge, officially opened in 1935, features a distinctive design, encompassing a graceful arched structure that stretches approximately 1,178 meters across the vibrant waters of the Little Belt. The bridge has undergone renovations and enhancements over the years to adapt to evolving engineering standards and increased traffic demands, ensuring its continued significance as a vital transportation link on the Danish transportation network. In 1996, a comprehensive study was conducted to assess the train load on the bridge. The study focused on analyzing the dynamic effects and forces exerted by trains traversing the bridge, taking into account factors such as speed, weight distribution, and the frequency of train crossings. Instrumentation and monitoring systems were employed to collect data on the actual loads experienced by the bridge during train movements. Being almost 30 years since this study was conducted, it was considered appropriate to assess if the developed loads against which the structure was assessed were still relevant in current conditions. As a result, Ramboll were commissioned by Banedanmark to establish the 'current' characteristic uniform distributed load (UDL) by using up-to-date measurement and registering of actual trains, and subsequently employing stochastic modeling techniques. This paper presents the results of this analysis detailing (i) the collection and statistical assessment of train data, (ii) determination of the characteristic load on the bridge, for single and multiple passages, based upon this data,

DOI: 10.1201/9781003483755-145

(iii) the development of a theoretical model to emulate this load and (iv) finally comparison of the results of the analysis with those of the 1996 study.

Figure 1. Photo of the Little Belt Bridge anno 1935 and layout of the road and rails on the bridge.

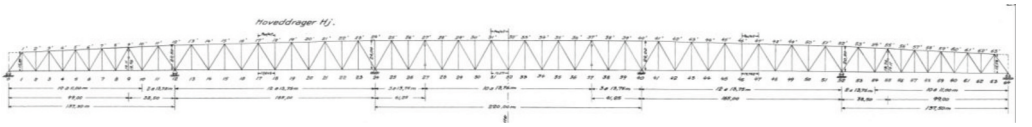

Figure 2. Extract from original drawing of the Little Belt Bridge anno 1935 showing the plan view.

1.1 *Characteristics of the Little Belt Bridge anno 1935*

The Little Belt Bridge anno 1935 as shown in Figure 1 is a riveted truss bridge carrying both two lanes of road traffic, sidewalk for pedestrians and two tracks for railway traffic. The total length of the bridge is 1,178m and with a width of 20.5m, The main steel structure has a total length of 825m divided into 5 spans as shown in Figure 2. The main span is 220m and the clearance 34m. The bridge is the only railway connection between Funen and Jutland, whereas the main road traffic is carried by the nearby cable supported Little Belt Bridge anno 1970. The global statical system of the Little Belt Bridge anno 1935 is described in Schaper (1935).

1.2 *Scope*

This paper presents the main results of a project initialized by Banedanmark, where the overall scope was a re-assessment of the load carrying capacity of the Little Belt Bridge anno 1935. This included determination of the characteristic uniform distributed load (UDL) from measurements/registration of actual trains through stochastic modelling. The stochastic determined characteristic UDL was to be applied instead of the Eurocode load scheme for the re-assessment of the bridge.

For the global system, the critical loading scenario is the uniformly distributed load (UDL) applied over the onerous part of the influence line, while the individual axle loads affect secondary elements.

A representative influence line for the global system is shown in Figure 3. From the figure it can be seen that the influence line is approximately 500m and that the onerous part is approx. 170m, which is approx. the same as the length of the span of 165m (see Figure 2), as positive

values indicates relieving part of the influence line and negative values indicate the onerous part. Hence, a conservative train length of 165m is assumed for the statistical analysis of the characteristic UDL to be used for design checks of the Little Belt Bridge anno 1935.

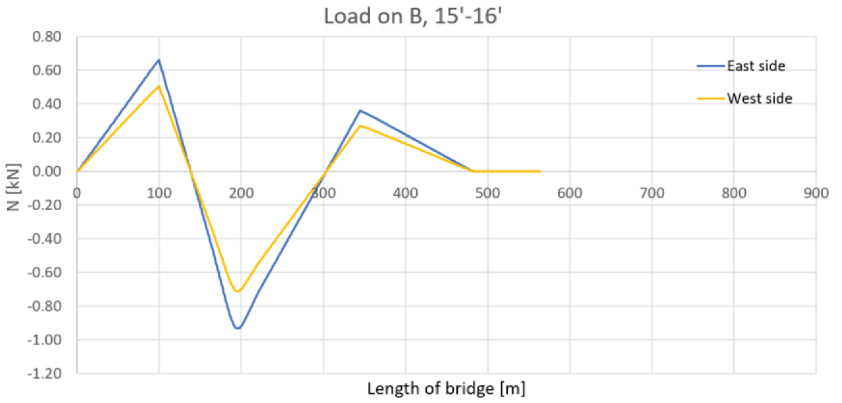

Figure 3. Global influence line of a critical section in the main girder system.

2 DATA

Banedanmark and the Danish Road Directorate are the owner of the Danish Rail Network and serves as the administrator of the Little Belt Bridge from 1935. Banedanmark has put approx. 6 years of rail traffic data for disposal, which contain the following information for all trains passing the measurement station at the city Bred on Funen, see Figure 4.

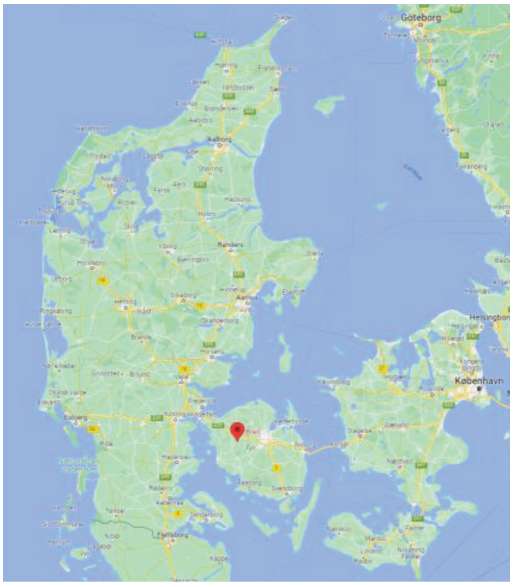

Figure 4. Map of Denmark, where the measurement station Bred on Funen is marked with red.

All trains passing Bred on Funen will also pass the Little Belt Bridge from 1935 hence it is assumed that the data obtained at Bred is directly transferrable for assessment of the Little Belt Bridge from 1935.

The following information is given in the data:

- Unique Train ID
- Timestamp per axle
- Number of axles per wagon
- Weight of each axle
- Speed of the axles (calculated based on timestamp of the axles)
- Direction (Funen-Jutland or Jutland-Funen)
- Average load on the right and left wheel
- Peak load on the right and left wheel
- For some wagons more detailed information is given such as IC3 or IC4 and others are named unknown

The raw data was assessed qualitatively to ensure that the data was applicable, and all the relevant information included.

2.1 *Data assessment*

The UDL for each train is calculated based on the fictive train length of 165m. For trains shorter than 165m it means that the total load of the given train is increased according by dividing with L_{train}/165m. For trains longer than 165m the maximum of a moving average of the UDL is used in the further analyses. Table 1 shows some characteristics of the available data together with the average and the standard deviation of the UDL for a given year and also for the average and standard deviation of the heaviest 730 trains for a given year.

Table 1. Overview of some of the characteristics of the measured/registered train data.

	Year		2016	2017	2018	2019	2020	2021
	Days with data	No.	292	365	365	365	366	365

	std. UDL (165 m)	[t/m]	0.94	0.93	0.92	0.91	0.88	0.83
	Average UDL of the 730 heaviest trains (165 m)	[t/m]	4.66	4.94	4.95	4.81	4.58	4.07
	std. UDL of the 730 heaviest trains (165 m)	[t/m]	0.51	0.53	0.55	0.68	0.58	0.43
Westbound	Trains	No.	25,295	33,206	32,974	30,755	18,328*	
	Axles	No.	791,443	1,003,406	977,794	869,615	529,364	
	Average UDL (165 m)	[t/m]	1.55	1.56	1.56	1.54	1.52	
	std. UDL (165 m)	[t/m]	0.95	0.95	0.95	0.82	0.97	
	Average UDL of the 730 heaviest trains (165 m)	[t/m]	4.86	5.33	5.31	5.01	4.66	
	std. UDL of the 730 heaviest trains (165 m)	[t/m]	0.70	0.76	0.82	0.80	0.83	

* Data towards the end of year 2020 for the westbound direction is suspicious, however, it is assessed not to influence the overall conclusions in Rambøll (2023a).

3 CHARACTERISTIC TRAIN LOAD

The characteristic train load for one and two tracks is assessed in the following sections based on the data presented in Section 2. As the load effect is a linear function of the load the two expressions are exchanged without further introduction.

3.1 *Train on one track*

Assuming that the arrival of a train on the bridge follows a Poisson process with an arrival rate of ν_i (number of trains i per year) the annual extreme value distribution of the load effect can be described as (Ditlevsen & Madsen, 1994):

$$F_{max}(x) = \exp(-\nu T(1 - F_s(x)))$$

where T = 1 year and $F_s(x)$ is the cumulative distribution function of the load effect. The characteristic UDL is taken as the 98%-fractile of the annual extreme value distribution.

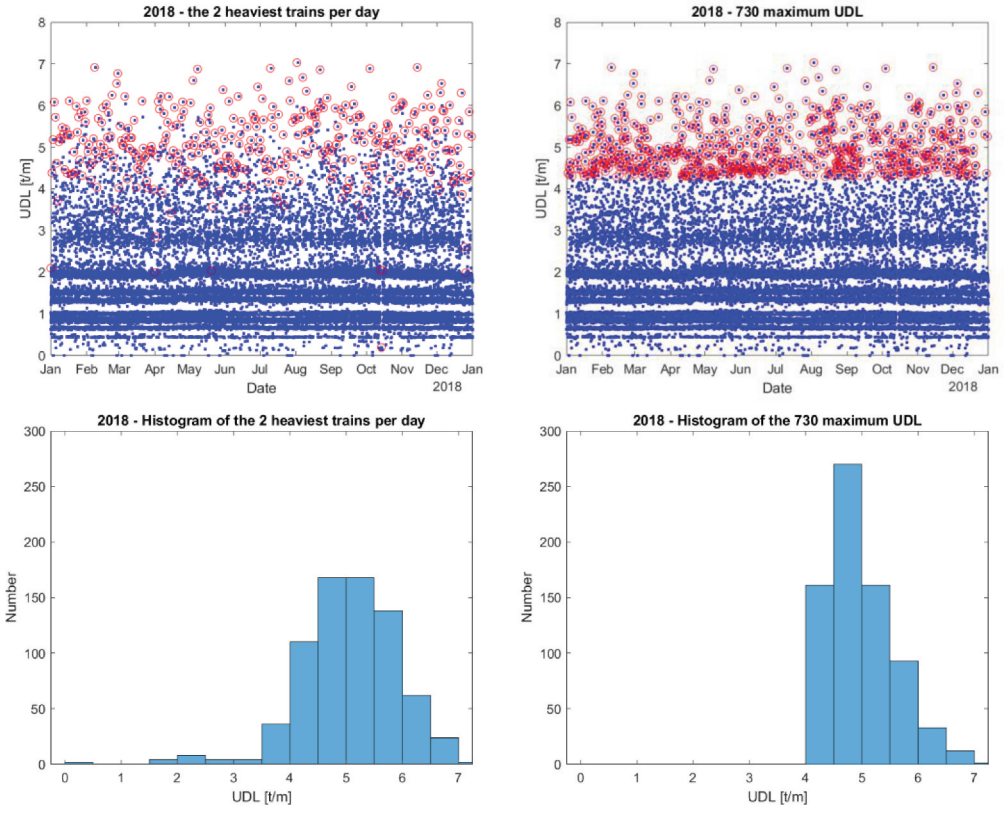

Figure 5. The two figures at the top show the two daily maxima of the UDL (marked with red) and the 730 heaviest train (marked with red) based on UDL independent of the date to the left and right respectively. Below are the associated histograms shown.

For selection of the trains to use for estimation of the extreme value distribution a daily maxima and peak-over-threshold method is used. Figure 5 to the left shows the 2 heaviest (UDL 165m) daily trains and associated histogram, whereas to the right the 730 heaviest train for year 2018 is shown together with the associated histogram. The average UDL changes from 4.68 t/m to 4.95 t/m and the standard deviation of the UDL from 0.89 t/m to 0.55 t/m between the two methods of peak selection. Hence, the characteristic value is larger when choosing the 2 daily maxima as the standard deviation is higher, however, since the load of the bridge in the ultimate limit state is independent on the load history it is assessed to be more appropriate to select the peaks as the 730 heaviest trains per year.

Figures 6 and 7 show the characteristic UDL as function of the number of yearly number of trains accounted for in the extreme value analysis for east- and westbound direction

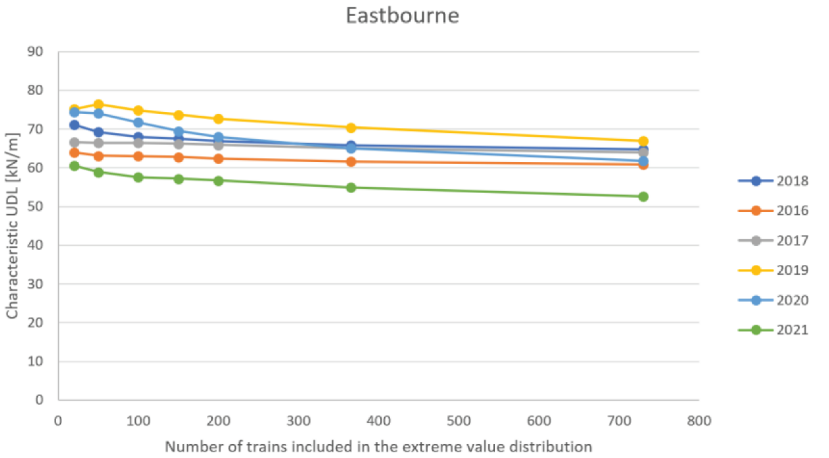

Figure 6. Characteristic UDL based on approx. 6 years of Eastbourne train data for different numbers of maxima included in the extreme value analysis.

respectively. For the eastbound direction a small tendency for the characteristic UDL to decrease with increase of the number of trains included in the extreme value analysis. The characteristic UDL used for earlier re-assessment of the Little Belt Bridge anno 1935 is 72.6 kN/m, hence comparing the values found in Figure 6 with this the characteristic UDL found from the actual measured/registered trains as presented in Section 2 is in general lower.

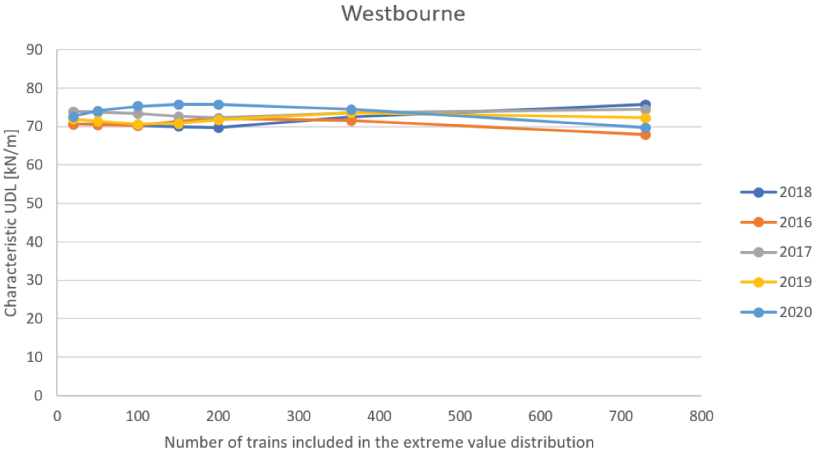

Figure 7. Characteristic UDL based on approx. 5 years of Westbourne train data.

For the westbound direction the same tendency as seen in the eastbound direction is not found. Here it is found that the characteristic UDL is reasonable constant with the number of number of trains selected for the extreme value analysis. In general, the characteristic UDL is higher for the westbound direction than for the eastbound direction. However, overall for the years between 2018-2020 for the westbound direction the characteristic UDL based on measured/registered trains is fairly comparable with the 72.6 kN/m as used in earlier re-assessment – spanning between 69.7 kN/m to 75.8 kN/m.

3.2 *Trains on two tracks*

Again, it is assumed that the arrival of one train follows a Poisson process, it is furthermore assumed that arrival of two trains simultaneously follows a Poisson process. This is seen as

a reasonable assumption as the passage of a train on the bridge is below 1 minute, which blurry the effect from timetables.

The annual extreme value distribution of the load effect of two trains simultaneously on the bridge can be given as (Ditlevsen & Madsen, 1994):

$$F_{max}(x) = \exp(-\nu_{12} T(1 - F_s(x)))$$

where ν_{12} is the yearly arrival rate of two heavy trains on the bridge simultaneously determined by:

$$\nu_{12} = \nu_1 \nu_2 (d_1 + d_2) \frac{24}{12}$$

where ν_1 and ν_2 is the speed of the train in the east- and westbound direction and the d_1 and d_2 is the duration of the load effect from passage of a train in track one and two respectively.

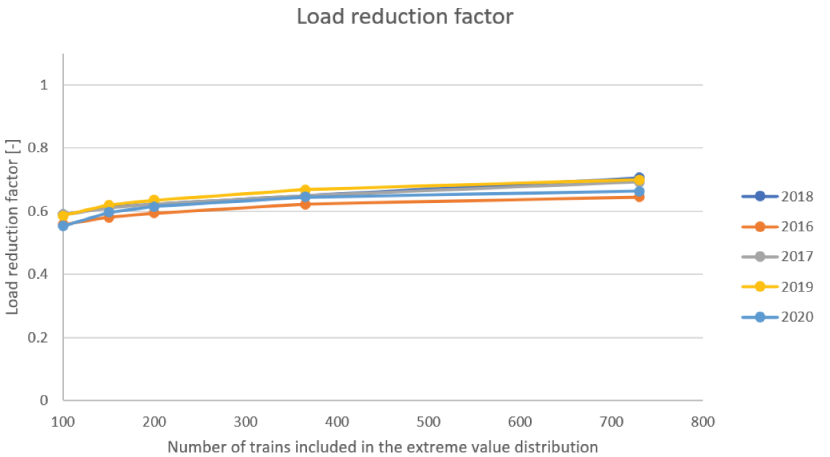

Figure 8. Load reduction factor as function of number of trains included in the extreme value distribution.

The load reduction factor with simultaneously trains on both tracks used in the re-assessment of the global load effects is determined based on measured/registered data and shown in Figure 7. Here it is seen that for between 200 to 730 heavy trains per year in the extreme value distribution that the load reduction factor is about 0.60-0.71, which is comparable with the 0,77 used in earlier re-assessment by Rambøll, however, still lower. Reading Figure 5 and 7 together it seen that the characteristic load decreases with the number of trains accounted for the in the extreme value analysis, whereas the reduction factor increases, hence the total load is approximately constant and independent on the number of trains used for the extreme value analysis.

4 THEORETICAL MODEL

In 1996 the Little Belt Bridge anno 1935 was re-assessed in both ultimate and fatigue limit state (ULS and FLS) (COWI 1996). In association with this re-assessment the characteristic UDL was assessed based on a theoretical train load model created for the Great Belt Link, the basis for the train load model is given in Table 2. The Great Belt Link is located on the same stretch as the Little Belt Bridge anno 1935. Some of the freight trains passing the measuring station at Bred on Funen might unload or load at Funen, hence not fully representative of the train load passing the Great Belt Link. However, this is assessed to be a minor change in the train load and the measured/registered data is assessed to be fairly representative for trains passing the Great Belt Link as well.

The characteristic UDL and load reduction factor on the basis of the data shown in Table 2 is calculated as described in Section 3. The results are shown in Table 3.

Table 2. Background parameters for the train load model used for the design of the Great Belt Link.

	Average Axle Weight [t]	Std. Axle Weight [t]	Average UDL [t/m]	Std. UDL [t/m]
Eastbound	19.4	2.1	6.45	0.20
Westbound	19.4	2.1	6.45	0.20

Table 3. Results based on the theoretical model for the Great Belt Link.

Trains per track per day	Characteristic UDL [kN/m]	Load reduction factor
2	72.6	0.77
4	72.9	0.81
10	73.3	0.83

The results of above presented theoretical analysis is comparable with the results of the analysis of the characteristic UDL and load reduction factor based on measured/registered data of trains passing the Little Belt Bridge anno 1935. This means that the theoretical model established for the design of the Great Belt Link to a large extent is representative for global load effects with same order of magnitude as for the Little Belt Bridge anno 1935 and the West Bridge of the Great Belt passing.

5 CONCLUSIONS

Based on measured/registered data of actual trains at Bred on Funen in Denmark close to the Little Belt Bridge anno 1935 the characteristic uniform distributed load (UDL) is found in the above analysis. The results of the analysis are comparable with the results of the theoretical train load model based on train characteristics made for the design of the Great Belt Bridge. The approach for reaching this result was a qualitative rough assessment of the raw data to ensure applicability of the data. The assumptions around the stochastic modelling of the train load from previously re-assessment were re-visited and found applicable hence, also used in the most recent re-assessment of the Little Belt Bridge anno 1935. This included modelling of the global influence length, moving average evaluation of all train passage together with extreme value selection and comparison of the effect on the characteristic values by choosing 2 daily maxima or the 730 heaviest trains per year.

This means that the characteristic UDL of 72.6 kN/m and a load reduction factor of 0.77 for simultaneously trains on two tracks are still applicable and have been used in the most recent re-assessment of the Little Belt Bridge anno 1935, proving that the theoretical train load model developed for the design of the Great Belt Bridge was a close approximation of the future train load.

ABSTRACT: Compared to small and medium-span bridges, long-span bridges have longer loading spaces and more complex extreme response value scenarios. It is shown that the phenomena of heavy vehicle aggregation and heavy vehicle queuing are important factors affecting the response extremes of long-span bridges both in congested and free flow traffic situations. Therefore, is necessary to study the correlation between heavy vehicle weights for extreme response value scenarios in long-span bridges. Based on previous studies, this paper analyzes and demonstrates in detail the necessity to account for the correlation between vehicle weights when considering extreme response value scenarios, and proposes a methodology for its modeling. It is concluded that a correlation length of 100 meters is recommended, and that for the most extreme response scenarios involving long-span bridges, it is necessary to re-evaluate the correlation between GVWs.

1 INTRODUCTION

The traffic load is one of the most important variable actions for the accurate design and assessment of existing bridges. Due to the spatial and temporal high randomness and variability on the weights of vehicles, there are massive feasible loading scenarios during bridge operation. Therefore, it is challenging to model all of the actual values of traffic load on bridges in a deterministic way. Probabilistic concepts should be employed to consider the numerous sources of uncertainty in the traffic modeling.

Numerous studies have been already devoted to the study of traffic load effects in long-span bridges. Because the corresponding dominating traffic distribution scenarios are notably distinct, the responses to the traffic load of bridges with long-loaded lengths are different from those with medium or small-loaded lengths (Caprani 2013, O'Brien et al. 2012, Caprani et al. 2008, Chen & Cai 2007). The traffic load of long-span bridges is governed by high-volume traffic or congestion. Because the span is long and there are numerous vehicles on several lanes, the influence of groups of trucks is important for their structural assessment (Chen & Wu 2011, Xu et al. 2012). Due to the characteristics of influence lines of short and medium-span bridges, the

DOI: 10.1201/9781003483755-146

maximum response of multi-lane bridges with spans less than 60 m is determined by a single heavy truck, two trucks side-by-side, or two trucks following in the same lane for continuous spans (Soriano et al. 2017). Meanwhile, the research of Caprani et al. (2008) shows that it is not realistic to believe that two truck events drive the design of short to medium-span bridges. Clearly, four truck events play an important role (Caprani et al. 2008). Comparatively, long-span bridges have more diverse and complicated extreme response scenarios.

Based on the long-term WIM data and congestion situation, Hwang & Kim (2019) proposed a multi-lane load model for long-span bridges and found that the load effect by the proposed congested model shows comparable values to AASHTO LRFD or Honshu-Shikoku bridge design code. Guo & Caprani (2019) focused on load patterning on long-span bridges and proposed a rational and practical load patterning method based on both congested and free-flow traffic. They suggested that the design traffic load model for long-span bridges can be obtained by reducing traffic load levels currently specified in the codes. However, the above studies are mainly concerned with the extreme load effects for long-span bridges, while the vehicle scenarios that cause these extreme response values are also of interest.

Indeed, previous traffic load models have shortcomings when it comes to representing the complicated spatial distribution of traffic loads on the bridge deck quantitatively. Actually, the probability of the spatial distribution pattern of vehicles on a bridge deck with long-span provoking maximum load effects is vital for assessing bridge safety and also helps to understand the performance of bridges under vehicle loads. During the period of operation, the formation of platoons, which is the grouping of heavy vehicles, may pose a significant threat to the safety of long-span bridges. The proportion of heavy vehicles in the traffic flow is more critical to the structural effect than the traffic flow itself (Lipari et al. 2017). Various spatial patterns of vehicle distribution will induce varying load effects, according to the influence line/surface of the considered effect. At the same time, the traditional simulation method only focuses on simulating traffic flow and ignores extreme response scenarios. This makes it a low efficient and highly costly method, particularly when calculating extreme responses over long reference periods.

Considering the limitation of traditional vehicle load models in spatial distribution modeling, Chen et al. (2019) proposed a probabilistic approach for modeling the spatial distribution of heavy vehicles for long-span bridges by utilizing an undirected graphical method. Wang et al. (2024) proposed a probabilistic model to describe the heavy vehicle distribution on the bridge deck when extreme response is obtained. In the presented model, the heavy vehicle concentration phenomenon was described by considering the correlation relationship between the adjacent gross vehicle weights (GVWs).

In this paper, based on the probabilistic model for vehicle scenarios leading to extreme load effects proposed in the research of Wang et al. (2024), the necessity and methodology of considering the correlation of GVWs in the simulation of vehicle spatial distribution is further discussed. The paper is structured as follows: Chapter 2 presents discussions on the reason for assuming a correlation between GVWs and the method to consider its level. Chapter 3 gives the results and discussions obtained by different levels of correlation for some selected load effects. The main conclusions of this study are summarized in Chapter 4.

2 CORRELATION BETWEEN ADJACENT GVWS

2.1 *The reason for assuming a correlation between GVWs*

According to previous research, it is accepted that there is a correlation between GVWs of the same lane and adjacent lanes in a multi-lane highway. Nowak (1993, 1995) investigated three values of GVW correlation for trucks in the same lane and adjacent lanes: $\rho = 0$ (no correlation), $\rho = 0.5$ (partial correlation), and $\rho = 1$ (full correlation), where ρ is the Pearson correlation coefficient. Based on simulations, the full correlation of truck GVWs was concluded to govern two-lane traffic loading and was also validated through site observations in the US. More recently, in a comprehensive traffic loading study, O'Brien & Enright (2011) found there were correlations between the GVWs of successive

trucks from WIM data in the EU and the inter-lane truck GVWs were also correlated based on the inter-lane gap. These correlations resulted in an increase of up to 8% in lifetime maximum loading. Zhou et al. (2018) found that the GVW of successive trucks is correlated and that the autocorrelation coefficient for two accompanying trucks with a time gap below 5 seconds is 5%.

Based on the above research, a correlation length in the autocorrelation function for GVWs is assumed in the proposed model. It should be noted that the proposed model is seeking scenarios that can produce extreme load responses, therefore, the correlation between the GVWs within a certain range must be more pronounced (i.e., scenarios with high correlations are more likely to produce extreme responses).

The maximum response of bridges with spans less than 60 m is determined by a single heavy truck, two trucks side-by-side, or two trucks following in the same lane for continuous spans (Chen & Wu 2011). Comparatively, long-span bridges have more diverse extreme response scenarios, and the influence of platooning becomes more important (Soriano et al. 2017, Hwang & Kim 2019). Thus, as the length of the loaded part contributing to the structural response (the so-called load length) increases, the governing scenario necessarily contains more heavy vehicles (e.g., all heavy vehicles within 200 meters make a non-negligible contribution to the extremes). In summary, the correlation between several GVWs must be reconsidered for the extreme response scenarios for long-span bridges.

Meanwhile, the gap assumption in traffic flow, especially in congested traffic, is very important and can make a huge difference to the result (Micu et al. 2019). To develop a model for scenarios of extreme LE, it is necessary to develop a spatial distribution model of heavy vehicles on the bridge deck. To resolve the modeling of vehicle location on the bridge deck, the bridge deck is divided into several cells according to the lane and specific constant cell length, dl. dl is determined according to the statistical data of the length of heavy vehicles. According to Chen et al. (2019), the average length of large vehicles is 15.13 m. Based on the measured WIM data, the total wheelbase (i.e., the distance from the first axle to the last axle) of the multi-axle vehicle shows a peak value of 17.5 m. Considering the influences of the front and rear overhang of the heavy vehicle, and the gap between the vehicles while driving, the length of the cell should be slightly longer than the wheelbase. Therefore, the length of the cells is taken as 20 m.

2.2 *How to consider the correlation level*

Several consecutive trucks in one lane or side-by-side trucks in adjacent lanes are the critical scenarios causing the extreme load effect, threatening the safety of bridge structures. The governing loading combination for long-loading length is always several groups of trucks and numerous on-bridge vehicles, not several side-by-side trucks or several following trucks. Therefore, in the proposed model it is assumed that there is a two-by-two correlation between the GVWs of all vehicles within a certain length of the same lane for scenarios of maximum-response-per-day event, rather than simply assuming a correlation between the GVWs of two key heavy vehicles. However, GVWs in vehicle sequences generated merely by Monte-Carlo simulation are independent of each other (Zhou et al. 2018). Therefore, Nataf transformation was employed to consider the correlation between GVWs as explained below.

The objective of setting the correlation parameters is to describe the correlation between GVWs within a certain length in the same lane for the proposed scenarios, which is reflected by the correlation function. The Pearson coefficient of correlation is adopted to characterize the correlation of GVW as expressed in Equation (1):

$$\rho_{j,k} = \frac{\alpha_{j,k}}{\lambda_j \cdot \lambda_k}, \tag{1}$$

where $\rho_{j,\,k}$ represents the coefficient of correlation between the GVW of locations l_j and l_k (i.e., the distance between j and k is short), $\alpha_{j,\,k}$ corresponds to the covariance between the GVWs, λ_j

and λ_k indicate the standard deviations of the GVWs at l_j and l_k, respectively. It is common sense that the correlation coefficient $\rho_{j,\ k}$ between two GVWs becomes weaker with increasing distance lag, $|\ l_j - l_k\ |$. Referring to engineering cases in related research, the following exponential correlation function is employed (Li & Zhang 2016, Mahadevan & Haldar 1991):

$$\rho_{j,k}\ = \exp\left(-\frac{\left|l_j - l_k\right|}{D}\right), \tag{2}$$

where D represents the scale factor reflecting the correlation length. Considering a cell the space occupied by a heavy truck (a value of 20 m is considered here), for instance, if $|\ l_j - l_k\ |$ takes the value of one centroid interval of adjacent cells (which means $|\ l_j - l_k\ | = 20$ m), then, $\rho_{j,\ k} = 0.3679$, 0.6703, and 0.8187 when D is 20 m, 50 m, and 100 m respectively (i.e., $\rho_{j,k}\ = \exp\left(-\frac{20}{20}\right) = 0.3679, \quad \rho_{j,k}\ = \exp\left(-\frac{20}{50}\right) = 0.6703, \quad \rho_{j,k}\ = \exp\left(-\frac{20}{100}\right) = 0.8187$).

Nataf transformation can be used to transfer any random variables into standard Gaussian distribution (Zhao et al. 2020). The marginal cumulative density functions (CDF) of an n-dimensional correlated random vector $\vec{\beta} = [\beta_1,\ \beta_2, \ldots, \beta_n]$ is $F_j(\beta_j)$, and the correlation coefficient matrix $K = \left[\mathrm{K}_{j,k} = \kappa_{j,k}\right]$. By Nataf transformation, $\vec{\beta}$ can be transferred into independent standard normal variables $\vec{\zeta} = \left[\zeta_j\right]$. The procedure of Nataf transformation is as follows (Der Kiureghian & Liu 1986):

Correlated standard normal variables $\vec{\xi} = \left[\xi_j\right]$ are transferred from $\vec{\beta}$ by Equation (3).

$$\xi_j = \Phi^{-1}\left(F_j\left(\beta_j\right)\right) \tag{3}$$

where $\Phi^{-\ 1}(\cdot)$ is the inverse CDF of standard Gaussian distribution. The correlation coefficient matrix of $\vec{\xi}$ is supposed as $K' = \left[\kappa'_{j,k}\right]$. Then the relationship between $\kappa_{j,k}$ and $\kappa'_{j,k}$ is shown as Equation (4).

$$\kappa_{j,k} = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\frac{F_j^{-1}\left(\Phi\left(\beta_j\right)\right) - E\left(\beta_j\right)}{SD\left(\beta_j\right)}\cdot\frac{F_k^{-1}(\Phi(\beta_k)) - E(\beta_k)}{SD(\beta_k)}\omega\left(\beta_j,\beta_k;\kappa'_{j,k}\right)d\beta_j d\beta_k \tag{4}$$

where $\omega\left(\beta_j,\beta_k;\kappa'_{j,k}\right)$ is given by Equation (5), $E(\cdot)$ and $SD(\cdot)$ are the mean and standard deviation of variables, respectively.

$$\omega\left(\beta_j,\beta_k;\kappa'_{j,k}\right) = \frac{1}{2\pi\sqrt{1-\kappa'^2_{j,k}}}exp\left\{-\frac{\beta_j^2 - 2\kappa'_{j,k}\beta_j\beta_k + \beta_k^2}{2\left(1-\kappa'^2_{j,k}\right)}\right\} \tag{5}$$

According to Equations (4) and (5), $\kappa'_{j,k}$ can be calculated by $\kappa_{j,k}$. The relationship between $\kappa_{j,k}$ and $\kappa'_{j,k}$ can be simplified as Equation (6). $P_{j,k}$ can be approximately estimated by a polynomial as Equation (7).

$$\kappa'_{j,k} = P_{j,k}\cdot\kappa_{j,k} \tag{6}$$

$$P_{j,k} = \frac{\kappa'_{j,k}}{\kappa_{j,k}} = p_1\kappa_{j,k}^3 + p_2\kappa_{j,k}^2 + p_3\kappa_{j,k} + p_4 \tag{7}$$

where the parameters p_1 to p_4 can be calculated by the Monte Carlo method.

Since the covariance matrix of $\vec{\xi}$ is positive definite, $\mathbf{K}'$ can be decomposed into a lower and an upper triangular matrix via Cholesky factorization as shown in Equation (8):

$$\mathrm{K}' = \mathrm{A}\cdot\mathrm{A}^{\mathrm{T}} = \begin{bmatrix} a_{11} & 0 & \cdots & 0 \\ a_{12} & a_{22} & \cdots & 0 \\ \vdots & \vdots & & \vdots \\ a_{1n} & a_{2n} & \cdots & a_{nn} \end{bmatrix}\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ 0 & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & & \vdots \\ 0 & 0 & \cdots & a_{nn} \end{bmatrix} = \begin{bmatrix} 1 & \kappa'_{12} & \cdots & \kappa'_{1n} \\ \kappa'_{12} & 1 & \cdots & \kappa'_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \kappa'_{1n} & \kappa'_{2n} & \cdots & 1 \end{bmatrix} \tag{8}$$

where **A** is a lower triangular matrix. Therefore, the variables $\vec{\xi}$ can be expressed as the product of **A** and the independent standard normal variables $\vec{\zeta}$, as shown in Equation (9):

$$\vec{\xi} = \mathbf{A} \cdot \vec{\zeta} \tag{9}$$

Then the relationship of the independent standard normal variables $\vec{\zeta}$ and the original correlated variables $\vec{\beta}$ can be established as Equation (10):

$$\begin{aligned} \beta_1 &= F_1^{-1}(\Phi(a_{11}\zeta_1)) \\ \beta_2 &= F_2^{-1}(\Phi(a_{21}\zeta_1 + a_{22}\zeta_2)) \\ &\vdots \\ \beta_n &= F_n^{-1}(\Phi(a_{n1}\zeta_1 + a_{n2}\zeta_2 + \cdots + a_{nn}\zeta_n)) \end{aligned} \tag{10}$$

where $\Phi(\cdot)$ is the CDF of standard Gaussian distribution. Then, the Monte Carlo method is used to analyze the scenarios of extreme load effect, in which the correlated GVWs are simulated according to Equation (10).

2.3 *The immeasurability of the correlation parameters*

Taking a correlation length of 100 m as an example, Figure 1 depicts the GVW correlation between the first heavy vehicle (the red one) and other simulated heavy vehicles with a possible presence in the same lane. In the figure, it can be seen that the correlation between simulated GVWs based on the Nataf method becomes smaller as the distance increases. In Figure 1, the correlation length in the Nataf simulation is 100 m and it can be seen that when the distance between the trucks is 100 m, the correlation between the GVWs of the two vehicles is 0.3679. When the distance is greater than 120 m, the correlation between the GVWs of the two vehicles is basically less than 0.3 (i.e., a weaker correlation).

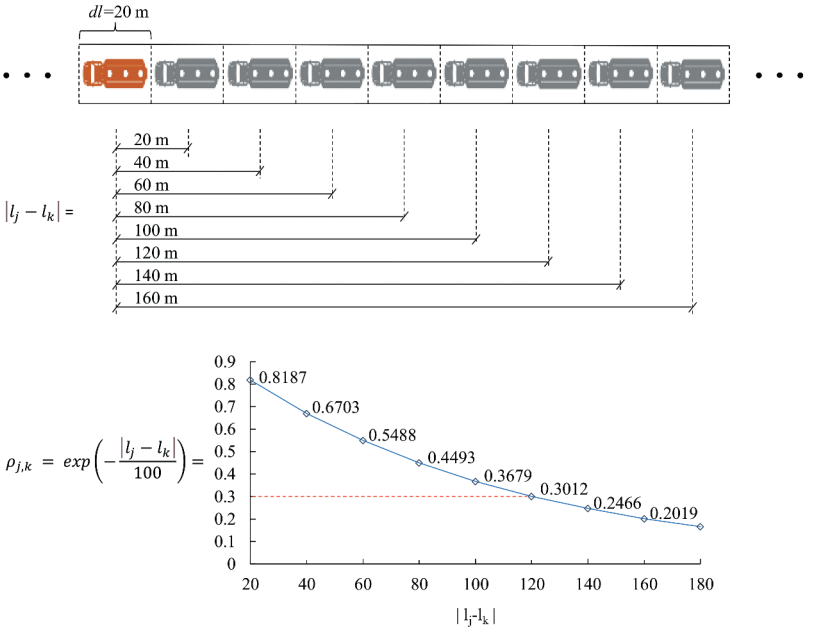

Figure 1. The correlation between the GVWs of simulated heavy vehicles for D=100 m.

Based on the above description, the larger the correlation length D, the higher the level of correlation of GVWs between heavy vehicles in the lane. Therefore, the value of D has an important influence in the correlation between GVWs and, at the end, in the loading effects.

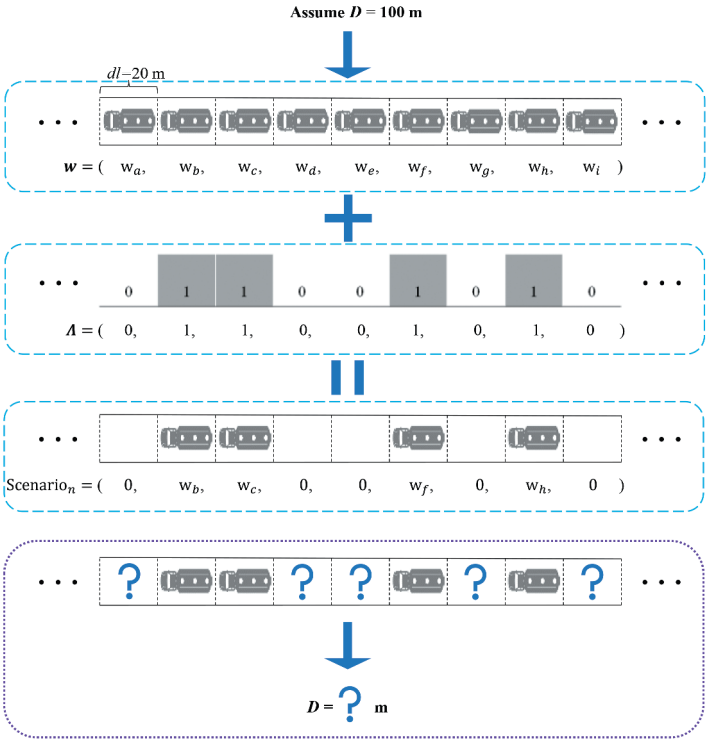

Figure 2. The process of simulation of correlated GVWs and its immeasurability.

However, the value of D is not measurable according to the simulation of maximum response scenarios as presented in (Wang et al. 2024). In fact, as shown in Figure 2, where the simulation process is presented, if only the extreme response scenarios are available and the GVWs in the blank cells are not known, the correlation lengths cannot be calculated. It also should be noted that the Kriging interpolation method, which is very popular in the field of geotechnical engineering, can be used to solve this problem, which will be the subject of future work. As the actual value of D cannot be known, in the present study the aim is to see which is the sensitivity of the maximum load effects to its value. Just reasonable assumptions are made on the correlation lengths, i.e., 20 m, 50 m, and 100 m. and their effect on the obtained results are analyzed and discussed. The process is as follows: Firstly, the GVW correlation length of multi-vehicle events is assumed (i.e., 20 m, 50 m, 100 m); Secondly, the GVW simulation with correlation is performed based on the Nataf method; Thirdly, the presence or absence of heavy vehicles in each cell is simulated based on the Poisson method (Wang et al. 2024); Finally, the simulated vehicle scenario is obtained and the load effect calculated.

3 RESULTS AND DISCUSSION

The method has been applied to two kinds of effects of a cable-stayed bridge, first is the axial force of the longest cable at mid-span; second is the vertical deflection of main girder at mid-span of the main span. The elevation of the cable-stayed bridge and the influence lines of the effects are shown in Figure 3, meanwhile, the cable of the first effect is marked with the green dot-dash line in the figure. Figure 4 displays the differences between the CDF of the effects for different correlation levels. Figure 4 (a) shows the CDF of the extremum of vertical deflection, and Figure 4 (b) shows the CDF of the extremum of axial cable force. The subfigures are the partial magnification.

For low response values, it becomes evident that the influence of the correlation length is negligible. However, in the calculation of the maximum load effects, the higher extreme values are of interest. It can be seen that when the CDF value is more than 0.9, the influence of D is evident and the exceeding probability is larger for the extreme effect simulated with a higher correlation length. Assuming no correlation at all provides results on the unsafe side in the order of 10% when compared with the results for D = 100m, which is a reasonable guess. The extreme value increases with the increase of the correlation in the GVWs, as a result of the assumption of the value of the correlation length. This is because the distribution of the effect extremum of simulated scenarios has longer tail behavior for a larger correlation. At a high CDF value as shown in subfigures in Figure 4, the effect extremum increases significantly with increasing correlation coefficient of GVWs. This follows the physical meaning that a larger probability of heavy vehicle queuing will lead to a larger probability of occurrence of extreme response values. An obvious fact is that the correlation coefficient of GVWs has a direct relationship with the probability of heavy vehicle queuing. It can also be seen that, with a sufficient number of Monte Carlo simulations, statistical differences in the simulation results under different correlations can be manifested.

4 CONCLUSIONS

Due to the fact that a greater variety of extreme response scenarios are present in long-span bridges, and the impact of truck groups is significant, in this paper a simulation approach of on-bridge deck vehicle distribution considering the correlation level of vehicles is concerned to evaluate the influence of the correlation length in the extreme values of the response. The

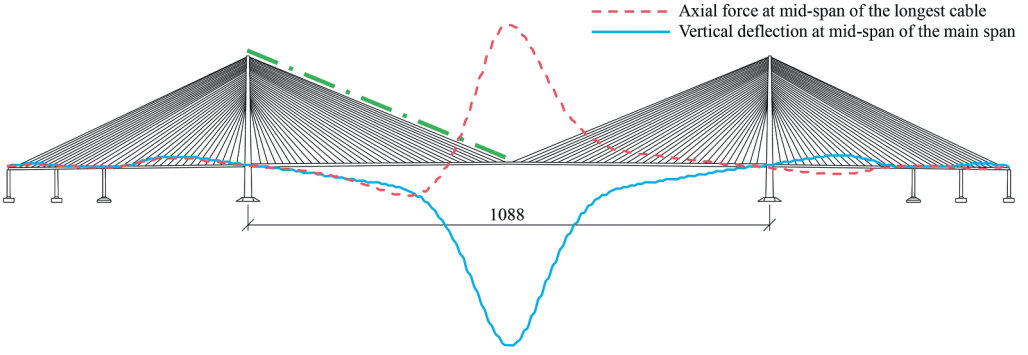

Figure 3. The elevation of the investigated cable-stayed bridge and the effects' influence lines.

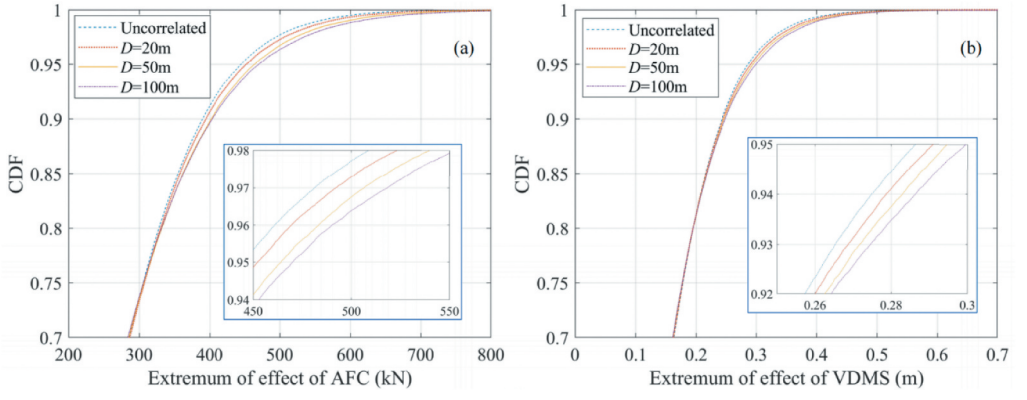

Figure 4. Response results (CDF) of two effects under different correlation levels: (a) axial force at mid-span of the longest cable; (b) vertical deflection at mid-span of the main span.

necessity and methodology of considering the correlation of GVWs are carefully discussed. It is found that with the increase of correlation level of neighboring GVWs, the simulated load effects are more prone to get extreme values, which means an increasing probability of the most unfavorable spatial arrangement of on-bridge vehicles. The correlation model is based on the concept of a correlation length. Due to the impossibility of calculating this length, several values are assumed and their influence on the simulated results analyzed. Based on the results obtained for several correlation lengths, it is recommended that the correlation level should be chosen as 100 meters. Meanwhile, it is necessary to reevaluate the association between GVWs for the most extreme response scenarios involving long-span bridges.

PyBTLS: A Python package for traffic load simulation on short-to-medium bridges

Z. Zhou
Ph.D. Candidate, Monash University, Melbourne, VIC, Australia

C. Caprani
Associate Professor, Monash University, Melbourne, VIC, Australia

ABSTRACT: PyBTLS is an open-source Python package developed for the efficient simulation of traffic loads on short-to-medium-span bridges, under a GPLv3 license. This tool addresses the gap in the bridge research field regarding generating new bridge structure load effect data with its corresponding traffic record from a known traffic condition. With the benefit of bridge structure load effect data, bridge traffic load models can be more comprehensive; therefore, the precision of bridge design and assessments can be enhanced. PyBTLS is based on C++ fundamentally but offers a user-friendly Python application programming interface (API). Users can easily generate diverse traffic scenarios and conduct load effect calculations with integrated or customized influence lines for long time periods. This paper introduces PyBTLS's basis and functionalities broadly, along with a real-world application case to indicate its workflow. Beyond its current capabilities, under the open-source license, contributions from bridge engineering researchers are welcomed. It is hoped that the release of this software will help accelerate research and practice.

1 INTRODUCTION

Economic development accompanied by freight growth is leading to higher traffic loads on bridges. Concurrently, the capacity of bridges is dropping due to structural ageing. Thus, to ensure safety, the assessment of existing bridges becomes increasingly significant. According to reliability theory, assessment results rely on the collected bridge information, and the information characterised by greater randomness is most significant (OBrien et al., 2015). Traffic, as one of the most variable sources of load on bridges, has been a focal point of research in recent decades. To acquire more comprehensive traffic data for more precise traffic load models, bridge engineers have employed technologies such as strain-sensor networks and Weigh-in-Motion (WIM) systems (Moses, 1979).

Although traffic and structure monitoring technologies have significantly enhanced the accuracy of traffic load models, their installations, due to budget constraints, are mostly limited to long-span bridges serving as major traffic infrastructures, such as Melbourne's West Gate Bridge (Roadsys, 2022). For the most common short-to-medium-span road bridges, there is a notable gap in the efficient acquisition of traffic load data. A category of research, exemplified by Zhang and Au (2017), generates traffic load data by manually adjusting their simplified traffic, which is inefficient and could potentially lead to biases.

The newly-released Python package PyBTLS (i.e., bridge traffic load simulation) addresses the research and practice gaps by facilitating state-of-the-art traffic simulations on any short-to-medium-span bridges; typically for spans are less than about 50 metres. The traffic in these simulations can be generated from known traffic conditions, where a known traffic condition

DOI: 10.1201/9781003483755-147

is defined by its vehicle characteristics (e.g., number of axles, axle spacings, axle weights, etc.) and traffic flow characteristics (e.g., traffic volume, traffic composition, etc.). The vehicle characteristics can be obtained through WIM systems installed in that region; The traffic flow characteristics can be acquired via relatively inexpensive methods, such as loop detectors or computer-vision-based vehicle counting and classification. With the benefit of bridge traffic load data from the simulations, more precise traffic load models can be proposed for bridge design standards worldwide, or the distributions of load effect can be used in the reliability assessment of an existing bridge.

In this paper, the general information of PyBTLS and its functionalities is introduced broadly first. Then, PyBTLS's classes and their interrelations are presented. Finally, the workflow of a PyBTLS simulation is introduced via a real-world bridge assessment project.

2 GENERAL INFORMATION AND FUNCTIONALITIES

PyBTLS is wrapped from a Windows-only C++ program BTLS (Caprani, 2021) via pybind11 (Schreiner et al., 2023), a Python-C++ wrapping library. This wrapping makes PyBTLS cross-platform, and it also simultaneously benefits from both the convenience of Python and the efficiency of C++. PyBTLS follows the GPLv3 open-source license (Free Software Foundation, 2007).

The software implements the calculation and evolution methodologies described in Chapter 3 of OBrien et al. (2021).

2.1 *Assumptions*

The main assumptions of PyBTLS, suitable for short-to-medium span bridges are:

- The vehicles do not have lane-change behaviours; such behaviour is not included in the traffic evolution model.
- The vehicles are at constant velocities when crossing the bridge.

2.2 *Functionalities*

The key functionalities of PyBTLS are:

- PyBTLS can conduct the following pre-processing:
  - Classify vehicles based on a vehicle classification scheme.
  - Classify vehicles based on common vehicle properties, such as the number of axles, gross vehicle weight, etc.
  - Get statistical information from a WIM database (e.g., quantiles, standard deviation, etc.).
  - Divide a WIM database into several sub-databases.
  - Assemble a new WIM database from the provided sub-databases.
- PyBTLS has four basic simulating modes:
  - Calculate load effects caused by a single vehicle, which is useful for validations.
  - Generate traffic according to a traffic generation model and calculate its load effects. This can be done in memory, and so extremely long-run simulations are possible (1000s of years of traffic).
  - Calculate load effects caused by recorded traffic read in from a WIM file.
  - Generate traffic according to one of the traffic generation models and output to file.
- For the output, PyBTLS can:
  - Extract statistical information from recorded or generated traffic.
  - Record time-history data of the load effects.
  - Indicate the amplitudes of the load effects of each event (i.e., number of vehicles on bridge changes).

  - Conduct block-maximum or peak-over-threshold analysis on the generated traffic load effect data to derive extreme load events (OBrien et al., 2015).
  - Conduct rainflow-counting analysis (Lee and Tjhung, 2011) on the generated traffic load data to derive fatigue load events.
- PyBTLS can conduct the following post-processing:
  - Plot the load effect simulation outputs.

3 CLASS MAP

PyBTLS is written in an object-oriented style. This means that the common functionalities of certain classes are abstracted into base classes, while the details of each implementation are in derived classes. In particular, this makes it relatively easy to add new vehicle generators, and new traffic generators as shown below.

The simulation-relevant classes in PyBTLS and their interrelationships are elucidated in Figure 1. The classes are as follows:

- `Vehicle`: This class is designed for the customization of vehicles. A vehicle instance requires the following fundamental attributes: number of axles, axle spacings, axle weights, and axle widths.
- `Bridge`: This class is pivotal for traffic load calculation. In PyBTLS, the essence of a load effect on a bridge is conceptualized as a series of influence lines (each corresponding to a lane) or an influence surface. Although most influence lines or surfaces have complex shapes and should be defined by discrete data points calculated from the structure analysis packages such as PyCBA (Caprani, 2023) and ospgrillage (Ngan and Caprani, 2022), PyBTLS still incorporates nine built-in influence lines according to their mathematical expressions, as depicted in Table 1. A bridge instance can be set with multiple load effects for different bridge components.

Table 1. The built-in influence lines in PyBTLS.

PyBTLS Index	Influence Line	Number of Spans
1	Sagging moment at mid span	1
2	Hogging moment at mid support	2
3	Shear force at left support	1
4	Shear force at right support	1
5	Shear force at right support	2
6	Shear force at left support	2
7	Total amount of loads on the bridge (i.e., a unit IL)	Any
8	Hogging moment at the second support	3
9	Hogging moment at the third support	3

- `TrafficGenerator`: This is the class for traffic generation, and each lane should have a generator. A `TrafficGenerator` instance requires the following inputs: a vehicle generator (which creates the physical vehicle), a headway generator for creating the haps between vehicles, and a lane flow composition, for managing flow rates and vehicle occurrences. The lane flow composition includes hourly average speed information of the traffic flow and the hourly traffic composition.
  - PyBTLS currently contains three types of vehicle generators:
    - `VehicleGenGrave`: Utilizes statistical distributions of common trucks based on several European site data (Grave, 2002). The VehicleGenGrave is not readily applicable outside Europe due to varying legal truck configurations by region.
    - `VehicleGenGarage`: Generates vehicles through random sampling based on the collected WIM database.

  - `VehicleGenNominal`: Generates identical vehicles based on a user-defined vehicle, which is very useful for validations or similar studies.
- PyBTLS currently offers four types of headway generators:
  - `HeadwayGenNHM`: Based on a truck-only headway distribution concluded from the highway on Auxerre (Grave, 2002).
  - `HeadwayGenConstant`: Sets identical headway and speed for all vehicles.
  - `HeadwayGenCongested`: It adopts an input nominal axle gap, representing the average spacing between vehicles in traffic congestion, along with a coefficient of variation for the gap to ensure randomness (Blacoe et al., 2012).
  - `HeadwayGenFreeflow`: It uses a Poisson arrival assumption based on the normalized headway model (Crespo-Minguillon and Casas, 1997).

- `TrafficLoader`: This class is used for loading a recorded traffic flow. Users can also customize a traffic flow by creating and assembling each Vehicle instance.
- `OutputConfig`: This class determines the output of the simulation.
- `Simulation`: Depending on the input argument, this class automatically runs the corresponding simulating mode.

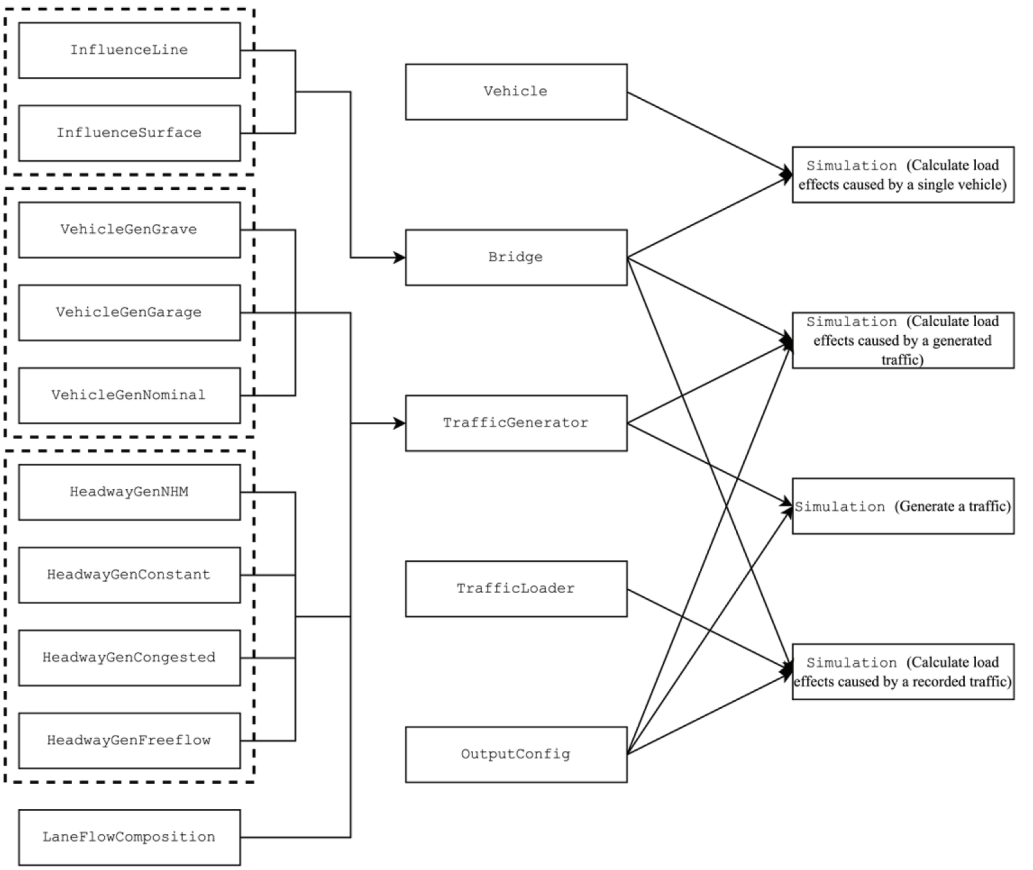

Figure 1. Class map of PyBTLS.

4 EXAMPLE

To demonstrate how PyBTLS can be applied, an example from a past Austroads-sponsored (Australian road research agencies) project in which BTLS was used is introduced here to illustrate the general workflow of PyBTLS. The project focused on integrating the

probability-based bridge assessment (PBBA) framework into existing Australian road bridges' assessment procedures (Melhem and Caprani, 2022). The selected bridges were representative, but they were not equipped with sensor networks for monitoring. Therefore, within the constraints of a limited budget and project timeline, employing BTLS to generate artificial traffic load data emerged as a good option. The following part shows the fundamental code for conducting the simulation for one of the bridges in the project, with explanations.

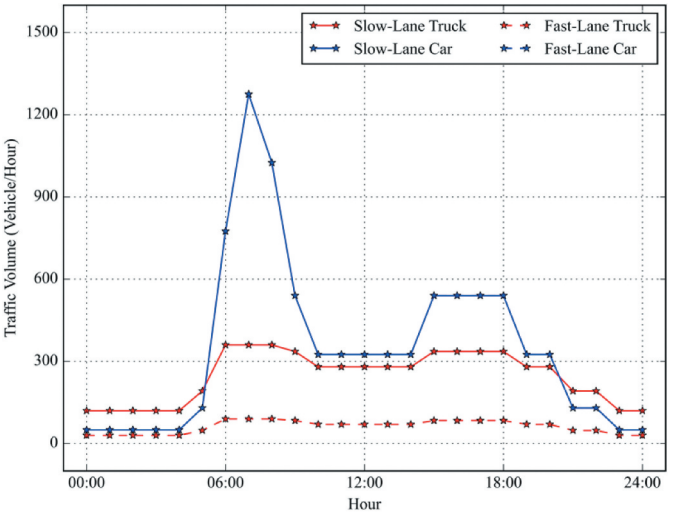

Figure 2. The traffic flow for demonstration.

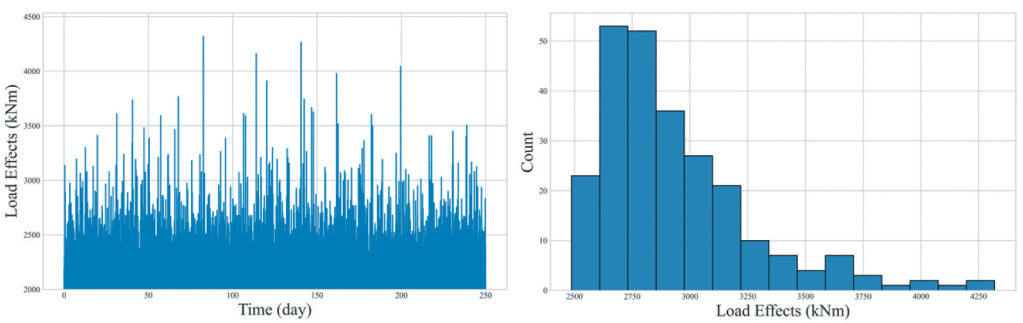
Here, we consider a 20-metre single-span bridge with two lanes of unidirectional traffic. The hourly traffic flow rates are shown in Figure 2 (Lipari, 2013). The midspan bending moment is sought. In the project, 100 years of traffic data was generated, but in the demonstration, we only generated 1 year (250 working days). The steps are shown in Figure 3 below.



A description of each line of the source code is given:

- Line 1: Import the package.
- Line 2 – 9: Regard the bridge as simply supported, and the midspan bending moment for a simply supported bridge is built-in to PyBTLS (see Table 1). Then, the influence line shapes are the same for both two lanes but with different weights according to transverse distribution of the load across the bridge deck.
- Line 10 – 17: The `VehicleGenGarage` is selected as the vehicle generator. The busiest bridge in Melbourne, West Gate Bridge, had installed a pavement WIM system, which recorded millions of vehicles. Thus, a truck garage file from the WGB is taken to represent Australian freight. The kernel ensures the randomness of the trucks during the sampling instead of just repeating the garage. The kernel is made by bias and standard deviation values for gross vehicle weight, axle group weights and axle group spacings.
- Line 18: The `HeadwayGenFreeflow` is selected as the headway generator with a minimum vehicle gap of 0.1 second and minimum vehicle spacing of 1 metre. This approach is conservative according to Chapter 3 of OBrien et al. (2021).
- Line 19 – 38: The lane flow compositions of the two lanes are defined based on the data in Figure 2.
- Line 39 – 41: Establish a traffic generator.
- Line 42 – 44: Set an output configuration to obtain time history and block maximum data. The block size is set to 1 day.
- Line 45 – 53: Use the bridge, traffic generator, and output configuration objects to create a simulation task. In practice, by repeating Line 2 – 44 with corresponding input arguments, more than one simulation task can be created.

(a) Time history (b) Block Maximum histogram

Figure 4. The outputs from the demonstration.

- Line 54: After all simulation tasks are created, they are suspended until users call the `run()` method to start running. When there is more than one simulation task being created, PyBTLS uses multiprocessing to run these simulations simultaneously. In this demonstration, only one simulation task was created, and it occupied one minute runtime on a core of an Apple M1Pro chip.
- Line 55 – 56: Plot the time-history and block-maximum result by the PyBTLS post-processing module, Figure 4.

5 CONCLUSION

In summary, PyBTLS has the capability to expand the traffic load database for short and medium-span bridges, thereby greatly enhancing the accuracy of bridge traffic models. It facilitates studies leading to new traffic load models for codes; and also facilitates the development of load effect distributions for the structural reliability assessment of existing bridges. Such an approach helps to extend the utility of existing WIM stations.

The traffic and load effect data generated by PyBTLS can be used in studies related to bridge strength and fatigue. As an open-source package, interested researchers and practitioners can contribute to PyBTLS to expand its capabilities as required for application in different countries and contexts.

ABSTRACT: The diagnosis of the Rochers Noirs Viaduct, listed as a Heritage Building in 2000 and closed to traffic since 2006, revealed some significant defects in the suspension cables that shall be completely renewed. Furthermore, the upper steel decking, only designed to support personnel maintaining the original railway line, is unfit for future use and shall also be fully replaced to enable the re-opening of the viaduct for soft mobilities. Some rehabilitation works also need to be undertaken on the masonry and ironworking. As of November 2023, the deck is supported by a temporary suspension, the old suspension has been dismantled, the new suspension has been installed, and the load transfer from temporary to new suspension is about to take place, while the painting works are ongoing.

1 PRESENTATION OF THE BRIDGE

The Rochers Noirs Viaduct was built between 1911 and 1913, between the rural cities of Soursac and Lapleau in the Correze department in France. Its originality lies in a hybrid suspension (Figure 1) made of two fans, comprising inclined stay cables linked to two half parabolic cables, the whole being assembled as a triangulated mesh. Each cable mesh is connected to an upper catenary cable, called an Ordish, through vertical hangers. This type of rigid suspension system was developed in order to allow trains of the Transcorrézien line to cross the bridge.

At deck level, the crossbeams connected to the suspension cables by vertical hangers are spaced at 11.80m intervals with a main span of 140m. The deck is 5.0m wide and is made of two longitudinal inner I girders under the rails at 1m spacing and two external I girders, made of riveted assembled plates. The deck is elevated at 90m above the Luzege river. The masonry pylons reach respective heights of 55m on the Soursac side and 43m on the Lapleau side.

The Tramway line was closed in 1959, and the viaduct was then transformed into a road bridge in 1963. The viaduct has been closed to traffic since 2006, following evidence of severe defects on the suspension cables. The bridge is now being restored to enable reopening to public for soft mobilities at the end of 2024.

DOI: 10.1201/9781003483755-148

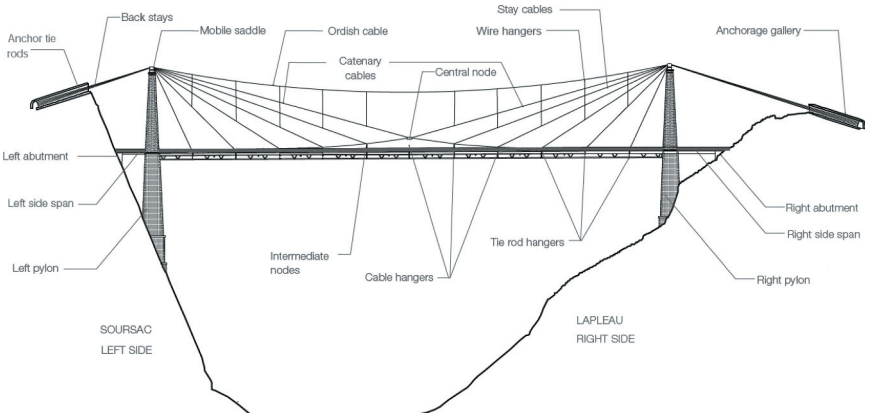

Figure 1. Glossary of the viaduct of the Rochers Noirs (© RL&A).

2 HERITAGE CONTEXT

2.1 *A local network amongst the national networks*

At the time of the industrial revolution in the mid-19th century, passenger lines connected the first railways intended to transport coal. The national network developed rapidly, but large companies were not interested in regional railways considered as unprofitable. In order to enhance the development of railway lines in the rest of the territory, the State regulates the development of the network and wants to provide Corrèze with a secondary network, the Paris-Orléans-Corrèze. Since large population areas are not serviced by this line, the General Council opts for the creation of a complementary tram network in Corrèze. The Rochers Noirs viaduct constitutes the strong point of the Tulle-Ussel line.

2.2 *Invention of the Gisclard suspension system*

Albert Gisclard was born in 1844. After entering the Ecole Polytechnique at the age of 20, he joined military engineering where he designed many types of bridges, with the aim of quickly and efficiently replacing those destroyed during conflicts. In 1900, he filed a patent for a suspension bridge allowing the passage of much heavier loads than on traditional suspension bridges which were invented and built by Marc Seguin, then improved by Ferdinand Arnodin. "The cables are arranged in a very particular and complex pattern, casting sockets are placed at their ends and at their intersections, to form a rigid system of triangles and polygons which can be calculated from the rules of static and which gives to the structural system a great rigidity which was lacking in medium- and long-span suspension bridges". To test the feasibility and effectiveness of the system, he gave the construction license to the Arnodin company.

2.3 *Adopting the Gisclard system for the Rochers Noirs Viaduct*

The configuration of the land, the curves to be respected on the Lapleau side, the tunnel on te Soursac side and the depth of the ravine encouraged the Tramways Company of Corrèze to rule out ordinary metal bridges due to the financial cost. The solution of a suspension bridge was chosen and a comparative study between several systems was performed. These preliminary studies were carried out in 1909, when the Gisclard suspension bridge at La Cassagne in France had just been completed and gave interesting results during the load test. The technical and economic advantages of this new type of bridge were thus recognized, and the Gisclard system was adopted for the crossing of the Luzège. The bridge was inaugurated in 1913 (Figure 2).

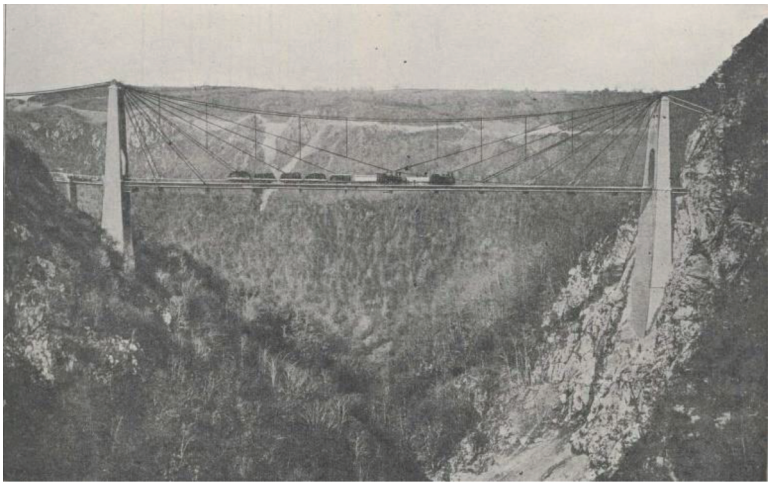

Figure 2. Load testing during bridge opening [1].

2.4 *Content of the work permit on listed Heritage Building*

The bridge was listed as a Heritage Building in 2000 due to its unique features as an exceptional work of art, testimony to avant-garde technology and emblematic of the research for theoretical and constructive innovations in the early 1900s. It is one of the only remaining examples of a Gisclard bridge still preserved today. The restoration project, presented as part of the work permit on a/the Listed Heritage Building, was necessary to rediscover the use of the Rochers Noirs Viaduct, an essential condition for the transmission of this heritage. Its new function as a bridge for soft mobilities will guarantee its maintenance and therefore its long-term conservation. The main challenge is to find a compromise which allows both the preservation and highlighting of the historical building, while respecting the authenticity of the form and material and ensuring the safety of users.

3 DETAILED INSPECTION AND BRIDGE DIAGNOSIS

The purpose of the diagnosis carried out in 2020 at the start of the project was to update the health condition of the viaduct. The Setec Diades inspectors did not observe significant development of defects since the last bridge inspection in 2005. However, the viaduct is still subject to ageing and climatic hazards.

The suspension components show signs of widespread external corrosion, due to the deterioration of the existing anti-corrosion coating. Putty defects are systematically observed at the cable ends at socket entry level.

These visual findings on the condition of the cables are supplemented by the results of auscultation campaigns conducted by the Owner to assess the internal condition of the cables. In fact, three electromagnetic inspection campaigns were previously carried out, in 1979, 1982 and 2004. Considering evidence of multiple internal wire breaks, the condition of the cables was considered to be severely deteriorated. The result of the 1982 inspection of cables was the main trigger for the road traffic closure on the bridge. Finally, hardness tests on the tie rods of the suspension carried out in 2004 concluded that all the tie rods were fragile at cold temperature such that the bridge was totally closed to public in 2005.

The mobile saddles at the top of the pylons were first considered to be in good visual condition. However, the endoscopy inspection carried out subsequently revealed a general state of rusting between the rollers and the base plates (Figure 3). Hence, the mobile saddles were considered to be blocked and not functional since they could not move freely at pylon tops, a condition for the proper structural behaviour of the masonry pylons.

Figure 3. Mobile saddle and rolling cylinders at pylon top (© setec diades).

The steel beams of the deck have a deteriorated anti-corrosion coating. However, the general structural condition of the beams is considered satisfactory. Some occasional repairs are to be expected for the most significant defects, in particular due to the poor water drainage details of the deck with the installation in 1960 of drainage tubes directly above the cross beams.

The decking shows significant deformations, and even some localized tears. Its drainage is almost non-existent, and the corrosion is widespread (Figure 4).

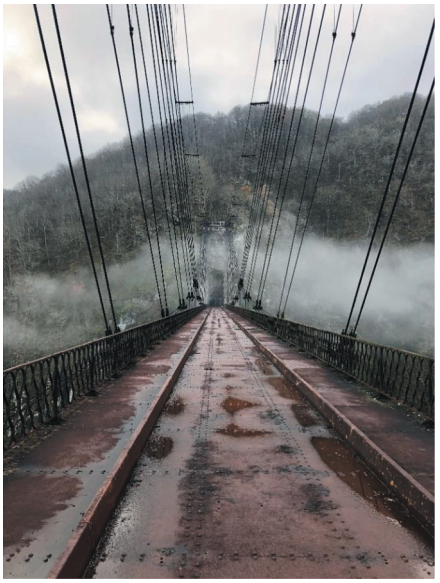

Figure 4. State of steel decking before replacement works (© setec diades).

The handrails do not meet current standard requirements but have notable heritage value. They will be restored and strengthened (Figure 5).

The anchorage galleries, directly dug into the rock cliffs with a horseshoe shape, are also a specific feature of this bridge. They are subject to constant ambient humidity and significant water stagnation at their low point, due to the absence of drainage. The resulting condition of the tie rods anchoring the back stays is very poor, with advanced corrosion and significant section losses, even though they were renewed in 1985.

The state of conservation of the masonry of the pylons is very good. The inspection was carried out by drone by establishing orthophotographs. However, some areas are hidden, either by heavy covers of vegetation or, at the top of the pylon, by drippings of coal pitch used as cable coating.

Figure 5. In situ test for the new handrail (© setec diades).

4 DESIGN STUDIES OF THE RESTORATION PROJECT

4.1 *Structural assessment of the viaduct*

The bridge was modelled and recalculated in the future configuration using a large displacement finite element model with the Pythagore© software developed by Setec tpi. It was also fully modelled in 3D on Tekla (Figure 6).

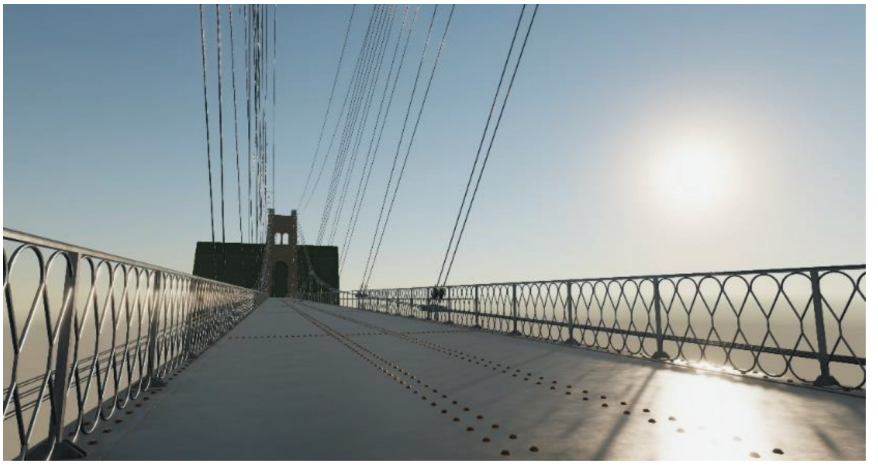

Figure 6. Tekla model of the bridge (© Setec tpi).

The original test train weighed 137.5t, while the Eurocode pedestrian load represents 190t distributed over the entire main span. In addition, the decking must be able to support at all points the loads of isolated wheels from the accidental 12t vehicle prescribed by the Eurocode for pedestrian bridges, while the wheels of the train could only be located onto the inner longitudinal girders of the deck under the rails. The existing decking, made up of an unstiffened 6mm steel sheet designed only for railway maintenance personnel loads, is therefore unsuitable for future use and must be replaced entirely. The new decking will be made up of a 10mm steel plate fitted with 10mm x 100mm transversal stiffeners spaced every 250mm. The verifications in the future situation also include the comfort criteria for pedestrian bridges, the verification of the temporary stages during cable replacement works, and the finite element verification of the retained elements of the suspension, namely the mobile saddles, the steel cylinders at intermediates nodes and the central node.

4.2 *Suspension replacement*

The existing cables are replaced by cables of identical technology, namely Open Spiral Strand (OSS) cables with wires having a rope grade of 1770 MPa. Despite the increase of the rope grade compared to the existing one, the diameter of the new cables is set at 85% of the existing

diameter by the Works Permit on Heritage Building, for the sake of cost-efficiency. The tie rods connecting the cables together are replaced by high resilience steel tie rods. The existing base plates and rollers of the mobile saddle, which were heavily corroded, are replaced by identical stainless-steel elements. The iron cylinders located at the intersection nodes of the triangulated cable mesh, the central nodes, and the mobile saddles, are preserved due to their high heritage value and their satisfactory health condition, after ultrasonic inspection and structural assessment my modelling are carried out.

4.3 *Masonry works*

The project also includes a regeneration of the masonry which includes cleaning the facings, removing the vegetation covering the masonry of the piers and abutments, removing backfill material accumulated behind the piers, dismantling and then reassembling the disorganized masonry, general repointing of the exterior facings, and finally the application of aqua fortis to the facings. Suitability tests on the colour of the joint relining material were carried out in the presence of the DRAC Région Nouvelle Aquitaine and the Architect.

4.4 *Paint works*

The decking will be painted with an ACQPA C4H ANV complex, covered with a non-slip waterproofing complex and fitted with drain tubes that are long enough to purge rainwater without splashing on the beams. All metal beams will be repainted under confinement with a black ACQPA C4H AMV complex in accordance with the original colour of the bridge. The cables will be provided with double protection by the mean of hot dip galvanisation plus paint protection according to ITSEOA recommendations. The tie rods in the anchorage galleries will also be coated with double protection galvanization plus painting, due to the humid environment in the anchor galleries. Additional drains are to be core-drilled at the low points of the anchor galleries down to road level to continuously evacuate infiltration water from the galleries, reducing the ambient humidity and therefore the development of the corrosion of the tie rods in the anchorage galleries.

5 RESTORATION WORKS

5.1 *General methodology*

Suspension replacement is the first task to be carried out for obvious safety reasons. Once complete, the decking can then be replaced safely. The repair works on the pylons, the restoration and strengthening of the handrails, and paint works are carried out after the load transfer onto the temporary suspension and in parallel with other suspension tasks and decking replacement.

5.2 *Detailed design*

The detailed design is based on a complete topographical survey of the viaduct by a scanner, supplemented by manual on site measurements. Three general calculation models were used:

- a calculation model for assessing the existing situation before works on site to determine the allowable loads during construction,
- a calculation model of the bridge in the temporary stages, to assess the suspension replacement works,
- a calculation model of the bridge to verify the bridge after it is re-opened to public for soft mobilities.

These calculation models were carried out with SCIA finite element models in 3D (Figure 7), in non-linear and large displacements analysis. These models are also used for load transfer calculations and to design the large number of temporary works required on site. In terms of drawings, a complete 3D CAD model of the bridge in the different phases of work and in its environment enabled the design of new elements and numerous temporary works. In total, 97 drawings and 41 calculation notes will have been produced.

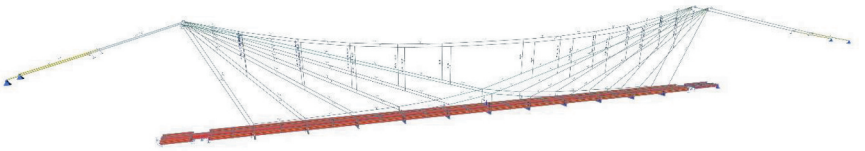

Figure 7. Detailed design structural model (© Baudin Châteauneuf).

5.3 *Temporary suspension principles*

The temporary suspension is made of typical parabolic suspension cables placed above the existing suspension. To facilitate the connection of the vertical hangers to the deck, the spacing between the two fans of the temporary suspension is reduced in the main span part by a set of strut and tie.

Figure 8. Temporary suspension cables and steel frame at pylon tops (© Jean-Dominique Lamy).

At the top of each pylon leg, the temporary suspension rests on a metal frame (Figure 8) supported on two reinforced concrete anchor blocks placed on either side of the leg. The loads are transferred to the masonry by friction through to six pre-stressed horizontal bars clamped to the masonry. The geometry of these frames has been designed to facilitate the disassembly and assembly of the cables, the mobile saddle refurbishment, and the replacement of the rollers.

The temporary cables are anchored in the existing horseshoe anchorage galleries following the same principle as the existing cables. The position of these cables has been carefully studied to allow the cohabitation of the two suspension systems and the handling of all the anchoring elements (plates, tie rods, deflectors).

Due to restricted accessibility on site, the studies included strong assembly constraints. Indeed, the design of the temporary frames placed at pylon tops allowed assembly and dismantling in assemblies of less than 1t, which made it possible to carry out the helicopter transport of these structures (2 times 10t after assembly).

The existing state of the deck also limited access and equipment on the structure. Accordingly, the suspension was designed to be assembled almost entirely on the ground before erection. The suspension was erected with portable traction.

5.4 *Manufacturing for heritage listed Bridge*

The new cables of the bridge were manufactured in the Châteauneuf sur Loire workshop with a stranding machine allowing the manufacture of Open Spiral Strand cables identical in appearance and technology to the existing cables (Figure 9).

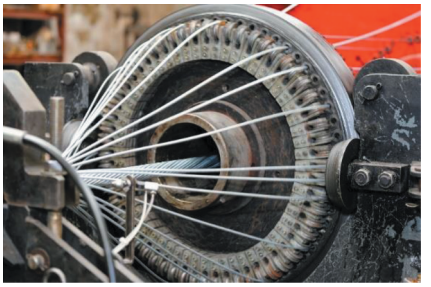

Figure 9. Stranding machine in operation (© Jean-Dominique Lamy).

The new cable sockets were manufactured with a shape very similar to that of the existing sockets. The diversity of cable diameters, and shapes and types of sockets led to the creation of 27 different pieces. The heaviest socket is a massive piece of steel weighing 93kg.

The new decking will be connected to the bridge beams using the arrangement of existing holes. The existing rivets holes will be reused, and the use of rounded head bolts will preserve the aesthetics of the riveted structures, while being more economic than traditional rivets installed at a high temperature with furnace on site.

5.5 *Load transfer*

After the installation of the temporary suspension, the last step of securing the structure was carried out: the load transfer n°1. 101 hydraulic jacks with a capacity of 10 tonnes to 100 tonnes are being used for the load transfer. The jacks are positioned on the temporary vertical hangers and the back stays of the two suspensions. These operations are carried out in stages whose order and jacking strokes have been studied to limit the movement of the saddles, considering that the existing saddles are blocked. At the end of each stage, an analysis of the geometry and pressure measurements are carried out to validate the conformity of the phase and to continue the load transfer. As of October 2023, the bridge is supported by the temporary suspension and the existing Gisclard suspension has been removed (Figure 10).

Figure 10. Bridge configuration in Octobre 2023 with temporary suspension (© Baudin Châteauneuf).

ABSTRACT: Many in-service Reinforced concrete box culverts (RCBCs), designed according to older design codes using lighter design truck weights, may require restrictive load posting when rated for current design and permit loads although no structural distress is observed. Most load rating engineers typically utilize 2 dimensional (2D) structural frame software, which leads to fast but highly conservative results. The ratings are negatively affected by the conservative live-load attenuation through soil fill, along with the inability of the 2D method to account for any lateral load distribution. The present study aimed to load rate RCBCs based on strains obtained from field testing. The testing evaluated strains induced by live-load distribution through soil fill when load rating eighteen (18) cast-in-place RCBCs in Kentucky. RCBCs with one-, two-, three-, and four-cells were load tested and the effects of truck live loads analyzed. Fill heights varied from 0 m to 3.6 m, cell spans from 3.0 m to 6.7 m, and culvert spans from 6.7 m to 18.6 m. Strain gauges were attached to the interior surfaces of culverts and the data recorded corresponding to known truck loads and positions. Irrespective of the number of cells in the RCBC, strain variations in the top slab were similar with change in fill height. Maximum strains in the top slabs measured less than 10 microstrain, a value at which live-load effects could be considered negligible, at fill heights greater than 3.05 m. The load rating based on field tests improved both Inventory and Operating rating factors for all tested RCBCs.

1 INTRODUCTION

1.1 *Culvert load rating*

Guidelines from the Federal Highway Administration (FHWA) in the United States categorize structures with a span equal to or greater than 6.1 m as bridges. Culverts meeting this criterion are designated as bridge-size culverts. The majority of bridge-sized culverts take the form of Reinforced Concrete Box Culverts (RCBCs). In Kentucky, more than 90% of these culverts are RCBCs, and of that percentage, over 98% are of the cast-in-place (CIP) variety. A significant portion, exceeding 90%, of Kentucky's RCBCs were constructed before the introduction of Load and Resistance Factor Design (LRFD) Specifications by American Association of State Highway and Transportation Officials (AASHTO) in 1994. Despite having been in service for decades with no apparent structural deterioration, many of these pre-LRFD RCBCs may require load posting when assessed for current design and permit vehicles, particularly those designed according to older codes and for lighter truck weights.

DOI: 10.1201/9781003483755-149

This discrepancy between field inspections and calculated load rating results for culverts has been observed by highway officials at both state and federal levels (Wood et al. 2016).

The prevailing method involves load rating the different components within a RCBC, assuming a unit width for the culvert, as per AASHTO's Manual for Bridge Evaluation (MBE 2018). The capacity of the load rated RCBC member (e.g. top slab, walls, bottom slab) is determined based on material and sectional properties, as well as the rating level. Additional information for capacity calculation may be obtained from field inspections of the culvert condition. Flexure, shear, and axial stresses constitute the dead- and live-load effects used for analytical load ratings.

Computer programs like BRASS-CULVERT (WYDOT, 2013) efficiently conduct analyses using plane 2D frame elements. While load rating through 3D finite element analysis (FEA) offers advantages such as accounting for soil-structure interaction and improved load distribution, this approach can be expensive, time-intensive, and challenging to develop due to the frequently unknown properties of backfill soil. In a standard analytical load rating, calculating dead load effects attributable to self-weight, soil fill, and pavement is relatively straightforward based on material unit weights. The assessment of live-load effects on various reinforced concrete elements of a RCBC is a more intricate process, involving several parameters (AASHTO 2018). These parameters encompass live-load attenuation through the soil fill in both longitudinal and transverse directions, estimated dynamic effects, live-load surcharge, and the consideration of multiple presence effects when more than one traffic lane is loaded. AASHTO LRFD Specifications (2020) provide guidance on deriving live-load effects for RCBCs based on fill height. Live-load effects determined in adherence to these specifications can sometimes be overly conservative, as noted by Okeil et al. (2018) and Orton (2015). According to Wood et al. (2016), older in-service RCBCs often exhibit minimal structural damage, yet calculated load ratings suggest inadequate capacity for the rating truck, necessitating load posting or potentially replacement.

1.2 *Research on culvert testing*

Tadros et al. (1989) conducted experimental assessments of pressures induced by live loads on RCBCs, comparing them with theoretical outcomes and prior AASHTO Standard Specifications. Abdel-Karim et al. (1990) suggested that live-load effects can be disregarded when they constitute less than 5% of the total load effect. They also noted that rigid pavements and the two-way action in the top slab can assist in distributing the effects of wheel loads onto culverts. The influence of pavement stiffness was experimentally assessed by Acharya et al. (2016), revealing that three times less deflection occurred when the truck was positioned over concrete pavement compared to an unsurfaced area. Evaluation of the AASHTO LRFD Specification load distribution for culverts with low fill (fill depth < 0.6 m) using finite element analysis was carried out by McGrath et al. (2005). It was concluded that these low fill culverts should be designed ignoring the live load attenuation through the fill depth. McGrath et al. (2005) also found shear failure rarely controlled the failure in RCBCs and determined that the load distribution width parallel to the span should be increased in the AASHTO LRFD Specifications to account for two-way action in the top slab.

Orton et al. (2015) conducted load tests on ten bridge-size RCBCs in Missouri, featuring fill depths ranging from 0.8 m to 4.0 m. Among these, two had 3-cells, while the rest had 2-cells. The study revealed that live load effects decreased with increasing fill depth, concluding that the AASHTO LRFD Specifications are more conservative at lower fill depths compared to greater fill depths. In a separate study, Okeil et al. (2018) conducted load tests on eight bridge-size RCBCs in Louisiana. This included one 2-cell culvert, while the remaining culverts were 3-, 4-, or 5-cell structures with cell spans ranging from 1.5 m to 2.4 m. Calibrated finite element models of the RCBCs indicated that the rating factor increased with the fill-height to span-length ratio.

2 LOAD TESTING OF CULVERTS

2.1 *The need for load tests*

The culvert load testing was a component of a broader study aimed at assessing and load rating 1,169 bridge sized RCBCs in Kentucky. After a thorough review of methods and software,

BRASS-CULVERT, developed by the Wyoming Department of Transportation (WYDOT, 2013), was selected due to its rapid analysis capabilities using plane frame elements. This software, incorporating the latest AASHTO Specifications and standard truck types, serves as an efficient and user-friendly load rating tool. In the analysis of a culvert, axle live loads are distributed through the fill depth based on relevant AASHTO guidance. However, the software does not account for the transverse load distribution by the culvert top slab, or the distribution of axle loads due to asphalt pavement. Load rating results indicated that 64.8% of the culverts have an Inventory Rating Factor less than 1, with 94.5% of the failures occurring within the top slab (74.3% in flexure and 20.2% in shear). Given that over 60% of the RCBCs had been in service for at least 60 years (constructed prior to 1959) without observable structural degradation, the results from BRASS-CULVERT were deemed excessively conservative. Load testing was identified as (1) a way of identifying the actual load distribution of RCBCs through compacted backfill under truck live loads; (2) a method of load rating RCBCs in general, provided the necessary range of spans and fill heights were included in the test matrix; and (3) a load rating tool for culverts that lack plans or have incomplete plans.

2.2 *Test outline*

Field load testing used loaded trucks, with scale-measured axle weights, and strain gauges attached to the interior surfaces of culverts. Most data came from design plans, although fill

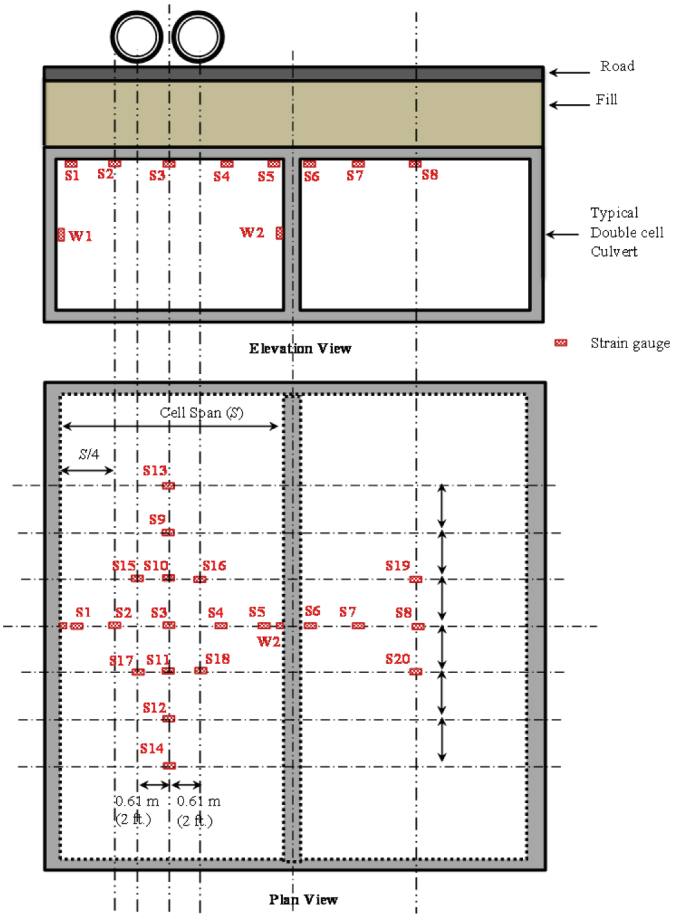

Figure 1. Typical strain gauge layout for a 2-cell culvert.

heights were field measured using a survey level. This was a result of design values in plans being inaccurate, possibly due to changes in roadway elevations over time. Eighteen (18) RCBCs in Kentucky with one-, two-, three-, and four-cells were load tested and the effects of truck live loads analyzed. Fill heights varied from 0 m to 3.6 m, cell spans from 3.0 m to 6.7 m, and culvert spans from 6.7 m to 18.6 m. The principal instrumentation utilized were reusable strain gauges affixed to the concrete surface through two metal tabs attached with adhesive. Figure 1 illustrates a typical strain gauge layout on the top slab and walls for a 2-cell RCBC.

These gauges were attached to nodes that wirelessly transmitted strain data to a laptop. Strain gauges were laid out in a cruciform pattern centered at midspan of the primary cell. This cell was evaluated in detail and hence more extensively gauged. For 3-cell culverts only two cells were instrumented; the interior cell was considered the primary cell. A typical gauge setup in the primary cell of a low-fill RCBC is shown in Figure 2. The truck load applied on a 4-cell RCBC, along with the data acquisition carried out from the creek bank, is seen in Figure 3. Both single rear axle and tandem rear axle trucks were used for the live-load application. Truck weights were measured before testing on a certified load scale. Multiple load cases, along different wheel paths, were used in the testing. Prior to testing, tire positions were pre-marked on the road surface to accurately position the axles.

Figure 2. Strain gauges on a primary cell.

Figure 3. Truck loading and data acquisition.

3 LOAD TEST RESULTS

3.1 *Normalizing truck weights*

Various trucks were employed for testing, each with different axle weights. The recorded strains underwent normalization to equivalent AASHTO truck weights, specifically the HS20 loading (145 kN rear axles). It was assumed that the strains fell within the linear response region. The normalization of strains relied on the ratio between positive moments induced on the top slab by the rear axle weights of the test truck and those of the AASHTO truck. This normalization was feasible since maximum positive strains consistently occurred when the rear axle(s) were positioned at the midspan of the culvert cell, with the front axle either off the culvert or situated on an adjacent cell. The AASHTO LRFD Specifications load distribution was assumed when attenuating live-load pressure through the fill depth. In the FEA software SAP2000 (CSI, 2018), the top slab was modeled as a continuous beam, and corresponding moments were calculated for both the test truck and AASHTO truck. Assuming an uncracked concrete section was critical for obtaining the most conservative load rating results. The moments generated by the rear axle of the test truck ranged from 81.2% to 110.7% of the moments produced by the AASHTO truck.

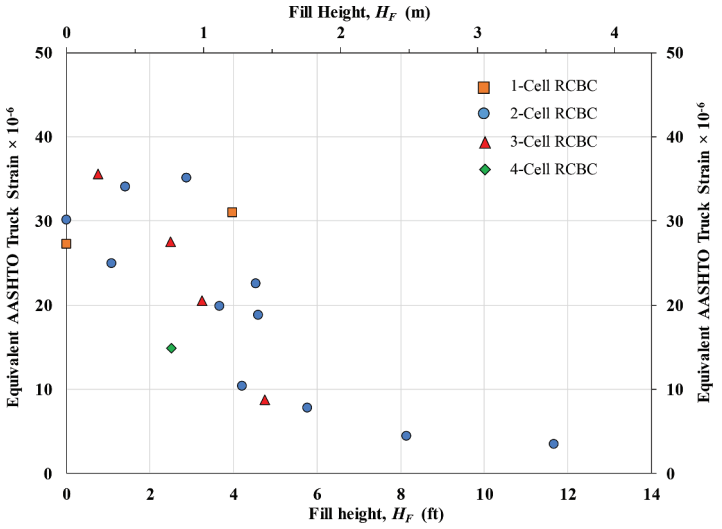

Figure 4. Maximum positive strain variation with fill height.

3.2 *Maximum strain variation with fill height*

In Figure 4, equivalent AASHTO truck strains, derived from the maximum positive strains observed during the load tests for all tested culverts, are plotted against the measured fill heights. The figure also indicates the number of cells in each culvert. The data presented in Figure 4 reveals that as the fill height increased, the maximum positive strain in the top slab declined. This trend is consistent for both 2- and 3-cell culverts, and the strain data for the lone 4-cell culvert tested also aligns with this pattern. Beyond a fill height of 1.8 m, strains are less than 10×10^{-6}. The data suggests, contrary to the AASHTO guidelines, that live-load effects become negligible beyond a specific fill height, regardless of the number of cells in the culvert.

3.3 *Load rating based on load tests*

Field-measured strains were utilized to perform load rating on the RCBC top slabs for flexure in accordance with MBE guidelines for diagnostic load testing. Ratings derived from field measurements were adjusted by considering the analytical load rating factor and accounting

for observed benefits in the load testing. Maximum positive strains, and in the case of multi-cell culverts, negative strains 150 mm from the interior wall, were taken into consideration and updated using the MBE relationship in Equation (1):

$$RF_T = RF_c K \tag{1}$$

where

RF_T = load-rating factor for the live-load capacity based on the load test result

RF_c = rating factor based on calculations prior to incorporating test results

K = adjustment factor resulting from the comparison of measured test behavior with the analytical model

Inventory and operating rating factors for an AASHTO truck based on LRFR that were calculated are provided in Table 1 along with the corresponding rating from BRASS-CULVERT (WYDOT, 2013) for positive bending of the top slab. BRASS-CULVERT analyzes RCBCs as plane frame elements and allows easy and quick development of the culvert model, specifying the size of the reinforcement within the slabs and walls as well as the material properties of the steel and concrete for each culvert. While effects such as lateral earth and water pressure are considered, since soil structure interaction is not considered, only the unit weight of soil is required as an input. But as seen in Table 1, the load rating based on the 2D software provides very highly conservative rating factors. The load rating based on field tests improved both Inventory and Operating rating factors for all tested RCBCs. Similar results were observed for other load rating vehicles as well.

Table 1. Load rating of tested culverts.

120B00037N	2.04	6.68	2.64	8.66

4 CONCLUSIONS

The effect of truck live loads was investigated for the top slab of eighteen (18) cast-in-place (CIP) reinforced concrete bridge-size culverts (RCBCs). These RCBCs included configurations with one-, two-, three-, and four-cells, featuring fill heights (H_F) ranging from 0 m to 3.6 m, clear cell spans (S) spanning from 3.0 m to 6.7 m, and culvert spans varying between

6.7 m and 18.6 m. Reusable strain gauges affixed to the interior surfaces of the culverts was used to investigate the effects, and trucks with known axle weights served as the live load. Positive strains measured in the top slab were converted to equivalent AASHTO truck strains for comparison. The load rating based on the load test results improved the rating for all culverts tested. The study supports the following conclusions:

- With increasing fill height, the maximum positive live-load strain, ε_{LL}^{+}, in the top slab under the AASHTO truck load becomes negligible ($\varepsilon_{LL}^{+} < 10\times10^{-6}$) for fill heights $H_F > 3.05$ m.
- In contrast to AASHTO guidelines for multicell culverts, fill height does not need to surpass the clear distance between end walls for live-load effects to be considered negligible.

Seismic finite element method simulation of a soil-steel bridge with a gravel-rubber mix

T. Maleska, D. Beben & J. Nowacka
Faculty of Civil Engineering and Architecture, Opole University of Technology, Opole, Poland

A. Fiamingo & M.R. Massimino
Department of Civil Engineering and Architecture, University of Catania, Catania, Italy

ABSTRACT: Soil–steel complex bridges have been applied for many years in transport infra- structure. They are widely used in North America, Europe and Australia. The design codes and calculation methods related to soil–steel complex bridges and culverts specify, among others, the re- quirements for backfill. The typical backfill should be well-granulated sands and well-compacted gravels of harsh, coarse, or round grains. The behaviour of these bridges under static loads is relatively well understood. However, the response of these bridges to dynamic loads, especially seismic loads, is not fully known. Examples from the United States and Australia show that earthquakes damaged such bridges. Therefore, new solutions for the backfill are currently being sought to increase damping properties to minimize dynamic influences. The present study deals with a numerical simulation of a soil-steel complex bridge using a gravel-rubber mixture from end-of-life tire recycling as the backfill. A nonlinear model with El Centro records and the time history method was used. Using the DIANA program, numerical calculations were performed for two cases, i.e., the bridge shell covered with a traditional backfill and the gravel-rubber mix. The bridge has two closed pipe arches in its cross-sec- tion. The load-carrying structure was constructed as two shells assembled from corrugated steel plate sheets (depth = 0.05 m, pitch = 0.15 m, plate thickness = 0.003 m, shell span = 4.40 m, shell height = 2.80 m). The results suggest that the gravel-rubber mix can be used in soil-steel complex bridges as an alternative to traditional backfill. This results in better absorption of the seismic energy by the gravel-rubber mix than the conventional granular backfill. An indirect effect is the use of tire recycling, which is part of the sustainable development of the construction industry.

1 INTRODUCTION

Soil-steel complex bridges are becoming increasingly common in our landscape (Figure 1). This state of affairs is influenced by the numerous advantages of these structures, i.e., primarily the speed of construction and construction costs of this type of object (Beben 2020). The economic aspect is essential nowadays, and in the case of soil-steel bridges, there is a chance to reduce construction costs by up to 60% compared to traditional bridges made of steel or concrete. How- ever, due to their construction (a thin corrugated shell covered with soil), buried steel structures (pipelines, bridges, culverts, pipes, and tunnels) seem sensitive to seismic shocks, as shown in Figure 2. Therefore, searching for a backfill material that would reduce seismic excitation is nec- essary.

In earthquake engineering, recent studies Tsang (2009) show that Geotechnical Seismic Isola- tion (GSI) is a potential and emerging technique to mitigate the seismic effects on structural sys- tems involving Dynamic Soil Structure Interaction (DSSI). The main idea is to

DOI: 10.1201/9781003483755-150

improve the foun- dation soil and, therefore, to reduce the accelerations and the seismic energy that reach the foundations (Forcellini, 2017, Tsang 2022). Different geo-materials can be adopted as GSI (Somma et al. 2022, Tsiavos et al. 2022), among which the Gravel Rubber Mixtures (GRMs). GRMs represent an eco-sustainable solution because the rubber grains are obtained from ELTs (End of Life Tires), whose disposal is an environmental problem. The sustainability and ad- vantages of the GRMs have been investigated by laboratory and in-situ tests (Anastasiadis et al. 2012, Senetakis & Anastasiadis 2015, Pitilakis et al. 2021), but only a few numerical analyses on structures and infrastructures have been performed (Chiaro et al. 2023, Abate et al. 2023). Thanks to the lower shear stiffness and high-damping material, the GRMs are a promising GSI system, ensuring high-energy dissipation due to the rubber inclusions.

Figure 1. Example of the soil-steel bridge in Opole (Poland).

The analysis of soil-steel bridges/culverts subjected to seismic excitation has already been un- dertaken. It is concerned with the determination of the impact of (i) boundary conditions (Maleska & Beben 2023a), (ii) soil cover height (Maleska & Beben 2022, 2023b, Lee et al. 2006), (iii) assessment of the effectiveness of the use of additional longitudinal ribs to strengthen the shell (Maleska et al. 2021), (iv) EPS relieving elements (Maleska et al. 2019, Santos et al. 2020). Mah- goub & El Naggar (2021) presented some aspects of the seismic design of soil-steel culverts.

Thus, the impact of the backfill type on the seismic response of soil-steel bridges has yet to be studied. Therefore, this study aimed to determine the reaction of the soil-steel bridge under seis- mic load, in which a backfill mixed with granulated rubber from ELTs was used. In soil-steel bridges, the backfill is the essential element of the structure, where, in combination with the cor- rugated steel shell, it creates a load-bearing quasi-composite structure. The study analysed dis- placements and accelerations for two bridge models (Model I – standard backfill and Model II – GRM backfill) under seismic excitation using a finite element code.

2 DESCRIPTION OF RESEARCH APPROACH

2.1 *Description of the investigated real bridge*

The analysed structure is a railway soil–steel complex bridge located in Krosnowice in the Lower Silesian Voivodeship, Poland. This structure consists of two shells (Figure 3). The steel shells of this object have a pipe-arch section and are constructed of corrugated steel plates (CSP) with a thickness of t = 3 mm and dimensions of 50 × 150 mm. The shells in the bridge structure have a span of L1 = L2 = 4.4 m and are erected directly on the ground (Figure 3b). The clear height of the shells is 2.8 m. The individual sheets of the CSPs are fixed with M20 high-strength bolts. The backfill height above the CSP shells is equal to 2.4 m. The length of the bridge in the steel shell crown is 16.0 m and 21.8 m at the base.

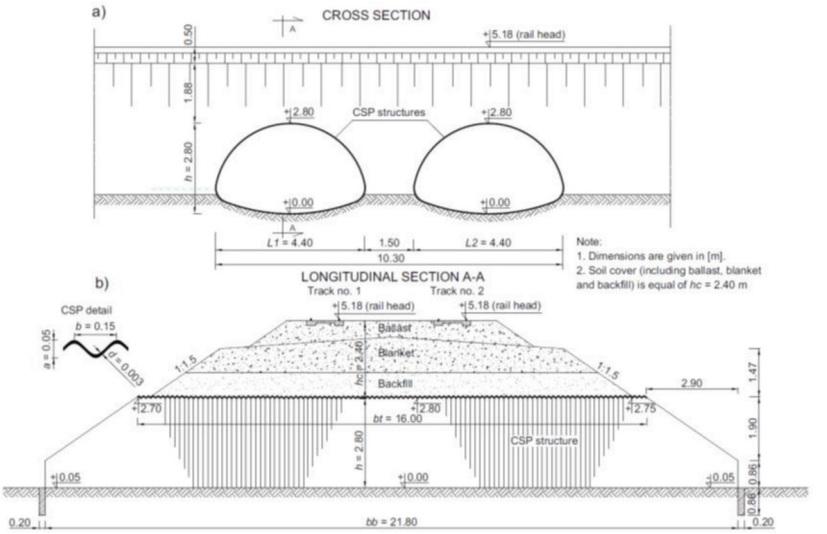

Figure 3. Analysed bridge: a) cross-section and b) longitudinal section.

2.2 *Description of the developed numerical model*

2.2.1 *Steel shell*

As mentioned, these shells are characterized by a pipe-arch cross-section and are constructed of CSPs with dimensions of 50 × 150 mm and a thickness of t = 3 mm. Considering the corrugation parameters, the area cross-section was 3.77 mm^2/mm, and the moment of inertia was 1176.60 mm^4/mm. The following properties of steel were used in the DIANA FEA: Young modulus 205 GPa, density 7850 kg/m^3, Poisson ratio of 0.3 and strength yield of 235 MPa.

2.2.2 *Backfill*

Two types of backfill were considered in the study: (i) standard backfill (Model I) and (ii) GRM backfill (Model II). In the case of the standard backfill (Model I), the nonlinear hyperbolic Dun- can-Chang constitutive model was used (Table 1). The GRM (Model II) had the following prop- erties: a content of rubber equal to 45% and a content of gravel equal to 55% (for the total volume of the mixture), Gs=2.07 (specific gravity), D50,R/D50,G =1.2 (ratio between the mean diameter of the rubber grain and that of the gravel grain), Dr = 50% (relative density), (v) γ =20.3 kN/m^3 (density). GRM was modelled using the Hardening Soil with small strains constitutive model with the parameters included in Table 1.

2.2.3 *Boundary conditions*

The boundary conditions were used as pinned support, shown in Figure 4a. A detailed description of these boundary conditions was presented in the paper by Maleska & Beben (2023a).

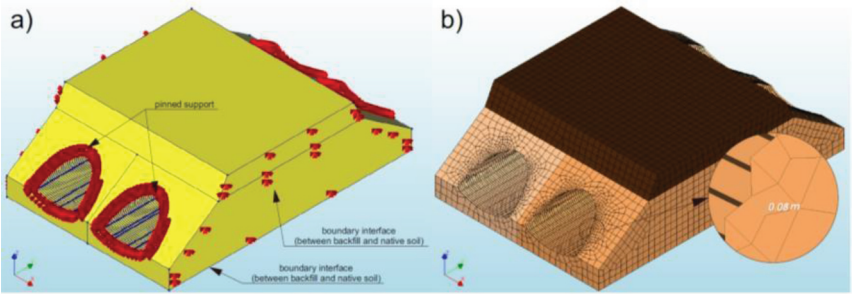

Figure 4. Numerical model of the bridge: a) boundary conditions, b) mesh of finite elements.

Table 1. Properties of the backfills used for the numerical analysis.

Duncan-Chang constitutive model – standard backfill (Model I)

The shear strain level at which the secant shear modulus was reduced by about 70% of the initial shear modulus [-]	8.49E-05

2.2.4 *Seismic excitation*

El Centro records from the USA were used as seismic excitation in the DIANA FEA numerical program (Figure 5). This record dates from May 18, 1940, and is considered destructive. Intensity X characterizes it on the Mercalli scale (6.9 on the Richter scale). This excitation is irregular (strongly stochastic). In addition, it should be added that this record is characterized by an ex- tended zone of high intensity, which translates into a significant impact on structures. Most engi- neering structures cannot cope with such a strong excitation, so it was decided to use it in this study.

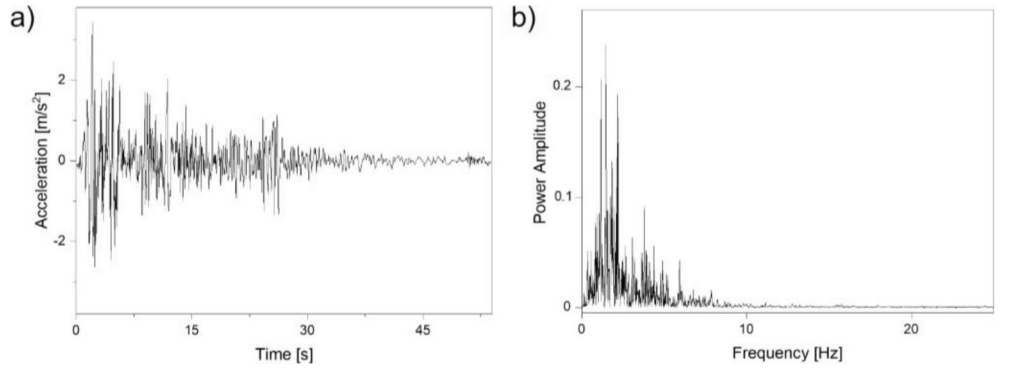

Figure 5. El Centro time-history for the direction of a) X (NS), b) spectrum response of X (NS).

2.2.5 *Interface*

The interaction between the backfill and the steel shell has been considered by applying an auto- matic interface with the "Coulomb friction" function. In this function, the angle of internal friction of 39°, the dilation angle of 5°, the stiffness of 100000 kN/m^3, and the cohesion of 3 kPa were assumed.

3 RESULTS OF NUMERICAL SIMULATIONS

3.1 *General remarks*

The DIANA FEA numerical program based on the finite element method using the time history method, which is recommended by the design standards (AASHTO 2017, CHBDC 2017 or CEN 2005), was used to assess the impact of seismic excitation on the tested object. The time history method analyses the response and behaviour of the structure in individual time steps throughout the duration of the given seismic excitation as a result of the numerical analysis obtained displace- ment and acceleration results for two models (Model I – standard backfill and Model II – GRM).

3.2 *Displacements*

The numerical analysis shows that the largest displacements in the soil-steel bridge shell were recorded in Model II, where the GRM was used. In this model, the maximum displacement due to seismic excitation was –4.89 × 10^{-3} m (Figure 6b). Whereas Model I had a smaller displacement than Model II by 80% and was –9.65 × 10^{-4} m (Figure 6a).

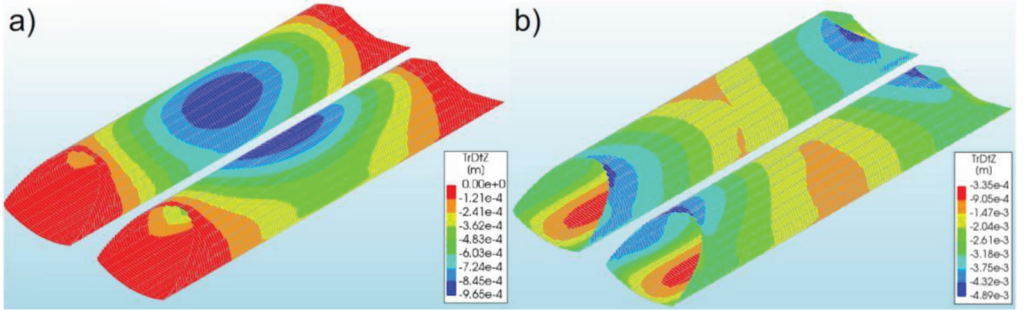

Figure 6. Maps of maximal vertical displacements in the CSP shells of models: a) I and b) II.

Different places of occurrence of maximum displacements in both models were also noticed. In Model I with standard backfill, the maximum displacements were recorded in the middle of the length of the CSP shells in their crown (Figure 6a). The maximum displacements in Model I are concentrated over a larger area of shells, while in Model II, the maximum displacements are dis- persed (Figure 6b). In Model II, the maximum displacements were recorded on small fragments of the inlet and outlet in both shells.

It should be added that in both models at the inlet and outlet of the bridge, the use of RC collars was simulated (as the pinned supports), which is consistent with the general practice in construct- ing this type of bridge. The obtained results show that in the case of the GRM (Model II), there are small concentrations of displacements in the area of the RC collars, and for a typical backfill (Model I), they are shifted to the centre of the shell near the crown.

In addition, it can be seen that the maximum displacements in Model II (Figure 7b) occurred around 50 seconds of the earthquake duration, while in Model I (Figure 7a), the maximum displace- ments were recorded around 6-7 seconds of the excitation duration. It can be seen that the struc- tures are excited differently, so they have different dynamic characteristics.

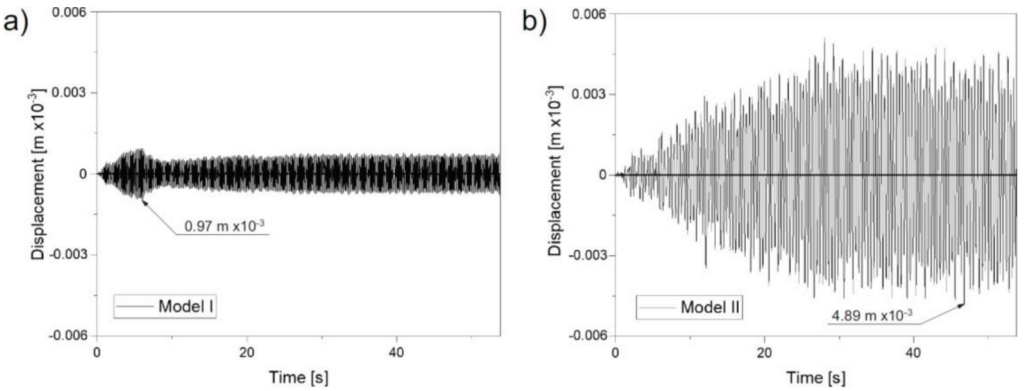

Figure 7. Time History of vertical displacements of bridge models: a) I and b) II.

3.3 *Accelerations*

The highest accelerations of 6.04 m/s^2 (Figure 8b) were recorded in Model II (gravel-rubber mix). On the other hand, in Model I (standard backfill), accelerations were lower by 38% compared to Model II and amounted to 3.74 m/s^2 (Figure 8a).

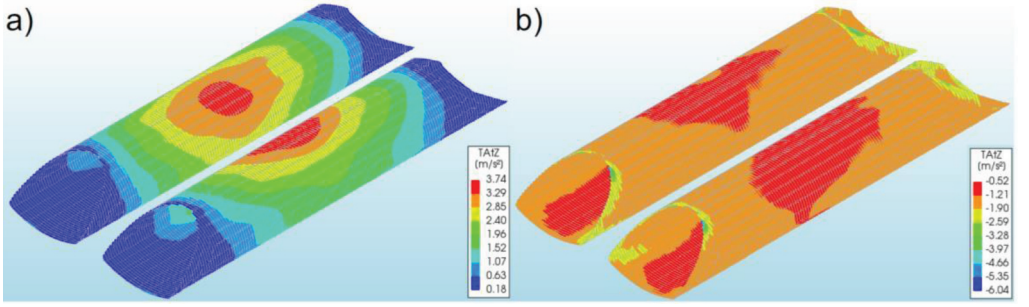

Figure 8. Maps of maximal accelerations of CSP shell of models: a) I and b) II.

The places of maximum accelerations were analogous to displacements, i.e. in Model I (stand- ard backfill), they were noted in the middle of the length of the shells, in their crown (Figure 8a). The places of maximum accelerations in Model I were concentrated, while in

Model II, the max- imum accelerations were dispersed over a larger area. In Model II (Figure 8b), maximum accelera- tions were recorded at the inlet and outlet in both shells. Moreover, these accelerations were local, covering a small area of steel shells.

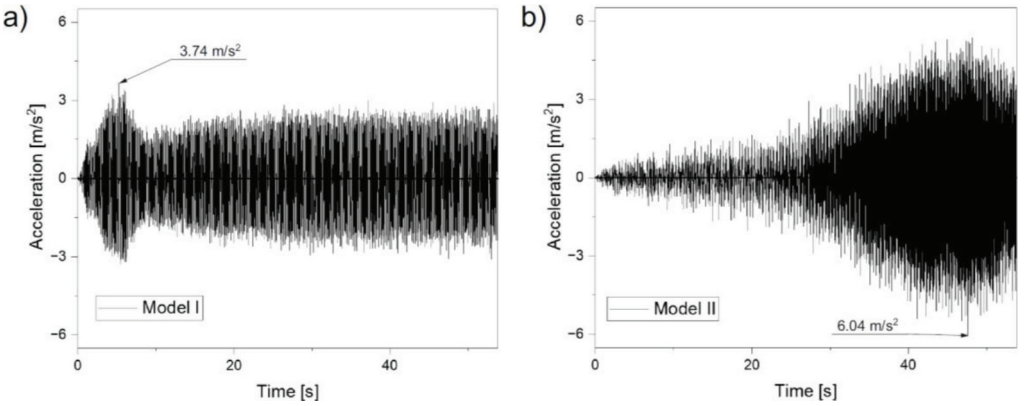

Figure 9. Time history of accelerations of bridge models: a) I and b) II.

It should also be emphasized that the maximum accelerations in Models I and II were recorded at a similar time as in the case of displacements. In Model I (Figure 9a), the maximum accelerations were recorded around 6-7 seconds of the excitation duration, while in Model II (Figure 9b), around 50 seconds of the seismic excitation duration.

4 CONCLUSIONS

As a result of the numerical analysis, it can be concluded that using a backfill mixed with 45% by volume of granulated rubber from ELTs in its composition does not reduce displacements and accelerations in the analysed soil-steel bridge. However, it should be noted that the bridge built using GRM (Model II) has a much better ability to distribute the seismic load over a larger area (no load concentration). In addition, after the analysis, it can be concluded that:

- displacements of the soil-steel bridge caused by seismic excitation are small, but various types of backfills reveal different bridge behaviour. The question arises: shouldn't slightly larger dis- placements be allowed at the expense of a more favourable distribution of loads over a larger area?
- maximum displacements and accelerations in Model II (GRM) occur much later than in Model I (standard backfill). This proves the higher seismic resistance of Model II,
- the obtained results prove the great possibilities of using backfill with the addition of used tires as an alternative to traditional backfill in constructing soil-steel bridges in seismic areas.

In conclusion, further research is needed to determine the effect of GRM in soil-steel bridges/culverts under different types of loads. In the future, it is planned to conduct experimental tests of the soil-steel bridge using a GRM under static and cyclic loads caused by the simulation of passing vehicles. In addition, it is planned to carry out tests for a varied composition of the backfill, assuming a variable ratio of pieces of used tires to the soil.

Long-term monitoring of earth pressure in a soil-steel composite railway tunnel

T. Maleska & D. Beben
Faculty of Civil Engineering and Architecture, Opole University of Technology, Katowicka, Opole, Poland

J. Vaslestad
Norwegian University of Life Sciences/Norwegian Public Roads Administration, Operations and Maintenance, Moss, Norway

ABSTRACT: Objects in transport infrastructure, such as bridges, tunnels and culverts, are usually built using reinforced concrete structures. However, since the 1970s, many structures have been constructed with corrugated steel plates and surrounding backfill to form soil-steel composite structures. The paper analyses the soil-steel composite railway tunnel located in Tolpinrud, Norway. The analysed tunnel has a cross-section in the form of a pipe arch with a 7.81 m span and a 6.92 m rise. The tunnel is constructed of steel plates with a 200 mm corrugation pitch, 55 mm depth and 6.8 mm plate thickness. The depth of the soil cover over the steel shell crown varied from 1.1 to 1.6 m. The study's main aim is to show the long-term behaviour of the soil-steel tunnel as well as earth pressure, which has been monitored for 25 years. Experimental studies of the soil-steel railway tunnel were compared with the results of finite element analyses (FEA) performed in the numerical program DIANA FEA. The numerical analysis took into account subsidence and earth pressure during the operation of the tunnel. The long-term behaviour of the soil-steel tunnel demonstrates that there are changes in earth pressure distribution and structural response over time after construction. The numerical analysis performed can be helpful in the design of new soil-steel tunnels and bridges situated on roads and railways. In addition, the study results may help assess the technical condition of the existing soil-steel composite structures.

1 INTRODUCTION

Over the last two decades, a significant increase in the construction of soil-steel structures (bridges, culverts and tunnels) has been observed (Beben, 2020). The increasing interest in these structures is mainly influenced by their advantages, such as (i) speed of assembly, (ii) low construction costs, (iii) continuity of construction, (iv) possibility of off-site construction, and (v) inclusion of sustainable development concepts. Many such structures can be found in the USA, Canada and Europe (Figure 1).

The study of soil-steel bridges has been conducted for many years. Many aspects and work conditions of soil-steel structures under various loads have been analysed. The tests were carried out mainly under static and dynamic loads. In the case of static tests, the influence of the soil pressure on the shell during the backfilling process was analysed by Koruszewicz & Kunecki (2011) and Maleska & Beben (2019), among others. The impact of live loads from vehicles on the soil-steel bridge was presented by, for example, Yea et al. (2014), Wadi et al. (2018) or in laboratory conditions by Mai et al. (2014), Garcia et al. (2015). In terms of dynamic loads, analyses of these objects concerned the impact of passing trucks or trains (Beben, 2013, Flener & Karoumi, 2009). Structures with spans up to 6 m are most often considered. Only a few studies have been conducted on soil-steel tunnels (Vaslestad, 1989,

DOI: 10.1201/9781003483755-151

Kunecki et al. 2007). Analysing the seismic impact on these structures is particularly rare (Mahgoub & El Naggar, 2021, Maleska & Beben, 2021). In seismic design practice for bridges, the loads caused by earthquakes in a seismically active region are often several times more severe than those arising from other causes. The long-term monitoring of the RC tunnel was presented by Maleska et al. (2022).

Figure 1. Example of soil-steel composite tunnel.

As can be seen, most of the analyses and tests concerned soil-steel structure behaviour under specific short-term loads. Therefore, long-term studies are needed to consider these structures' behaviour over time. The primary purpose of this paper is to show the long-term earth pressure (monitoring for 25 years) on the soil-steel tunnel.

2 DESCRIPTION OF EXPERIMENTAL TESTING AND NUMERICAL MODELLING

2.1 *Tunnel description and experimental testing*

The analysed soil-steel tunnel is located at Hønefoss, about 60 km north of Oslo in Norway and completed in 1982. The structure serves as a railroad tunnel under the main road. The shell structure consists of a pipe arch with a 7.81 m span and a 6.92 m rise (Figure 2). The total length of the tunnel is 106 m.

The tunnel is constructed of corrugation steel plates (CSP) with a 200 mm pitch, 55 mm depth and 6.8 mm plate thickness. The shell structure of the tunnel was strengthened using two longitudinal RC beams (0.7×0.7 m). These beams were situated at the quarter points of the shell (Figure 2). It should be added that the analysed tunnel was designed based on static calculations, the contractor's experience and the literature available at that time. The tunnel shell was backfilled using gravel and sand compacted to a minimum 97% Standard Proctor. The backfill was placed in 0.20 m thick layers and adequately compacted using a vibratory roller and bulldozer. The depth of the soil cover over the shell crown varied from 1.1 to 1.6 m (1.1 m was adopted in numerical analysis (Figure 2)). The in-situ soil is a medium-stiff clay with undrained shear strength from 40 to 80 kN/m^2. RC front walls were used to strengthen the tunnel's inlet and outlet. The savings compared to a typical RC tunnel cost were about 25% (Vaslestad, 1989).

During experimental testing, earth pressure cells of the Glotzl type were mounted on the structure 25 m from the northern end and 50 m from the north end (Figure 3). Four earth pressure cells were used in each section. Using specially constructed brackets, four earth pressure cells (measurement points) were bolted onto the steel structure. The brackets have the same corrugation and radius as the

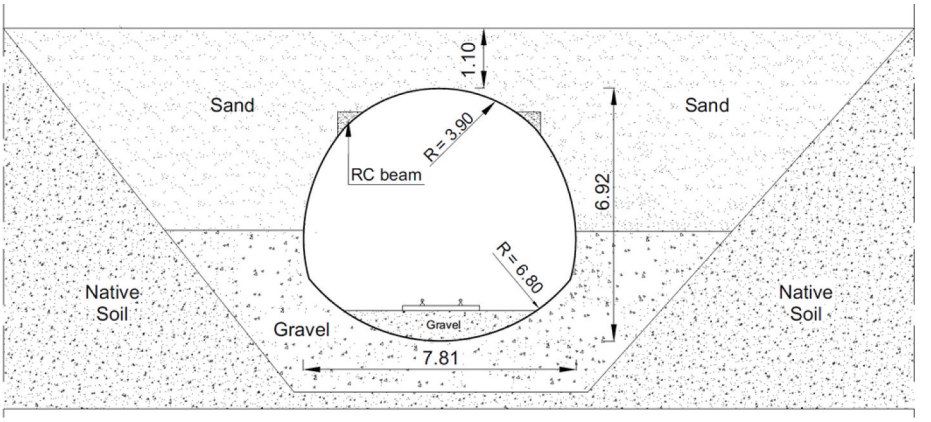

Figure 2. Cross-section of the analysed soil-steel composite tunnel (dimensions are given in [m]).

culvert structure. The earth pressure on the tunnel structure was tested in the steel shell crown (point #1), at the bottom of the tunnel (point #2), on the side walls on the left (point #3) and on the right (point #4). The earth pressure cells are 0.30 m × 0.40 m × 0.005 m. The brackets are 0.60 m × 0.80 m. Calibration of the cells was performed by the manufacturer and was found to agree well with calibration checks in the laboratory. Calibration of the cells with temperature variations from +20°C to –30°C was also performed in the laboratory. Thermistors were placed near each earth pressure cell and in the backfill to give data for temperature corrections and freezing depths (Vaslestad, 1989).

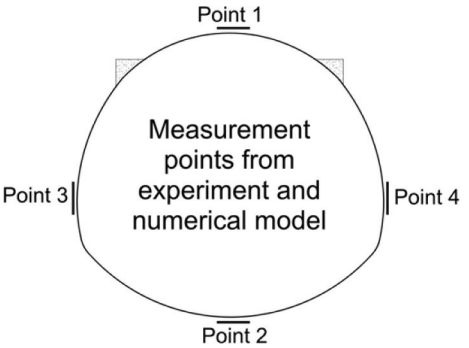

Figure 3. Location of measurement points from earth pressure cells for Tolpinrud tunnel.

2.2 *Description of the FEM model*

The computational analysis used DIANA FEA software based on the finite element method (FEM). This software is dedicated to analysing soil behaviour, where advanced study of the impact of soil on structures is required, e.g., over time. The backfill (gravel and sand) was modelled using a Duncan-ßChang non-linear elastic hyperbolic model (Duncan & Chang, 1970) (solid elements of HX24L type) with Young's moduli of 100 MPa (gravel) and 38.42 MPa (sand), a Poisson ratio of 0.2, densities of 2050 kg/m^3 (gravel) and 2010 kg/m^3 (sand), 3 kPa cohesion, dilation angles of 5° (gravel) and 5.6° (sand), internal friction angles of 39° (gravel) and 34.6° (sand), a failure ratio of 0.7, a 1000 N/m^2 unloading-reloading stiffness, a 0.25 exponent for the unloading reloading curve, a 101350 N/m^2 reference pressure, 350 N/m^2 minimum compressive stress and a 1.1 exponent for the backbone curve.

The shell was modelled as a real object using corrugation profiles with RC beams. The CSP was modelled as an elastic-plastic model (shell curved elements – Q24IF) with a 205 GPa Young's modulus, a 7850 kg/m^3 density, a 0.3 Poisson ratio and a 235 MPa yield strength for

the steel. An 8.29 mm^2/mm cross-sectional area, a 3213.20 mm^4/mm moment of inertia and a 103.65 mm^3/mm elastic section modulus were also used.

The RC beams were modelled using enhanced truss elements according to Eurocode (EC 1992-1-1, 2008). The C30/37 concrete had the following parameters: 0.2 Poisson ratio, 30 MPa characteristic cylinder compressive strength, 38 MPa mean compressive strength, 2.90 MPa mean tensile strength, 32837 MPa elastic modulus, 20 MPa design compressive strength (for αcc = 1.00), 17 MPa design compressive strength (for αcc = 0.85), 1.35 MPa design tensile strength (for αct = 1.00), 0.151% minimum longitudinal tension reinforcement ratio and 0.088% minimum shear reinforcement ratio.

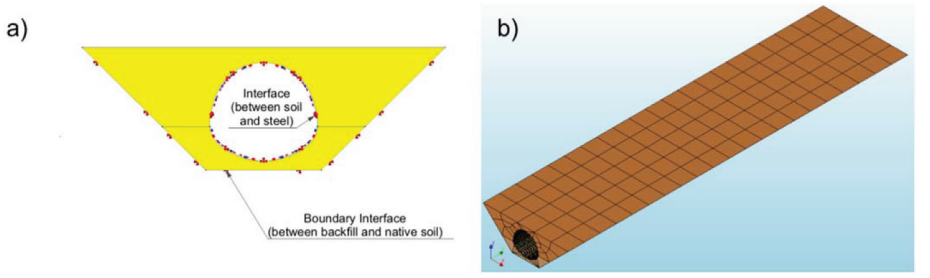

Figure 4. A numerical model of the soil-steel tunnel: a) boundary conditions and b) finite element mesh.

The soil-structure interaction was modelled using an automatic interface. The properties of the interface were a "Coulomb friction" function with a 39° internal friction angle, 3 kPa cohesion, 5° dilation angle and 100000 kN/m^3 rigidity.

The boundary conditions were modelled as hinged support at the inlet and outlet of the tunnel (Figure 4a). This approach simulates the RC front walls like in a real tunnel. In addition, the base and sidewalls of the numerical model were also restricted using hinged supports using the special function ("boundary interface" – Figure 4a) in the DIANA FEA program. This function allows the correct interaction between the backfill and boundary edge (native soil).

Obviously, the impact on the obtained results has the density of the finite element mesh (Figure 4b). Therefore, in the initial stage of numerical calculations, the influence of finite element mesh density in the tested soil-steel tunnel was analysed. It was found that finite elements did not exceed 5.0 m for the backfill and 1.0 m for the steel shell. These dimensions of finite elements can allow a compromise between the result's accuracy and the duration of calculations to be obtained. However, the discretisation of the backfill near the steel shell was much denser. The soil mesh size was only a few centimetres near the shell curves.

3 ANALYSIS OF FEM AND MEASUREMENT RESULTS

3.1 *General remarks*

In engineering practice, it is rare for the monitoring period of objects to be as long as, in this case, 25 years. The presented experimental research lasted from 1981 to 2006. Another important aspect is that an object made of corrugated sheets was used for the study. It is a complex structure that, combined with the soil, creates a composite structure whose properties, e.g., soil stiffness, may change over time. The analysis of such a structure is complicated and ambiguous, as shown in this study.

3.2 *Earth pressure*

As presented earlier, a structure located in Norway was used to analyse the impact of earth pressure on the structure of a soil-steel tunnel. The earth pressure was recorded at 4 points shown in Figure 3, where the values from the FEM numerical analysis were also read.

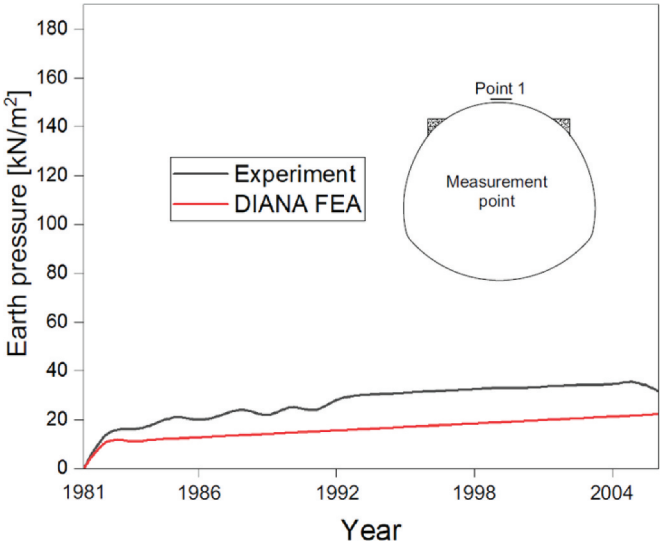

Figure 5. Earth pressure at tunnel crown (measurement point #1) for experiment and FEM model.

Analysing the earth pressure near the tunnel crown (point #1 – Figure 5), it can be seen that the earth pressure increases with the period of tunnel operation. In the case of experimental studies and FEM calculations, it was reported that the maximum values were obtained in a similar period, i.e. near 24 (experimental test) and 25 years (FEM analysis). The maximum measured earth pressure was approximately 35 kN/m^2, while from the numerical analysis in this place, it was about 22 kN/m^2, so they were 37% lower than the measured values. Moreover, it can be seen that after the first year of monitoring, the measured earth pressure was 14 kN/m^2, and the FEM model obtained 11 kN/m^2. The difference was about 20%. It should be added that the earth pressure course was almost linear in the case of the experiment and linear in the case of the FEM analysis.

In the case of point #2, located under the bottom of the steel tunnel (Figure 6), a different trend can be observed than in the case of earth pressure at the level of the tunnel crown. At point #2, in the period of approximately 6 years from the beginning of the measurements, the earth pressure in the case of the experiment was higher than in the remaining years. In the second year of monitoring, the maximum earth pressure was approximately 37 kN/m^2. Moreover, it can be seen that in the period from 1992 to 2005, the earth pressure had an approximately constant value of about 24 kN/m^2. However, in the case of FEM analysis, it was noted that during the first two years, the earth pressure increased (to approximately 140 kN/m^2) and then began to decrease (to about 132 kN/m^2). Only after roughly the 4th year of tunnel operation did the earth pressure gradually increase linearly to reach the maximum value, i.e. 153 kN/m^2. Comparing the maximum results from numerical and experimental tests, it can be seen that the difference is more significant than in the case of the earth pressure in the tunnel crown (point #1). This may be because the soil located under the bottom of the tunnel probably changes its parameters due to soil compaction related to the operation of the railway tunnel. This may increase the stiffness of the soil under the tunnel and thus stabilise the earth pressure at a lower level than indicated by numerical calculations because such phenomena are difficult to reproduce in the FEM model.

In the case of the analysis of the earth pressure near the side wall of the tunnel (point #3 – Figure 7), it can be seen that the values in the case of both the experiment and the FEM analysis increase from the moment the tunnel operation began. They reached the maximum value in the final monitoring period, i.e. after 25 years, and amounted to a maximum of 125 kN/m^2 in the case of experimental tests, while in the FEM analysis it was 178 kN/m^2. Therefore, the difference between the experiment and the calculations was 42%. It should be noted that after

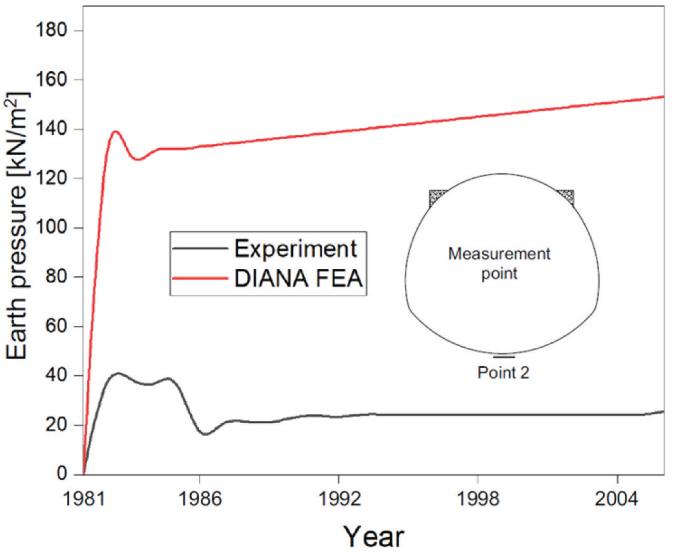

Figure 6. Earth pressure below the tunnel (point #2) obtained from the experiment and FEM analysis.

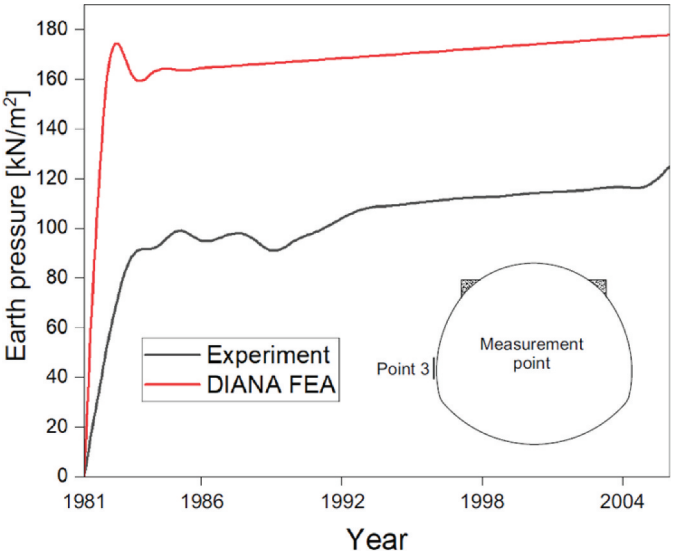

Figure 7. Earth pressures near the side wall (point #3) obtained from tests and the FEM model.

the first year of analysis, in the case of the numerical model, the earth pressure reached approximately 175 kN/m^2, then decreased to about 160 kN/m^2, and then gradually increased, reaching a maximum in the last year of monitoring (178 kN/m^2). In the case of experimental tests, the earth pressure increased from the 3rd year (99 kN/m^2) and then decreased slightly until 1989 (91 kN/m^2). Then, from 1990, the earth pressure gradually increased, reaching a maximum (125 kN/m^2) in the last year of monitoring (25th year of measurements – 2006).

In the last of the tested points (location near the side wall of the tunnel – point #4 (Figure 8)), it can be observed that the earth pressures obtained from experimental tests were more linear than in point #3, located on the other side of the tunnel, also nearby side wall. It was noticed that the earth pressure gradually increased until it reached a maximum value of 125 kN/m^2 (the same as in point #3). However, in the case of the FEM analysis,

the trend was the same as in the case of point #3, i.e. at the beginning, the earth pressure reached 175 kN/m^2, then decreased to approximately 160 kN/m^2, and then increased linearly again, reaching a maximum in the last year of the analysis (178 kN/m^2).

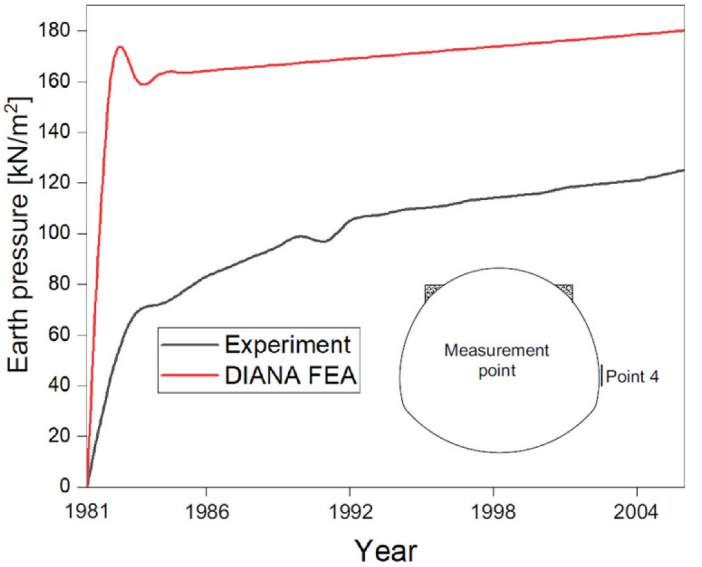

Figure 8. Earth pressure at the side wall of the tunnel (point #4) received from experiment and model FEM.

In the case of both analysed points located near the side walls of the tunnel (#3 and 4), such significant differences between the experimental and numerical results indicate that it is difficult to take into account in the FEM model the phenomena occurring in the soil over time. Similarly to point #2 located under the tunnel. Additionally, taking into account the phenomenon of arching, i.e. the redistribution of loads around a flexible steel shell, in the FEA model is also difficult. These parameters are selected based more on the researcher's experience than the actual conditions in a given structure.

Moreover, the existing differences between experimental and numerical results may be caused by many reasons, such as the estimation of the soil constitutive model parameters and boundary locations (maybe too close to the tunnel). In addition, the soil constitutive model does not consider soil plasticity, which may play a valuable role in the examined case history.

4 CONCLUSION

As a result of monitoring carried out over 25 years, a constant increase in earth pressure around the soil-steel tunnel was observed. Additionally, as a result of the experimental tests and FEM analysis, the following conclusions can be drawn:

- The most significant increase in earth pressure occurs until the first year of monitoring, then the pressure stabilises with a gradual, linear increase.
- The highest earth pressures were recorded at points #3 and 4, which were located near the tunnel's side walls. However, the lowest earth pressures occurred near the crown of the steel shell.
- The most significant agreement between the experiment and FEM analysis was obtained for the case at point #1 (steel shell crown) in the first year of monitoring, which was approximately 20%. However, after 25 years of measurement, this difference was already

37%. A much larger discrepancy (from about 40% to over 300%) from the results was noticed at the remaining measurement points (#2–4). This is due to the difficulty in taking into account the soil behaviour over time and the arching phenomenon in the FEM model.

In summary, further research is necessary to estimate the correct behaviour of the soil-steel tunnel structure over time. The discrepancies between the numerical values may also be influenced by the fact that there is railway traffic in the tunnel, causing vibrations that were not considered in the numerical analysis. Vibrations emitted by passing trains may affect soil compaction other than that described in the available literature and implemented in the FEM software. Additionally, the size of the FE model (i.e. the extent of the soil around the steel tunnel structure included in the model construction), estimation of the soil constitutive model parameters, and boundary locations of the FE model may also be important. In the future, it is planned to perform additional FEM calculations taking into account the aspects mentioned above.

Experimental tests of a soil-steel culvert with a shallow soil cover under static loading

T. Maleska, D. Beben, P. Bobra & B. Jedraszak
Faculty of Civil Engineering and Architecture, Opole University of Technology, Opole, Poland

ABSTRACT: Soil-steel culverts and bridges are more and more often an element of road and railway infrastructure in Poland and the world. In many cases, using an appropriate soil cover depth over such structures is impossible, which is necessary to operate these objects safely. Therefore, the paper's primary purpose is to assess the behaviour of the soil-steel culvert with a soil cover height of 0.20 m above the steel shell. This height of soil cover of structures is extremely low, below the requirements of standards (e.g., Canadian Standards). The tested soil-steel culvert has the following dimensions: (i) span 2.1 m, (ii) height 1.45 m, (iii) length 2.32 m, (iv) sheet thickness 2.5 mm, and the wave profile is 68×13 mm. Experimental tests were carried out in a laboratory in a specially constructed test box with dimensions of 2.32 m × 4.34 m × 2.49 m. As a result of the tests, the behaviour of this structure under static load was observed. A standardised static road load was used in the model tests of the soil-steel culvert. During the tests, the vehicle load was simulated by concentrated force (loading speed was 1 kN/s, and the maximum load duration was 600 seconds). The tests measured displacements and strains of the corrugated steel shell under a given load. The obtained results are of great cognitive importance, as similar studies have not been performed so far.

1 INTRODUTION

Steel culverts made of corrugated sheets are increasingly an element of road and railway infrastructure in Poland and worldwide (Beben 2020). Figure 1 shows an example of a soil-steel bridge. In many cases, applying appropriate soil cover over such structures is impossible, which is necessary to operate these objects safely. Moreover, the minimum soil cover height is required by standards or design recommendations (CHBDC 2017, Rowinska et al. 2004).

So far, there are studies on the influence of the height of soil cover above soil-steel structures. In the paper by Flener (2010), the results obtained using the Canadian standard (CHBDC 2017) were compared with the FEM results. In this case, the height of the soil cover above the steel shell was from 2.5 to 4.08 m. Significant discrepancies were observed between the standard results and those obtained from FEM, which reached over 50%. In the work of Elshimi et al. (2011), soil cover heights in the range of 0.45–1.5 m were analysed. The effect of backfill pressure on the steel coating was determined. An increase in internal forces and displacements was observed in objects with increased soil above the shell structure. The influence of the backfill height with different methods of foundation of the steel shell was analysed in the work of Wysokowski et al. (2007). The analysed arch structure was founded on two types of foundations, i.e., a rigid foundation (reinforced concrete foundation strip) and a flexible foundation (corrugated steel plate). It was found that the type of foundation used did not matter much for the displacements in the crown. The obtained results were compared for seven heights of backfill layers. The displacements from the experiment and FEM analysis were at a comparable level, and the differences between them did not exceed a few percent. Regarding the influence of the soil cover height, Maleska & Beben (2022 and 2023)

DOI: 10.1201/9781003483755-152

investigated the response of a soil-steel bridge using seismic excitations. It was found that the effect of backfill is noticeable and depends on many factors, i.e. boundary conditions, structure span, etc. Moreover, it was found that further research is necessary on the impact of the backfill height on the soil-steel structure.

It should be added that the analysis of soil-steel bridges under static load is primarily a search for an answer to the question: what will be the deformations of the steel shell caused by the placement and compaction of the backfill (construction stage), and what will be the impact of static loads from vehicles? Analyses of the impact of backfill compaction on soil-steel bridges were undertaken, among others, by Taleb & Moore (1999), Manko & Beben (2005), Pittino & Gosler (2006), Beben (2012), Kunecki (2014), Maleska & Beben (2019). It was found that during backfilling, displacement and bending moments in the shell are quite high, especially in the initial backfill layers.

Figure 1. View of soil-steel bridge from Norway.

The primary purpose of the research carried out in this study was to assess the behaviour of a soil-steel culvert with a shallow soil cover of 0.20 m above the steel shell. This made it possible to determine the object's behaviour under the tested static load. This research is of great innovative importance due to the analysis of a quasi-composite bridge structure and the possibility of using lower soil cover than the relevant standards require. The study analysed the course of strains and displacements over time for a steel corrugated shell for applied loads in the 0–37.5 kN range.

2 DESCRIPTION OF LABORATORY TEST

2.1 *Culvert shape and dimension of steel box*

The problem in this type of laboratory testing is to test the largest possible object without scaling or other simplifications. Therefore, the experimental tests were carried out in the laboratory in a specially constructed research box (Figure 2) with dimensions of 2.32 m × 4.34 m × 2.49 m. The tested steel culvert made of corrugated sheets had the following sizes: (i) span 2.1 m, (ii) height 1.45 m, (iii) length 2.32 m, (iv) thickness of the sheets was 2.5 mm.

The tested corrugated sheet culvert is made of S250 steel. The backfill consisted of a gravel mix. The backfill was placed in layers every 0.20 m to a height of 2.00 m. The backfill used in the experimental tests is a standard aggregate used to construct this type of facility. As part of these tests, the following loading forces were performed: (i) 5 kN (weight of a typical passenger car,

approximately 2 tons), (ii) 10 kN (car with a curb weight of up to 4 tons), (iii) 25 kN (weight of a small truck up to 10 tons), (iv) 30 kN (truck weight up to 12 tons), (v) 35 kN (truck weight up to 14 tons) and (vi) 37.5 kN (truck weight up to 15 tons - maximum load).

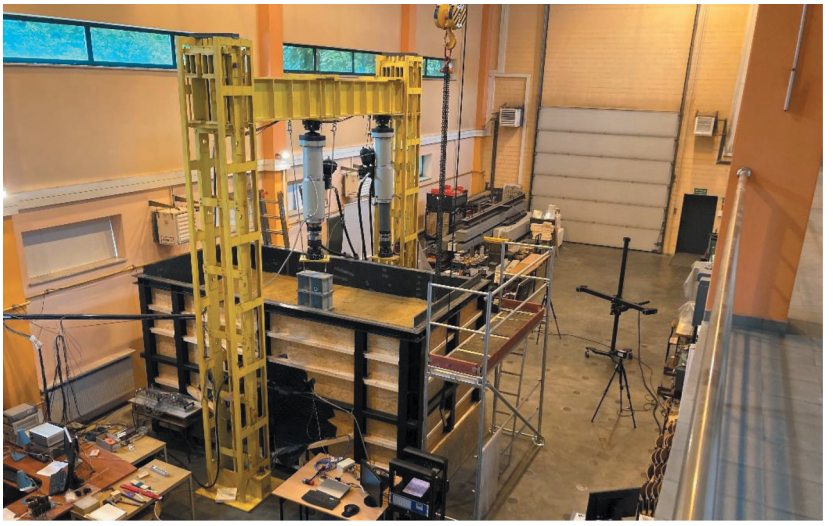

Figure 2. View of the experimental test in a laboratory.

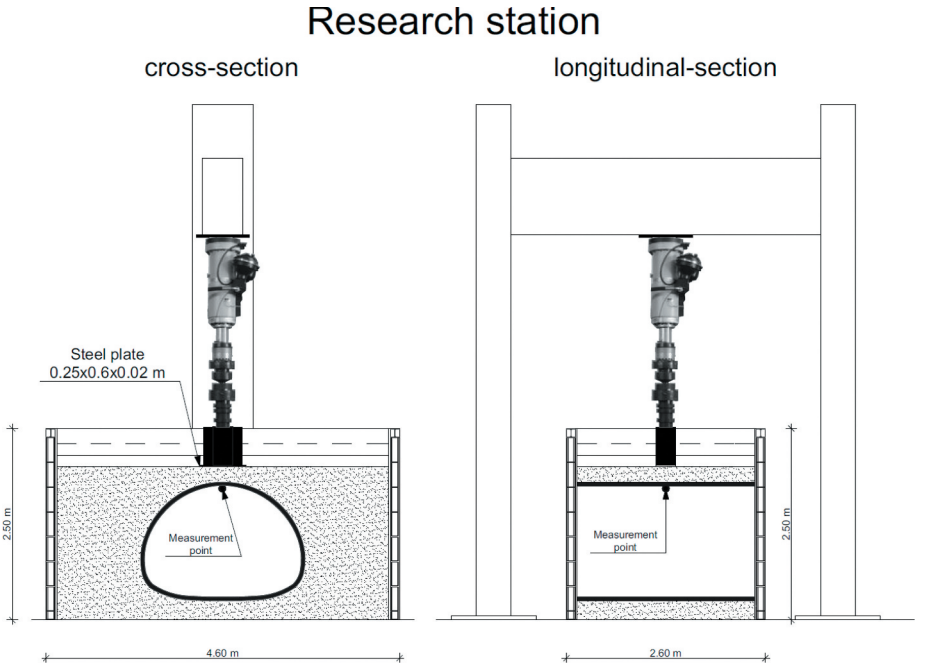

Figure 3. View of the experimental research site.

2.2 *Description of the experiment*

For model tests of the culvert, static load from concentrated force was simulated. It was applied to the soil from a hydraulic cylinder via a steel sheet with dimensions of 0.25×0.6×0.02 m and other transition elements (Figure 3). The force was applied exactly at the centre of the culvert's

span and length. The set static force increased at a rate of 1 kN/s (t_1) (Figure 4) from 0 kN to a maximum value of 37.5 kN. The increase in static load from 0 kN to the maximum value (F_{max} = 37.5 kN) lasted 10 minutes (t_1), and then the maximum load was maintained for 10 minutes (t_2). Subsequently, the set load decreased from the maximum value until the culvert was completely relieved at a speed of 1 kN/s (t_3). After unloading the tested structure, the measurement was maintained for the next 10 minutes to observe how the steel shell returned to its initial state (t_4).

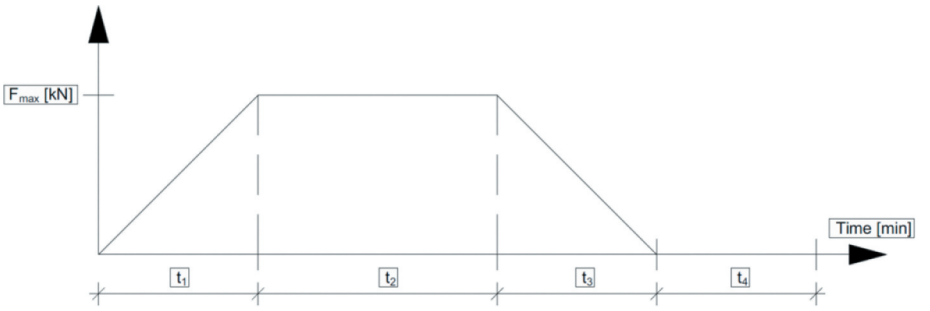

Figure 4. A time period of applied loads from the experiment.

In order to generate the required force, a steel frame was used with a hydraulic actuator placed on it, the operating range of which ranged from 0 to 250 kN. Strain gauges (TFs-10/120 (K)) were used to record the strains of the steel shell. The registration of displacements was made using LVDT sensors. The arrangement of measurement sensors (strain gauges and LVDTs) is shown in Figure 5, but in this paper, it is limited to presenting displacements and strains in the shell crown (cross-section B-B and point $4C_{lg}$), where the maximum values usually occur. A static force was also applied directly above the sensors (Figure 3).

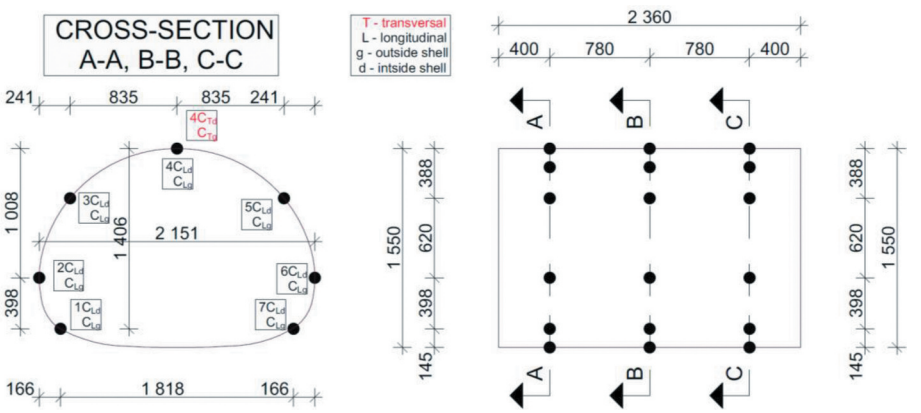

Figure 5. View of the measurement points.

3 RESULTS

3.1 *General remarks*

During the research, it was necessary to determine the parameter that would be the limit for the maximum load-bearing capacity of the tested structure. It should be added that the purpose of the tests was not to destroy the structure but only to assess its behaviour under a given load and

to determine the impact of deformations of the culvert shell under a given load. It was decided that this parameter would be the maximum deformation of the steel shell and, therefore, the maximum effort of the steel shell. Knowing the deformation of the steel shell and the strength parameters, it is possible to determine the effort of the steel shell by the maximum stress (yield strength). For the tested steel shell, the yield strength was 250 MPa. Therefore, in the tests carried out, attempts were made to obtain the maximum external load without exceeding the yield strength of steel. The value of the tested experimental model with a soil cover of 0.20 m was 37.5 kN. It should be noted that the soil cover of 0.20 m is shallow and unacceptable by standards (CHBDC 2017).

3.2 *Strains*

After conducting the experimental tests, it can be seen that in the experimental model with a soil cover height of only 0.20 m (below the CHBDC 2017 recommendations), a maximum load of only 37.5 kN was obtained from the concentrated static force. At this load, deformations of –1150 μm/m were recorded (Figure 6), equating to a stress of approximately 230 MPa in the steel shell of the bridge. This stress was considered limiting because the yield stress declared by the manufacturer was 250 MPa. Therefore, higher external load values were not chosen to avoid the destruction of the model.

However, in the remaining cases, smaller strains of the steel shell were achieved. The strain values ranged from –46 μm/m to –979 μm/m; therefore, the steel strain ranged from 9.2 MPa to 195.8 MPa. It can be seen that for loads in the range of 5–10 kN, the strain values were 4% (–46 μm/m) and 8% (–94 μm/m) of the maximum deformation values of the force of 37.5 kN, respectively. However, from a load value of 25 kN, a significant increase in strains in the steel shell can be observed. For a load of 25 kN (43% of the maximum given load), the strain value was –498 μm/m, and for a force of 30 kN (55% of the maximum load), the strain was equal to –634 μm/m. However, for a force of 35 kN (85% of the value from a force of 37.5 kN), a strain of –979 μm/m was recorded.

It is also worth paying attention to the time histories of strains presented in Figure 6. They show that as a result of applying a load, the shell immediately absorbed the given external load, and therefore, the steel shell was strained. In the case of unloading, the maximum strain values were quickly reduced and reached near the initial state. The recorded permanent strains did not exceed 27%. The noticeable relationship increases as the applied load increases. Therefore, the structure is flexible, probably due to the shallow soil cover.

3.3 *Displacements*

In the case of maximum displacements (Figure 7), similar relationships and trends were observed as in the case of strains (Figure 6). In the tested experimental model (soil cover height equal to 0.20 m), the maximum displacements for a concentrated force of 37.5 kN were 8.45 mm. In the remaining load cases tested (5–35 kN), it was noticed that the displacements were lower and ranged from 0.31 mm to 7.73 mm. A displacement of 0.31 mm was recorded for a load of 5 kN (4% of the maximum displacement of 37.5 kN) and a displacement of 7.73 mm for a load of 35 kN (94% of 37.5 kN). In other load cases, the following values of vertical displacements in the shell crown were obtained: (i) 5.46 mm - from a force of 30 kN (65% of the load 37.5 kN), (ii) 4.75 mm - from a force of 25 kN (56% of the load 37.5 kN) and (iii) 0.80 mm – from a force of 10 kN (9% of the load of 37.5 kN).

Moreover, by analysing Figure 7, one can notice a similarity to strains with a rapid increase in displacements immediately after applying a specific load. However, in the case of unloading, there is a quick return to the initial state (permanent displacements observed not exceeding 37%). This behaviour of displacements also proves the correctness of the results because the tendency of their appearance in the steel is closely related to the effort of the shell and, therefore, to their strains.

In addition, it is essential to determine whether the tested soil-steel culvert does not exceed the permissible displacement levels provided for in the standards and recommendations. The

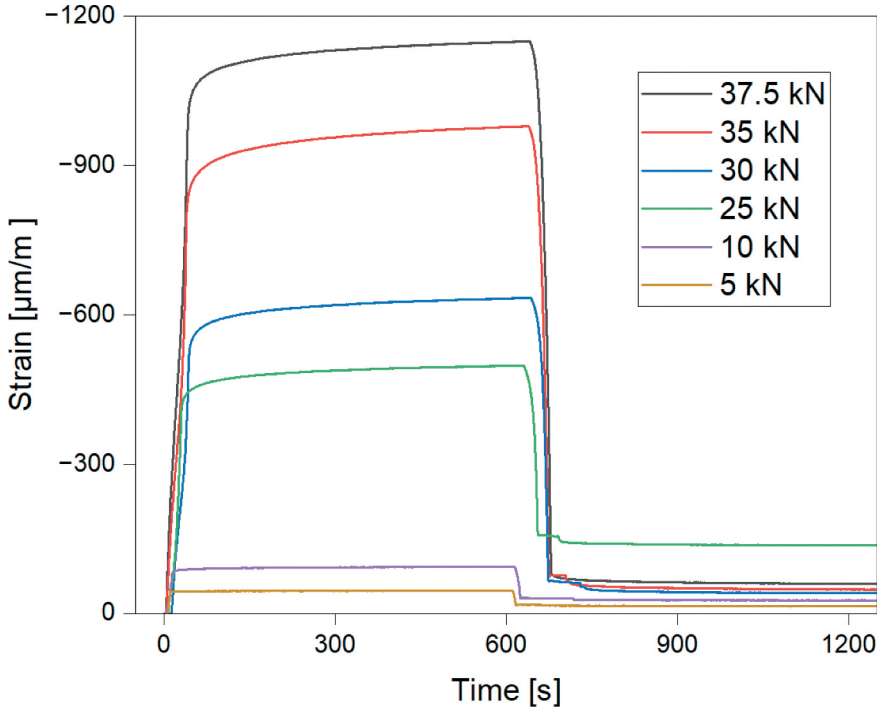

Figure 6. Maximum strains from an experiment in the time domain.

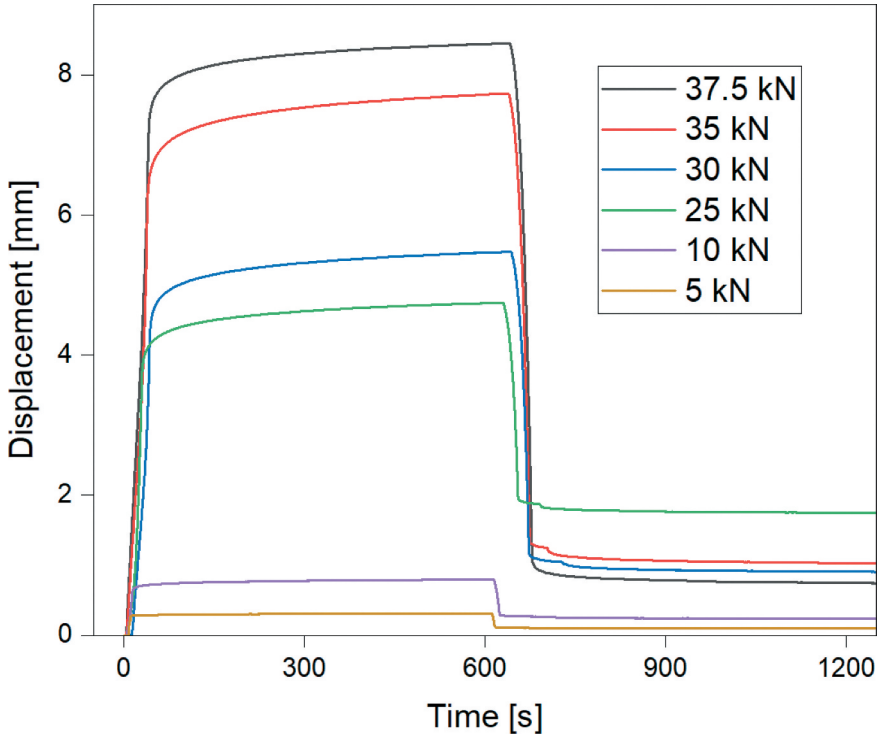

Figure 7. Maximum displacements from an experiment in the time domain.

maximum design displacement is determined as the allowable deflection of the buried bridges/culverts, which should not exceed the value calculated based on the following conditions, namely:

(i) 5% of the span, i.e. 105 mm (AASHTO 2017),
(ii) 0.5% of the span, i.e. 10.5 mm (CHBDC 2017),
(iii) 2% of the span, i.e. 42 mm (CSPI 2007),
(iv) 10% of the rise, i.e. 145 mm (NCSPA 2018).

It is clearly visible that the conditions resulting from the NCSPA (2018), AASHTO (2017) and CSPI (2007) recommendations are less restrictive than the requirements proposed by CHBDC (2017) for the buried bridges/culverts. As shown in the study, the maximum displacement of the culvert was 8.45 mm is smaller than the permissible values calculated under the above four conditions. The above conditions are caused by a conservative approach to determining the limit values (not considering the soil-structure interaction phenomenon and increased safety factors).

4 CONCLUSION

After preliminary tests, it can be concluded that the structure of the soil-steel culvert, despite the extremely low level (lower than the recommendations of standards and guidelines), is able to transfer a load equal to the wheel pressure of a truck weighing 15 tons. Moreover, after the research carried out, it can be concluded that:

- The displacements and strains of the shell increased with the load, but two main increases in the tested values are visible, i.e. after applying a load of 25 kN and 35 kN. For loads above 25 kN, displacements and strains increased slowly over time.
- The structure of the culvert with a low soil cover behaved elastically under a given load, which was manifested by a quick response to the given loads and unloading of the structure. Permanent displacements and strains of the steel culvert were recorded as 37% and 27% (approximately 10 minutes after unloading), respectively.
- According to various standards and recommendations, the permissible displacements of the tested soil-steel culvert were not exceeded. However, the CHBDC standard (2017) approach is closest to the maximum measured displacement.

To sum up, further research is necessary to assess the behaviour of soil-steel structures with low soil cover, as there are many practical cases where the use of such shallow cover is necessary. It makes sense to strengthen soil-steel bridges with various types of geogrids and geotextiles because this may bring significant benefits in the form of increased load-bearing capacity of the structure. As a result, this may translate into lower material consumption and workload of people and equipment, resulting in lower costs of building a new facility or cheaper modernisation of an existing facility. Therefore, further research will examine materials that strengthen the soil above the steel shell or stress-relieving materials that cause the redistribution of stresses in the soil and shell resulting from external loads.

ACKNOWLEDGEMENTS

The authors would like to thank ViaCon Polska from Rydzyna for providing the steel culvert for experimental tests and ROLMEX from Dobrodzień for helping construct the steel box. The research was carried out as part of the MINIATURA project financed by the National Science Centre.

Maximum shear strength of prestressed concrete deep beams

X. Duanmu & D. Xu
Tongji University, Shanghai, China

K. Hu
Anhui Transportation Holding Group Co., Ltd., Hefei, China

ABSTRACT: The shear performance of prestressed deep girders is pivotal for accelerated bridge construction. There are few tests on prestressed deep girders and even fewer discussions on their upper shear limits. This study introduces four full-scale post-tensioned bonded prestressed concrete T-beam tests and the upper limit value provisions are summarized. The four T-beam shear tests and comparative analysis of other test results reveal that the upper limit value of prestressed concrete deep beams is influenced by reinforcement and shear span ratio. Longitudinal prestress enhances cracking and ultimate loading, while the effect of the vertical component of prestressing is controversial and requires further investigation. The AASHTO method was found to be more appropriate for the upper limit values of T-beams, compared with the ACI 318-19 specification. Struct and Tie Model (STM) underestimated the shear strength.

1 INTRODUCTION

In recent years, with the rapid advancement of China's bridge design and construction technology, particularly in the industrialized construction of assembled bridges such as small box girders and T girders, the study of shear resistance in prestressed concrete deep beam components has become a crucial research problem.

Shear tests on prestressed I-beams with a/h ratios less than 2.0 were conducted by Arthur (1965), Mahgoub (1975), Kang (1989), Shahawy (1996), Tan (1999a), and Laskar (2010), encompassing pre-tensioning tests. Teng(1998), Tan(1999b), Wang(2009) and Yang(2020) carried out tests on unbonded post-tensioned rectangular beams with short shear spans. Wang (2009) conducted tests on bonded post-tensioned prestressed rectangular beams. However, to the best of the author's knowledge, no tests have been performed on bonded post-tensioned concrete T-beams with short shear spans, and there is a scarcity of experiments on post-tensioning, especially those involving bonded post-tensioning.

As a typical method for fast prefabricated bridge construction, post-tensioning is in high demand. Full-scale tests are essential for a more accurate reflection of structural responses. To advance the understanding of shear resistance in prestressed concrete deep beams, this paper presents the findings from laboratory tests conducted on four full-scale prestressed concrete T-beam tests.

Simultaneously, the upper limit of concrete bridge shear strength, also known as minimum web thickness requirements, constitutes a significant aspect of concrete design specifications. The stipulation of shear strength upper limit values can influence the design of web thickness. In many countries, due to these regulations, webs are typically variable in thickness, posing challenges to industrial development. Currently, there is limited discussion on the shear strength upper limit values for prestressed concrete deep beams. This paper discuss the parameters which have influence on the shear strength of prestressed deep beam. The primary methods for designing deep beams are empirical formulae or STM models. This paper reviews

DOI: 10.1201/9781003483755-153

upper limit value methods in ACI 318-19 (ACI Committee 318, 2019) and LRFD bridge design specifications (AASHTO, 2020), compares them with collected experimental data. Then the authors will discuss the specifications on STM models in ACI 318-19 and AASHTO, points out current research deficiencies.

2 GENERAL METHODS

2.1 *Upper limit of the deep beam*

The AASHTO code employs the Modified Compression-Field Theory (MCFT) for design, and the maximum load capacity of a pure shear concrete member is $0.5\nu f_c^{'}$ (AASHTO, 2020). In the code, the $\tau/f_c^{'}$ is given according to MCFT, that is, the reasonable range of values of 0.5ν is from 0.05 to 0.25, with 0.25 as the upper limit value, i.e. 0.5ν=0.5, thus:

$$V \leq 0.25 f_c^{'} b_v d_v + V_P \tag{1}$$

where $f_c^{'}$ denotes the compressive strength of the concrete cylinder, b_v is the width of the web, and d_v is the effective height, which can be taken as $0.9h_0$. V_P is the vertical component of the prestressing force.

ACI's Committee 326 (1962) analyzed the test data and found that with higher stirrup ratios, the compression zone would break down before the web reinforcement yielded, thus requiring a limit on its maximum value (ACI Committee 318, 2019). The following formula is used for the current ACI 318-19 code upper limit for shear design:

$$V \leq 10\sqrt{f_c^{'}} b_v d_v \tag{2}$$

The symbols' significance aligns with those in the AASHTO code. The code considers crack resistance during design to ensure the structure's crack width remains within a defined range under service loads.

2.2 *STM of the deep beam*

An increasing number of deep beam designs are adopting the Strut-and-Tie Method (STM), derived from the plasticity lower bound theorem. This method necessitates the concrete to be fully plasticity developed, along with a specific arrangement of reinforcement in the web. In instances where the web lacks sufficient reinforcement, the concrete strength is discounted. Therefore, when the stirrup ratio is appropriately provided, it can be regarded as the upper limit of shear for deep beams.

In the context of deep beams reinforced with minimal web reinforcement adhering to Equation 4, the code does not explicitly delineate the contribution of prestress to shear capacity.

$$\theta = \tan^{-1}\left(\frac{0.9d}{a}\right) \tag{3}$$

$$\sum \frac{A_{si}}{b_s s_i} \sin^2 \alpha_i \geq 0.0025 \tag{4}$$

$$V_{c,cal} = 0.85\nu(l_b \sin\theta + w_t \cos\theta) b_w f_c^{'} \tag{5}$$

where θ represents the strut angle, d denotes the effective depth, a signifies the shear span, s_i represents the spacing between layers of reinforcement. Each layer has a reinforcement area denoted as A_{si} and crosses the inclined strut at an angle α_i with respect to its axis. b_s is the width of the strut. The recommended value for ν in the code is 0.75; otherwise, it defaults to ν = 0.4. l_b

refers to the width of the bearing, w_t represents the effective height of concrete concentric with a tie, and b_w denotes the web width.

In the AASHTO specification, the Strut-and-Tie Method (STM) closely resembles that of ACI's. The primary difference lies in the coefficient of effective concrete strength, denoted as ν, determined by Equation 8. This computation relies on the satisfaction of Equations 7 and 8, with a specified value of 0.45 assigned for structures lacking crack control reinforcement.

$$\frac{A_h}{b_w s_h} \geq 0.003 \tag{6}$$

$$\frac{A_v}{b_w s_v} \geq 0.003 \tag{7}$$

$$v = 0.85 - \frac{f'_c}{20(\text{ksi})} (0.45 \leq v \leq 0.65) \tag{8}$$

where, s_h and s_v represent the spacing between layers of horizontal or vertical reinforcement, respectively. Each layer is characterized by a reinforcement area denoted as A_h or A_v. When adequately reinforced, STM's maximum shear capacity closely aligns. The discount factor for ACI is 0.85 × 0.75 = 0.64, and for AASHTO, it is 0.65.

3 TEST RESULTS

3.1 *Test setup*

Two prestressed deep beams, as illustrated in Figure 1, were fabricated and subjected to failure testing. The design was derived from a prestressed concrete lightweight T-beam bridge with a 25 m span. The bridge features a width of 12.75 m, a girder height of 1.605 m, and is composed of four T-beams arranged transversely, each with a single girder width of 2 m.

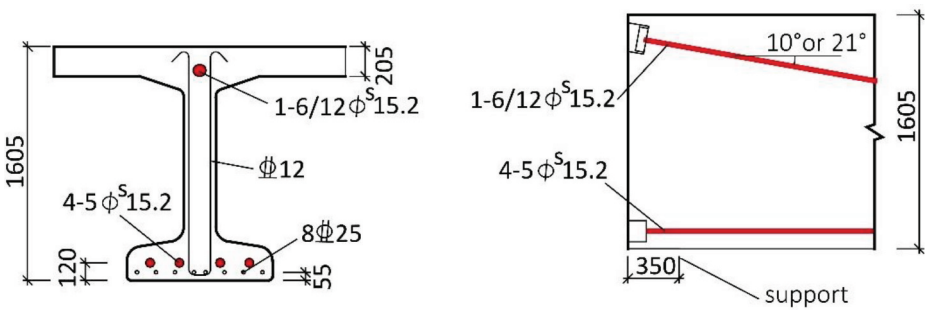

Figure 1. End sections of test beams (Unit: mm).

The web plate has a thickness of 0.22 m, the flange plate has a thickness of 0.2 m, the bottom flange width is 1.0 m, and the entire bridge adopts an equal cross-section arrangement. The girder's bottom is equipped with 8 HRB400 bars of φ25 mm, and the stirrup reinforcement ratio is 1.03%. In the bottom flange, 4 bundles of 5-φs15.2 mm prestressing tendons are arranged, while in the web plate, 1 bundle of 12-φs15.2 mm or 6-φs15.2 mm prestressing tendon is arranged, with bending angles of 10° or 21°, respectively. The cross-sectional form of the test beam and its end reinforcement are depicted in Figure 2. For clarity, Table 1 provides a summary of the main parameters in the test beams.
