The present contribution is organized as follows. In the next section, the overall procedure of i-AOMA is illustrated. Afterward, the current bridge case study benchmark, i.e. the Hardanger bridge is described. This case study allows to highlight advantages and potentialities of the proposed i-AOMA.

2 INTELLIGENT AOMA

In the conventional stabilization diagram, the SSI-cov algorithm might inadvertently identify spurious modes with no relation to the actual structural modes of interest. This issue arises due to the inherent characteristics of the SSI algorithm, stemming from the unknown of the actual degrees of freedom (DOFs) in real-world structures. A conservative approach involves the overestimation of the structural system order, despite this often leading to the rise of non-physical poles alongside the real ones (Rainieri & Fabbrocino 2014b). Furthermore, a poor selection of SSI governing parameters can exacerbate meaningless results. Recently, (Zhou, Li, & Han 2022, Zhou & Li 2022) endeavored to enhance SSI's accuracy in identifying true structural modal parameters. They introduced a Monte Carlo-based approach defining the stabilization diagram by varying two input parameters: the length of signals within a shorter time window and the maximum model order. Their work demonstrated that executing numerous Monte Carlo simulations of these parameters and subsequent SSI-cov analyses led to occasional detection of spurious modal alignments, while consistently identifying the actual structural modes in virtually all the recurring analyses. However, their method has limitations. Firstly, it suggests an arbitrary number of Monte Carlo simulations equal to 100, without a clear convergence criterion. Secondly, it still requires users to arbitrarily define the time shift, impacting the reliability of the proposed AOMA framework and limiting its automation. Moreover, despite a Monte-Carlo-based approach no uncertainty evaluation was carried on.

Therefore, this study aims to address these issues by illustrating a recently developed intelligent-driven automatic OMA named intelligent-AOMA (i-AOMA) that meets the core requirements of contemporary AOMA approaches, without relying on prevalent ML-based clustering techniques. Inspired by the initial studies of (Zhou, Li, & Han 2022, Zhou & Li 2022), the proposed intelligent-AOMA increases the automation degree by incorporating the time shift parameter into the Monte Carlo sampling, eliminating the need for meticulous user intervention. The proposed methodology consists of two main steps. Phase 1 (Figure 1 left), involves quasi-

Monte Carlo sampling (Owen 2017) of four key SSI-cov control parameters: time shift (number of block rows of the Hankel matrix), time window length, time target, and maximum model order (Rainieri & Fabbrocino 2014b). This initial exploration stage necessitates users to broadly define the permissible range of input parameters. The number of exploratory Monte Carlo simulations influences the subsequent ML-based phase 2; here, the authors adopt 100 simulations based on prior recommendations (Zhou & Li 2022). However, unfeasible parameter sets, due to incorrect combinations or excessive computational time, are automatically excluded to optimize computational resources. Stability check criteria retain only stable poles among the generated stabilization diagrams. Post-processing involves overlapping diagrams to identify recurrent stable pole alignments, achieved without traditional clustering algorithms but via kernel density estimation (KDE) (Gramacki 2018). This method discerns poles around sharp peaks associated with physically stable alignments within a retaining frequency band, enabling selection based on an automatic statistics-based criterion.

The second step (Figure 1 right) relies on a ML-based approach, specifically a random forest (RF) algorithm (Raschka & Mirjalili 2019, G´eron 2022), to intelligently guide quasi-Monte Carlo sampling toward the most promising parameter sets. RF training utilizes results from the previous exploratory step, assigning an information content (IC) parameter to each simulation. Due to its ensemble nature, the RF is one of the simplest and yet powerful ML tools not requiring a sophisticated tuning procedure of its hyperparameters. The IC reflects the ratio of poles falling within the KDE-based frequency bands to total stable poles computed in every simulation, aiding in excluding parameter sets likely to yield insignificant results. Convergence analysis of mode shapes occurs at intervals of 50 actually computed simulations, ensuring stability according to a defined variation range according to the acceptable shifting convergence band rule (ASCBR) (Ata 2007). According to the generalized sample variance matrix, (Ziegel 2003) of the mode shapes associated with the found natural frequency recurrent physical modes, the convergence criteria was set to a relative variation of the trace of the generalized sample variance matrix within ±0.02 for 50 iterations (Ata 2007). Post-convergence procedures mirror those at the end of the exploratory step, viz. overlapping all the stabilization diagrams and extracting recurrent modes with a KDE criterion, and finally analyzing confidence bands for uncertainty evaluation in modal parameters.

Further details about the i-AOMA are presented in (Rosso, Aloisio, Parol, Marano, & Quaranta 2023).

3 CASE STUDY: HARDANGER BRIDGE IN NORWAY

The case study analyzed in the present paper is the Hardanger Bridge (Petersen, Øiseth, & Lourens 2019, Fenerci, Andreas Kv˚ale,Wiig Petersen, Rønnquist, & Øiseth 2021), located in the Hardangerfjord on the west coast of Norway, a geographical and topographical complex region

with steep mountains and wide fjord, see Figure 2. This suspension bridge is 1308 m long, composed of a slender steel box deck of 3.2 m high and 18.3 m wide, hosting two traffic and one bicycle lanes, supported by 2 main cables with 130 hangers and two extreme pylons up to 200 m high. Since 2013, the bridge has been equipped with a continuous long-term monitoring system implemented by the Norwegian University of Science and Technology (NTNU), composed of 20 triaxial accelerometers with a sampling rate of 200 Hz (see Figure 3) placed on the deck and pylons, together with 9 sonic anemometers. The local geographical context involves strong wind loads whose effects make the dynamic identification process challenging (Petersen, Øiseth, & Lourens 2019, Petersen, Øiseth, & Lourens 2020). Both raw and organized long-term wind and acceleration data for SHM purposes have been published in an open-access repository (Fenerci, Andreas Kv˚ale, Wiig Petersen, Rønnquist, & Øiseth 2021).

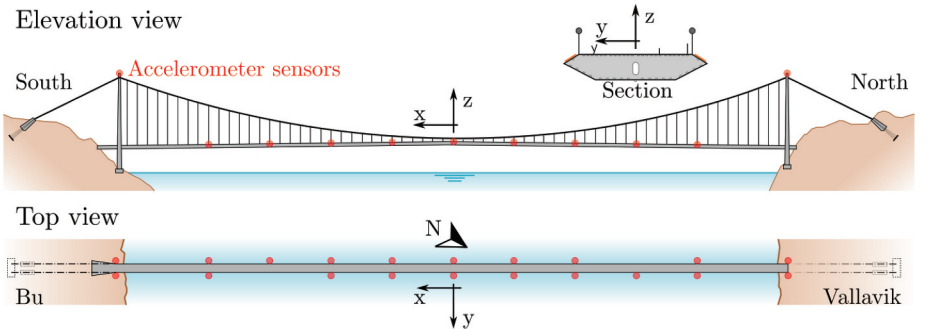

Figure 3. Accelerometer sensors layout on the Hardanger Bridge.

4 AUTOMATIC IDENTIFICATION OF THE HARDANGER BRIDGE

The case study represents a compelling experimental benchmark for the i-AOMA method, both for structural and environmental reasons. Furthermore, as reported in the literature, the first eleven modes are closely spaced within a very low frequency range (below 0.4 Hz) (Petersen, Øiseth, & Lourens 2020, Petersen, Øiseth, Nord, & Lourens 2019, Fenerci & Øiseth 2017). Among the available data (Fenerci, Andreas Kv˚ale, Wiig Petersen, Rønnquist, & Øiseth 2021), the recordings processed for the present application last 31 min and the sampling frequency is equal to 200 Hz. The data refer to under the environmental conditions of sustained wind and were collected on the 12th November 2015 at 23:54:31 (local time) with a recorded wind speed of 14.02±2.28m/s. The data have been decimated with a factor of 20, in such a way to focus on the range 0-5 Hz range (Nyquist frequency). To speed up the identification process, the maximum order of the stabilization diagram within the i-AOMA procedure was imposed to 360 and the maximum block rows number was limited to 100.

The order of magnitude of the recorded accelerations can be retrieved by Figure 4 where the first ten singular values of the power spectral density (PSD) are also reported. Figure 4 confirms that the current data activates several modes within the 1 Hz range. A total of 100 MC simulations has been set for the i-AOMA phase 1 to construct the training set for the subsequent RF intelligently driven sampling scheme. Thereafter, additional 1,150 useful results have been collected in phase 2 reaching the convergence of the trace covariance of 25 modes found within the inspected frequency range. The overlapped stabilization diagrams are reported in Figure 5, whereas the normalized KDE and the relative clusters are reported in Figure 6. Only the first 11 modes falling below 0.4 Hz are examined hereafter.

A limited number of results is available in the existing literature for the considered case study. For instance, in (Øiseth, R¨onnquist, Kv˚ale, & Sigbj¨ornsson 2015) only 4 modes have been identified under a mean wind speed velocity of 16 m/s, whereas only 9 modes have been found (Fenerci & Øiseth 2017). Nonetheless, an outstanding agreement has been underlined between the identified natural frequencies with the i-AOMA method compared with (Petersen, Øiseth, & Lourens 2019, Petersen, Øiseth, Nord, & Lourens 2019, Petersen, Øiseth, & Lourens 2020) as reported in Table 1. Herein, the modes naming convention follows the dominant motion of each mode, i.e. H stands for horizontal, V means vertical and T denotes torsional mode shapes. It is worth noting that in terms of the relative difference between the natural frequencies values, the i-AOMA method provided values in excellent agreement with the existing OMA results and even with calibrated finite element models (FEM) modal analysis.

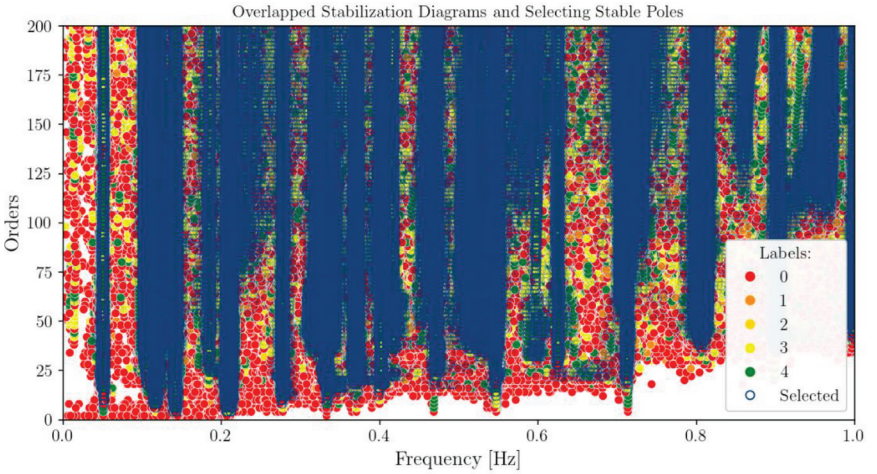

Figure 5. Overlapped stabilization diagram at the end of i-AOMA phase 2.

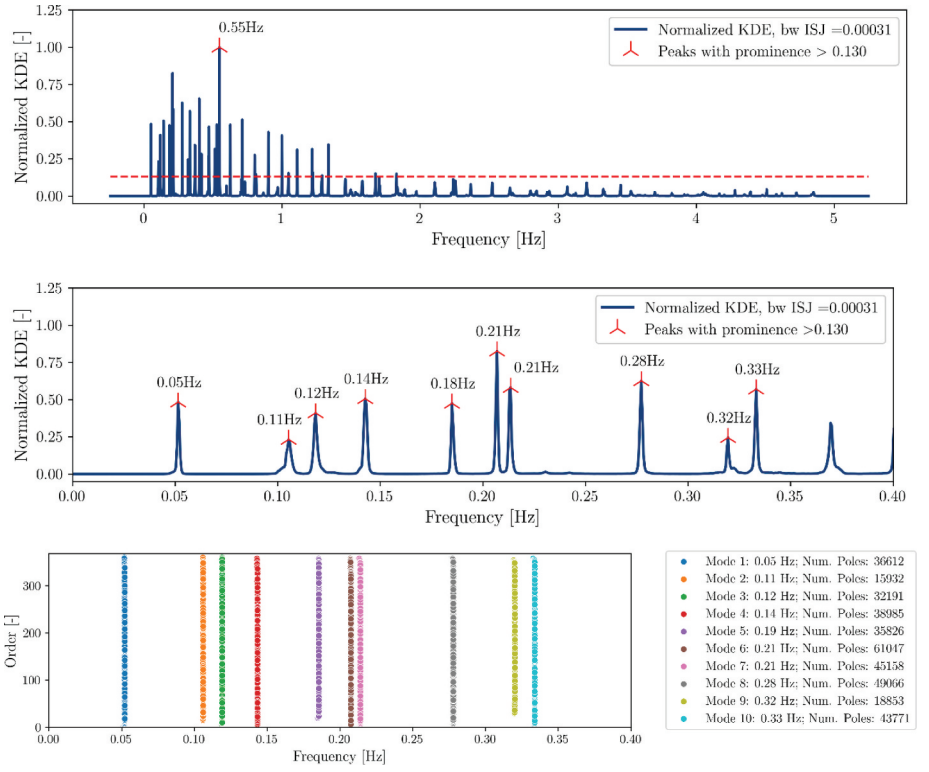

Figure 6. Normalized KDE automatic mode clusters extraction.

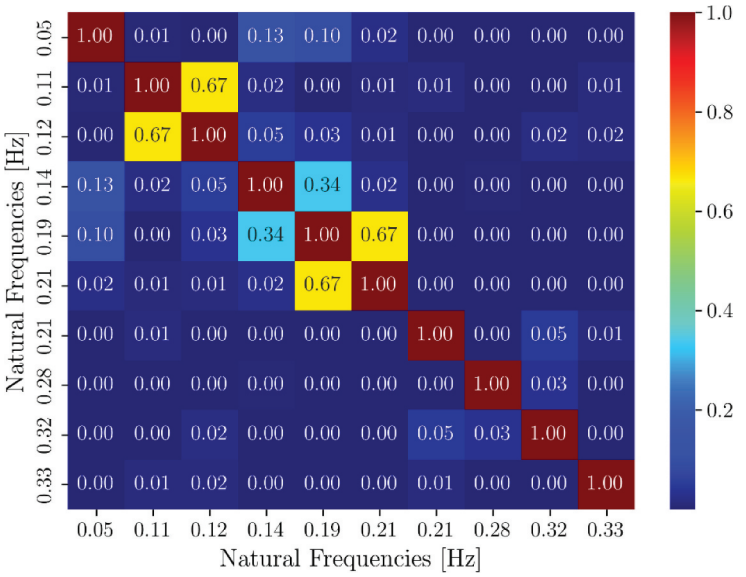

Figure 7. MAC among the identified modes.

However, comparing the damping ratios between i-AOMA and FEM literature solutions, the resulting values appear generally overestimated by the i-AOMA. From this comparison, it seems that the i-AOMA procedure was successfully able to identify all the actual first eleven modes. However, the mode shape interpretation should be deeply inspected since the modal

assurance criterion illustrated in Figure7 computed for the i-AOMA identified modes evidenced quite strong correlations between 0.11 and 0.12 Hz modes, and between 0.19 and 0.21 Hz ones.

5 CONCLUSIONS

In the current study, the potentialities of the recently developed intelligent Automatic Operational Modal Analysis (i-AOMA) method have been illustrated. The i-AOMA algorithm represents one of the steps ahead in continuous monitoring by increasing the automation level of OMA procedures. Furthermore, the adoption of machine-learning-based random forest algorithm did not require careful tuning of hyperparameters due to its ensemble robust nature. Specifically, the proposed framework was applied to a challenging bridge case study, the slender suspended Hardanger bridge located in Norway in a fjord area. This case study represents a widely studied and quite well-validated benchmark in the existing literature because of the availability of long-term wind and acceleration data collected from the Norwegian University of Science and Technology (NTNU) since 2013 and published on an open-source repository. After selecting recorded data under sustained wind speed environmental conditions, the i-AOMA procedure was outstandingly able to identify the first eleven very closely spaced modes presenting very low frequencies (below 1 Hz). Future developments should better investigate the median mode shapes and relative uncertainties since the modal assurance criterion evidenced a relatively high degree of correlation between the 2nd and 3rd modes and between the 4th and 5th ones.

Managing aging bridges under seismic hazards through deep reinforcement learning

Z. Metwally & C.P. Andriotis

F. Molaioni
Department of Civil Engineering and Computer Science Engineering, University of Rome Tor Vergata, Rome, Italy

ABSTRACT: Structural systems must satisfy multiple performance and functionality requirements during their life cycle, withstanding safety-reducing degradation mechanisms and hazards. Intervention strategies must be planned accordingly to maintain structural integrity and minimize total life-cycle costs and risks, posing a complex optimization problem. Recent advances in multi-agent deep reinforcement learning (DRL) in conjunction with partially observable Markov Decision Processes (POMDPs) have shown great potential for determining optimal structural integrity management policies for systems with large state and action spaces compared to traditional decision practices. This paper tackles the maintenance optimization problem of aging bridges in seismic-prone areas, creating an updatable environment that embeds chloride-induced corrosion and state-dependent seismic fragility throughout the bridge life-cycle. The evolution of the environment is captured by a dynamic Bayesian network, and it is further integrated with decentralized multi-agent DRL algorithms to identify near-optimal life-cycle decisions under risk constraints. Results on a multi-component bridge system show the suitability of the developed framework for minimizing expected life-cycle costs, and for providing detailed and adaptive policies that significantly outperform traditional condition- and time-based maintenance plans.

1 INTRODUCTION

Structural degradation of bridges, induced by time-dependent stressors and natural hazards, is a major threat to long-term structural safety. Controlling it becomes more and more crucial in the expanding and complexifying landscape of infrastructure networks. Many highway bridges worldwide have been constructed with outdated design principles, and are experiencing structural weakening due to aging and deterioration (Shekhar & Ghosh 2021). Late reports show, for instance, that almost half of the US bridges are more than 50 years old, with 35% requiring maintenance interventions of circa $125B. This raises the risk of disruptive transportation network closures, mobility restrictions, and potential failures (ASCE 2021). These figures highlight a broader challenge facing many countries: a growing stock of aging infrastructure that are reaching or have well exceeded their design life.

Among different deterioration mechanisms, corrosion, which is typically initiated by the penetration of aggressive substances (e.g., chlorides), is a threat that can compromise the ability of structural systems to withstand the design loads, resulting in a decreased structural reliability and, hence, increased vulnerability to natural hazards (Choe et al.

DOI: 10.1201/9781003483755-403

2008). Specifically, corrosion of reinforcement bars, which is typically associated with reinforcement mass loss, spalling of the concrete cover, and bond slippage, is shown to affect the strength and ductility of bridge components such as RC columns, bridge piers, and bearings (Rinaldi et al. 2022). The phenomenon manifests itself through uniform area reduction along the rebar length, as well as nonuniform spatially distributed local pits or cavities (Bertolini et al. 2004).

It is well understood that the severity of seismic consequences on RC bridges is magnified due to corrosion. Therefore, recent studies have developed formulations to quantify seismic fragility under corrosion. A common assumption is to consider uniform corrosion, therefore, uniform cross-sectional area losses (Alipour et al. 2011; Rao et al. 2017; Deng et al. 2018). Yet in more recent studies, it is shown that pitting corrosion can be more critical compared to uniform corrosion, especially in RC bridge columns, as it can reduce the lateral load capacity due to localized weakening (Shekhar & Ghosh 2021). Accounting for both effects, Molaioni et al. 2023 proposed a DBN approach to continuously track the seismic fragility of reinforced concrete bridges throughout the life-cycle. Bridges are treated as multi-component systems that include columns and different types of bearings. The aging of bridges is rigorously incorporated in the approach, considering mass loss due to pitting corrosion and associated secondary effects of strength reduction, cracking, and loss of confinement, in addition to deterioration of steel bearings and corresponding modified cyclic behavior. Overall, literature suggests that modeling aging bridges as heterogeneous multi-component systems, and considering uniform and pitting corrosion alike for concrete members, in addition to reduction of strength and ductility of rebars, loss of concrete cover, and deterioration of steel fixed and expansion bearings, can significantly enhance our predictive capabilities. The next question to be addressed is how we can harness such predictive models to synthesize precise optimal life-cycle maintenance and retrofit plans given the complexity and uncertainties of the involved systems and phenomena.

Over the past years, there has been increasing attention to the development of life-cycle decision optimization methodologies for infrastructure management, aimed at meeting this challenge in the most eco-socio-economically aware ways (Arunraj & Maiti 2007; Bucher & Frangopol 2006). Conventional approaches for determining maintenance policies for structural systems build largely upon heuristic decision rules, which are based on engineering judgment about intervals or thresholds for interventions and observations. Such plans can be optimized either through exhaustive search or genetic algorithms. Another family of advanced optimization formulations sets up the problem as a Partially Observable Markov Decision Process (POMDP), solving the sequential decision-making task in a closed-loop fashion by incorporating observations and uncertainties of the underlying environment (Papakonstantinou & Shinozuka, 2014). Solutions can be traced effectively through value-based iteration methods in low- to medium-sized systems (Papakonstantinou & Shinozuka, 2014; Papakonstantinou et al., 2018), or through Deep Reinforcement Learning (DRL) in large-scale ones (Andriotis & Papakonstantinou 2019, 2021).

Embracing these advances, we articulate the seismic management problem of aging bridges as a POMDP and solve it through Deep Decentralized Multi-agent Actor Critic (DDMAC) DRL architectures (Andriotis & Papakonstantinou, 2021). DDMAC allows us to deal with the curse of dimensionality, namely the exponential explosion of state and action spaces with an increasing number of components. The actors assimilate centralized system information and produce a decentralized policy for each component, guided by a single critic network which is a surrogate of the life-cycle cost. Thereby, DDMAC allows actor outputs to scale linearly with components, while exploiting system-level information. Constraints are also incorporated either through state augmentation or a primal-dual optimization approach. A sparser version of DDMAC relying on local component information and centralized training with decentralized execution is introduced in (Saifullah et al. 2024). The temporal behavior of the structural system and its stressors are described by a Dynamic Bayesian Network (DBN), as developed by (Molaioni et al. 2023). This allows uncertainty propagation, state updating due to

observations, and coupling with DRL in a principled manner (Morato et al. 2023). The environment states are defined as probabilistic distributions, i.e., beliefs, rather than deterministic scalars.

Overall, this paper introduces a framework that integrates chloride-induced deterioration of components, state-dependent seismic fragility, probabilistic hazard analysis, maintenance actions, associated costs, and structural risk with DRL to optimize life-cycle intervention policies. Exemplifying the approach in a case study of pre-70's bridges, structures are idealized as multi-component systems that include columns, high-type expansion bearings, high-type fixed bearings, and low-type fixed bearings. The aging of bridges is rigorously incorporated considering mass loss due to uniform and pitting corrosion, and associated secondary effects (Molaioni et al. 2023). Our approach results in substantial improvement in minimizing the life-cycle costs compared to traditional maintenance policies, offering detailed and dynamic maintenance plans at the component level, which are, however, risk-compliant and near-optimal at the system-level.

2 SEQUENTIAL DECISION-MAKING

The sequential decision-making problem is formulated as a Partially Observable Markov Decision Process (POMDP). Transfer between states is defined by a transition probability model, which is the probability of moving to a new state, s_{t+1}, in the coming time step, given the current state, s_t, when taking action a_t, i.e., $\Pr(s_{t+1} \mid s_t, a_t)$. Based on s_{t+1}, s_t, and the imposed action a_t, a cost c_t is received, which is a measure of the desirability of the environment state and imposed action. The environment is perceived through noisy observations, o_t, conditional on the actual hidden state, s_t, and the imposed action a_{t-1}, according to an observation model which defines the probability of observing o_t given s_t and a_t, i.e., $\Pr(o_t \mid s_t, a_{t-1})$. Leveraging the transition and observation models, sufficient statistics that encode all the previous observation and action history, i.e., beliefs, can be formed which can be forwarded to the agent. The agent is tasked with learning the best mapping between belief b_t and potential actions, i.e., a policy $\pi=\Pr(a_t \mid b_t)$.

Throughout training, π is constantly updated to determine an optimal policy π^* within a region of feasible policies Π_c, defined by the set of stochastic and deterministic constraints of the optimization problem (Andriotis and Papakonstantinou, 2021):

$$\pi^* = \underset{\pi \in \Pi_c}{\arg\min}\, \mathbb{E}\left(\sum_{t=0}^{T} \gamma^t c_t \mid a_t \sim \pi(o_{0:t}, a_{0:t-1}), b_0 \right) \tag{1}$$

where γ is a positive discount factor lower than 1.0 translating future costs to the current value.

The optimized policy π^* can be written in terms of the initial belief b_0, which is updatable after each decision step in a Bayesian manner in the POMDP framework, as follows:

$$\pi^* = \underset{\pi \in \Pi_c}{\arg\min}\, V^{\pi}(b_0) \tag{2}$$

where V^{π} is the value function, which is a surrogate of the expected cumulative costs throughout the life-cycle until termination, $t=T$.

Here, the actor and critic neural networks parameterize the policy and value functions, respectively, following an off-policy approach, as follows:

$$g_{\theta}{}^{i} = \mathbb{E}\left[w_t \nabla_{\theta}{}^{i} \log \pi^{i}\left(a_t^i \mid b_t; \theta^i\right) A^{\pi}(b_t, a_t) \right] \tag{3}$$

$$g_{\varphi} = \mathbb{E}\left[w_t \nabla_{\varphi} V^{\pi}(b_t) A^{\pi}(b_t, a_t) \right] \tag{4}$$

where i is the index of the i^{th} actor; θ^i is the actor neural network weights vector; φ is the critic neural network weights vector;, w_t is an importance sampling weight; and A^π is the advantage function. The advantage function used takes the form:

$$A^\pi(b_t, a_t) = c(b_t, a_t) + \gamma V^\pi(b_{t+1}; \varphi) - V^\pi(b_t; \varphi) \tag{5}$$

3 STATE-DEPENDENT SEISMIC FRAGILITY

To quantify the seismic risk, we need to integrate the probability of exceedance of specific damage states due to distinct seismic intensity measures, over the range of these intensity measures, based on the bridge site characteristics:

$$PA_s(t) = \int \Pr[SDS(t) > s_s | IM_t = x] \left| \frac{dH(x)}{dx} \right| dx \tag{6}$$

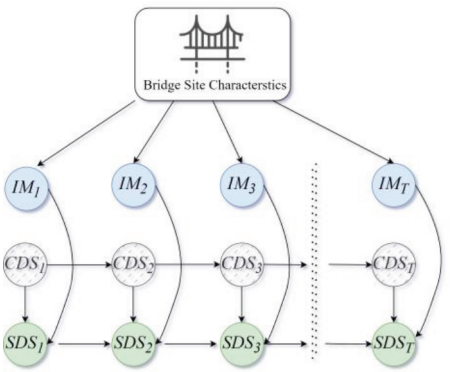

Figure 1. DBN for seismic fragility of aging bridges throughout the life-cycle.

where $PA_s(t)$ refers to the annual probability of exceedance of the seismic damage state (SDS=s_s) at time t; $H(x)$ is the hazard curve that quantifies the annual probability of exceedance given intensity measure IM_t=x, where x is typically the PGA magnitude at the bridge site.

To consider the effect of aging on the seismic fragility, it is important to consider the historical deterioration of the bridge component due to environmental factors (e.g., chloride-induced corrosion). In order to take this into account, the deterioration due to corrosion is modeled using non-stationary Markovian transition models conditioned on the prior corrosion state at time t-1, $\Pr(CDS_t = s_c | CDS_{t-1})$. Following the same rationale, the probability of exceedance of the seismic damage state, $SDS_t = s_s$, at time t, is defined given the associated corrosion damage state, the intensity measure, and the prior seismic damage state, $\Pr(SDS_t \geq s_s \mid CDS_t, IM_t, SDS_{t-1})$. The corresponding DBN is graphically shown in Figure 1. Accordingly, at a specific time, t, of the bridge life, associated with a nonstationary deterioration rate, the seismic fragility, given the complete histories of corrosion deterioration, seismic damages, and prior seismic hazards, is approximated as follows:

$$\Pr(SDS_t \geq s_s | CDS_{0:t}, IM_{0:t}, SDS_{0:t}); \Pr(SDS_t \geq s_s | CDS_t, IM_t, SDS_{t-1}) \tag{7}$$

4 APPLICATION

The developed framework, integrating state-dependent seismic fragility assessment and life-cycle decision optimization through multi-agent DRL, is applied to a case study of a transportation corridor comprising two bridges in series, as shown in Figure 2. Note that spatial ground motion variability is not examined here, i.e., the accelerograms for the two bridges are identical. The bridges are located in a seismic-prone area (Monti et al. 2023), with a hazard curve shown in Figure 2. Each bridge is a four-component system that contains columns (COL), High-Type Expansion Bearings (HTEB), High-Type Fixed Bearings (HTFB), and Low-Type Fixed Bearings (LTFB). The corrosion of the bridge components is defined in a discrete space that contains four CDSs, i.e., Sound, Initial, Progressive, Critical. The corrosion state of the columns (COL) is discretized according to the percentage of rebar mass loss, while the discretization for the bearings depends on the mass loss of the bolts, the reduction in steel plate thickness, and the additive coefficient of friction due to corrosion-induced interlocking effects. Readers with more interest in the modeling details are referred to (Molaioni et al. 2023). Similar to corrosion, the seismic damage states are discretized into five SDSs, i.e. Intact, Slight, Moderate, Extensive, Complete, with the latter corresponding to (near-)failure. Here, the five states are defined probabilistically using log-normal distributions for the curvature ductility and displacement limits for columns and bearings, respectively (Nielson, & DesRoches 2006). Correlations between component SDSs can be modeled as in (Song & Kang, 2009). However, they are omitted here in the interest of safety due to the lack of redundancy in the considered series system.

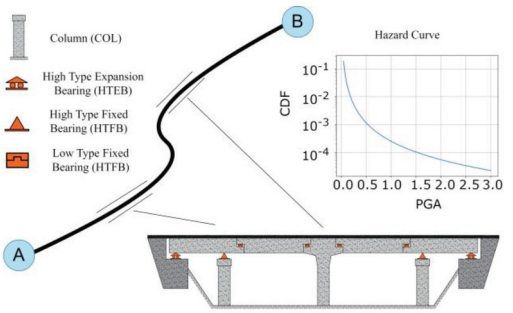

Figure 2. System information including bridge schematic and hazard curve.

Without loss of generality, seismic states are considered fully observable, whereas to capture the imprecision of annual corrosion state inspections, it is assumed that CDSs are observed with noise according to the following observation matrix (Andriotis & Papakonstantinou 2021):

$$\Pr(o_c|CDS_t = s_c) = \begin{array}{c} \\ s_{c,1} \\ s_{c,2} \\ s_{c,3} \\ s_{c,4} \end{array} \begin{array}{c} \begin{array}{cccc} o_{c,1} & o_{c,2} & o_{c,3} & o_{c,4} \end{array} \\ \begin{pmatrix} 0.84 & 0.13 & 0.02 & 0.01 \\ 0.11 & 0.77 & 0.09 & 0.03 \\ 0.02 & 0.16 & 0.70 & 0.12 \\ 0.01 & 0.02 & 0.13 & 0.84 \end{pmatrix} \end{array} \tag{8}$$

The aim is to optimize structural interventions over a 50-year planning horizon while constraining the expected risk of disconnection between points A and B to no greater than 5% in 50 years. Four maintenance actions are considered for columns (COL) and two actions for bearings (HTEB, HTFB,LTFB). These are shown in Table 1 in conjunction with the corresponding costs and effects on the corrosion and seismic damage states. In addition to these actions, the agent can choose to not interfere with the environment at a given decision step (i.e., Do Nothing). The costs associated with the potential actions are based on actual contract

prices (Tennessee Department of Transportation 2023, Ghosh & Padgett 2011). An additional mobilization cost of 15% of replacement cost is also imposed, which incentivizes taking simultaneous actions for similar components. Note that identical components within the same bridge are treated as one component within this setting.

In order to optimize the life-cycle cost considering the aforementioned maintenance actions, costs, and risk constraints, the DDMAC and DDMAC-CTDE multi-agent algorithms are adopted for policy training. In both algorithms, the actor network consists of 8 separate control units, corresponding to the components of the two-bridges corridor, with no parameter sharing among them. The two bridges work in series, i.e., losing one causes disconnection between A and B. The control units corresponding to the columns (COL) have a 5-dimensional softmax output, while the rest have a 3-dimensional output, which corresponds to the number of potential intervention actions. DDMAC control units share the system information, i.e., each unit has access to other units' information in addition to its

Table 1. Potential actions for each component, corrosponding cost, and state effects.

Component	Action	Cost	Action Effect
Columns (COL)	Thin Epoxy overlay	2149$	Restart deterioration rate;
	Epoxy Injection	3207$	Improve CDS & SDS by one; Delay CDS deterioration rate by 5 years;
	Concrete Repairs	2388$	Improve CDS & SDS by two;
	Replace	20000$	Bring to intact condition
Bearings (HTEB, HTFB, LTFB)	Replace Anchor Bolts	1112$	Improve CDS & SDS by one;
	Replace	2397$	Transition to intact condition

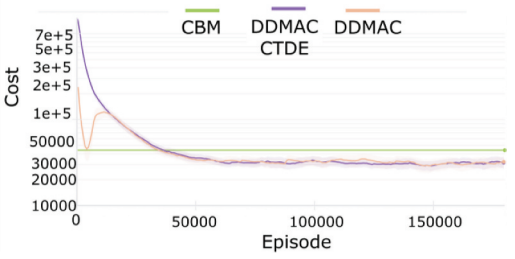

Figure 3. Training performance of DRL algorithms and comparison with baseline policy.

own. On the contrary, DDMAC-CTDE units adopt a decentralized information approach, where each unit accesses only its own information. In both algorithms, the actor units are guided by the critic network, which approximates the value function of the entire system with a one-dimensional linear output. For evaluating the performance of the learned policy, the DRL-based policy is compared to a condition-based baseline (CBM), where a corrective policy typically adopted to mitigate seismic damage (Ghosh & Padgett 2011) is imposed on top of a heuristically optimized condition-based maintenance policy on CDSs (CBM). Three training instances of each of the adopted DRL algorithms trained for 180K episodes, along with the optimized CBM, are shown in Figure 3. Both DDMAC and DDMAC-CTDE produce comparable training averages, and both overperform the optimized CBM by almost 28% in terms of expected life-cycle costs. It was observed that the trained policies managed to also adhere to the risk constraints, with a tendency to prescribe more preventive action in relatively early life-cycle phases, as shown by the cumulative cost and probability of failure evolution of 1000 random realizations shown in Figure 4.

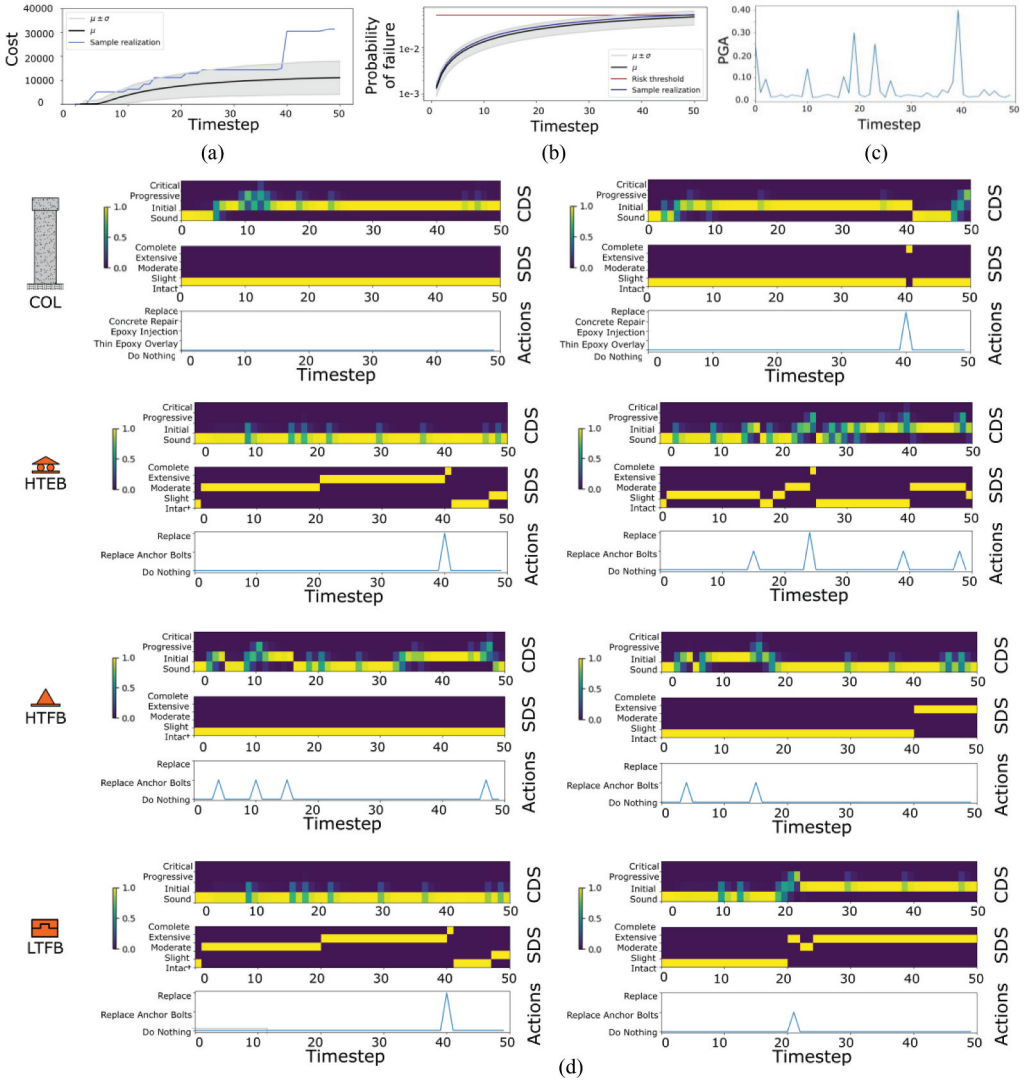

Figure 4. Policy realization: (a) Cost accumulation; (b) Probability of failure evolution; (c) Life-cycle seismic shocks; (d) CDS beliefs, SDSs, and actions.

To visualize the dynamics of the trained policy, a sample realization is presented in Figure 4, showing the observed seismic shocks characterized by the corresponding PGA on a temporal scale, followed by the corrosion CDS belief contours, the observed seismic SDS, and the imposed actions for each component. First, the trajectory starts with observing a relatively intense seismic event, with PGA≈0.25. This results in no seismic damage, except for damage in the HTEB components of both bridges, which are associated with the height fragility (Molaioni et al. 2023), in addition to slight damage in LTFB-1. While the agent decides to take no reactive action upon the damage, an intervention is made when corrosion deterioration is observed in other instances (e.g., HTEB-2 at year 15, LTFB-1 at year 4), which could have increased the vulnerability of such components to future shocks. Another major shock is observed around year 19, which causes different extents of damage across the bearing components, however, due to the prior preventive actions, no failure is observed throughout the system and the connectivity was maintained until two subsequent major shocks are observed at years 23 and 39. The latter causes failures in different spots, resulting in corrective replacement actions. It should be noted that the agent typically avoids

maintaining the columns due to the relatively high associated costs, and due to their higher reliability compared to other components, as shown in detail in (Molaioni et al. 2023), except when failed. Similarly, the agent prefers to impose preventive repairs instead of costly replacements for bearings. Finally, the agent leverages the mobilization incentive, by imposing simultaneous interventions to HTFB-1 and HTFB-2 at years 4 and 15.

5 CONCLUSIONS

In this paper, we introduce a framework for managing aging bridges subject to seismic hazards using dynamic Bayesian networks (DBNs) and Deep Reinforcement Learning (DRL). A virtual environment incorporates chloride-induced corrosion of bridge components and state-dependent seismic fragility functions, which are embedded in a DBN to allow for uncertainty propagation and state information updating throughout the life-cycle. Leveraging recent advances in multi-agent DRL in conjunction with partially observable Markov decision processes, the developed environment is probed by DRL agents operating on the belief space of the system, i.e., the dynamically updatable probabilistic distributions over component states. The framework is applied to identify a near-optimal 50-year intervention policy for a two-bridge transportation corridor located in a seismic-prone area, as well as the corresponding expected life-cycle cost under long-term risk constraints. A substantial improvement of 28% is observed in minimizing the life-cycle costs with DRL compared to traditional maintenance policies, while adhering to the imposed risk constraints. The introduced framework can be adopted, without loss of generality, to the management of other hazard- and deterioration-vulnerable systems, enhancing the safety, reliability, and cost-effectiveness of critical infrastructure networks.

Objective risk assessment for bridge management

Seyyed Amirhossein Moayyedi & David Y. Yang*
Portland State University, Portland, Oregon, USA

ABSTRACT: Bridges are subjected to various natural and/or human-induced hazards with considerable uncertainties arising from hazard characteristics, structural vulnerabilities, and damage consequences. Quantifying the associated risk requires the evaluation of a risk integral. However, its computation is incompatible with the prevailing risk estimation methods currently used in many bridge management systems (BMSs). Inaccurate risk assessment may result in the misallocation of often limited resources for risk mitigation. This paper presents a novel tabulation approach for accurate risk assessment that is also compatible with common BMS implementation. The proposed approach is built on the rigorous formulation of risk integrals. Nonetheless, it uses Gaussian quadrature to derive a series of weighted hazard scenarios that can be tabulated in BMSs to accurately tally the total risk. As a result, the proposed approach fills in the gap between accurate risk assessment with risk integrals and practical implementation in bridge management. Results from this study show that with the same number of hazard scenarios, the novel approach can significantly improve the accuracy of risk assessment. The potential of this approach in a multi-hazard setting is also discussed.

1 INTRODUCTION

Bridge management has traditionally been focused on the condition preservation through carefully planned life-cycle activities within a budgetary limit. Such plans are enacted to impede deterioration and/or accommodate increasing demand. Although there are calls to consider risks from various extreme events, existing approaches to risk assessment in transportation asset management rely heavily on engineering judgement, past experience, and limited data that roughly correlate with hazard intensities, bridge vulnerabilities, and damage consequences. This subjective or empirical approach to risk assessment contrasts to more objective methods that are underpinned by quantitative models of hazards, vulnerabilities, and consequences (e.g., FEMA 2020; NIST 2023). Nonetheless, these quantitative models do not fully consider the effects of deterioration on structural vulnerability under extreme events, thus hindering their direct application in bridge management.

The gap between bridge management and objective risk assessment leads to (a) inconsistency between risks assessed by different agencies or different experts and (b) neglect or inaccurate estimates of risks compounded by asset deterioration. As a result, resources may be allocated inefficiently due to (a) unreliable estimates of project benefits and (b) lack of coordination between condition preservation and risk mitigation needs. This paper presents a new method for risk assessment to overcome these shortcomings. Specifically, the new method unifies the assessments of structural deterioration and risks under extreme events. The focus is placed on the viability and potential of objective risk assessment in bridge management systems.

2 EXISTING METHODS FOR RISK ASSESSMENT IN BRIDGE MANAGEMENT

Risk assessment under extreme events has been implemented in several commonly used BMSs such as AASHTOWare™ BrM and AgileAssets™ in the US. These existing methods follow the general risk formulation that is expressed as the product of event likelihood and event consequences. In these systems, risks are usually estimated following the general procedure outlined below (hereafter referred to as the BMS procedure):

- Collect one or a limited number of hazard scenarios relevant to the asset performance. These are usually obtained from expert elicitation or past experience. They can be different hazards (e.g., earthquakes and floods) or one hazard with different return periods (thus different intensity levels).
- Estimate the annual likelihood of each hazard scenario. This can be determined from polls on experts or past experience of agencies. Results of probabilistic hazard analysis, e.g., those available through United States Geological Survey (USGS) for earthquakes (USGS 2022), can also be utilized in this step.
- Estimate the expected consequence under each hazard scenario. This can be similarly determined from expert polls or past experience. Alternatively, damage evaluation given the scenario event can be conducted using HAZUS or in-house tools. Note that this differs from a complete risk analysis as it is conditioned on the occurrence of a hazard event.
- Tabulate the risks associated with all hazard scenarios by multiplying the likelihoods and the expected consequences. Sum up the risks of hazard scenarios as the total annual risk associated with the asset. Tally all annual risks to determine the lifetime risk.

Due to the heavy reliance on expert elicitation, the procedure described above is mostly empirical and can vary considerably between different analysts and agencies (even for the same area and hazard under consideration). This is in contrast with the quantitative risk assessment approach that originated from the seismic analysis and design of structures (ATC 1978) and has since been expanded to many other hazards (McAllister et al. 2018) and regional damage assessment (Basöz & Mander 1999). For the quantitative assessment, the risk from an adverse event is expressed by the following equation, which is often referred to as a risk integral:

$$R = \int_{im} \left[\sum_{ds} cq(ds) \cdot p_{DS|IM}(ds|im) \right] \lambda_{IM}(im) dim \tag{1}$$

where a lower-case variable (*im* and *ds*) = sample from a random variable (represented by its upper-case counterparts, *IM* and *DS*); *IM* = intensity measure (IM) of an adverse event; $\lambda_{IM}(im)$ = value of the probability density function (PDF) at *IM* = *im* (i.e., the likelihood of a specific value *im* for the intensity measure, referred hereafter as an intensity level); *DS*|*IM* = damage states (DSs) conditioned on the intensity measure; $p_{DS\ |\ IM}(ds|im)$ = probability of a specific DS, *ds*, conditioned on a specific intensity level *im*; $cq(ds)$ = average consequence associated with a DS.

Compared to the BMS procedure, Equation 1 considers all possible intensity levels of a hazard probabilistically. This is a clear improvement to the existing BMS procedure where only one or a limited few intensity levels, usually adopted based on intensities for structural design, are considered. Equation 1 also incorporates the uncertainty related to the structural vulnerability, as represented by the conditional probabilities associated with different DSs. These conditional probabilities can be obtained using fragility curves, which provide the probabilities of reaching or surpassing a specific damage state given an intensity level (Buckle et al. 2006; Muntasir Billah & Shahria Alam 2015). Using Equation 1, objective risk can be achieved with a set of widely used or agreed models, including a hazard characterization model λ_{IM}, fragility curves to derive $p_{DS|IM}$, and the expected cost data for each DS $cq(ds)$. As long as these models are defined (e.g., using those provided in HAZUS), risk can be objectively quantified without relying on expert elicitation. Despite this advantage, an accurate evaluation of an integral is usually not compatible with the BMS procedure described previously.

3 RISK ASSESSMENT USING WEIGHTED HAZARD SCENARIOS

A new tabulation method is developed herein by leveraging a more accurate and efficient numerical integration method, i.e., the Gaussian quadrature method, which is also compatible with the BMS procedure. The objectives of this new method are (a) to reduce the number of hazard scenarios needed to accurately estimate the risk integral, and (b) to preserve the general implementation steps for easy integration with existing BMSs.

3.1 *Gaussian quadrature for numerical integration*

An n-point Gaussian quadrature is a rule to carry out integration numerically using integrand values at n strategically selected locations (termed integration points) and their associated weights (Chapra & Canale 2021). The most common Gaussian quadrature is the Gauss-Legendre quadrature, which is given as follows for a one-dimensional (1D) integral over domain $[-1, 1]$ (Abramowitz & Stegun 1972):

$$\int_{-1}^{1} f(\xi)d\xi \approx \sum_{i=1}^{n} \eta_i f(\xi_i) \tag{2}$$

where $f(\xi)$ = integrand function; ξ_i (i = 1, 2,. . ., n) = n integration points within $[-1, 1]$; η_i = the associated weights. It is worth mentioning that the quadrature rule is exact if $f(\xi)$ is a polynomial of up to $2n - 1$ degrees (Weisstein 1995). Therefore, if $f(\xi)$ can be reasonably approximated by a polynomial of up to $2n - 1$ degrees, the error of this quadrature can be small. Also, the domain $[-1, 1]$ can be easily converted to any definite integral domain through transformation (Abramowitz & Stegun 1972). Given the number of integration points n, the integration points ξ_i and weights η_i are independent of the integrand function and can be found in several references (e.g., Weisstein 1995). In cases where singularities may occur at the endpoints of the integral domain or where semi-infinite or infinite intervals are involved, other Gaussian quadrature rules can be applied, such as Chebyshev-Gauss, Gauss-Laguerre, or Gauss-Hermite quadratures (Weisstein 1995).

3.2 *Adapting Gaussian quadrature for risk integral*

Applying Gaussian quadrature with n points to Equation 1 gives rise to the following approximation of the risk integral:

$$\begin{aligned} R &= \int_{im=a}^{im=b} \left[\sum_{ds} cq(ds) \cdot p_{DS|IM}(ds|im) \right] \lambda_{IM}(im) dim \\ &\approx \sum_{i=1}^{n} w_i \cdot \left[\sum_{ds} cq(ds) \cdot p_{DS|IM}(ds|im_i) \right] \cdot v_{IM}(im_i) \end{aligned} \tag{3}$$

In this approximation, the risk can be regarded as the summation of risks of n weighted hazard scenarios. In particular, a hazard scenario is characterized by the intensity level im_i, which can be obtained from the integration domain $[a, b]$ and the Gaussian integration points as follows:

$$im_i = \frac{b-a}{2}(\xi_i + 1) + a \tag{4}$$

A nominal annual rate of occurrence, $v_{IM}(im_i)$, is defined as follows

$$v_{IM}(im_i) = \frac{b-a}{2}\lambda_{IM}(im_i) \tag{5}$$

Given the occurrence of a hazard scenario, the term within the square bracket in Equation 3 is the expected consequence conditioned on the hazard occurrence. Finally, the weight of a hazard

scenario, w_i, is equal to the integration weight of the ith integration points, i.e., $w_i = \eta_i$. It should be noted that the integration domain should be intensity levels responsible for the asset risk under adverse events. For instance, a domain [0.1g, 2.0g] for peak ground acceleration (PGA) may be used for estimating asset seismic risk if (a) an asset is extremely unlikely to damage with PGA less than 0.1g and (b) an earthquake causing PGA larger than 2.0g is extremely unlikely to happen in the region (and a lower PGA already causes collapse of most or all structures).

The weighted hazard scenarios used to approximate the risk integral have close resemblance to the BMS procedure described in the previous section. In fact, all steps within the BMS procedure have direct counterparts in Equation 3. The only addition is the scenario weights that can actually be merged to the expected consequence. The main advantage compared to the BMS procedure is that the selection of hazard scenarios and the expected consequences are no longer based on expert elicitation. Instead, they are derived from the hazard characteristics, structural fragilities, and the conditional consequences. Therefore, objective risk assessment is realized with this weighted hazard scenarios approach. To facilitate the application of this new approach, a Python package named "pyRiskTable" has been developed to automatically generate a comma-separated values (CSV) file containing weighted hazard scenarios given a target accuracy level of the estimated risk. More accurate estimation usually corresponds to a greater number of hazard scenarios (i.e., Gaussian integration points).

4 ILLUSTRATIVE EXAMPLES

The approach described in the previous section is illustrated herein by an example focusing on bridge seismic risk assessment. The result is compared in terms of accuracy to the BMS approach. This example is then leveraged to illustrate the implications of objective risk assessment on life-cycle management of deteriorating assets. Although focusing herein on an individual bridge, the proposed approach can also be applied for a system of bridges in common management systems. For instance, following the example below, the seismic risk of bridge portfolios can be analyzed for each bridge using the regional hazard model from USGS (2022) and the fragility curves for different types of bridges in HAZUS (FEMA 2020).

4.1 *Hazard characteristics, bridge fragilities, and damage consequences*

In this example, a fictional hazard curve based on an idealized fault 10 km away from the site is considered following Baker (2013). The fault is assumed to only generate magnitude 6.5 earthquakes with a return period of 100 years. Using probabilistic seismic hazard analysis, the following hazard curve can be derived (Cornell et al. 1979; Baker 2013):

$$\begin{aligned} \overline{\ln PGA} &= -0.152 + 0.859M - 1.803\ln(d+25) \\ \omega_{IM}(im) &= 1 - \Phi\left(\frac{\ln im - \overline{\ln PGA}}{\sigma}\right) \end{aligned} \tag{6}$$

where M = magnitude of the earthquakes generated at the fault (M = 6.5 in this example); d = distance between the site and the fault in kilometers (d = 10 km in this example); Φ = cumulative distribution function (CDF) of a standard normal distribution; σ = dispersion factor of the PGA (i.e., the standard deviation of the logarithmic PGA) at the site, and σ = 0.57 is assumed herein (Cornell et al. 1979). This hazard curve gives the annual rate of exceedance $\omega_{IM}(im)$ under different PGA levels. Both the hazard curve and the hazard likelihood (i.e., the derivative of the hazard curve with respect to PGA) are shown in Figure 1. It should be noted that the hazard curve has a maximum annual rate of exceedance of 0.01 due to the assumed return period of earthquakes at this idealistic fault.

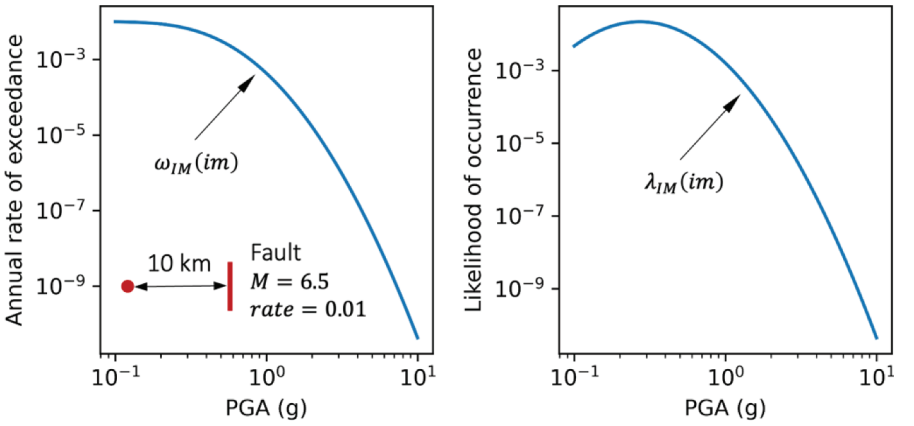

Figure 1. Hazard curve (left) and its gradient (right).

Fragility curves in Basöz and Mander (1999) are used to determine the DS probabilities given an intensity level at the site. For each DS, the fragility curve is modeled by the CDF of a lognormal distribution defined by two parameters, median PGA and the dispersion factor (i.e., the standard deviation of lnPGA). Table 1 gives the two parameters used for each DS. The DS probability can be determined by comparing the fragility curves between two consecutive DSs, as illustrated in Figure 2.

Table 1. Parameters of fragility curves.

Damage state	Median IM (in g)	Dispersion ($\sigma_{\ln PGA}$)
Slight	0.30	0.6
Moderate	0.36	0.6
Extensive	0.49	0.6
Complete	0.71	0.6

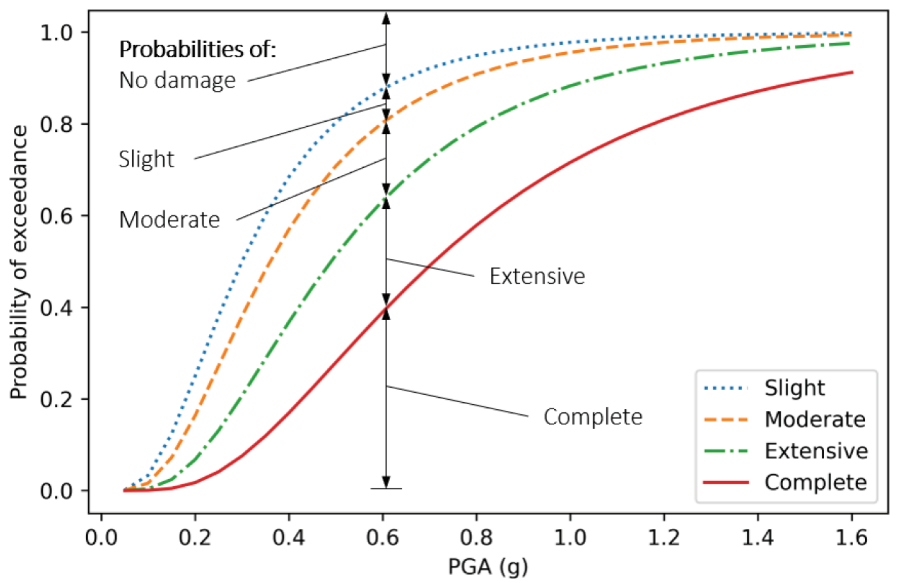

Figure 2. Fragility curves and damage state probabilities.

4.2 *Seismic risk assessment with weighted hazard scenarios*

Weighted hazard scenarios are generated using the proposed approach. Based on the generated hazard scenarios, the seismic risk of the bridge can be computed. The integral domain is selected based on the lower and upper limits of intensity levels that correspond to two return periods, namely 100 years and 100,000 years. Six hazard scenarios are used for risk assessment because the accuracy gain is marginal (less than 5%) with more scenarios. Table 2 presents the hazard characteristics, event likelihoods, scenario weights, and damage consequences for these six scenarios. By tabulating the weighted risks of these scenarios (calculated as the product of the likelihood, consequence, and weight), the total seismic risk is 0.00340 (in terms of cost ratio). This is very close (within 2% margin) to the precise value of the risk integral (0.00332) evaluated based on Equation 1 with numerical integration using Gaussian quadrature with 16 integration points (as implemented in SciPy, a Python package for scientific computing (Virtanen et al. 2020)).

Table 2. Weighted hazard scenario approach for risk assessment (new approach).

Hazard scenario	Description (return period, PGA in g)	Annual rate	Consequence (cost ratio)	Weight	Risk (cost ratio)
1	104 yr, PGA=0.136	1.119E-02	0.021	0.171	4.078E-05
2	240 yr, PGA=0.424	1.712E-02	0.348	0.361	2.148E-03
3	1435 yr, PGA=0.873	2.855E-03	0.752	0.468	1.004E-03
4	8873 yr, PGA=1.379	3.991E-04	0.916	0.468	1.711E-04
5	36247 yr, PGA=1.828	8.597E-05	0.966	0.361	2.995E-05
6	82265 yr, PGA=2.116	3.502E-05	0.980	0.171	5.879E-06
				Total risk	0.00340

To demonstrate the advantages of the new approach over the BMS procedure, six typical hazard scenarios are utilized to estimate the risk with the BMS procedure. The return periods of these scenarios are selected because they are commonly used in either expert-based seismic risk assessment or seismic analysis and design of structures. Table 3 presents the return periods, corresponding event likelihoods, implied intensity levels, and damage consequences of all scenarios. The risks associated with the scenarios and the total risk are also presented in Table 3. It can be observed that the total risk obtained from the BMS procedure underestimates the precise risk by 36% (0.002117 vs. 0.00332).

Table 3. BMS procedure for risk assessment (existing approach).

Hazard scenario	Description (return period, PGA in g)	Annual rate	Consequence (cost ratio)	Risk (cost ratio)
1	225 yr, PGA=0.326	2.444E-03	0.326	7.958E-04
2	500 yr, PGA=0.554	9.740E-04	0.554	5.397E-04

			Total risk	0.002117

4.3 *Seismic risk of deteriorating bridges*

The proposed approach can also be used for the seismic risk of deteriorating assets. Due to structural deterioration, the seismic resistance of a structure may decrease over time. This can impact the shape of fragility curves, especially the median values of different DSs in Table 1 (Ghosh & Padgett 2010). To model this effect, it is assumed that the median value changes over time based on the following equation:

$$r(t) = 1 - at \tag{7}$$

where $r(t)$ = the ratio of the median value at time t (in years in service) to the initial values in Table 1; a = annual deterioration rate, assumed to be 0.01 for this illustrative example.

Using this deterioration model, the benefit-to-cost ratio (BCR) of two maintenance strategies are compared to showcase the effect of accurate risk assessment on strategy selection. These strategies are

- Strategy 1: Maintain the bridge every two years to immediately rectify any deterioration accumulated in the two-year interval and restore the structure to its initial performance.
- Strategy 2: Only provide one major maintenance in year 40 within the 75-year service life to fix the deterioration accumulated in the first 40 years and restore the structure to its initial performance.

The cost of a maintenance action in each strategy is assumed to be proportional to the extent of performance improvement in order to restore the median value of the fragility curve back to its initial level. Therefore, the cost ratio associated with a maintenance action can be expressed as $1 - r$ where r is the structural performance considering deterioration, defined in accordance with Equation 7.

From a risk reduction perspective, the benefit of a maintenance strategy is quantified as the reduction in lifetime seismic risk, which is defined as the summation of annual seismic risks over the bridge service life. This reduction is calculated by subtracting seismic lifetime risk with a maintenance strategy from that without any maintenance. Based on the cost and benefit models, the BCRs of both strategies can be evaluated. It should be noted that the example herein is limited to the benefit of maintenance actions in terms of reducing seismic risk. Annual seismic risks are estimated using scenario events in Table 2 and Table 3, representing the new approach and the BMS procedure respectively. Note that the expected consequence of each event changes over time using the deteriorated fragility curves characterized by Equation 7.

Figure 3 shows the results of the BCR comparison. It can be observed that when the new approach for objective risk assessment is used, Strategy 2 is clearly more advantageous than Strategy 1, with an approximately 8% higher BCR. On the other hand, when the BMS procedure is used, the difference between the two strategies is negligible, which can complicate the decision-making process. Additionally, the BCR is significantly underestimated when using the existing BMS procedure. Hence, inaccurate risk assessment with the existing BMS procedure may lead to erroneous ranking of different maintenance or retrofitting strategies. The objective risk assessment, as proposed in this paper, provides a viable rectification for this drawback.

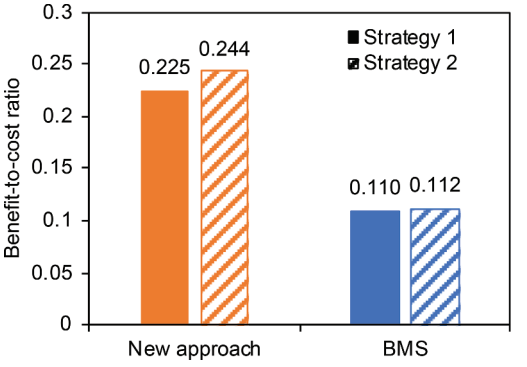

Figure 3. BCR comparison of maintenance strategies using different methods.

5 CONCLUSIONS

The risk assessment approach based on weighted hazard scenarios is a novel method to potentially fill the gap between risk assessment and bridge management. Rather than rely on expert elicitation for hazard scenarios, the new approach to objective risk assessment can

automatically and consistently generate weighted hazard scenarios to be included in the risk analysis. The new approach is built on the rigorous formulation of risk integrals. The preservation of a tabulated implementation allows for the direct integration of objective risk assessment in common bridge management frameworks. In particular, it is most convenient to apply the new approach as a pre-processing step when setting up the risk assessment task within a bridge management system. In summary, the following conclusions can be drawn:

- Compared to existing risk assessment methods in bridge management, the new approach can yield much higher accuracy with the same number of hazard scenarios. The format of the generated scenarios is similar to that used in existing systems except for a weighting factor that can be merged to event consequences. As a result, the generated hazards can be directly leveraged by existing BMSs to achieve objective risk assessment.
- It is empirically demonstrated that existing approaches to risk assessment do not always deliver reliable rankings of maintenance strategies in terms of risk-based benefit-to-cost ratios. This means that the lifetime risk of deteriorating assets cannot be assessed by simply incorporating age- or condition-dependent fragility curves to BMSs. Instead, the new approach to picking hazard scenarios is a necessary step toward risk-based transportation asset management.

Drone-based photogrammetric indoor inspection of box girder bridges

J.C. Avendaño, J. Leander & R. Karoumi
KTH Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: Digital inspections methods have gained increasing interest in the civil engineering field for assessing the condition of various structures including buildings and bridges. These methods are used primarily to evaluate the external surface condition of the structure. However, in the case of bridges, their application when inspecting the interior of these structures remains uncommon. This paper presents a case study for inspecting the interior of a concrete box girder bridge, the Strängnäs bridge. The inspection involved gathering data using a commercial drone, creating a photogrammetrical model, detecting and quantifying damages by employing a Convolutional Neural Network (CNN). The analysis successfully detected 60 cm long concrete cracks, a total area of 3.5 m^2 leakage and corrosion over 40 cm. The study addressed the difficulties such as insufficient lighting, lack of GPS signal and dust clouds reducing visibility. Despite these obstacles, the study demonstrated the effectiveness of indoor drone-based inspections.

1 INTRODUCTION

The condition assessment of bridges, tunnels, buildings, and other infrastructure is essential to ensure their proper functioning over time. Traditionally, these assessments are performed manually, are costly and are time consuming. However, the use of image-based inspections supported by tools such as Unmanned Aerial Vehicles (UAV), often known as drones, can reduce inspection time up to 80% [1].

Digital inspections are gaining popularity in structural health monitoring, due to the possibility to combine methods such as machine learning algorithms, computer vision methods and photogrammetry among others to obtain useful results. Among machine learning methods, Convolutional Neural Networks (CNN) are often used to automate the process of detect and analyze surface damages [2][3]. Moreover, computer vision techniques are used in many cases to quantify damages such as cracks [4]–[6]. Furthermore, photogrammetric models have proven useful to perform condition assessments for bridges and tunnels [7]–[9].

These tools represent an advantage in the decision-making process to determine focus areas for further detailed inspections and planning for maintenance actions. Nevertheless, the studies are usually focused on the exterior of structures whereas the interior is overlooked for structures like box-girder bridges. As for tunnels, indoor bridges inspections correspond to enclosed spaces usually without Global Positioning System (GPS) signal used by drones for navigation, insufficient light, constrained locations, and presence of dust [10].

Considering this, the present work aims to study the feasibility of image-based inspections inside a box-girder bridge by using a commercial drone, applying machine learning and photogrammetry to evaluate the condition of the bridge.

DOI: 10.1201/9781003483755-405

2 METHODOLOGY

The methodology for the indoor inspection of the box-girder bridge is composed by three steps: data acquisition, processing, and characterization. Data acquisition consists of gathering images of the surfaces of interest using a commercial drone. The processing of the data consists of creating a 3D photogrammetrical model and identify damages with a neural network. The characterization correspond to the quantification of the damages identified. The procedure is illustrated in Figure 1.

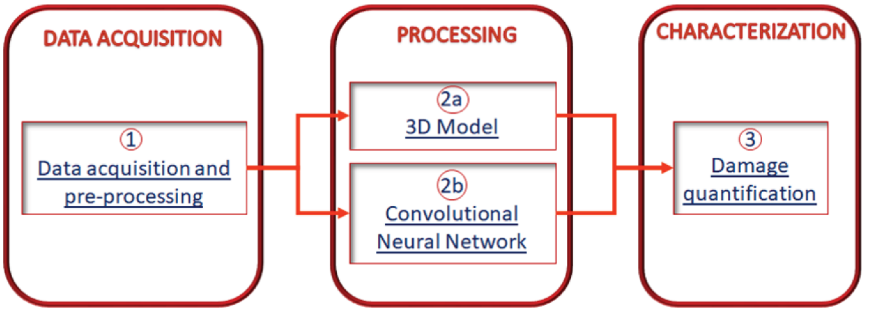

Figure 1. Methodology overview.

2.1 *Data acquisition*

For the data acquisition, a DJI Mavic 2 Pro was used equipped with a 1-inch sensor camera composed by 20 million-pixel. The camera has a 0.5 m focus distance meaning that the closest distance the drone can be from the surface to obtain a clear image is 0.5 m. It has a wind resistance of 29 km/h allowing it to hoover in a precise manner. This equipment has an omnidirectional obstacle sensing using an infrared sensing system and multiple cameras to avoid collision against the structure. The lack of natural light inside the bridge makes it necessary to provide an additional source of light in order to obtain proper images. This is done using a single lamp with a light output of 1300 lumens. The lamp is pointed towards the surface the drone is facing to have clear images.

During image capture, a systematic zigzag sequence was employed. The drone moved horizontally, altering its altitude, and then moved horizontally again. When doing this, a horizontal overlap of 70% and a 30% vertical overlap between images is assured.

2.2 *Photogrammetric model*

Photogrammetry is the process of obtaining measurements of objects and surfaces based on images [11]. Based on stereoscopic viewing, the overlap of different images allows obtaining three-dimensional information of an object. For this study, a 3D model of the internal part of a box bridge is created in order to inspect the different surfaces of the box. The model is created using the software Pix4D which transforms the gathered data into a point cloud. Additionally, the software creates a texture mesh between the different points enhancing the visualization of the object. In this case, the focus is centered in the ceiling of the structure since it is the most difficult part to reach for a conventional manual inspection. Once the photogrammetric model is obtained, it is possible to quantify elements of interest such as corroded areas or other damages in the structure.

2.3 *Convolutional Neural Network (CNN)*

The process of crack detection is performed using a pre-trained neural network requiring a fine-tunning procedure in order to adapt the network for crack detection in concrete. For

this work, the pre-trained VGG16 network is selected for the task since it has a better performance than other networks such as InceptionV3 or ResNet for crack classification [12]. Additionally, through python open libraries like Keras, it is possible to download this network facilitating the implementation.

The VGG16 network corresponds to a pre-trained network containing a set of predefined parameters (weights) used to identify other types of objects. To do the fine-tuning process and adapt the network for crack detection, a data set is used to modify the existent weights in the network and thus eliminating the need to train the network and its weights from the beginning. This process allows to speed up the process of training the model to detect the desired damage. The initial parameters such as learning rate, batch size or epochs, where adjusted for the fine-tuning process. For this case, the training of the network was performed using a total of 12852 images evenly split between images of concrete containing cracks and concrete without cracks [3].

It is important to mention that the data set used contains only one type of damage since it was not possible to create a dataset that contained a balanced amount of images of multiple damages and thus avoid a bias in the network.

2.4 *Image analysis*

Once a crack has been identified, different computer vision methods are used to isolate the pixels that compose the crack in order to quantify the width and length of the cracks. The process consists of first transforming the images from RGB color scale to greyscale. Subsequently, analyzing the intensity distribution of the images is performed followed by identifying outliers which correspond to the pixels constituting the crack. The outliers are selected by determining the Median Absolute Deviation (MAD) [13]. The MAD evaluates a dataset and measures the variability of the data. The MAD is calculated as:

$$MAD = median\left(\left|X_i - \tilde{X}\right|\right) \tag{1}$$

where X_i is each element of the data series, $\tilde{X}$ is the median of the data series. With this, a threshold T is calculated following equation (2) to filter the image and isolate the crack pixels:

$$T = \tilde{X} - k * MAD \tag{2}$$

where k is a scale factor that correspond to 3.5 in normally distributed series [14]. The centerline of the remaining pixel regions is determined representing the skeleton of the crack. The length of the cracks corresponds to the length of these skeletons. To determine the width of the crack it is first necessary to define the edges of the crack. This is done taking the previously defined regions and applying an edge detector method, in this case, the Laplacian edge detector. Once the centerline and the edges are defined, the orthogonal distances between each point of the skeleton and the edges are calculated and thus the width of the crack is obtained.

In the case of identifying other damages, the task is performed manually based on the 3D photogrammetrical model created. The model is inspected to determine the regions where leakage, corrosion or other damages may be present. Once the regions are defined, the area is quantified using the software used to create the model.

3 CASE STUDY

A case study is presented where the methodology is applied in the interior of the Strängnäs bridge. This concrete box girder bridge is 5 m wide inside and has a variable height. The test was performed in a 15 m long section situated near one of the supports where the height variates approximately between 5 to 7 m. The images obtained correspond to the inside of the box close to one of the columns supports. Figure 2, present parts of the concrete walls and ceiling in the box.

Figure 2. Inside of box girder close to a support.

After the data was gathered, the 3D photogrammetrical model was created to obtain the texture mesh to better visualize the concrete surface. The time needed to collect the data in the section studied was 25 minutes showing the efficiency of the proposed method.

4 RESULTS

The results of the inspection are presented first in terms of the model created using photogrammetry, the output of the CNN-based crack detection and finally the quantification of the damages found.

4.1 *Photogrammetric model*

The model created represents the ceiling of the box since the focus was centered on this part when taking the images. This is due to the fact that the ceiling represents the major difficulty in the inspection because of the height of the section and because it is the location where the major defects could be seen with the naked eye. The result model is formed by about 7.2 million points in the 3D space and the resulting mesh is presented in Figure 3.

Figure 3. Photogrammetrical model.

The model has black areas and discontinuities due to a lack of points in those areas and the difficulty to create points due to the lack of GPS. Indeed, the absence of GPS poses a challenge since it contributes to the identification of corresponding points between the different images leading to the creation of points in the 3D space. Since the analysis was focused on the ceiling rather than the sidewalls, the discontinuities are located primarily on that area. A more complete model can be obtained adding images from the sidewalls. The model is used to study the ceiling from a front angle instead as skewed angles such as those presented in Figure 2 which simplifies the investigation of the present damages in that section of the bridge. An example of this is presented in Figure 4. From this figure it is possible to identify

different damages such as corrosion and leakage in the structure coming, for example, from the results of extracting concrete cores in the deck.

Figure 4. Box ceiling from 3D photogrammetrical model.

4.2 *CNN results*

The CNN is used to analyze the gathered images and detect cracks in the concrete. The network outputs the sections of the images where cracks are located. Although the bridge is in good state and does not present major defects, the CNN was able to identify cracks in some parts of the section studied. An example of the images obtained is presented in Figure 5.

Figure 5. Images identified as Cracked by the CNN.

It's important to note that some of the results of the CNN correspond to false positives since elements like the shadow of the drone are interpreted as cracks due to their shape. Nevertheless, these can be easily identified as false positives by the inspector when analyzing the results.

4.3 *Quantification of damages*

The damage quantification is made using both the photogrammetrical model, which allows to measure distances and areas, and the image analysis process. In Figure 6 different areas enclosing leakage in the ceiling section of the box are highlighted. The total area enclosed corresponds to 3.5 m^2 retrieved from the model. The section showing dark brown marks in the ceiling, suggesting traces of corrosion, can be seen as straight lines in the transversal direction of the bridge. These lines have a total length of 0.4 m.

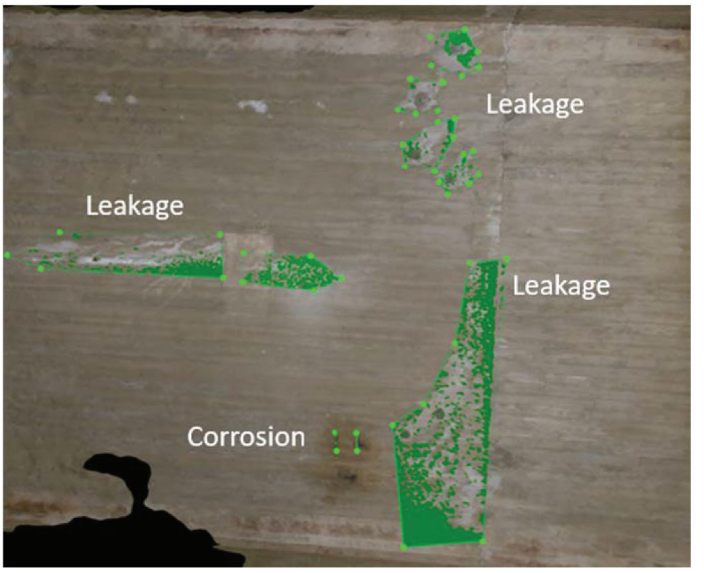

Figure 6. Measurements from the 3D photogrammetrical model.

For the sections that have been labeled as cracked by the CNN the process of quantification is applied to obtain the area of the crack, the edges, the centerline and width. An example of the result of the quantification is presented in Figure 7. The crack is presented in high contrast colors, the area of the crack is presented in yellow, the edges in blue and the centerline is presented in red.

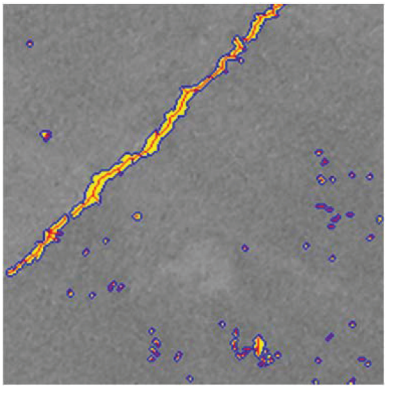

Figure 7. Quantification result.

From the results obtained, it is possible to determine the length of the cracks, giving as result a total of 60 cm of cracks with an average width of 0.3 mm.

5 DISCUSSION AND CONCLUSIONS

The purpose of this field case study was to see the possibility of applying drone inspections inside box girder bridges focusing on detecting damages in the structure. The quantification of the results depends on the quality of the data gathered during the inspection. In this process, the lack of GPS signal for the drone affects its location system as well as its infrared sensors needed to

avoid obstacles thus the complexity of the flight is increased. Furthermore, the absence of GPS signal affects the photogrammetric process relying only on the relation between surface textures.

Additionally, insufficient light and the effect of the drone propellers creating currents of air generating dust clouds can reduce the quality of the images obtained leading to unclear surface images thus, potentially generating errors in the CNN output or the quantification process. Despite the challenges mentioned, it was possible to obtain clear images of the concrete surfaces that allow the application of the CNN, the creation of the photogrammetrical model and the quantification of damages.

The developed photogrammetrical model, though presenting dark spots and discontinuities, proved effective to detect and quantify leakage and corrosion. This shows the utility of 3D photogrammetrical models to obtain valuable information about the damages in a structure.

It was possible to automatically find cracks in some of the concrete surfaces using the machine learning algorithms. The results obtained as an output contain different images with crack-like objects such as shadows from the drone. This can be improved by developing the algorithms used with new data from different bridges. Although the CNN focused on cracks, it can be tuned to be able to detect damages like the ones seen on the photogrammetrical model (leakage and corrosion among others).

Digital inspections as the one presented in this study, serve as an assessment tool for inspector or decision takers to obtain insights of the structural condition and determine further inspection and maintenance plans. Additionally, in this study only a commercial drone and an additional light were used taking less than an hour to obtain the data, proving the cost effectiveness and efficiency of this methodology.

Although the case study shows that it is indeed possible to perform indoor drone-based inspections for structures like box-girder bridges, ongoing research is necessary to continue improving the results. Further research should focus on improving the data quality, addressing challenges like adequate levels of lighting, dust management and the absence of GPS signal. Continuous research on these topics will improve the reliability and applicability of indoor drone-based inspections for large structures.

ACKNOWLEDGEMENTS

This paper was produced as part of the Mistra InfraMaint research program with funding from Mistra, the Swedish Foundation for Strategic Environmental Research. Additionally, the authors would like to acknowledge the Swedish Transport Administration (Trafikverket) for giving access to the bridge.

Decision algorithms for the managing of steel railway bridges

Jordan Garcia, Francisco Javier & Campo Rumoroso Iván
PEDELTA, Barcelona, Spain

ABSTRACT: As a part of the recently funded EU project BRIDGITISE, which focuses on the digitalization of bridge management through the development of innovative approaches to information management, the decision algorithms to be able to manage bridges across their lifetime are a key part of the process. In steel bridges, corrosion, fatigue, fracture, and buckling are the most common processes governing the structural behaviour of the bridge. All these failure processes are influenced by the actual loads, geometrical imperfections, and loose of thickness by corrosion in the steel members. The evolution of these parameters along the lifecycle of the bridge is unknown in the design stage, before its construction and opening to traffic, and some assumptions are made based on the Codes, which at their turn are based on statistical analysis of specimens and previous experience. Nevertheless, the specific conditions for each bridge are different, and with the data collected during the lifecycle of the bridge, the structural analysis and the structural verifications can be updated. This allows updating the maintenance manual and program. This paper will focus on showing which parameters should be monitored in a steel railway bridge and how to use this information to make decisions for the bridge maintenance to guarantee the required structural safety.

1 INTRODUCTION

Extending the lifespan of existing bridges is imperative for advancing sustainability in construction, as it offers notable advantages over the alternative of demolition and reconstruction, including reduction of materials and energy consumption, which increases its sustainability. Nevertheless, there are cases where bridge demolition has been proposed due to an insufficient understanding of the bridge's behaviour.

Numerous pathologies can cause the proposal of bridge demolition, with corrosion and fatigue being particularly critical for steel bridges. Both conditions share the characteristic of manifesting over prolonged periods and potentially leading to catastrophic consequences.

While current fatigue models are suitable for designing new bridges, they may be considered overly conservative for existing bridges in some instances, as observed by the authors. For example, evaluation based on available data may indicate an expected fatigue life termination years before, yet inspections reveal no visual evidence of crack initiation. In those cases, the AASHTO MBE (FHWA-NHI 2016) proposes a probabilistic approach combined with inspections to extend bridge fatigue life. However, this approach lacks consideration of the actual bridge behaviour, introducing potential risks.

Corrosion presents a similar challenge due to the numerous variables involved, including moisture, oxygen, and de-icing agents, making the development of an accurate model for a specific location difficult.

Long-term instrumentation emerges as a promising approach for predicting bridge ubehaviour, leveraging actual data from the structure (García-Sánchez, 2016) (Leander& Karoumi

DOI: 10.1201/9781003483755-406

2018). However, the effective management of sensor-generated information poses a current challenge, where machine learning can play a pivotal role.

Addressing these challenges, the recently funded EU project BRIDGITISE aims to digitalize bridge management by developing innovative information management approaches. The project will create and validate technologies for effective bridge information management, supporting decisions pertinent to bridge integrity management throughout its lifecycle. The project consortium, comprising universities, research centers, industrial companies, and end-users, combines diverse expertise.

This paper outlines Pedelta's contribution to the BRIDGITISE project, beginning with the motivation derived from in-house projects. Subsequently, the project's description and goals are delineated, culminating in an exposition of one of the bridges slated for study within the project.

2 PREVIOUS EXPERIENCE

2.1 *Feixa Llarga Bridge*

The Feixa Llarga bridge is located at the entrance to the free trade zone of Puerto de Barcelona, Barcelona Harbour. The bridge has eleven spans, with a main central span of 27 m over the railway line and five access spans of 21 m on each side. The width of the bridge is 7 meters.

The uniqueness of the bridge lies in its construction. It is a modular steel bridge built in the early 70s. The deck consists of two Pi orthotropic steel girders bolted together in the center. The substructure is a pi-shaped steel frame.

Figure 1. Feixa Llarga Bridge.

As depicted in Figure 1, the structure under consideration exhibits multiple welds and low category fatigue details. Among other damages in the bridge, ome of those welds were broken, and Pedelta was retained to develop the rehabilitation project.

During the inspection, the identification of cracks, particularly in the deck welds, was notable; however, no evidence of material failure was discerned. Subsequent calculations indicated a low expected fatigue life for certain details. This precarious situation was attributed to a combination of suboptimal detailing, exemplified by the bottom flange of girders in Figure 1, short lightweight spans - where the predominant load is solely the live load - and the

high traffic intensity of trucks. Consequently, a recommendation was made to close the traffic o the bridge and undertake structural retrofitting.

An alternative proposal was extended to the client, suggesting the option of reopening the bridge to traffic while implementing a vigilant monitoring system. However, the client elected to confront the challenges posed by traffic diversions. Ultimately, the bridge underwent retrofitting and was reopened to traffic after a closure period of 2.5 years.

In this case, the incorporation of instrumentation aimed to establish performance indicators and scrutinize their evolution. Nonetheless, the sheer volume of information collected posed a considerable challenge in terms of effective management. Moreover, a comprehensive understanding of the bridge's behaviour through instrumentation would have been instrumental in validating the assumptions considered in the project.

2.2 *Alicante Denia Line*

Ferrocarrils de la Generalitat Valenciana (FGV) operates a railway line spanning from Alicante to Denia in the Comunitat Valenciana region. This railway network links Alicante to various popular resort towns, including Benidorm, Altea, and Calpe. Spanning nearly 100 km, the railway's initial construction dates back to the early 20th century, encompassing diverse types of structures such as underpasses, overpasses, pedestrian crossings, culverts, viaducts, and tunnels. These structures exhibit a wide range of typologies, materials, and construction ages, with some remaining in their original state, others undergoing repair, rehabilitation, or enhancement, and some being entirely replaced.

In 2018, FGV procured a new fleet of modern trains, prompting Pedelta's engagement to conduct a thorough load capacity assessment on the existing bridges, considering the implications of the new train loads. Additionally, Pedelta was tasked with an extensive preliminary research effort involving the compilation of existing information on the bridges and the execution of various on-site tests, including concrete compressive strength tests, reinforcing steel tests, and non-destructive tests.

The subsequent inspection and assessment report affirmed the compatibility of the new trains with most of the existing structures. However, it was recommended that two aged steel bridges be replaced in the coming years due to fatigue life concerns. A more detailed evaluation considering the real behaviour might have potentially extended the operational life of these bridges.

2.3 *Sant Boi HSR Bridge over the Llobregat River*

Completed in 2007, this bridge was the first steel structure to be built on the High-Speed Railway joining the cities of Madrid and Barcelona. The 870 m long bridge comprises two parts: a 340 m long steel–concrete structure which spans a five-lane highway and a railway; and a continuous prestressed concrete box girder viaduct across the Llobregat River with a longest span of 50 m. The steel bridge is a continuous structure with six spans measuring 44+63+63+ 63+63+44 m respectively. The bridge consists of a king post truss with curved diagonals, which supports a composite steel-concrete deck. The 14 m wide deck accommodates two ballasted tracks, for a total bridge width of 17 m. The bridge is shown in Figure 2.

Pedelta assumed responsibility for the design across all phases of the project, encompassing conceptual design, detailed design, and construction assistance. As expected, 15 years post-construction, the bridge has exhibited no structural pathologies aside from typical coating deterioration. Notwithstanding this favourable condition, owing to the unique characteristics of the structure, it has remained under the continuous monitoring purview of the administration (ADIF) since its construction.

Even though the bridge was designed according to the most contemporary codes applicable at the time of its construction, distinctive structures like this one may manifest unforeseen behaviours not explicitly addressed in prevailing design codes. Consequently, the ongoing monitoring of the structure is crucial. Furthermore, it is recommended to leverage the

Figure 2. Sant Boi HSR Bridge.

information gleaned from this monitoring process to enhance our understanding of the structure's performance and, if necessary, inform any potential adjustments or interventions. One of the critical issues in this bridge design was the joint between the transverse steel beams and the longitudinal lateral trusses. The joint stiffness played a significant role in the fatigue design of these transverse joints, which extend along the whole bridge length. Monitoring the actual stresses and deformations at these joints would have helped to more accurately predict its actual behaviour for future similar designs and to have further information about the fatigue lifespan of these joints compared with the expected.

3 PROJECT DESCRIPTION

The examples elucidated in the preceding section underscore the role of Structural Health Monitoring (SHM) in enhancing the safety of both existing structures and new complex constructions. However, these instances also illuminate some challenges associated with SHM:

- Information Volume: The copious amount of data generated by SHM poses a challenge in terms of effective handling, necessitating the development of new algorithms for processing.
- Perceived Cost: Despite its efficacy, there persists a perception among some administrations that SHM is expensive. Consequently, alternative solutions are sometimes favoured, even if they imply the reconstruction of the structure.

Besides, the first and the second examples also reveal that current fatigue models may be conservative in some cases.

Furthermore, the first and second examples underscore that existing fatigue models may exhibit conservatism in certain cases.

These challenges, among others, motivate Pedelta's active participation in the BRIDGITISE project. Specifically, Pedelta is contributing to Task NEURAL, focusing on Machine Learning for deterioration prediction based on digital information streams. The overarching objective of this project is to devise a methodology rooted in long-term monitoring, particularly with small-scale systems, to prognosticate deterioration phenomena like corrosion wastage and fatigue. The ultimate goal is to develop a tool capable of extending the service life of bridges and salvaging structures deemed condemned.

An inherent advantage of SHM is its capacity to enhance understanding of a structure's real behaviour. For instance, it enables the assessment of connection stiffness in steel structures and facilitates the consideration of actual stiffness by accounting for concrete cracking in concrete structures. Additionally, SHM reduces the necessity of conservative assumptions

during analysis. The schematic representation of the project's conceptual framework is delineated in Figure 3.

The initial phase involves the extensive collection of data from diverse sensors embedded in the structure over an extended period. Notably, the endeavour aims to strategically minimize the number of sensors utilized to optimize monitoring costs, given the prevailing hesitancy among some administrations owing to financial considerations.

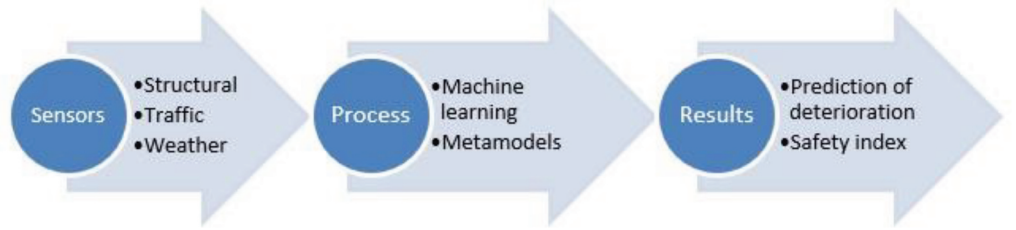

Figure 3. Project framework.

Subsequently, in the second phase, the gathered information undergoes rigorous processing. Machine learning constitutes a pivotal aspect of this project, as it will be employed to construct metamodels for interpreting monitoring data and predicting deterioration. Various machine-learning algorithms will be systematically evaluated and validated to enhance the efficiency of predictions. The anticipated outcome of the project involves the amalgamation of machine learning methodologies, encompassing neural networks, support vector machines, and decision trees, to facilitate accurate deterioration predictions.

The ultimate objective of this project is twofold: firstly, the precise prediction of deterioration, as elucidated earlier; secondly, the establishment of a safety measure for the structure, termed, for example, the Safety Index.

In the subsequent phase of the project, the metamodel, initially developed using numerical data, will undergo adaptation, training, and validation using real-case study data. This phase, conducted under the supervision of Pedelta, will involve the explanation of one of the selected bridges in the ensuing section.

4 CASE STUDY

4.1 *Bridge description*

Pedelta has been commissioned by Ferrocarrils de la Generalitat de Catalunya (FGC) to conduct an assessment and prepare a rehabilitation plan for the Road Vic Bridge in Manresa, Catalunya. The selection of this bridge for study within the framework of the BRIDGITISE project is motivated by the various pathologies it exhibits, as delineated below. This bridge serves as an exemplary case for examination and analysis within the broader scope of the BRIDGITISE project.

Dating back to 1924, the Road Vic Bridge comprises a singular span measuring 17.3 meters. It features a main truss on each side, spaced at 8.8 meters. Designed to accommodate the passage of two metric railway tracks, the bridge supports the sleepers of each track on two longitudinal stringers, with these stringers being upheld every 1.8 meters by transverse beams. A picture of the bridge is shown in Figure 4.

The bridge is located in the corridor of the Potash Mines of Suria.

Figure 4. Road Vic Bridge.

4.2 *Pathologies of the bridge*

The degradation incurred from the decades-long transport of potash without protective covering has been substantial. To address this degradation, a series of retrofitting measures were implemented on the Road Vic Bridge, including the addition of numerous L-shaped steel profiles and an increase in the plan bracing. However, a noteworthy challenge arises from the retrofitting approach, as it was made by combining welding and bolts without apparently paying attention to fatigue-related issues.

The issues articulated align seamlessly with the objectives of the project:

- Corrosion wastage: The prolonged exposure to potash has led to the degradation of multiple elements in the bridge. Furthermore, the addition of new reinforcing steel profiles has concealed certain areas, introducing uncertainties in predicting the evolution of corrosion within the bridge.
- Fatigue: The bridge's susceptibility to fatigue is heightened due to its relatively short span, resulting in the predominant influence of live loads. Compounding this vulnerability is the fact that the primary loads on the bridge are railway trains, which exert a higher weight compared to road bridges. Furthermore, the lack of comprehensive knowledge during the initial construction, coupled with the subsequent implementation of numerous retrofits, has led to the incorporation of multiple suboptimal fatigue details. These factors collectively contribute to an elevated risk of fatigue-related issues in the structural integrity of the Road Vic Bridge.

4.3 *Preliminary evaluation*

Preceding the inspection of the bridge, a preliminary analysis was conducted to assess and identify the critical elements of the structure.

The analysis was executed utilizing the Sofistik software. The structural model of the bridge predominantly employed beam elements for most components, except for two plates. Figure 5 illustrates the representation of the bridge within the structural model.

The Ultimate Limit State (ULS) analysis indicated that the structural capacity of the bridge appears to be adequate for the loads stipulated by the owner. Notably, only the vertical members exhibited overstresses in the Serviceability Limit State (SLS). Importantly, no physical evidence of damage was detected during the inspection of these members. Consequently, it is hypothesized that the observed overstresses may stem from the assumption of a rigid connection between the transverse beams and the vertical members. The implementation of SHM is anticipated to facilitate the determination of the actual stiffness of this connection, providing valuable insights into the behaviour of the bridge under various loading conditions.

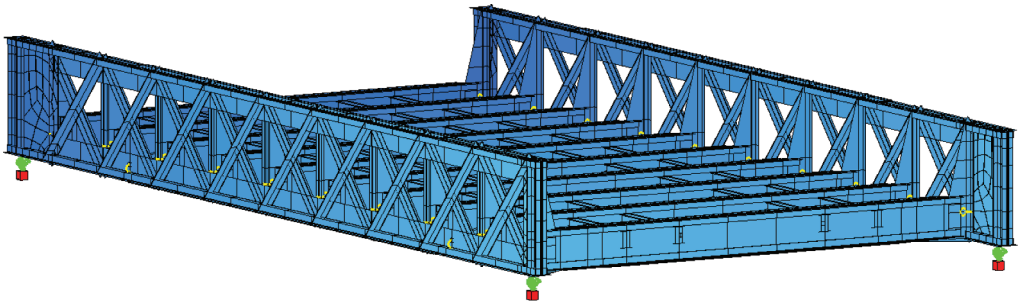

Figure 5. Structural model.

An additional critical calculation performed on the bridge involved a comprehensive fatigue analysis. Ferrocarrils de la Generalitat de Catalunya (FGC) maintains an extensive record of traffic over the bridge spanning several decades, detailing locomotive types and hoppers. This historical data allows for a thorough fatigue analysis of the bridge.

In the preliminary analysis, certain details were identified as approaching the end of their fatigue life. However, these details are highly sensitive to various parameters, including the dynamic impact factor and the effectiveness of the added reinforcing elements. Consequently, the monitoring plan proposed within the framework of the BRIDGITISE project is anticipated to play a pivotal role in accurately assessing the remaining fatigue life of the bridge. This proactive approach aligns with best practices in infrastructure management, ensuring the ongoing safety and longevity of the bridge over the Vic Road in Manresa..

Another relevant calculation performed in the bridge has been the fatigue analysis. FGC has kept a register of the traffic over the bridge for decades, including the types of locomotives and hoppers. Then, it is possible to analyze the fatigue in the bridge.

During the preliminary analysis conducted, some details were found to be close to the end of its fatigue life. However, they are also very sensitive to different parameters such as the dynamic impact factor, or the effectiveness of the reinforcing elements added. Consequently, the monitoring plan of the bridge within the frame of the project BRIDGITISE will help to properly address the evaluation of the fatigue remaining life of the bridge.

4.4 *Monitoring plan*

The devised monitoring plan for the bridge encompasses various sensor types to comprehensively capture its behaviour.

The initial category comprises environmental sensors, including a weather station to correlate results with weather conditions. Temperature sensors on the top and bottom chords will track thermal displacements, and the installation of a camera aims to provide supplementary information about traffic over the bridge. Given the significant impact of environmental conditions on corrosion, corrosion sensors will be strategically placed to analyze corrosion evolution in different sections of the bridge.

The next set of sensors includes displacement sensors and accelerometers. These sensors, situated at quarter-spans, midspan, and bearings, will detect any variations in the deflected shape of the bridge at rest or its dynamic properties, serving as indicators of potential damage progression. Additionally, strain gauges will be installed in critical sections identified during the preliminary analysis, with a focus on minimizing their number

The overarching goal of the monitoring plan is to utilize small-scale systems, thereby minimizing the sensor count and capitalizing on correlations between them. For example, information about transverse beams will be obtained from sensors in the main truss, eliminating the need for sensors on critical sections of each transverse beam. This approach not only optimizes cost-effectiveness but also streamlines the management of the monitoring system.

5 CONCLUSION

The imperative to extend the lifespan of existing bridges for the sake of sustainability in construction is underscored by the advantages it holds over demolition and reconstruction. The challenges posed by insufficient understanding of a bridge's behaviour, leading to unnecessary demolition proposals in some cases, emphasize the need for advanced methodologies. Pathologies such as corrosion and fatigue, particularly critical for steel bridges, necessitate innovative approaches.

While existing fatigue models may prove conservative for existing bridges, the BRIDGITISE project, in which Pedelta actively participates, seeks to address these challenges through machine learning-based deterioration prediction. The case study of the Bridge over the Vic Road in Manresa exemplifies the complexity of issues related to corrosion and fatigue, emphasizing the importance of a comprehensive monitoring plan. The proposed plan strategically integrates environmental sensors, displacement sensors, accelerometers, and corrosion sensors, employing a small-scale system to optimize cost-effectiveness. The project's ultimate goal is not only to predict deterioration accurately but also to establish a safety index for structures, contributing to the sustainable management of bridge infrastructure.

ABSTRACT: Recent research has explored the potential of using the dynamic response of passing vehicles to conduct Structural Health Monitoring (SHM) efficiently. Various types of vehicles, including cars, vans, trucks, and even manually propelled carts, have been employed in this approach, with different configurations of exciters and receivers. A noteworthy development in this field involves the inclusion of lightweight vehicles like bicycles and scooters. Lightweight vehicles offer several advantages, including their affordability, sustainability, and minimal environmental impact. These vehicles have a negligible impact on the dynamic behavior of structures due to their low speeds and negligible mass, making them ideal for monitoring structures that are challenging to access, such as footbridges. This paper provides a comprehensive review of recent literature on the application of lightweight vehicles in SHM of urban bridges. It emphasizes the potential benefits and current challenges associated with these applications while offering insights into future research directions.

1 INTRODUCTION

Bridge management stands as a pressing concern for transport authorities worldwide, facing the challenges arising from the convergence of aging structures, limited economic resources, and the escalating impact of climate change-induced calamities that expedite the degradation of critical assets. To address these challenges, the assessment of the structural health of bridge has traditionally relied on visual inspections and testing campaigns conducted by specialized technicians (Poli et al. 2023). However, in recent decades, Structural Health Monitoring (SHM) methods have emerged as a promising alternative, seeking to provide continuous surveillance and early detection of structural issues (Cunha et al. 2018, Karakostas et al. 2023).

Conventionally, SHM techniques have predominantly involved the installation of dedicated sensing devices directly onto bridges, comprising sensors, cables, and acquisition systems. These systems allow for the extraction of damage-sensitive features from physical measurements, which may offer insights into structural health over time. Among SHM techniques, vibration-based SHM, based on dynamic measurements, presents a notable advantage: it

DOI: 10.1201/9781003483755-407

allows for assessment of global structural integrity even when sensors are not in close proximity to damage locations. However, traditional SHM systems bear drawbacks associated with high installation costs, dependency on accessible power sources, and ongoing maintenance expenses, often complicating the estimation of their economic benefits over the initial investment (Giordano et al. 2023).

In response to these challenges, the concept of "Indirect" or "Drive-By" Structural Health Monitoring (ISHM) has gained interest. ISHM exploits the dynamic response of instrumented vehicles as they cross bridges. This approach aims to reduce costs associated with the installation of dedicated SHM systems. As far as the authors' knowledge, the initial theoretical exploration of using moving vehicles with installed sensors was introduced by Yang et al. in 2004, demonstrating the feasibility of this approach (Yang et al. 2004). Subsequent studies extended this concept, coining the term "indirect SHM" to distinguish it from traditional "direct SHM" methods employing contact sensors (Cerda et al. 2012).

Over the past fifteen years, a proliferation of scientific research has presented various ISHM approaches based on vibration signals collected onboard moving vehicles and considering various exciter-receiver configurations. Some ISHM approaches use vehicles expressly designed for monitoring applications (Lin & Yang 2005), while others exploit regular vehicles, such as cars and trucks, to serve as both instruments and exciters (Kim & Lynch 2012). Recent research has taken an interesting turn towards the feasibility of using lightweight vehicles such as bikes and scooters for ISHM applications (Quqa et al. 2022). Additionally, ISHM strategies incorporating data collected by smartphones have been proposed, taking advantage of the widespread availability and connectivity of these devices for crowdsensing applications.

In the coming four years, the topic of ISHM based on crowdsensing and mobile data, as well as lightweight vehicles, will be directly addressed in one of the Ph.D. projects developed within the new Marie Skłodowska-Curie Actions (MSCA) doctoral network named "BRIDGITISE," initiated on January 1, 2024, with financial support from the European Commission (see www.bridgitise.polimi.it). The BRIDGITISE doctoral network is dedicated to advancing the digitalization of bridge management throughout its lifecycle by pioneering innovative approaches to information management. This initiative involves launching a network comprising 16 Ph.D. projects, each contributing to the overarching goal of enhancing bridge management through digital means. One of these projects, called "Crowd," specifically focuses on developing a crowdsensing strategy to extract structural information from sensors mounted on vehicles or smartphones.

This paper aims to provide a preliminary literature review on indirect vibration-based SHM for bridges, with a specific focus on the integration of lightweight vehicles like bikes and scooters. Serving as an exploration preceding the commencement of the Crowd project, this literature review also includes a preliminary application of ISHM using bikes to demonstrate the feasibility of this approach.

The paper is organized as follows: the BRIDGITISE project is presented in the second section. The Scopus literature review is presented in section 3. Section 4 provides insight into ISHM using lightweight vehicles and presents an application. Finally, conclusions are given, and future works are presented.

2 THE "BRIDGITISE" PROJECT

The BRIDGITISE doctoral network focuses on advancing the digitalization of bridge management across the entire lifecycle. The project's core idea is to develop and validate on-site technologies that are both innovative and cost-effective for managing bridge information. The initiative is organized into three main research clusters: creating low-cost, large-scale, and automatic technologies for managing bridge information; adapting Artificial Intelligence and IoT technologies for bridges; and designing digital decision support tools for comprehensive bridge management.

With 16 PhD projects aligned with these clusters, the network collaborates with six universities, one research center, and seventeen industrial partners. Industrial collaboration provides practical case studies for applying and validating research findings, enhancing the doctoral candidates'

skills for diverse sectors. The BRIDGITISE network aims to deliver technology-enhanced training tools, workshops, and an open platform for sharing bridge management data.

One specific project within the network, named "Crowd", addresses the challenges of large-scale monitoring using crowdsensing, considering cost-effectiveness and scalability. This project will propose a system identification approach based on crowdsensed data, focusing on efficient and reliable data transmission to a cloud unit. It also considers the impact of sensors and carriers on collected data, with validation planned on real bridges. The project further aims to develop an IoT information transmission protocol through a smartphone application, engaging bridge users in data collection. The results will be systematically compared with those from traditional monitoring systems. The "Crowd" project is scheduled to officially start in mid-2024 and is expected to span a duration of three years.

3 LITERATURE OVERVIEW ON ISHM

3.1 *Scopus analysis*

In this section, an overview of the state of the art in the field of ISHM of bridges is presented, based on an analysis of the Scopus database conducted in December 2023. The database query employed specific keywords to narrow down the focus to SHM-related literature, using ("Indirect" OR "drive-by") AND "structural" AND "health" AND "monitoring" AND "bridge" as the search terms. This search yielded a total of 177 documents published between 2006 and 2024 including both conference and journal papers.

For contextual comparison, a broader set of keywords, "structural" AND "health" AND "monitoring" AND "bridge," was utilized, resulting in 8635 documents published between 1988 and 2024. This broader search encompasses a comprehensive body of literature covering various aspects of SHM in the context of bridges, highlighting the relatively modest portion of literature dedicated specifically to ISHM. The analysis presented serves as a preliminary exploration of the literature on ISHM for bridges, and it is important to note that the reported numbers may be conservative. Specifically, the chosen keywords for the search might not encompass all relevant papers, such as those addressing dynamic identification, see e.g. (Yang et al. 2013, Di Matteo et al. 2022), leading to a potential underestimation.

The identified 177 ISHM documents underwent a meticulous analysis, leading to the exclusion of 61 documents either unavailable or unrelated to the topic of interest. The resulting dataset includes documents published between 2010 and 2024 and provides a focused and relevant collection of documents specifically addressing ISHM of bridges. Figure 1 illustrates the number of publications over the years, indicating an upward trend in scientific production related to ISHM.

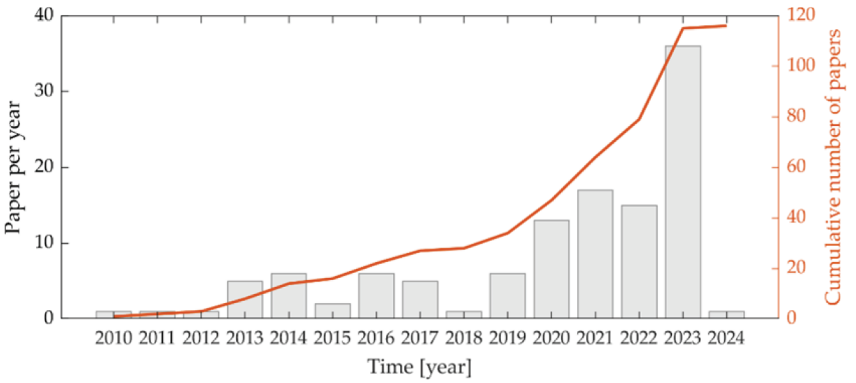

Figure 1. Number of papers published per year and their cumulative number over time.

Concerning the content of the papers identified in the analysis, 7 are literature reviews, while the majority focus on proposing ISHM strategies and associated algorithms. The majority of the remaining papers focus on proposing ISHM strategies and the relevant algorithms. These strategies are predominantly demonstrated through numerical simulations, constituting 42% of the corpus, or laboratory tests, which account for 41%. Notably, a relatively small portion of the papers includes on-site demonstrations (17%). In the subset of papers that feature on-site demonstrations, various vehicles are employed as carriers for sensors, underscoring the flexibility and adaptability of ISHM strategies to different modes of transportation. Specifically, the most commonly used vehicles are cars, representing 28% of the cases. Trains are the second most prevalent, accounting for 22% of the on-site demonstrations. Additionally, vans, trucks, and bikes each contribute to 11% of the cases. Applications involving bikes focus on footbridges, while applications involving vans, trucks, and cars predominantly center on concrete girder bridges. Figure 2 provides a visual representation of the results of the literature review.

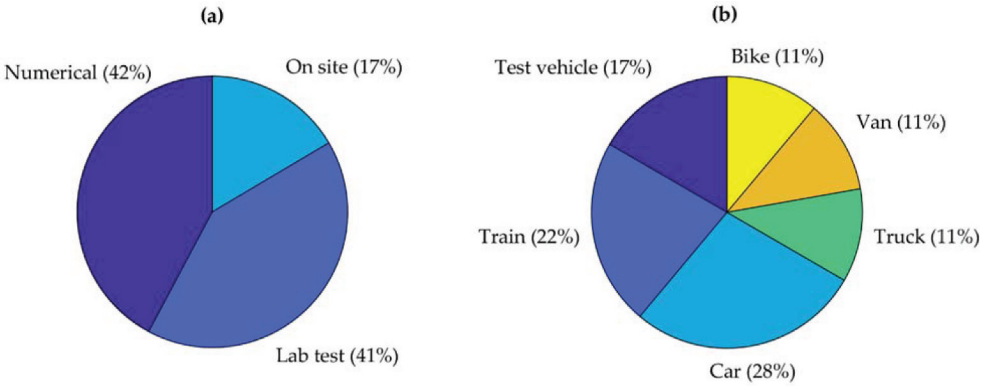

Figure 2. Pie charts: (a) Application type; (b) Vehicles types for on site tests.

3.2 *Focus on lightweight vehicles*

The integration of lightweight vehicles, such as bikes and scooters, in ISHM introduces several advantages that align with contemporary sustainability and urban mobility considerations. These vehicles offer cost-effective solutions with high sustainability, as emphasized by their low cost and positive environmental impact in urban areas, contributing to the reduction of traffic congestion. Moreover, the intrinsic characteristics of lightweight vehicles, including low speed and negligible mass relative to monitored structures, ensure that their dynamic behavior has minimal impact on the structures being monitored. This characteristic becomes especially beneficial when monitoring structures that are inaccessible to larger vehicles, such as footbridges.

However, potential challenges associated with the use of lightweight vehicles for ISHM exist. Factors than can influence the reliability of data collected from lightweight vehicles such as noise effects introduced by the vehicle's operator, vehicle dynamics, and the inherent uncertainty in data when recorded by smartphones (which often come equipped with low-cost sensors). Despite these challenges, the advent of crowdsourcing data presents an opportunity to enhance the overall quality of ISHM results. This improvement becomes particularly notable when users employ standardized vehicle types, ensuring known vehicle properties.

Shared micromobility services, such as bike and scooter sharing platforms, emerge as promising contributors to ISHM strategies. These services typically offer a limited variety of vehicle types within a given urban area. This standardization simplifies the integration of crowdsourced data into ISHM processes, contributing to more reliable and consistent monitoring outcomes.

To the best of the authors' knowledge, three recent works specifically address the utilization of lightweight vehicles for ISHM, i.e. (Quqa et al. 2022, Li et al. 2023, May et al. 2023).

Nevertheless, the number of publications on this topic is expected to grow in the coming years due to the escalating interest in ISHM.

The first study explores the application of shared micromobility vehicles, such as bicycles and electric kick scooters, for monitoring urban bridges (Quqa et al. 2022). This was the first paper exploring the use of lightweight vehicles for ISHM applications. An automatic ISHM strategy is proposed based on the data collected by smartphones temporarily installed on shared micromobility vehicles. The framework is demonstrated on a real footbridge using an urban bicycle. The following section provides a more detailed presentation of this strategy.

These results are validated and extended by other authors, who performed field tests involving direct and indirect monitoring of a bicycle/pedestrian traffic bridge (May et al. 2023). The bridge deck and bicycle frame were equipped with wireless accelerometers, transmitting data during passages. The tests included multiple traversals to counteract road surface roughness effects through ensemble averaging. The study suggests several novel contributions, including the demonstration that low-cost sensor-carrying human-powered vehicles can excite and record bridge dynamics. Simultaneous sensing of the vehicle and bridge is highlighted to reduce potential ambiguity. Additionally, the introduction of the concept of using pedaling cadence to increase the visibility of bridge modes is presented.

The third study describes a novel indirect method for identifying the frequency of footbridges using vibrations from ordinary scooters (Li et al. 2023). The authors build a three-degree-of-freedom finite element model for a scooter and simulate a simply supported footbridge using beam elements. The presence of road roughness is considered in the numerical model. The key conclusions drawn from the research are as follows: (1) The road roughness has a strong influence on the identification of the footbridge frequencies. Without considering road roughness, the footbridge frequencies can be directly determined from the scooter's vibrations. However, these frequencies are covered by noise when road roughness is present; (2) Factors such as environmental noise, footbridge damping, and tire damping primarily impact the high-frequency range (> 20 Hz in this study), while the identification of low-order frequencies (first two frequencies in this study) of the footbridge is minimally affected.

4 APPLICATION

The viability of employing micromobility vehicles (in this case, bicycles) to acquire modal or operational parameters commonly used in vibration-based SHM methods, such as natural frequencies, mode shapes, or Operating Deflection Shapes (ODSs), is demonstrated on a footbridge situated in Bologna, Italy, spanning the A13 motorway between Bologna and Padova (Figure 3a). Comprehensive details about this structure are available in References (Majowiecki 2005, Majowiecki & Cosentino 2011, Quqa et al. 2022). A smartphone (iPhone SE, second generation, 2020) installed on a typical city bicycle (Figure 3b) was employed to gather different data types while traversing the bridge, namely, acceleration and angular velocity recorded along three orthogonal axes, three magnetic field measurements, and three position logs encompassing latitude, longitude, and altitude.

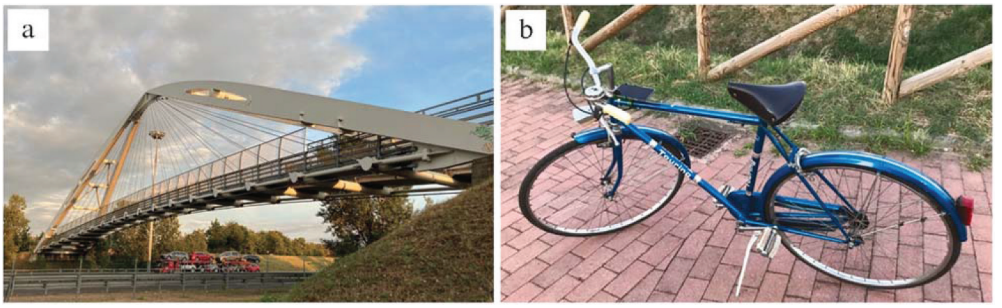

Figure 3. Case study: (a) Bridge view, (b) Instrumented bicycle.

Crowdsourcing is simulated by traversing the bridge and collecting data multiple times (in total, 36 rounds of riding back and forth across the footbridge). The duration of each sample varied between 45 and 70 seconds, based on the user velocity. All tests were conducted under operational conditions, with the presence of at least one pedestrian or a runner crossing the bridge. The measurements were captured using the MATLAB Mobile app (MathWorks 2021), and the algorithms were subsequently applied on a PC to identify the first natural frequency of the bridge and the ODS of a narrow frequency range centered in that value. Each dataset collected underwent processing following the procedure outlined in Figure 4, encompassing the following steps:

1) Identification of bridge dynamic features: First, a band-pass filter is applied to the vertical acceleration data to extract the response component in a user-defined frequency range (previously selected based on a rough estimate of the fundamental natural frequency of the bridge). Then, the amplitude of the structural response within this range is calculated using the Hilbert transform and interpreted as the ODS of the structure in the proximity of its main natural frequency.
2) Identification of Sensor Location: GPS and all Inertial Measurement Unit (IMU) measurements, excluding vertical accelerations, are employed to estimate the vehicle (and sensor) location with high spatial resolution through an extended Kalman filter. This process helps identify where the vertical acceleration data (and thus the identified ODS amplitude) was collected on the bridge. Then, the first principal component of the obtained position (in geographical coordinates) is used to express the sensor location with respect to the bridge axis, employing a 1D reference system aligned along the bridge.
3) Estimation of a dense ODS: The ODS amplitudes identified in step (1), which are dependent on the specific path and speed of the vehicle, are realigned at the locations identified in step (2) through linear interpolation. This alignment allows for averaging the amplitudes identified by different vehicles.
4) Averaging of ODS amplitudes: The ODSs identified during a set of passages are averaged to enhance the robustness of the identification process and mitigate noise effects.

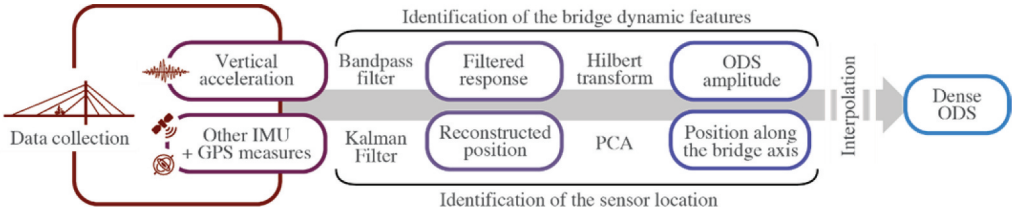

Figure 4. Scheme of the proposed identification procedure.

Figure 5 illustrates the power spectra of 36 vertical acceleration time series gathered on the bicycle, compared with the spectrum of a 5-minutes bridge response obtained by placing the smartphone at 1/4 of the bridge span from the eastern support. The fundamental resonant frequency of the bridge previously identified by other authors (Majowiecki & Cosentino 2011) is 2.52 Hz. This frequency aligns well with the one identified in this study using the fixed sensor. Additionally, a distinct peak at the same frequency is evident in the vehicle response. Specifically, the average peak frequency over the conducted tests is 2.53 Hz, with a standard deviation of 0.035 Hz. This observation suggests that human biomechanics and pavement roughness do not significantly affect the identification results in this application. Indeed, the pavement of pedestrian bridges typically has a smooth surface, and bicycle speeds are generally low, thereby minimizing the impact of road surface profiles on the recorded response (Lin & Yang 2005, Malekjafarian et al. 2015).

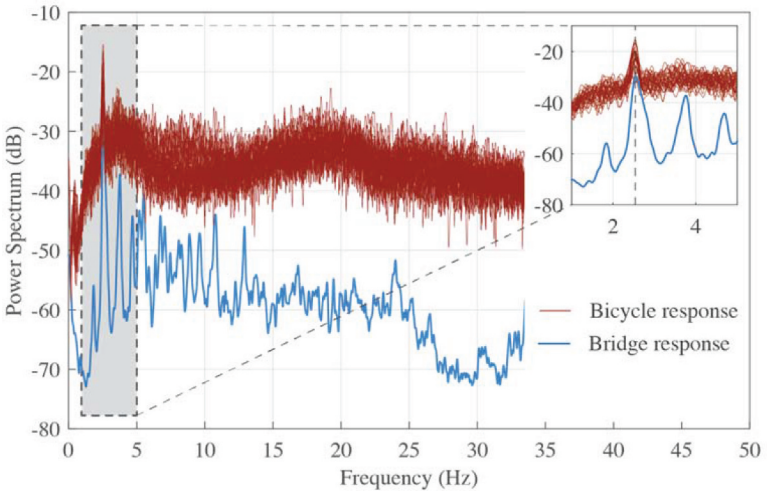

Figure 5. Power spectra of the bicycle and the bridge responses.

To derive an approximation of the ODS of the bridge around its principal resonant frequency, the methodology outlined in Figure 4 was applied, using a frequency range of 2.5 ± 0.3 Hz for filtering. Further details on the parameters chosen for the Kalman filter can be found in Reference (Quqa et al. 2022). In Figure 6, the thin red lines represent the ODSs computed within the specified frequency range from the 36 datasets collected onboard the moving bicycle. The thick red line represents the average of the identified ODSs, which shows good agreement with the mode shape of the first mode identified by previous studies (Majowiecki & Cosentino 2011). This agreement is particularly noticeable in the central part, where the dynamics of the bicycle impacting the bridge joints are mitigated. Additionally, a slight asymmetry in the shape is observable, with higher amplitudes on the left-hand side, aligning with reference values.

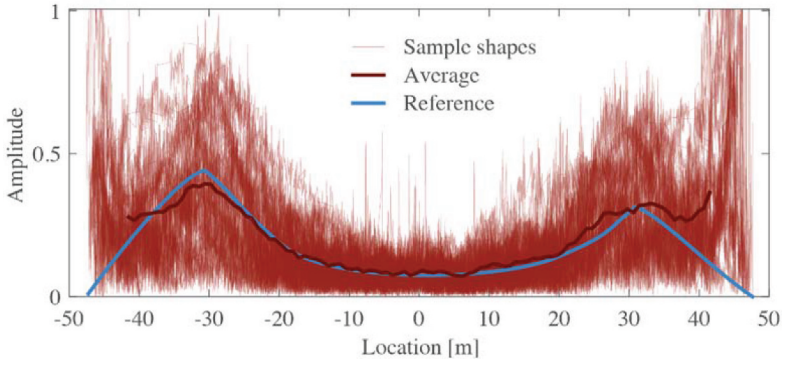

Figure 6. Identified ODS (separate samples and their averages) and reference mode shape obtained in Reference (Majowiecki & Cosentino 2011).

5 CONCLUSIONS AND FUTURE WORKS

This paper provided a preliminary exploration of ISHM, emphasizing the role of lightweight vehicles as carriers of sensors for this purpose. In general terms, the increasing interest in ISHM is evident from the growing number of publications in this field, as highlighted by the

analysis of the Scopus database. However, most of the reviewed documents focus on numerical simulations and lab tests, emphasizing the need for on-site validations.

Focusing on lightweight vehicles, such as bikes and scooters, recent studies emphasize their suitability of ISHM in applications for footbridges and crowdsensing approaches. The possibility of extracting modal parameters using sensors installed on lightweight vehicles has been proven numerically and experimentally. In this paper, a case study is presented to show the feasibility of these approaches.

Nevertheless, as highlighted by several authors, further studies are required to validate this approach and investigate several aspects related to the characteristics of the vehicle, the user, the bridge and the environmental conditions. More specifically, for bicycles, factors worth of investigation include the user's weight, pedaling frequencies, travel speeds, different gear ratios, and the impact of tire inflation pressure on bicycle-bridge interaction. Similarly, for scooters, a detailed investigation into factors like scooter speeds, walking pedestrians, engine noise, and varying environmental conditions is crucial.

Looking ahead, the "Crowd" project within the BRIDGITISE MSCA doctoral network, starting in mid-2024, is expected to make significant contributions to the realm of lightweight vehicles driven ISHM.

Simultaneous WET and WIT with Q-learning for wireless bridge sensors network

Muhammad Tauseef Mushtaq, Veronico Giuseppe, Nicola Cordeschi, Alfredo Grieco & Gennaro Boggia
Politecnico di Bari, Bari, Italy

ABSTRACT: Wireless Powered Communication Networks play a crucial role in Internet of Things scenarios which operate with low energy sensors. In this regard, simultaneous wireless energy transmission (WET) and wireless information transmission (WIT) are proposed for continuous data transmission with low energy sensors. These sensors can be deployed on bridges that are hit by disasters. However, these low-energy networks demand a random data transmission and hence require access points to decode the packets accordingly. Hence it is challenging to design a slot selection algorithm that provides a better throughput. On this subject, we present a Q-Learning-based algorithm that harnesses the qualities of deep reinforcement learning and enhances the throughput. In our algorithm, we enhance the slot allocation of each user with the influence of a few physical layer properties. Results show an improved slot allocation mechanism leads to better throughpu

1 INTRODUCTION

Wireless-powered sensor networks are a future technology which enables future smart cities and other industrial systems. When discussing smart cities, it's essential to consider smart buildings and infrastructures, such as bridges and roads, alongside intelligent autonomous vehicles. This leads us to emphasize the importance of smart-bridges, which serve as critical infrastructure for urban areas. During an unfortunate event or flooding, gathering essential data about bridges is imperative. The information can be catagories in two ways; how much damage bridge have suffered?, and how much water/vehicle load bridge can still manage? It's important to highlight that routine information gathering for bridges can also be accomplished through these networks. This creates a need to create a portable or remote network that can collect this key information. However, these networks' performance is limited by the amount of battery a sensor occupies which is deployed on the bridge. Our work is related to WP1 topic of Bridgsite; "Collect Bridge Information". Our proposed work is related to low-cost sensors with edge computing capacity to optimize the volume of information to transmit for Bridgesite project. Low-cost communication systems require minimum amount of data transfers between a Hybrid Access Point (HAP) and deployed sensors subject to lower utilization of energy and other resources. HAP are responsible for both wireless energy and information transmission. That is why to acquire optimised and up to data low-cost bridge wireless networks require a random access protocol such as Irregular repeated slotted ALOHA (IRSA) or it's variants to achieve these goals. Later on, our paper is focused on efficient data acquisition from low-cost bridge sensor networks.

That is why recharging (WET) and acquiring information (WIT) are very important. Portable communication scenarios such as disaster-hit areas, industrial Internet of things, or Mission-critical communications rely on the sensors deployed in the field with the ability to harvest energy. Healthcare, smart cities, and transportation are other systems that require

DOI: 10.1201/9781003483755-408

energy harvesting. Hence the idea of Wireless Power Communication (WPCN) has widely spread to maximize throughput using simultaneous WET and WIT. In WPCN a dedicated HAP is responsible for simultaneous energy and information transmission. HAP also ensures that there are no collisions and success full data transmission of each user is possible without any error. literature suggests that the network layer has not enjoyed tremendous improvement during the past while the physical layer has taken a huge leap in catering to such scenarios. The physical layer benefits 5G in indoor scenarios or UWB frequency. Similarly, beamforming also plays a critical role in low-energy networks with its directional signal capabilities. Hence, there needs an improvement on the resource allocation part to rep the fruit of much more efficient sensors and access points. For the scenarios mentioned above, IRSA has played a crucial role. IRSA randomly selects slots for replicas of each user providing no control over access points. Recently, a study has been done to improve random access performance.

This includes the introduction of machine learning algorithms for random access, the introduction of mini-slots, and time-offset. Time Offset (TO) increases the probability of successful full packet transmission by allowing users to send their data with a random offset of a constant length Hu, Y. 2022. Similarly, another method is to introduce the mini-slots before the transmission Ayoub, I 2021, Dumas, C. 2021. Mini-slots are small jamming signals from the users to inform HAP and other users about the slots where they will send replicas. Deep reinforcement learning-based methods also use a Q-learning algorithm to select the slots for each user Li, Y 2022, Choi, H 2019. These slot selection decisions are based on the battery level of each user and hence require an access point to interfere in the decision.

Nonetheless, all the methods lack incorporating the physical qualities of the system such as channel quality, and distance between UE and Access point. Despite the introduction of mini slots, time offset, and ML on the network layer for random access, there is a dire need to make the network layer more aware of the environmental effects. To the best of the authors' knowledge, this type of analysis is not done before. Hence, we present a better and improved decision process based on Q-Learning which incorporates channel quality, battery level, and distance between UE and HAP.

In this paper, we consider a nonlinear energy harvesting scenario with simultaneous capabilities of WET and WIT. It is uncommon to incorporate the effect of efficiency of energy harvesting in the WPCN environment at the network layer. In this regard, most of the decisions involved on the network layer are related to slot selection. Therefore, not only an

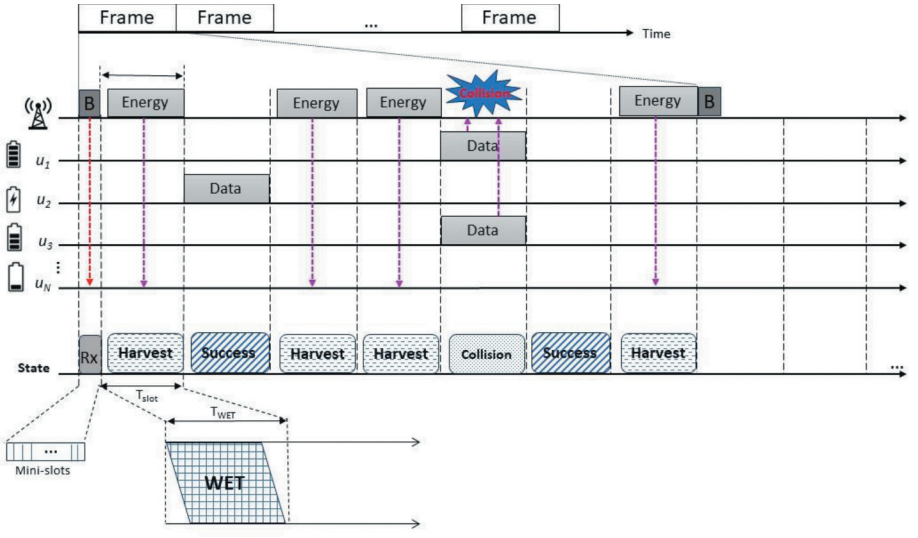

Figure 1. System model.

intelligent slot selection mechanism is required but it should also consider the efficiency of energy harvesting. For this purpose, we introduce a nonlinear energy harvesting model and calculate the harvested energy. By the end of each frame, the network layer has realistic information about the battery level of sensors. Finally, we can exploit this information or intelligent decision-making of slot selection for not only WET but also for WIT.

The rest of the paper is as follows. Section 2 describes the system model of a wireless-powered IoT network. Section 3. presents Q-learning algorithms which can manage the number of replicas along with energy harvesting slots. In section 4, we discuss the results obtained from these algorithms while section 5 concludes the work and provides future suggestions.

2 SYSTEM MODEL

We consider an IoT scenario with energy harvesting capabilities as shown in Figure 1. The system consists of sensors deployed in the field. We name them as $u_1, u_2, \ldots, u_N$. As per the requirement of IoT systems, sensors are always in saturation mode, which means they always have data to transmit. However, sensors' ability to send data is limited by various factors. These factors depend on the physical conditions of the environment such as distance, channel quality, available power, and line of sight. Packet transmission consists of different frames as shown in Figure 1. To send these packets, a sensor needs to select slots for their multiple copies of packets called replicas. Therefore, a sensor needs to decide intelligently for the number of replicas and placement of these replicas in slots of each frame. In our model, sensors are directed intelligently to choose the number of replicas. Available battery and channel are major parameters that influence this decision. It is worth mentioning here that these decisions are collectively made for each user at HAP using a machine learning algorithm called Q-Learning. Details of this algorithm will be provided in the next section.

After providing an overview of the system model, we explain each parameter that is involved in our system. First, we consider a nonlinear energy harvesting (NLEH) model for our system as it is closer to real scenarios. Before defining our non-linear model for energy harvesting, we need to define the following parameters. We define distance dn as the distance between HAP and nth user equipment. During the operation of Wireless Energy Transmission (WET), the power of HAP is denoted by P. Each user's equipment has a battery with limited capacity and energy harvesting capabilities. We define μ as the amount of energy required by UE to transmit one data packet. Hence, we can assume that if a user has a battery level available of μ = 2 then this user can send a maximum of two packets in one frame. It is also safe to assume that if a user does not have enough energy, then it has to wait for the WET phase and harvest enough energy to be able to again send data packets. WET capabilities of the system depend on multiple factors such as distance, channel quality, and power of HAP. Therefore, in our system channel quality is as important as battery level. We model our channel as a Rician channel. We assume an IoT scenario in which HAP enjoys a LOS with UE. Therefore, we consider the Rician channel which provides us with a LOS component along with NLOS components (multi-path). Considering this, the Rician channel hn between nth UE and HAP with K-factor κ, can be modeled as:

$$h_n = \sqrt{\frac{\kappa}{\kappa+1}}\bar{h}_n + \tilde{h}_n \in \mathbb{C}, \tag{1}$$

where $\bar{h}_n$ is the LOS component, which represents the large-scale fading and $\tilde{h}_n \in \mathbb{C}(0,1)$ represents NLOS small scale fading due to multi-path propagation. After modeling the channel and given the distance between HAP and UE, we evaluate the nth gain as:

$$\gamma_n = \left| \sqrt{\beta (d_n)^{-2}} w_n^H h_n \right|^2, \tag{2}$$

where w_n^H is the beam-forming vector. Whereas β represents channel power gain at a reference distance of 1m which we define as follows:

$$\beta = \frac{c^2}{16\pi^2 f_c}, \tag{3}$$

here the carrier frequency is denoted by f_c. In our system, we consider Ultra-Wide Band (UWB) frequency for harvesting which ranges from 5.98 GHz to 8.80 GHz and c represents the speed of light.

The above equations show that our system model considers the channel, power gain, and energy transmission limitations of HAP more realistically. Hence, next, we define our NLEH model as:

$$E_n = \frac{\alpha_o P \delta \gamma_n}{\alpha_1 P \gamma_n + \alpha_1}, \tag{4}$$

where $\alpha_o = 0.399$, $\alpha_o = 0.826$ are positive constant obtained from Lacovelli, G. 2023. Considering that each slot is dedicated to either WET or WIT, we can say that each WET is exactly the time dedicated to one slot. We define this time with δ. It is worth noting with the above definitions that UE will need several slots to charge its battery. Hence it is more evident that intelligent use of battery is necessary in such scenarios.

3 JOINT ACTION LEARNER (JAL) WITH NON-LINEAR ENERGY HARVESTING (NLEH)

Joint Action Learner (JAL) was first introduced in ref. It takes advantage of the learning capabilities of a deep reinforcement learning-based algorithm called Q-Learning. In this regard, we take another step forward and make the decision process of Q-learning more efficient. We introduce the channel quality parameter along with an enhanced battery charging model. Starting with the state of the algorithm, we define it as $S_t = \{s_{t1}, s_{t2}, \ldots, s_{tN}\}$. The state is the combination of available power and channel quality of each user such that $s_{tn} = (p_{tn}, c_{tn})$. Where pt n is the power available at the sensor and ct n is the channel quality of the sensor. The algorithm decides the number of replicas for each user and decides the specific actions for each defined as $A_t = \{a_{t1}, \ldots, a_{tN}\}$. With each user, we also relate a reward matrix defined as R_t. The reward is based on the action taken by each user. Considering these basic parameters of JAL, we provide the following points to better understand the workings of JAL.

- Each UE is equipped with a battery capable of storing 3μ units of battery, where μ = 0.5Wh.
- Users need a minimum of a μ amount of battery to send one packet. Hence, a user can send a maximum of three packets with a fully charged battery.
- With each energy harvesting slot, UE will collect power from HAP and update its battery accordingly.
- We assume perfect CSI at HAP. Hence, it is safe to assume HAP can send a perfect beam of energy towards the users.
- User to HAP distance and channel condition limits harvesting capability of each user. A user experiences low battery recharge during WET when it does not experience LOS with HAP and vice versa.
- In our simulation, we consider each user to be at a varying distance from HAP. Distance ranges from 0.8 meters to 2 meters. These values are obtained from experimental results in ref. We also assume that the distance between UE and HAP remains constant for the whole duration frame.
- Time for each slot is δ = 0.05Sec. While the parameters of JAL have values ρ = 0.5, ξ= 0.7.
- HAP also keeps track of battery level by calculating the harvested energy using Eq. 4.
- Each user also encodes its battery information along with the data. This helps the HAP in syncing the battery information.

By considering all the above information, we now define our algorithm in Algo.1. We reduce the computational cost of each user by keeping track of channel and battery information at HAP. Hence HAP is responsible for scheduling the packets in slots based on the available battery unit and channel quality. Q-Learning updates and optimizes the Q-values using Bellman's equation defined as,

$$Q(s_t, a_t) = (1 - \alpha)Q(s_t, a_t) + \alpha(r(s_t, a_t) + \gamma \, \boldsymbol{max} Q(s_{t+1}, a_t)), \tag{5}$$

where $r(s_t, a_t)$ is the reward collected after taking a specific action. After learning through JAL, HAP directs the sensors for the next transmission. A summary of our JAL algorithm is provided below in the Algo. 1.

Algorithm 1 JAL with Non Linear Energy Harvesting (JAL-NLEH)

Initialize Parameters ρ, ξ
Initialize $Q(S, A)$ randomly
for For each frame t **do**
  HAP collects s_i^t
  Obtain the joint state $S_t = \{s_1^t, s_2^t, ...s_M^t\}$
  Generate random number x
  if $x < \epsilon$ **then**
    Select a joint action randomly
  else
    Select a joint action by solving
    $A_t(S_t) = argmax_{A \in \mathcal{A}} Q(S_t, A_t)$
  end if
end for
for device $i \in M$ **do**
  Randomly select data slots for action $a_i^t \in A_t$
  Harvest energy using Eq. 4
  Collect the reward r_i^t
  Observe the next state S_i^{t+1}
end for
Calculate the joint reward: $R_t = \sum_{i=1}^{M} r_i^t$
Obtain the next joint state: $S_{t+1} = \{s_1^{t+1}, s_2^{t+1}, ..., s_M^{t+1}\}$
Find $max_{A \in \mathcal{A}} Q(S_{t+1}, A)$
Update the Q-value using Bellman's equation

Figure 2. Algorithm 1.

4 RESULTS AND DISCUSSION

In this section, we first present a comparison of idle slots for IRSA and JAL-NLEH. While we prove that JAL-NLEH performs better in terms of creating more slots for energy harvesting, we focus our remaining results on the performance of JAL-NLEH in different scenarios. We see how varying the channel quality and available battery can affect the number of replicas.

Before describing the results, we present the following scenario. First, the HAP initializes the Q-Table with random values from 0 to 6, then for each frame, collects the state for each user. The battery state is initialized at 0.05Wh and the quality of the channel is measured using envelop. The HAP decodes the packets according to Successive Interference Cancellation (SIC), and then each user receives a reward that is: 0 if none of its packets successfully decoded at HAP, 1 if any packet decoded HAP but collision occurs with another user, 2 if they were successfully decoded. This reward system ensures that HAP instructs users to send more replicas when channel quality is low. HAP looks for idle slots in each frame and uses them for WET. After performing WET, it obtains new channel quality and remaining power for each user and updates its joint state.

Figure 3 shows a comparison of idle slots for IRSA and JALNLEH. Here the number of users is 8 while the number of slots in a frame is also 8 while the Rician channel K-factor is $\kappa = 8$. Hence, we can assume that competition between users for slots is high. As we can observe JAL-NLEH manages to create more idle slots which are crucial for energy harvesting

as compared to IRSA. This is because IRSA does not have the advantage of battery and channel information while JAL-NLEH has many parameters such as channel, and battery information of users to work with. A comprehensive analysis of idle slots, decoded packets, and collided packets is shown in Figure 4. Here, we also consider the extreme scenario where competition for slots is very high. Our algorithm not only aims at reducing the number of collisions but also manages to create more idle slots for energy harvesting. It is worth mentioning that the probability of having more than 6 collisions is almost negligible while at the same time probability of idle slots has been also on the higher side.

In Figure 5, We keep our number of slots and users constant while varying the channel quality κ. We can observe two trends here, first is before idle slots are 5, and second, after the idle slots are more than 5. We explain this trend by explaining the battery reservation goal of JAL-NLEH. We can see an increasing trend in the probability of number of idle slots and after 6 number of idle slots, we see a decreasing trend. This shows that it is relatively easy for JAL-NLEH to create 6 number of slots as compared to a higher (more than 6) number of slots. We can also see how the channel affects the probability of idle slots. For example, for the worst channel i.e. κ = 4, probability is lesser than for $\kappa = 6$ *and* 8. Another worth noting analysis from these results is that performance for κ = 6 and 8 is not much different than each other. It is because our algorithm is optimized to create more idle slots and it enhances its performance when the conditions get tough. Another observation one can make is that our algorithm is optimized for channels with moderate values $\kappa = 6$ *and* 8 which are the conditions for outdoor channels.

Finally, in Figure 6, we present a collective result for different settings and $\kappa = 6$. It is observable from the figure that our algorithm always performs much better in conditions that matter the most.

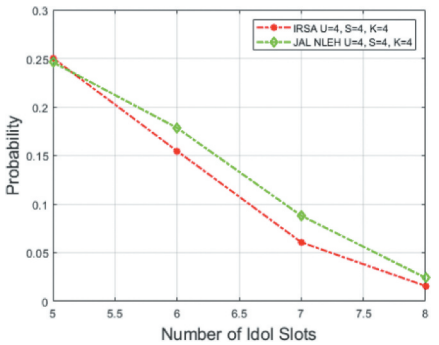

Figure 3. Probability of idol slots with $\kappa = 8$ for IRSA and JAL NLEH.

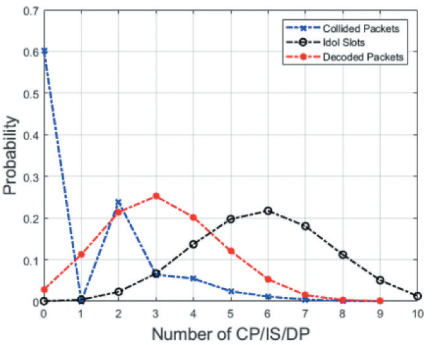

Figure 4. Comparison of Decoded packets, idol slots, and collided packets for $\kappa = 8$ users=10, and slots=10.

5 CONCLUSION AND FUTURE WORK

We have shown the key to achieving better performance in tougher scenarios for random slot selection of bridge sensor networks. We have also shown the importance of information related to physical layer characteristics at the mac level layer. This can help in improving the decision capability of the Mac layer. In this way, we can achieve more efficient with minimum age of information data for bridges which may be hit by disaster or flooding. We can also conclude that traditional IRSA needs improvements and these improvements can be made by enhancing the decision-making ability empowered by machine learning. For future work, we would like to extend this work with a continuous optimization/machine-learning algorithm such as proximity policy optimization (PPO) which does not require quantizing the battery and channel levels hence improving the results.

ABSTRACT: The multiplicity of possible different and possibly interacting processes contributing or governing deterioration processes in bridges requires systems representations way beyond the deterministic approach where the focus is on few processes and corresponding models. A Probabilistic Digital Twin (PDT), supported by Structural Health Monitoring (SHM) and big data from observations and monitoring, can provide a novel contribution to support integrity management with knowledge improved over time. This paper explores the preliminary analyses for the future full development of the PDT as part of the Bridgitise Project. An approach to build the PDT of a bridge will be developed using FEM modelling of the deterioration effects. The simulated structural responses under deterioration progressing in time will be used to develop a PDT model that will then be utilized as a representation of the best available knowledge and applied to generate simulations of very significant numbers of structural performance scenarios over time.

1 INTRODUCTION

At present, a considerable number of European bridges, constructed in the 1950s and 1960s, are either nearing or surpassing the end of their intended design lifespan. Frequently, these bridges operate under conditions significantly diverging from their original design assumptions, exacerbated by accelerated deterioration attributed to the impacts of climate change (Croce et al. 2019). Economy and Society can face significant challenges due to adverse effects and long-term consequences associated with the malfunction or collapse of infrastructure assets. In recent years, the escalating number of critical incidents affecting transportation infrastructure networks, specifically bridges and tunnels, has underscored the importance of considering safety risks, maintenance deficiencies, aging, and progressive deterioration processes when assessing the remaining design service life (Strauss et al. 2022). To address this, it becomes essential to incorporate suspected damage or deterioration mechanisms into the re-evaluation and re-formulation of limit states assessment methods (fib Model Code for Concrete Structures 2010 2013 & fib Bulletin No. 109 2022). This task proves to be complex, particularly given the spatial and temporal variability in the effects of damage or deterioration, necessitating an explicit representation of the intricate system interactions within the structure. Consequently, integrating additional information obtained through inspection, testing, and monitoring for existing structures enhances our understanding of uncertainties and risk differentiation for both new and existing structures (Darò et al. 2022). This enhanced knowledge applies to both the resistance side, involving a more refined

DOI: 10.1201/9781003483755-409

characterization of material behavior and deterioration mechanisms, and the actions side (Allaix et al. 2022, Hellebrandt et al. 2016). In terms of the latter, the composition of traffic carried by most bridges today, in both volume and load, is considerably more demanding than initially considered during the design phase. Moreover, ongoing advancements in technologies such as automotive driving, alternative fuels, and electric vehicles exert a profound impact on mobility, directly influencing actions required for bridge design and verification. For instance, these developments affect traffic loads (e.g., the impact of platooning) and introduce new hazards (e.g., altered fire risks due to alternative fuels). Furthermore, the evolving climate, including extreme wind, snow, temperature, and precipitation conditions, is also relevant to the loads and exposure considerations for structures. Climate change adds another layer of significance to the design of new structures or the assessment of existing ones (Strauss, Malioka & Faber 2009).

The effective maintenance of infrastructure plays a crucial role in ensuring the safety, performance, and long-term sustainability of assets (Darò et al. 2022). However, the current European approach to managing bridge assets relies heavily on methods of limited effectiveness, such as routine manual/visual inspections, subjective evaluations by experts, and corrective maintenance practices. Although there is a growing trend towards the adoption of preventive and condition-based maintenance strategies, these are not yet widely implemented and are primarily reserved for critical assets (Strauss et al. 2022). Efficient management is imperative to ensure the continued functionality of Europe's transport infrastructure and to prepare it for forthcoming social, economic, and environmental changes.

The advent of digital transformation, facilitated by disruptive technologies such as distributed sensors, drones, crowdsensing, satellite radar, Building Information Modelling (BIM), digital twins, Internet of Things (IoT), and Artificial Intelligence (AI), can provide extensive data to inform decision-making. The integration of existing knowledge and engineering insights with digital information has the potential to promote a resource-efficient approach to construction and bridge integrity management (BrIM). This approach paves the way for achieving sustainable societal developments.

The recently funded EU project BRIDGITISE is dedicated to advancing the digitalization of bridge management by introducing innovative approaches to information management. The project aims to create and validate cutting-edge technologies that enhance the efficient management of bridge information. These technologies are designed to support decision-making processes crucial for bridge integrity management throughout the entire lifecycle. The project consortium is a collaboration of universities, research centers, industrial companies, bridge design and assessment firms, and end-users, collectively contributing to the success of the project. BRIDGITISE will take up this research and training challenges, proposing a new paradigm for the first Industrial Doctorate within the EU that will pave the way to the training of new generations of researchers and professionals with expertise in digital BrIM. BRIDGITISE builds on the results of the international research networks (COST Action TU1402, 2015-2019), (COST Action TU1406, 2015-2019), as well as recent funded EU research projects such as IM-SAFE (H2020 CSA IM-SAFE, 2020-2022).

The present paper focuses on the ESR Project TWINS within BRIDGITISE, providing an insight into the project background, ongoing development, and future expected results. The ESR project responds to the increasing need to control the bridges network structural behavior with reliable indicators supported by robust algorithms. The multiplicity of possibly different and possibly interacting processes contributing or governing deterioration processes in bridges requires systems representations way beyond the deterministic approach where there is only focus on one or two processes and corresponding models. PDT, supported by SHM and semi-big data from observations and monitoring, can provide a novel contribution to solve this issue and may support integrity management with knowledge improved substantially over time.

The findings of the research program are valuable for asset owners, road operators, SHM engineering companies, bridge designers as well as other researchers in the monitoring and diagnostics field. The damage detection analysis contributes filling the gap between the research and the real applications, deepening the (nowadays limited) knowledge regarding the detectable damage effects on prestressed structures in both static and dynamic conditions and actively supporting the paradigm-shift towards a proactive maintenance approach.

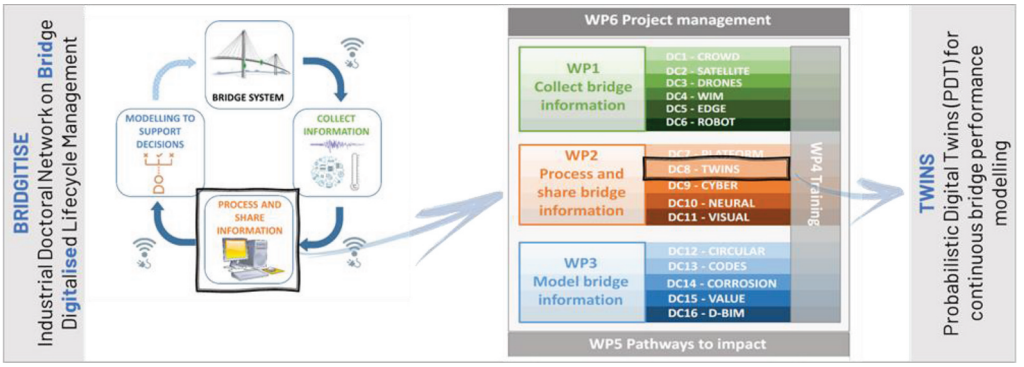

Figure 1. ESR TWINS Project within BRIDGITISE.

2 BRIDGE DAMAGE QUANTIFICATION AND PERFORMANCE MODELING: STATE OF THE ART, SCIENTIFIC GAPS AND BARRIERS

The life cycle management process for both new and existing concrete structures involves condition control, which is the comprehensive approach to ensuring the structural integrity throughout its lifespan. This process encompasses condition surveys, performance assessments, and the evaluation of maintenance strategies. Although management systems that capture deterioration processes are commonly employed in conjunction with analyses, they typically rely on deterministic performance prediction models. These models describe the anticipated future condition by establishing a functional correlation between structural condition characteristics (e.g., age) and the attributes of mechanical, chemical, and physical processes or agents. As the use of surveying technologies for acquiring information on the current condition of bridges becomes more prevalent, there is a notable shift towards data-informed approaches to condition control (Allaix, Bigaj-van Vliet & Cerar 2022). Moreover, the technological progress has recently increased with the spreading of IoT sensing devices (Alovisi et al. 2022). Recent research Projects such as the EU-funded H2020 CSA IM-SAFE focused on characterizing and systematizing performance indicators for both bridge structures and tunnel systems (Strauss et al. 2022). Within the context of employing monitoring systems for condition surveys, the IM-SAFE project provided a foundation for the use of performance indicators for bridges and tunnels, aiming to clarify the linkage between performance indicators and observations, and detailing how these indicators are or should be integrated into performance and risk assessments. Another extensive research has been collected in (fib Model Code for Concrete Structures 2010 2013 & fib Bulletin No. 109 2022) regarding the state-of-the-art on existing concrete structures life management, testing and structural health monitoring.

The SHM monitoring field, based on continuous data and the application of AI techniques and use of Digital Twins, has seen an increase in interest and applications only in the last decades, and as such there is still the need to further develop knowledge on damage indicators and techniques to locate and quantify the damage in reinforced concrete and prestressed structures and correlate the effect with the structural reliability. Research should focus on exploring data analytics techniques with a combination of different sensors technologies, to translate the research findings into robust and automatic data processes/algorithms for the continuous structural monitoring and quantification of model and measurements uncertainties. The fast-paced development of knowledge in the monitoring field of bridges in the recent years combined with increasing applications on real-case scenarios will enable the analysis of the structural response of existing bridge under ongoing deterioration processes. Sacertis Ingegneria S. r.l., Industrial Partner supporting the TWINS ERS development, has gained experience on the use of dense sensing on an Italian bridge network of over 150 bridges (Darò et al. 2023) that will be made available throughout the project development.

Excellence in the field of structural monitoring and diagnostics requires specific competences that encompasses various expertise: civil engineering, data analytics, programming skills, probabilistic and statistical knowledge, electronic background. This implies gaps in the data interpretation and structural response modelling due to the lack of such a wide training spectrum in a single doctoral program. The TWINS ERS Projects aims to keep the pace with the technological advancement (sensing devices) as well as the development of new data processing techniques applied to the civil engineering field, focusing on the definition of a Probabilistic Digital Twin (PDT), supported by SHM and semi-big data from observations and monitoring, that can provide a novel contribution to support integrity management with knowledge improved substantially over time.

3 UNCERTAINTIES IN THE DAMAGE DEFINITION: A PROBABILISTIC APPROACH

In civil engineering, numerical or mathematical models serve to simulate the behavior of real systems, enabling analysis, prediction, and design. In case of new structures, the numerical model employed for design verification often incorporates a higher degree of simplification. The scenario becomes more intricate when dealing with existing structures. In such cases, information regarding materials, history of loads, and interventions or modifications applied to the structure may be either unknown or only partially known.

When utilizing performance models, it is crucial to employ calibrated models achieved through parameter identification or estimation using model updating techniques. Model updating primarily aims to adjust unknown system properties, represented as parameters in numerical models, based on the observed behavior of the system of interest. In such analyses, special attention must be given to defining and modeling deterioration processes over time, to provide a preliminary assessment of structural performance evolution during the residual service life. While a conservative design does not typically result in a significant increase in structural cost, a conservative assessment may lead to unnecessary and costly repairs or replacement. To reduce model uncertainty, more refined and calibrated structural models (e.g., non-linear finite element models) can be utilized. Nonlinear finite element analysis is particularly useful for concrete structures in areas where simplified analytical models fail to predict structural resistances accurately, such as situations where nonlinear behavior related to material properties or geometry significantly affects structural reliability or where load effects are challenging to assess, due to the interaction between structural members or to the dynamic nature of the phenomenon.

Observations gathered from inspection, monitoring, and testing fall into two categories:

- Direct information: pertains to properties used in the assessment and verification that can be directly measured.
- Indirect information: relates to properties that cannot be directly measured. To address this, a specific indicator must be defined, and a model is required to connect the indicator to the relevant property (COST Action TU1406, 2015-2019).

Decisions concerning structures should account for all uncertainties of relevance for their performances such as measurement errors, aleatory uncertainties (affecting direct information, such as measured parameters, due to their inherent variability), model uncertainty (affecting indirect information which cannot be directly measured and is estimated using a model that links them to measured parameters), statistical uncertainty (due to a limited number of information) or other epistemic uncertainties (lack of knowledge about the structural system (as-built), numerical modeling uncertainties). Uncertainties related to data collection processes should also be considered in structural assessments using probability theory (ISO-2394, 2015). This can involve the use of probabilistic methods for performing reliability analysis or for updating the characteristic and design values of basic variables. Basic variables can be represented through random variables, random processes, and random fields, both discrete and continuous, depending on the nature of the problem. Probabilistic models should describe the uncertainties of individual random basic variables and account for dependencies among them.

When assessing existing structures, it is inappropriate to neglect the influence of deterioration, as these structures are already affected by damage mechanisms. Reliability analysis should consider the combined effects of cumulative deterioration and relevant actions during the service life. Models should explicitly incorporate the effects of deterioration on resistance, quantifying material-specific uncertainties. This approach allows the inclusion of damage performance models, consideration of multiple damage scenarios, and calibration of the models based on the structural condition at the beginning of the monitoring period. The spatial distribution of deterioration processes should also be considered, and uncertainties associated with models describing the propagation of deterioration over time should be addressed.

Structural health monitoring techniques can be employed to provide information about environmental influences, degradation processes, or structural performance, reducing uncertainties. In-depth experimental investigations become essential to reconstruct the structural organization, ascertain the materials used, understand their characteristics, and determine the potential state of degradation. Only through these comprehensive investigations is it possible to develop a reliable numerical model for existing structures. As per most of the standards analyzed, e.g. (CEN/TC- 250 2020, ISO-13822 2010 & ISO-2394 2015), updating the information relevant to the properties and the performance is an essential part of the assessment of existing structures. In assessment, an existing structure can be inspected/tested so that load, resistance, environmental parameters, and global static and dynamic response can be measured on-site and used to update the structural model.

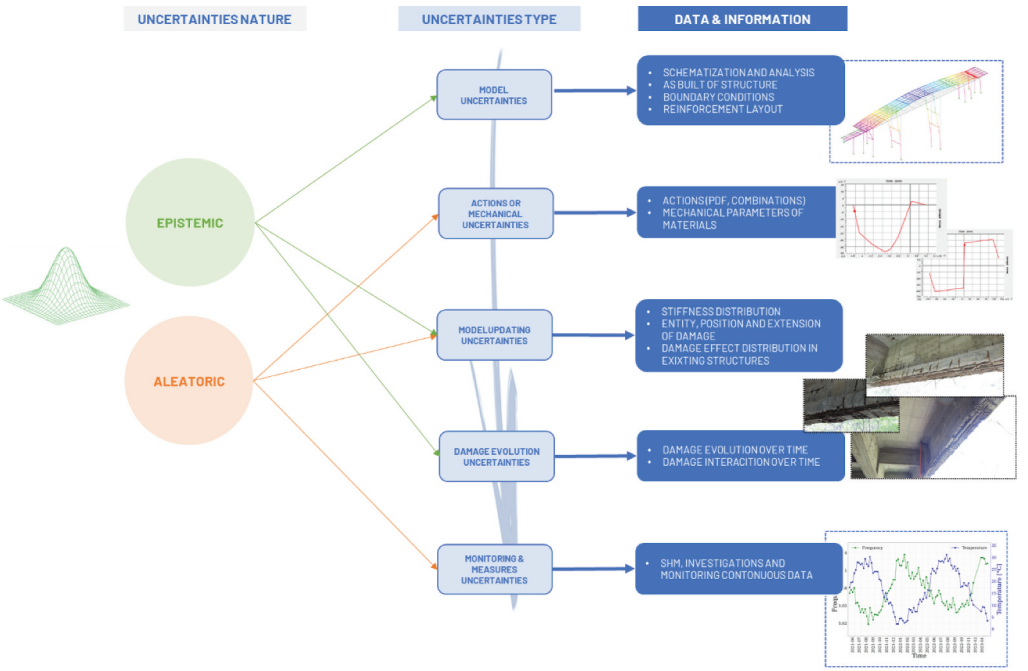

Figure 2. Uncertainties nature, type and basic variables to be described following a probabilistic approach in a PDT definition.

The information updating process can involve classical statistical methods or a Bayesian approach:

- Classical statistical methods: these methods revolve around estimating certain statistics of the parameters (e.g., mean values and/or covariance matrices) to optimize the correspondence between the statistics of the model's output and those of the observed data. This can

be achieved through analytical means (classical statistical inference methods) or numerically (stochastic model inversion) (Govers 2010);

- Bayesian approach: introduced in structural dynamics by one study (Beck & Katafygiotis, 1998), is a method of statistical inference that utilizes Bayes' theorem to update the probability of a hypothesis as new evidence or information becomes available. Through Bayes' theorem, prior probabilistic models constructed based on a priori information can be transformed into posterior models using available experimental data and the probabilistic prediction error model.

4 PROBABILISTIC DIGITAL TWINS (PDT) FOR BRIDGE INTEGRITY MANAGEMENT

Although materials, loads, boundary conditions as well as entity, position and extension of damage are random variables, they are often assumed in practice as deterministic during the modeling process as such simplification allows to strongly reduce the computational efforts of the modeling. However, integrity management often requires decisions that encompass long-term future performance affected by high uncertainty. Due to their deterministic nature, traditional digital twins may struggle to capturing uncertainties. Decision-making can be enhanced by connecting probabilistic models to the digital twin in the so-called Probabilistic Digital Twin (PDT). PDTs create a virtual representation of the structure that incorporates probabilistic models for material properties (e.g. concrete and steel strength), deterioration processes (e.g. corrosion and fatigues), loads (e.g. traffic, wind, seismic, environmental conditions) considering uncertainties in their distribution and variation in time. A probabilistic analysis (e.g. Montecarlo simulation) is performed to assess the structural response under varying conditions and to evaluate the probability of failure and remaining useful life of critical components. Real-time data from SHM are integrated in the PDT to refine the probabilistic models. PDTs can quantify and propagate uncertainties arising from measurement noise, component failure/degradation models, or uncertain relationships among events. In structural reliability analysis, failure probabilities are often computed based on the deterministic physical model of the structure developed during design or using a model updated using Structural Health Monitoring (SHM) data, as described in the previous section. PDTs allow for the continuous updating of the failure probabilities, providing insights into the remaining useful life of the structure. In the case of bridges with multiple potential failure locations, the simulation of a vast number of scenarios using a PDT can be computationally expensive. To address this challenge, surrogate models, which are approximate models trained for example by computationally expensive models, are frequently employed to expedite uncertainty analysis and decision-making processes. This simplification enables obtaining near-real-time predictions.

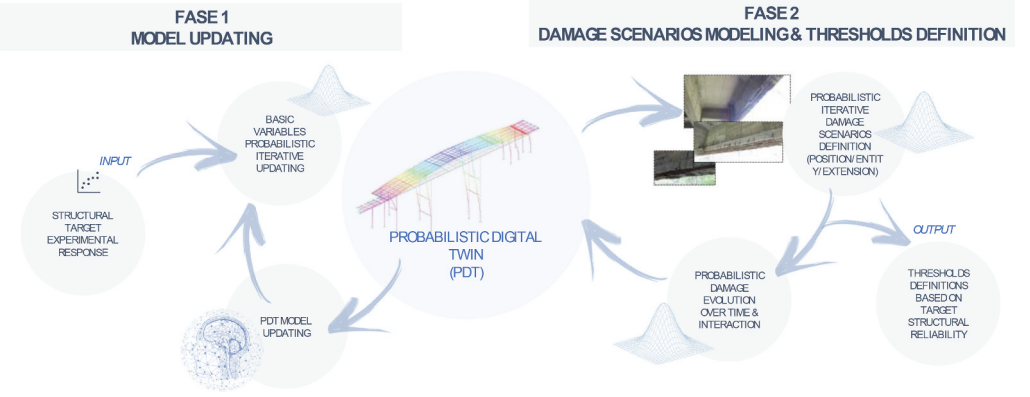

Figure 3. Model updating, damage scenarios modeling and thresholds definition using a probabilistic approach in a PDT definition.

In the TWINS project, we aim to develop an approach for constructing a Probabilistic Digital Twin (PDT) of a bridge by utilizing nonlinear finite element (FE) modeling to simulate the impact of deterioration, coupled with monitoring information provided by the industrial supervisor (Sacertis Ingegneria S.r.l). The investigation will encompass the exploration of multiple interactive damage scenarios, employing a probabilistic approach, where all the uncertainties are taken into considerations and varied during the iterative model updating analysis and thresholds definition. This approach is designed to enhance damage detection, structural assessment, and integrity management of the assets.

5 PROJECT METHODOLOGY AND EXPECTED RESULTS

In this project, an approach to build the PDT of a bridge will therefore be developed making use of nonlinear finite element (FE) modelling of the effect of the deterioration and monitoring information. The combination of multiple interactive damage scenarios will be investigated following a probabilistic approach to support the damage detection, structural assessment and integrity management of the assets. The expected results are as follows:

- New or refined knowledge regarding the effects on the structural performance and condition of various damage scenarios of reinforced and prestressed bridges;
- Identification of structural performance degradation combining FE modelling and real data collection;
- Development of a procedure to identify, estimate and locate damages in reinforced and prestressed concrete bridges based on a combination of static and dynamic indicators though the definition of a PDT of the reference bridge;
- Validation of the methodologies using both laboratory and field testing, consideration taken of uncertainties introduced by sensors measurements and of model uncertainties on the definition of the damage level;
- Correlation to the safety assessment and structural reliability with respect to the damage evolution forecast;
- Aim to foster a proactive maintenance approach in the asset management.

6 CONCLUSIONS

The rapid evolution of knowledge in bridge monitoring over recent years, coupled with an increasing number of real-case applications, is poised to facilitate the analysis of structural responses in existing bridges undergoing ongoing deterioration processes. The multitude of potentially diverse and interacting processes influencing or governing deterioration in bridges calls for system representations beyond the deterministic approach, which typically focuses on one or two processes and their corresponding models. Presently, there is limited knowledge regarding effective indicators and techniques to correlate observable performance in infrastructure structures with their structural reliability. Addressing this challenge, a Probabilistic Digital Twin (PDT), supported by Structural Health Monitoring (SHM) and big data derived from observations and monitoring, emerges as a promising solution. The present paper explored the preliminary analysis that lays the groundwork for the future full development of the PDT as part of the Bridgitise Project. Within the Bridgitise framework, an approach to construct the PDT of a bridge will be developed through the TWINS ERS Project, which endeavors to stay abreast of technological advancements, both in sensing devices and the development of new data processing techniques tailored to civil engineering. The project focuses on the novel approach that the PDT can provide to enhance knowledge and support integrity management over time. This involves leveraging nonlinear Finite Element modeling to simulate the effects of deterioration, combined with continuous monitoring data from real case studies. Sacertis Ingegneria S.r.l., an Industrial Partner contributing to the development of TWINS ERS, has garnered

expertise in dense sensing across an Italian bridge network comprising over 150 bridges, an experience that will be made accessible throughout the project development.

Nonlinear structural analysis of 50-year-old PC bridge deck beams under load testing

M. Anghileri & F. Biondini
Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: A robust validation of life-cycle reliability analyses and residual capacity assessment procedures is a difficult task to be performed due to limited availability of data of existing deteriorating bridges. This paper deals with computational modeling and experimental validation of nonlinear finite element analysis of deteriorating prestressed concrete (PC) structures. The structural modeling is developed with different levels of complexity and computational cost using a PC beam finite element model accounting for material nonlinearities and a bi-dimensional finite element model for plane stress analysis formulated in accordance with the Modified Compression Field Theory. The finite element approaches and the modeling strategies are validated based on the results of full-scale load tests up to collapse collected from the BRIDGE|50 research project aimed at investigating the residual structural capacity of 50-year-old PC bridge deck beams under different loading and damage scenarios.

1 INTRODUCTION

Life-cycle safety, reliability, and robustness assessment of deteriorating structures should be based on structural analysis frameworks capable to account for multiple time-variant factors, including the effects of aging and deterioration, loadings, environmental exposure, maintenance and repair interventions (Biondini and Frangopol 2016, ASCE 2023). Efficient and accurate life-cycle criteria, methods and tools need to rely on robust validation and accurate calibration procedures based on experimental evidence and data from existing structures. Even though life-cycle models for damage processes are well established in literature, their validation is a difficult task because of limited availability of data, particularly on condition state and time-variant performance of existing reinforced concrete (RC) and prestressed concrete (PC) structures (Biondini and Frangopol 2018). Gathering new data from both inspection of existing structures and experimental tests is therefore of essence for a successful implementation in practice of life-cycle methods. Within this context, the BRIDGE|50 research project has been established by Politecnico di Milano and Politecnico di Torino as part of an agreement with public authorities and private companies for a wide experimental campaign on a group of 29 PC deck beams and two PC pier caps taken from a viaduct dismantled in Turin, Italy, after a 50-year lifetime (Biondini et al. 2021a, 2021b). The experimental campaign includes non-destructive and laboratory tests on concrete and steel samples and full-scale load tests on the PC deck beams under several loading schemes (i.e., three- and four-point bending tests) to investigate both flexural and shear failures, and different damage scenarios for residual performance evaluations. Additional details about the research project and the ongoing experimental campaign can be found in Biondini et al. (2021a,b), Tondolo et al. (2021, 2022), Anghileri (2022), Savino et al. (2023). This paper presents the validation of nonlinear structural analysis methods based on the experimental results of load tests performed on two sets of PC deck beams, one with beams in a good state of preservation and one with beams affected by significant damage induced during the dismantling of the viaduct or intentionally applied prior to the experimental testing to investigate the residual structural performance.

2 FULL-SCALE LOAD TESTS OF PC BRIDGE DECK BEAMS

2.1 *PC bridge deck beams*

The PC bridge deck beams investigated in this paper have been dismantled from a 50-year-old viaduct and stored in a dedicated testing site managed by Politecnico di Torino. The beams have length of about 19.40 m and composite cross-section made of a precast PC I-beam and a top cast-in-situ RC slab. The RC slab was cast with the precast PC beams already in place under the effects of beam self-weight and prestressing. The precast beams are prestressed by twenty 7-wire steel strands. The nominal diameter of the steel strands is 12.7 mm (effective area 99 mm^2). The initial prestressing stress, net of instantaneous and estimated long-term losses, as reported in the technical design documentation, is σ_{pd}=836 MPa. Based on the results of full-scale load tests and diagnostic activities, the actual residual prestressing has been estimated as σ_p=614 MPa. This reduced value with respect to the design value is likely due to larger instantaneous and/or long-term prestressing losses and steel corrosion effects. The material mechanical properties have been evaluated from the available technical documentation, including the results of non-destructive and laboratory tests on both concrete and steel samples (Anghileri et al. 2023, Savino et al. 2023).

2.2 *Full-scale load test program*

Multiple full-scale load tests have been performed with a dedicated testing framework (Figure 1a) The tests are based on a four-point bending scheme (Figure 1b) with different shear span ratio $\alpha=a/l$ (i.e., a=shear span; l=half beam span), to investigate bending and shear failures of the PC beams with or without the top RC slab. The loading system includes four actuators, two for each point load. The applied load is transferred by two transverse steel beams to the PC beam simply-supported at both ends by the steel reaction frame through bridge bearings. The setup of the experimental sensors installed have been designed in order to monitor the global beam structural response during the full-scale load tests by means of displacement potentiometers, the local concrete and steel behaviour, and the strand slip and bearing settlements through transducers.

(a) (b)

Figure 1. (a) View of the experimental testing framework during a load test. (b) Four-point loading scheme, with shear span ratio $\alpha=a/l$, and setup of the measurement sensors.

The experimental program is ongoing. The first three beams of the series (Beams #1, #2, and #3) have been tested under three-point bending (i.e., $\alpha\approx1.00$). These beams attained a structural failure with full crushing in compression of the top RC slab in the critical region at mid-span. To investigate the structural capacity of the PC beam only, a fourth PC beam has been tested under three-point bending after the removal of the top RC slab (Beam #4). This beam reported a full-crushing in compression of the top region of the beam at mid-span. Two additional beams with top slab (Beams #5 and #6) have been tested under four-point bending (i.e., $\alpha\approx0.68$). These beams exhibited a structural failure which started with full crushing in compression of the top slab at mid-span or close to the applied loads, and then propagated through the entire beam cross-section.

This first group of six tested beams exhibited local damage in the end regions due to corrosion with steel mass loss and concrete spalling. These effects can be attributed to inadequacy of bridge water conveyance system and use of road salts during the bridge lifetime (Carsana et al. 2022, 2023). However, the visual inspection of the tested beams in the failure regions observed no significant corrosion of the prestressing strands. The effects of corrosion are therefore not considered in the experimental validation of this group of six beams.

A second group of PC beams characterized by significant structural damage is considered in this paper. During the dismantling of the viaduct, a core drilling machine has been used to create holes in the deck to accommodate the equipment for lifting the beams. These activities led to remove part of the concrete from both the top RC slab and bottom PC beam flange in different regions (i.e., mid-span and at about 4 meters from the beam ends). For some beams, these operations also led to unintentionally cut some prestressing strands and reinforcing steel bars located at the bottom beam flange (Figure 2a). These damaged beams are considered to investigate the role of structural damage on the structural response. The first damaged beam tested, namely Beam #7, presented four strands cut at the bottom flange of the beam both at mid-span and at about 4 meters from the beam ends (Figure 2a). The next beam, namely Beam #8, presented strands cutting at about 4 meters from the beam ends only, with no significant damage at the beam mid-span. Beam #8 under four-point bending test ($\alpha \approx 0.68$) showed a full-crushing in compression of the top slab at mid-span region and reported a structural response, in terms of load versus displacement diagram, similar to the behavior of undamaged beams tested with the same shear span ratio. Therefore, Beam #8 will not be considered in this paper for the experimental validation. Another beam, namely Beam #9, has been intentionally damaged by removing concrete cover and cutting eight prestressing strands at the bottom flange of the beam at mid-span region (Figure 2b).

3 FINITE ELEMENT MODELING OF PC BRIDGE DECK BEAMS

3.1 *Finite element modeling of RC/PC concrete structures*

Finite element formulations for nonlinear analysis of RC/PC structures have been proposed in literature with emphasis on a wide spectrum of features, including element discretization, robustness of the formulation, accuracy of the solution process, and computational cost (Malerba 1998).

A trade-off on these factors can be achieved by RC/PC beam finite elements (BFEs). The BFE formulation considered in this paper assumes the linearity of the cross-sectional strain field, accounts for the nonlinear constitutive laws of the materials, and neglects shear failures and bond-slip of steel. The structure is discretized in beam finite elements, the member cross-section

is subdivided into four-node isoparametric subdomains, as shown in Figure 3a, and numerical integration is performed using a Gauss-Lobatto quadrature rule (Bontempi et al. 1995).

BFEs allow for good accuracy if structural behavior is dominated by flexural failure modes. To account for shear effects and local stress-diffusion phenomena the Modified Compression Field Theory (MCFT) is considered for nonlinear plane-stress analysis of RC/PC structures (Vecchio and Collins 1986). The MCFT-based formulation is used in this paper also to better capture the beam-to-slab interaction effects affecting the structural response of the investigated PC deck beams. The structure is discretized into 2D constant strain triangle (CST) finite elements with smeared reinforcement, as shown in Figure 3b (Bontempi et al. 1994). Additional details about the adopted BFE- and MCFT-based formulations can be found in Anghileri (2022).

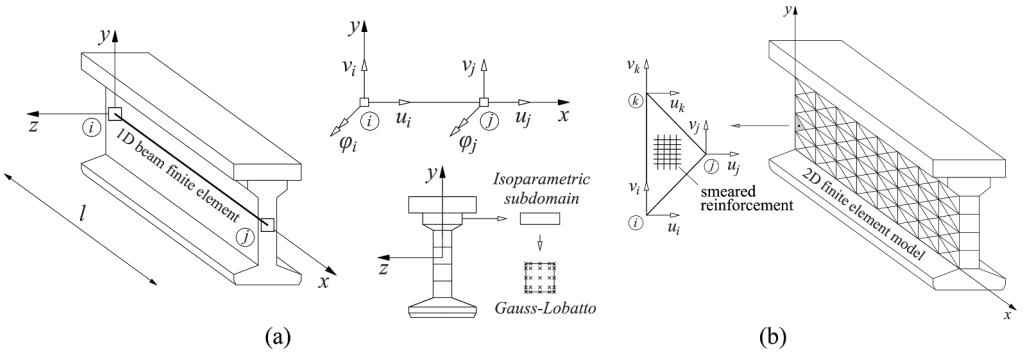

Figure 3. (a) BFE model with nodal displacements, isoparametric discretization, and Gauss-Lobatto integration scheme; (b) MCFT model with nodal displacements and CST elements with smeared reinforcement.

3.2 *BFE- and MCFT-based structural modeling*

The BFE model of PC deck beams with or without top RC slab exploits the symmetry and it is based on a discretization with 13 elements for the half deck beam, with one outer element with rectangular cross-section at the support region, one adjacent element with linearly varying width of beam web, and eleven inner elements with I-shaped cross-section. The slab is modelled using 13 additional elements with rectangular cross-section and the same discretization of the beam. The element nodal points are located at beam-slab interface and the offsets of the beam and slab axes are accounted for by transformation of coordinates.

The MCFT plane stress finite element model of PC decks beam exploits the symmetry and it is based on a discretization with 1128 CST finite elements for the half deck beam. The stirrups are modeled as smeared reinforcement over the beam volume (diameter of 8 mm and spacing of 250 mm and 100 mm for the inner beam segment with I-shaped cross-section and the outer beam segments with rectangular cross-section, respectively, as detected with pacometer-scan activity). Longitudinal reinforcing bars and prestressing strands are modelled as truss elements built over the CST finite element mesh. Separate nodal points are considered at the beam-slab interface with links to model the beam-to-slab interaction (Anghileri 2022, Anghileri and Biondini 2022, 2023).

For both BFE and MCFT formulations, the model discretization and numerical integration have been established for a trade-off between accuracy and computational cost.

4 NONLINEAR ANALYSIS AND EXPERIMENTAL VALIDATION

The BRIDGE|50 experimental activities are complemented by extensive numerical analyses to investigate the structural behavior of the tested beams and support a proper planning of the full-scale load tests. The non-destructive and laboratory tests performed on concrete,

reinforcing steel, and prestressing steel allowed to better calibrate the material mechanical characteristics. As an example, the original design documentation reported that the compressive strength recorded after 28 days of the precast PC beams averaged 50.3 MPa over 4 samples (Savino et al. 2023). However, uni-axial compressive strength tests performed on 17 samples extracted from several beams after the dismantling of the viaduct achieved a sample mean and CoV of concrete compressive strength equals to 29.94 MPa and 0.15, respectively, showing good agreement with the results of non-destructive tests processed through the SonReb method (Anghileri et al. 2023).

Visual inspection activities performed after the full-scale load tests allows also to better identify the reinforcing steel layout in both precast PC beam and cast-in-situ RC slab which was not exhaustively reported in the original design documentation.

The nonlinear structural analysis of both undamaged and damaged PC deck beams is performed in the following for numerical validation of the finite element formulations based on the results of the full-scale load tests. The experimental load protocol consists of a first loading phase up to concrete cracking, a stop under loading for the assessment of the concrete cracking pattern, a subsequent total unloading, and a reloading up to the beam collapse. The nonlinear finite element analyses are carried out under monotonic loading.

4.1 *Nonlinear analysis of undamaged PC beams without top slab*

The PC deck beam without top RC slab has been tested under a three-point loading (i.e., $\alpha \approx 1.00$) up to collapse. The beam exhibited a full-crushing in compression of the top mid-span region with collapse load Q=129 kN. To investigate the role of data and information gathered during the experimental campaign, nonlinear analyses have been performed considering the following case studies: Case (I) assumes the prestressing level (σ_{pd}) and material mechanical properties reported in the original design documentation and neglects the presence of the reinforcing steel bars; Case (II) introduces the material mechanical properties estimated from diagnostics; Case (III) additionally accounts for the estimated residual prestressing level σ_p; Case (IV) takes also into account the presence of the reinforcing steel bars. Figure 4a compares BFE-based numerical results and experimental results under three-point bending ($\alpha \approx 1.00$) in terms of load Q versus mid-span displacement d, net of self-weight and prestressing, of the PC beam without RC slab (Beam #4) for the four case studies. The close correspondence of Case (IV) with experimental results allows to validate the finite element formulation and the results of the experimental activities. Moreover, for Case (IV) Figure 4b indicates high accuracy also in terms of load versus concrete axial strain at mid-span region recorded through transducers located at the top and bottom slab of the beam.

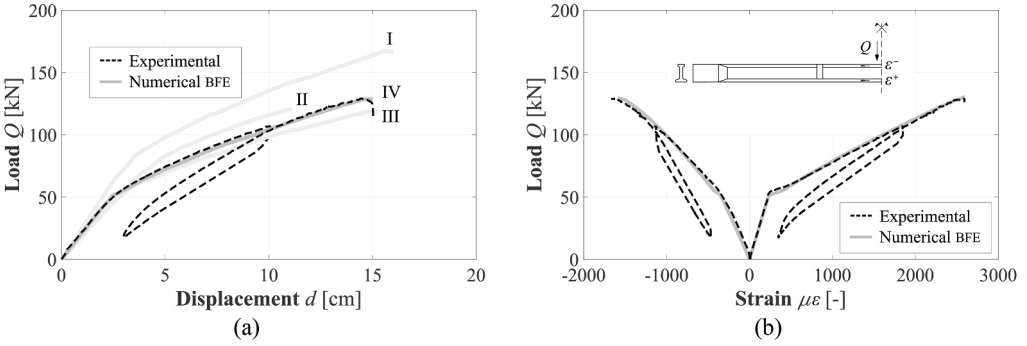

Figure 4. Numerical (BFE) vs experimental results for a PC beam without top slab (Beam #4): (a) Load Q vs mid-span displacement d for four Cases (I)-(IV); (b) Load Q vs axial strain ε at mid-span for Case (IV).

4.2 *Nonlinear analysis of undamaged PC beams with top slab*

A PC deck beam with RC slab under three-point loading (i.e., $\alpha \approx 1.00$) exhibited a failure in compression of the top slab in the critical mid-span region with ultimate load Q=161 kN and lack of connection between beam and slab at incipient collapse. To investigate the role of the top slab in the structural response, three different case studies are considered: Case (I) refers to a beam without top slab; Case (II) assumes monolithic beam-to-slab connection; Case (III) is based on separate beam and slab connected with links. In case (III), nonlinear analysis is developed based on a two-level incremental approach to account for the effects of the bridge construction process. In a first stage, the beam only is loaded with self-weight and prestressing. In a second stage, the two separate sets of finite elements (i.e. PC beam and RC slab) are connected at each pair of nodal points at the beam-slab interface by rigid links in the direction normal to the beam axis. The beam-slab interaction in the longitudinal direction is modeled by means of a set of longitudinal elastic links to be activated in the second stage only. These links are rigid up to concrete cracking. After concrete cracking, the links are elastic with stiffness k estimated to best fit the experimental results. Figure 5a compares MCFT-based numerical results and experimental results under three-point bending ($\alpha \approx 1.00$), in terms of load Q versus mid-span displacement d, net of self-weight and prestressing, of one of the tested PC beams with RC slab (Beam #2) for the three case studies. The best-fit stiffness value at beam-slab interface for the three-point loading scheme is k=3000 N/mm. A four-point bending test with shear span ratio $\alpha \approx 0.68$ has been also adopted for the PC beams with slab. The failure mechanism reported full crushing in compression of top slab near the applied load. Figure 5b compares the experimental results of one of these tests with ultimate collapse load Q=254 kN, in terms of Q versus mid-span displacement d, net of self-weight and prestressing, and the numerical MCFT-based numerical results (Beam #6) for Case (III). The best-fit stiffness value at beam-slab interface for the four-point loading scheme is k=11500 N/mm.

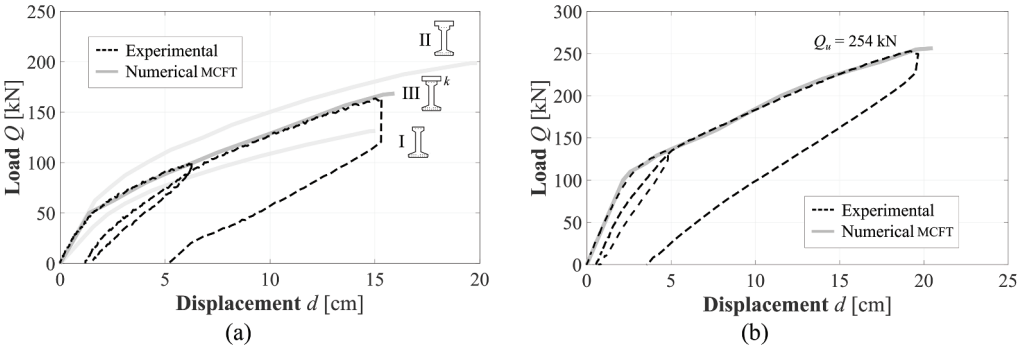

Figure 5. Load Q vs mid-span displacement d of PC beam with top slab: Numerical (MCFT) vs experimental results under (a) three-point loading (Beam #2) for three Cases (I)-(III), and (b) four-point loading (Beam #6) for Case (III).

The good agreement between experimental and numerical results obtained for both BFE and MCFT validates the finite element formulations and the modeling strategies under flexural failures. Additional details about the experimental results and numerical validation of the finite element models for the first group of undamaged beams can be found in Anghileri and Biondini (2022, 2023). Further investigations are necessary based on future load tests with reduced shear span ratios to investigate the accuracy of the proposed modeling under shear failures.

4.3 *Nonlinear analysis of damaged PC beams*

The PC deck beams with top slab and structural damage have been tested under four-point loading (i.e., $\alpha \approx 0.68$) up to collapse. Beam #7, with part of the concrete removed from both

the top slab and bottom beam flange and four strands cut at the bottom flange, both at mid-span and at about 4 meters from the beam ends, has been tested with preliminary loading phase up to Q=118 kN, a subsequent unloading and final reloading up to the collapse load Q=211 kN. The failure mechanism was characterized by the crushing in compression of top slab and cracking in tension of the bottom beam flange in the mid-span region (Figure 6a). Beam #9, damaged with intentional cut of eight prestressing strands in the mid-span region, has been tested with a first loading phase up to Q=77 kN, a subsequent unloading and final reloading up to the collapse load Q=145 kN, attained with a full crushing in compression of the top slab (Figure 6b).

(a) (b)

Figure 6. Failure mechanisms: (a) Beam #7, with crushing in compression of the top slab and cracking in tension of the bottom beam flange; (b) Beam #9, with crushing in compression of the top slab.

The nonlinear finite element analysis of beams #7 and #9 is carried out considering the removal of the cut strands and steel bars from the finite element meshes. Moreover, beam and slab width has been properly reduced to reproduce the concrete damage. Figure 7 compares numerical and experimental results in terms of load Q versus mid-span displacement d, net of self-weight and prestressing, for Beam #7 (Figure 7a) and Beam #9 (Figure 7b) after the four-point bending test. The best-fit stiffness value at beam-slab interface is k=11500 N/mm also for the damaged beams.

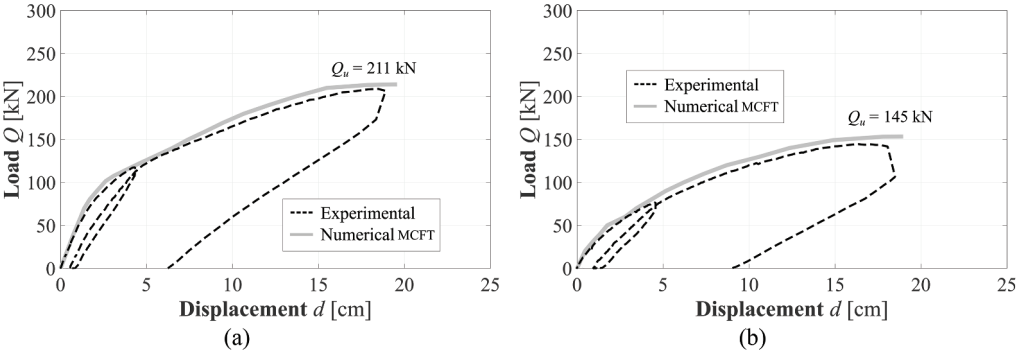

Figure 7. Numerical (MCFT) vs experimental results in terms of load Q vs mid-span displacement d of PC beams under four-point loading: (a) Beam #7; (b) Beam #9.

Overall, the good agreement between numerical and experimental results considering different damage scenarios validates the finite element formulations and the damage modeling strategies under flexural failures. Further investigations are necessary based on future load tests under shear failures. Despite this need, the results of the validation process presented in this

paper allows to complement the experimental activities with numerical analysis to further investigate the structural behavior of the tested beams and support a proper planning of the ongoing load tests.

5 CONCLUSIONS

The comparison of experimental and numerical results based on nonlinear finite element analysis of RC/PC structures has been presented. The results of full-scale load tests on several 50-year-old PC bridge deck beams under different loading and damage scenarios have been considered for the validation process. The structural modeling has been developed with different levels of complexity and computational cost using a PC beam finite element model accounting for material nonlinearities and a bi-dimensional finite element model for plane-stress analysis formulated in accordance with the Modified Compression Field Theory. The material characteristics and the modeling strategies have been calibrated based on the results of visual inspection activities, non-destructive tests and laboratory tests on both concrete and steel samples. The role of structural damage in the residual capacity of PC beams has been also investigated. The impact of data and information gathered during the overall experimental campaign on the beam structural response have been evaluated through the comparison of experimental and numerical results considering different case studies. The good agreement between numerical and experimental results allows to validate the finite element formulation and the modeling strategies and to support a proper planning of future full-scale load tests associated to different shear span ratio and additional damage scenarios. Future developments will be devoted at evaluating the accuracy of the finite element models with full-scale load tests associated to shear-dominant failure mechanisms and characterized by beams under corrosion. Moreover, the large amount of data and experimental outcomes will allow to extend the validation process on a statistical basis for a probabilistic description of the structural response of the investigated PC bridge deck beams.

F. Biondini
Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The structural elements considered in this paper are stored in the testing site of BRIDGE|50 research project after the dismantling of a 50-year-old viaduct. They are representative of the use of reinforced and prestressed concrete in the XX century and offer the opportunity to characterize corrosion behavior of full-scale concrete deck beams under different degradation conditions through experimental investigations. This paper presents the results obtained by means of electrochemical methods (such as corrosion potential and electrical resistivity) and by performing some chemical and physical analyses on concrete samples collected from selected beams. Such results provide the bases to investigate the feasibility of applying electrochemical techniques aimed at advanced repair strategies of existing deck beams for eventually reusing them in new constructions. On the other hand, the application of such techniques might also allow to induce on the same beams accelerated ageing processes for simulating more aggressive conditions.

1 INTRODUCTION

Since the beginning of the last Century, the use of reinforced concrete (RC) became a worldwide common practice in the construction of structures and infrastructures. Unfortunately, the widespread use of RC has raised serious durability problems as a consequence of corrosion of steel reinforcement which is an electrochemical phenomenon, as illustrated in Figure 1a (Bertolini et al. 2013, Carsana et al. 2023). Nowadays, durability has become a critical issue for life-cycle assessment, maintenance, monitoring, and management of existing concrete structures (Biondini & Frangopol 2016). For this reason, tools and procedures for monitoring of corrosion in RC structures, which are essential to achieve suitable levels of durability (Carsana et al. 2022), have been developed (Bertolini 2008).

As known, corrosion processes affecting the service life of RC structures include initiation of corrosion, in which the reinforcement is passive but some phenomena can lead to loss of passivity (e.g. carbonation or chloride penetration) and corrosion propagation after the steel is depassivated (Bertolini 2008). The duration of the initiation phase depends on the depth of reinforcing bars, the quality of concrete cover and the penetration rate of the aggressive agents as well as on the microclimatic conditions at the concrete surface.

The initiation time can also be affected by any form of polarization of the steel reinforcement promoted by means of applying electrochemical techniques which relay on the same principles of corrosion, as shown in Figure 1b. For instance, a small amount of cathodic polarization makes the occurrence of pitting less probable and increases the initiation time, while an anodic polarization, which might be due to an electric connection with reinforcement

DOI: 10.1201/9781003483755-411

with higher potential or external electric fields, could promote corrosion initiation (Bertolini et al. 2008).

The knowledge of corrosion process and availability of methods for its control play an important role for providing practitioners with adequate tools to solve durability problems of reinforced concrete structures (Bertolini et al. 2013, Biondini & Frangopol 2019, Elsener et al. 2003).

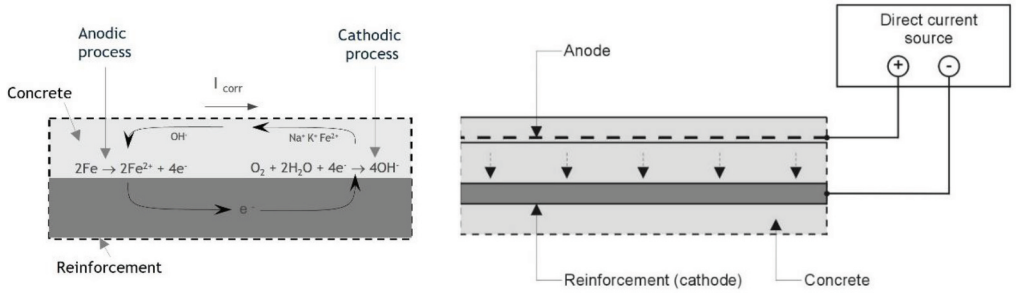

Figure 1. (a) Corrosion process of reinforcing steel in non-protective concrete at microscopic level. (b) Scheme of electrochemical techniques applied on a reinforced concrete element.

To this aim, it is important to advance knowledge not only through experimental studies carried out in laboratory, but also by means of corrosion investigations on real-scale structural elements.

A strong impulse along these research lines is given by the BRIDGE|50 research project which involves Politecnico di Milano and Politecnico di Torino, as well as several public authorities and private companies, for a large experimental campaign aimed at investigating the residual structural performance of an existing 80-span prestressed concrete (PC) viaduct demolished after a 50-year service life (Biondini et al. 2021a, 2021b).

The BRIDGE|50 research project is allowing to exploit the results obtained on real-scale elements, deriving from a long exposure to operating conditions and currently stored in a testing area (Figure 2) dedicated at both non-destructive (Carsana et al. 2021a) and destructive testing.

Figure 2. View of the PC deck beams stored in the BRIDGE|50 testing site.

This paper presents the results obtained by means of electrochemical methods (COST 2003), such as the measurement of corrosion potential and electrical resistivity, and by performing some chemical and physical analysis on concrete samples collected from selected beams. Such results provide the bases to investigate the application of electrochemical techniques aimed at advanced repair strategies of existing deck beams for eventually reusing them in the new constructions. On the other hand, the application of such techniques might allow also to induce on the same beams accelerated ageing processes for simulating more aggressive degradation conditions.

2 EXPERIMENTAL PROCEDURE

2.1 *Testing site*

In 2019, after a 50-year lifetime in an urban environment of Northen Italy (Turin), Corso Grosseto Viaduct was demolished. The viaduct consisted of 80 spans of variable length from 16 meter to 24 meter. Each span of the deck is composed by 10 inner precast PC I-beams and two external precast box girders with U-shape with top slabs (box-beams), all supported by PC pier caps. Two adjacent spans of the viaduct have been preserved and deconstructed, including 29 precast PC beams (twenty-five I-beams and four box-beams) and two pier caps. These elements are currently stored in a testing area dedicated to both corrosion and structural investigations. Based on visual inspection, few beams (one for each type), considered representative of different degradation conditions, were subjected to electrochemical measurements (see Carsana et al. 2021a for more details). Moreover, some concrete samples were also collected on the selected beams.

2.2 *Electrochemical measurements and sampling*

In order to assess the degradation state of reinforcing steel bars of the inspected PC deck beams, the cover depth of the outermost bars was detected with a magnetic-type covermeter. The corrosion behavior of the reinforcement was investigated by means of electrochemical measurements.

The corrosion potential of steel was mapped on the concrete surface using a CSE (Copper Sulphate Electrode, $Cu/CuSO_4$) reference electrode (Elsener). The electrical resistivity of concrete was measured by placing a resistivity probe connected to a conductivity-meter on the surface.

Preliminary measurements of corrosion rate were also carried out in some localized zones of inspected PC elements. The sampling of concrete for laboratory analysis was also carried out.

Cores of diameter 45.5 mm and length of at least 160 mm were taken from the longitudinal or transversal front of structural elements. Moreover, several samples of concrete powders were also collected directly by drilling at several depths with a tip of 10 mm diameter being this method considered much less invasive than taking a concrete core.

Carbonation depth was measured by spraying phenolphthalein on concrete powders collected at increasing depth or on concrete cores taken from RC/PC beams. Chloride analyses were carried out both on concrete powder samples as well as on 10 mm concrete slices in which each core was divided to determine total chlorides profile as a function of depth. Both powder samples and concrete slices, the latter once ground, were dried and digested in hot nitric acid. The chloride content was measured by means of potentiometric titration and expressed as percentage of the dry concrete.

3 RESULTS

3.1 *Corrosion assessment*

Measurements of corrosion potential (E_{corr}) versus CSE reference electrode were carried out on the longitudinal front of a pier cap along the nodes of a grid traced on the concrete surface

with 30 cm spacing, at different distances from the top of the element (Figure 3). According to the criteria of the American Standard ASTM C876, for E_{corr}> -200 (mV vs CSE) the probability of corrosion is less than 10% while for E_{corr}< -350 (mV vs CSE) the probability of corrosion is higher than 90%. Overall, the corrosion potentials measured on a selected pier cap were higher than -240 mV vs CSE. In several parts of the pier cap corrosion potential showed values lower than -350 mV vs CSE, highlighting that, at the time of the measurements, the corrosion rate of steel bars was not negligible. In fact, the corrosion conditions of steel bars of the pier cap appeared quite severe (Figure 3b). Pier cap showed evident signs of deterioration from corrosion of the reinforcements to wide detachments of the concrete cover; moreover, parts of the reinforcements were no longer embedded in concrete and they were heavily corroded.

Similar measurements were also carried out on one of the several I-beams stored in the testing site and considered visually similar. More positive corrosion potentials were measured on I-beam (Figure 4a). Overall, values higher than -200 mV vs CSE were measured at the time of inspection, regardless the height. No clear signs of corrosion-induced damage were observed on I-beams, except in their end parts where concrete segregation was visible (Figure 4b). The presence of segregation and macro-voids (Neville 2011) could have led to early degradation in those parts.

The interpretation of the corrosion potential is not so obvious because the concrete cover and its resistivity, in addition to the actual corrosion potential of the steel, influence the readings at the concrete surface at the inspection time. Important information can be obtained by considering also results from both electrical resistivity and corrosion rate measurements. For instance, Figure 5a shows the relationship between the corrosion potential of steel and the electrical resistivity of concrete measured on a box beam in the testing site. It can be deduced that the points associated to negative corrosion potentials and low electrical resistivity represent wet corroding zones, where steel bars are in contact with carbonated and/or chloride-contaminated concrete, while those with positive potentials and high resistivity indicate dry conditions and passive zones. The outcomes of investigations reported in a previous paper (Carsana et al. 2021) indicate that lower values of potential were only measured along the first 12-15 m of the beam in its bottom part where the concrete showed also the lowest electrical resistivity and it is affected by phenomena of efflorescence which could confirm the use of deicing salts. Inspected deck beams were monitored also in terms of corrosion rate. The worst conditions were observed on steel bars of the pier cap and box beam for which average corrosion rates of 4,18 mA/m^2 and 6,21 mA/m^2, respectively, were measured (Figure 5b). Conversely, a negligible corrosion probability is confirmed by a corrosion rate of 0,74 mA/m^2 for the inspected I-beam.

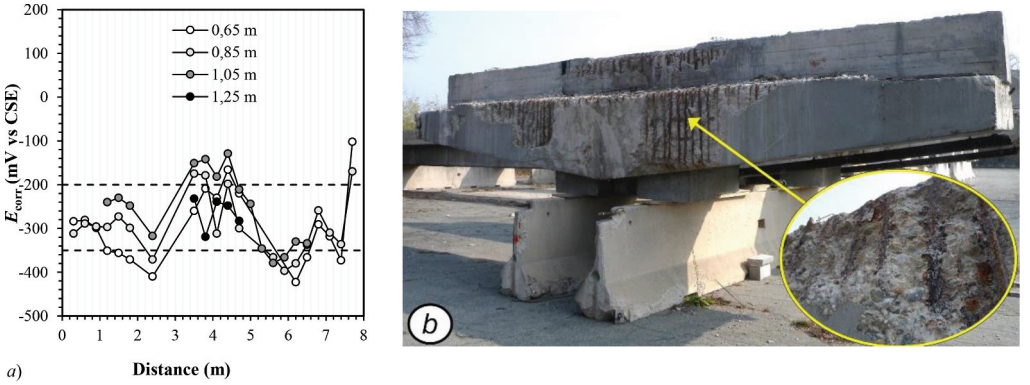

Figure 3. (a) Corrosion potential (E_{corr}) profiles measured on the longitudinal front of a pier cap at different heights. (b) View of degradation state of the pier cap.

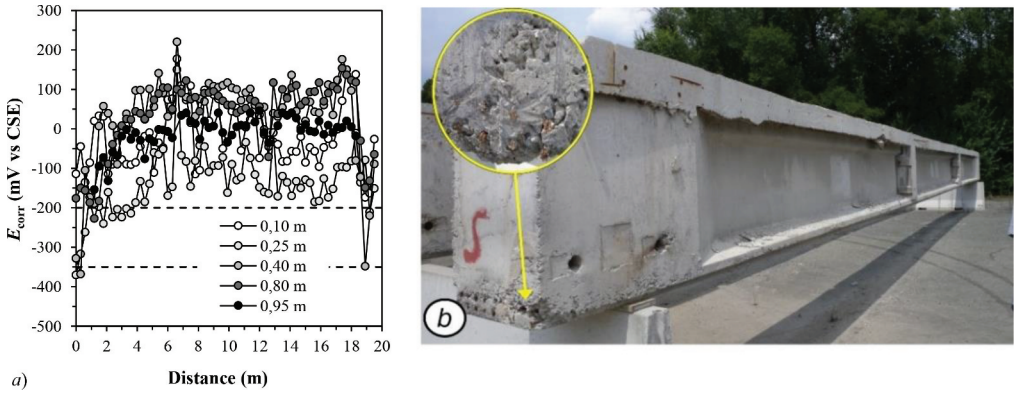

Figure 4. (a) Corrosion potential (E_{corr}) profiles measured on the longitudinal front of a box beam at different heights. (b) View of degradation state of the box beam.

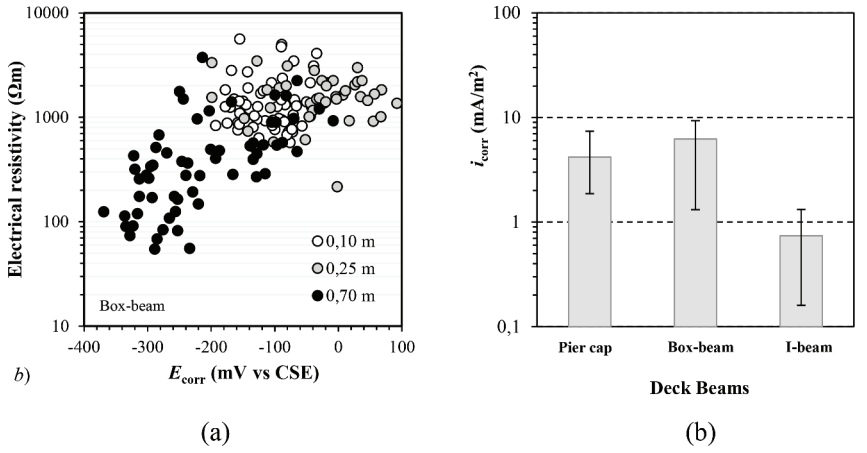

Figure 5. (a) Corrosion potential of steel reinforcements versus concrete electrical resistivity measured on the longitudinal front of a box beam. (b) Corrosion rate measured on different representative deck beams (pier cap, box beam, and I-beam) along their longitudinal front.

To assess the actual state of steel bars embedded in concrete, the evaluation of electrochemical aspects should be integrated with further analyses. Thus, taking of concrete samples is necessary to also evaluate the carbonation depth (Figure 6a) and chloride content of concrete (Figure 6b) at the time of measurement and to allow to predict the future deterioration of the structure or to assess its residual lifetime.

From the comparison of the average value of the carbonation depth with the average value of the concrete cover thickness (Figure 6a), it follows that steel reinforcement of longitudinal and transversal front of inspected I-beam should be in contact with an alkaline concrete. Concrete of pier cap and box beam showed to be less carbonated than that of I-beam. Based on the carbonation depth measured after 50 years on I-beams and related carbonation coefficient (3,2 mm/$y^{0.5}$), it can be inferred that the carbonation front will reach steel rebars no earlier than the next 50 years. Since the carbonation fronts also of box beam and pier cap are lower than the average values of reinforcement depth (22-23 mm), it could be deduced that rebars were mainly corroding at the time of inspection for other causes. Samples collected from same structural elements have been also subjected to the measurement of chlorides content. Figure 6b shows that the chloride profile measured on inspected pier cap overcome the critical

chlorides threshold for carbon steel (0,05-0,125% in mass of concrete) also far beyond average cover thickness with maximum values of 0,42% vs concrete mass. Conversely, for deck beam the risk of chlorides-induced corrosion shall be considered low at inspection time. In fact, chlorides content was below critical chlorides threshold at any concrete depth.

Results presented in this section has highlighted that the main causes of structural deterioration are associated to chloride penetration due to de-icing salt especially for the inspected pier cap and box-beam. In fact, significant signs of degradation were often observed in those parts of the bridge deck that were exposed to wetting, probably in absence of adequate systems of collection and conveyance of rainwater coming from the span, especially in correspondence of pier caps which support the terminal parts of beams (Figure 3b).

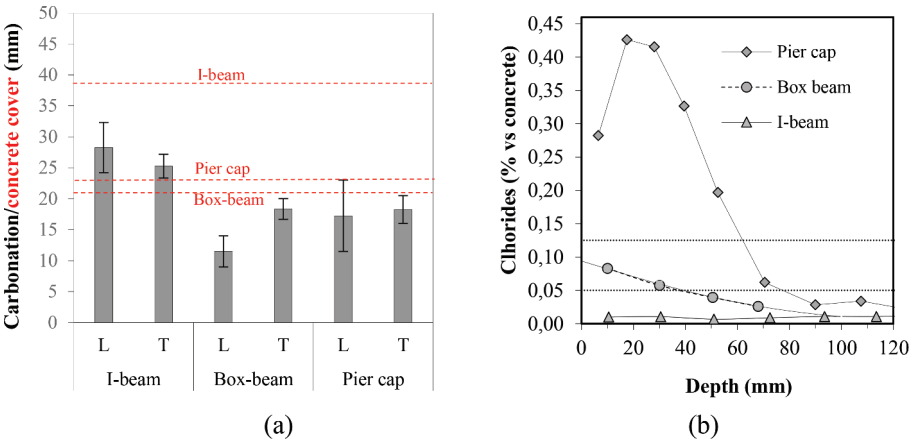

Figure 6. (a) Results of phenolphthalein test carried out on concrete samples collected from both longitudinal (L) and transversal front (T) of inspected deck-beams. Average concrete cover for each structural element is indicated with a dotted red line. (b) Chlorides profiles of inspected deck-beams (dotted lines indicate typical minimum and maximum values of critical chloride threshold).

3.2 *Further corrosion investigations*

Based on electrochemical measurements carried out on several structural elements stored in the testing site, it can be pointed out that the best conditions were observed on steel rebars of I-beams; in fact, a negligible corrosion probability was confirmed in terms of corrosion potential (mainly ranging between -150 mV and -50 mV vs CSE) and corrosion rate lower than 1 mA/m^2. Moreover, the presence of negligible chlorides content (below critical chlorides threshold at any depth), as well as a carbonation depth lower than concrete cover, allow to state that steel rebars of I-beams are in passive state being embedded in a protective concrete.

For this reason, among all deck beams stored in the testing site, I-beams are the most suitable to be subjected to further corrosion investigations.

The obtained results establish the bases to investigate the application of electrochemical techniques aimed at monitoring (1) the initiation and propagation of corrosion of I-beams due to exposure to more aggressive conditions than those to which they have been exposed so far and, subsequently, (2) the evolution of corrosion of the reinforcements once started in I-beams. In particular, the control of corrosion evolution should be aimed at developing advanced repair strategies of existing deck beams for eventually reusing them in new constructions. This challenge will require to carefully assess which of the different repair techniques (Bertolini et al. 2013) could be considered for structural elements already corroding due to carbonation or chloride penetration.

Considering the obtained results, the next experimental studies will focus on monitoring of corrosion process of I-beams when exposed to conditions different from those at the time of inspection, for instance after thorough wetting with water in case of active rebars (Bertolini

et al. 2008) or after ponding cycles with chlorides solution to simulate natural penetration of chlorides in concrete and promote pitting corrosion initiation. As an alternative, the application of electrochemical techniques might allow also to induce on comparable beams accelerated ageing processes for simulating more aggressive degradation conditions (Bertolini et al. 2013).

The I-beams stored in the testing site are also suitable for sampling of concrete portions of sufficiently large volume to include steel rebars. Some reinforced specimens could be obtained by coring selected zones of the I-beams and could be appropriately prepared and equipped for electrochemical tests in laboratory or natural exposure conditions (Redaelli et al. 2014). The corrosion behavior of steel rebars of such reinforced specimens could be studied as a function of concrete moisture and temperature, both in free corrosion conditions and through polarization of steel potential. Finally, the comparison of electrochemical parameters obtained by means of in-situ tests made on the real scale elements and laboratory studies on reinforced specimens might also considered.

4 CONCLUSIONS

In the framework of the multiparter research project BRIDGE|50, a wide experimental campaign of field and laboratory tests concerning real scale RC/PC elements, such as those collected from a 80-span viaduct dismantled in Turin in 2019 after 50 years of service life and stored in a dedicated testing site, is ongoing.

The results presented and discussed in this paper have highlighted that the main causes of deterioration of such structural elements are associated to chloride penetration due to de-icing salts. Significant signs of degradation were observed in those structural elements of the deck (such as pier caps and box-beams) that were more often exposed to wetting, probably in absence of adequate systems of collection of water coming from the span.

Based on electrochemical measurements carried out on several structural elements stored in testing site, it can be pointed out that the best conditions were often observed for I-beams. Therefore, I-beams result the most suitable to be subjected to further corrosion investigations aimed at investigating the possible application of different electrochemical techniques on real-scale elements. On the other hand, it could be useful and interesting to provide and plan a similar trial on low scale by exploiting reinforced specimens sampled from selected zones of same I-beams and appropriately prepared to be subjected to electrochemical tests.

ABSTRACT: This paper presents the results of three large scale experimental tests within the survey conducted on 50-year-old prestressed concrete (PC) girders for the BRIDGE|50 research project (www.bridge50.org). The girders were retrieved from a viaduct before dismantling operations once located in the urban area of Turin, Italy. Together with other structural members they represent one of the most prominent project of this type worldwide. The PC elements have 19.2 m span length and I-shaped cross section with 14 cm cast-in situ slab with variable damage due to deterioration caused by both service and lifting operations during dismantling phase. For each specimen, static tests have carried out applying monotonic or cyclic loading up to the ultimate load, measuring deflections, loads and strains in several positions for two I beams and one box beam. The results of the tests in terms of load-deflection responses and strains are reported for each beam investigated and compared considering previous tests from the same project already reported in literature. The experimental findings highlight the specific structural response and residual capacity of the tested members in presence of damage, cyclic loading and different tested section. The outcomes of the project will provide a valuable database of reference for the assessment of the residual structural performance of existing bridges.

1 INTRODUCTION

Bridges in service are subjected to environmental exposure which is responsible of durability problems. The impact of these aggressive attacks may involve a significant reduction up to the total loss of load-carrying capacity. Moreover, traffic demand is continuously growing, both in terms of number and weight of vehicles. In addition, as civil infrastructures age, uncertainties on the prediction of structural response increase due to the deterioration mechanisms and their scattered nature (Ellingwood 2005, Biondini & Frangopol 2016). As a result, structural assessment has received much attention in recent decades from different perspectives, including structural health monitoring techniques employed to collect data for structural condition evaluation and early warning detection. Most of the experimental research activity in this field has been done investigating laboratory specimens, under controlled environment. However, full-scale load tests on existing structures are fundamentals to better understand the structural behaviour and to calibrate structural models. The latter applies to models from structure to material scale that are even more required for safety evaluations (Franceschini et al. 2022, 2023). But, large-scale tests on civil infrastructures, are not widely performed also because they involve irreversible damages which led to the dismissing of the structure or part of it. Furthermore, huge human, financial, and material efforts are required, and as reported in Recupero & Spinella (2019), only few studies have been carried out on full-scale prestressed concrete (PC) girders from decommissioned bridges around the world (Wang et al. 2020). Assessment of existing bridges requires a thorough understanding of their structural behavior.

DOI: 10.1201/9781003483755-412

However, the investigations usually concern small samples of structural members and basically focusing on few characteristic parameters of the structural response. A systematic assessment of a number of specimens under different loading test setups is required to investigate the failure mechanisms and thus developing realistic estimates of the residual capacity. Moreover, this survey allows to take into account the influence of coupled precast and cast in situ concrete parts which work together in the final configuration.

BRIDGE|50 research project was specifically defined to study the residual structural performance of 50-year-old viaduct members and provide a framework for safety assessment and residual lifetime evaluation of existing bridges (Biondini et al. 2020, 2021). A wide experimental campaign was planned to investigate PC I-girders, PC box girders, and pier caps recovered from the C.so Grosseto viaduct, a viaduct built in Turin in 1970 and decommissioned in 2019. Updated information on the BRIDGE|50 research program is posted on the project website (www.bridge50.org). Multiple load test setups were considered to study flexural, flexural/shear, and shear failure mechanisms. The first group of four PC beams was tested under three-point bending configuration and detailed in Tondolo et al. (2021, 2022) and Savino et al. (2023a). The second set of members, subjected to a four-point bending test setup are reported in Savino et al (2023b). The present paper reports the experimental results of the third group of three beams tested under four-point bending configuration up to failure. The reported parameters not only extend the database aimed at providing further knowledge on the structural response of 50-year-old PC beams but could be used to setup and calibrate mechanical models.

2 CORSO GROSSETO VIADUCT

The Corso Grosseto viaduct was a road bridge located in Turin, Italy (Savino et al. 2020). The structural scheme of the PC viaduct was with simply supported spans: a widespread solution in Italy and around the world. The deck was composed by ten PC I-shaped girders and two PC box girders at the edges, with a support distance between 16.0 and 24.0 m and two diaphragms connected the longitudinal girders at the third points (see Figure 1). The superstructure was completed by a cast-in-situ slab of 140 mm.

An overview of the retrieved structural members in their original deck configuration is shown in Figure 1. The elements coloured represent the collected ones; the girders depicted in blue belong to the first and second group of tests whereas the elements highlighted in red refer to the girders investigated and reported in the present work. All the elements were properly identified with a code, according to the original configuration. The PC beams studied in the present work were identified as B5-P46/47, BX2-Ab/P47, B2-P46/47 according to classification reported in Savino et al. (2023).

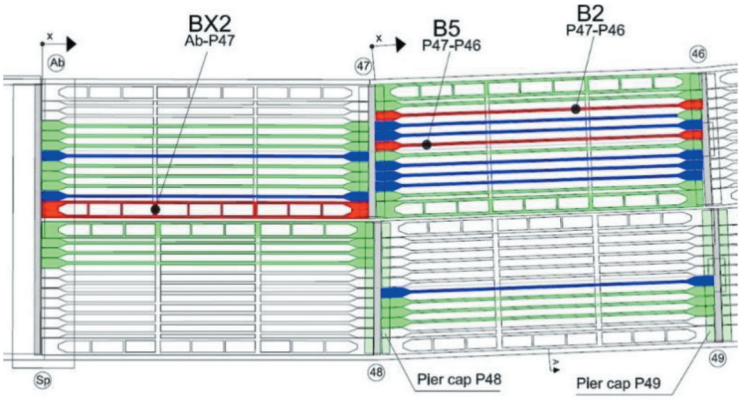

Figure 1. Layout of the retrieved and studied elements (green: beams to be tested; blue: previously tested and reported in other papers; red: investigated in this paper).

2.1 *Tested girders details*

All the girder beams were 19.5 m long, with I-shaped cross-section as shown in Figure 2a for beams B5-P46/47 and B2-P46/47 and box-section as shown in Figure 2b for beam BX2-Ab /P47 (from design documentation). Cover depths were 45 mm for prestressed strands and 10 mm for ordinary reinforcement. Prestressing reinforcement was composed of seven-wire strands with a nominal diameter of 12.7 mm and according to the design documentation, the tensile strength was of 1638 MPa. The prestressed reinforcement configuration consisted of 17 strands for I-beams and 34 strands for box-beam, located in the bottom flange. Additionally, there were 3 strands for I-beams and 6 strands for box-beams located in the top flange. The stirrups are made by 8 mm ribbed steel spaced of 250 mm. The 14 cm cast-in-situ slab was reinforced with a square pattern of rebars. The maximum allowable stress for the strands at the tensioning stage was 1400 MPa. The concrete compressive strength at 28 days was designed to be 30 MPa. No specific requirements were reported for the cast-in-situ slab.

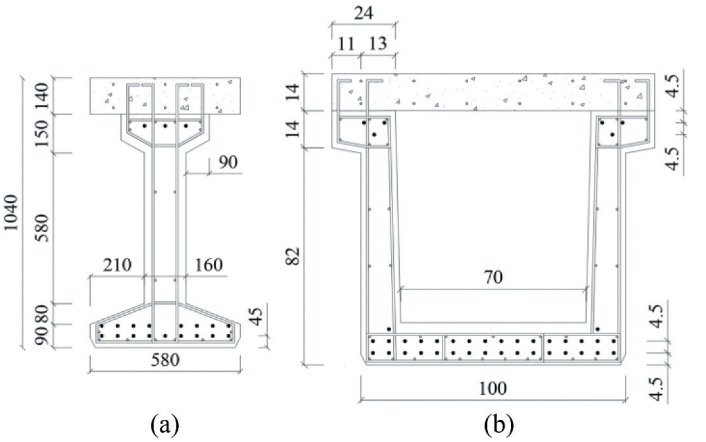

Figure 2. Cross-section of the beams (units in mm): (a) I-beam; (b) Box-beam (from design documentation).

According to the diagnostic campaign performed before the load tests session, the beams investigated in this paper were considered in good conditions. Beam B5-P46/47 was intentionally damaged by cutting 8 strands at the midspan to induce a different failure mode from that observed in previous tests (Savino at al. 2023b), as depicted in Figure 3. The damage was created by cutting a total of eight strands in the bottom flange at a distance of 60.0 cm from the girder midspan on either side.

Girder BX2-Ab/P47 had the curb on the top slab; in order to avoid torsional effect, a preventive regularization of the upper surface was carried out by cutting it with a diamond blade.

3 SETUP OF THE FULL-SCALE LOAD TESTS

For the purpose of testing the PC girders, a proper reaction steel frame was made available by the Interdepartmental Center SISCON (Safety of Infrastructures and Constructions) of Politecnico di Torino. Each beam was tested under a simply supported static scheme under a four-point loading configuration adopting shear spans of 650 cm. The loading system details and the specifics of the employed equipment can be found in Savino et al. (2023a). The girders were tested according to multiple loading phases. The multiple loading cycles also allowed to perform the dynamic characterization of the specimens at different level of damages (Quattrone et al. 2020, Sabia et al. 2021, 2022, 2023). In particular, the first loading phase was

Figure 3. Strands cutting in B5-P46/47 girder (bottom view).

meant to reach the stabilized cracking pattern to evaluate the residual prestressing during the following crack reopening phase.

In detail, B5-P46/P47 was tested with two loading cycles, Bx2-Ab-P47 was tested with three cycles of which the second cycle had maximum loading corresponding to half of the expected capacity; finally, B2-P46/P47 was tested with three sets of five cycles each before reaching the final stage up to failure. This choice was motivated by the intention to induce the effect of cumulative damage at different levels and collect the effects on both the dynamic behaviour and residual resistance of the girder. All load tests were performed with a fixed loading rate under force control and were stopped upon the occurrence of failure, as indicated by load reduction detected by the load cells and confirmed by evident damage recorded by the measuring devices. The setup of measuring devices for girders B5-P46/P47 and B2-P46/P47 are reported in Savino et al. (2023b). In these tests the equipment was placed on one side of the beam; in particular the side protected by the insulation was chosen and it also corresponded to the one under direct vision from the control station. Instead, the setup for the box girder BX2-Ab/P47 is reported in Figure 4, where the pattern of devices installed on the web is mirrored on the opposite side (not reported in Figure 4). This layout was selected to monitor both webs of the box girder and identify any asymmetrical behaviour during the test.

For all the tests, the arrangement of devices has been defined according to the load test setup, considering two main zones: the shear span and the bending span. Along the shear span, specifically near the transverse beam, linear variable displacement transducers (LVDTs) were installed on aluminium frames oriented at 45° angle, with a measurement base of 707 mm. Such sensors were labelled with the code "SHxxA/B", where "xx" indicates the progressive number, "A" refers to the frames with a negative slope, and "B" refers to the frames with positive slopes. In the bending zone, specifically across the midspan, the LVDTs were installed on horizontal frames with a measurement base of 400 mm. They were denoted by "BxxT/C", where "xx" indicates the progressive number, "T" refers to the LVDTs installed on the bottom flange, and "C" refers to the remaining positions.

Furthermore, four electrical strain gauges were mounted as follows: on the top and bottom flanges of the precast beam along the left vertical alignment of the midspan, on the cast-in-situ slab, and the last on the prestressing strand, at 120 cm away from the midspan. Three displacement transducers were installed at each end of the girder to measure vertical and horizontal displacements at the supports, and the potential slipping of a strand. Another displacement transducer was place along the shear span to measure potential sliding of the cast-in-situ slab. The vertical deflections along the beam were measured using nine potentiometer transducers connected to the bottom of the girders ("D01-09" in Figure 4).

4 TEST RESULTS AND DISCUSSION

This paper includes a subset of the comprehensive results obtained from the full-scale load tests. These diagrams were chosen to show the overall structural response of the girders

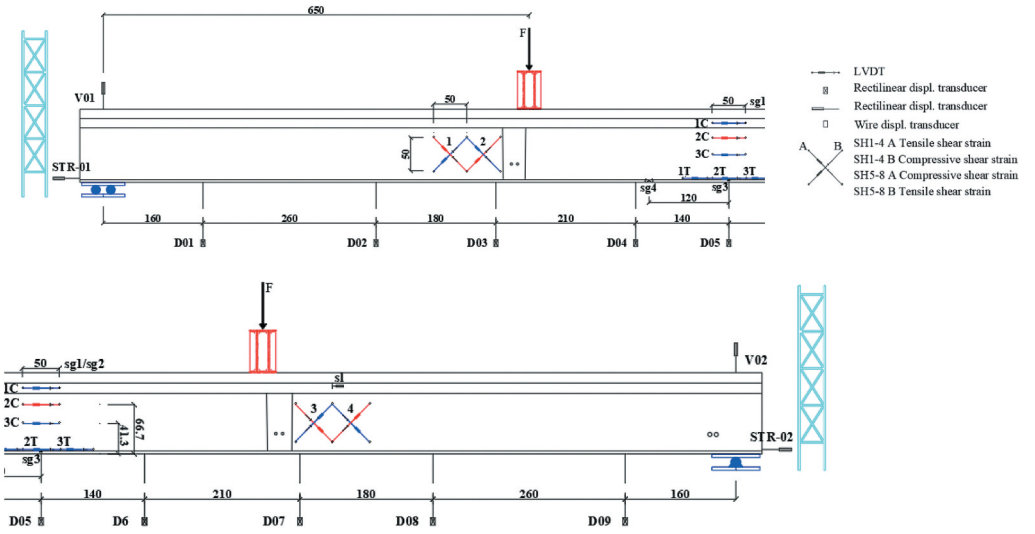

Figure 4. Layout of the testing system with measuring devices for girder BX2-Ab/P47 (units in cm).

together with some specific readings during the tests. All the diagrams have been obtained by referring to the load applied by a single jack. Therefore, the total load applied to the specimen can be found multiplying by 4. Figures 5a-c present the midspan deflection versus the applied load for the three girders. In Figure 5d a focus of the first two sets of cycles for girder B2-P46 /P47 is reported.

A global overview confirms for the specimens a structural behaviour defined by three phases: a linear elastic branch, a concrete tensile cracking that induced stiffness reduction and brittle failure after reaching the maximum load. The girder B5-P46/P7 in Figure 5a shows earlier non-linear behaviour attributable to the cutting of 8 strands across the midspan and this obviously anticipate the first cracking and determines the reduced initial stiffness of the beam. This is evident if comparison is made with previous test results reported in Savino et al. (2023b). All the three specimens reached the collapse due to crushing of the cast in situ top slab. Beam B2-P46 /P47 completely failed and followed down to the safety support system of the reaction frame whereas the test for the other two girders was stopped before global collapse.

The failure mode was similar with that registered for the previous girders tested under four-point bending configuration (Savino et al. 2023a 2023b). As previously stated, beam B5-P46/47 was intentionally damaged to induce a more ductile behaviour than what observed for other identical beams reported in Savino et al. (2023b). The ultimate loads were 72.4 kN, 241.5 kN and 126.2 kN for beams B5-P46/47, BX2-P46/P47 and B2-P46/47 respectively. The structural capacity reduction for beam B5-P46/P47 with respect to an identical girder named B6-Ab/47 and reported in Savino et al. (2023b) but with undamaged strands corresponds to a 42.8%.

The BX2-P46/P47 shows a higher stiffness due to its box section made with two webs of 130 mm and the double number of strands used in comparison with I girder B2-P46/47 reported in this work (see Figure 2). A residual deflection registered after the cycles evidenced the role of non-linearities also due to tensile cracking and possible mechanical interlock. The test on girder B2-P46/P47 was specifically meant to produce progressive damage by cycles of increasing load levels. It can be noted from Figures 5c and 5d that most of the damage was determined by the first cycle of each set whereas small additional damage has been registered for the other four cycles. A progressive residual deformation is visible but, even in case of the last spare cycle before the last branch bringing to collapse, its descending branch was almost aligned with the previous readings without evident stiffness reduction.

Figure 6a shows the strain distribution measured across the midspan along the cross section (see horizontal transducers type in Figure 4) at various loads for girder B5-P46/P47. According to the diagram of the first two steps (10 kN and 20 kN) the section has a plain

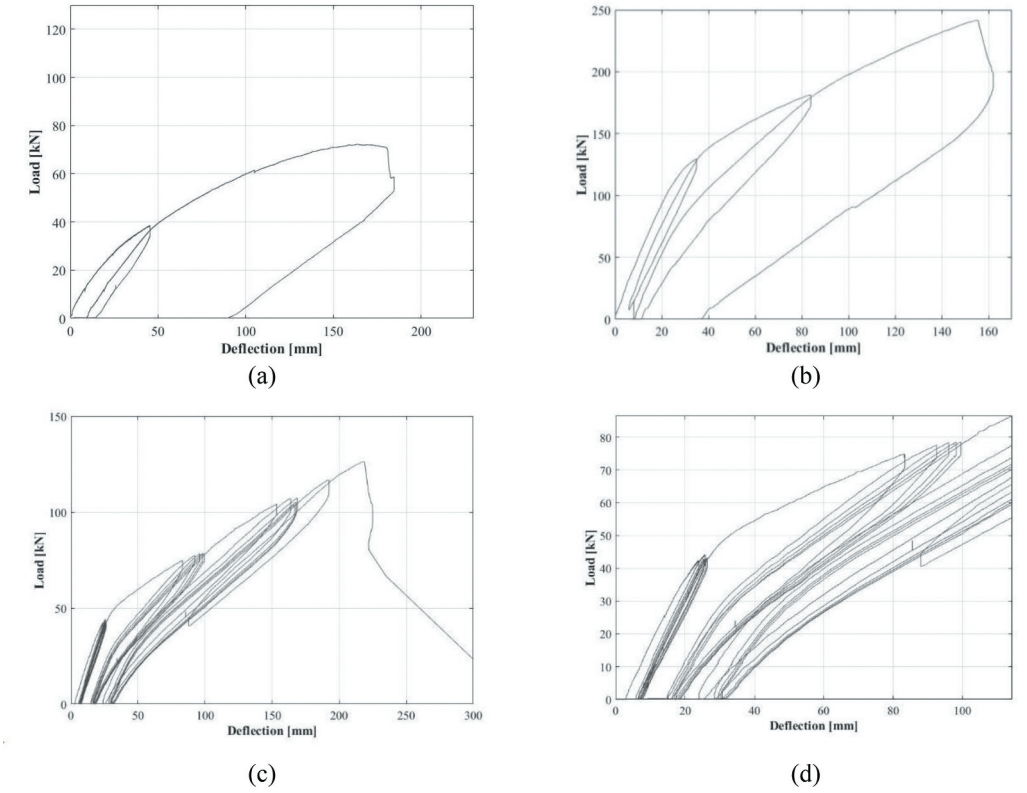

Figure 5. Load vs deflection diagrams: (a) B5-P46/47; (b) BX2-Ab/P47; B2-P46/47: (c) full results and (d) detail.

deformation. At cracking stage the effective depth of the compressive zone was about 0.49 m. When cracking occurred, the neutral axis shifted up and the strain distribution became non-linear. At ultimate condition the neutral axis reached the value of 0.23 m and therefore only the cast-in-situ top slab with a part of the top flange of the precast beam were in compression. The same diagram is reported in Figure 6b for girder B6-Ab/P47 (undamaged in Savino et al. 2023b) that had, even up to collapse, a deeper neutral axis. This highlights the effect of the full prestressing pattern for undamaged girder. Finally, the type of collapse for girder B5-P46/P47 that had 8 strand cut highlight the limited ductility even in presence of around 47% of the tensed steel in the section.

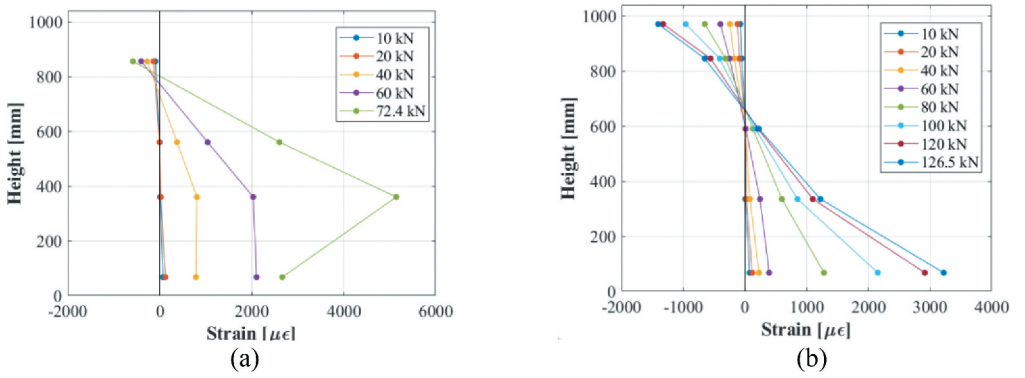

Figure 6. Cross-section strain sg1: C-01, C-02, C-03, and T-01 of B5-P46/47 and (b) B6-Ab-P47.

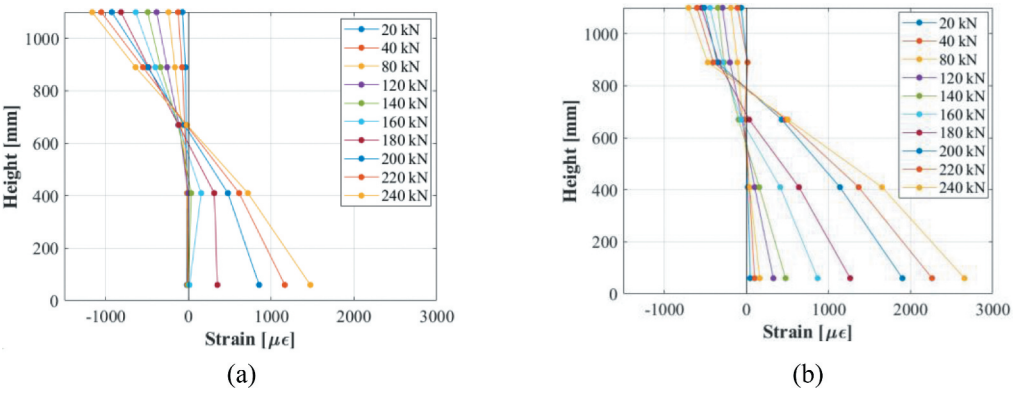

Figure 7. Cross-section strain of BX2-Ab/P47 girder: (a) inner side; (b) exposed side.

Due to the different exposure and consequent damage, the box girder BX2-Ab/P47 was under investigation for what concerns the strains distribution on both the two webs. In Figure 7, the strain distributions are reported. A noticeable difference between the inner side (Figure 7a) and the exposed side (Figure 7b) is observed, becoming more evident beyond a load level of 160 kN. At this stage, a larger shift of the neutral axis is recorded by the outer web. At ultimate condition, the ratio between the depth of the compressive zone and the effective depth were 0.63 and 0.52 for the inner and exposed web, respectively. Therefore, a non-symmetric behaviour can be noted with major deformation attributable to the web with much visible damage (see Figures 8a,b).

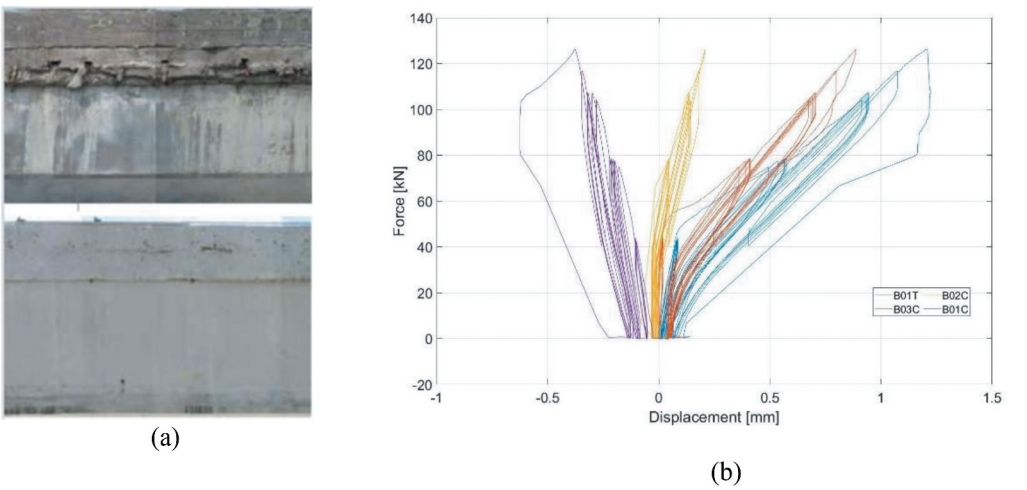

Figure 8. (a) Comparison of the inner (bottom) and exposed side (top) of the beam Bx2-Ab/P47; b) Load versus displacements of the transducers used for tension (T) and compression (C) for girder B2-P46/P47.

In Figure 8b the load-displacement diagrams of four transducers in the top flange (B01C), web (B02C, B03C) and bottom slab (B01T) of the beam B2-P46/P47 are reported. These devices were installed across the midspan and therefore in the most loaded zone of the girder. It is evident that after the first set of cycle for curve of B01T, a cracking occurred and a permanent modification with slope reduction of the curve is registered; all the other three devices, measured the displacements and report slope of the curve similar to the first loading up to the last cycle. B01C and B01T as devices placed in the most compressed and tensed zones respectively show some residual displacement. It can be stated that, even for the most

loaded zone of the beam the accumulated damage resulted to be very limited up to brittle failure in crushing of the cast-in-situ top slab.

5 CONCLUSIONS

An experimental activity on bridge girders has been conducted to study the structural behaviour of 50-year-old PC members at both service and ultimate load levels. Three large-scale experimental tests have been reported. Specimens with different level of damage, geometry, and loading protocol were tested. The results have been analysed considering deflections, strains as well as ultimate bearing capacities. All the tests reported in this work have shown a flexural failure with brittle crushing of the cast-in-situ slab. These findings can be further analysed and compared with the outcomes obtained for the previous bridge girders tested under the BRIDGE|50 research project highlighting a wide number of peculiarities of the residual capacity of PC bridge girders.

Dynamic response of damaged precast bridge girders

D. Sabia, A. Quattrone, F. Tondolo & P. Savino
Department of Structural, Geotechnical and Building Engineering, Politecnico di Torino, Torino, Italy

ABSTRACT: This paper presents a comprehensive dynamic test campaign conducted on pre-stressed concrete bridge beams sourced from a 50-year-old decommissioned viaduct in Turin, Italy, as part of the BRIDGE|50 research project. Individual beams were subjected to dynamic testing to assess the impact of varying levels of damage on their dynamic properties. Vibration data was collected before applying static loads, after reaching the first cracking condition, and after reaching maximum load capacity, and analysed to identify principal modal components. The findings underscore the correlation between damage progression and dynamic response, demonstrating the effectiveness of vibration tests in detecting and tracking damage evolution. Specifically, this study presents the experimental results pertaining to the tested I-shape beams.

1 INTRODUCTION

The vibration-based methods are one of the most widely adopted diagnostic tools in the field of structural monitoring of infrastructures. Vibration-based methods are widely applied in structural health monitoring techniques to follow the evolution of structural integrity, due to the direct dependence between the dynamic behaviour and the structural stiffness. Moreover, their appeal has increased due to the ease of managing the continuous streaming of large amount of data and inferring information by means of data mining algorithms. In literature, several studies report the results of experimental dynamic investigations on beam-like pre-stressed structures, focusing on their use as symptoms of the onset of damage or the evolution of deterioration over time (Quat-trone et al. 2012, Guiglia et al. 2014). For instance, a shift in the modal properties of a bridge can indicate variations in the stiffness or mass distributions, which can be caused by structural damages, modifications of constrain condition or the deterioration of the mechanical properties of the materials (Demarie et al. 2019).

However, these alterations can be challenging to be discerned in service condition due to the concurrent influences of multiple factors. The identification of modal parameters is affected by several noise sources and errors in the analyses process. Additionally, the influence of the variation of temperature and traffic conditions can influence the dynamic response of the structure, complicating the detection of stiffness-related variations induced by damages.

A continuous monitoring of these parameters can confirm the occurrence of even small variations, reducing the influence of error sources, highlighting the possible occurrence of damages. Consequently, conducting controlled tests on structures approaching the end of their service life can contribute significantly to provide more precise definitions of sensitivity limits and thresholds applicable to permanent monitoring systems.

The BRIDGE|50 research project, started in 2020, aims at deeply investigate the behaviour of aged bridge girders at the end of their service lives (Biondini et al. 2021). The research activities will be devoted to accurately investigate the structural performances and characterize the material properties of a representative portion of a viaduct dismantled after 50 years of service life, namely 25 prestressed concrete beams, 4 box girders and 2 pier caps.

The girders are tested in a controlled environments up to failure to determine their ultimate resistance. The dynamic tests have been performed adopting the simply supported configuration

DOI: 10.1201/9781003483755-413

simulating the original structural scheme. Vibrations have been collected before the execution of the static tests, in intermediate cracked state and at the end of static tests, after the application of the ultimate loading condition. The aim is to estimate the influence of the structural damage on the dynamic characteristics of the beams. Moreover, controlled damages are applied to a subset of beams by cutting strands at different locations. In this paper the results of the dynamic test campaign on a set of 8 I-shaped beams are reported.

2 THE CORSO GROSSETO VIADUCT

The Corso Grosseto viaduct was built in 1970. It was originally constituted by 90 concrete decks having variable spans, from 16 m to 24 m, and a total length of 1400 m (Figure 1). Each deck was composed of 10 precast prestressed concrete I-beams and 2 external precast prestressed concrete U-beams, simply supported at piers, and connected transversely by 3 equally spaced diaphragms and, on the top, by a 0.14 m concrete slab (Figure 2). A set of 25 prestressed concrete beams constituting the decks have been dismounted and collected in a testing area, where a bench test has been realized to perform both static and dynamic tests. The collected structural elements belong to the first four decks of the southern part of the viaduct, highlighted in green in Figure 2-a. The technical drawings of the I-beams cross section and the on-site casted slab, object of the present work, are shown in Figure 2 - b.

Figure 1. Corso Grosseto viaduct before the dismantling.

3 STATIC TEST CAMPAIGN

According to the preliminary visual inspection carried out to map the presence of corrosion, cracks, and spalling, the beams have been classified in good structural condition (Table 1). The beams B07 and B08 have been damaged during the dismantling phases, when strands at the bottom flanges were cut. The B07 had two strands cut on both sides of the lower flange, at distances of 3.7, 9.6, and two at 15.5 m from the end section. The B08 girder had four strands cut on one side at distances of 3.8 and 15.5 m. The B09 girder was damaged cutting 8 strands in two symmetrical positions 0.60 m from the midspan, resulting in a reduction of circa 40% of the total prestressing steel in the sections. The static test procedure consists in applying an increasing static load up to the reaching the ultimate load capacity by means of four hydraulic jacks. An

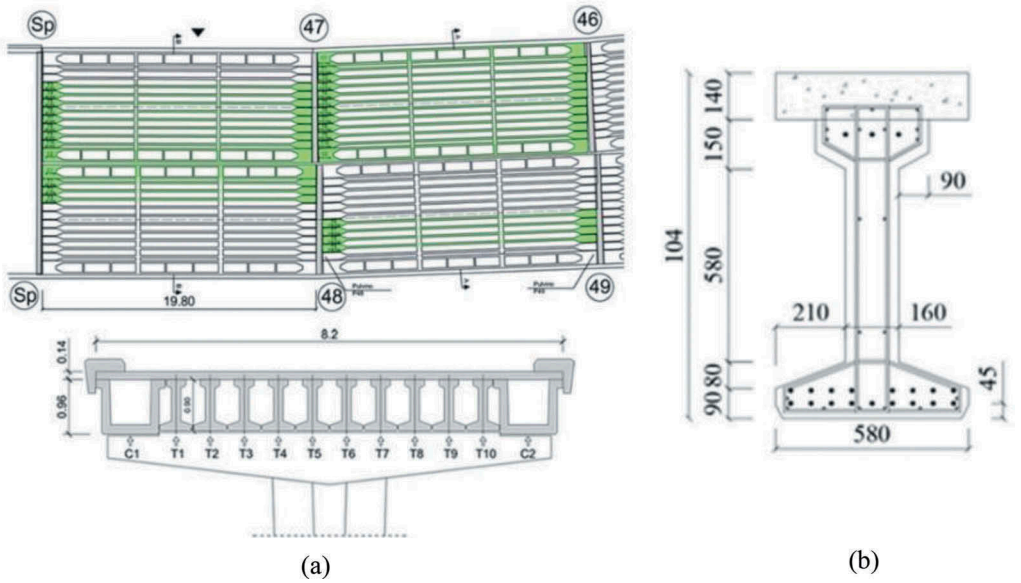

Figure 2. (a) Drawing of the first four decks of the southern part of the viaduct. In green, the beams collected. (b) The I-shaped beam cross section (measures in mm).

intermediate unloading phase was made to evaluate the residual prestressing load and the effects of the opening of the cracks on the dynamic parameters (Savino et al. 2023). The test on B02 beam has been performed in a three-point bending scheme (shear span 9.3 m), whereas a four-point scheme (shear span 6.5 m) was adopted for testing B05 to B11 girders, aimed at investigating the shear-bending interaction. The B11 was tested applying cyclic loading at three increasing load levels to explore the effects of cumulating damages. The B12 have been tested in four-point bending scheme adopting a shear span of 4 m. The beams have been loaded up to reach the ultimate condition highlighting a brittle rupture due to the crushing of the upper slab. The principal results are summarized in Table 1. For each girder, the ultimate flexural strengths M_R is calculated in the rupture section considering the effects of the self-weight, the weight of the load application systems and the maximum force applied by the hydraulic actuators during the test.

Table 1. Results of the static tests.

Beam	Position in the deck	Type	Testing Scheme	Condition	M_R (kNm)
B02	B8-P47/46	I	3-Point	Undamaged	2012
B05	B7-P47/46	I	4-Point	Undamaged	2057
B06	B6-SP/47	I	4-Point	Undamaged	1907
B07	B6-P49/48	I	4-Point	Damaged (4 strands cut at- 1/3 span and at midspan)	1845
B08	B10-SP/47	I	4-Point	Damaged (4 strands cut at- 1/3 span)	2080
B09	B5-P47/46	I	4-Point	Damaged (8 strands cut at midspan)	1412
B11	B2-P47-46	I	4-Point	Undamaged. Cyclic loading	2111
B12	B1-P47/46	I	4-Point	Undamaged	1968

4 DYNAMIC TEST CAMPAIGN

The setup adopted for the dynamic test of the beams is constituted by a set of 10 uniaxial capacitive accelerometers, glued on the top slab, having a sensitivity of 1V/g. The test setup is showed in Figure 3. The acceleration signals were acquired at a 512 Hz sampling frequency for both ambient noise and impact hammer excitations. The impact tests were carried out by hitting the beams with an instrumented hammer in vertical direction in the halfway of two consecutive positions. Dynamic tests were performed by removing the load application systems from the upper slab to replicate as closely as possible the constraint conditions typical of a simply supported isostatic beam.

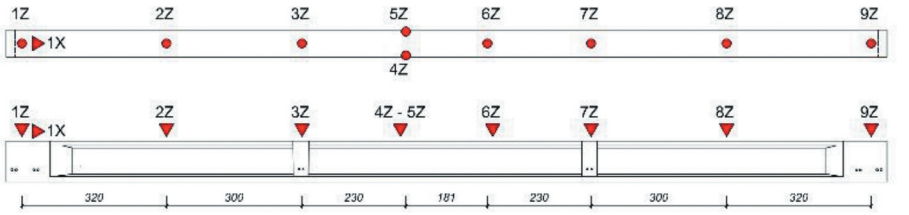

Figure 3. Dynamic test setup.

Dynamic tests were performed on all beams prior to the application of static loads (Phase 0). Whenever possible, the tests were repeated in an intermediate condition (Phase 1), and at the end of the static test (Phase 2), following the attainment of the ultimate failure load (Figure 4). The Phase 1 corresponds to the unloading condition, subsequent the reaching of the full cracked condition, identified in Table 2 as a fraction of the ultimate bending moment reached during the static tests calculated in the rupture section.

4.1 *Experimental modal analysis*

The extraction of the principal modal components is performed evaluating the frequency response function (FRF) matrix with respect of the input given by means of the instrumented hammer. The element of FRF matrix $H_{k,j}(\omega)$ maps the input $F_k(\omega)$, applied at the k-th degree of freedom (DOF), and the output Y_j measured at the j-th DOF. In case of acceleration as output signals, the FRF matrix is expressed in the accelerance form (Ljung, 1999). The generic element of the accelerance matrix, expressed in terms of modal properties, is given by:

$$H_{j,k}(\omega) = \frac{\ddot{Y}(\omega)}{F_k(\omega)} = -\omega^2 \sum_{r=1}^{N} \frac{1}{m_r} \frac{{}^r\psi_j \, {}^r\psi_k}{\omega_r^2 - \omega^2 + 2i\omega\omega_r} \tag{1}$$

The FRF is a complex function which amplitude has a maximum at the resonant frequency. The magnitude of the modal coefficient is taken as the value of the imaginary part at resonance.

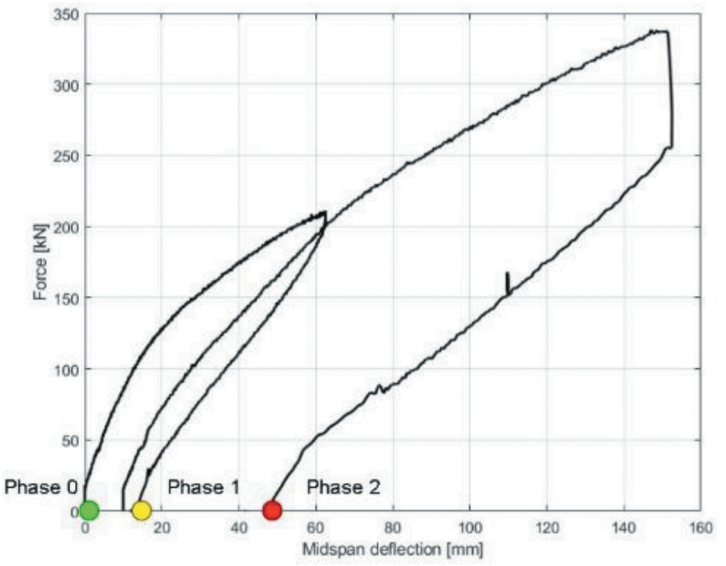

Figure 4. Force – midspan deflection. The dots indicate the phase test.

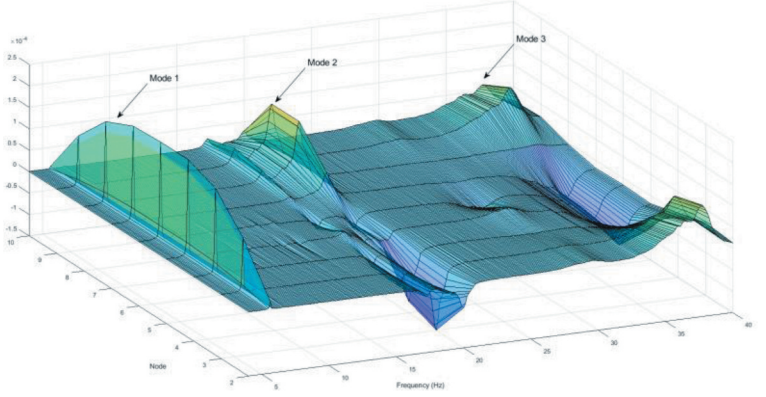

Figure 5. Example of mode shapes of the first three bending modes of the beam B06 – phase 0.

The sign is either positive or negative, considering the direction of the peak along imaginary axis. This implies that the phase angle is either 0° or 180°. After a preliminary analysis of the spectral content, the signals were pretreated by filtering out of the bandwidth [0 - 100 Hz], removing the trends. The FRFs have been estimated basing on each singular impulse acceleration data and then averaged for each hitting position. The first three modal components are clearly identified as shown by the example proposed in Figure 5. The mode shapes associated to these components correspond to the three main flexural modes of the beam. The modal coordinates are estimated by the imaginary part of the FRFs.

5 RESULTS OF THE DYNAMIC IDENTIFICATION

In this paragraph the results of the dynamic identification are proposed. The Table 3 reports the mean values of frequencies and damping estimated at the three phases for each beam. It can be noted that at the increase of the damage level correspond the reduction of the modal frequencies and the increasing trend of damping ratios.

Table 3. Mean modal frequencies and damping ratios.

		Phase 0			Phase 1			Phase 2		
		mode 1	mode 2	mode 3	mode 1	mode 2	mode 3	mode 1	mode 2	mode 3

NP: test not performed

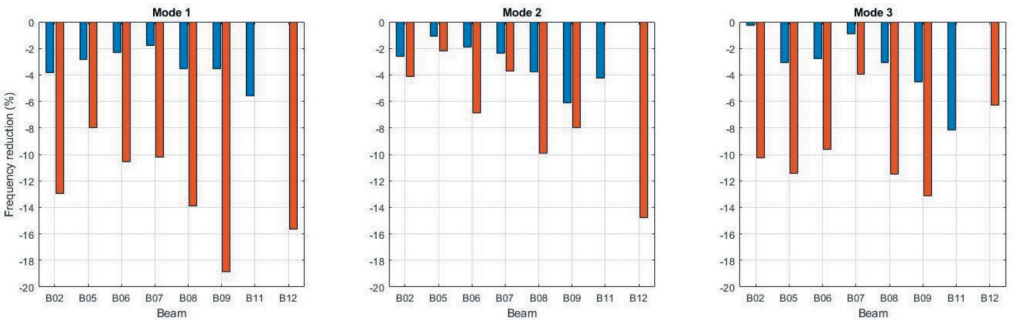

Figure 6. Relative modal frequencies reduction.

The Figure 6 shows the relative reduction of the modal frequencies at the different damage levels.

The following figures illustrate, as an example, the comparison between the mode shapes at different damage levels (phases 0, 1 and 2) for girder B08. It worth noting that small but noticeable differences can be observed with the increasing of damages. Similar results have been found for the other girders.

The reductions of the frequencies of the first mode vary in range of about 2-6% for Phase 1 tests and about 8-19% for Phase 2. The entities of these reductions are comparable to the findings reported in similar experimental campaign present in literature (Quattrone et al. 2012).

It can be noticed that the variation of the first and third modes for B11 in Phase 1 are considerably higher than the mean values obtained in the other samples. It seems indicating a noticeable effect of the diffusion of cracks induced by the application of a higher number of loading cycles at the intermediate level.

The girder B09, which was damaged cutting the 40% of the prestressing strands concentrated at midspan, showed the higher reduction at the ultimate level (Phase 2). The crack pattern of B09 observed at the end of the tests evidences a concentration of cracks in the midspan, where the rupture occurred. In Figure 8 the comparison with the girder B05 shows the spreader diffusion of cracks in case of absence of concentrated damages.

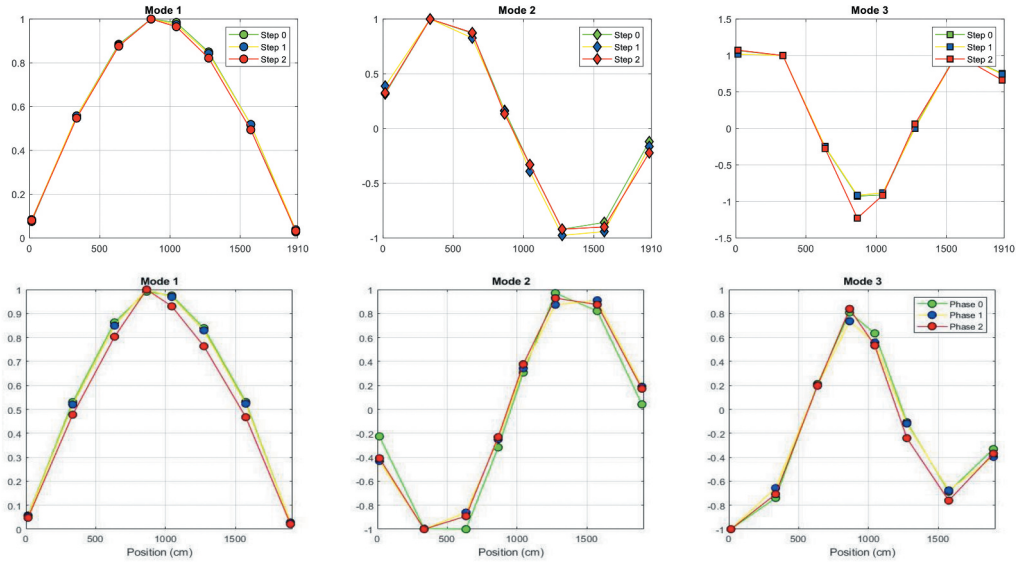

Figure 7. Modal shapes. top: girder B06. bottom: girder B09.

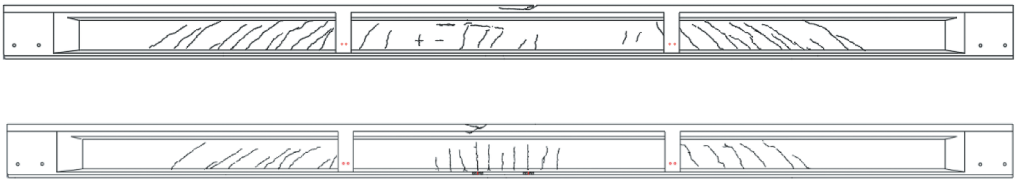

Figure 8. Cracks pattern after failure. top: girder B05. bottom: girder B09.

The Figure 9 highlights in red the domain of variation of the identified modal frequencies, normalized with respect of the undamaged condition, highlighting the wider scattering of the higher modal frequencies.

Figure 9. Domain of variation of the identified modal frequencies.

6 CONCLUSIONS

This work presents the results of the experimental dynamic campaign performed on a set of bridge girders dismounted after 50 years of service life. The tests are part of the BRIDGE|50 research project.

The girders have been characterized for different damage levels induced by static tests. The variation of the modal parameters has been observed and, albeit the small magnitude, the

variations of the structural condition are clearly detectable, confirming the capability of the dynamic structural identification to follow the evolution of damage. The experimental results here presented should be very useful in the field of permanent structural health monitoring. Future works will refine the estimation of damping ratio and the implementation of damage localization and quantification techniques.

ABSTRACT: Information accessibility is a fundamental aspect for an adequate management of existing infrastructures. While BIM methodology has been proposed as an effective method for design and management activities, few examples exist in the integration of data from several techniques in a unique database for horizontal infrastructures. The present paper describes an innovative framework for integrating testing, inspections and monitoring activities on existing bridges following BIM methodology. Information requirements and model organization are specified for bridge elements and bridge management data following Italian regulations as a reference. A practical application example of this methodology is presented considering data from the Bridge|50 research project. The outcome of this work demonstrates that the approach pro-posed provides functionality and openness of the database for bridge management and testing activities. Furthermore, it confirms the utility of BIM to integrate and correlate data from different sources and improve the procedures of infrastructure management.

1 INTRODUCTION

Existing infrastructures, such as bridges and viaducts, play a crucial role in guaranteeing the social and economic wellbeing of the inhabitants of a territory. Nonetheless, an increasing quantity of European existing bridges have reached or are reaching the end of their life cycle. This affection is worsened due to the increase in traffic loads and the effects of climatic change. Due to this situation, a big interest has been deployed by public entities, motorway concessionaries and research institutes to study the techniques needed for correct infrastructure management.

Activities such as inspection, testing, and monitoring are fundamental to guarantee the functionality of the existing infrastructures. These activities are normally regulated by public administration who release guidelines and monitoring plans for the infrastructure. The great amount of data needed on a periodic basis creates further challenges in the bridge management process.

Building Information Modelling (BIM) comes as a logical solution to this problem as it aims for a methodology for infrastructure design and management, where all data is digitalized in a central platform. In fact, the usage of a Bridge Management System (BMS) where concepts such as Geographical Information System (GIS) for the territory and BIM for the single infrastructure is usually recommended. (Wan et al., 2019).

Nonetheless, as BIM was initially created for the design phases of vertical infrastructure, big question mark still exists in its usage for management operations in horizontal infrastructure.

Some examples of BIM usage for bridge management can be seen in the literature. For instance, some authors focus on the application of innovative techniques for digitalizing inspection data (Belcore et al., 2022) while a different research focus is the integration of BIM with data coming from procedures of Structural Health Monitoring. (Davila et al., 2017).

DOI: 10.1201/9781003483755-414

These examples give a notion of the existing procedures that can be used for the management of infrastructures, however a standard procedure and a clear explanation regarding the information that should be included in a BIM model for bridge management is still needed.

2 DATA REQUIREMENTS AND CODES

2.1 *Bridge and viaducts management data*

In Italy, an official guideline for bridge risk evaluation was first issued in 2020 and then ratified in 2022. (Ministero delle Infrastrutture e dei Trasporti, 2020).

The guideline proposes a multilevel risk analysis, where the level of information to be retrieved increases as the level of analysis increases. All bridges in the Italian network are subjected to level 0,1 and 2 (census, visual inspection, and risk classification). According to the classification given in level 2, further visual inspections are scheduled, or the passage to a further level of analysis (3 or 4) that includes testing activities, structural modelling, or the application of a monitoring system, is decided.

Following this guideline different information requirements can be defined according to the level of analysis. For example, in level 0, general aspects regarding the bridge and the context where it is located are determined. In level 1, a list of common defects and a criterion for defect characterization is given. Clearly, bridges with a higher risk attention class have higher information demand. For instance, a bridge that goes to level of analysis 4 needs to consider information regarding non-destructive testing, monitoring systems and structural analysis, other than the basic information of the initial levels.

Regarding the single test procedures and its data requirements, reference is made from normative standard such as ISO, EN or from Italian specific guidelines (UNI).

2.2 *Bridge BIM model*

As digital transformation gained interest in the public sector, regional and national administrations have also issued legislation regarding the usage of open-BIM (models that are readable and functional regardless of the software). In Italy the most relevant legislation regarding this topic is the so-called BIM decree (DM 560-2017) where deadlines are established for the public administrations to progressively adopt open-BIM methodology in civil works procedures. This legislation has been latter updated and currently states January of 2025 as final date for the mandatory implementation of BIM in Italian public processes (works of over 1 million euros).

Nonetheless, regarding the technical specification about BIM modeling, international organizations like UNI, EN and ISO set the basic principles. For open-BIM models the main guidelines are given by BuildingSmart association. The central recommendation given to guarantee the exchangeability of data is the usage of Industry Foundation Classes (IFC) data format. This means setting the BIM model following an object hierarchic organization that is standard depending on the type of infrastructure that is modelled. In the update IFC4.3 the BIM model organization as well as the different categories -*IFCclasses*- and attributes for the bridge and viaducts elements are described. (BuildingSmart, 2020).

2.3 *Management activities in BIM*

A bridge BIM model that is useful for management activities needs to merge information from both previous subchapters; this means, following BIM standards for bridge BIM modeling when it can be developed (e.g. bridge geometrical elements), but adapting the information and elements included in the model according to the needs of the risk assessment guidelines.

Evidently, not all types of data stated in the bridge risk assessment guideline can/should be included in a digital model of a bridge for maintenance purposes. In this sense, a clear differentiation needs to be made between a BIM model and a Common Data Environment (CDE).

A CDE is a cloud-based space in which information regarding a project is available for the participants (Werbrouck et al., 2019). The main principle is that all models, technical drawings, and documents are stored and managed in the CDE and not in the single BIM model. In this sense, the bridge BIM model should include only the basic information to understand the bridge geometry, its context, and the inspection/testing activities performed over time. For further information regarding these activities the BIM model should include links to the external documents (situated in the CDE).

This paper intends to give a general framework of BIM methodology for existing bridges specially focusing on the treatment of data coming from infrastructure management activities.

This work is included in the BRIDGE|50 project, a research collaboration between universities, public and private partners to perform a large number of experimental tests on bridge beams previously dismantled from a demolished viaduct in the city of Turin, Italy. Arguments such as the digitalization of defect inspections, the BIM modelling of testing and monitoring activities, the updatability of models on time and the organization of BIM model and CDE will be treated.

3 CASE STUDY

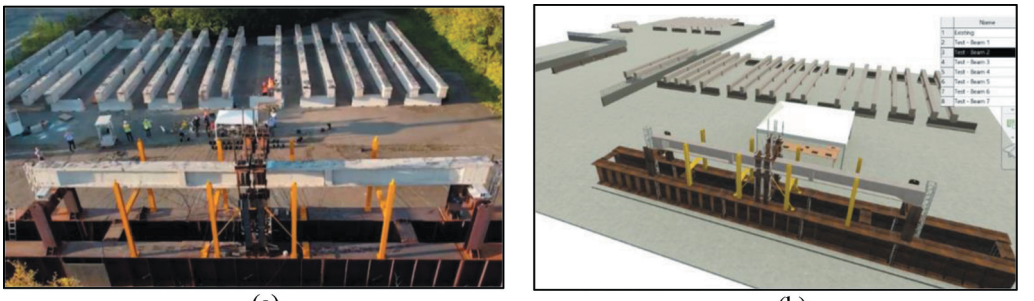
The Bridge|50 project is among the largest research projects on bridge beams currently in Europe and in the world (Bridge50.org). The project studies the structural performance of 29 prestressed beams and 2 pier caps that were dismantled in 2019 from a viaduct at the end of its life cycle (50 years). The viaduct presented a simple supported scheme with 10 prestressed concrete I-section beams and 2 prestressed U-shaped edge beams supporting a 14 cm thickness concrete slab (Savino et al., 2020). Since the campaign started, the beams have been moved to a testing site and a series of visual inspections and testing (rebound hammer, corrosion potential, concrete drilling, etc.) have been performed. The most peculiar testing activity is a large-scale static and dynamic loading test protocol that is performed in a reaction-frame specifically built for the project. The response of the beams to the loading tests is measured using sensors positioned on their surface and the load capacity up to collapse is determined (Savino et al., 2023). Once the beam has been tested, it is moved away from the reaction frame and further inspection/testing activities are performed to analyze the effects of the generated damage. In this research work the digitalization process of the first 7 beams tested up to collapse will be explained.

Even though this case study treats single bridge beams instead of an operating bridge, a parallel can be made between the information needs of the project and the one of a bridge still in service. The large quantity of inspections and testing data obtained from each beam can be compared to the amount of information that is obtained from a complete analysis of an existing bridge; furthermore, the requirement to update the information in time as the campaign goes on gives a valuable example of how digital strategies can be applied for long-time inspections/testing activities for existing bridges.

4 APPLICATION OF THE BIM METHODOLOGY

4.1 *CDE and organization of project data*

It was decided in an initial phase of the experimental campaign that a cloud based CDE was going to be used to manage all project related data. In the CDE, data is allocated differentiating between general data about the project and data regarding the single beam elements. For each beam in the project a specific data folder is assigned and information regarding the technical/historical documents, testing and inspection activities and the models created for the single beam are stored inside. This means that every beam studied has a unique BIM model, and the latter is linked together with the external information located in the respective data folder. On the other hand,



the general information about the project (historical documents, project schedule, technical documents, global models, etc.) is stored in a different folder inside the CDE. This global information folder also includes a BIM model (federative testing campaign model), that acts as a collector of all the single beam models and is used to get a general perspective of the testing campaign and the different campaign phases. The federated model as well as the single BIM models are created using *Autodesk Revit*, however they are exported in IFC format, following the BuildingSmart indications for open-BIM.

4.2 *Federative testing campaign model*

Based on previous work on digitalization of the testing campaign (Rodriguez et al, 2022), the general BIM model is created. This general model is a virtual replica of the testing site, where all components present on site (testing reaction frame, new jersey barriers where the beams are supported, etc.) are modeled either as internal components or as external families. Similarly, in this model, every single BIM model of the beam elements is linked and positioned according to the real location of the beams in the different phase in the testing site.

Regarding the data included in this model, the level 0 of the Italian guidelines for bridge risk assessment is taken as a reference. This information is also complemented with general data about the specifics of the research project that is needed for an understanding of the campaign. This data is added following either pre-compiled options according to the guideline (e.g. bridge alignment options: straight or curvilinear) or free fields (text/number/yes-no) options. Information regarding technical documentation of the project is available using URL hyperlinks that correlate external documentation in the CDE with the data requirements of the model.

Finally, to be able to follow the different stages of the testing campaign the "phase-filter" tool of the software is used. This tool allows the creation of a timeline in the model, where digital objects attributes can be linked to the data selected. The timeline is created with the different dates when the full-scale loading tests were performed in the beams. For example, in the data-phase "Beam – 1", the respective beam moves location to a testing position, inside the reaction frame and in data-phase "Beam – 2", the beam-1 changes to the location after the large-scale test and the beam 2 occupies its place on the reaction frame. Evidently, the information about the model as well as the data of the single beam model also changes according to the data-phase.

(a) (b)

Figure 1. (a) Testing site. (b) Federative model of testing site in phase -Beam 2-.

4.3 *Building the single beam models*

Different BIM models were created in single files following the unique characteristics and particularities of every beam. The family class in *Revit* was defined as *StructuralBeamElement* (translates into *IfcBeam* in open-BIM specifics). Then, once again, the Italian guideline is used as reference for the data included in the model. In this case, information about level 0 as well as information about inspections (ordinary and extraordinary) was included.

To be able to manage the big amount of information needed for every defect finding (cracks, delamination, etc.) it was decided to manage this data as an external family element that is dependent or hosted by the main *IfcBeam* element. The same consideration is made for the testing data, that is treated as an external family, but also dependent on the main beam element.

A final step in the modelling procedure is the usage of the phase-filter tool to update information in the beam models according to the evolution of the testing campaign. Different phases were created in the project according to when the main testing activities took place (see Table 1). The selected phase updates all the general information in the model as well as the specific information about the damage and testing families.

Table 1. Campaign phases for beam 3.

Phase	Tests
Testing phase 1 (NOV.2021)	Visual inspection, Rebound Hammer, Corrosion potential
Testing phase 2 (APR.2022)	Core drilling
Testing phase 3 (OCT.2023)	Full scale loading test
Testing phase 4 (NOV.2023)	Visual inspection, Tensile of steel, Residual prestress, Compression of concrete, Elastic modulus of concrete

4.4 *Defect data elements*

Following a similar procedure as explained by Isalovic et al. (2020) external dependent families were created using the *IfcSurfaceFeature* class. The geometry was created following a semiautomatic procedure taking advantage of an accurate defect modelling performed in an initial phase (Rodriguez et al, 2021). Then information regarding the defect characterization was added to the single families following the defect characterization of level 1 of the Italian guidelines. External documentation regarding the single defects was linked with URL hyperlink.

The defects families were modelled locally with respect to the beam families to ensure the correct placement and connection between defect and structural element.

As explained before, the information regarding beam damage needs to be updated with re- spect to the same timeline created in the beam family object; therefore, a second defect inspec- tion was made in the mechanical tested beam elements -after the full-scale loading test- and the information about new cracking was updated in the respective phase of the digital model.

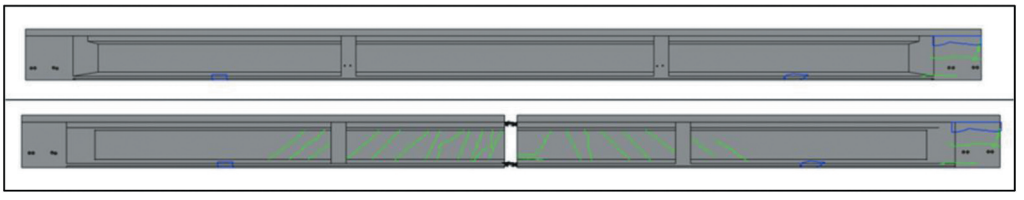


Figure 2. Defect families positioned in beam 1 before and after large-scale mechanical test.

4.5 *Testing results data elements*

Considering the lack of standards for the digitalization of testing information, an experimental approach was tested, using once again the *IfcSurfaceFeature* class to generate a link between beam element and test element. Then, to represent the testing activities in terms of type and location, different conceptual, basic geometries were assigned to the area where the different typologies of tests were performed. (e.g. square for rebound hammer test, circle for pull-out test, etc.). This test geometry was positioned locally with reference to the beam families to ensure the correct

placement according to the actual test location. To standardize the test-data objects and considering that every typology of test has different data requirements it was decided to include just general information about the test activity in the BIM objects and leaving other type of documentation (technical specifications, normative documents, test reports, etc.) linked through hyperlinks. This data was also connected to the phase-filter tool to be updated according to the phases of the testing campaign.

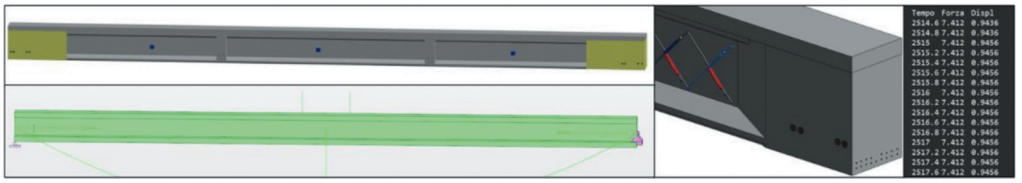
This procedure was replicated for all the different non-destructive tests applied to the beams: rebound-hammer, concrete pull-out (compression, tension, and alkalinity tests), corrosion potential, tensile test, residual prestress test.

Table 2. Example of data for the different model elements.

Data in model			
Category	PropertySet	Parameter name	Parameter Type
	AINOP Code		Text
IfcBridge	Bridge Identification	Type of connection	Text
		Structural typology	Text
		ID	Number
IfcBeam	Element identification	Bridge element type	Text
		Bridge span	Number
		Defect code	Text
IfcSurfaceFeature - Defects	Defect characterization	Weight - G	Text
		Extension	Text
IfcSurfaceFeature -		Type of test	Text
Tests	Test data	Operator	Text
		Link to test report	URL

4.6 *Sensors/monitoring data elements*

Four different data sensor families were created corresponding to the 4 typologies of sensors used during the large-scale loading-test (Used to read displacement and strains due to bending and shear-placed on concrete, and steel-stirrups and strands-). The families were created using *Revit* category *DataEquipment* that automatically translates into *IfcSensor* according to the specifics of open-BIM. The geometry of the sensors was created following the geometrical specification sheets. This typology of family is also hosted by the main *IfcBeam* element and in this sense positioned locally with reference to the beam families. Once again, to standardize the typology of family used and not create a great number of parameters for every single object, it was decided to include basic data regarding the sensor to the BIM object (e.g. sensor code, typology, connection type, connection server, data receiver, etc..) and connect it through a URL hyperlink to the sensor database. This decision is beneficial also considering the operation and manageability of the BIM model preventing data overloading using an external database. This procedure was applied for sensors deployed on the beam surface during the full-scale loading test but could be replicated with any type of structural health monitoring solution.



4.7 *Structural models*

Different structural models were created through the different stages of the life of the beam during the experimental campaign. These structural models represent the typology of data that needs to be retrieved in bridges at further levels of analysis according to the risk assessment guidelines (level 3 and 4). Taking into account that with every additional inspection/testing phase more information was acquired about the beams in study, the level of reliability of the proposed structural models should increase as well.

To be able to link the evolution of the structural models with respect to the evolution of the testing campaign, a correlation of structural/BIM models was created. Software from the

same software house -*Autodesk Robot*- was used in the structural analysis to facilitate the interoperability of different software.

A specific structural model was created according to every phase of the model where a certain specification in the *IfcBeam* was updated (e.g. material properties). The variation of the required property was transmitted to the structural model by an export/update task available thanks to the existing connection between the two software.

(a) (b)

Figure 3. (a) Test families inside beam model and connection with structural model. (b) Sensor detail and link with sensor database.

4.8 *IFC export*

To ensure the openness and readability of the created files a passage from *Revit* file to IFC file needs to be established. In this sense operations called class-mapping and parameter-mapping are implemented. This means checking that the software native element category corresponds to the correct *IfcClass* specified for the bridge elements in the Open-BIM guidelines. Moreover, to ensure that the data included in the model is exported as attributes to the *IfcClass* an external text file is created to "guide" the software in the exportation settings. In this external file the data parameters included in the model are enumerated and organized to be exported in *IfcPropertySets* according to the different object classes.

The IFC standard does not include a function that updates data in time as the phase-filter tool; therefore, different BIM models are exported according to the different phases created.

5 RESULTS AND CONCLUSIONS

In the present paper a framework for the creation of BIM models for bridge maintenance activities is proposed using a testing campaign on bridge beam as a case-study. The integration of information from inspection, testing, monitoring, and structural analysis using BIM methodology is specified. Maintenance data requirements were defined following Italian normative for bridge risk assessment while data modelling requirements were defined following open-BIM standards. Even though the case study treats single bridge elements and not an operating bridge, a parallel can be made considering the big quantity of data retrieved and the duration of the project.

Firstly, a clear differentiation between CDE and BIM model information requirements was stated. This differentiation is the basis of the BIM methodology applied as external documentation is stored in the CDE and single BIM models are created containing only basic information of bridge management activities.

The first model described was the global federative model that assists the tracking of the experimental campaign phases. This federative model acts as container of the other digital models of the beams and gives context to the experimental campaign. The fundamental characteristic of this model is its possibility to be updated thanks to the phase-filters. The time-integration demonstrated to be an excellent tool for the organization of bridge management data, as it allows an easy follow-up of the testing phases. In fact, this tool demonstrated such good results that it was also used to treat the inspection and testing activities in the single beam models.

Regarding to the latter, a description about the modelling characteristics of bridge elements following open-BIM standards was specified. Nonetheless, the innovation in the procedure was emphasized in the modelling methodology for inspection, testing and sensor/monitoring data. In this sense, specifics about the included data, the BIM characteristics and geometric characteristics of the elements was stated.

Starting by the BIM format, specific *IFCclasses* (external families) were used to treat this type of information. This external families were, however, dependant to the "main" structural element. Hence, they were attached to the main family and positioned with a local reference to this element. This methodology demonstrated to be satisfactory solution to treat bridge maintenance information as specifics about every single defect/test can be given, but also a direct correlation between the "host" object and the element is created. Likewise, the possibility to position the external element taking as a reference the structural main element helps the rapid visualization and contextualization of data with respect to the structural element analysed.

Regarding the geometry of the elements modelled, the real geometry about defects and sensors was considered. On the other hand, for the testing activities just basic geometry to differentiate between the different tests was created. Considering the global purpose of the model, this type of geometrical simplification does not compromise its functionality as a rapid differentiation between tests can still be determined according to the selected shape and the position and extension of the test is still respected.

With respect to the data that was included in these external objects, the basic idea was to standardize the data regardless of the type of defect/test to be treated. In this sense, a certain number of parameters were created in the BIM objects and external documentation (such as tests results, inspection documents, sensor data, etc.) were related to the model elements through the usage of dynamic links. This decision is beneficial for the model as it allows a correlation of information from different sources in a single database, without adding extra-computational demand to the visualization of the information.

A final explanation regarding the correlation of structural analysis models with BIM models was also stated. In this sense, the link between both typologies of models was established performing exports/updates of the BIM model to the structural analysis software once the characteristic of the same were updated. This process exhibits ones again the benefits of creating a timeline in the model as more information from tests/inspection means a better understanding of the beam characteristics and thus, a better structural analysis model.

Finally, the export of the BIM model following open-BIM standards was performed. This example showed the passage from software-constrained model to an open model without losing information regarding the categories of the objects or their attributes. Nonetheless, the inability of the IFC standard to keep track of the timeline created resulted in multiple files corresponding to the phases created.

The conclusions of the work demonstrate the possibility of treating bridge management data with BIM methodology including basic information about the bridge characteristics -level 0 of guideline- but also complex information corresponding to the superior levels of analysis. Even though a first standardization framework was proposed, future developments are needed in the IFC guidelines to better include information regarding defects and testing.

The result of the methodology demonstrates that time integration with the data inserted in an open-BIM model results in a key-aspect to consider for a BIM model for bridge maintenance. Therefore, a future upgrade in the IFC schema is also needed to consider this sort of information allowing the creation of a unique database for all management phases.

Super-resolution enhanced vehicle recognition method for long-span bridge

Xin Shan, Jingxuan Zhang, Yue Pan, Yunlong Ma & Dalei Wang
Tongji University, Shanghai, China

ABSTRACT: With the rapid advancement of vehicle load monitoring systems, incorporating dynamic weighing and multi-view visual technologies, acquiring precise vehicle loads across large fields of view on bridge surfaces has become crucial for bridge health monitoring. However, for ultra-long-span bridges, due to the limitations of single-camera focal length and depth of field, multi-camera and re-identification technologies are usually necessary to achieve full-bridge coverage. This approach inevitably leads to high system construction costs, large data transmission and processing costs, and compromises system robustness. To overcome these challenges, this paper proposes a vehicle load monitoring method for large-span bridges enhanced by super-resolution technology. The proposed approach introduces a clustering segmentation technique based on image clarity, enabling recognition and cropping of far-focal blur areas. Then, a super-resolution image enhancement network is designed to restore the resolution of blurry regions. Finally, a vehicle recognition algorithm based on YOLO is implemented to achieve wide-field vehicle recognition in single-view images. The research results demonstrate that super-resolution technology can effectively improve vehicle recognition accuracy and robustness within blurry areas of vehicle monitoring images, thus achieving wide-field bridge surface vehicle monitoring under single-view conditions. By significantly reducing the cost and complexity of vehicle monitoring systems, this method provides important value for bridge traffic management and real-time performance evaluation.

1 GENERAL INSTRUCTIONS

1.1 *Current status of vehicle detection on long-span bridges*

Dynamic load measurement is vital in bridge engineering for design, maintenance, and lifecycle analysis. This typically involves measuring axle loads and their positions on bridges. Weigh-In-Motion (WIM) technology, crucial for traffic and civil engineering, measures vehicle weight and related parameters. However, WIM systems, embedded in bridge structures, only provide load data at specific sections, lacking insight into changes in vehicle speed and routes which are important for long-span bridge management and performance analysis.

For ultra-large-span bridges, the limited range of monocular cameras necessitates using multi-camera systems and re-identification technology for full coverage. While effective, this approach incurs high construction and operational costs due to numerous cameras, complex data transmission, and processing challenges. These limitations highlight the need for integrating visual and tracking technologies to establish an effective vehicle load monitoring system.

1.2 *Introduction of a super-resolution enhanced object detection network*

To optimize vehicle load detection on long-span bridges, this study introduces a method combining super-resolution (SR) technology with object detection. SR enhances low-resolution images into high-resolution ones, a technique increasingly applied in various fields due to deep learning advancements. Our novel model integrates a super-resolution network with an object detection model, processing blurry images for improved vehicle recognition. This approach adapts to the

DOI: 10.1201/9781003483755-415

limitations of monocular cameras on long-span bridges, enhancing data clarity for more accurate detection and tracking, thereby optimizing vehicle load detection systems.

2 OVERVIEW OF OUR METHODS

This paper presents a novel vehicle load monitoring method for large-span bridges, employing super-resolution technology as shown in Figure 1. Addressing the limitations of traditional methods in ultra-long-span bridges, our approach enhances the clarity of input images using a fusion of Laplacian operators and Fourier transforms, crucial for creating high-quality datasets.

The method combines a Residual Dense Network (RDN) with YOLOv8 for target detection, significantly improving accuracy in blurred images. This integrated approach not only enhances vehicle recognition in areas affected by camera depth-of-field but also enables efficient bridge surface monitoring from a single viewpoint. The result is a more cost-effective and robust system for bridge traffic management and performance evaluation.

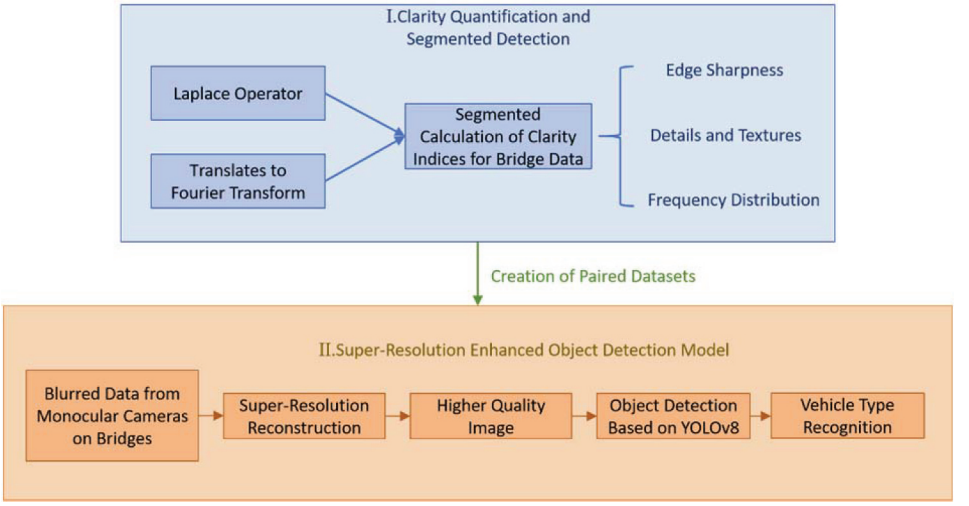

Figure 1. The overall framework for super-resolution enhanced method for vehicle recognition on long-span bridges.

3 CLARITY QUANTIFICATION AND SEGMENTED DETECTION

Clarity Quantification and Segmented Detection is achieved via three core procedures, namely the perspective correction, the segmentation of images, and clarity assessment.

The perspective correction is to correct geometrical distortions in images due to varying camera angles. Next, image segmentation is applied to these transformed images, isolating the images into different parts for targeted analysis. Finally, using a combination of Laplace Operator and Translates to Fourier Transform we designed an index. This index is crucial for assessing the quality of each segmented vehicle image, ensuring the use for further paired datasets making.

3.1 *Perspective correction*

A traffic camera on a long-span bridge was set for an oblique view, causing image distortions corrected by photogrammetric projective transformation. Using ground control points (GCPs) and total stations, the coordinates were transformed into a 3D frame, as depicted in Figure 2. This process, a homography transformation, involved correcting distortions and aligning images with reality, significantly enhancing accuracy and perspective.

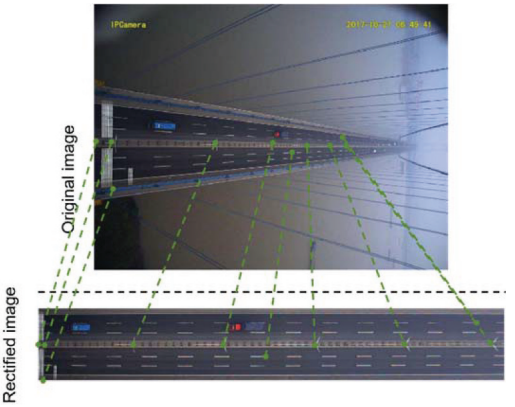

Figure 2. GCPs and corresponding pixels on image in the rectification.

3.2 *Images segmentation*

Image blurriness decreases with distance from the camera's center. For effective super-resolution network training across varying blur levels, the image was segmented into four parts, named Part 1 to Part 4, based on distance from the camera center. This approach, illustrated in Figure 3, enables focused training for each segment, enhancing the network's response to different blur intensities and providing segment-specific enhancements.

Figure 3. A schematic diagram of an image divided into four parts.

3.3 *Clarity assessment*

3.3.1 *Laplacian operator*

Laplacian operator is a second-order derivative operator used in image processing to highlight edges. For a two-dimensional image, the Laplacian operator L is defined as the sum of the second derivatives of the image intensity I with respect to x and y:

$$L = \frac{\partial^2 I}{\partial x^2} + \frac{\partial^2 I}{\partial y^2} \tag{1}$$

In discrete form, this second derivative can be approximated using a convolution operation. For a 3x3 kernel, the Laplacian operator can be represented by the following kernel:

$$\begin{bmatrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{bmatrix} \tag{2}$$

This convolution highlights the contrast in edges, serving as an indicator of image sharpness. Sharper images will exhibit more distinct edges in the Laplacian-processed output, reflecting higher quality.

3.3.2 *Fourier transform*

Fourier transformation shifts the image from the spatial to the frequency domain, revealing details about its sharpness.

The 2D Discrete Fourier Transform (DFT) for a digital image $f(x, y)$ is defined as:

$$F(u,v) = \sum_{x=0}^{M-1} \sum_{y=0}^{N-1} f(x,y) e^{-2\pi i \left(\frac{ux}{M} + \frac{vy}{N}\right)} \tag{3}$$

Here, M and N are the image dimensions, with the summation over all pixels. High-frequency components in the DFT spectrum correlate with image edges and fine details, indicative of sharpness. A predominance of high frequencies suggests a clearer image, while a lack of such frequencies implies blurriness.

3.3.3 *Image clarity assessment based on laplacian operator and fourier transform*

The utilization of the YOLOv8 object detection model, known for its sensitivity to edge sharpness and texture detail in images, necessitates a comprehensive image clarity assessment approach in this study. Two evaluative indices, the Laplacian operator for edge sharpness scenarios (like edge and motion blur) and the Fourier Transform for texture detail scenarios (such as linear interpolation down-sampling and Gaussian blur), are integrated for image clarity quantification. This approach, employing distinct evaluative techniques, is designed to improve image quality assessment's effectiveness and accuracy, laying a foundation for creating high-quality datasets essential for YOLOv8's optimal performance in object detection scenarios.

4 SUPER-RESOLUTION ENHANCED OBJECT DETECTION MODEL

4.1 *Residual dense network for image super-resolution overview*

RDN is selected for its exemplary capability in reconstructing high-resolution images from low-resolution counterparts, primarily due to its dense feature extraction and residual learning mechanism. The architecture is adept at preserving image details, essential for subsequent detection processes.

The key principle of RDN is encapsulated in the dense feature fusion strategy, formulated as:

$$F_{DF}(x) = H_{DF}([F_{D1}, F_{D2}, \ldots, F_{DD}]) \tag{4}$$

where F_{Di} denotes the dense block function, D the number of dense blocks, x the input feature map, and H_{DF} represents the dense feature fusion function.

The global feature fusion, defined as F_{GF}, integrates the original image features with the dense features:

$$F_{GF}(x) = H_{GF}(F_{DF}(x), F_0(x)) \tag{5}$$

where $F_0(x)$ is the initial shallow feature extraction from the input image x.

4.2 *YOLOv8 overview*

YOLOv8 serves as the object detection model in our study due to its fast and accurate detection capabilities. The model operates on the principle of dividing the image into a grid and predicting bounding boxes and class probabilities for each grid cell.

The key operation of YOLOv8 can be summarized in the formula:

$$O(x) = \sigma(Conv(F(x))) \tag{6}$$

where $F(x)$ represents the feature extraction function, $Conv$denotes the convolutional operation, and σ is the sigmoid function for probability prediction.

4.3 *Proposed integrated model*

The integration model strategically places RDN as a 'head' in the YOLOv8 framework as shown in Figure 4. This design allows the system to first perform super-resolution processing on input images, focusing on enhancing edges and textures, crucial for accurate object detection.

The combined operation can be represented as:

$$y(x) = YOLOv8\,(F_{GF}(RDN(x))) \tag{7}$$

where $RDN(x)$ enhances the input image x followed by F_{GF} applying global feature fusion, and YOLOv8 conducting the detection and classification.

The model supports selective component training, with parameters enabling the freezing of either the RDN or YOLOv8 sections. This facilitates focused training on either super-resolution enhancement or object detection efficiency.

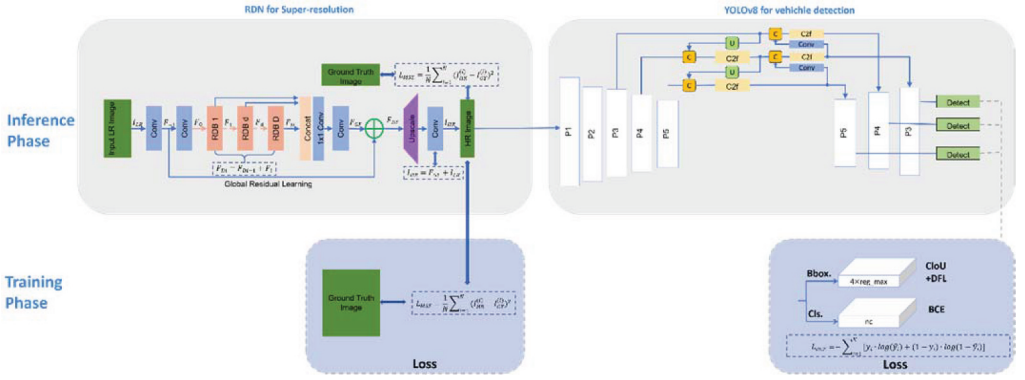

Figure 4. Two stages based vehicle detection network.

5 DATA AND EXPERIMENT

5.1 *Dataset and testing areas*

A surveillance camera, positioned mid-way on the Jiangyin Bridge's pylon crossbeam, captures 1920x1080 pixel footage at 25 fps from an 85-meter height. The recorded area spans 192 by 29.5 meters. Post-recording, footage is trimmed to 295x1920 pixels using 12 GCPs, with

Figure 5. Examples of recorded frames.

each pixel representing 10 ground truth diameters. Subsequently, a vehicle benchmark dataset for detector training is created, with 4000 video frames annotated for three vehicle types.

5.2 *Vehicle detection on YOLOv8*

5.2.1 *Training*

We split the dataset into 80% training, 10% validation, and 10% testing. Different network architectures were trained on this dataset with a batch size of 32 and an initial learning rate of 0.004. Data augmentation included random horizontal flips and crops. Networks were initialized using weights pre-trained on the COCO dataset and trained via the Tensorflow Object Detection API on an NVIDIA GeForce RTX 2080 Ti GPU. The model's performance was evaluated using the mAP score at an IoU threshold, defined as

$$\mathrm{IoU}(A, B) = \frac{\left|A \cap^{B}\right|}{\left|A \cup^{B}\right|} \tag{8}$$

where A and B are the areas of ground truth and detected objects, respectively. Precision and recall are calculated using

$$\text{precision} = \frac{TP}{TP + FP} \tag{9}$$

and

$$\text{recall} = \frac{TP}{TP + FN} \tag{10}$$

with *TP*, *FP*, and *FN* denoting true positives, false positives, and false negatives. Both IoU and confidence thresholds were set at 0.5.

5.2.2 *Evaluation*

During evaluation, our model exhibited strong performance with an overall mAP50 of 0.981 and mAP50-95 of 0.919 across 200 images with 1736 instances, which is shown in Table 1.

Table 1. Evaluation result of YOLOv8.

Class	Images	Instances	R	mAP50	mAP50-95
all	200	1736	0.955	0.981	0.919
Car	200	1060	0.988	0.995	0.927
Bus	200	102	0.928	0.96	0.903
Truck	200	574	0.949	0.988	0.925

5.3 *Creation of paired datasets for super-resolution networks*

5.3.1 *Segmented testing performance of vehicle detection*

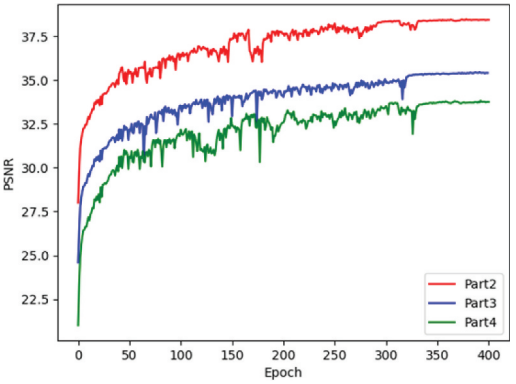
200 frames from the Jiangyin Bridge were selected for annotation (as depicted in Figure 6) and segmented into four parts following the guidelines in Section 3.2. Each part was then evaluated using the YOLOv8 model, as detailed in Section 5.2. The results indicated a decrease in detection accuracy with increased distance from the camera, linked to varying blur levels across the segments. To address the image quality degradation from the camera's depth of field, specific super-resolution (SR) training datasets for each segment were developed, consisting of high-resolution images similar to part 1 and low-resolution counterparts for parts 2 to 4. The trained SR networks aim to uniformly enhance image clarity to the level of part 1.

Figure 6. Segment vehicle detection and clarity assessment.

To accurately simulate real-world blur in datasets for parts 2 to 4, clarity assessment methods from Section 3.3 were utilized. The down-sampling process involved techniques like interpolation and various blurs, with parameters fine-tuned to reflect actual image conditions. This yielded three sets of high-resolution and low-resolution image pairs for each segment, effectively demonstrating the quality enhancement as depicted in the respective sections.

5.4 *Super-resolution enhancement on RDN*

Utilizing the generated matched datasets, the Residual Dense Network (RDN) was trained separately for the three distinct parts of the image. The training settings were meticulously configured: a learning rate of 1×10^{-4}, a batch size of 32, a patch size of 32 for image segmentation, and a total of 400 epochs. During training, the Peak Signal-to-Noise Ratio (PSNR) values for parts 2 to 4 were obtained, as shown in Figure 7.



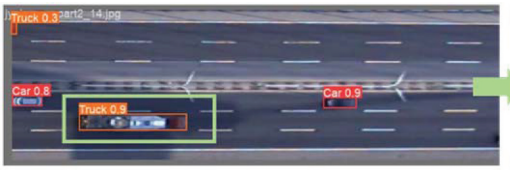


Figure 7. Variation curve of PSNR values during the training process of RDN.

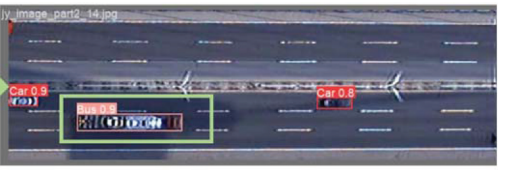
PSNR, a key metric in image processing, quantitatively assesses super-resolution reconstruction quality by comparing it with the original high-quality images (ground truth). Higher PSNR values, exceeding 30 in all three reconstructed sections, indicate successful image enhancement.



5.5 *Result and discussion*

After the new model was trained, it was used for image restoration and detection, with the results as follows.

For part 2, which originally had relatively high clarity, the recall rate and mAP50 showed marginal improvement. However, a significant enhancement was observed in mAP50-95. This suggests that the super-resolution reconstruction in this part led to a higher probability of accurate recognition, primarily due to the subtle refinement of image details.

Class	Images	Instances	R	mAP50	mAP50-95
all	200	2056	0.884	0.897	0.665
Car	200	1222	0.979	0.96	0.743
Bus	200	100	0.83	0.846	0.611
Truck	200	734	0.842	0.884	0.641

Class	Images	Instances	R	mAP50	mAP50-95
all	200	2056	0.893	0.905	0.732
Car	200	1222	0.938	0.976	0.811
Bus	200	100	0.846	0.86	0.679
Truck	200	734	0.894	0.885	0.706

Figure 8. Comparison of detection performance before and after SR enhancement for part 2.

In the case of part 3, characterized by lower clarity, the enhancements were primarily observed in the recall rate and mAP50. Post-processing through our network substantially reduced instances of incorrect and duplicate detections. This improvement can be attributed to the super-resolution network's capability to restore vehicle textures and finer details, thereby enhancing the overall detection accuracy.

Truck	200	674	0.777	0.897	0.62

Figure 9. Comparison of detection performance before and after SR enhancement for part 3.

For part 4, which had the lowest clarity, the primary improvement was in mAP50. The super-resolution processing notably facilitated the detection of previously undetectable vehicles, likely due to the sharpening of edges by the super-resolution network.

6 CONCLUSION

This study introduces a novel method combining super-resolution technology with object detection for vehicle load monitoring on long-span bridges, enhancing detection accuracy significantly. Our experiments demonstrate the method's effectiveness in extending the monitoring capabilities of single-camera systems. The findings suggest potential future improvements in traffic management and bridge monitoring. Future work could explore algorithms that merge super-resolution with object detection and analyze continuous video data, further enhancing monitoring precision and range.

ABSTRACT: In the field of structural health monitoring, advancements in computer and sensor technologies have facilitated the acquisition of vast amounts of structural response data. However, assessing the current state of a structure alone is often insufficient, and a more comprehensive approach involves estimating its future characteristics, a concept commonly known as damage prognosis. Such estimations rely not only on the natural ageing of the structure but also on accurately predicting changes in applied loads over time. This paper investigates a method for dynamic load estimation based on heterogeneous operational data using physics-informed Gaussian processes (GPs). A machine learning model is constructed as a multi-output GP, with covariance and cross-covariance kernels derived analytically from time-domain derivatives of displacements, velocities, and accelerations. Training is carried out in modal space via maximum likelihood estimation using a comprehensive set of measurement data. Coupling the trained model with the harmonic oscillator differential equation yields a hybrid Bayesian framework for dynamic load estimation. The efficacy of the model is demonstrated through an aerodynamic analysis of the Great Belt East Bridge. The buffeting response is numerically computed using the linear unsteady assumption, and the associated non-linear force is reconstructed using noisy synthetic sensor measurements. Results indicate a good agreement between the applied forces and the mean predicted dynamic load in low-frequency ranges, while high-frequency content is effectively captured by the Bayesian formulation as an increase in uncertainty. The developed model is a reliable approach for load reconstruction and can be directly integrated into a damage prognosis framework when continuous measurement data is available.

1 INTRODUCTION

In the design of contemporary structures, engineers commonly rely on codes of practice or empirical guidelines to calculate the loads that structures might encounter over their lifespan. Nevertheless, in practical scenarios, these loads often exhibit time-varying characteristics and may not be entirely known during the design phase. Adding to this challenge is the increasing uncertainty associated with loads arising from environmental effects, a trend exacerbated by the ongoing impacts of climate change. This issue not only poses difficulties in the design of new structures but also presents a challenge in predicting the future conditions of existing structures. The latter task, coupled with structural health monitoring, constitutes a procedure that forms an integral part of a damage prognosis framework, as illustrated in Figure 1 (Farrar & Lieven, 2006).

Force reconstruction can be carried out in several different ways, based for instance on data-driven techniques (Liu et. al., 2022, Nonomura et. al., 2018, Petersen et. al., 2022, Tondo et. al., 2023b), optimization strategies (Wang et. al. 2015), defined basis functions (He et. al., 2018),

DOI: 10.1201/9781003483755-416

and many other models (Sanchez & Benaroya, 2014). This study proposes methodology based in stochastic processes using Gaussian process for machine learning (Rasmussen & Williams, 2006). The proposed framework integrates data-driven models with physics-based formulations, eliminating the need for regularization and inherently accommodating noise properties. It offers flexibility to integrate diverse data types and sets characterized by varying quality levels.

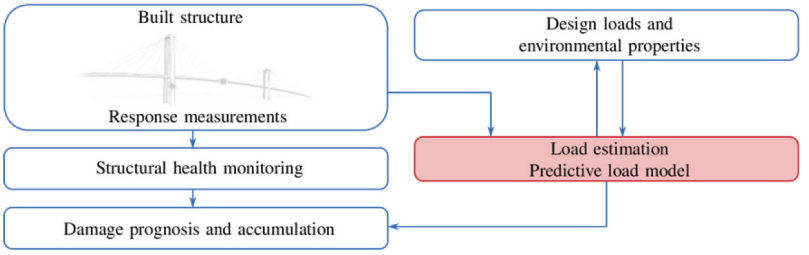

Figure 1. Damage prognosis framework as per Farrar & Lieven (2006). The estimation of the current load conditions based on measurement data, detailed in red, is used as a basis to update the design loads, create predictive load models, and determine probable future damage.

This paper presents a case study involving the reconstruction of aerodynamic forces acting on the Great Belt East bridge. The structural response is computed through the application of the linear unsteady aerodynamic model, and subsequently, white noise is introduced to the responses to replicate measurement conditions. The resultant noisy data is then downsampled and employed as training data for a physics-informed machine learning model established within the Gaussian process framework. The model effectively yields a Bayesian view on the underlying forces that produced the original responses. To assess the efficacy of the approach, comparisons between true and reconstructed signals are conducted. Additionally, the predictions are integrated with a structural finite element model, providing valuable insights into the structural responses and internal forces arising from aerodynamic loading.

The organization of this paper is as follows: Section 2 presents a general framework of the proposed model and develops the prediction procedure in three separate steps. Section 3 defines the aerodynamic analysis properties and presents the results of the force reconstruction scheme. Lastly, Section 4 presents conclusions and an overview of possible future investigations.

2 GAUSSIAN PROCESS FOR FORCE RECONSTRUCTION

The physics-informed Bayesian machine learning model derived in this work is composed of three different building blocks (c.f. Figure 2):

1. A multi-output Gaussian process model for structural responses (displacements, velocities and accelerations) is built and trained using collected measurement data (Sec 2.1).
2. A hybrid GP force model is built combining the machine learning framework with the partial differential equation describing the system oscillation (Section 2.2).
3. Force predictions are carried out by combining the hybrid force model from Section 2.2 with the trained response model from Section 2.1 (Section 2.3).

2.1 *Model for observable responses*

Externally applied forces in bridges cause internal stresses and, in general, a displacement response. When the applied load varies in time, the displacement response can be measured continuously and modelled as

$$u = f(t) + \varepsilon \tag{1}$$

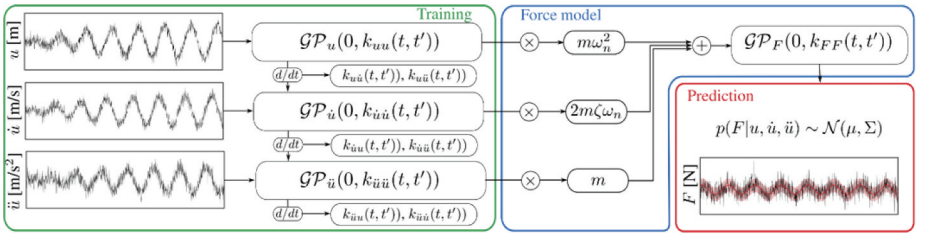

Figure 2. Framework for the physics-informed Gaussian process: (green) models for measured data are created and jointly trained. A force model (blue) is built combining the previous models and the harmonic oscillator's differential equation, which can be used for predictions (red).

where t is the time and $\varepsilon = \mathcal{N}\left(0, \sigma_{n,u}^2\right)$ the Gaussian noise in the measurement system, defined by a variance $\sigma_{n,u}^2$. The same principle of a stochastic process applies to the velocity and acceleration signals, where each of them has a particular noise variance $\sigma_{n,\dot{u}}^2$ and $\sigma^2{}_{n,\ddot{u}}$. Assuming the underlying deflection response is a stochastic zero-mean Gaussian process, a model can be created such that

$$u(t) \sim \mathcal{G}P\left(0,\ k_{uu}(t,t') + \sigma_{n,u}^2 \delta(t,t')\right) \tag{2}$$

where δ is the Kronecker-Delta operator and k_{uu} is a covariance kernel that measures similarity between time instances t and t '. The displacement response is herein assumed to be continuous and smooth in time, and thus k_{uu} can be modelled by the squared exponential (SE) kernel

$$k_{uu}(t,t';\sigma_s,\ell) = \sigma_s^2 \exp\left(-\frac{1}{2}\left(\frac{t-t'}{\ell}\right)^2\right) \tag{3}$$

in which σ_s is a standard deviation amplitude and ℓ is a length scale controlling the kernel smoothness (Rasmussen & Williams 2006). Since velocities $\dot{u}$ and accelerations $\ddot{u}$ are time-derivatives of the displacements and exploiting the fact and any linear operation to a Gaussian process result in another GP, physics-informed covariance and cross-covariance kernels can also be created for velocities $k_{\dot{u}\dot{u}}$ and accelerations $k_{\ddot{u}\ddot{u}}$, such that

$$k_{u\dot{u}} = \frac{d}{dt'}k_{uu},\ \cdots k_{\dot{u}\dot{u}} = \frac{d}{dt}\frac{d}{dt'}k_{uu} \tag{4}$$

and

$$k_{u\ddot{u}} = \frac{d^2}{dt'^2}k_{uu} \cdots k_{\ddot{u}\ddot{u}} = \frac{d^2}{dt^2}\frac{d^2}{dt'^2}k_{uu} \tag{5}$$

While Gaussian processes are considered non-parametric models, the specific characteristics of covariance kernel and noise assumptions introduce model parameters that need to be determined based on the training data. When measurements are taken for deflections, velocities, and accelerations, the parameter set to be determined is denoted as $\theta = \left\{\sigma_s, \ell, \sigma_{n,u}, \sigma_{n,\dot{u}}, \sigma_{n,\ddot{u}}\right\}$ The consideration of measurement noise depends on the availability of data for a particular quantity, either excluding it when no data is collected or incorporating it when multiple datasets with varying properties are at hand (Tondo et al. 2022, 2023a). Parameter determination is achieved using maximum likelihood estimation

$$\boldsymbol{\theta}_{\text{opt}} = \text{argmax}_{\boldsymbol{\theta}} \log p(\boldsymbol{y}|\boldsymbol{t},\boldsymbol{\theta}) = \text{argmax}_{\boldsymbol{\theta}}\left(-\frac{1}{2}\boldsymbol{y}^{\mathrm{T}}\boldsymbol{K}^{-1}\boldsymbol{y} - \frac{1}{2}\log|\boldsymbol{K}| - \frac{N}{2}\log 2\pi\right) \tag{6}$$

where N is the number of data points, $y = [u, \dot{u}, \ddot{u}]^{\mathrm{T}}$ collects the training data and K is a block-covariance matrix calculated via the kernel formulations,

$$\boldsymbol{K} = \begin{bmatrix} k_{uu}(\boldsymbol{t},\boldsymbol{t}') + \sigma_{n,u}^2\delta(\boldsymbol{t},\boldsymbol{t}') & k_{u\dot{u}}(\boldsymbol{t},\boldsymbol{t}') & k_{u\ddot{u}}(\boldsymbol{t},\boldsymbol{t}') \\ k_{\dot{u}u}(\boldsymbol{t},\boldsymbol{t}') & k_{\dot{u}\dot{u}}(\boldsymbol{t},\boldsymbol{t}') + \sigma_{n,\dot{u}}^2\delta(\boldsymbol{t},\boldsymbol{t}') & k_{\dot{u}\ddot{u}}(\boldsymbol{t},\boldsymbol{t}') \\ k_{\ddot{u}u}(\boldsymbol{t},\boldsymbol{t}') & k_{\ddot{u}\dot{u}}(\boldsymbol{t},\boldsymbol{t}') & k_{\ddot{u}\ddot{u}}(\boldsymbol{t},\boldsymbol{t}') + \sigma_{n,\ddot{u}}^2\delta(\boldsymbol{t},\boldsymbol{t}') \end{bmatrix} \tag{7}$$

for the specific measurement times t. Maximization of Equation (6) is achieved by gradient ascent via quasi-Newton BFGS optimization. Although not explicitly shown, it is worth noting that the derived formulation does not require a regular time-step interval, providing flexibility in cases of missing response time-steps or imperfect sensor synchronization (Tondo et al. 2023b).

2.2 *Force model*

The response of a harmonic oscillator to an arbitrary dynamic loading F is given by the second-order inhomogeneous differential equation

$$m\ddot{u} + 2m\zeta\omega_n\dot{u} + m\omega_n^2 u = F \tag{8}$$

where m is the oscillator's mass, ζ is the damping ratio to critical and ω_n is the oscillator's circular natural frequency. Combining the derived response kernels with the oscillator model from Equation (8) gives rise to a physics-informed cross-covariance model between the dynamic load and the deflection,

$$k_{Fu}(t,t';\sigma_s,\ell) = mk_{\ddot{u}u} + 2m\zeta\omega_n k_{\dot{u}u} + m\omega_n^2 k_{uu} \tag{9}$$

while the models for velocities and accelerations are generated similarly. The force covariance is calculated by applying Equation (8) to the second time index of k_{Fu}, yielding

$$k_{FF}(t,t';\sigma_s,\ell) = mk_{F\ddot{u}} + 2m\zeta\omega_n k_{F\dot{u}} + m\omega_n^2 k_{Fu} \tag{10}$$

2.3 *Force prediction*

The force signal that generated the measured responses can be reconstructed using the trained measurement model from Section 2.1 and the force model from Section 2.2. The joint distribution of the data collected in y and the force vector F is constructed as

$$p(\boldsymbol{y},\boldsymbol{F}) = \mathcal{N}\left(\begin{bmatrix}\boldsymbol{0}\\ \boldsymbol{0}\end{bmatrix}, \begin{bmatrix}\boldsymbol{K} & \boldsymbol{K}_* \\ \boldsymbol{K}_*^{\mathrm{T}} & \boldsymbol{K}_{**}\end{bmatrix}\right) \tag{11}$$

where $K_* = [k_{Fu}(\boldsymbol{t}_*,\boldsymbol{t}'), k_{F\dot{u}}(\boldsymbol{t}_*,\boldsymbol{t}'), k_{F\ddot{u}}(\boldsymbol{t}_*,\boldsymbol{t}')]^{\mathrm{T}}$ and $\boldsymbol{K}_{**} = k_{FF}(\boldsymbol{t}_*\boldsymbol{t}'_*)$, with $\boldsymbol{t}_*$ being the time instants for force prediction. Conditioning the force model on the measurement data yields

$$p(\boldsymbol{F}|\boldsymbol{y}) = \mathcal{N}\left(\boldsymbol{\mu} = \boldsymbol{K}_*^{\mathrm{T}}\boldsymbol{K}^{-1}y, \boldsymbol{\Sigma} = \boldsymbol{K}_{**} - \boldsymbol{K}_*^{T}\boldsymbol{K}^{-1}\boldsymbol{K}_*\right) \tag{12}$$

which defines the prediction's mean values $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$ shown in Figure 2.

3 AERODYNAMIC FORCE RECONSTRUCTION

3.1 *Numerical model and aerodynamic analysis*

The model developed for force identification is now used to reconstruct the aerodynamic forces applied to a numerical model of the Great Belt East Bridge in Denmark. A sketch of the suspension bridge, along with its cross-section and the coordinate system for the aerodynamic forces are shown in Figure 3 (top). Modal analysis was carried out after the effects of self-weight considering third order geometric non-linearity were taken into account, and the results were validated with literature reports (Larsen, 1993). A total of 22 vibration modes (c.f. Figure 3,

bottom) were used in the dynamic analysis of the structure, carried out with a sampling rate of f_s = 20 Hz and assuming a modal damping ratio of ζ = 0.5 %.

A reduced order model based on the linear unsteady assumption (Caracoglia & Jones, 2003) is used to numerically calculate the aerodynamic response of the bridge. The mean wind speed was defined as U = 30 m/s. Correlated turbulent wind time-histories are generated following von Kármán spectrum (c.f. Figure 4), assuming turbulence intensities of I_u = 11 % and I_w = 6 %, and turbulence length scales of L_u = 108 m and L_w = 60 m. Buffeting analysis was carried out assuming Sears' model for aerodynamic admittance, and the cross-section static wind coefficients and aerodynamic derivatives are obtained from Kavrakov & Morgenthal (2018).

Based on the aerodynamic model, the structural modal and global responses are obtained, as shown in Figure 5 for the case of the first bending mode (f = 0.100 Hz).

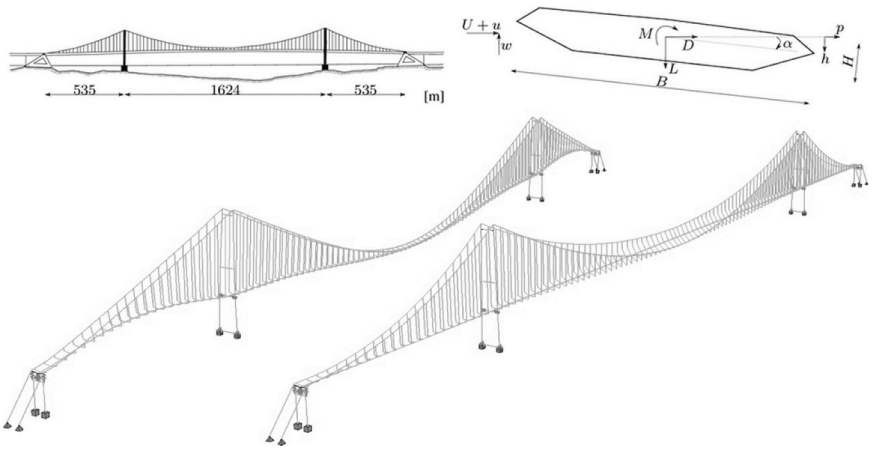

Figure 3. Numerical model of the Great Belt East Bridge. Top: longitudinal schematic with the span lengths (left) and the coordinate system for aerodynamic forces (right). Bottom: the first bending (f = 0.100 Hz, left) and torsional (f = 0.278 Hz, right) mode shapes.

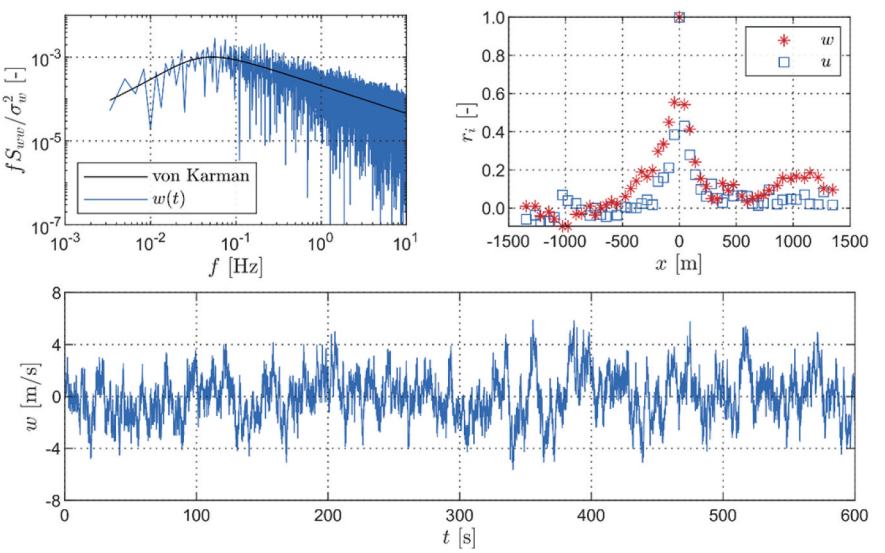

Figure 4. Top: generated turbulence spectrum in the vertical direction w in comparison to von Kármán model (left), and the correlation coefficient along the bridge length w.r.t. the midspan (x = 0 m). Bottom: the generated turbulence signal at midspan.

3.2 *Force reconstruction*

The computed modal responses can now be used as inputs to the physics-informed Gaussian process to recover the dynamic load that excited the structure. For that matter, the responses are initially contaminated with white noise characterized by a signal to noise ratio (SNR) of 20, to simulate the practical aspects of realistic measurement data. In addition, a sparse selection of the noise data was used during training, selected based on a constant interval with a sampling rate of f_s = 1 Hz. The modal responses and selected training points are shown in Figure 5.

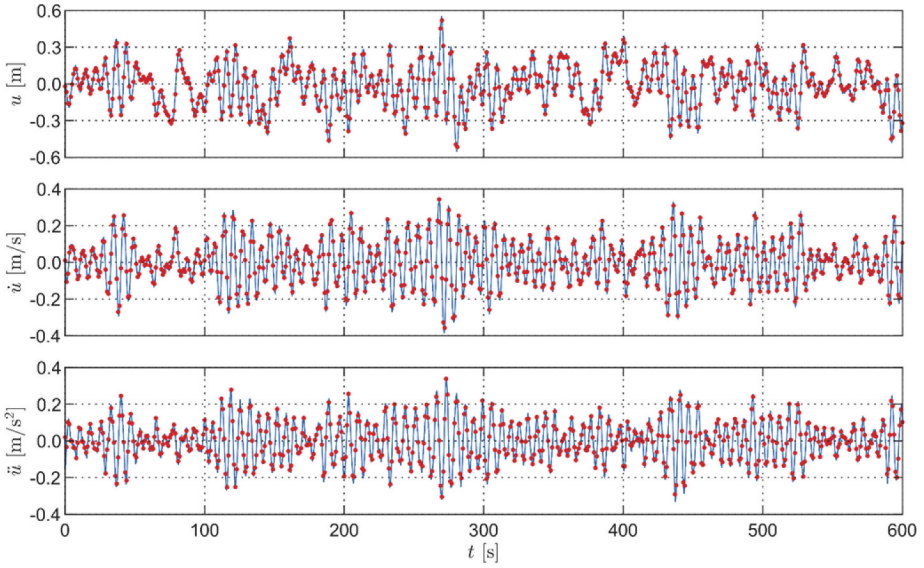

Figure 5. Calculated modal responses (from top to bottom: displacement, velocity, and acceleration) using the LU aerodynamic model and the turbulence characteristics defined in Section 3.1. The red dots represent the training points provided to the GP model.

Once the GP model is trained, the forces can be predicted by leveraging the physical laws built into the machine learning framework. The underlying modal force for the first bending mode shape is shown in Figure 6 (top). A good agreement is observed between the predicted and original forcing signals in a mean sense, despite the true force signal containing multiple harmonic components, governed typically by the structural modal frequencies. The prediction uncertainty range is observed to increase close to the peaks of the predicted forces. If a shorter time window is analysed (cf. Figure 6, bottom left), however, it is evident that the predictions are a smoothened version of the true force, with the GP effectively acting as a low-pass filter of the original signal and capturing high-frequency content by its uncertainty measurement. This is also verified by the power spectral density of the force S_{FF}, as shown in Figure 6 (bottom right), where a good agreement is observed until f = 1 Hz, corresponding to the sampling frequency of the data used for training.

The assessment of prediction quality for all 22 modes is carried out through the mean squared error, measured in relation to the normalized true force. While modal contributions to the global response are relative to both forcing and structural properties, consistent root mean square error (RMSE) values ranging from 0.05 to 0.15 are identified across all modes. Consequently, the predictions exhibit uniform quality levels. It is important to note, however, that this uniformity may not always hold true in practical scenarios, due to the presence of varying degrees of noise within the measurement data.

In addition to force prediction, the integration of the trained physics-informed Gaussian process model with a finite element representation of the structure facilitates the forecasting of global responses and internal forces throughout the training period. This is illustrated in Figure 7, where the case of global displacement at midspan and the internal bending moment at the base of one of

the piers. The high quality of force prediction is evident in the evaluation of global responses, which closely align with the outcomes derived from the original linear unsteady model. A similar behavior is noted in the frequency domain, where responses are accurately estimated up to the sampling frequency of the training data provided to the Gaussian process model.

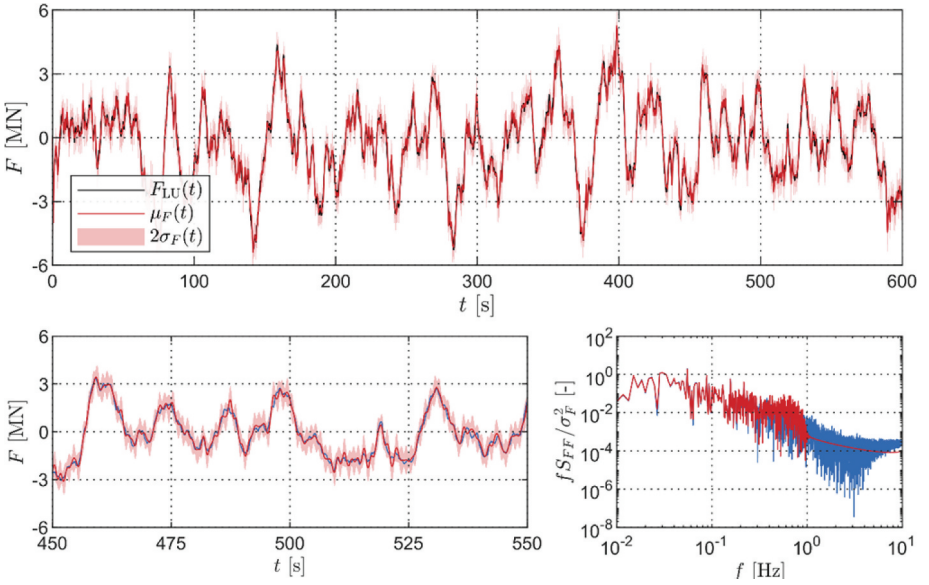

Figure 6. Top: the true modal force for the aerodynamic analysis according to the LU model and the mean and uncertainty ranges of the physics-informed Gaussian process predictions. Bottom: a detailed depiction of the predicted force signal (left) and the comparison of the power spectral density of the true and predicted mean force (right).

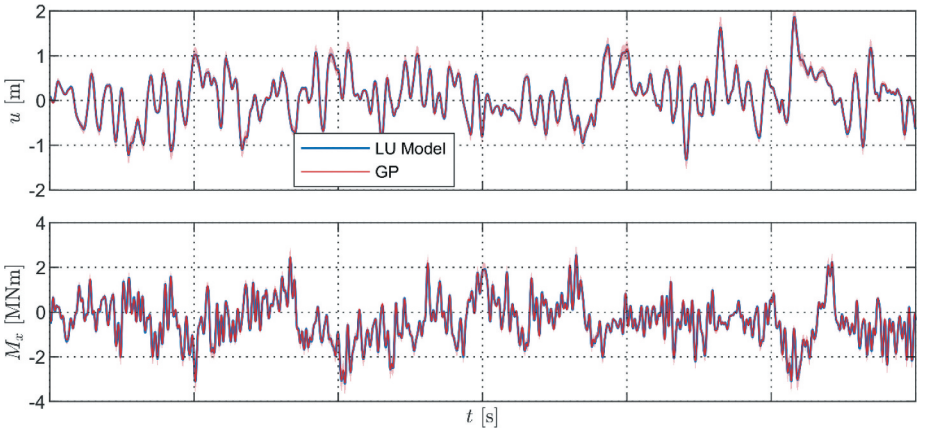

Figure 7. Top: the vertical response at midspan in global coordinates, for the original LU model and the reconstructed response using the forces identified with the Gaussian process (GP) model. Bottom: the bending moment at one of the pier supports.

4 CONCLUSIONS

In summary, an innovative stochastic method for reconstructing dynamic forces based on sensor measurement data is introduced, constructed utilizing Gaussian process regression for machine

learning, incorporating established differential equations to capture relationships between physical properties. This hybrid formulation facilitates the integration of heterogeneous and multi-fidelity data during the training process. Unlike conventional optimization problems where regularization schemes often pose challenges, our approach circumvents such issues through the inherent trade-off between data fitting and model complexity afforded by the Gaussian likelihood. Additionally, this choice ensures complete analytical tractability for posterior sampling.

Force predictions were compared and discussed in relation to the standard linear unsteady model for aerodynamic loads. It is noteworthy that the model's capacity to represent a broad spectrum of frequency content is contingent upon the sampling rate of the training data. For high-frequency training data, challenges arise as the optimization for Gaussian processes exhibits scalability issues with an increasing number of training points. Although the derived model seamlessly accommodates cases of missing steps or unsynchronized training data, these scenarios were not specifically addressed in this study.

Furthermore, the integration of probabilistic force predictions with a finite element solver provides a statistical perspective on global responses and, consequently, internal forces. The outcomes of this analytical approach yield valuable insights for evaluating structural performance, enabling condition diagnostics, and facilitating prognosis. In conclusion, the presented framework serves as a robust statistical tool for dynamic force reconstruction with direct applications in model validation and structural health monitoring. While the results herein pertain to a specific case study, we anticipate the generalizability of the framework to various structural systems and dynamic loading properties.

ABSTRACT: In 2021, 42% of bridges in the United States were used beyond their design life, incurring a repair cost of approximately $125 billion. To reduce future repair costs of bridges, novel inspection methods have been recently proposed that use unoccupied aerial vehicles to inspect bridge defects, where a computer vision-based model processes the data to assess bridge condition. Although this technology can provide significant advantages in decreasing inspection costs and labor, inspection accuracy relies on the quality of images and the computer vision model. Therefore, this study develops a multi-task deep learning framework that combines object detection and semantic segmentation models to detect important structural details and quantify corrosion level in steel bridges with high precision and speed (i.e., inference time). The framework leverages high-performing computing and high-definition images to minimize resizing effects on model accuracy. For each module, two different deep learning architectures were developed and compared in terms of accuracy and inference time. The results show the efficiency of deep learning models for both tasks. For an intersection over a union threshold of 50%, the object detection models of YOLOv8 and SSD RetinaNet50 achieve mean average precision of 96.6% and 85.2%, respectively. In addition, the segmentation models of YOLOv8 and DeeplabV3+ achieved an F1 score of 61.5% and 28%, respectively.

1 INTRODUCTION

In 2021, 42% of bridges in the United States were used beyond their design life, and were projected to incur a repair cost of approximately $125 billion (Abdallah et al., 2022). Therefore, ongoing monitoring and inspection are critical to allocating funding for maintenance and repair activities and ensuring bridge serviceability. These inspections are performed visually for the most part, and if needed, through non-destructive testing. Nevertheless, performing such inspections is costly and complex, requires skilled labor, and could disrupt common functions of bridges (e.g., lane closure). These issues are further compounded by limited financial resources and the large bridge inventories.

Unoccupied aerial vehicles (UAVs) have been proposed as an innovative bridge inspection tool to aid with visual inspection of large bridge inventories. UAV-based inspection may be more economical, efficient, and allows for a safer inspection with little disruption to bridge function (Seo et al., 2018). Such advantages have led to the emergence of a wealth of research and the favorable reception of UAVs by different federal agencies and state departments of transportation.

DOI: 10.1201/9781003483755-417

UAV-based inspection video and imagery are often post-processed using computer vision (CV) techniques to assess the bridge conditions. Subsequently, the quality of the inspection relies on the accuracy of the employed CV technique. The applied CV techniques can be classified into three main categories (Spencer et al., 2019): (1) image classification, which classifies an entire image into a specific class, (2) object detection, which assigns all possible objects of interest in an image into their corresponding classes, and (3) semantic segmentation, which divides all the pixels of an image into several segments, where each segment is assigned to its corresponding class.

Recently, deep learning models were proposed to perform CV tasks. For example, Atha and Jahanshahi compared several convolutional neural network architectures to identify corrosion on metallic surfaces (Atha & Jahanshahi, 2018). Burton et al. developed a deep learning algorithm to detect corrosion using automated segmentation without the need for per-pixel labeled data, albeit the model showed limitations with respect to non-uniform illumination and shadows (Burton et al., 2022). Lastly, Bianchi and Hebdon developed a semantic segmentation model based on Deeplab architecture for corrosion identification in steel bridges (Bianchi & Hebdon, 2022).

This paper develops a multi-task deep learning framework to process UAV-based steel bridge inspection. The framework aims to assist the inspector in detecting important structural steel details and quantifying corrosion level in the detected details. This multi-task approach paves the path towards a more "context-aware" CV model, as the presence of corrosion in non-critical details will not largely affect the bridge condition. Additionally, the framework combines low inference time and high accuracy to facilitate a real-time inspection approach.

2 METHODOLOGY

2.1 *Overview*

The developed framework comprises two modules: (a) an object detection module, and (b) a corrosion segmentation model. The first module aims to identify four critical details in steel bridges, including bearing, out-of-plane stiffeners, gusset plates, and cover plate termination. In contrast, the second module aims to detect the corroded area of images. The combined output from the two modules will be aggregated to generate actionable information on bridge condition.

2.2 *Data augmentation*

The COCO-Bridge-2021+ dataset (Bianchi et al., 2021) was selected to train object detection models. Before training, the dataset was checked, and minor corrections were made on (i) the annotation XML file of original images to match the actual image size, and (ii) removing zero-size image dimensions of several annotations. In addition, the first 436 images from the COCO-Bridge-2021+ dataset were collected and annotated for the corrosion segmentation model. The corrosion annotation was restricted to only steel elements, and any corrosion in the reinforcement of the concrete elements was ignored. In addition, only corrosions classified as severe and poor (AASHTO, 2019) were annotated since they can lead to section loss. Therefore, the annotation

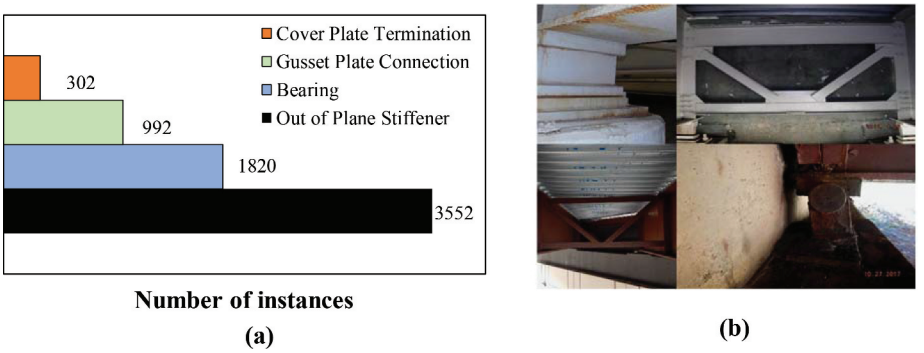

Figure 1. (a) Number of difference instances in the dataset, (b) Example of mosaic data augmentation.

did not include instances with freckled rust (fair condition). As shown in 1.a the selected dataset is highly imbalanced (i.e., there are vastly different object instances for different classes). To address this issue, two different remedies were used: (1) various data augmentation techniques were applied, and (2) dual focal loss (Hossain et al., 2021) was used as the objective of CV models.

The resulting datasets (object detection and corrosion) were augmented, which is the process of increasing the size of a training dataset by manipulating the images using different CV techniques. This process improves the model's general performance and reduces the effect of overfitting. Among various techniques, a combination of mosaic, horizontal flip, and adjusted brightness were used. Mosaic augmentation combines four images of the training dataset, merges them into one image, and then randomly crops the image to get the final output image. Mosaic augmentation helps models identify details, particularly smaller details, in different locations of any image. Figure 1.b shows a sample augmented image after applying the mosaic technique. Horizontal flipping mirrors an image about its vertical axis, increasing the dataset's size without confusing the trained model in this application. For example, another technique (vertical flipping) could confuse the training as an inverted bridge is not physically meaningful, leading to poor accuracy on the test set. Lastly, adjusted brightness was randomly applied with a tolerance of 20% to images to account for different lighting conditions. The 20% threshold was chosen to restrict brightness and prevent losing image details.

2.3 *Training platform*

Deep-learning frameworks handle images as tensors of rank 4 (i.e., several three-dimensional matrices on different channels). Such dimensionality leads to computational challenges in training CV models using CPUs. Therefore, this study used the graphical processing unit (GPU) of the Lonestar6 supercomputer at the Texas Advanced Computing Center (TACC). Lonestar6 supports three Nvidia A100 PCIE GPUs, each with 40 GB RAM for a single GPU node. Due to the high computational power of Lonestar6, object detection models were trained on high-definition images with 1024x1024 size with no memory failure issues, whereas segmentation models were trained on relatively smaller images with 512x512 size.

2.4 *Model evaluation*

The performance of deep learning models can be evaluated through different metrics, dictated by the problem definition and its associated loss functions. Intersection over union (IOU) is the crux of performance evaluation metrics in object detection and segmentation models. IOU is defined as the intersection between the model's prediction and ground truth bounding box/segmentation mask divided by the union of the same parameters, where ground truth refers to the object in the image.

This study uses mean average precision (mAP) as the primary evaluation metric for object detection models. mAP is a widely used performance metric based on IOU, precision (i.e., the ratio of true positive to the total predicted positive), and recall (the ratio of true positive to the actual positive cases). The area under the precision-recall curve is the average precision for a specific class, where mAP provides the mean of average precision over different classes. mAPs are typically represented at IOU thresholds that differentiate between a true positive and a false positive for a given prediction. For example, a prediction with an IOU larger than the IOU threshold is considered true positive. Here, two IOU thresholds were chosen: (a) mAP50 (i.e., IOU at 50%), and (b) mAP50-95 (i.e., the average mAP using different IOU thresholds ranging from 50% to 95% with 5% increments). For semantic segmentation, the F1 score was used, which is the harmonic mean of precision and recall.

3 OBJECT DETECTION MODULE

Two different object detection models were examined for this module, as will be discussed next.

3.1 *Single-shot multi-box object detection model*

Single-shot multi-box object detection (SSD) model is a fast architecture since it uses only one stage to detect objects in a certain image. An SSD RetinaNet50 was used as the first model for the object detection module. The selected SSD model uses ResNet50 as its feature extractor in a feature pyramid network architecture.

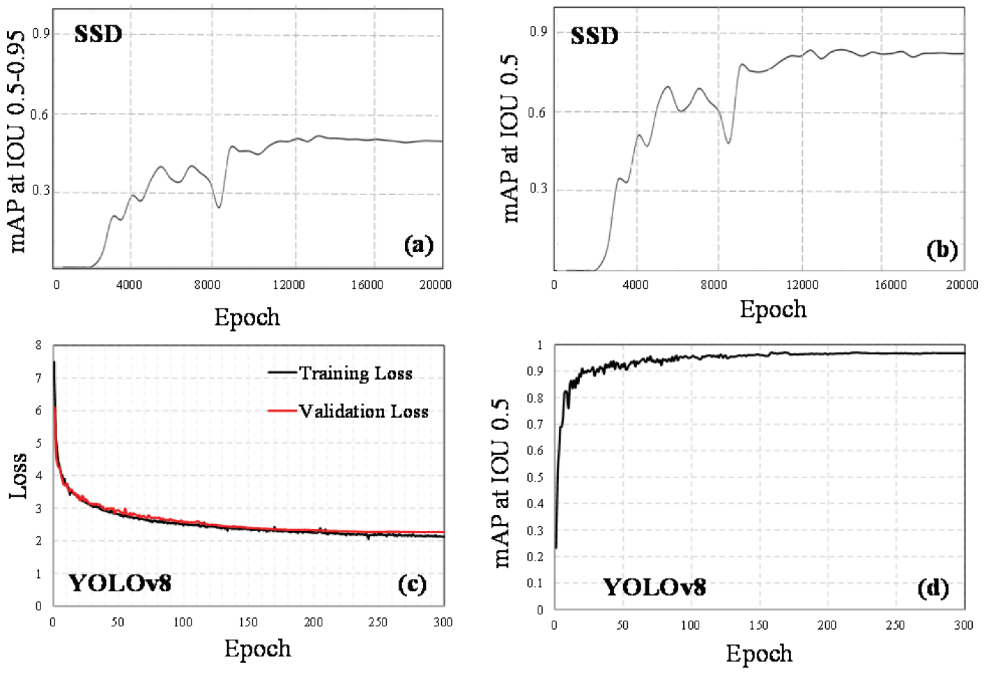

Figure 2. (a) mAP50 and (b) mAP50-95 for SSD model. (c) loss function and (d) mAP50 for YOLOv8 object detection model.

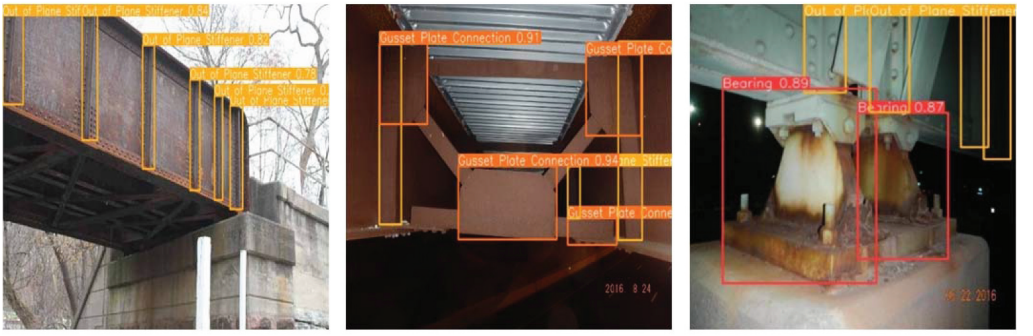
Transfer learning was applied to improve model accuracy since the COCO-Bridge-2021+ dataset is relatively small (i.e., 1470 images). The transfer learning concept uses a pre-trained model from a larger dataset as the starting point to train the same model on another smaller dataset. A pre-trained SSD RetinaNet50 model on the Microsoft COCO dataset was used from Tensorflow 2 Detection Model Zoo to train the current SSD model.



The training was carried out using the object detection API of TensorFlow through a configuration pipeline in a text format to alter training hyperparameters. First, two TensorFlow records (i.e., a binary file format that TensorFlow supports, which stores an image dataset and its corresponding annotation ground truth bounding boxes efficiently in one file) were generated. The first record was for the training dataset, and the second one was for the testing dataset. Second, all training hyperparameters were set through a configuration file.

SSD model was trained using a stochastic gradient descent optimizer with a momentum of 0.9. The learning rate is a cosine function that decays from 0.005. The anchor boxes aspect ratios used were 1.0, 2.0, 0.5, 0.33, 3.0, 0.25, and 0.2. These values were selected after plotting all ground truth bounding boxes' aspect ratios in a histogram, as most objects have an aspect ratio of less than 0.4. Consequently, aspect ratios of 0.25 and 0.20 were added to enable the SSD model to detect slender objects. Non-maximum suppression stage had an IOU of 0.5 and a confidence threshold of 0.25. The non-maximum suppression stage is the final stage in most object detection models that filters all predictions made by the SSD model. A rectified linear function (RELU) was used as the activation function to introduce the nonlinearity in the deep learning mode. Batch size was taken as 30, which shows the number of images processed into the GPU in a single iteration.

A weight regularization layer and a dropout regularization were applied to limit the overfitting issue. Weight regularization adds a penalty term to the total loss to penalize large weight, reducing the effect of overfitting. Several different rates were examined for weight regularization, and a rate of 0.01 was found to be the optimum in limiting the overfitting issue. In contrast, the dropout regularization layer drops a specific percentage of the network weights to zero to constrain model complexity and reduce overfitting, where a dropout rate of 60% was applied to the developed SSD model.

(a) SSD model

(b) YOLOv8 models.

Figure 3. Examples of inferences for (a) SSD and (b) YOLOv8 object detection models.

Figures 2.a and 2.b show mAP50 and mAP50-95 for the SSD model. As shown in Figures 2. a and 2.b, the SSD model reaches a maximum mAP50 and mAP50-95 of 85.2% and 52.3%, respectively. Figure 3.a shows several examples of SSD inferences. The average inference time was 486 *ms* with a standard deviation of 65 *ms*. It can be observed that SSD fails to detect all the slender objects (e.g., out-of-plane stiffener) in these images.

3.2 *YOLOv8 object detection model*

"You only Look Once (YOLO)" object detection model was the second model to be examined (Wong et al., 2019), where YOLO version 8 (YOLOv8) was selected. YOLOv8 provides two advantages over SSD to tackle the COCO-Bridge-2021+ challenges: (1) an anchor-free object detector (i.e., no need for optimizing the anchor boxes aspect ratio to obtain better results), and (2) dual focal loss function which has a better performance for datasets with class imbalance issue. Dual focal loss is a variant of the cross-entropy loss function, providing the capability to focus on classes in a specific dataset with fewer instances. It should be mentioned that dual focal loss was developed to address the vanishing gradient problem encountered in focal loss. The "nano" version of YOLOv8 was selected due to its higher speed than other versions of YOLOv8. A high-level API was used for model training, evaluation, and prediction. The same stochastic gradient descent optimizer with a momentum of 0.9 was used. A cosine function that decays from 0.004 was used for the learning rate. A dropout regularization was applied with a dropout rate of 50%. Similarly, a weight decay of 0.001 was used to limit overfitting. Non-maximum suppression stage had an IOU of 0.5 and a confidence threshold of 0.25. The batch size was 30.

Figures 2.c and 2.d show the loss curves for training and evaluation sets and mAP50 of the YOLOv8 object detection model. Figure 2.c indicates that the model does not exhibit overfitting, whereas Figure 2.d shows that the model achieved a mAP50 of 96.6%. It should be noted that the

model's mAP50-95 was 75.95%. Figure 3.b shows the YOLOv8 inferences for the same images as SSD. Overall, the model shows higher detection capability, as exhibited by identifying slender objects in the background and overshadowed. The mean inference time for this model was 180 *ms* with a standard deviation of 53 *ms*.

4 SEMANTIC SEGMENTATION MODULE

Two different semantic segmentation models were examined for this module, as will be discussed next.

4.1 *Deeplab V3+ segmentation model*

Deeplab V3+ (Chen et al., 2018) was used as the first segmentation model and trained using Keras API. Keras API is a wrapper for the TensorFlow deep-learning framework that facilitates training, evaluation, and prediction processes.

A combination of Dice loss function and focal loss function was used. The Dice loss function calculates the difference between the ground truth mask and the predicted mask during training. Therefore, the Dice loss function reduces the difference and achieves object localization. Conversely, the focal loss function classifies if a pixel belongs to corroded areas.

Deeplab V3+ was trained by a stochastic gradient descent optimizer with a momentum of 0.9 and a learning rate that decays from 0.004 to 0.002. A dropout regularization was applied with a dropout rate of 50%. In addition, a weight decay of 0.01 has been applied to the optimizer. Batch size was taken as 30.

Figure 4.a shows the F1 score of the Deeplab V3+ model on the test set. As shown in Figure 4. a, the F1 score reaches only 28%. Figure 5.a shows several examples of Deeplab V3+ inferences. Overall, the model fails to detect corroded areas completely, particularly for shadowed areas and where a combination of freckles and severe corrosion exists. It should be noted that the mean inference time for this model was 284 *ms* with a standard deviation of 17 *ms*.

4.2 *YOLOv8 segmentation model*

YOLOv8 also provides a segmentation version, which was used to identify corrosion. The YOLOv8 segmentation model was trained using a stochastic gradient descent optimizer with a momentum equal to 0.9 and a learning rate in terms of a cosine function that decays from 0.005. A dropout regularization was applied with a dropout rate of 50%. In addition, a weight decay of 0.015 has been applied to the optimizer. Non-maximum suppression stage had an IOU of 0.5 and a confidence threshold of 0.25. The batch size was 60.

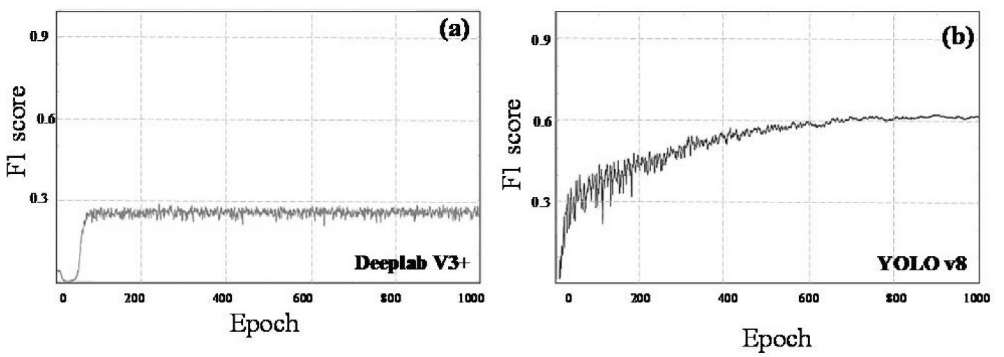


Figure 4. Comparison of model accuracy for (a) Deeplab V3+ and (b) YOLO v8 semantic segmentation models.

(a) Deeplab V3+

(b) YOLOv

Figure 5. Examples of inferences for (a) Deeplab V3+ and (b) YOLOv8 segmentation models.

Figure 4.b shows the F1 score of the YOLOv8 segmentation model, which reaches 61.5%. Figure 5.a shows several examples of YOLOv8 segmentation model inferences. While the model performs better than the Deeplab V3+ model, it still misses smaller corroded areas. It should be noted that the mean inference time for this model was 97 *ms* with a standard deviation of 31 *ms*.

5 CONCLUSION

This paper presented a novel multi-task deep learning framework to identify several important details of steel bridges and quantify the corrosion level at those details. The framework comprises an object detection and a semantic segmentation module that works in parallel to generate "context-aware" condition data. Different deep learning models were developed and compared for each module, and the results were compared in terms of accuracy and inference time. The following summarizes the main findings:

- For the object detection module, YOLOv8 provided 84.7% higher accuracy in terms of mAP at IOU of 0.5 and 62.9% faster inference time than the SSD model.
- For the semantic segmentation module, YOLO v8 provided 119.6%% higher accuracy in terms of F1 score and 65.8%% lower inference time than the Deeplab V3 + model.
- The application of dual focal loss and augmentation could alleviate accuracy issues of highly imbalanced small datasets of structural details for object detection tasks.

Tests of TIG welded lap joint between Fe-SMA and steel

Zhiyi Zhang, Xuhong Qiang & Xu Jiang*
College of Civil Engineering, Tongji University, Shanghai, China

Ping Jin
Pinghu Urban Development Investment (Group) Co., Ltd, Pinghu, China

ABSTRACT: Iron-based shape memory alloy (Fe-SMA) has been applied to reinforce steel bridges with structural adhesive. However, the adhesive bonding is vulnerable to erosion and elevated temperature, making its reliability doubtful. As a type of ferroalloy, the weldability of Fe-SMA with commonly used structural steel has been verified. Therefore, the study of the lap joint of Fe-SMA and steel by welding is of significance in the field of bridge maintenance. In this paper, a series of mechanical tests of the TIG welded lap joint of Fe-SMA-structural steel Q355 was conducted. Fillet weld length, filler materials, and the thickness of materials were considered to investigate their influence on the mechanical properties of the Fe-SMA-Q355 lap joint. Results indicate that the lap joint has an adequate capacity in tension, which means the prestress caused by the shape memory effect of Fe-SMA can be transmitted by the reasonably designed Fe-SMA-Q355 welded lap joint

1 INTRODUCTION

As a novel material, iron-based shape memory alloy (Fe-SMA) has become a hotspot in civil engineering because of its unique shape memory effect. Prestress can be easily obtained after pre-stretching, anchoring, and heating according to the reversible martensite phase transformation (Cladera et al. 2014). Compared with the conventional reinforcement method, there is no need for complex tensioning equipment in the process of prestress production, reducing the space demand and workload on site. Researchers have applied the Fe-SMA reinforcement system to the reinforcement of steel structures (Izadi et al. 2018a, Izadi et al. 2018b, Qiang et al. 2023a) and concrete structures (Rojob & El-Hacha 2018, Czaderski et al. 2014), having achieved meaningful theoretical and practical results.

Further, taking advantage of the low space requirements of Fe-SMA reinforcement, Wu (Qiang et al. 2023b) successfully applied Fe-SMA to the crack repair of the steel bridge diaphragm in Sutong Bridge in Jiangsu, China. Transmitting the compression prestress by structural adhesive, the local stress amplitude and stress concentration were effectively reduced, with a noticeable decline in the fatigue notch factor. However, the reliability of adhesive connections in humid environments especially applied to bridges, remains questionable and requires further verification.

Welding is one of the commonly used connection methods between metals in civil engineering. Its low cost, convenient operation, and high-temperature resistance make it have great potential in the application of the Fe-SMA reinforcement system. Regarding similar metals, the weldability of Fe-SMA has been verified utilizing TIG welding (Dong et al. 2006, Druker et al. 2015, Lin et al. 2000)), electron beam welding (Dong et al. 2006), and laser welding (Zhou et al. 2010, Zhou et al. 2012). For dissimilar metals, Zhou (Zhou et al. 2015) and Liu (Liu et al. 2020) used laser welding to connect Fe-SMA with 304 stainless steel, achieving high-quality joints by optimizing technological parameters, and Sun (Sun et al. 2002) used flash butt welding to connect Fe-SMA with 45 steel, a kind of carbon structural steel.

*Corresponding author: jiangxu@tongji.edu.cn

DOI: 10.1201/9781003483755-418

So, it is reasonable to propose a welded Fe-SMA reinforcement system, where the welded connection between Fe-SMA and structural steel plays an important role. The feasibility of the welded connection is an important foundation for the establishment of the whole reinforcement system. Further, the mechanical properties of the welded connection directly determine the upper limit of the transmitting prestress, thus affecting the system's efficiency. The authors have conducted a related foundational work (Qiang et al. 2023c) about the microstructure and mechanical properties of the butt welded joint between Fe-SMA and structural steel Q235 (a kind of mild steel commonly used in recent 20 years in China). TIG welding was used due to its low heat input, high quality, and stability of electric arc. Results indicate that the joints with proper welding parameters and filler materials were well-formed and had adequate capacity to transmit the reinforcement prestress.

Different from the common butt joint form in weldability verification research, the connection of the Fe-SMA reinforcement system is closer to the lap joint form, and its structure, stress, and influencing factors are also different. So, in this paper, the form of the lap joint which is closer to the actual situation has been prepared and their mechanical properties have been tested. Influencing factors such as fillet weld length, filler material, and thicknesses of base materials have been considered.

2 TEST PROCEDURE

2.1 *Materials*

The proposed welded Fe-SMA reinforcement system as the study object is simplified as a lap joint with a transverse fillet weld (illustrated in Figure 1) to test its mechanical properties. Meanwhile, a welded joint can usually be simplified into three parts: two sides of base materials and the filler as the connection. Thus, there are three types of materials used in this research: Fe-SMA (as the reinforcement material to produce the stress), Q355 (as the structural material), and ER309L (as the filler material).

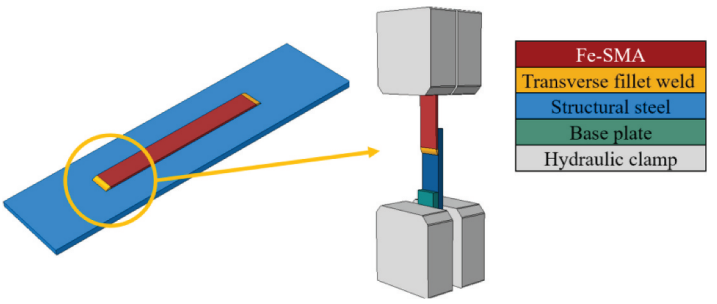

Figure 1. Simplified study object.

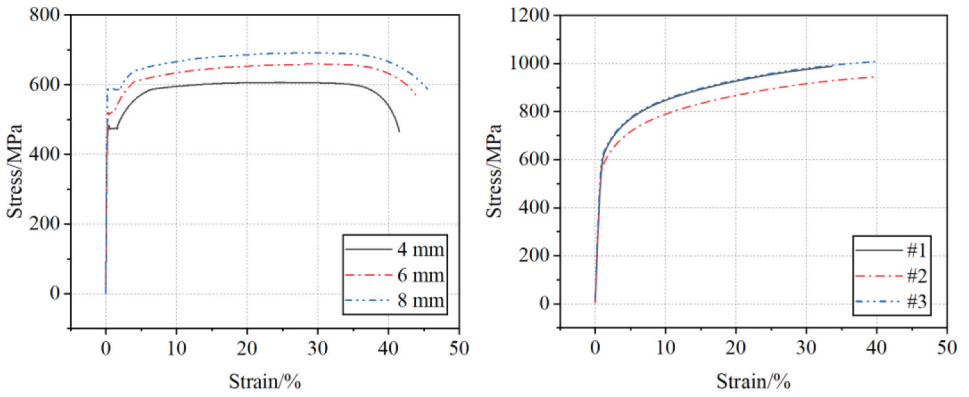
The Fe-SMA used in this study was invented by our research group and manufactured by smelting in the vacuum introduction furnace and then preparing by hot forging process with a width of 106 mm. To consider the influence of Fe-SMA's thickness on the performance of welded joints, two thicknesses including 1.5 mm and 3 mm are selected.

As the most commonly used structural steel in China, Q355 is a type of low-alloy structural steel. The letter "Q" in its name "Q355" means yield strength, and "355" indicates its grade with the specified value. It can be said that the Chinese structural steel Q355 is highly similar to the European structural steel S355. Considering the usage scenario of the Fe-SMA reinforcement system, Q355 is selected to represent the structural material in bridge.



According to the previous research (Qiang et al. 2023c), ER309L is selected to be the filler material here due to the uniform fusion zone transition, smooth hardness changes, and similar strength to base materials. The ER309L welding wires with a diameter of 2 mm were used to match the size of the transverse fillet weld. Besides, considering that Fe-SMA is also a kind of

ferroalloy, the author tentatively tried to use self-developed Fe-SMA wire, cut from the base material, as the filler material with a base size of 1.5 mm × 1.5 mm. The chemical composition of all test materials is shown in Table 1.

Table 1. Chemical composition of test materials (unit: mass fraction %).

Material	C	Mn	Si	Cr	Ni	Nb
Fe-SMA	0.1	15	4.5	10	5	0.03
Q355	0.15	0.58	0.14	0.026	0.009	/
ER309L	0.019	2.1	0.54	23.26	13.73	/

To obtain the mechanical properties of the base materials, pretests were conducted. The stress-strain curves of Fe-SMA and Q355 are shown in Figure 2. The elastic modulus, yield strength, ultimate strength, and breaking elongation of Fe-SMA, Q355 (obtained from the pretest), and ER309L (obtained from the product warranty) are shown in Table 2.

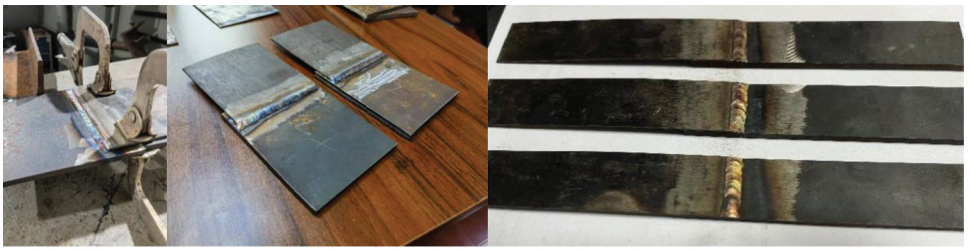
(a) Q355 (b) Fe-SMA

Figure 2. Stress-strain curves of Q355 and Fe-SMA.

Table 2. Mechanical properties of test materials.

Material	E/GPa	σ_s/MPa	σ_u/MPa	δ/%
Fe-SMA	166.0	496.3	980.1	37.6
Q355-4 mm	260.1	474.5	606.9	41.1
Q355-6 mm	223.7	516.9	660.3	43.8
Q355-8 mm	264.2	587.1	691.1	45.5
ER309L	/	/	580.0	39.0

2.2 *Specimen preparation and test setup*



After pre-trial, direct current with optimizing welding parameters was used in lap joint with higher current for better penetration, different from the pulse current used in TIG welded butt joint between Fe-SMA and structural steel Q235 (Qiang et al. 2023c), shown in Table 3.

The whole process of specimen preparation is shown in Figure 3. First, to ensure the welding continuity and the quality stability of the fillet weld, a piece of Fe-SMA plate with a width of 106 mm and a steel plate slightly wider than 106 mm were welded with ER309L welding wire to

Table 3. Welding parameters.

Current/A	Voltage/V	Welding speed/(mm·s^{-1})	Shielding gas flow/(L·min^{-1})	Shielding gas concentration
110	11-13	106/90	15	Ar-99.99%

obtain a large lap welding plate (Figure 3(b)). The lap length with little effect on the stress distribution of the joint is designed to be 25 mm. At the beginning of the welding, the initial temperature is relatively low. Thus, the heating of the base material and the formation of the molten pool will affect the stability of heat input, increasing the reinforcement at the initial section of the fillet weld. Then, at the end of the welding, the final section of the fillet weld should be filled with an arc pit before the extinguishing of the welding arc, making it not lower than the surface of the weld. Therefore, the quality and strength of the welding at the beginning and end of the fillet weld are discrete. So, the specimens were cut from the middle continuous section (Figure 3(c)) to eliminate the influence by discarding the start and the end sections.

(a) welding process (b) welding plate (c) cutting specimen

Figure 3. Specimen preparation.

To explore the possibility of transmitting prestress produced by Fe-SMA in the Fe-SMA reinforcement system, four factors affecting the tensile properties of the lap joint are considered in the test: first one is the fillet weld length, highly correlated with the length of the tensile part. The second one is the thickness of the steel, which may influence the formation of the molten pool and the stress distribution of the fillet weld on the side of the steel. The third one is the thickness of Fe-SMA, associated with the height and size of the fillet weld. The fourth one is the filler material, directly influencing the strength of the fillet weld, which is regarded as the weakness of the lap joint. The definitions of all design dimensions of specimens are plotted in Figure 4, and all parameters are listed in the group shown in Table 4.

After the specimen preparation, the tensile tests with a tensile velocity of 1.5 mm/min until the specimen fractured were carried out through the MTS universal testing machine in the Fire Safety of Engineering Structures Testing Division of the State Key Laboratory of

Disaster Reduction in Civil Engineering. To reduce the deviation of specimens caused by structural eccentricity, a steel base plate with the same thickness as the steel plate was set on the side of the clamping end of the steel (shown in Figure 1).

3 TEST RESULTS AND DISCUSSION

3.1 *Test results*

Figure 5 shows the deformation of the lap joint specimen during tension. In the beginning, the specimen was set straight for tension. After bearing a minor load, the steel plate adjacent to the fillet weld became bent and the bending deformation increased rapidly with the continuous rise of load in this period. After reaching a certain load, the development of bending deformation turned to stop, and the specimen showed a straight tension again, followed by final fracture.

(a) clamping (b) bending phenomenon (c) fracture

Figure 5. Deformation of the specimen during the tensile test.

Specimens have two failure modes distinguished by the location of the failure (seen Figure 6). For failure mode I, the specimen was cracked in the welding zone and the crack corresponding to failure mode I usually appears a twist on one side of the weld, which proves that there is still a certain heterogeneity inside the fillet weld. On the contrary, the crack in failure mode II occurs at the fusion zone near the side of Fe-SMA, with a straight fracture trend.

3.2 *Discussion*

Key indexes of all specimens obtained from the tensile test are listed in Table 5, and load-displacement curves of all specimens are plotted in Figure 7 respectively by group. As the control group, specimen DH3-6-30-A is added to all groups for comparison and analysis.

In general, all curves are highly similar. At a relatively low load level, the first stiffness mutation occurs, making the lap joint stiffness lower than the initial stiffness. Subsequently, lap joints with high bearing capacity will undergo a second stiffness mutation, and the stiffness

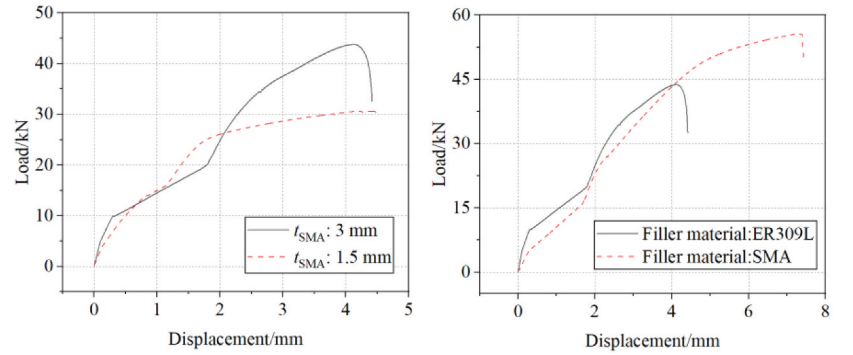
Note: P_u is the ultimate load, Δ_u is the displacement corresponding to P_u, and $\delta_{Fe\text{-}SMA}$ is the equivalent stress acting on the Fe-SMA plate, calculated by P_u.



increases to a similar level before the first mutation. Then, the stiffness gradually decreases with the rise of the load, and the fracture occurs soon after reaching the ultimate load. According to the experimental phenomenon, the stiffness mutation can be demonstrated by the inevitable eccentricity of the structure. For the three components of the joint, the weld is always not the main contributor to deformation due to its narrow area. In the early stage, the deformation of the joint is mainly provided by steel and Fe-SMA. So, before the first mutation and after the second mutation, the steel is still in the linear elastic stage, and the Fe-SMA stiffness has only slight reduction, resulting in a similar level of lap joints' stiffnesses. In the stiffness reduction stage, the section rotation of the steel plate caused the interface between the fillet weld and the steel plate to rise, making the displacement increased and stiffness reduced. Finally, the equivalent stress of each lap joint with different configurations is over 430 MPa, much higher than the maximum prestress 294 MPa produced by Fe-SMA (Qiang et al, 2023d).

Results of specimens with only different fillet weld lengths are shown in Figure 7(a). In general, the ultimate load of the lap joint varies approximately linearly with the length of the fillet weld length. In contrast, the ductility of all specimens is basically at the same level except for the DH3-6-10-A with an apparent low displacement. Specimens with fillet weld length of 10 mm and 20 mm has no second stiffness mutation, indicating that the specimens fractured before the end of bending deformation. Similar relations occur in the group of steel thickness, where the ultimate load and displacement increase with the rise of the steel thickness.

Compared with thick Fe-SMA, lap joint with thin Fe-SMA has a higher equivalent stress (see Figure 7(c)), reflecting the higher welding quality of the thin joint. Nevertheless, the equivalent stress is calculated only to account for the transmission of the prestress. For the Fe-SMA reinforcement system, the overall efficiency still depends on the total load that the joint can transmit. After achieving the requirements of transmitting prestress, the compressive stress acting on the structure increases with a thicker Fe-SMA plate. Thus, although the thin

(a) Fillet weld length (b) Steel thickness

(c) Fe-SMA thickness (d) Filler material

Figure 7. Load-displacement curves divided by group.

joint has a better welding quality, the Fe-SMA thickness in application needs to be selected according to the requirement of prestress.

About the filler material, the tentative Fe-SMA wire lap joint has achieved outstanding mechanical performance, illustrated in Figure 7(d). Although the self-developed Fe-SMA wire is not a kind of standard welding wire, its own excellent mechanical properties with high strength and good ductility are still reflected in the mechanical performance of the lap joint. However, the excellent mechanical performance of the lap joint using Fe-SMA wire is based on the different welding processes. Due to the size limitations of the self-developed Fe-SMA wire and the lack of composition of standard welding wire (such as the arc stabilizer and deoxidizer), the welding process is not as stable as when using ER309L, with sparks and crackles. After trials and optimization, the two-pass welding was used to ensure the well formation of the lap joint. Therefore, whether Fe-SMA can be directly used as welding wire for welding needs further research and verification.

4 CONCLUSION

In this paper, TIG welded lap joints between Fe-SMA and structural steel Q355 were prepared. Four design parameters affecting the tensile properties of lap joints were considered including fillet weld length, filler material, and thicknesses of two base materials. The study achieves the following conclusions:

(1) With suitable welding parameters, the TIG welded lap joints between Fe-SMA and structural steel Q355 with high quality can be attained.

(2) The ultimate load of lap joints increases with the rise of fillet weld length and steel thickness.
(3) Lap joint shows a higher weld quality with thin Fe-SMA, but the actual selected Fe-SMA thickness in the Fe-SMA reinforcement system depends on the prestress requirement.
(4) Lap joint with self-developed Fe-SMA wire has a outstanding mechanical performance. However, considering the potential problems with welding instability and non-standard composition, whether Fe-SMA wire can be used in the welding of Fe-SMA reinforcement system is still worthy of further study.

Based on the research on the butt joint, the experimental study on the lap joint in this paper further confirms the possibility of using welded joints to transmit the prestress produced by the Fe-SMA reinforcement system. Thus, the resistance of the Fe-SMA reinforcement system to humid environments is improved, and the scope of application in bridge is expanded.

A decision method for ship-bridge collision pre-warning based on vision and radar data fusion

Hongyu Zhuang, Dalei Wang, Zhenxiong Gu, Yiqing Dong & Junjie Wang
College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: The active collision avoidance and pre-warning system prove highly effective in minimizing ship-bridge collisions. Existing research mainly leans on single-source data for assessing the risk of such collisions, yet single-source data inherently harbor limitations. In this study, we propose an active collision avoidance and pre-warning decision method based on vision and radar data fusion. Two risk identification models are designed to fit different environmental conditions. The method is tested on Youdungang bridge and shows fair risk identification ability. The future holds promise for delving deeper into the potential of multi-source data fusion within this domain.

1 INTRODUCTION

Ship-bridge collision accidents often result in huge economic losses, making it important to establish the active collision avoidance and pre-warning system. Ship trajectory acquisition is the basis of collision pre-warning. Ship trajectories are usually acquired by remote sensing (RS) (Wei *et al.*, 2020), synthetic aperture radar (SAR) (Zhu *et al.*, 2022), camera (Zhang *et al.*, 2021; Zhang and Hou, 2022) and automatic identification system (AIS) (Zhang *et al.*, 2022). However, these data sources each have their own shortcomings. SAR lacks the image texture features required to reconstruct the event scene, RS and cameras have insufficient resistance to environmental interference, and the frequency of AIS data collection is usually low, making it difficult to meet the demands of real-time alerts. Therefore, there is a need for a method based on multi-source data fusion to overcome the limitations of single-source data and improve the effectiveness of the pre-warning system.

This study aims to propose an active collision avoidance and pre-warning decision method based on vision and radar data fusion. Appropriate object detection model and millimeter-wave radar have been applied to obtain accurate ship trajectory information. The risk of ship-bridge collision is assessed by predicting and analyzing collected ship trajectory based on two risk identification models, which should be applied to different environmental conditions.

2 METHOD

2.1 *Vision-based ship trajectory acquisition*

To obtain ship trajectories, the collected camera data needs to be processed through a specific object detection neural network to obtain ship bounding boxes. These bounding boxes contain the pixel coordinate information of ships, which can be transformed into world coordinates with a homography matrix. By using a target tracking algorithm, ship trajectories can be generated, and furtherly the motion and geometric characteristics of ships can be extracted.

DOI: 10.1201/9781003483755-419

2.1.1 *Ship detection*

YOLOX (Ge *et al.*, 2021) is adopted as the ship detection model for this study. YOLOX's model structure integrates improvements in the backbone network, introduces the YOLOP module for anchor-free prediction, incorporates a dynamic head, and supports multi-scale detection. These elements collectively contribute to YOLOX's outstanding object detection performance. To train the model for ship detection, it is necessary to establish a dataset that encompasses ship images in the corresponding bridge scene. The dataset should include images from various time periods, different weather conditions, and different types of ships to enhance the model's generalization capability.

2.1.2 *Mapping between pixel and world coordinates*

The relationship between the pixel coordinates and the world coordinates of ships can be represented by the homography matrix H. The principle of photogrammetry gives a variety of ways to solve the homography matrix, and the four-point calibration method (Hughes *et al.*, 2014) is used in this study. Since the matrix has 8 independent parameters, it is necessary to obtain the world coordinates and corresponding pixel coordinates of at least 4 control points to solve all parameters.

2.1.3 *Ship tracking and trajectory acquisition*

DeepSORT (Wojke *et al.*, 2017), short for "Deep Simple Online and Realtime Tracking", is an object tracking algorithm designed to track multiple objects in real-time video streams. It is an extension of the SORT algorithm, combining deep learning techniques with a classic tracking algorithm to improve tracking accuracy, especially in crowded scenes. DeepSORT algorithm is adopted in this study to distinguish the trajectory point set of each ship target and avoid frequent ID switches caused by short-term occlusion, so as to generate stable trajectories.

2.2 *Radar-based ship trajectory acquisition*

Radar exhibits a robust resistance to interference compared to cameras, ensuring reliable detection even in challenging conditions. Operating within the wavelength range between microwave and infrared waves, millimeter wave radar combines the benefits of both, boasting excellent penetration capabilities and extended propagation distances. Consequently, this study utilizes millimeter wave radar for ship trajectory acquisition.

Radar leverages the Doppler effect to extract velocity information from transmitted and received signals, while the orientation angle is derived from the velocity difference between array antennas. The aggregation of returning signals from all directions results in a radar point cloud. Leveraging this radar point cloud, target tracking algorithms can effectively discern the presence of ships and formulate trajectories. The fundamental steps of classical multi-target tracking methods involve data association followed by single-target filtering (Liu and Wang, 2021).

2.3 *Ship feature extraction and data fusion method*

The ultimate goal of conducting ship detection and acquiring ship trajectories is to extract the motion and geometric characteristics of ships, thereby providing a basis for subsequent data fusion and risk identification. The motion characteristics of a ship typically include its position, speed, direction, etc. For vision-based trajectories, data processing such as averaging or regression is necessary to obtain motion characteristics, while geometric features are inherent in ship bounding boxes. In the case of radar-based trajectories, the process of generating the trajectory already extracts the motion characteristics of the ship, but it is unable to capture geometric features.

Common data fusion methods include decision-level fusion, data-level fusion, and feature-level fusion (Wei *et al.*, 2022). Decision-level fusion is more flexible and convenient to use, thus is adopted in this study. Here, decision-level fusion refers to the integration of data

obtained from radar and cameras. Each source of data undergoes its own independent processing to obtain the trajectories and features of ships. Subsequently, through a well-designed risk identification strategy and warning scheme, these data are unified and utilized, thereby achieving good results in ship detection and pre-warning.

2.4 *Risk identification and pre-warning approach*

The overall strategy employed for ship-bridge collision risk identification is to parameterize the risk rate R. For different environmental conditions, two risk identification models are utilized. Specifically, during daytime periods with normal meteorological conditions, where vision-based method can accurately detect ship targets, video data serves as the primary basis for risk identification. A risk identification model based on trajectory prediction is employed in this scenario. On the other hand, during adverse weather conditions such as heavy rain, thick fog, or during nighttime, when video data struggles to correctly detect ship targets and obtaining ship dimensions is challenging, radar data becomes the main basis for risk identification. In such cases, a model based on pre-defined risk zones of the navigational channel is used to calculate the risk rate. The two models should be designed according to the engineering conditions of the actual bridge. The corresponding pre-warning strategy involves triggering an audio-visual alarm system and reporting to the management department when the risk rate exceeds a certain threshold.

3 EXPERIMENT AND RESULTS

3.1 *Basic information*

To verify the effectiveness of the decision-making method proposed in this study, we conducted an experiment at Youdungang Bridge in Shanghai, demonstrating the results of risk identification. Youdungang Bridge is a small-span arch bridge with a span of about 60m and a height of about 5m. Camera and millimeter-wave radar are installed on both sides to monitor passing ships. The navigable ships under the bridge mainly include cargo ships and speedboats. Figure 1 provides an illustration of the bridge, and Figure 2 shows the relevant sensors.

Figure 1. Youdungang bridge.

Figure 2. Radar and camera.

3.2 *Vision-based trajectory acquisition and feature extraction*

3.2.1 *Trajectory acquisition*

The initial step involves training the YOLOX model. A ship dataset is specifically established based on the video data captured by the camera on Yaudungang bridge. This dataset is structured in COCO format and comprises 453 images randomly split into training and test sets.

The model undergoes 300 epochs of training, and the changes in the loss function and mean Average Precision (mAP) values (IoU threshold from 0.5 to 0.95) throughout this process are

depicted in Figure 3. Achieving a maximum mAP of 0.718 reflects a satisfactory training outcome that meets practical requirements. The YOLOX model effectively extracts bounding boxes of ships from input images, and the center of each bounding box is approximated as the pixel coordinate of a ship.

Upon mapping pixel and world coordinates and applying the DeepSORT algorithm, ship trajectories can be derived and projected onto a standardized world coordinate plane. Subsequently, a five-point sliding average method is employed to smooth the trajectories. Figure 4 illustrates a processed ship trajectory, verifying the effect of target tracking.

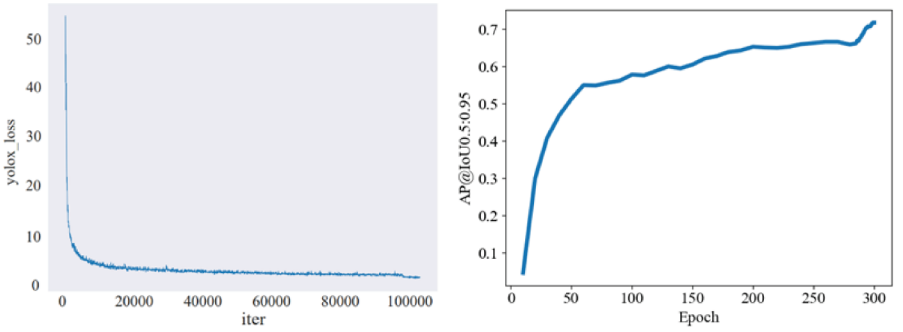

Figure 3. Loss function and mAP change.

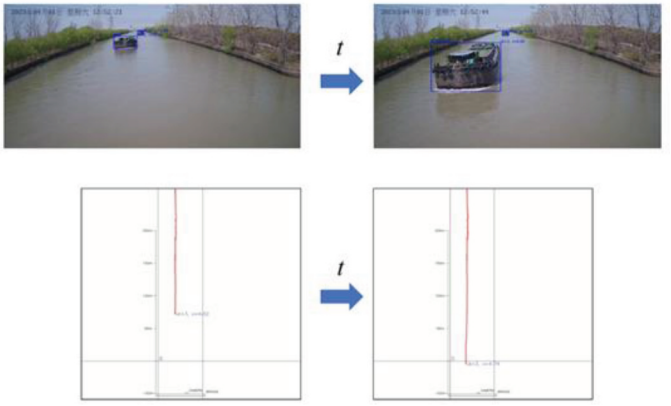

Figure 4. Target tracking and ship trajectories.

3.2.2 *Feature extraction*

Ship velocity is determined using a moving average method. The ship's current speed is computed as the average speed over the preceding frames, while the ship's direction is denoted by a unit vector expressed in world coordinates, akin to the velocity calculation method.

In practical scenarios, it has been observed that calculating the ship-bridge collision risk rate based on video data is highly sensitive to directional changes at long distances. Consequently, the false alarm rate can become exceptionally high. To mitigate this, a piecewise function is applied to the moving average interval of direction:

$$n_a = \begin{cases} 10n & d \geq 100 \\ 3n & 50 < d < 100 \\ n & d \leq 50 \end{cases} \tag{1}$$

where n_a = the adjusted sliding average interval; n = the preset standard interval; d = the distance of the ship target from the camera.

The geometric features of ships usually require specific measurement devices such as laser radar to obtain. However, in this case, the absence of corresponding equipment limits the measurement, while the collision risk of arch bridges is closely related to the geometric characteristics of the ships. Considering the unique perspective of the camera in this case, an approximate method using bounding boxes can be employed to calculate the height and width of the ships. This method can be described as:

$$\begin{cases} H = k_H(d)H_b \\ B = k_B(d)B_b \end{cases} \tag{2}$$

where H and B are the height and width of the ship; H_b and H_b are the height and width of the bounding box measured at a certain distance d, in this case d is 200m; $k_H(d)$ and $k_B(d)$ are two approximation coefficients that can be obtained by linear regression when the distance d is fixed.

3.3 *Radar-based trajectory acquisition and feature extraction*

Relying on existing clustering algorithms and filtering algorithms, radar-based acquisition and feature extraction of trajectories are relatively straightforward. The millimeter-wave radar used in this study is equipped with relevant data processing modules, capable of directly outputting the speed and position information of ships. Table 1 gives the output data format of radar.

Table 1. Radar output data.

No	Radar ID	Datetime	Shi ID	Velocity	X	Y
1	00002B14	2023-05-07 12:06:20	00000DEA	2.20	-19.60	163.40
2	00002B14	2023-05-07 12:06:21	00000DEA	2.20	-20.00	165.20
3	00002B14	2023-05-07 12:06:22	00000DEA	2.20	-20.40	167.20
4	00002B14	2023-05-07 12:06:23	00000DEA	2.20	-20.80	169.20

3.4 *Data fusion and risk identification models*

3.4.1 *Temporal and spatial alignment*

In order to achieve data fusion, the radar-based and video-based trajectories should correspond in both time and space. Temporal alignment is straightforward due to the real-time monitoring, but spatial alignment requires mapping radar coordinates to the world coordinate plane. Radar coordinates can be mapped to world coordinates through translation and rotation operations. This transformation can be described as:

$$\begin{bmatrix} X \\ Y \\ 1 \end{bmatrix} = \begin{bmatrix} \cos\varphi & -\sin\varphi & X_0 \\ \sin\varphi & \cos\varphi & Y_0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} X_R \\ Y_R \\ 1 \end{bmatrix} \tag{3}$$

where (X, Y) = the ship's world coordinates; (X_R, Y_R) = the ship's radar coordinates; (X_R, Y_R) = the coordinates of the radar origin in the world coordinate system; φ = the deflection angle of the radar coordinate system relative to the world coordinate system.

The parameters in the transformation can be easily solved by mapping temporally aligned video and radar data.

3.4.2 *Risk identification model based on trajectory prediction*

Based on the constant velocity assumption, the future trajectory is envisioned as the trajectory that the ship would follow if it maintains its current speed and direction. Consequently, the ship's

position upon reaching and passing the bridge is considered as the intersection point between the tangent of the trajectory and two reference lines, as illustrated in Figure 5. The final risk rate is taken as the larger one of the risk rates calculated based on two reference lines.

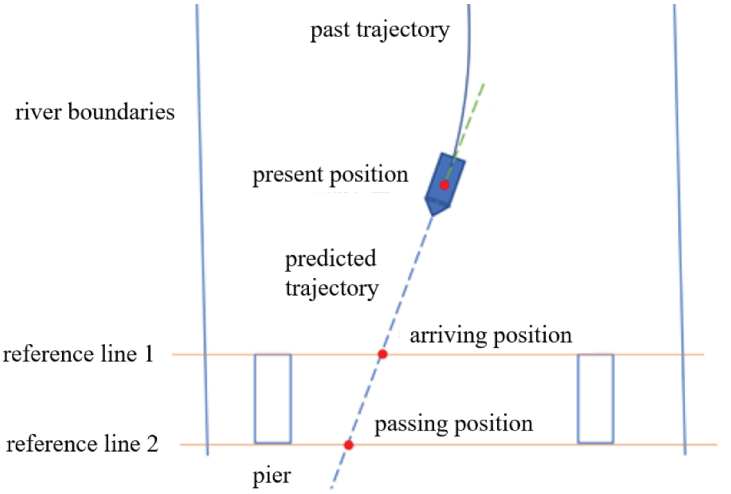

Figure 5. Trajectory prediction.

Figure 6 shows the risk identification model based on track prediction. The steps for the calculation are as follows:

(1) Determine the arch axis equation, consider a quadratic parabola in this case:

$$h = h_0 - kx^2 - h' \tag{4}$$

where h_0 = the elevation at the top of the arch axis; h' = a constant considering the thickness of the arch; k = the shape factor of the arch.

(2) Solve the position of ship-bridge collision x_c:

$$x_c = \frac{1}{k}\sqrt{h_0 - h' - H - h_w} \tag{5}$$

where H = height of ship; h_w = water surface elevation.

(3) According to x_c, calculate the limit position x_l at which the ship would hit the arch precisely, and the dangerous position x_d where the ship would be at risk of collision:

$$x_l = x_c - \frac{1}{2}B \tag{6}$$

$$x_d = x_c - B \tag{7}$$

where B = width of ship.

(4) The ship's basic risk rate of collision is determined to be quadratic:

$$R = \begin{cases} \frac{1}{x_d^2}x^2 & 0 \le x \le x_d \\ \frac{2}{x_d}x - 1 & x > x_d \end{cases} \tag{8}$$

(5) In order to reduce the false alarm rate, the basic risk rate is corrected. When the distance between ship and bridge is still large, the slightest directional adjustment may

bring about a large change in the predicted position under the bridge, resulting in a high false alarm rate. Therefore, it is adjusted according to the time remaining for the ship to arrive at the bridge:

$$R' = \alpha R \tag{9}$$

where α is a risk reduction factor, which satisfies:

$$\alpha = \begin{cases} 0 & t_r \geq 80 \\ 0.02(80 - t_r) & 30 < t_r < 80 \\ 1 & t_r < 30 \end{cases} \tag{10}$$

where t_r = the time remaining for the ship to arrive at the bridge.

Some of this model's risk identification results are shown in Figure 7. It is obvious that the identified risk rate can generally reflect the actual collision risk, and the motion and geometric feature of ship exert a clear influence on the results.

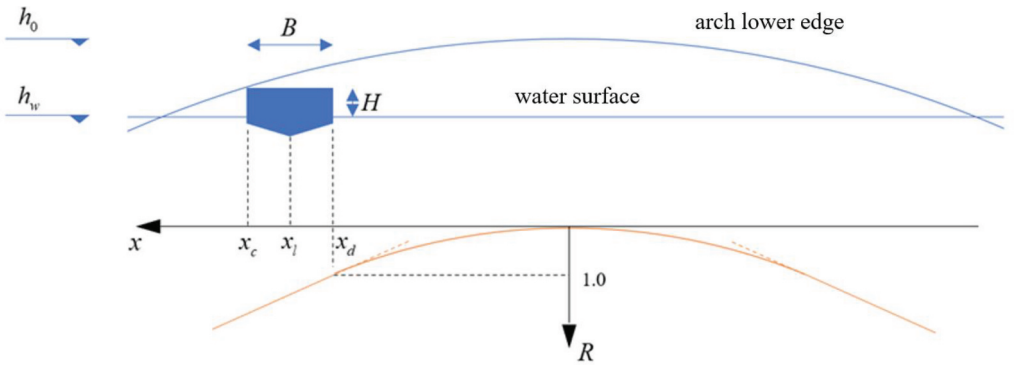

Figure 6. Risk identification model based on trajectory prediction.

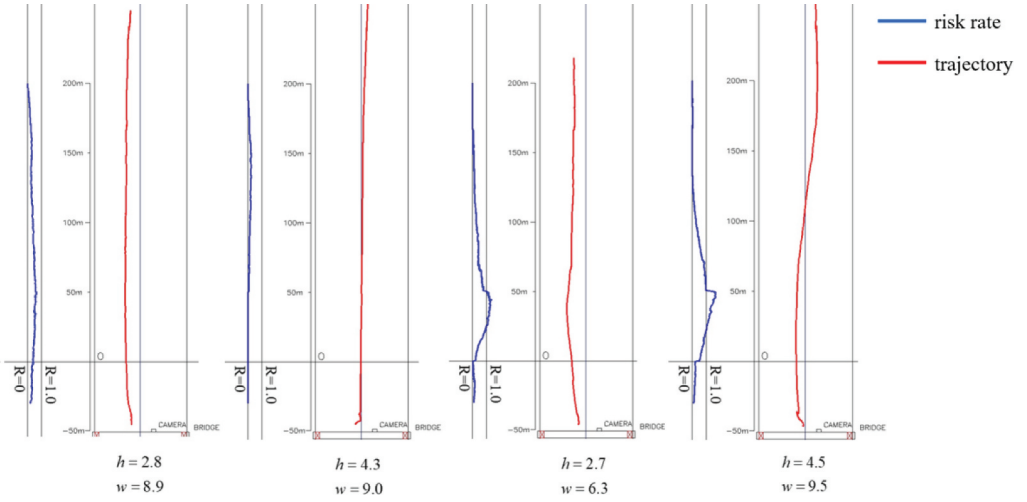

Figure 7. Identification results of the model based on trajectory prediction.

3.4.3 *Risk identification model based on pre-defined risk zones*

This model divides the waterway into safe zone, hazard zone and severe hazard zone according to the risk of ship-bridge collision, as shown in Figure 8. Among them, the safety zone refers to the area where all ships can pass normally, the hazard zone refers to the area where the largest ship is at risk of colliding with the bridge, and the severe hazard zone refers to the area where smaller ships are also at risk of colliding with the bridge. The specific classification criteria can be determined by statistical methods, and the risk of collision can be determined by x_d defined in equation 7.

The basic risk rate function of collision is determined as:

$$R = \begin{cases} \frac{1}{x_d^l} x & 0 \le x \le x_d^l \\ \frac{x - x_d^l}{x_d^m - x_d^l} + 1 & x > x_d^l \end{cases} \tag{11}$$

where x_d^m = the dangerous position of smaller ships; x_d^l = the dangerous position of larger ships. The risk rate can also be adjusted according to equation 9.

Some risk identification results of this model are shown in Figure 9. Ship trajectories are successfully acquired despite poor environmental conditions. The risk rate is highly identical to the trajectory itself due to the linearity of this identification model.

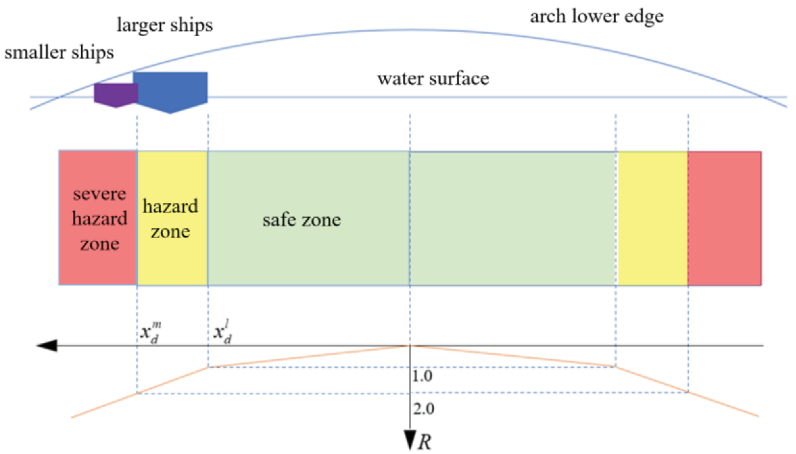

Figure 8. Risk identification model based on pre-defined risk zones.

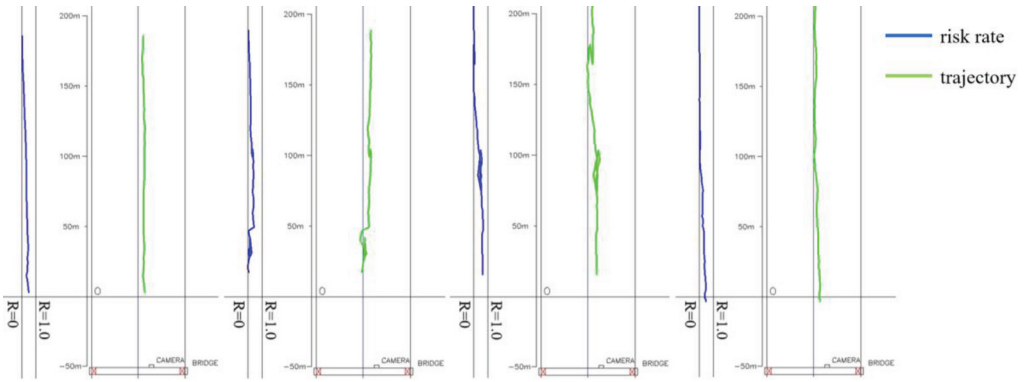

Figure 9. Identification results of the model based on defining risk zones.

4 CONCLUSION

To enhance warning reliability, we present a decision-making approach for ship-bridge collision pre-warning through the fusion of vision and radar data. Tailored to the distinct characteristics of cameras and radar, we devised a data fusion strategy employing diverse risk identification models for different environmental conditions. This decision-making method harnesses the strengths of both sensors, enabling comprehensive, round-the-clock monitoring of the pre-warning system. Experimental results demonstrate the method's effectiveness in risk identification, validating the significance of multi-source data fusion. Future experiments are anticipated to delve deeper into the potential of this approach, paving the way for further advancements in the application of data fusion within this domain.

ABSTRACT: In the current small and medium-sized bridges in the daily safety inspections, such as high dependence on inspectors and lack of quantifiable scientific basis. In practice, Professional engineers spend an enormous amount of time check the textual description and looking at image data of damages to bridge members, such as girders, bearings, expansion joints, and piers that are acquired from periodic inspections, and then determining make a rating of the bridge condition. Therefore, it is necessary to develop a practical method for the evaluation of bridge soundness to assess the degree of structural health. In this paper, the maintenance priority evaluation of bridge integrity of small and medium span bridges is examined using the Support Vector Machines (SVM), Decision Tree (DT), and Random Forest (RF) of artificial intelligence (Al) techniques. Based on the model, three types of bridge is used, an algorithm is proposed as useful feature to provide the engineering expertise for the inspection of bridges. This proposed method was able to substitute engineer judgement to distinguish the health rating of I. The input data were the degrees of deterioration of the structural parts and the output data were the soundness of the structure. The results showed that the inspection item of crack location and exposed direction of steel bars gives good assessment on whether bridge maintenance works are needed or not.

1 INTRODUCTION

Condition rating of bridges is specified in many countries since it provides a basis for the decision-making of maintenance actions such as repair, strengthening, or limitation of passing vehicle weight. In practice, bridge inspectors use their judgment to evaluate and appraise maintenance problems and critical deterioration on site, and then make a rating of the bridge condition. Generally, periodic inspection bridge by bridge with visual and nondestructive techniques is widely adopted around the world, such as in the United States, Japan, Korea, China, Australia, and European countries (De-Cheng Feng et al. 2023). The engineers for condition rating must be familiar with relevant condition rating standards and be experienced with bridge inspection practice. Considering that a condition rating is required for each bridge with a large amount of data buried in the inspection reports, it is a time-consuming and labor-intensive task. Therefore, it is paramount to propose methodologies for efficient and accurate condition rating of bridges. To achieve fast and automated bridge condition rating, in the past few years, machine learning (ML) methods have enjoyed fast development based on relevant information from bridge database or inspection (Karim, M. M. et al. 2020, Nishimuta,Y. et al. 2023, Saman Karimi, S. et al. 2023, Shimma, Y. et al. 2023, Suzuki,T. et al. 2019)

DOI: 10.1201/9781003483755-420

A novel approach for estimating bridge condition rating is introduced, utilizing ML techniques. Findings in this study suggest that the ML approach can capture the information buried in the inspection reports and provide a promising tool for efficient and accurate bridge condition rating.

2 METHODOLOGY AND MACHINE LEARNING TECHNIQUES

Three commonly used algorithms, i.e., Decision Tree (DT), Support Vector Machine (SVM), and Random Forest (RF), are employed to build up accurate and reliable prediction models for the condition rating of bridges.

2.1 *Decision Tree (DT)*

Decision trees are a very effective method of supervised learning. A tree-structured model that can be used for both classification and regression problems. It aims is the partition of a data-set into groups as homogeneous as possible in terms of the variable to be predicted. A decision tree is generally made up of tree nodes and directed edges. It takes as input a set of classified data, and outputs a tree that resembles to an orientation diagram where each end node (leaf) is a decision (a class) and each non- final node (internal) represents a test (De-Cheng Feng et al. 2023). Here, the classification and regression tree algorithm which is based on the mean square error is adopted. Supposing the input space can be divided into N sub-spaces R_1,R_2, . . .,R_N, the decision tree model can be expressed as

$$\hat{y} = f_{DT}(\mathrm{X}) = \sum_{n=1}^{N} c_n \mathrm{I}(\mathrm{X} \in \mathrm{R}_n) \tag{1}$$

where x is the input variables; I(·) is the indicator function; and c_n is the prediction value by the n^{th} leaf node.

2.2 *Support Vector Machine (SVM)*

An Support vector machine is a type of binary supervised machine learning. SVM are based on the induction principle of structural risk minimization, which aims to minimize a test error by controlling two contradictory factors: a functional risk from empirical data and a capacity for the set of real-valued functions (Cortes et al. 1995; Vapnik et al. 1998). An SVM algorithm aims to find the optimal separating hyperplane that effectively separates the data points into the labeled classes. In essence, the input variables are mapped to a high dimensional feature space by nonlinear transformation, and then a hyperplane is found in the space for linear classification or regression. This mapping process generally adopts the kernel function method. The specific learning strategy of SVM is to maximize the left and right data interval of the hyperplane, which can be abstracted into the mathematical problem of solving convex quadratic programming, and the learning algorithm of SVM is the optimization algorithm of solving convex quadratic programming. The main parameters are parameters of kernel function and penalty coefficient in optimization (De-Cheng Feng et al. 2023). Taking the binary classification problem as an example, the SVM model can be defined as

$$\hat{y} = f_{SVM}(\mathrm{X}) = \beta^T \mathrm{X} - \mathrm{b} \tag{2}$$

where β and b denote the normal vector and the bias constant from zero, respectively.

2.3 *Random Forest (RF)*

The DT and SVM, or some other supervised learning methods, are actually individual-type algorithms, which only generate a single predictive model. Random forest is one typical ensemble

method that belongs to the bagging family. Random forests is a substantial modification of bagging that builds a large collection of de-correlated trees, and then averages them. It takes advantage of two powerful techniques,i.e., bootstrap and random feature selection. At every step of building a tree, N samples are randomly selected as a subset with bootstrap from the entire database, and K features are randomly selected and used as the split node to build a DT with the subset (De-Cheng Feng et al. 2023). After several (or M) steps, one obtains MDTs from the above procedure, and the final output is the average of all the outputs by the M trees as follows:

$$\hat{y} = \frac{1}{M}\sum_{i=1}^{M} f_{DT,i}(X) \tag{3}$$

where f_{DT}, i(·) is the weak learner by the DT method at step i ≤ M. In addition to the original parameters of DT, the number of trees is an extra yet important parameter.

3 VISUAL INSPECTION OF BRIDGES

In our study, we followed the conventional criteria to classify structure members' degree of health. Additionally, we focused on the main girder of the single-span girder bridge as well as the multi-span continuous girder bridges. We only examined main members (girders) in this study.

Introduction on the Regional Network of Bridges with Inspection Reports. As mentioned above, the database is established with inspection reports of a regional network of highway bridges located in Inner Mongolia, China. A total of 25 bridges in different health conditions are collected, which are reinforced concrete or pres-stressed concrete bridges or arch bridges. They almost cover the west area of Inner Mongolia, and are representative of regional bridges. The variations of bridge types and condition ratings are further illustrated in Figure 1 to Figure 3. Figure 1 shows the distribution of the bridges type. Figure 2 shows the distribution of the bridges with different span lengths, i.e., long-span bridges (40-150 m), medium-span bridges (20-40 m), and small-span bridges (5-20 m). Among medium-span bridges and small-span bridges take the most percentage of 40% and 48%, respectively. The distribution of bridges with condition ratings is displayed in Figure 3, which is according to the results of the inspection reports. In the conventional criteria, among the bridges were labeled as Levels 1, 2, 3, 4, and 5, respectively. Note that damage of bridges becomes severe from Levels 1 to 5, which requires different maintenance actions. The bridge need for response by maintenance work and also bridge need for repair according to next inspection shows a bridge inspector's required knowledge and judgement skill, which helps determine whether the bridge's owners need to repair the bridge. It is important to distinguish the soundness rank as being 1, 2, or 3. Figure 4 to Figure 6 shows the distribution of the number of bridges and the type of deterioration. Figure 4 shows that the arch bridge deterioration of mortar joints fall off had a high proportion compared to other types of deterioration. Figure 5 shows that the pre-stressed concrete slab bridge deterioration of crack and exposed steel bar and fall off had a high proportion compared to other types of deterioration. Figure 6 shows that the reinforced concrete slab bridge deterioration of crack had a high proportion compared to other types of deterioration.

In this case study, we examined the deteriorating feature of crack and exposed steel bars. Because of the limited amount of bridge inspection data, only two types of bridge inspection data were used, the corresponding health ratings of which were 2 and 3. In this study, the 83 pieces of inspection data pertaining to the deterioration of crack and exposed steel bars were used. The inspection reports were completed after the field inspection of the bridges visually or with nondestructive devices, and then the condition rating of bridges is conducted by experienced engineers through information processing of bridge member damages. The engineers should have professional knowledge about the bridges and be familiar with relevant inspection and maintenance standards. In this paper, the condition rating was conducted following the Chinese code for maintenance of highway bridges (JTG H, Code for Maintenance of Highway Bridges and Culvert, 2004), where the bridge health condition is divided into five levels, i.e., Levels 1 to 5. The bridges

of Level 1 are in good condition, bridges of Level 2 require only minor repairs or daily maintenance to ensure their safety, bridges of Level 3 are in a relatively poor state with many defects, and a small number of functional diseases have taken place, which need to be repaired accordingly. In bridges of Levels 4 and 5, a lot of severe material defects have appeared and the structural functionality greatly deteriorated, thus the safety of these bridges is questionable and the traffic should be closed for special inspection and major repairs. Considering that only a limited number of inspected bridges are rated as Levels 4 and 5 in the data-set. Thus, they are usually combined together and finally levels are designed as the condition ratings of the bridges. In this study, the statistical analyses of two levels of health were conducted. The inspectors' influences on the inspection data were not considered in this current study. These analyses were conducted using the analysis software Waikato Environment for Knowledge Analysis WEKA version 3.9. We conducted this experiment using the classification solver.

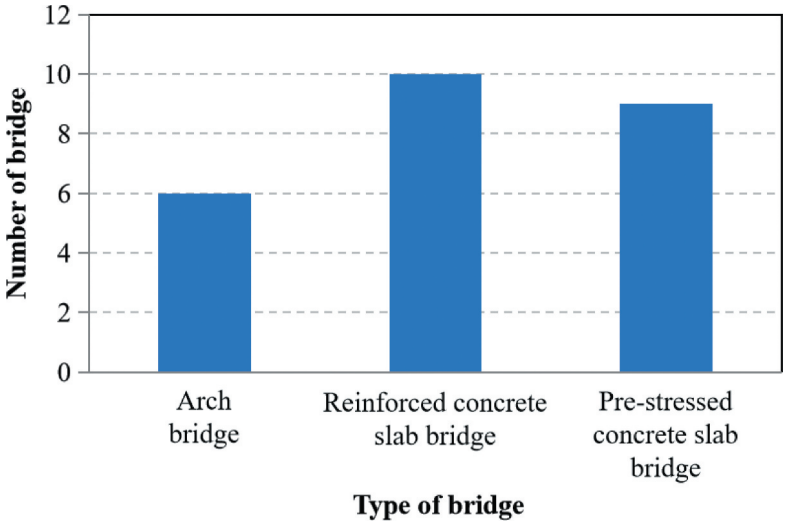

Figure 1. Distribution of bridge number and bridge type.

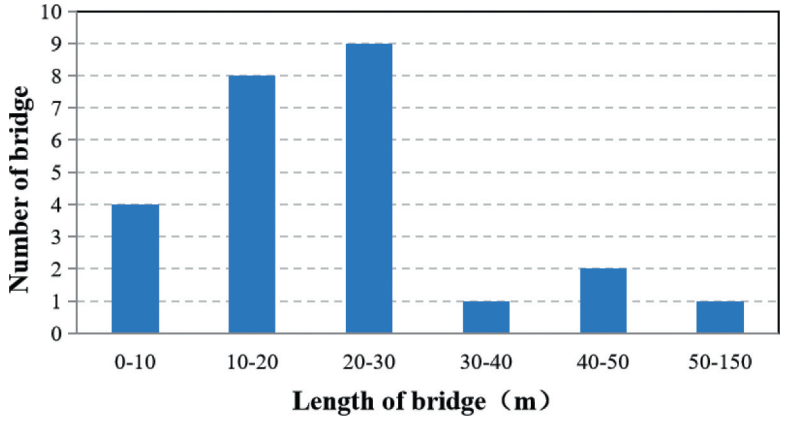

Figure 2. Distribution of bridge number and bridge length.

As pointed out in the pre-processing of the inspection data, all practical implementations adhered to strict requirements for training and testing. The first requirement was that all data were numerical. Therefore, if categorical features were present, they were converted to

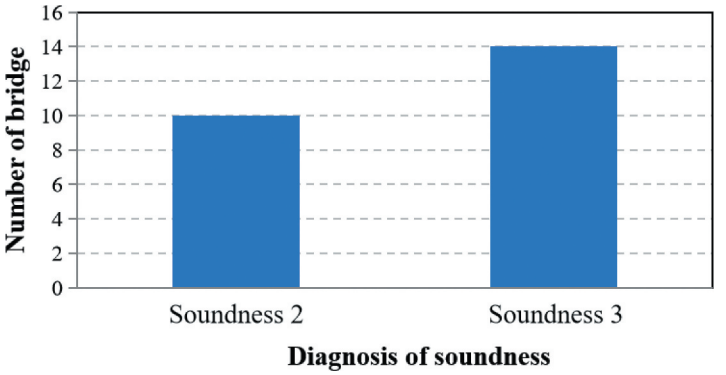

Figure 3. Distribution of bridge number and sound diagnosis.

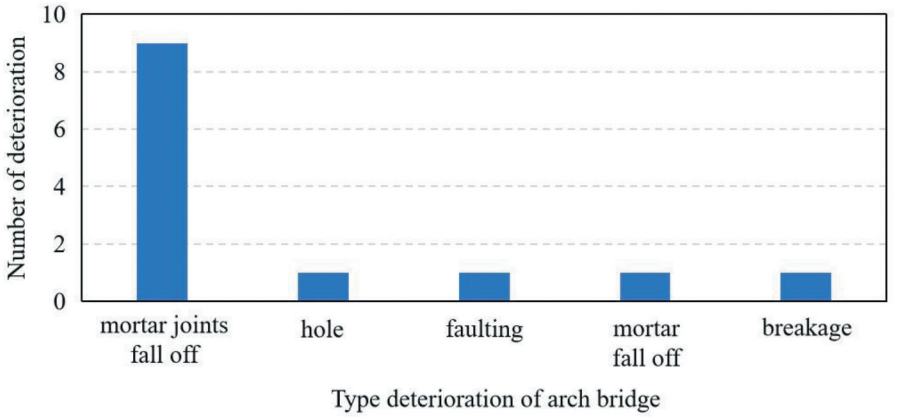

Figure 4. Distribution of bridge number and deterioration type (Arch bridge).

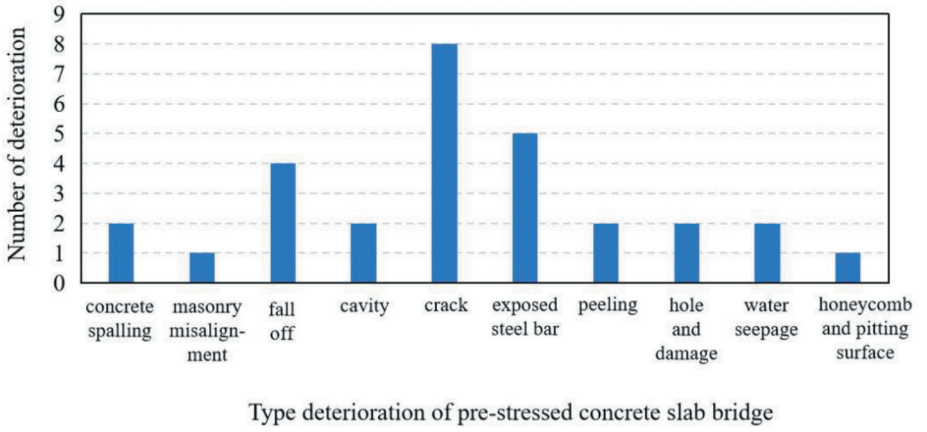

Figure 5. Distribution of bridge number and deterioration type (Reinforced concrete slab bridge).

numerical values using variable transformation techniques. To ensure that all feature variables were treated equally, it was best to use the feature "normalization" before training the model. The input data were the degree of deterioration of each concrete slab's inspection item, and the output data were the concrete slab's degree of health. Because our model's dataset was

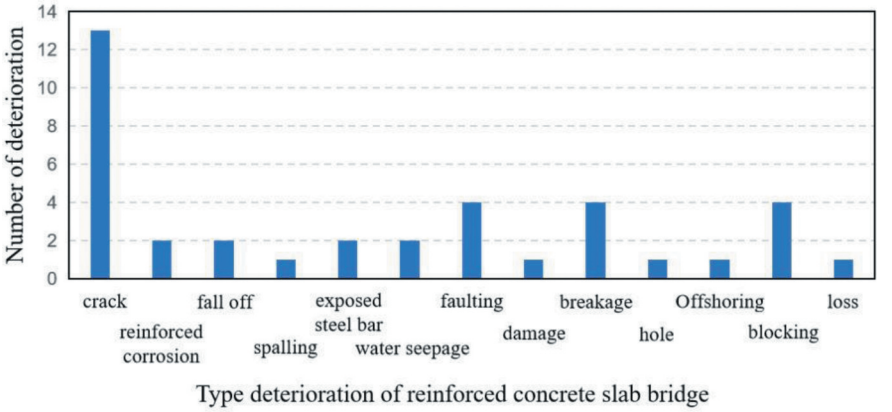

Figure 6. Distribution of bridge number and deterioration type (Pre-stressed concrete slab bridge).

small, we applied the classifier in a leave-one-out cross-validation. The leave-one-out cross-validation uses an entire model fit for all the data except a single point. It then makes a prediction at the point that can be compared to the actual value, which is iterated over the training dataset to obtain test errors for the labels of health ratings. We conducted this experiment by using the classification solver in a LIBSVM with grid search and k-fold cross-validation to find the optimal hyper parameters (a soft margin constant C and width of a Gaussian kernel y).

4 PREDICTION RESULTS AND DISCUSSION

Various metrics were used to evaluate the bridge health condition, such as accuracy, precision, sensitivity and specificity. This metrics are explained in more detail below.

Accuracy can be defined as the ratio of correct model predictions to the total number of tested images, as shown in Equation 4:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{FP} + \text{TN} + \text{FN}} \tag{4}$$

Precision (Eq. 5) defines how many of the images predicted as positive were predicted by the model correctly:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \tag{5}$$

Sensitivity, shown in Equation 6, defines how many of all true positive images were correctly predicted by the model:

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \tag{6}$$

Specificity (Eq. 7) defines how many of all true negative images were correctly predicted by the model:

$$\text{Specificity} = \frac{\text{TP}}{\text{TN} + \text{FP}} \tag{7}$$

In addition, the trade-off between sensitivity and specificity can be represented graphically as an ROC curve. It can be understood as a plot of the probability of correctly classifying the positive examples against the rate of incorrectly classifying true negative examples. The ROC curve can be constructed by plotting these pairs of values on the graph with 1-specificity on the x axis and sensitivity on the y axis. Situations in which datasets are unbalanced arise frequently in real-world problems; in these cases, model evaluation is done with criteria other than accuracy. Metrics extracted from ROC curves, such as the area under the ROC curve (AUC), can be a good alternative for model evaluation; this is because the ROC curve can determine the difference between errors on positive or negative examples (Rakotomamonjy et al. 2004).

Table 1. Useful attribute combines.

Case	Training data	Test data	Ratio of number	Correctly classified accuracy	TP	FP	Accurancy	Recall	F value	Area under ROC curve (AUC)
Pre-stressed	13	7	2	57%	1	1	0.6	1	0.7	0.5
concrete slab	13	7	2	66.70%	1	1	0.7	1	0.8	0.5
bridge	13	7	2	71%	1	1	0.7	1	0.8	0.5
Reinforced	8	4	2	75%	0.5	0	1	0.5	0.7	0.75
concrete slab	8	4	2	75%	1	0.5	0.7	1	0.8	0.75
bridge	8	4	2	50%	0.3	0	1	0.3	0.5	0.67

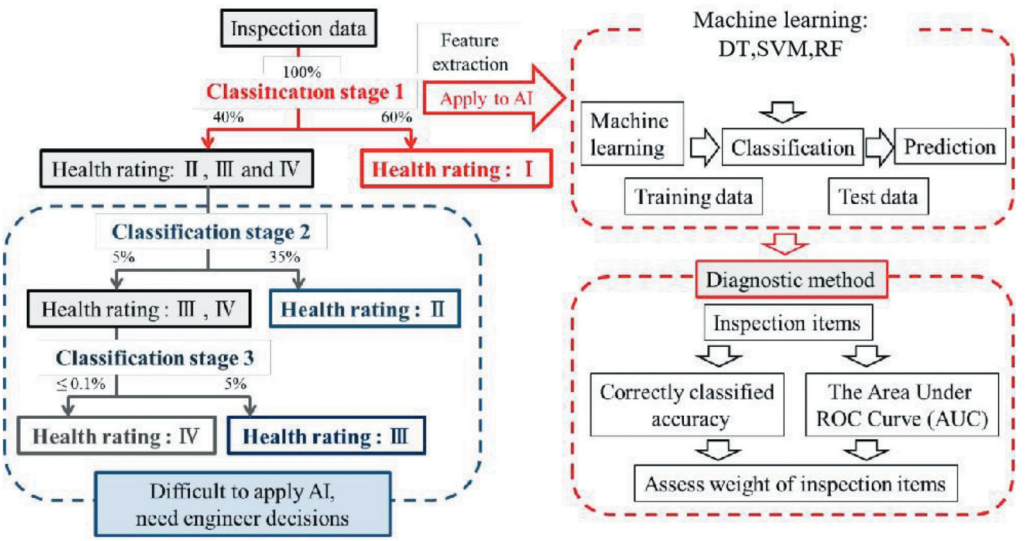

Figure 7. Concept diagram of sound diagnosis.

Feature importance and selection can give an objective utility of features (Arong et al. 2020, 2018). We need to manually create an objective utility feature of inspection items. Above the ML numerical results, a useful feature combination denote in Table 1. The concept of a proposed diagnostic optimization method for bridge integrity is described in Figure 7. Regional governments are constantly distressed by the lack of a maintenance budget and maintenance experts. This proposed diagnostic optimization method can assist regional governments in determining bridges' health and integrity, which are generally decided by own experience of each maintenance experts.

5 CONCLUSION

This paper explores a rapid condition rating method using a machine learning model based on inspection data of bridges. The technique is used to extract the information in the text description of the bridge inspection reports and convert them into digital vectors. The methodology is verified with the condition rating of 25 bridges of different types and health conditions in Inner Mongolia, China. According to the ML analysis, the different feature combinations by using an experienced inspector's training data to predict the class label. Thus, this proposed bridge integrity evaluation method can help and assist regional governments determine bridges' degree of health.

FUNDING

ABSTRACT: We present our research innovation in enterprise visual inspection for civil infrastructures. We train and adapt AI foundation models to work on high-resolution images collected by drones for detecting and segmenting very small defects in large areas and with high precision. Further, we provide support to reliability engineers by measuring defects with computer vision and by providing additional information that is required to assess damage severity and plan maintenance interventions. We provide access to our research innovation through our SaaS IBM Inspecto. IBM Inspecto is a research-industry platform developed by IBM Research that leverages foundation models and advanced computer vision methods to fully digitalize the visual inspection process, accelerating and improving accuracy in critical inspection tasks. In this work, we present visual inspection results on the Storebælt Bridge in collaboration with Sund & Bælt, as well as on other applications.

1 INTRODUCTION

The maintenance and inspection of infrastructure elements, such as bridges, tunnels, roads, runways, and dams, is of immense significance for public safety and for maintaining economic activity. Despite that, most visual inspections are carried out manually, and infrastructure operators are faced with the challenging task of detecting every problem before it gets expensive to be repaired, or even too dangerous for civilians. Manual visual inspections make maintenance cycles longer than they should be, as they require that a person physically inspects the entire surface of an infrastructure. Civil engineers not only need to detect problems but also to review them and decide what action must be taken. As a result, our global network of infrastructures is inspected less frequently than it should be and, in some cases, inspection job plans are only partially executed. For instance, in today's inspection reports, only major detected problems are included, and their location is only roughly indicated. This may cause further issues downstream of the process when selected defects are repaired with imprecise information. Moreover, if something is not included in such reports, it is practically impossible to verify in the future if that was an actual mistake or if no problem was visible at that time. With the infrastructure network becoming older and older every year, all these challenges risk causing major fatalities, as we have already seen in examples such as the collapse of the Morandi Bridge in Italy in 2018[1].

The last decade has marked incredible technical progress in AI and Machine Learning (ML) with remarkable success stories in the fields of computer vision, natural language pro-

1. https://en.wikipedia.org/wiki/Ponte_Morandi

DOI: 10.1201/9781003483755-421

cessing, and other domains. This wave of success and excitement in AI has been in large part driven by Deep Learning (LeCun 2015), and recently by Foundation Models (FMs), i.e., deep neural networks that are trained on large broad unlabeled datasets and that can be deployed on a wide range of downstream tasks.

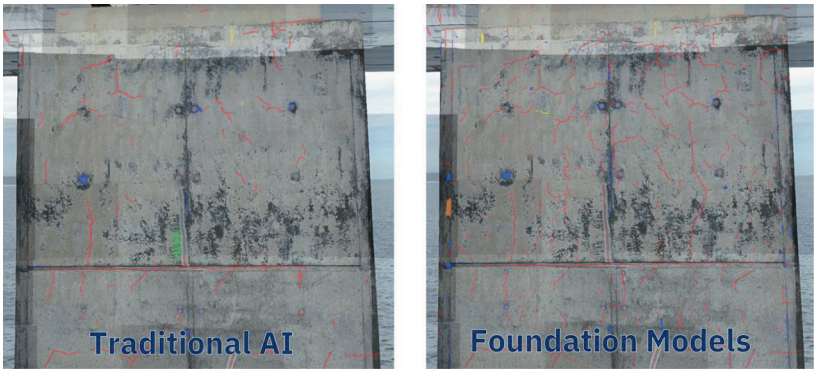

Figure 1. Comparison of AI results on Storebaelt Pillar 3 south face. Left: traditional supervised learning. Right: FM.

While ML has seen increased adoption in the civil engineering domain in recent years, for instance in applications like condition assessment (Bianchi 2022), novelty detection for structural health monitoring (Manzini 2022), or other structural engineering tasks (Salehi 2018), the impact of FMs specifically on civil engineering is however still in its infancy, owing to a gap between research development and application use cases. Part of this gap is due to the non-straightforward adoption of model results into existing operational flows.

To close this gap, we present IBM Inspecto, a research-industry platform developed by IBM Research in collaboration with our engineering partner Sund & Bælt, that leverages FMs and advanced computer vision methods to fully digitalize the visual inspection process, accelerating and improving accuracy in critical inspection tasks. This paper is organized as follows: Section 2 introduces AI FMs and discusses their benefit for visual inspection of civil infrastructures, Section 3 presents IBM Inspecto and describes how domain experts can consume results of AI FMs in a convenient way. Finally, Section 4 describes future directions and conclusions of this work.

2 FOUNDATION MODELS FOR VISUAL INSPECTION

Deep learning computer vision models are adept at sifting through large image datasets typical acquired by use of drones to identify high-risk elements like structural cracks or visible corrosion in steel reinforcement bars in bridges. The accuracy and efficacy of these models hinge on access to a substantial volume of annotated data. However, obtaining high-quality labels, especially for rare occurrences like structural defects, is both challenging and expensive. This issue is accentuated in visual inspection scenarios, where the rarity of defects and the complexity of tasks like object detection and instance segmentation compound the difficulty and cost of labeling.

Recently, Self-supervised learning (SSL) has emerged as a pivotal approach in the realm of computer vision, especially for pre-training FMs on large amounts of unlabeled data. SSL is also becoming a cornerstone in civil engineering applications, particularly for the critical task of visual inspection. It is now common that large datasets are becoming available thanks to the automation of data collection methods, such as drone data acquisitions over bridges. This abundance of unlabeled data is an ideal candidate for

SSL, where models are trained on data that they label themselves through predefined pretext tasks. SSL's history in computer vision spans several years, featuring techniques like denoising autoencoders and Siamese networks. More recent innovations include self-supervised pretraining approaches like PIRL (Mirsa, 2019), BYOL (Grill, 2020), MOCO (He, 2020), and SimCLR (Chen 2020), further advanced by integrating vision transformer architectures, as seen in Vision Transformer (ViT) (Dosovitskiy, 2019), DINO (Zhang, 2022), MSN (Assran, 2022), and Masked Auto Encoder (MAE) (He, 2021). The significance of SSL pretraining is twofold: it not only improves the overall performance of models but also makes them adept at learning from a few examples in downstream tasks.

In the context of bridge defect detection, our experiments have focused on SSL pretraining to develop FMs. We utilized the MAE technique, where a significant portion of an image is masked, and the model is trained to reconstruct the unmasked image. This approach not only aids the model in understanding the intricacies of concrete bridge structures but also enhances its ability to pinpoint defects.

Results demonstrate that an FM pre-trained on images of concrete bridges boosts performance in defect detection tasks. This is further highlighted in Figure 1, where given a qualitative assessment we can see that FMs have a much higher recall over traditional models. Furthermore, due to the use of large ViT models, the image resolution is kept more intact when compared to convolutional-based methods. This further refines the detection and allows the model to identify the defects with less background noise, this can then lead to better measurements and therefore ranking of the defects.

2.1 *Detailing the training method*

In the preceding section, we mention that we developed an FM employing the MAE technique. This is executed through a hierarchical, four-stage training process. Initially, the model undergoes pre-training via SSL, devoid of any labeling, on a diverse collection of common object datasets. This phase is instrumental in enabling the model to hone its capability for abstracting pertinent information from a broad spectrum of images, irrespective of their relevance to civil infrastructure or bridges specifically.

Progressing to the second stage, the model's training continues under the SSL paradigm. It is during this phase that the model is exposed to a 'source dataset', comprising an extensive collection of unlabeled imagery predominantly featuring concrete structures, with a significant focus on bridges. This dataset encompasses a variety of structures, including the Storebælt Bridge, but extends to incorporate bridges from multiple geographical regions and other concrete edifices. The primary objective of this stage is to refine the model's proficiency in extracting salient features specifically from images of concrete structures.

The third stage of the model's training, adhering once again to SSL principles, narrows the focus exclusively to the Storebælt Bridge. The dataset in this stage is composed solely of images captured of this bridge, creating a specialized data domain that the model learns to navigate. This targeted approach is pivotal in fine-tuning the model's ability to interpret the specific characteristics inherent in the Storebælt Bridge imagery. Notably, a subset of this dataset, encompassing approximately 1000 images, is annotated with roughly 8000 identified defects, and is used in the fourth stage of training.

In the fourth and final stage, the model is trained using supervised learning. This phase employs a cascade Mask R-CNN head that sits on top of the pre-trained model backbone which was pre-trained in the previous steps. This adapts the model to i) object detection, i.e., identifying bounding boxes around objects of interest, and ii) instance segmentation, i.e., identifying the pixels within each box corresponding to defects. That multifaceted training approach ensures that the model is not only versed in general image comprehension but is also finely attuned to the nuances of concrete structure imagery, particularly that of the Storebælt Bridge, thereby enhancing its efficacy in defect detection and segmentation tasks.

3 IBM INSPECTO

IBM Inspecto is an industry research platform for enterprise visual inspection developed by IBM Research. With IBM Inspecto, engineers and domain experts are guided through the visual inspection process with support for all the phases of engineering inspection, including long-term management of large amounts of data, intuitive navigation of complex assets with unique image stitching technology, maps, hierarchy, and 3D models, high-resolution defect detection powered with AI FMs trained on the world largest curated infrastructure image dataset, automatic measurement of detected defects, assisted engineering review process and customizable report generation.

In more detail, IBM Inspecto features the following components:

- Image viewer: enable ordered access to large amounts of inspection images and in structured folders.
- Prediction viewer: displays the results of the AI models and automatically extracts associated attributes, such as crack length to represent pixel-accurate segmentation masks of defects.
- Overview viewer: allows the user to view large sections of the infrastructure and navigate in real-time. It also enables understanding of the context in which a defect was detected.
- Merged predictions and overview: enables the user to understand the relationships and positions of all defects and consolidates multiple detections of a defect in different images into a single prediction.
- Statistical viewer: aggregated statistics are provided on all detected defects, both for individual images and for the entire merged overview.
- Report generator: enables the generation of customized for all data captured in the inspection, with detailed views of each defect, important attributes, and direct links to OCL for an enlarged view of the visualized defect. Georeferencing allows runway maintenance staff to manually check defects on the runway and repair damages with a sealant.

3.1 *Great Belt bridge inspection*

In this section, we demonstrate IBM Inspecto on the Storebælt[2] bridge. After the data has been uploaded to the service and analyzed by our fine-tuned FMs, the engineer can start the

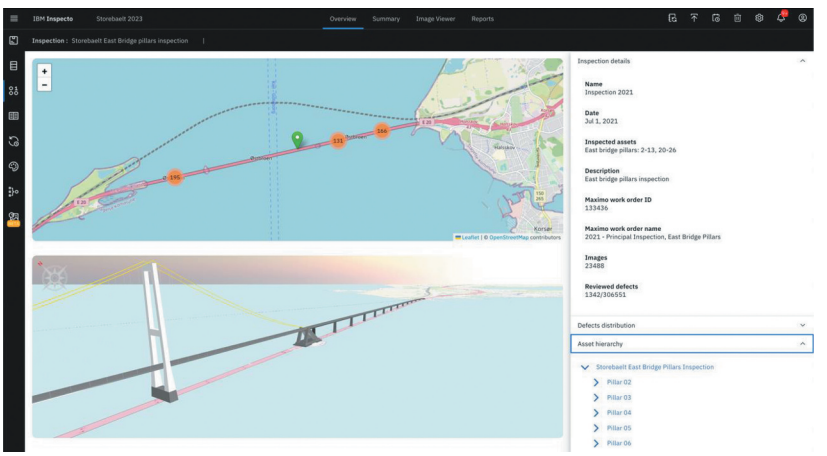

Figure 2. IBM Inspecto overview page. This page contains a summary of the performed visual inspection, including a map with the location of drone capturing points, the 3D model, as well as access to the bridge hierarchy and corresponding IBM Maximo work orders.

2. https://storebaelt.dk/en/

visual inspection process from the overview page in Figure 2: such a view conveniently allows the user to navigate around the entire infrastructure and have a first overview of the number of surfaces that have been inspected as well as of the number of defects detected by AI.

From the overview page, the civil engineer can access any element and inspect the concrete surface in detail. In Figures 3 and 4 we show an example view of one face of pillar 3 on the Storebælt. The stitched view is zoomable up to native high-resolution of the individual images, that are collected with the DJI Matrice 300 drone, using high-resolution grid mode.

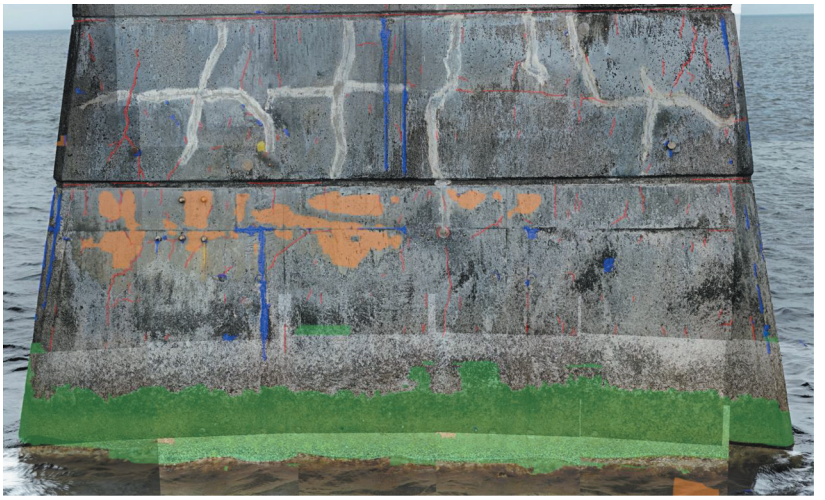

Figure 3. IBM Inspecto high-resolution analysis of the Storebælt pillar 3, south face, bottom region. The view is made of 30 high-resolution images automatically stitched together by our algorithm. Our fine-tuned AI FM detects cracks (red) net-cracks (orange), spalling (blue), rust (yellow), crack with precipitation (pink), as well as algae (green).

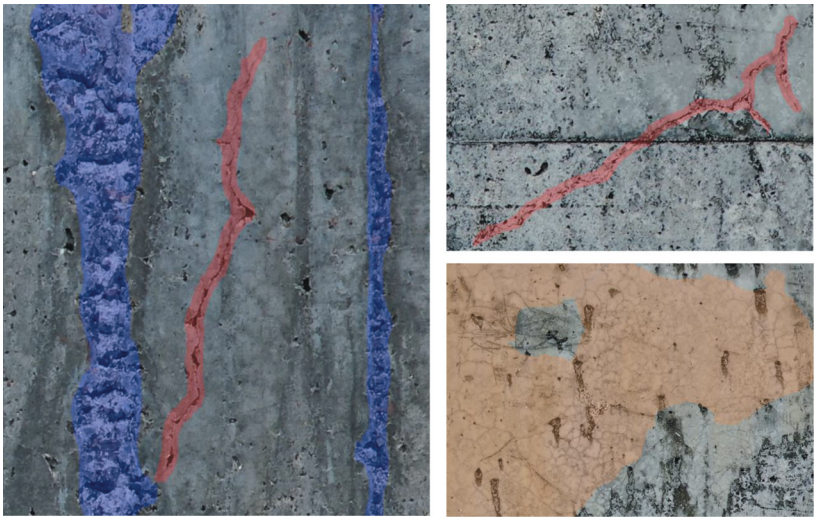

Figure 4. IBM Inspecto high-resolution analysis of the Storebælt pillar 3, south face, bottom region. A few selected zoomed areas to show the precision of masks generated by our AI FM.

List of all detected findings

Figure 5. IBM Inspecto summary table to be included in the asset inspection report. Note that the indicated severity scores and comments scores are randomly generated for demonstration purposes and do not represent the actual condition of the bridge.

Once the civil engineer has terminated reviewing the bridge surface, a customizable report can be generated including all necessary information. IBM Inspecto reports are available both as HTML as well as PDF. In Figure 5, an example of a summary table with all the detected defects on pillar 3 south face, is provided. The table shows on the top the most severe defects and includes links to view them in the service.

3.2 *Other examples of applications*

We successfully applied IBM Inspecto to a variety of other applications, from older bridges like the Stenungsund in Sweden (see Figure 6) to the Dübendorf Airbase Runway (see Figures 7 and 8). These two applications show how our AI FMs can adapt easily to predict defects on very different types of concrete surfaces. The Stenungsund bridge is very representative of most bridges in Europe and the US, which were built more than 50 years ago and have major signs of deterioration, such as areas with spalling with corroded rebars. We could reach very precise detection accuracy by fine-tuning the model with roughly 500 images.

Figure 6. IBM Inspecto results on the Stenungsund bridge: the image shows large instances of spalling with corroded rebars that our model detected correctly.

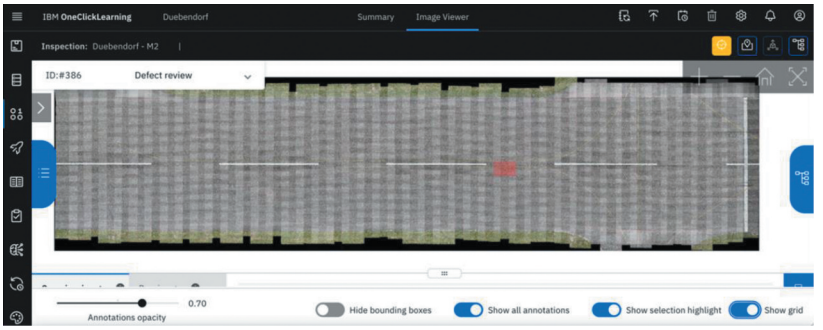

Figure 7. IBM Inspecto results on the Dubendorf Airbase: we inspected 250m of the runway with more than 800 high-resolution images automatically stitched together.

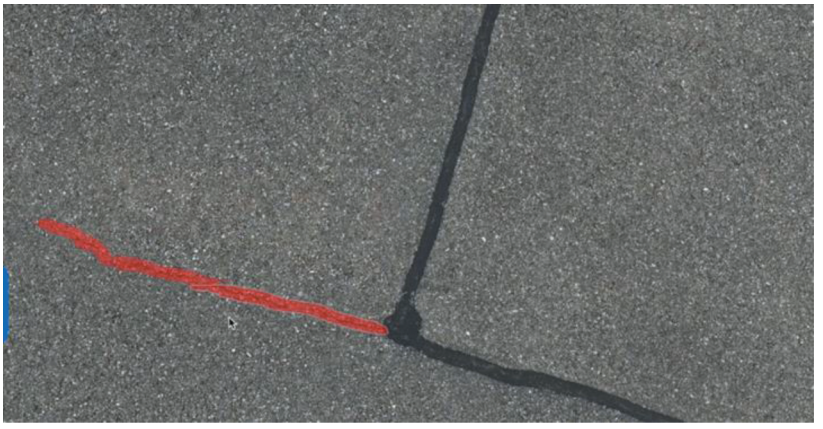

Figure 8. A detail of a crack that was previously repaired on the Dubendorf Airbase and that continued to grow later.

The Dübendorf Airbase runway surface is also quite different than concrete bridge walls. Nevertheless, our algorithm has been able to completely reconstruct the global overview stitched image and analyze it detecting even the smallest crack without any fine-tuning. A nice example in Figure 8 shows a crack that continued to grow after repair, with our model being able to detect only the new branch precisely next to the repaired patch.

4 CONCLUSIONS AND FUTURE WORKS

In this paper, we presented IBM Inspecto, a research-industry platform powered by IBM Research foundation models. We apply IBM Inspecto to the Storebælt Bridge in collaboration with Sund & Bælt, as well as on other applications. We demonstrate key features such as the intuitive navigation, the accurate detection of defects in high-resolution images, and the automated generation of customizable reports. IBM Inspecto aims to reduce the time and cost of visual inspection of complex assets, while digitalizing completely the entire inspection process and can be applied to a wide variety of infrastructures, from bridges to buildings, roads, and runways.

We are currently extending IBM Inspecto with additional AI features that will further accelerate the inspection process. First, we are developing a defect review assistant, powered by multi-modal FMs. Our review assistant will learn from a small, selected number of domain experts who manually reviewed defects, to then perform an automated review of all the other thousands of defects detected by our AI FMs. We envision that this process will accelerate the

review of the detected defects by at least one if not two orders of magnitude. To allow users to extend our pre-trained models and detect other types of defects that are present on their infrastructures, we are developing a Visual Prompting Lab service. There, engineers will just need to provide a few examples of images and swiftly scribble on top of the new type of defects to teach the algorithm what they would like to be detected. The process will be naturally intuitive and require minimal data and human labor. Finally, we will enable the users to compare inspected surfaces over time. Leveraging our stitched images, IBM Inspecto will conveniently show what has changed over each surface from the previous inspection, without asking to the user to re-annotate and re-assess previously assessed defects, thus further reducing the work to be done in every future inspection.

ABSTRACT: Visual inspection remains an essential tool for assessing structural damage. Damage detection is a challenging task for those specifying, designing, and deploying SHM systems. Often only traditional visual inspection processes are available to determine the type and extent of structural damage. For bridge structures in the UK, a regime of general (every two years) and principal (every six years) inspections is often followed. Such visual inspections are time-consuming and costly in terms of both labour and financial resources. Therefore, the possibility of completing more of the bridge visual inspection process offsite has many potential benefits for bridge owners and managers during the service life of the asset. Recent research conducted at the University of Bristol in collaboration with industrial partners has examined how to make the best use of metrics derived from visual inspection data when assessing bridge condition and planning maintenance activities. Recent research into which aspects of the current visual inspection regime in the UK could potentially be moved offsite has also been carried out. This paper summarises these research efforts and discusses how AI may be used as part of future enhancements to visual inspection data capture and analysis.

1 INTRODUCTION

1.1 *Background*

The UK has aging infrastructure stock, often described as an 'asset time bomb' (Thurlby 2013, Thurlby & Rimell 2015). Therefore, assessing current asset condition and residual life is important for bridge managers. A key element of asset condition assessment is to be able to detect damage across the entire stock (in this case of bridges) and identify differences by region or asset type/class. 'Damage detection', although the most useful form of Structural Health Monitoring (SHM), is arguably the most difficult to realise in field conditions (see the SHM categories and discussion in Webb et al. 2015). The key method for damage detection in current practice remains visual inspection (VI) (e.g. Wallbank 1989, Moore et al. 2001, Lea & Middleton 2002, Middleton 2004, McRobbie et al. 2015, Bennetts 2019, Bennetts et al. 2016, 2020). In the UK, the following default visual inspection regime is often followed: principal visual inspections (conducted by inspectors operating within touching distance of the bridge) scheduled every six years and general inspections every two years (see HA 2007 and Bennetts et al. 2016). The aforementioned VI regime may be

DOI: 10.1201/9781003483755-422

varied on a risk-basis (HE, 2021). Bennetts et al. (2023) conducted a study using VI data from 200 sample bridges from the UK highway network and concluded that 81% of the inspections were carried out in 'strict compliance' with BD63/07 (the standard at the time of the study; see HA 2007) and 93% were within 'the spirit' of the standard (see also Bennetts 2019).

1.2 *Paper outline*

This paper summarises recent research on the following topics: the use of VI data and metrics for asset management processes (section 2); how aspects of the VI process may be carried out offsite using new technologies, leading to a hybrid VI system (section 3) and ways in which recent advances in artificial intelligence (AI)/machine learning (ML) may influence aspects of VI processes in the future (section 4).

2 USING VI DATA AND METRICS FOR ASSET MANAGEMENT

2.1 *Importance Of VI in bridge engineering*

Bennetts et al. (2016, 2020) conducted a series of semi-structured interviews to elicit the use of VI and SHM in the UK bridge management community. The use of VI data and associated metrics is varied across the industry. The use of SHM was reported to be limited except in specific instances (Bennetts et al. 2020). Colford et al. (2022) note that SHM is not an alternative to inspections. Bennetts et al. (2021) argued that the inspection intervals used in UK practice (two years and six years) make detecting change difficult, especially at individual asset level. Bennetts et al. (2020) as part of hierarchical process modelling and their survey of bridge engineering professionals, identified the following high-level processes: 'understanding the stock', 'making decisions' and 'implementing interventions' (Bennetts et al. 2020, p. 214), shown in Figure 1.

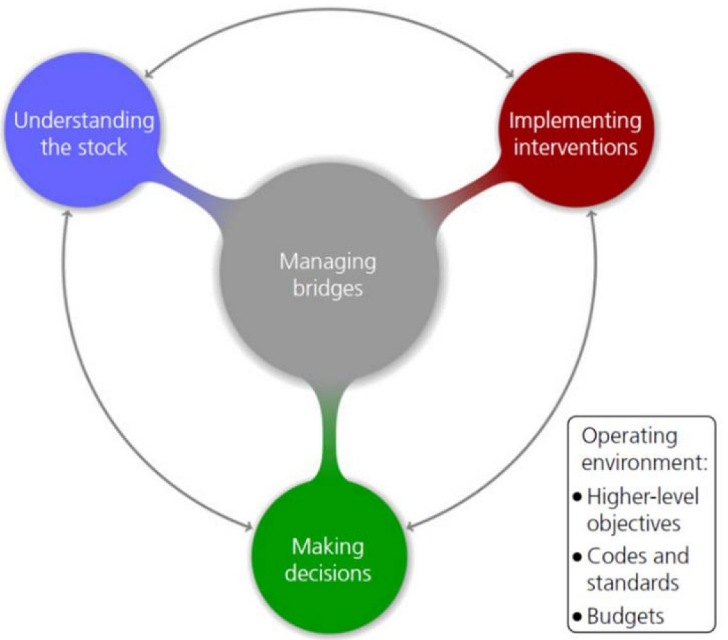

Figure 1. High-level model of the bridge management system (taken from Bennetts et al. 2020, used under the terms of the cc-by 4.0 licence).

2.2 *Bridge condition indicators*

VI data can be used to calculate Bridge Condition Indicator (BCI) metrics (defined in detail in Sterritt 2002). These metrics can be aggregated and analysed to study asset condition changes at stock/regional level (Bennetts et al. 2018a, 2018b). BCI metrics can be used to show varying asset deterioration across UK regions. For example, Figure 2 shows the reduction of BCI_{ave} and BCI_{crit} scores for a population of bridges (Bennetts et al. 2018b). As stated in Bennetts et al. (2018b, p. 26):

> "The average score, BCI_{ave} is calculated from the raw defect scores, taking the worst defects on each component type, weighted by the structural importance of each element. The critical score represents the worst defect on the most important structural components."

(See Sterritt (2002) for more details on the calculation of the aforementioned metrics.)

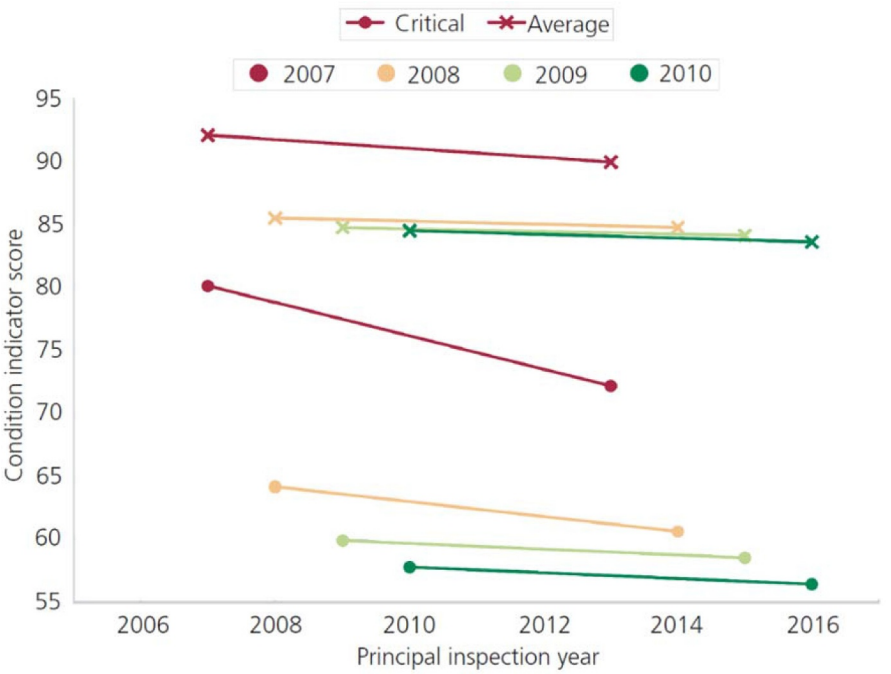

Figure 2. Change in condition between successive inspections for populations of structures that were inspected in the same year. The conditions of these populations of bridges are plotted as the average BCI_{crit} and BCI_{ave} scores for the population, weighted by deck area. A total of 2397 bridges are included in the plot (taken from Bennetts et al. 2018b, used under the terms of the cc-by 4.0 licence).

3 OFFSITE VISUAL INSPECTION PROCESSES

Visual inspection is a costly exercise for asset owners and managers (Bennetts 2019). Visual inspection requires human inspectors to work outside in varied weather conditions, often at night and frequently in high-traffic environments (e.g. Bennetts 2019). As an aside, in the case of assessing bridge scour, for VI to be carried out, divers are necessary to detect potential scour holes formed due to floods below the foundations of a bridge (cf. Selvakumaran et al. 2018, Pregnolato et al. 2021). The need for divers implies an increased safety risk which needs to be managed. Moreover, another issue of VI is the lack of skilled inspectors for which the UK has introduced the Bridge Inspector Training Scheme (BICS) (Lantra 2023). Therefore, efforts to move VI processes offsite have the potential to supplement/enhance existing VI/SHM efforts (McRobbie et al. 2015, Nepomuceno 2022, Nepomuceno et al. 2022a, 2022b).

Nepomuceno et al. (2022b) (Figure 3) have recently presented a possible schema for moving parts of the VI process offsite: future realisation of such efforts will require improved technologies for image capture (see the recent paper of Nepomuceno et al. 2022a for a detailed review of new technologies to assist VI processes and the best practice guide for bridge monitoring by Middleton et al. 2016). New technologies may include use of 360° cameras, precision drone-based camera

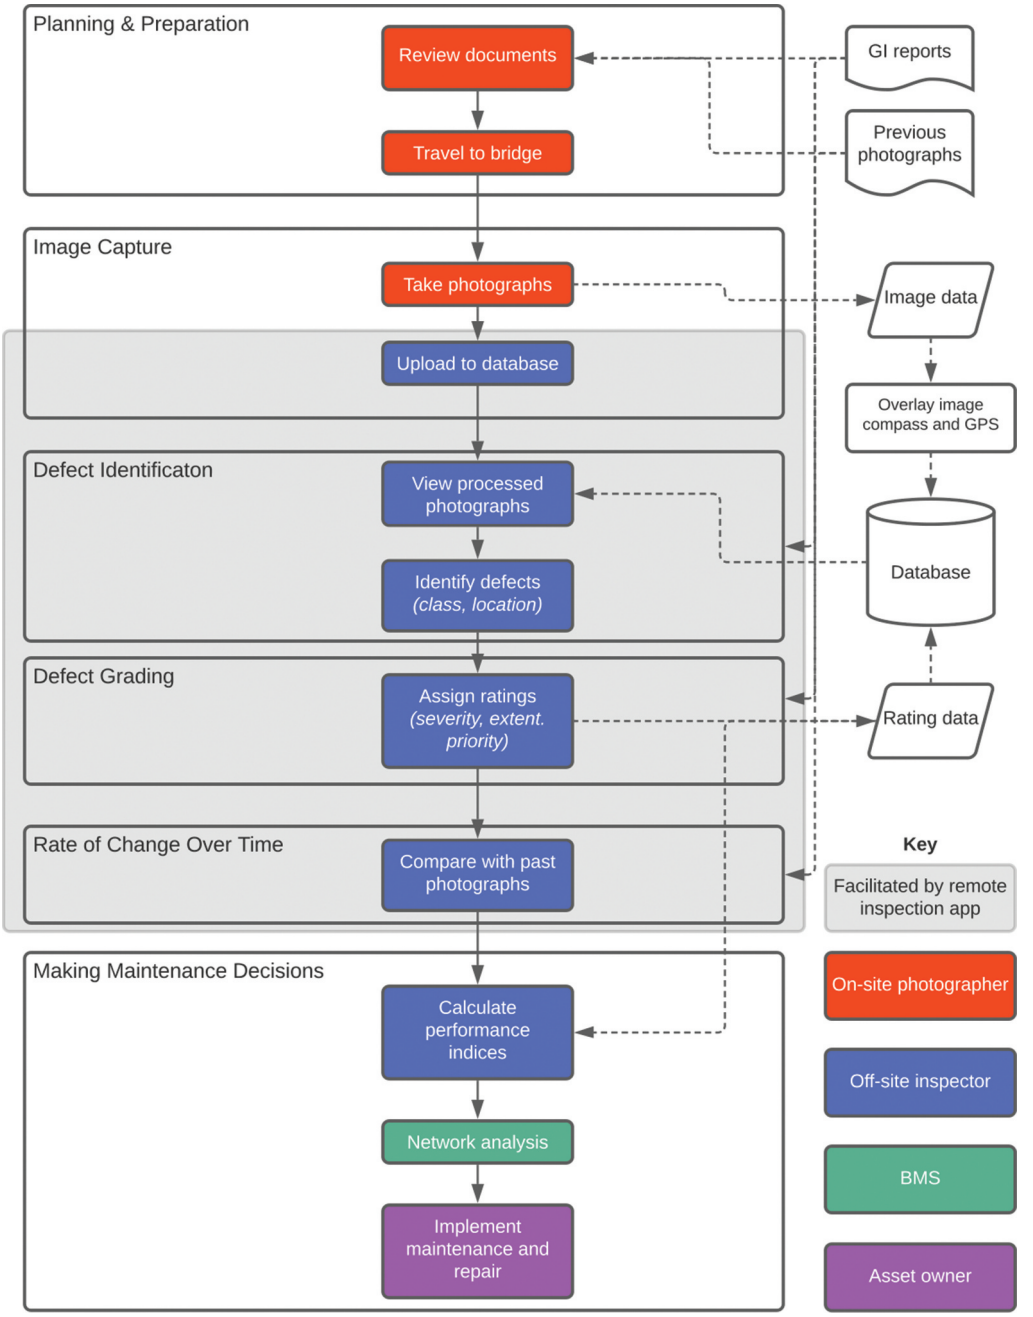

Figure 3. Workflow diagram of remote inspection schema (created in Lucidchart (2022)) (adapted from Nepomuceno et al. 2022b, used under the terms of the cc-by 4.0 licence).

systems, interferometric synthetic-aperture radar (InSAR) as well as virtual reality and computer vision (Nepomuceno et al. 2022a, 2022b). For the specific case of bridge scour, fibre optic installations, sonar and InSAR are devices that could potentially mitigate the need for divers in some instances (cf. Prendergast & Gavin 2014, Selvakumaran et al. 2018, Vardanega *et al.* 2021). Even if technological advances allow image capture to be done remotely with photographs and video, (i.e. assessed by human inspectors offsite) it is not guaranteed that the accuracy and precision of defect identification will be acceptable for those taking decisions based on this data.

Nepomuceno et al. (2021, 2023) presented preliminary survey data showing that the ratings from onsite and offsite inspectors tended to more closely agree for higher severity defects (see also Nepomuceno 2022). Further studies are needed to standardise off-site assessment of captured images. Regardless of whether the defect detection outcomes are the same offsite, decisions about maintenance and intervention still depend on the VI data and associated metrics. These considerations persist regardless on whether the process stays similar to current practices or shifts towards being more technologically driven and conducted partially remotely.

4 POTENTIAL FUTURE INFLUENCES OF AI IN VI WORKFLOW

4.1 *Recent AI uses in structural engineering*

Use of AI is expected to increase in many fields, including bridge engineering. Alexander et al. (2022) used deep learning methods for crack detection on structures. Munawar et al. (2022) used ML methods for crack detection processes. Luleci & Catbas (2023b) suggested population-based structural health monitoring (PBSHM) approaches for pre-stressed bridges. Luleci & Catbas (2023a) present a recent review of deep generative models (DGMs) in SHM. Luleci & Catbas (2023a) conclude that data scarcity remains a challenge in the field of bridge engineering (see also the review of Catbas & Avci 2023 which mentions in part the use of virtual reality in bridge SHM). Stacy (2023) notes that data alone is not sufficient for good decision making. Projects such as the Data Analytics Facility for National Infrastructure (DAFNI) may help with the analysis of future larger datasets (Matthews et al. 2023).

AI approaches may assist with data analysis and pattern recognition across large datasets. AI offers potential improvements across the VI process. For example, AI could potentially be used to evaluate trends from stock-level (regional) data sets of VI metrics, further enhancing what can be gleaned from 'manual' analysis of large structural data sets such as those reported in Bennetts et al. (2018a, 2018b).

There are potential concerns/limitations, such as the fact that semi-automated or fully automated processes may detect specific instances of bridge damage (i.e. the defect location). There are also concerns on how well severity will be assessed with AI methods compared to human inspectors. For instance, from an asset management perspective, if a bridge with a defect of a similar extent and severity is repaired and this is reflected in the data set the AI is applied to; would AI-based processes recommend repair in other similar cases and if so on what basis? Asset managers may not be able to deduce why AI prioritisation or recommendations have been made and hence the context for decisions/recommendations may become less clear and less able to be scrutinised by other stakeholders.

4.2 *Engineering judgement*

Bennetts et al. (2016) showed using data from semi-structured interviews that engineering judgement is very important in taking bridge management decisions. In the context of a potentially AI enhanced VI process, what is the fundamental role of the 'engineer'? Engineering judgement is needed to take decisions regarding assignment of design parameters and for catching errors in design processes (cf. Peck 1980, Petroski 1993, Vardanega & Bolton 2016). In the case of VI 'judgement' is exercised when assessing the 'extent' or 'severity' of the defect. Judgment is also needed when prioritising bridges for maintenance expenditure. A future question for bridge managers using AI processes will be how they will be able to

safely overrule AI recommendations when they produce results that do not align with their own engineering judgement.

5 SUMMARY

This paper has reviewed recent research efforts on the use of VI data for associated bridge condition metrics – these data have the potential to be further analysed using AI tools. Use of VI data is still widely used for assessing structural condition and therefore there is a relevant question on how much of this time-consuming and expensive process can be conducted offsite. Survey data has shown some offsite evaluation of defect severity can be potentially considered, although more data is needed to confirm if off-site inspectors can replace on-site inspectors (assuming comprehensive image capture can be carried out using new and an emerging technological solutions). Finally, with the recent prominence of AI, further research of on the use of AI in VI should be undertaken.

Performance evaluation of TMDs for a continuous steel box girder

G.L. Liu, X.H. Hu & R.J. Ma
Tongji University, Shanghai, China

ABSTRACT: Tuned Mass Damper (TMD) is widely utilized for vibration control in bridge due to its exceptional damping effectiveness. However, its performance may gradually deteriorate over time. Hence, the reassessment of TMD performance is necessary. This study focuses on TMDs equipped in the Chong Qi Bridge in China. By analyzing the health monitoring data, the dynamic characteristic parameters of the main girder were derived, and the correlation between wind speed and acceleration was studied. On-site random vibration tests were conducted by locking or activating each TMD to investigate the overall bridge vibration during the test process. Based on the test data, the influence of TMDs on the damping ratio of the entire bridge was analyzed, and a new indicator was proposed to quantitatively evaluate the working performanceof TMDs. Free vibration tests were performed on TMDs, and the frequency and damping ratio were measured using a self-developed mobile app.

1 INTRODUCTION

The continuous steel box girder bridge has advantages such as light weight, convenience in construction, good seismic performance and extensive application. However, as the span of the bridge increases, its flexibility also increases, and it becomes more susceptible to wind-induced vibration such as vortex-induced vibration (VIV), which may lead to significant vibration responses, adversely affecting traffic safety. Therefore, it is necessary to take measures to suppress the vibration response of the bridge structure.

Common control measures for wind-induced vibration include aerodynamic measures and mechanical measures. Aerodynamic measures can reduce the wind sensitivity of bridges by optimizing the bridge cross-sectional shape, such as the installation of wind deflectors, stabilizing plates, etc. (Fujino & Siringoringo, 2013). Mechanical measures often refer to dampers, such as Tuned Mass Dampers (TMDs), which can dissipate the vibration energy of the main girder through passive resonance. TMD is used on numerous bridges, such as the Rio-Niteroi Bridge (Battista & Pfeil, 2000) and Trans-Tokyo Bay Crossing bridge (Fujino & Yoshida, 2002). Wang et al. (2014) studied the control of bridge flutter using Multiple Tuned Mass Dampers (MTMDs) and optimized the parameters of MTMDs. Nagarajaiah & Jung (2014) made an introduction to Smart Tuned Mass Dampers (STMD), which had variable stiffness and damping. Debnath et al. (2016) conducted researches on simultaneous control of lateral, vertical, and torsional vibrations using TMD. Chen et al. (2017) experimentally studied the control effect of Eddy Current Tuned Mass Damper (ECTMD) on cantilever beam vibrations. Dai et al. (2019) proposed a design method of TMD parameters with the goal of improving robustness. Li et al. (2023) focused on wind-induced vibration control of irregular bridges and studied an optimized design method using spatially distributed TMD-type counterweights.

The analysis of vibration control effects is an essential aspect of the safety assessment of bridge structures, and scholars have conducted numerous studies on the evaluation of damping effects of TMDs. Van Nimmen et al. (2016) studied the vibration response of a pedestrian bridge equipped with TMD under crowd load through numerical simulation, evaluating the damping performance of TMD. Kim et al. (2017) identified bridge modal damping ratios

DOI: 10.1201/9781003483755-423

based on monitoring data and observed a significant increase in modal damping ratios after TMD was installed. Bayat et al. (2021) investigated the performance of TMD in suppressing vertical vibration of bridges under vehicle load through numerical methods, and conducted parameter analysis on damping performance. Sun et al. (2022) proposed a machine learning-based approach to assess the effectiveness of TMD based on monitoring data.

With the growth of service time, the performance of the TMD may degrade, necessitating a reassessment of its vibration suppression capability. Existing studies on TMD performance evaluation are still not comprehensive enough, with insufficient researches based on monitoring data, and lack attention on the dynamic behavior of TMD itself. This study takes the Chong Qi Bridge in China as an example. Modal parameters of the main girder were identified based on monitoring data, and the correlation between the vibration acceleration and wind speed was studied. On-site experiments were conducted with the TMD individually locked or activated, and changes in the vibration of the main girder and TMDs were analyzed. The dynamic characteristics of TMDs were identified using a self-developed mobile application. Finally, conclusions regarding the performance evaluation of TMDs in the Chong Qi Bridge are provided.

2 DESCRIPTION OF CHONG QI BRIDGE

The Chong Qi Bridge is a cross-river passage connecting Chongming Island and Qidong City in Jiangsu Province. The bridge was opened to traffic on December 24, 2011, and has been in operation for 12 years. The main bridge is arranged as four main spans of 185m and two side spans of 102m. The main girder adopts the design of a separative continuous steel box girder.

TMDs are installed on both sides of each main span to reduce VIV responses. There are four TMDs installed at the midspan of each main span, totaling 32 TMDs for the entire bridge (Figure 1), named U01-U16 (U for Upstream) and D01-D16 (D for Downstream). The TMDs primarily suppress the first vertical mode vibration of the bridge, and hence the design frequency of the TMD is set at 0.5Hz, close to the frequency of the first vertical mode. After optimization analysis of damping efficiency, the damping ratio of the TMD is set at 10%(Meinhardt et al., 2014).

The Chong Qi Bridge is equipped with a comprehensive structural health monitoring system. Anemometers are positioned on either side of Span3 (Figure 1) to measure the wind speed. Unidirectional accelerometers are distributed on each span and each TMD to measure the vertical vibration response of the structure.

3 ANALYSIS OF HISTORICAL MONITORING DATA

3.1 *Identification of main girder modal parameters*

The Random Decrement Technique (RDT) is a time-domain signal processing method which can extract free decay vibration signals from random vibration signals. This method is achieved by using an appropriate threshold to cut the original signal, obtaining Random

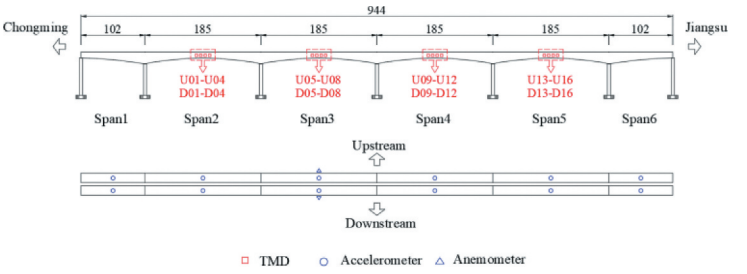

Figure 1. Overall layout and sensor arrangement of the Chong Qi Bridge.

Decrement Signature (RDS) results with the same initial value, and then averaging all RDSs to obtain the free decay vibration signal, but it's only applied for single degree-of-freedom systems. Huang et al. (1998) proposed the Empirical Mode Decomposition (EMD) method, which can decompose the original signal into a series of intrinsic mode functions (IMFs). However, EMD cannot decompose the response of systems with crowded modes. Chen & Wang (2012) introduced a signal decomposition method based on Hilbert transform, known as Analytical Mode Decomposition (AMD). This method can effectively decompose dense frequency signals, making it suitable for modal parameter identification (Wang & Chen, 2014).

The procedure of modal parameter identification is as follows. Firstly, use the peak-picking method to determine the first four vertical mode frequencies. Secondly, process the signal by AMD. Thirdly, apply RDT to each decomposed signal, and use the least squares method to fit the free decay vibration signal, then the frequency and damping ratio can be obtained. Taking a segment of the main girder vibration signal as an example, the analysis of the first vertical mode is shown in Figure 2, and the frequency is 0.510Hz while the damping ratio is 4.054%.

After obtaining vibration signals from October 2021 to December 2022, 10-minute signals were used as samples for identification, and daily vertical modal frequencies and damping ratios were acquired (Figure 3). Taking the average value as the representative value, the results are shown in Table 1. Actual frequencies are generally consistent with frequencies of the finite element model. The damping ratio of the first vertical mode is much greater than the design requirement of 1.15% (Qin et al., 2014), indicating that TMDs can significantly increase the damping ratio.

Table 1. Mean values of main girder modal parameters.

Mode	FEM frequency Hz	Actual frequency Hz	Actual damping ratio %
1st mode	0.519	0.512	4.341
2nd mode	0.679	0.657	3.498
3rd mode	0.883	0.875	2.463
4th mode	1.121	1.097	2.025

3.2 *Wind-induced vibration response analysis*

A correlation analysis was conducted between the wind speed and the vibration acceleration. Data with wind speeds below 6 m/s were excluded to minimize the influence of other factors. The wind speed was taken as the 10-minute average value, and the acceleration was taken as the root mean square value of a 10-minute period. Taking the main girder on the downstream side and TMD D06 for example, the calculated results of correlation coefficients are shown in Figure 4.

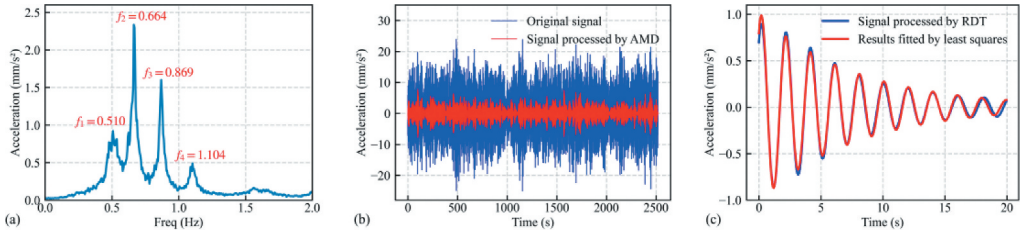

Figure 2. Process of modal parameter identification (a) Amplitude spectrum. (b) AMD processing. (c) RDT Processing and Fitting.

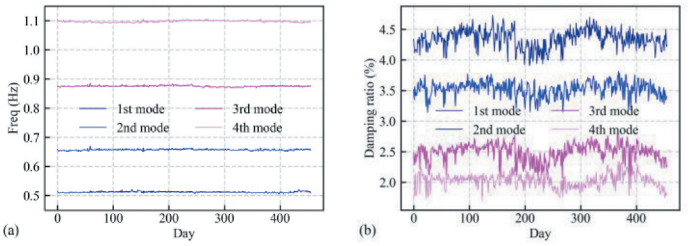

Figure 3. Daily identification results of the main girder modal parameters (a) Frequency. (b) Damping ratio.

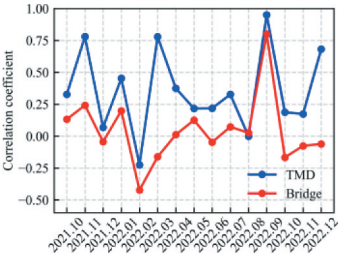

Figure 4. Correlation coefficients between acceleration and wind speed.

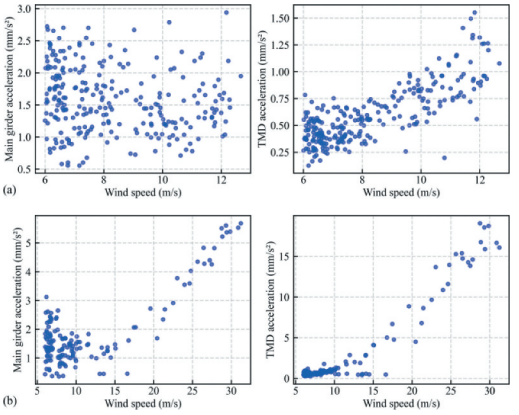

Figure 5. Acceleration against wind speed (a) 2022.03. (b) 2022.09.

For the main girder, the period with a significant correlation between wind speed and acceleration is only in September 2022 when wind speeds exceeded 15 m/s (Figure 5b). At other times, the correlation is not obvious. For the TMD, the correlation between wind speed and acceleration is more pronounced compared with the main girder. Even when the correlation between wind speed and main girder acceleration is weak, there is still a noticeable correlation between wind speed and TMD acceleration, as observed in March 2022 (Figure 5a).

The vibration of the main girder is significantly influenced by wind speed only when the wind speed is high (larger than 15 m/s). During such periods, vibrations of both the main girder and the TMD increase with the wind speed increasing. At ordinary wind speeds, the TMD vibration is significantly affected by wind speed, while the main girder vibration is less

affected. In other words, the vibration energy is transferred from the main girder to the TMD, thereby suppressing the wind-induced vibration of the main girder.

4 ON-SITE RANDOM VIBRATION TEST

4.1 *Test scheme*

An ambient vibration test was conducted on the upstream side of the main girder by sequentially locking or activating each TMD. The acceleration time history of the main girder and TMDs during this process was measured using the accelerometer of the health monitoring system. The test was started by locking the TMD one by one. Each time, only one TMD of a span was locked, and measurement was taken for 10 minutes before locking the next TMD of the next span. This process was repeated until all TMDs were locked. Subsequently, TMDs were activated span by span, with all four TMDs of an entire span being activated simultaneously. After activating TMDs of one span, measurement was taken for 20 minutes before activating TMDs of the next span. This process was repeated until all TMDs were activated.

4.2 *Overall bridge vibration analysis*

The acceleration time history of the main girder during the test process was processed using the complex Morlet wavelet transform to obtain a time-frequency diagram (Figure 6). With each TMD sequentially locked, the vibration energy corresponding to the first two vertical modes noticeably increased, while the energy of higher order vertical modes hardly varied. With TMDs of each span activated, the vibration energy of the first two vertical modes rapidly decreased, while the energy of higher order vertical modes remained almost unchanged. When all TMDs were active, the vibration energy was mainly concentrated in higher order vertical modes. After locking all TMDs, the vibration energy of each mode became similar.

Using the modal parameter identification method discussed in section 3.1, the damping ratio variation of each vertical mode of the main girder during the test process is presented in Figure 7. During the sequential locking of TMDs, the damping ratio of the main girder shows a decreasing trend. The most significant change is observed in the damping ratio of the first vertical mode, while the damping ratios of higher order modes remain relatively constant. In the process of sequentially activating TMDs, damping ratios of each mode gradually increase

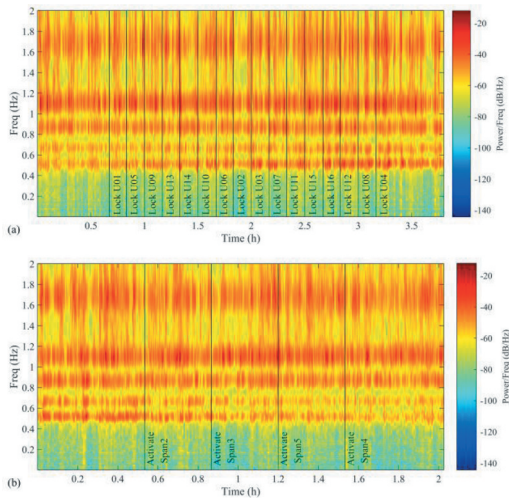

Figure 6. Time-frequency diagram of the main girder vibration during the test process (a) TMDs sequentially locked. (b) TMDs sequentially activated.

and eventually return to their initial values. Due to the uncertainty in the identification of the damping ratio, the damping ratio during the locking process does not monotonically decrease, and thus, these results are intended for qualitative analysis only.

The above results indicate that TMDs primarily suppress the first vertical mode vibration, with a weak control effect on higher order modes, which is consistent with the design principle. Additionally, even if half of TMDs are locked, the damping ratio of the first vertical mode remains higher than 1.15%, indicating that the bridge has a high level of safety redundancy.

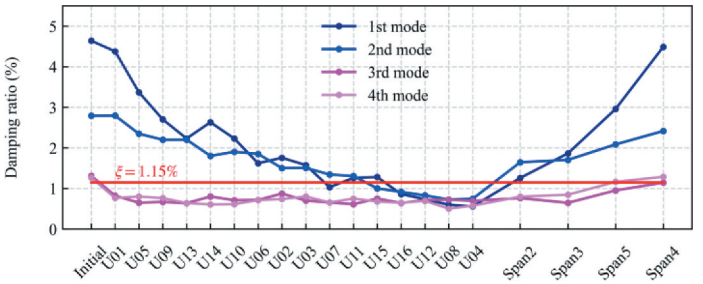

Figure 7. Variation in damping ratios of the main girder during the test process.

4.3 *TMD vibration analysis*

Taking TMD U01-U04 as examples, acceleration time history was obtained when all TMDs were activated and when all TMDs were locked. The acceleration signals were then low-pass filtered to extract vibration near the frequency of the first vertical mode of the bridge (Figure 8) When all TMDs were activated, the vibration amplitudes of U02-U04 were significantly larger than that of the main girder, and the phases of their vibrations delayed to approximately 90 degrees after the main girder. The vibration of U01 was close to that of the main girder, indicating that it did not exhibit effective vibration reduction. When all TMDs were locked, vibrations of TMDs were all close to the main girder vibration.

In order to quantitatively analyze the performance of TMDs, a new evaluation index is proposed. The vibration amplitude spectra of TMDs and the main girder (denoted as P_{TMD} and P_{girder}) in a same time period were calculated. The ratio of these two spectra was then obtained to eliminate the influence of differences in environmental excitations during different time periods, getting a dimensionless result. The maximum value of this ratio is denoted as η, as shown in Equation 1. η is used to measure the extent of energy transfer from the main girder to the TMD. A higher η value indicates a more efficient transfer of vibration energy, reflecting better working performance of the TMD.

$$\eta = \max\left(\frac{P_{TMD}}{P_{girder}}\right) \tag{1}$$

The calculation results of $P_{\mathrm{TMD}}/P_{\mathrm{girder}}$ of U01-U04 before and after being locked are shown in Figure 9. Before being locked, the vibration of the TMD was significantly larger than the main girder vibration ($\eta > 1$). After being locked, the TMD vibration became close to the main girder vibration, showing that they performed similar forced vibrations ($\eta \approx 1$). Before the lock of the TMD, η appeared at the frequency of about 0.5Hz, corresponding to the first vertical mode of the main girder, further proving that the TMD primarily absorbed the vibration energy of the first vertical mode. The η value of U01 is relatively small, suggesting that its working performance is not as effective as other TMDs.

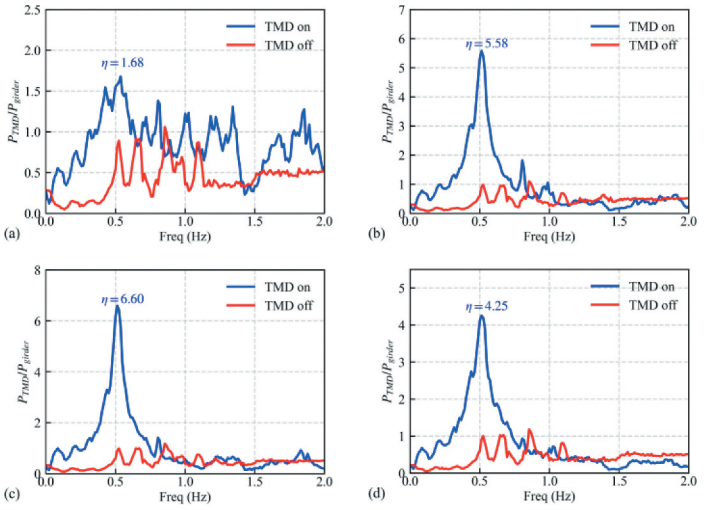

Figure 9. Vibration amplitude ratio of TMDs to the main girder (a) U01. (b) U02. (c) U03. (d) U04.

5 IDENTIFICATION OF TMD DYNAMIC CHARACTERISTICS

Dynamic characteristics of the TMD can be identified through free vibration test. In this process, an initial excitation is applied to the TMD, and the acceleration of the TMD during the free decay vibration is measured. The least squares method is then employed to identify the frequency and damping ratio of the TMD, and the principle is consistent with Figure 2(c). Generally, this measurement is performed using the accelerometers installed on the TMD. However, the acquirement and analysis of data from the monitoring system are not convenient. Therefore, a TMD dynamic characteristic identification app has been developed. This app is written by JavaScript, and can utilize the built-in accelerometer of the phone and identify the frequency and damping ratio.

16 TMDs on the upstream side were tested. The result obtained from the app is shown in Figure 10, demonstrating an acceleration resolution of 0.0001 m/s². The dynamic characteristics of TMDs are shown in Figure 11, frequencies are all around 0.5 Hz and damping ratios are within the range of 0.07 to 0.13 (considering a manufacturing error of 30%). This indicates that the dynamic characteristics of TMDs still meet the design requirement. Differences in TMD working performance analyzed in section 4.3 might be attributed to the installation error or other factors.

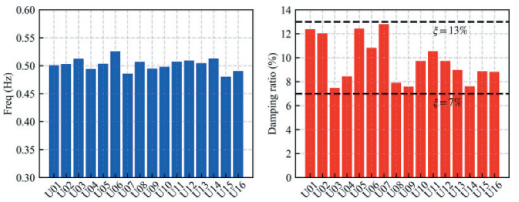

Figure 11. Dynamic characteristics of TMDs.

6 SUMMARY

This paper takes TMDs installed in the Chong Qi Bridge as a case study, and research findings of TMD evaluation are as follows.

1. Based on monitoring data, the frequencies and damping ratios of the main girder were identified by the AMD+RDT method. The damping ratios are significantly higher than the design requirement, indicating that TMDs provide a remarkable increasement in the damping ratio.
2. The wind-induced vibration responses of the main girder and TMDs were analyzed. The TMD vibration showed a stronger correlation with wind speed compared to that of the main girder, suggesting that TMDs convert the main girder vibration into their own vibration.
3. During the locking of TMDs in the on-site test, the vibration of the main girder increased, and the damping ratio decreased. The reduction in the damping ratio was most significant for the first vertical mode, showing that TMDs primarily reduce the first vertical mode vibration.
4. A quantitative evaluation index for TMD working performance was proposed. Taking TMD U01-U04 as examples, the analysis results showed significant changes in this index before and after TMD being locked, with U01 exhibiting poorer working performance compared to others.
5. Through the free vibration test, the inherent frequency and damping ratio of each TMD were measured by a self-developed app, and the results were within the design range.

This study conducted a comprehensive evaluation of TMDs in a continuous steel box girder. The methods employed can be applied to TMDs in other bridges, and provide recommendations for the routine inspection and maintenance based on the evaluation results of the TMD.

ABSTRACT: Evaluation of structural health via modal characteristics is effective when using regression methods such as machine learning. In certain instances, training data is generated through numerical analysis to ensure a robust dataset. However, this approach may lead to reduced model accuracy when applied to real-world structures, a result of overfitting due to discrepancies between input data in training and prediction. In this paper, to deal with thickness estimation in steel members using local vibration modes sensitive to damage, a model construction method using data augmentation is proposed to suppress overfitting. First, finite element analysis and experimental tests on a steel member are performed to assess the differences in modal characteristics between the training and prediction phases. The constructed thickness estimation model is then applied to actual measurement data, showing that the proposed method outperforms conventional models without data augmentation by over 40%.

1 INTRODUCTION

In recent years, the aging of infrastructure such as bridges and tunnels has become increasingly evident. Regular health assessments of these structures are essential. Traditional inspection methods often involve manual tasks such as visual inspection and hammer testing. However, these methods can pose safety risks during high-altitude inspection. For structures in operation, constraints on inspection times require operational efficiency. In these cases, the identification of sensitive natural modes related to structural defects through non-contact vibration measurement techniques, such as laser Doppler Vibrometers (LDVs) and accelerometers, has proven to be effective.

Conversely, methods that utilize regression techniques, such as machine learning, have been proposed to identify structural defects by analyzing natural modes acquired through non-contact measurements (Lee et al. 2021). Ogawa et al. (2023) developed a method that uses vibration data to evaluate the thickness reduction and the location of defects in steel members. This approach employs machine learning and leverages natural frequencies and mode shapes, which are collectively referred to as mode characteristics. Although obtaining empirical data for training is ideal, it presents a significant challenge due to the high costs of measuring civil structures such as bridges. Hence, simplified numerical analyses are often employed to generate training data.

However, in real-world structures, factors such as boundary conditions, thickness distribution, axial force variations, and mode identification methods often diverge from those in the simplified numerical analysis models used to create training data. Ignoring such differences may lead to overfitting and diminish the predictive accuracy of machine learning models when

DOI: 10.1201/9781003483755-424

they are applied to measured data obtained from actual structures. Consequently, this study proposes a method to enhance the accuracy of a machine learning model that estimates the thickness of steel members using characteristics of local vibration modes. This method quantitatively evaluates the differences between mode characteristics derived from actual structure measurements and those used in the training data. Furthermore, the study proposes a model construction approach that incorporates data augmentation to improve accuracy.

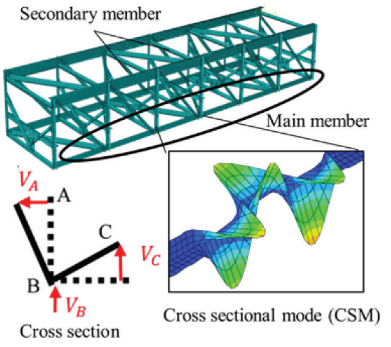

Figure 1. Cross sectional mode (CSM).

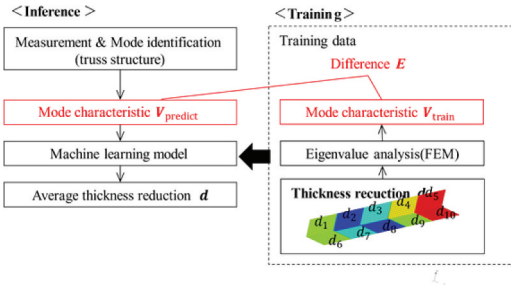

Figure 2. Overview of the thickness estimation method.

2 OVERVIEW OF THICKNESS ESTIMATION METHOD

In this study, we demonstrate the application of the model construction method on thickness estimation of an angle steel member, which is the main member of belt conveyor support structures in industrial facilities. The authors have previously investigated methods for extracting specific local vibration modes, such as cross sectional modes (CSM), which are highly sensitive to thickness reduction (Figure 1). A discriminative indicator, the CSM index (CSMI), has been proposed to characterize the cross-sectional features of CSM. Using CSMI, 1st, 2nd, and 3rd target modes are extracted from modal analysis on FEA or measurement data.

Then, a machine learning model is constructed based on the thickness estimation method shown in Figure 2. This allows the estimation of the thickness reduction rate (d) with the mode characteristics (V) as input. The definitions of V and d are as follows:

$$\boldsymbol{V} = \left(f_1, f_2, f_3, \boldsymbol{\phi}_1, \boldsymbol{\phi}_2, \boldsymbol{\phi}_3\right) \tag{1}$$

$$\boldsymbol{d} = (d_1, d_2, d_3, d_4, d_5, d_6, d_7, d_8, d_9, d_{10}) \tag{2}$$

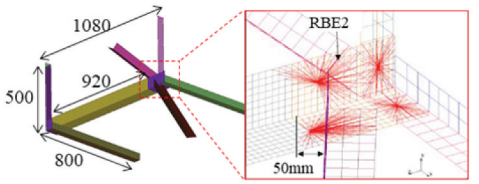
Here, f_i and $\boldsymbol{\phi}_i$ (i =1, 2, 3) represent the natural frequency and mode shape of mode order i, respectively. The average thickness reduction rate of the 10-sectioned angle steel member, denoted as d_{sec} (sec=1,2...10), is also included. The components of $\boldsymbol{\phi}_i$ are normalized to values between 0 and 1 by dividing them by the maximum value at all output points.

3 PROPOSED METHOD FOR MACHINE LERANING MODEL CONSTRUCTION

3.1 *Measurement and analysis condition*

The difference $\boldsymbol{E}$ is defined by the following equation:

$$\boldsymbol{E} = \boldsymbol{V}_{\text{predict}} - \boldsymbol{V}_{\text{train}} \tag{3}$$



Where $\boldsymbol{V}_{\text{train}}$ denotes the mode characteristics in the training data, and $\boldsymbol{V}_{\text{predict}}$ denotes the mode characteristics during inference obtained through measurements on real-world structures. The study focuses on four factors listed in Table 1 and evaluates the differences $\boldsymbol{E}_k$(k=1,

2, 3, 4) based on numerical analysis or measurement tests that reproduce the conditions in training and inference. Subsequently, these differences are quantitatively assessed using Equation 3. The following sections describe the meanings of $\boldsymbol{E}_k$ and the conditions for numerical analysis and measurement tests used for their evaluation.

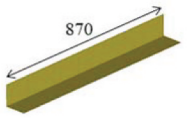


Table 1. Evaluation condition of differences.

Type and cause of difference	Target	Specimen: Number of cases	Specimen: Dimension (mm)	Boundary condition *1	Thickness reduction *2	Axial force (N/mm^2)	Method
E_1 Boundary condition	$V_{predict}$ V_{train}	20	L90*90*870*6	Structure Single	Real	—	FEA
E_2 Thickness distribution	$V_{predict}$ V_{train}	20	L90*90*870*6	Single	Real Uniform	—	FEA
E_3 Axial force variation	$V_{predict}$ V_{train}	2	L65*65*1400*6	Single	Real	26 21	Measurement
E_4 Mode estimation method	$V_{predict}$ V_{train}	6	L65*65*1400*6	Single	Real/ Uniform	—	Measurement FEA

*1 Structure – structure model including secondary member
Single – single-member model
*2 Real – continuous thickness distribution in real corrosion condition
Uniform – uniform thickness distribution at each of the 10 sections

Element type	4 nodes shell element
Mesh size	10mm
Young's modulus (GPa)	205
Poisson ratio	0.3
Density (kg/m^3)	7850

a) **Difference based on boundary condition E_1**

In the method, a single-member model is employed to generate training data where both ends of the member are completely fixed. However, in actual structures, the main member is constrained by multiple secondary members. Although CSM exhibits characteristics localized to a single member, the difference E_1 arises due to the difference in boundary conditions. To evaluate this, a structural model that includes secondary members, reproducing the boundary conditions in the structure, is used to calculate E_1, along with the single-member model used for training data.

The thickness cases in the analysis model are based on the thickness distribution measurement results from 20 test specimens. These specimens were sourced from angle steel members, including thickness reduction due to corrosion, taken from the lower chord, web, and

diagonal members of belt conveyor supports that have been exposed to outdoor conditions for approximately 40 years.

For the modeling process, the finite element analysis software MSC MARC 2021.3 was used to create the single-member model and a structural model, as depicted in Figure 3. Eigenvalue analysis was then performed to calculate $\boldsymbol{V}$. The dimensions of the models were set to correspond to the member within the actual structure (90*90*1080*6 mm). Detailed settings for both models are outlined in Table 2.

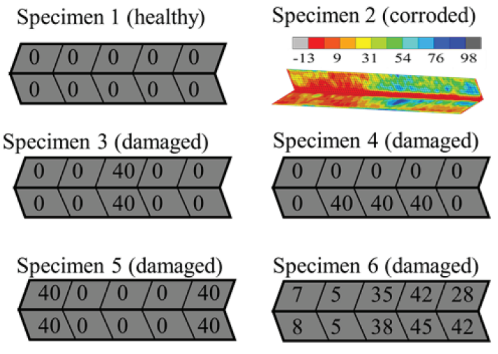
b) **Difference due to thickness distribution $\boldsymbol{E}_2$**

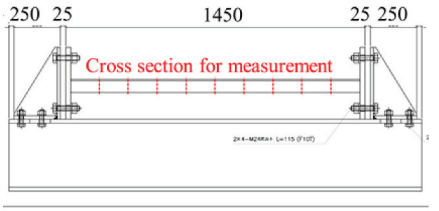
Although in real-world corroded members, thickness spatial distribution is continuous, in generating training data a uniform thickness was assigned to each of the ten sections. However, the uniform thickness diverges from the continuous thickness variation in corroded members, leading to difference $\boldsymbol{E}_2$. To address this, we use the analysis results from a scenario where the thickness of actual corroded members is set using a single-member model, referred to as the actual corrosion model, and another where the average thickness is uniformly set within a section, referred to as the uniform corrosion model. $\boldsymbol{E}_2$ is calculated using Equation 3. In this context, both models are identical to the single-member model constructed in a), with the only difference being the method of setting the thickness.

c) **Difference due to axial force $\boldsymbol{E}_3$**

In structures currently in service, axial forces vary depending on the external force and the location of the member, leading to fluctuations in mode characteristics (Bokaian, 1990). However, the mode characteristics in the training data do not consider the influence of axial forces, resulting in the existence of difference $\boldsymbol{E}_3$. To evaluate $\boldsymbol{E}_3$, a measurement test was conducted on two steel members (both L65*65*1400*6mm) with artificially induced axial force variations; one of these members represents an intact member (Test Specimen 1), and the other represents an actual corroded member cut from a belt conveyor steel frame (Test Specimen 2). The specimens were securely fixed at both ends using a base plate with bolt holes welded to both ends of the member. Tensile forces were introduced to a maximum force of N_{max} =20 kN and a minimum force of N_{min} =16 kN. In this study, N_{min} was assumed for the learning condition, and N_{max} was assumed for the inference condition.

Vibration was excited by hammering the members, and the response was measured using two laser Doppler vibrometers (LDVs) from Polytech (RSV-150/PDV-100). The Eigensystem realization algorithm (ERA) (Juang and Pappa, 1985) was employed to calculate the mode shapes and natural frequencies. This method involved peak picking on the power spectrum to identify mode candidates, and the mode with the closest natural frequency to the identified candidate was selected as the CSM for each mode order.





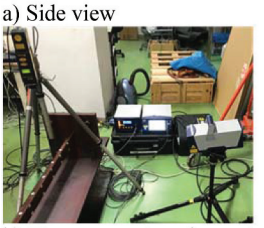


Figure 4. Specimens.

a) Side view

b) Measurement equipment

Figure 5. Measurement settings.

d) **Difference due to mode estimation errors $\boldsymbol{E}_4$**

The inference input $\boldsymbol{V}_{\text{predict}}$ for the real-world structure is derived from raw data obtained from the LDVs. This raw data is processed using fast Fourier transform (FFT), peak picking, and the ERA to extract vibration mode candidates. However, this process is subject to errors, such as temperature and humidity conditions affecting the LDVs, mechanical errors, sampling errors, and inaccuracies in the analysis method used for CSM identification. The training data $\boldsymbol{V}_{\text{train}}$ is obtained from the finite element model through eigenvalue analysis, followed by the extraction of vibration mode candidates and CSM identification using discriminative indicators. However, errors not considered in a)–c) may be present. Modeling and reproduction errors arise from settings in the FE model, such as mesh size and mechanical properties.

To evaluate the difference $\boldsymbol{E}_4$ resulting from errors in $\boldsymbol{V}_{\text{predict}}$ and $\boldsymbol{V}_{\text{train}}$, a measurement test was conducted on single-member specimens and a corresponding analytical model. Six specimens were considered, including the specimens used in c) (Specimens 1 and 2) and additional specimens (Specimens 3, 4, 5, 6) with artificial degradation using a grinder. The corrosion for each specimen is shown in Figure 4. The measurement setting was the same as in c). The thickness setting for FE model was determined by the measured average thickness of the specimens. The analytical model, with the same boundary conditions as in a), was reconstructed to match the dimensions of the target specimen (L65*65*1400*6mm).

3.2 *Evaluation of differences*

When the differences E_k for all test specimens and cross-sections follow a probability density function ($p(E_k)$), the probability density function $p(E)$ for the differences E caused by multiple factors can be expressed as follows:

$$p(E) = \sum\nolimits_k p(E_k) \tag{4}$$

For simplicity, assuming that each considered factor is independent, the components of the mean μ_j and standard deviation σ_j of E can be expressed using the mean $\mu_{k,j}$ and standard deviation $\sigma_{k,j}$ components of E_k as follows:

$$\mu_j = \sum\nolimits_k \mu_{k,j} (j = 1, 2, , , 3 + 3m) \tag{5}$$

$$\sigma_j = \sqrt{\sum\nolimits_k \sigma_{k,j}^2} \, (j = 1, 2, , , 3 + 3m) \tag{6}$$

Here, j ranges from 1 to $j = 1, 2 \ldots 3 + 3m$, where m is the dimensionality of the mode shape $\boldsymbol{\phi}_i$, i.e., the number of output points of the mode shape. In this study, five cross-sections along the member axis with points A, B, C were considered (m =3*5=15).

3.3 *Generation of training data*

Finite element (FE) models are created for individual steel members, following the specifications of the target structures. A uniform thickness is assigned to ten sections of each member, aligning with the specified dimensions.

A training dataset is generated by simulating mode characteristics for the assigned thickness patterns using the FE models. The differences $\boldsymbol{E}$ are calculated for the generated training data using the approach outlined in Section 3.1. Data augmentation is applied to $\boldsymbol{V}_{\text{train}}$ by introducing random noise, which conforms to a normal distribution, to each component ($j = 1, 2, , , 3 + 3m$) of the differences $\boldsymbol{E}$. This noise enriches the training dataset with instances that reflect the influence of differences $\boldsymbol{E}$, thereby contributing to enhanced generalization and mitigating overfitting during model training.

3.4 *Construction of machine learning model*

For comparison, two machine learning models, light gradient-boosting machine (LightGBM) (Ke et al., 2017) and neural network (NN), were evaluated. LightGBM, a variant of the gradient boosting decision tree (GBDT), is known for efficiently providing high-accuracy solutions based on decision trees. NNs, by contrast, use a structure comprising an input layer, an output layer, and several intermediate layers to represent input–output relationships by adjusting coefficients between nodes, thereby minimizing error. For the NN, a relatively simple configuration with only two intermediate layers was chosen, given that the input vector $\boldsymbol{V}$ comprises 48 components and the output vector $\boldsymbol{d}$ has 10 components. The ReLU activation function was utilized in this setup. Both machine learning methods were subject to hyperparameter tuning using the augmented dataset, aiming to minimize the risk of overfitting.

4 VALIDATION OF THE PROPOSED METHOD WITH A MEASUREMENT TEST

4.1 *Results of the difference evaluation*

Based on the condition mentioned in Section 3, the difference values were evaluated (Table 3). An example of the mode shape is shown in Figure 6. When $\boldsymbol{E}_{all}$ is the difference when considering all four factors mentioned above, the statistics, $\mu_{all,j}, \sigma_{all,j}$ (j=1, 2. . . 9), were calculated by Equations 5 and 6. The analysis of the standard deviation reveals that the natural frequency consistently varied by 4–5%, irrespective of the mode order. Conversely, the variations in the mode shape showed an increasing trend with the mode order, registering 6–9% for the 1st mode, 7–16% for the 2nd mode, and 15–28% for the 3rd mode. Additionally, the standard deviation of the mode shape was consistently larger than that of the natural frequency across all factors considered; this difference in standard deviation was more pronounced in the higher order modes.

In the following discussions, the mean values of the differences are $\mu_{k,j} = \mu_{all,j}$=0 (j=1, 2. . .9, k=1, 2, 3, 4) for the sake of simplicity, and the effect of the magnitude of the standard deviation on the estimation accuracy of the machine learning model is evaluated.

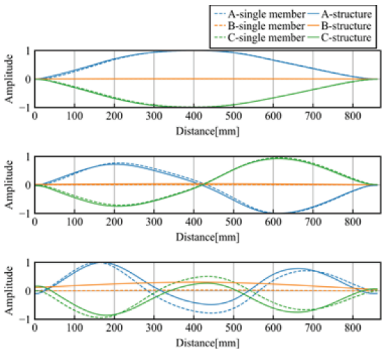

Figure 6. Example of a mode shape.

	Std.	4.5	4.3	4.3	8.5	6.5	15.6	7.8	27.2	15.8

4.2 *Generation of training data*

This section discusses the thickness estimation based on mode characteristics derived from actual measurement tests. For the generation of training data, the FE model from Section 3, which was adapted to match the dimensions of the test specimen, was used. This model

comprises 10 sections, each with a specific thickness pattern. Eigenvalue analysis was conducted for 300,000 combinations of random thickness patterns, with the values ranging within -10–90 %.

The differences incorporated in data augmentation are also examined. Mode characteristics from the six test specimens, as described in Section 3.1 under the measurement conditions excluding axial forces, constitute the input data for the model. Due to the fixation of these test specimens at both ends using a base plate, the boundary conditions are equivalent to those in the single-member model. The thickness distribution for test specimen 2 is based on actual corrosion conditions, whereas for test specimens 1 and 3–6, it follows simplified corrosion scenarios.

Consequently, it is assumed that for test specimens 1 and 3–6, considering only $\boldsymbol{E}_4$, and for test specimen 2, considering both $\boldsymbol{E}_2$ and $\boldsymbol{E}_4$, the value of $\bar{R}$ would be minimized. Specifically, $\bar{R}$ is defined as difference indicator that exists in inference, assuming the presence of random Gaussian noises with standard deviations $R_{T,j}, R_{V,j}$ in the training and inference data, respectively.

$$\bar{R} = \sqrt{\frac{\sum_{j=1}^{3+3m} \left(R_{V,j} - R_{T,j}\right)^2}{3+3m}} \tag{7}$$

When the value of $\bar{R}$ is small, it implies that the noise levels are the same in training and inference data, leading to a higher expected estimation accuracy. For comparative verification, three data augmentation patterns incorporating $\boldsymbol{E}_2$ and $\boldsymbol{E}_4$ are evaluated as described in Table 4.

4.3 *Comparison of the estimation result*

Figure 7 Shows the thickness estimation error of all sections of each specimen based on the following metric.

$$MAE = \frac{1}{10}\sum_{sec=1}^{10} \left(\widehat{d_{sec,n}} - d_{sec,n}\right) * 100 \tag{8}$$

Figure 8 Shows the estimated thickness reduction rate for each section of all the specimens, and Table 5 shows the thickness estimation error S (%) for all specimens and the improvement rate of the estimation error (%) based on case T0-Vm. The root mean square error (RMSE) of the estimate of d for all verification data N is calculated, and the thickness estimation accuracy is evaluated by the following estimation error S (%), considered by averaging 10 sections.

$$S = \frac{1}{10}\sum_{sec=1}^{10} \sqrt{\frac{\sum_{n=1}^{N} \left(\widehat{d_{sec,n}} - d_{sec,n}\right)^2}{N}} * 100 \tag{9}$$

In particular, the estimation error was minimized in Tp1-Vm regardless of the machine learning method, and the reduction rate was 40% or more when compared to the results by conventional method. This is attributed to the data augmentation pattern Tp1-Vm being suitable for all specimens except Specimen 2, indicating that it was the prevailing condition among the target specimens.

On the contrary, while Tp2-Vm was anticipated to be most suitable for Specimen 2, the smallest estimation error was observed in Tp1-Vm. This is because, despite the local thickness reduction in Specimen 2, its spatial thickness variation is not significant. Consequently, Tp2-Vm, which does not account for the difference due to thickness distribution E_4, most accurately represents the condition of Specimen 2.

Although there are exceptions, for 4 out of 6 specimens (specimens 1, 2, 3, and 5), the highest model estimation accuracy was achieved when the data was augmented in a way that minimized $\bar{R}$. This approach, involving the augmentation of training data to align the noise

variance of the training condition with that of the inference condition, has proven effective in constructing a model with a reduced risk of overfitting to the training data.

5 CONCLUSION

In a machine learning model that estimates the thickness of a member from local vibration mode characteristics, the difference between mode characteristics during training and inference is first quantified. Subsequently, the estimation accuracy of the model is compared when data augmentation, based on these evaluated differences, is implemented. Finally, a model is constructed using the augmented training data, considering the differences anticipated in the measurement test of a single-member test, and its estimation accuracy is verified. The findings of this study are summarized below.

1) The estimation error of the thickness estimation model is minimized when the training data is augmented such that the noise levels in both the training and inference data are approximately equal.

2) The discrepancy in mode characteristics, which serve as the input data for the machine learning model, between the training and inference data is found to be around 4–5% for the natural frequency, irrespective of the mode order. However, for the mode shape, it is evaluated to be 6–9% for 1st order modes, 7–16% for 2nd order modes, and 15–28% for 3rd order modes.

The results of this study suggest that the estimation accuracy of the model can be greatly improved by applying data augmentation to the training data according to the expected difference between the input data in inference and training.

ABSTRACT: This study examined the applicability of vibration measurement using a lightweight and compact automatic impactor and anomaly detection using machine learning as methods of simple and time-efficient non-destructive testing to evaluate damages in RC-members. In the experimental study, three RC beam specimens of different dimensions were made without stirrups to shear failure, and loading tests were conducted on each specimen. The training data for machine learning was collected before and after the loading tests, respectively, using an automatic impactor. Based on the vibration information obtained, a machine learning model was constructed using the data set and the autoencoder. The results showed that the anomaly values were larger in areas with shear cracks and wider crack widths, indicating the possibility of detecting shear cracks that are structurally significant with these methods of no-destructive testing.

1 INTRODUCTION

Infrastructure in Japan is aging rapidly. In addition, infrastructure requires early inspection in the event of earthquakes and other disasters. Therefore, it is desirable to improve the efficiency, sophistication, and automation of inspections of concrete structures.

Various non-destructive inspection methods have been proposed for concrete structures. For example, Chia-Chi et al. (2008) showed the possibility of combining active infrared thermography (IRT) and elastic wave technology to inspect the appearance of concrete structures effectively and efficiently. Murakawa et al. (2022) showed the potential of using portable vibration machines, laser vibrometers, and machine learning for nondestructive inspection of concrete structures. However, the previous methods require time and effort to collect the training data needed for machine learning. In previous studies, damage assessment methods have relied on modal parameters such as resonance frequency. Therefore, it is strongly desired to establish a method that is simple, and quick, but accurate, and capable of detecting structurally significant defects.

In this study, experiments were conducted using an automatic impact device. This device can strike the surface of a structure four times per second with the same force, and by mounting a sensor inside the device, the response acceleration of the structure's surface due to hammering can be measured. In this study, we attempted to diagnose the integrity of three RC beam specimens with different dimensions that had induced shear cracks, which are safety-critical damages to the structure, by utilizing the impact inspection device and machine learning.

DOI: 10.1201/9781003483755-425

2 EXPERIMENT PROGRAM

2.1 *Loading test*

A schematic of the RC beam specimens is shown in Figure 1-3. The test piece dimensions are shown in the figure, and the three specimens were designed to fail in shear. The compressive strength of the concrete with the test pieces is 28.9 MPa, the sound speed within concrete is c=3,780 m/s, and the mass density is 2,290 kg/m^3. Tensile test results for deformed steel bars are shown in Table 1. Loading conditions are shown in Figure 1~3. There are three different specimen sizes, which will be referred to as LS, MS, and SS specimens in order of increasing specimen height. RC beam specimens were supported on steel fulcrums and a vertical load in one direction was applied at the center of the span. In the specimens, the vertical load was removed when the shear crack occurred. With the specimen unloaded, a crack diagram of the specimen side-face was made, and the crack width was measured using a crack scale. Note that since this experiment was designed to investigate damage to the structure after an earthquake, cracks were observed only when the load was removed.

2.2 *Vibration test*

In this study, to evaluate the damage of a concrete beam specimen subjected to cracking, impacts were applied to the surface of the structure to measure the response acceleration near the point of impact. Measurements were taken using the mobile automatic impact device shown in Figure 4. This impact inspection device is an integrated unit consisting of an automatic hammer that strikes continuously at a rate of four blows per second and a magneto strictive sensor that detects elastic waves at 50 mm. When measuring, the red arrow in the Figure 4 is pushed against the structure, and when the wheel with the sensor attached adheres to the structure, the hammering begins. The hammer is a suction-accelerated electromagnetic impact hammer with a mass of 480 g. It can strike with a constant force regardless of the direction of impact.

In this study, this hammering device was moved against the test specimen as shown in Figure 4, and measurements were taken. This device strikes the test specimen about 8 to 10 times at each measuring point, and when it was finished, it moved to the next measuring point, stopping at each measuring point on the measuring line. The measuring line was set in the middle of the longitudinal direction, and the edge of the beam was about the height of the cross section in the horizontal direction from the edge of the beam. For example, in the case of the SS specimen, the first measuring point was 350 mm from the east end of the specimen, and from there 18 measuring points were set at 100 mm intervals up to 2,050 mm. Similarly, 22 points were set for the MS specimen and 26 points for the LS specimen. The same measuring line was measured 5 times before loading as training data and once after loading as test data.

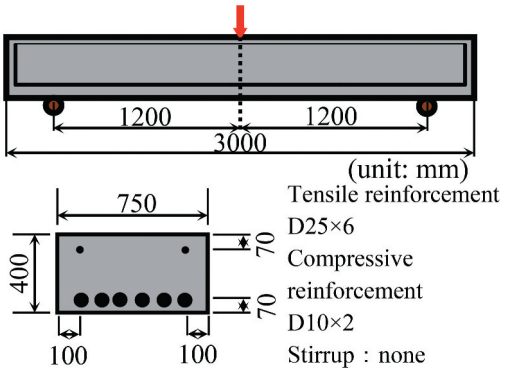

Figure 2. MS test specimen specifications.

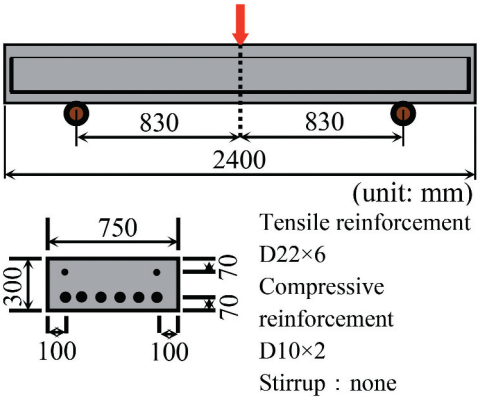

Figure 3. SS test specimen specifications.

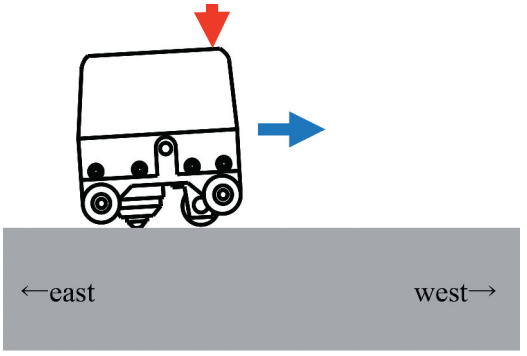

Figure 4. Automatic impact inspection device and how to operate.

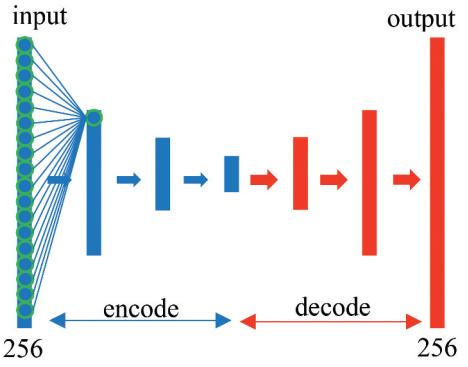

Figure 5. Autoencoder conceptual diagram.

In this study, acceleration waveforms recorded at a sampling frequency of 50 kHz were (1) cut into waveforms, (2) Fourier analyzed, and (3) sampled (training data only). (1) For a continuous acceleration waveform, the waveform was recorded for 0.1 s after the threshold value was exceeded, and after 0.1 s had elapsed, the wave was cut out of the continuous waveform to record the wave if the threshold value was exceeded again. The 0.1s was set to be an appropriate value between 0.01s, which is necessary for waveform analysis and the hammering interval of 0.25s. (2) Fast Fourier transform of 512 plots was performed. (3) In handling the machine, tapping miss occurs when pushing in and releasing. In creating the data set for training, we considered that using this data as is would result in the creation of a poor-quality data set, which may result in decreasing accuracy of anomaly detection, so we performed sampling by attaching conditions to the frequency response function obtained up to (2) above. The conditions were such that, for example, in the training data set for the MS specimen, amplitude values between 10,200 and 25,000 Hz that exceeded 0.05 when normalized by the maximum amplitude value, amplitude values between 3,420 and 4,200 Hz that similarly exceeded 0.3, and amplitude values between 1,950 and 3,220 Hz that similarly exceeded 0.05 were deleted. To eliminate any possibility of arbitrary conditioning in the creation of the data set for testing, the work described in (3) was not performed. Therefore, although the anomaly levels periodically increased, this method was adopted because there was no issue in observing the trend of the anomaly levels.

In this study, frequency response functions (256 parameters) with a resolution of 97.7 Hz from 0 to 25,000 Hz were provided as training data (1-dimensional data) for the machine learning described below.

3 MACHINE LEARNING

In this study, anomaly detection was performed using an autoencoder, a mathematical model of a neural network shown in Figure 5. The autoencoder consists of two elements, the encoding, and the decoding part, where the former compresses the nodes and the latter is the reverse of the former, where the nodes once compressed in the encoding part are returned to the input dimension. In this study, only the sound data before loading is given as training data for machine learning. Therefore, in the training phase of machine learning, we optimize the weights between layers for proper compression and reconstruction of the intact data. In the test phase, the test data is given as a mixture of both intact and defective data, but the input data and the reconstructed data are close to each other because the intact data has learned how to be compressed and reconstructed well in the learning phase. On the other hand, the defect data is unknown to the machine learning model, which has learned only the intact data, and does not know how to compress and reconstruct it. As a result, the reconstruction error, which is the difference between the input data and the reconstructed data calculated through compression, is larger than that of the intact data. By focusing on this feature and defining the degree of anomaly based on the absolute reconstruction error, it is possible to identify the location of defects.

In this study, the frequency response function has 256 parameters, so the number of nodes was set to the same 256. In the encoding section, the nodes were reduced by 1/2 in dimensionality, to 1/64 for the LS and MS specimens, and to 1/8 for the SS specimen. In the decoding section, the reverse of the encoding section was performed, and finally all the nodes were reconstructed to 256, the same dimension as the input. The optimization algorithm used for training was Adam, the activation function was ReLU for the hidden layer and ELU for the output layer, and the learning rate was set to 0.001 until epoch 40 and 0.0001 after epoch 40. The mini batch was set to 4, the loss function was sufficiently lowered to settle down and no over-learning occurred, and the epoch was set to 60.

The anomaly is based on the reconstruction error, which is the difference between the input and reconstructed data and was calculated using the following process. Since the frequency response function has steep multimodal characteristics, even a slight shift in the peak of the input data and the reconstructed data can result in a large reconstruction error. Therefore, a moving average was calculated over a five-parameter range to smooth the peaks of the frequency response function. The absolute reconstruction error was calculated for the input and reconstructed data processed in this way, and the anomaly was defined as the anomaly divided by the reconstruction area.

4 EXPERIMENTAL RESULTS

The load-displacement relationships for the three shear specimens are shown in Figure 6. Crack diagrams for each specimen are shown in Figure 7-9, and crack width distribution diagrams in Figure 10-12. Examples of vibration test results for each specimen are shown in Figure 13-15.

Shear cracking is serious damage that should be noted during post-earthquake emergency inspections because of the loss of load-bearing capacity of the member. In this experiment, the shear failure was designed to occur due to diagonal cracking without stirrups. In loading tests, diagonal cracks with angles of about 30-45 degrees were generated as designed. The purpose of this study is to efficiently investigate diagonal cracks that cannot be visually confirmed from the top surface of structures.

For the LS specimens, when the loading stage was 1du, no significant shear cracks were observed when looking at the specimens from the north, but when looking at the specimens

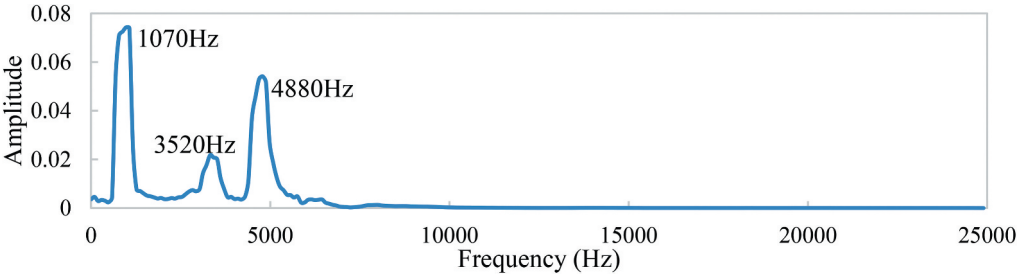

Figure 13. Frequency response function before LS specimen loading.

from the south, shear cracks were observed on the east side of the specimens (around 800 mm to 1,450 mm from the east end). The shear crack width was the largest on the east side viewed from the south side, with a maximum crack width of 0.3 mm. Flexural cracks were also observed in the center of the beam, although the crack width was not as large as the shear crack width. As for the resonance frequencies, before loading, peaks were mainly observed at 1,070 Hz, 3,520 Hz, and 4,880 Hz, as shown in Figure 13. On the other hand, the resonance frequency f_0 calculated by a simple calculation ignoring the steel bars is given by $f_0 = c/(2H)$, and $f_0 = 3780Hz$ is obtained by substituting the member thickness $H = 0.5m$ and the speed of sound within concrete $c = 3780m/s$. As a result, among the three peaks observed, a certain degree of validity was confirmed for 3,520 Hz.

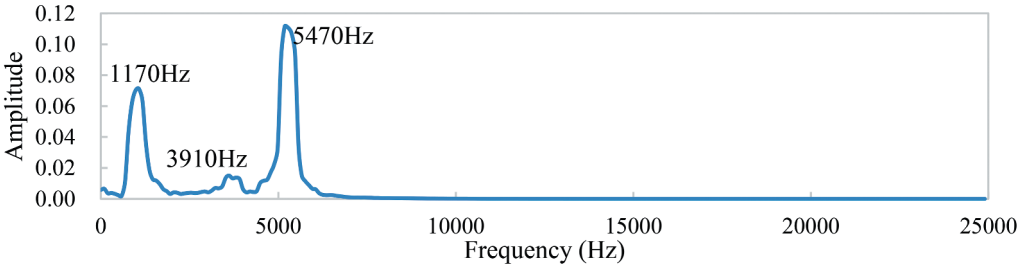

Figure 14. Frequency response function before MS specimen loading.

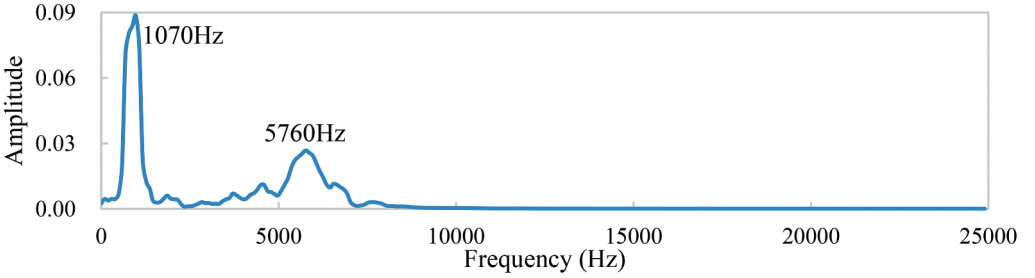

Figure 15. Frequency response function before SS specimen loading.

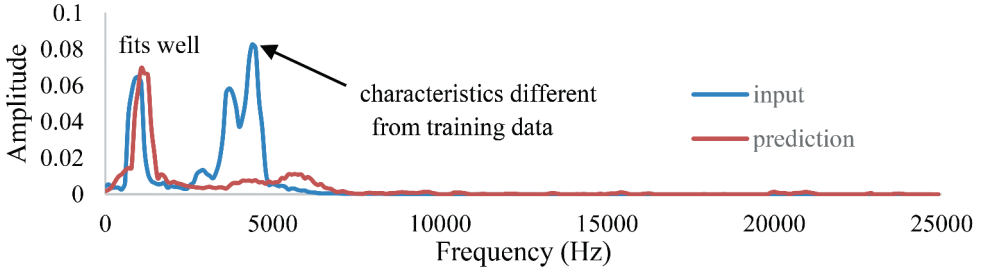

Figure 16. Comparison of input and reconstruction(prediction) data at SS specimen defects (1,450mm from east end of specimen).

As for the MS specimen, the crack diagram shows shear cracks on the east side of the specimen (700mm~1,500mm from the east end) when the loading stage was 1du and the specimen was viewed from the north side. The shear crack width was the widest on the east side viewed from the north side, with a maximum crack width of 0.65 mm. A single flexural crack was observed on the west side about 200 mm from the center of

the beam. As for the resonance frequencies, before loading, peaks were mainly observed at 1,170 Hz, 3,910 Hz, and 5,470 Hz, as shown in Figure 14. Using the same simple equation as before and substituting the member thickness $H = 0.4m$, $f_0 = 4725Hz$ was obtained.

The crack diagram of the SS specimen shows that when the loading stage was 1du, shear cracks could be observed on the east side (370mm~1,200mm from the east end) when the specimen was viewed from the north side. As for the crack width, the shear crack on the west side was wider than the shear crack on the east side by 200 mm from the center of the beam to the west, and the maximum crack width was 0.5 mm. As for the resonance frequency, before loading, peaks were observed mainly at 1,070 Hz and 5,760 Hz, as shown in Figure 15. Using the same simple equation as before and substituting the member thickness $H = 0.3m$, $f_0 = 6300Hz$ was obtained, which corresponds to the experimental value of 5,760Hz.

For all the specimens, the peaks appeared around 1,070 and 1,170 Hz, which are far from the resonance frequency values calculated from the simplified formula, but since the peaks appear in the data after loading as well, it is assumed that they are caused by the characteristics of the striking device and sensor rather than the vibration characteristics of the specimens. The peak was also observed in the post-loading data.

5 ANOMALY DETECTION RESULTS

This study attempts to extract features from the frequency response function using machine learning. In this experiment, training data for machine learning was collected for the specimens before loading. A trained model was constructed based on the training data set for each specimen. The frequency response functions collected after loading were inputted into the constructed model as test data, and the degree of anomaly was calculated. Figure 16 shows a comparison of the input data and the reconstructed data calculated through machine learning. From the figure, it can be seen that the training data for the SS specimen could not cope with the peak around 4,000 Hz, which was not characterized in the training data, resulting in a larger error.

The anomaly distributions of the three shear specimens along the axial direction are shown in Figure 17-19. Diagonal cracks largely block vertical excitation, making it relatively easy to detect anomalies.

For the LS specimen, the anomaly distribution is shown in Figure 17. Compared to the crack distribution in Figure 7 and the crack distribution width diagram in Figure 10, it can be seen that the anomaly values are larger at the defective points with shear cracks on the east side. The anomaly value is also larger for the flexural crack in the center of the beam. The crack width is not particularly large compared to other flexural cracks, but it is confirmed at almost the same location from the north and south viewpoints, which is assumed to be because the crack penetrates in the north-south direction and is surely located directly below the measuring line.

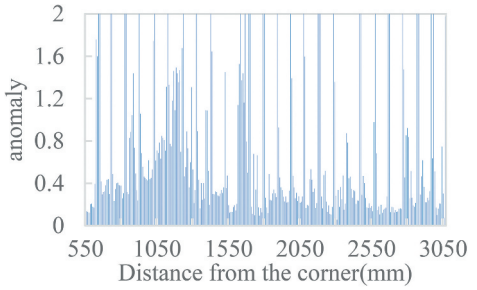

Figure 17. Anomaly distribution of LS specimen.

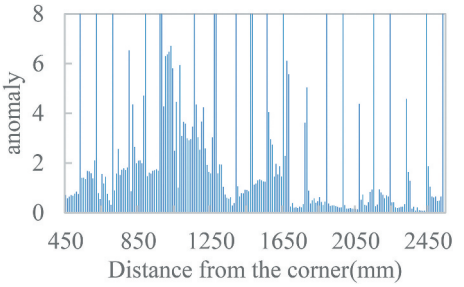

Figure 18. Anomaly distribution of MS specimen.

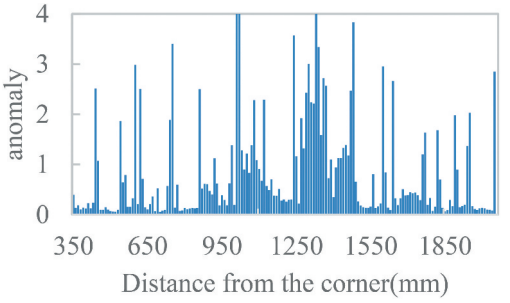

Figure 19. Anomaly distribution of SS specimen.

For the MS specimen, the distribution of anomalies is shown in Figure 18. Compared to the crack distribution in Figure 8 and the crack width distribution in Figure 11, the shear cracks on the east side have larger anomaly values. Among the shear cracks, the tendency for the anomaly values to increase at the locations with large crack widths can be seen from the distribution of anomaly values and crack widths. It can also be seen that the anomaly values are lower on the west side of the specimen where no cracks were observed.

For the SS specimen, the distribution of anomalies is shown in Figure 19. The location of shear cracks in the crack distribution in Figure 9 and the distribution of anomalies are not well matched. For the LS and MS specimens, the shear cracks had the widest crack widths, and the anomaly severity was also larger. However, the shear crack widths of the SS specimens were not particularly large compared to the other cracks, and in this respect, the SS specimens appeared different from the LS and MS specimens.

From the above results for the three types, the anomaly tended to be larger at shear cracks that could be structurally significant defects. Comparison of Figures 10-12 and 17-19 also shows that the degree of anomaly tends to increase with the crack width. These characteristics may be attributed to the following two reasons. 1) Diagonal cracks will block wave propagation more than vertical cracks that are parallel to the elastic wave 2) The larger the crack width, the less interlocking contact between the aggregate, thus interrupting the propagation of the elastic wave. For these two reasons, it can be inferred that the anomaly results are strongly influenced by the presence of diagonal shear cracks and crack widths.

6 CONCLUSIONS

This study demonstrated the possibility of using machine learning to detect defects in vibration measurements using an automatic impact device, using the obtained frequency response functions as information. In the experiment, loading tests were conducted on RC beam specimens of three different dimensions, and the response acceleration was collected before and after loading using an automatic impact inspection device. The findings obtained from these measurements and machine learning analysis are summarized below.

- In the RC beam loading tests, a combination of vibration characterization and machine learning using a lightweight, compact automatic impact device was able to detect structurally significant shear cracks.
- The machine learning model showed that the attribute of flexural or shear cracks (differences of crack angle, crack length, and crack density) affected the degree of anomaly.

However, since the vibration measurement in the loading test in this study was a trial effort, the relationship between the resulting data and its accuracy should be further investigated. In addition, the data measured while the automatic impact device was stopped at each measurement point was used in this study, but analysis of the data measured while the device was in motion is needed for more efficient inspection in the future. As a result, we will incorporate machine

learning methods that will be newly announced in the future to further improve the efficiency and accuracy of the system.

ACKNOWLEDGEMENTS

A part of this research was conducted with the support of JST FOREST Program (Grant Number JPMJFR2150, Japan), and the Japan Society for the Promotion of Science (Grant Number 22H01568).

An attempt to improve the accuracy of 3D point cloud considering bridge vibration effects

A. Akutsu, J. Lin & E. Sasaki
Civil and Environmental Engineering, Tokyo Institute of Technology, Meguro, Tokyo, Japan

ABSTRACT: Camera-based bridge inspections, where one can acquire information from a distance, have gained attention. Among them, this study focused on a 3D point cloud. Point cloud data is a set of points with 3D coordinate information and is expected to obtain detailed models with the current state of structures, such as those used in FE analysis. On the other hand, bridges are constantly vibrating due to external forces such as traffic and wind. Image-based point cloud requires the acquisition of measurement target images or videos from various distances and angles to construct a 3D model. Each acquired image with a different shooting timing contains different vibration information and the effect on each image feature point may be an error factor in 3D model construction. Therefore, in this study, the accuracy of 3D point cloud construction using videos has attempted to improve by considering the effects of bridge vibration.

1 INTRODUCTION

Visual inspection is one of the important inspection methods for bridge management. However, there are some problems that number of bridges to be inspected is increasing (Ministry of Infrastructure, Transport and Tourism (MILT), 2022), while the number of inspectors especially skilled inspectors is decreasing (Ministry of Infrastructure, Transport and Tourism, 2015). Besides, installing large inspection equipment or scaffoldings is time-consuming and costly.

To solve the abovementioned problems, the MLIT advocates i-Construction as it intends to increase productivity by integrating information and Communication Technology (ICT). One of the proposals is to inspect the bridge with high accuracy by processing and analyzing the captured photos or videos (Nishimura 2014 and Fujiwara et al. 2018). Image or video processing has the advantage of inspecting bridges remotely from a distance without damaging them and requires less manpower moreover, the inspectors can conduct inspections from a secured location.

Thus, this study focuses on a three-dimensional (3D) point cloud by photogrammetry that can transform two-dimensional images into 3D data. 3D point cloud data is a set of points with 3D coordinate information that represents the outer surface of an object or environment and 3D point cloud data can be obtained by processing the images or the videos of target bridges taken from different angles at different positions. The accuracy of the 3D point cloud construction has been improved since Structure from Motion (SfM) was introduced (Westoby et al. 2012, Lowe 2004, Snavely et al. 2008).

In recent years, research has been carried out on visual inspections applying 3D virtual space (Catbas et al. 2022), and it is envisaged that cracks and corrosion conditions can be checked in the same way as in normal visual inspections. In addition, technology for FE analysis using the 3D point cloud has been developed, and it is expected that analytical models will be constructed from the obtained 3D point cloud. As it is common to calculate the displacement and stress distribution of bridges in FE analysis, reducing the errors in the 3D point cloud for model construction directly leads to improved analysis results.

The authors especially focus on the fact that the bridges are constantly vibrated due to external forces such as wind and traffic and the vibration is not considered when constructing the 3D

DOI: 10.1201/9781003483755-426

point cloud. If the bridge vibrates when the images are taken, the bridge in the image will possibly be in a different position from the original state due to the occurring of displacement. Therefore, the usage of the images with vibration information to generate the 3D point cloud can be considered the accuracy of the 3D point cloud to decrease. For example, especially for short bridges, the amount of deflection is small and errors in the model construction have a significant influence on the analysis results. Moreover, as the accuracy of the 3D model construction in mm is assumed to be necessary to confirm the crack size in visual inspection and deflection of the target in FE analysis, this research aimed to reduce the error due to bridge vibration before the 3D point cloud construction. In this study, a 3D point cloud construction method has been proposed that can reduce the effects of vibration on bridges by applying the Phase Only Correlation Method (POC) to image processing to determine the vibration characteristics of bridges. Further, the applicability of the proposed method was verified by laboratory and field experiments.

2 CONCEPT OF 3D POINT CLOUD CONSTRUCTION CONSIDERING THE VIBRATION EFFECT OF BRIDGES

In this chapter, the ideas of the proposed method are described. Structure from Motion method, POC method, Statistical Outlier Removal (SOR) filter method, and RANSAC shape detection method are applied for 3D point cloud construction, analyzing object displacements in videos, and reducing noise.

2.1 *The basic approach of 3D point cloud construction by using structure from motion method*

SfM is the technique used to reconstruct 3D structures from 2D images. It involved taking a series of images of a scene from different positions. Also using the image to calculate the positions and orientation of the camera in each image. Then the information is used to triangulate the positions of points in the scene, which can be used to create a 3D point cloud of an optional object. The accuracy of the SfM reconstruction depends on the quality of the input images and the number of used images. SfM algorithms typically involve the following steps: first; Feature detection, Second; Feature matching, Third; Triangulation, and Finally; Dense 3D point cloud reconstruction.

SfM is a powerful tool for creating 3D models yet, it has limitations. It also requires a sufficient number of images with good overlap, so it may not work well for scenes with limited visibility. Moreover, if the objects in the frames move, the 3D positions of the detected feature points will deviate, which will affect the next feature point matching, the camera position estimation, and lead to the accuracy of the 3D point cloud decline. Therefore, this study especially focuses on the images from videos before constructing the 3D point cloud. The key idea of the proposed method is to use the frames of videos as images. That is, by extracting and using frames from the video that shows the bridge closest to the stationary state, the effect of feature point matching errors due to the bridge being in different vibration states in the image is eliminated.

2.2 *Acquisition of vibration characteristics by applying phase only correlation method*

The basic idea for acquiring the vibration characteristics is to analyze the obtained videos to calculate the difference between each frame. If the target is bridges, it is able to understand the difference is displacement due to the bridge vibration. In this study, to obtain this difference. The POC method was applied for the analysis. The POC method is a method of image registration that aligns two images by minimizing the difference in their phase spectrum. It is based on the idea that the phase spectrum of an image contains important information about its features and structures, and that aligning the phase spectra of two images also aligns their features and structures well. This study focused on how much two images need to move to align these images and using this value to evaluate the displacement between two images.

Figure 1 shows the flow of the POC method. Image 1 and Image 2 are the images which slightly moved and they need to overlap some parts. When the two images are similar, the

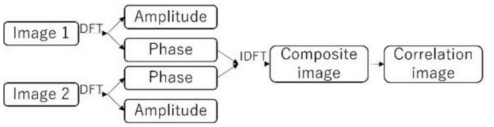

Figure 1. Flow of POC method.

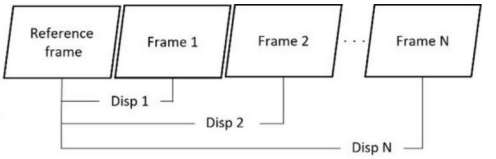

Figure 2. The idea of calculating displacement using video.

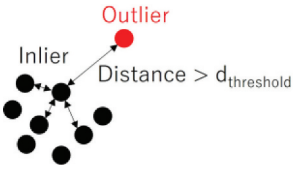

Figure 3. Schematic image of SOR filter.

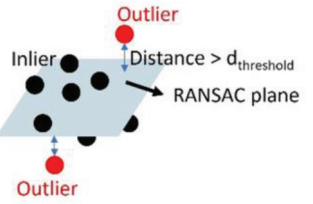

Figure 4. Schematic image of RANSAC shape detection.

POC function which is similar to the correlation coefficient, has a very sharp peak. The height of the correlation peak is useful as a measure of image similarity and it's used in "image matching" applications. On the other hand, the locus of the correlation peaks corresponds to the relative misalignment of the two images (Aoki et al. 2007). In the proposed method, using the locus of correlation peaks to obtain the amount of two images movement. The phase image obtained by applying the Fourier transform to an image contains contour information, while the amplitude image contains luminance information. In the POC method normalizes the amplitude information, which is luminance information, and thus has the advantage of being less affected by sunlight and other factors that can cause problems in outdoor shooting.

The idea of calculating bridge vibration and displacement by applying the POC method is shown in Figure 2. The selected frame as the first frame of the video is used as a reference frame. Then each subsequent frame is aligned with the first frame applying the POC method to obtain the displacement of each frame relative to the first frame. Furthermore, since the first frame is not in a displacement-free state, the center of the vibration can be observed by subtracting the average of all displacements from the obtained displacements. The displacement of the bridge in each frame of the video can be acquired, and the frame with the displacement value closest to the center of the vibration extracted as the frame of the bridge closest to the static state in the video.

2.3 *Proposal for 3D point cloud construction focuses on bridge vibration*

The proposed method in this study is to extract the frame with the closest frame to the center of the vibration, which is obtained in the aforementioned method that applies the POC method and use these extracted frames in each video to construct the 3D point cloud data to eliminate the effect of bridge vibration. Firstly, plan the shooting locations and then shoot a video at each position. Secondly, select the analysis area in the video and use the POC method to analyze the area to get the vertical vibration information and displacement. Thirdly, according to the vibration and displacement information, extract the frame with the closest from the center of the vibration in the video. Afterward, construct a 3D point cloud using the frames extricated from all the videos.

After the 3D point cloud data has been constructed, denoising and outlier removal are performed. In this study, the SOR filter method (Rusu et al. 2007) which is an iterative closest point algorithm implementation, and the RANSAC shape detection method (Bolles et al. 1981) which extracts shapes by randomly selecting the minimum set from a 3D point cloud

and constructing the corresponding shape primitives are selected. The schematic images of both the SOR filter method and the RANSAC shape detection method are shown in Figure 3 and Figure 4 respectively. As shown in the figures, when the threshold is chosen, the point is considered as an inlier if displacement is smaller than the threshold, otherwise it is an outlier. The number of outliers is also used to discuss the accuracy in the following chapters.

3 EXPERIMENTAL INVESTIGATION OF 3D POINT CLOUD CONSTRUCTION CONSIDERING THE VIBRATION EFFECT OF BRIDGES

In this chapter, to verify the applicability of the proposed method, laboratory experiments using a vibration testing machine and a steel specimen and experiments at a bridge site were indicated. The camera used in the experiment was a general-purpose digital single-lens reflex camera with a 35mm full-size CMOS sensor manufactured by SONY, and the focal length was 60mm. The video was recorded at 4K 24p. The amount of image misalignment is acquired as pixel values, and sub-pixel analysis can be applied to extremely small misalignments of 1 pixel or less.

3.1 *Laboratory experiment using vibration testing machine and steel specimen*

The experimental setup is shown in Figure 5. The test specimen was a steel square pipe (25mm×25mm×800mm), simulating a vibrating bridge, and was vibrated at 1 Hz using the vibration testing machine. The maximum vibration amplitude applied in the test was approximately 0.7 mm. The shooting location is shown in Figure 6. The camera positions were adjusted to be 0.3 m, 0.5 m, 0.75 m, and 1 m from the center of the specimen, and the angle was set at 0° in front of the specimen and moved in 15° increments from there to the 90° position. In addition, four camera heights were set, for a total of 112 shooting positions. Each video was taken about 10 seconds. Considering the number of frames, it is enough to analyze in 5 seconds. To verify the accuracy of the acquired vibration characteristics, the laser displacement sensor was also set under the test specimen (Figure 5).

3.1.1 *3D point cloud data construction*

In this stage, the vibration characteristics of all videos were first acquired by the proposed method applying POC method. The vibration frequencies calculated from the obtained video after performing Fourier transforming was 1.01Hz, which was a good match to the set on the vibration testing machine. The vertical displacement from both video and laser displacement meter are shown in Figure 7 and Figure 8 respectively. It was confirmed that the bridge displacement can be calculated well by the proposed method, although the recorded timings did not match those of the laser displacement meter and video.

In order to verify the accuracy of the proposed method (PM), which acquires the frame with the vertical displacement closest to the center of the vibration (zero-closing point), the case where the frame farthest from the vibration center is acquired (MAX), and the case where the frame is randomly acquired (RE), were investigated in this experiment (Figure 7). After extracting all three frames from the video, a total of three sets of frames were obtained. Then, these three sets of frames were then used to generate a 3D point cloud. In this study, Agisoft Matashape (Agisoft, 2023) software was used to construct the 3D point cloud data.

3.1.2 *Accuracy verification*

To verify the accuracy of the 3D point cloud construction, the state of surface generation, the number of outliers, and the number of feature points are used in this study. The 3D point cloud construction result of the proposed method is shown in Figure 9. Figure 10 shows the generated 3D point cloud of each method to evaluate the state of construction. Here, the front surface of the specimen is represented as an a-plane (red) and the top surface as a b-plane (blue). The proposed method PM neatly places feature points on the a-plane and the b-plane. However, in MAX and RE, noise is especially high on the top surface, and the feature points do not fit into one plane and that planes are generated at different positions, as in a b'-plane

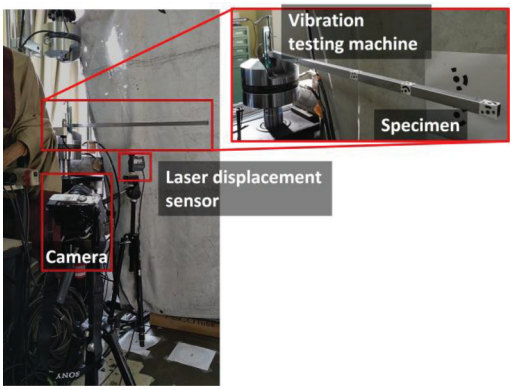

Figure 5. Experimental setup in the laboratory.

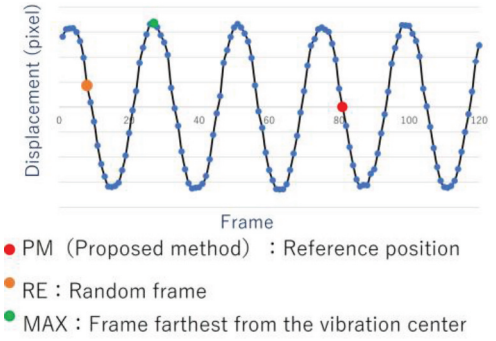

Figure 7. Displacement from video.

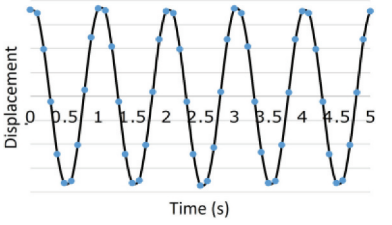

Figure 8. Displacement from laser displacement meter.

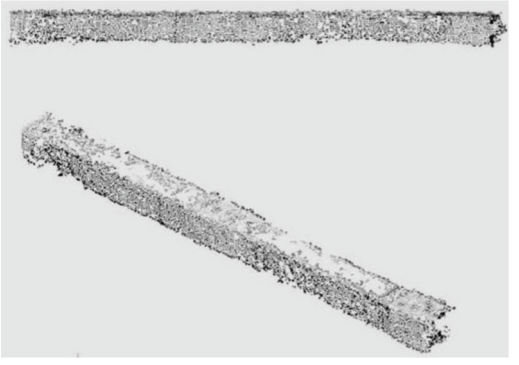

Figure 9. Generated 3D point cloud data of PM.

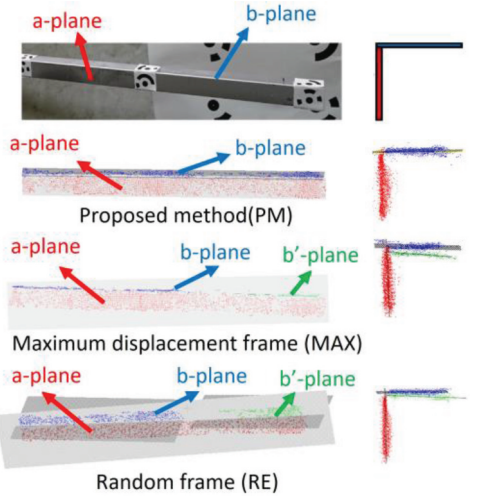

Figure 10. 3D point cloud data in each method.

shown in green. It can be considered due to the vibration, the top surface has more noise in MAX and RE.

After the 3D point cloud construction, denoising was performed by applying a noise reduction method based on the positional relationship between feature points using the SOR filter and the RANSAC shape detection method. It was also confirmed that the number and

percentage of noise removed by the above methods, i.e., outliers of feature points, were smaller when the proposed method (PM) was used than when the other methods were used.

3.2 *Field experiment to verify the feasibility of the proposed method for an existing real bridge*

In this section, an experiment using the proposed method on an existing real bridge has been performed. The flow of the experiment and the method of extracting the specified frames are the same as in the laboratory experiment.

The target bridge of the experiment is a wooden pedestrian bridge on the campus, 20.5 meters long and 4 meters wide. The target bridge and the experimental setup, and shooting positions are shown in Figure 11. In this experiment, due to the tree branches, one side of the bridge was photographed and especially focused on the red squared area in Figure 11 to investigate the construction errors. As shown in the lower right of Figure 11, 27 locations were selected at 3 to 12 m from the bottom of the bridge, with camera heights of 2 m, 2.5 m, and 3 m. The images were taken from a total of 81 locations. Moreover, a vibration generator was installed on the sidewalk (Figure 12) and forced vibration was applied in order to accurately determine the vibration conditions. The vibrator was activated to make the bridge vibrate while ensuring that no pedestrians were passing. The vibration generator was installed to vibrate at a frequency of 5.32Hz.

3.2.1 *Results of 3D point cloud data construction*

As in the laboratory experiments, the vibration information in all videos was acquired first. The vibration information acquired from a sample video is shown in Figure 13. The vibration frequency obtained from the video is 5.35 Hz, which is very close to that set in the vibration generator. Figure 14 shows the 3D point cloud construction result. Due to the tree branches or the angle of the camera, the high part of the bridge was difficult to generate, yet the focus area of the bridge could be well constructed.

3.2.2 *Accuracy verification and discussion*

As shown in Figure 14, the proposed method, PM, has feature points neatly placed on a single plane as in the laboratory experiment. In this experiment, the number of points to use for mean distance estimation was set to 6 and nSigema was 2. The result of applying the SOR filter after generating the 3D point cloud in each method is shown in Table 1. As shown in Table 1, there were 2.63 million, 2.6 million, and 2.55 million feature points in the focus area for PM, MAX, and RE, respectively, of which the percentage removed as outliers was the lowest for PM The percentage of feature points removed as outliers was the lowest for PM at 0.64%, and about 0.66 % and 0.68% for MAX and RE. From this result, it was confirmed the PM can eliminate the vibration effect.

As shown in Figure 14, due to the shooting position and angle, the point cloud of the board below the bridge is better constructed. Hence this component of the bridge is used as the comparison target when applying the RANSAC shape detection. The generated feature points on the plane of PM and MAX are shown in Figure 15. According to Figure 15, a point cloud constructed by PM could generate a complete surface, however, in the MAX, two different planes are generated due to the uneven distribution of the feature points. Moreover, the largest number of points on the plane was observed in PM and the mean distance from the plane to each feature point are smallest. Thus, it was also confirmed that the proposed method can be eliminated the vibration effect of the bridge when constructing 3D point cloud data with the RANSAC shape detection method as well as the SOR filter.

In this method, if the camera moves with bridges, the bridge vibration is canceled by the camera vibration, so the camera must be installed in a position where it is not affected by the bridge vibration. On the other hand, it can be assumed that the camera is shaken by wind and other influences. Therefore, it is important to take vibration into consideration, for example by using vibration isolating pads. As another countermeasure, as bridges have parts that hardly vibrate (e.g. piers), it is possible to remove the influence of the camera vibration by calculating the vibration of the camera itself and subtracting

it from the vibration analysis results of the bridge by performing the same video analysis on the parts that do not vibrate.

3.3 *Summary*

In this chapter, 3D point cloud data are constructed with the test specimen in the laboratory experiment and existing bridge by proposed method. The 3D point cloud

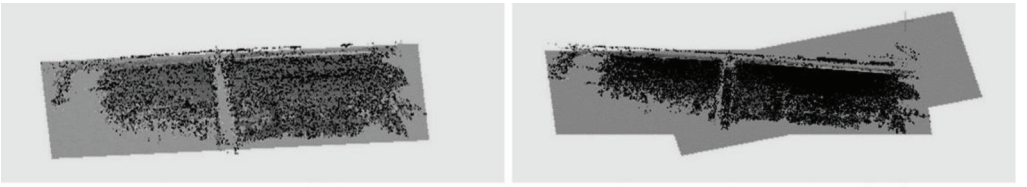

Figure 15. Generated plane with the feature points at the board below the bridge.

generated using two other frames (maximum displacement frame and random frame) from the same video is also compared. Comparing the 3D point cloud data after applying the SOR filter method and the RANSAC shape detection method, it was confirmed that the 3D point cloud generated using the proposed method has fewer outliers in both experiments. Therefore, it can be considered that the 3D point cloud generated by the proposed method is more accurate.

4 CONCLUSIONS

This study was conducted on 3D point cloud data, which have gained attention in recent years in bridge maintenance management, and focused on the effect of bridge vibration on 3D point cloud generated by photogrammetry. The conclusions in this study are described as follows:

(a) In this study, a method was proposed to eliminate the influence of bridge vibration on the accuracy of 3D point clouds: by using the POC method to acquire the bridge vibration information in the video used to generate 3D point clouds and then extracting the frames with the closest to the vibration center from the video, the deviation of bridge feature points in the photographs used to generate 3D point clouds was reduced. Using the method proposed in this study, only two steps, obtaining bridge vibration information through video analysis and extracting specific frames, are needed to be added to the usual process of generating 3D point clouds.
(b) The feasibility of the proposed method was verified by laboratory experiments. In the laboratory experiments, the maximum displacement frames and random frames were extracted separately from all the same videos, in addition to the specified frames of the proposed method, so as to ensure that the three sets of frames were obtained under the same conditions. Later, by comparing the 3D point clouds generated from these three sets of frames, it was verified that the proposed method in this experiment generates more accurate 3D point clouds.
(c) This study also discussed the feasibility of the proposed method for real existing bridges through field experiments. The experiment was performed by keeping the bridge vibrating by installing the vibration generator on the bridge, and the video was taken. After comparing 3D point clouds, it was clarified that the method can reduce the outlier points in the bridge 3D point cloud and improve the accuracy of the 3D point cloud.

In this study, the focus was on verifying the accuracy based on outliers and the construction state of the surface, as it was difficult to construct a complete 3D point cloud of the target bridge due to the limitations of the camera installation position. The verification of construction errors by comparing the constructed 3D model with real structures and the construction of an FE analysis model using the obtained 3D point cloud data will be the subject of future studies. Moreover, the availability of the proposed method for realistic bridges needs to be further improved.

Scour detection method of bridge foundation based on pier vibration mode under vehicle braking action

Y. Li, Z.H. Zhang, Z.B. Sun & H. Sun
School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin, Heilongjiang, China

ABSTRACT: Foundation scour poses a huge potential threat to bridge safety. A scour detection method of bridge pile foundation based on pier vibration mode excited by vehicle braking action was proposed and verified by numerical simulation and a laboratory test. Firstly, the horizontal vibration of bridge was excited by vehicle braking action, and the vibration modes sensitive to scour were identified from vibration signal. Secondly, the frequency change rate FCR and the flexibility-based displacement were defined as indicators to determine the scour location. Finally, with pier mode as input and scour state as output, a BP neural network model optimized by particle swarm optimization algorithm was constructed to predict the scour depth. Numerical and experimental studies showed that the vehicle braking force can effectively stimulate the local modes of the pier, and the scour indicators were very sensitive to scour. The scour depth can be accurately predicted using a small number of training samples and several vibration measuring points on the pier. The proposed method is simple to operate and can be embedded in the regular bridge load test to evaluate the bridge substructure synchronously.

1 INTRODUCTION

Bridge foundation scour is one of the important reasons for the failure of bridge across river. For example, about 60% of bridge failure events are related to scour in America (Wardhana & Hadipriono 2003). Scour occurs underwater and is difficult to observe directly. At present, scour detection is mainly through diving detection or sonar, radar and other equipment (Prendergast & Gavin 2014). However, these methods are not suitable for the short and medium-span highway bridges due to their complicated workflow and high cost.

The vibration-based bridge scour detection methods have gained great attention. Bridge vibration is mainly caused by traffic load, and the related researches are summarized as follows. Ko et al. (2010) proposed a scour detection method based on the mean Fourier spectrum of structural measured vibration. Prendergast et al. (2017) developed a numerical model of vehicle-bridge-soil dynamic interaction, and conducted the studies on scour detection based on vehicle-induced vibration. Kong and Cai (2016) numerically studied the feasibility of identifying scour from vehicle response. Foti and Sabia (2011) performed field tests on a severely scoured bridge, the dynamic characteristics and vehicle-induced vibration of the bridge were used to identify scour. Cheng et al. (2022) developed a mobile scour detection platform to test the fundamental frequency of the bridge and evaluate the substructure condition using the critical frequency ratio *RC*.

Finite element model updating (FEMU) is widely used to identify scour depth, which requires accurate vibration modes. Chen et al. (2014), and Li et al. (2017) identified the scour depth of cable-stayed Bridges. Zhan et al. (2022) identified the scour depth of highway girder bridges by FEMU. The proxy model approach may have advantages over FEMU. Liao et al. (2022) used the improved genetic algorithm (GA) to identify the scour depth of pile foundation of continuous beam bridge. He et al. (2023) proposed a Kriging model assisted by GA, which improved the computational efficiency and accuracy.

DOI: 10.1201/9781003483755-427

A scour detection method of bridge pile foundation based on vehicle braking action was proposed in this paper. Compared with routine traffic loads, braking forces can significantly stimulate the horizontal response and modes of bridges sensitive to scour (Zhang et al. 2022). Vehicle braking tests can be performed in regular bridge load tests with little additional testing cost. The main contents of this paper are as follows. Firstly, the scour detection method is introduced, including two steps of scour location and scour depth identification. Secondly, a numerical case is used to study the details and feasibility of the proposed method. Finally, a laboratory model experiment is carried out to verify the proposed method.

2 BRIDGE SCOUR DETECTION METHOD BASED ON VEHICLE BRAKING ACTION

2.1 *Identify bridge modes from structural vibration excited by braking action*

In a bridge dynamic load test, braking test is used to evaluate the dynamic performance of bridge. Vehicle braking causes axle load redistribution, and the total braking force $\mathbf{F_{xt}}$ of the vehicle will be allocated to the corresponding wheel position according to the new axle load distribution. Specific derivation process can be found in the literature (Zhang et al. 2022). Based on the modal superposition method, the vehicle-bridge coupled vibration during vehicle braking stage is established:

$$\begin{bmatrix} \boldsymbol{M}_{\mathrm{v}} & 0 \\ 0 & \boldsymbol{M}_{\mathrm{B}} \end{bmatrix} \begin{Bmatrix} \ddot{\boldsymbol{X}}_{\mathrm{v}} \\ \ddot{\boldsymbol{q}}_{\mathrm{B}} \end{Bmatrix} + \begin{bmatrix} \boldsymbol{C}_{\mathrm{v}} & \boldsymbol{C}_{\mathrm{vB}} \\ \boldsymbol{C}_{\mathrm{Bv}} & \boldsymbol{C}_{\mathrm{B}} + \boldsymbol{C}_{\mathrm{B}}^{\mathrm{v}} \end{bmatrix} \begin{Bmatrix} \dot{\boldsymbol{X}}_{\mathrm{v}} \\ \dot{\boldsymbol{q}}_{\mathrm{B}} \end{Bmatrix} + \begin{bmatrix} \boldsymbol{K}_{\mathrm{v}} & \boldsymbol{K}_{\mathrm{vB}} \\ \boldsymbol{K}_{\mathrm{Bv}} & \boldsymbol{K}_{\mathrm{B}} + \boldsymbol{K}_{\mathrm{B}}^{\mathrm{v}} \end{bmatrix} \begin{Bmatrix} \boldsymbol{X}_{\mathrm{v}} \\ \boldsymbol{q}_{\mathrm{B}} \end{Bmatrix} = \begin{Bmatrix} \boldsymbol{F}_{\mathrm{v}}^{\mathrm{r}} \\ \boldsymbol{F}_{\mathrm{B}}^{\mathrm{rG}} + \boldsymbol{F}_{xt} \end{Bmatrix} \tag{1}$$

where $\boldsymbol{M}$, $\boldsymbol{K}$, $\boldsymbol{C}$ and $\boldsymbol{F}$ respectively represent mass, stiffness, damping matrix and load vector. $\mathbf{X_v}$, $\dot{\mathbf{X}}_\mathbf{v}$ and $\ddot{\mathbf{X}}_\mathbf{v}$ respectively represent vehicle displacement, speed and acceleration response vectors. $\mathbf{q_B}$, $\dot{\mathbf{q}}_\mathbf{B}$ and $\ddot{\mathbf{q}}_\mathbf{B}$ respectively represent the bridge displacement, velocity and acceleration. Specific forms of these matrices can be found in references (Li et al. 2016; Zhang et al. 2022).

In the process of vehicle braking, the bridge is subjected to longitudinal short-term concentrated load and vertical wheel load. The braking force is approximately rectangular pulse excitation with a low spectral principal component, which can be used to excite structures with low natural frequency, such as bridges. As it is difficult to measure the load input, the output-only modal identification method is adopted. The frequency domain decomposition method (FDD) is used to identify the bridge modes. The modes identified by FDD are normalized relative to the unit mass matrix. In addition, the structural free attenuation signal after vehicle braking is used to reduce the interference of the vehicle.

2.2 *Indicators for detecting the foundation scour location*

The following indicators are defined for scour location based on the results of bridge modal identification under vehicle braking action.

(1) Frequency change rate

Frequency change rate *FCR* is defined as:

$$FCR = \frac{\Delta f_i}{f_i} \tag{2}$$

where f_i is the i-order natural frequency of the healthy structure, which can be tested before scour occurs; Δf_i the change of f_i caused by scour.

(2) Flexibility-based deflections

The flexibility matrix $\mathbf{G}$ of the structure reflects the relationship between the static load and the displacement of the structure, which can be estimated by the measured mode shape and frequency:

$$\mathrm{G} = \Phi \Lambda^{-1} \Phi^{T} \tag{3}$$

where $\Lambda^{-1}$is a diagonal matrix composed of the reciprocal of the square of the natural frequency arranged in ascending order.$\Phi = [\boldsymbol{\varphi}_{a,1} \quad \boldsymbol{\varphi}_{a,2} \quad \cdots \quad \boldsymbol{\varphi}_{a,n}]$, $\boldsymbol{\varphi}_{a,i}$ is the *i*-order mode shape normalized with respect to the mass matrix:

$$\boldsymbol{\varphi}_{a,i}^{T}\boldsymbol{M}\boldsymbol{\varphi}_{a,i} = \boldsymbol{I} \tag{4}$$

The mode shape $\boldsymbol{\varphi}_{m,i}$ identified by FDD method is normalized under the unit mass matrix:

$$\boldsymbol{\varphi}_{m,i}^{T}\boldsymbol{\varphi}_{m,i} = \boldsymbol{I} \tag{5}$$

The piers of the short and medium-span highway bridges are generally of equal section, and their mass matrix $\boldsymbol{M}$ is:

$$\boldsymbol{M} = m_0\boldsymbol{I} \tag{6}$$

where m_0 is a constant related to the element mass, **I** is the unit diagonal matrix.

It can be obtained by formula (5) ~ (7):

$$\boldsymbol{G_a} = \boldsymbol{\Phi_a}\boldsymbol{\Lambda}^{-1}\boldsymbol{\Phi_a}^{T} = \frac{1}{m_0}\boldsymbol{\Phi_m}\boldsymbol{\Lambda}^{-1}\boldsymbol{\Phi_m}^{T} = \frac{1}{m_0}\boldsymbol{G_m} \tag{7}$$

Eq. (7) shows that the $\boldsymbol{G}_{\mathbf{m}}$ and $\boldsymbol{G_a}$ has the same information, and they are equivalent in structural damage identification. The flexibility-based deflections δ is defined for scour identification:

$$\boldsymbol{\delta} = \boldsymbol{P}(\boldsymbol{G_{md}} - \boldsymbol{G_{m0}}) \tag{8}$$

where $\boldsymbol{P}$ is the unit force vector, $\boldsymbol{G_{md}}$ and $\boldsymbol{G_{m0}}$ is the pier flexibility matrix tested under health and scour conditions respectively, and $\boldsymbol{\delta}$ is the displacement difference under uniform horizontal unit load.

2.3 *Identification of foundation scour depth based on PSO-BPNN*

Back propagation neural network (BPNN) is one of the representative algorithms for solving multi-input and multi-output problems because of its strong nonlinear mapping ability. In order to improve the prediction accuracy of BPNN, Particle swarm optimization (PSO) is used to optimize the network weights. PSO is a swarm intelligence optimization algorithm with strong function extremum optimization ability.

After the scour location is determined, the scour depth is identified using the following steps:

(1) Establish the finite element model of the target pier based on the design data.
(2) Determine the range of scour depth and other key model parameters, and conduct multi-dimensional stratified sampling using Latin hypercube sampling method to obtain training and test sample sets.
(3) Frequency and mode shape with labels are obtained through modal analysis and input into the network for training.
(4) Input the measured frequency and mode shape into the trained network to predict the scour depth.

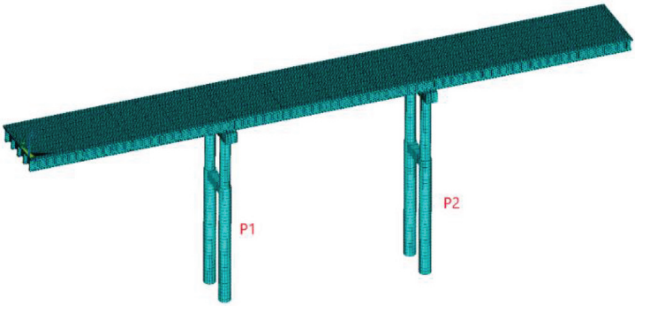
3 NUMERICAL VALIDATION OF THE PROPOSED METHOD

3.1 *Bridge information and finite element model*

A typical three-span concrete continuous beam bridge was selected for numerical study. The span of the bridge is 3×30 m and the width is 10.5m. The piers are concrete double cylindrical piers with a diameter of 1.5m. The height of the pier P1 is 8.0m, and the height of the pier P2 is 10.0m. The pile foundation is 18m long and 1.7m in diameter. Ptfe plate rubber supports are installed on abutments B0 and B3, and Plate rubber supports are installed on piers P1 and P2.

The finite element model of the bridge was built using the ANSYS, as shown in Figure 1. The superstructure and bent cap are simulated using solid element *Solid65*, the pier and

foundation are simulated using beam element *Beam188*, and the bearing is simulated using matrix element *Matrix27*. The bottom of the pile is fixed vertically, and the horizontal constraint of the pile is simulated using linear spring element *Combin14* (Prendergast et al. 2017). The stiffness of the soil spring is calculated according to the "M" method (TB 10002.5-2005). The foundation scour is simulated by removing the spring element above the scour line, and the stiffness of the remaining soil spring is recalculated according to the new ground elevation.



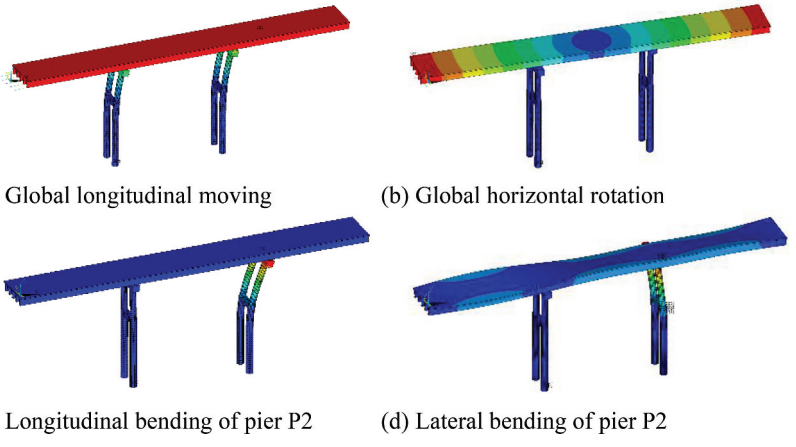


Figure 1. Finite element model of bridge.

3.2 *Influence of scour on dynamic characteristics of the bridge*

The scour depth of pier P2 is set to 0~4m to study the scour effect on the vibration mode of bridge. The frequencies sensitive to scour are shown in Table 1, and the corresponding mode shapes are shown in Figure 2.

Table 1. Frequencies sensitive to scour.

Vibration Mode	Frequency (Hz)				
	Intact	P2-1m	P2-2m	P2-3m	P2-4m
Global longitudinal moving	0.891	0.884	0.876	0.869	0.863
Global horizontal rotation	1.284	1.283	1.282	1.282	1.281
Longitudinal bending of pier P2	2.929	2.791	2.669	2.560	2.462
Transverse bending of pier P2	4.599	4.400	4.195	4.054	3.750
Torsion of pier P2	6.073	5.731	5.428	5.156	4.893
Second order longitudinal bend of pier P2	12.658	11.282	10.138	9.184	8.385
Second order lateral bend of pier P2	17.919	16.050	15.146	14.125	11.457

(a) Global longitudinal moving (b) Global horizontal rotation

(c) Longitudinal bending of pier P2 (d) Lateral bending of pier P2

Figure 2. Mode shapes of bridge.

Table 1 shows that foundation scour has little influence on the global modes of the bridge, but has great influence on the local modes (longitudinal, transverse and torsional modes) of the pier. This is because the free length of pier increases and the horizontal stiffness decreases due to scour.

3.3 *Dynamic response of the pier during vehicle braking.*

The vehicle-bridge coupled vibration was numerically simulated for the bridge. The test parameters are set as follows: a three-axle truck weighing 30t drives along the center line of lane 1 at a speed of 30km/h, and starts braking in the middle of the second span. The braking force rise time t_p is 0.3s, the braking force peak coefficient φ_p is 0.7, and the road roughness level is "good". Vehicle parameters and analysis principles are detailed in literature (Li et al. 2016). Figure 2 shows the acceleration response and spectrum at top of pier P2 during vehicle braking for different scour depths.

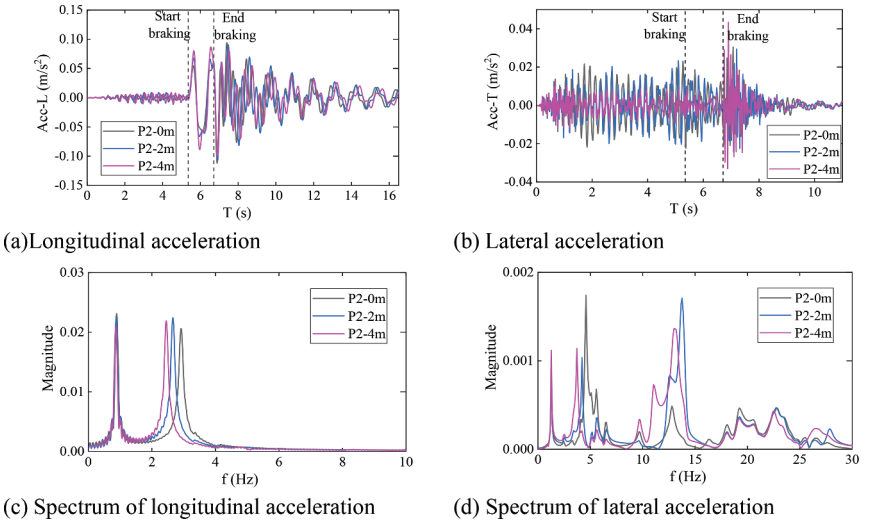

Figure 3. The acceleration response and spectrum at pier P2 top during vehicle braking.

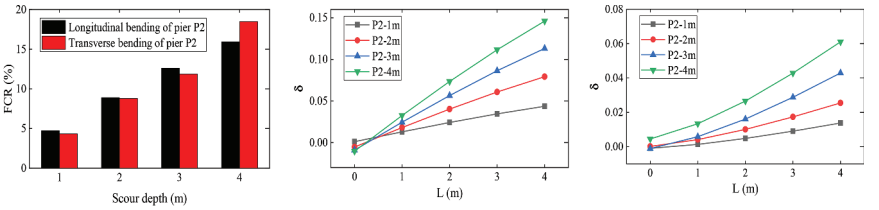
Figure 2(a) and (b) show that vehicle braking force can stimulate a larger acceleration response, and scour will lead to an increase in response amplitude. Figure 2 (c) shows that the vehicle braking force stimulates the global longitudinal moving modes and the longitudinal bending modes of pier, and these two order frequencies can be accurately observed and extracted from the spectrum. The first two frequencies in Figure 2 (d) correspond to the global horizontal torsion mode of bridge and the transverse bending mode of pier, respectively.



In conclusion, the smooth response spectrum with obvious peak value can be obtained under the vehicle braking action without interference from vehicle frequency, which has significant advantages in bridge modal identification.

3.4 *Validity verification of scour positioning indicators*

The pier modes are identified from the structural free attenuation signal after vehicles braking using the FDD method. The first two longitudinal modes and the first two lateral modes of the pier are used to calculate the scour indicators *FCR* and δ based on the Eq. (3) and Eq. (9). In practical engineering, the installation of sensors on piers in deep water area requires the bridge inspection vehicle to provide a working platform. Sensors can usually only be installed on the upper part of the pier. For this bridge, 5 measuring points are arranged downward at 1m intervals from the top of pier P2. When the scour depth of pier P2 is 0m~4m, the *FCR* and δ are shown in Figure 4.

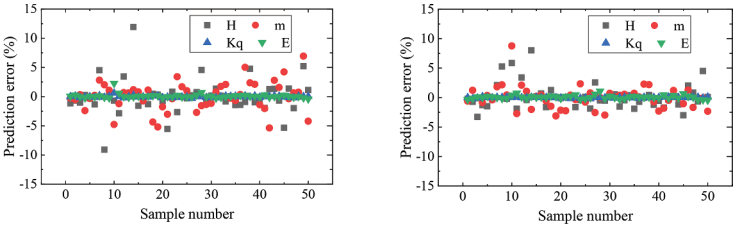
Figure 4(a) shows that the indicators *FCR* and δ increase with the increase of scour depth. The *FCR* is above 15% when the scour depth is 4m. Figure 4(b) ~ (c) shows that the δ value of the lower measuring point is greater than that of the upper measuring point, indicating that

the sensor on the pier should be arranged downward as far as possible. The δ for longitudinal modes is larger, indicating that the longitudinal flexibility of the bridge is larger.

(a) FCR (b) δ for longitudinal modes (c) δ for lateral modes

Figure. 4. Scour indicators FCR and δ under different scour depth (L is the distance between the sensor and the pier top).

3.5 *Scour depth identification based on PSO-BPNN*



Based on the method proposed in section 2.3, the flow of scour depth identification is illustrated by taking pier P2 as an example.

Firstly, considering the uncertainty of actual pier conditions, the scour depth H, the concrete elastic modulus E of the pier, the shear stiffness K_q of the support and the soil horizontal resistance coefficient m were selected as the optimization parameters. 500 samples were randomly selected within the sampling range shown in Table 2 using Latin hypercube sampling method. The label corresponding to i-sample is ***Outpot,i***=[H_i, E_i, Kq_i, m_i]. E_0, Kq_0 and m_0 in Table 2 are the standard values of parameters from the design data. Secondly, modal analysis is carried out on random samples. The first order longitudinal and transverse mode of pier are selected as the target parameters. The target parameter vector of the i-sample is ***Input,i***= [f_1,φ_{11}, φ_{12},. . ., f_2,φ_{21}, φ_{22},. . .]. Then, 450 samples are selected as the training set and the remaining 50 samples are selected as the test set. BPNN is trained with ***Input,i*** as output and ***Outpot,i*** as output.

Table 2. Sampling range of parameters.

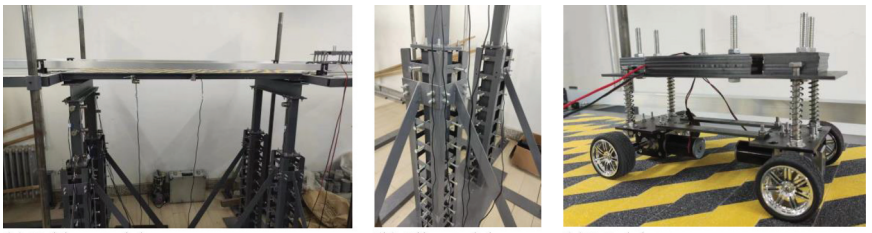
Parameters	H	m	Kq	E
Sampling range	0m ~ 6m	$0.5m_0$ ~ 1.5 m_0	$0.8K_{q0}$ ~1.2 K_{q0}	0.8 E_0~1.2 E_0

The test set was used to test the prediction accuracy of BPNN, and the results are shown in Figure 5. The results show that the proposed method can accurately predict the scour depth, and satisfactory results can be obtained with only 3 measuring points at the pier.

(a) Five measuring points (b) Three measuring points

Figure 5. Prediction accuracy of BPNN.

4 EXPERIMENTAL VALIDATION OF THE PROPOSED METHOD



A laboratory test was designed to validate the proposed method. The design process of the scale model was as follows. First, the similarity constants for model tests were derived based

on dimensional analysis. Secondly, taking a concrete simply supported bridge with a span of 30m as the prototype, the size similarity scale λ_L was selected as 20. The scale model was made using steel, so the elastic modulus similarity scale λ_E is 0.168. Finally, considering the purpose and conditions of the experiment, the similar scale of other parameters was calculated and the detailed model design was carried out.

The bridge model is a simple supported beam with a span of 1.5m, as shown in Figure 6(a). The pier is a double pillar pier with a height of 0.4m. The pile foundation is 1.0m long, and 10 layers of bolts are uniformly installed on the side of the pile to limit the horizontal deformation of the pile (shown in Figure 6(b)), so as to simulate the lateral constraint of soil on the pile. Foundation scour can be simulated by removing bolts. Rubber blocks are installed between the beam and the bent cap to simulate the support. The two-axle model car (shown in Figure 6(c)) is equipped with an electric drive system that allows uniform motion and braking.

In this test, 0/2/4/6 layers of bolts were successively removed on pier P2 to simulate four scour levels, called *level-0~level-3*. Nine unidirectional acceleration sensors, six longitudinal and three transverse, are installed on pier P2, as shown in Figure 6(b). Brake tests were carried out under four scour levels. The weight of the model car is 7.5kg, and the vehicle braking at a mid-span position at an initial speed of 1.0m/s.

According to the test results, the changes in pier frequency identified from the braking-induced responses are shown in Table 3. Taking the *level-0* as the benchmark state, the scour indicators δ under other three scour levels are shown in Figure 7. The two indicators increased significantly as the scour level increased, and the experimental results verify the validity of the proposed methods.

5 CONCLUSIONS

In this paper, a scour detection method of bridge pile foundation based on vehicle braking was proposed. Firstly, the scour indicators were defined to identify the scour location based on the pier modes stimulated by vehicle braking force. Secondly, a PSO-BPNN model was trained to predict the scour depth. Numerical and experimental studies validate the effectiveness of the proposed method. The main conclusions are as follows:

(1) The vehicle braking force can effectively stimulate the horizontal dynamic response and vibration mode of the pier sensitive to scouring.
(2) The proposed scour indicators FCR and δ are sensitive to scour and can be used to determine the scour location.
(3) The constructed PSO-BPNN model can accurately predict the scour depth, and a satisfactory prediction result can be obtained with a small number of vibration measurement points.
(4) The feasibility of the proposed method is verified by a model test.

Field test study of bridge scour diagnostic method based on time-varying frequency

Z.H. Zhang, Y. Li, C. Yang & H. Sun
School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin, Heilongjiang, China

ABSTRACT: Scour is one of the main hidden diseases of bridge substructure, which will lead to the significant loss of foundation stiffness and bearing capacity. A scour diagnostic method of pile foundation based on time-varying frequency was proposed and verified by several field bridge tests. Firstly, the traffic-induced vibration of the pier were collected, and the instantaneous frequency of the pier was extracted based on Wavelet Synchrosqueezed Transform. Secondly, the probability distribution of instantaneous frequency was fitted and the scour indicator was defined based on the confidence interval. Field test results showed that the vibration response of the middle part of the pier contains more high-order modal information than that of the top part. The scour indicator changed significantly for two tested piers with a height of 7.23m and 8.98m, which indirectly verified its sensitivity to the change of free length of piers. For short and medium-span bridges, effective vibration signals can be collected by a short test under open traffic conditions. The proposed method can be used for real-time monitoring or rapid detection of bridge scour.

1 INTRODUCTION

Bridge scour is a natural phenomenon caused by hydrodynamic action and is prevalent near the foundations of bridges crossing rivers. Flooding and scour are the main causes of bridge collapse accidents (Lagasse et al. 1998; Wardhana & Hadipriono 2003). Scour assessment is a key link in the assessment of bridge safety conditions. However, due to the concealment of scour, it is difficult for inspectors to detect abnormalities in the river bed through observation.

In recent years, vibration-based scour diagnostic method has received much attention due to its advantages of high efficiency, economy and no underwater work. Scour diagnosis is performed based on the correlation of dynamic response with scour state. Ko et al. (2010) verified the scour evaluation method based on the average spectrum of bridge vehicle-induced vibration through two field tests. Prendergast et al. (2017) studied the influence of scour on bridge vehicle-induced vibration through numerical simulation, and identified the frequency from the attenuation signal of the pier to identify scour. Foti and Sabia (2011) proved the feasibility of bridge dynamic characteristics and vehicle-induced vibration for scour identification through field tests. Malekjafarian et al. (2020) and Khan et al. (2021) used vehicle-induced vibration to construct the average normalized mode shape of the superstructure, and laboratory test were used to verify the feasibility of this indicator in identifying shallow foundation scour. Zhang et al. (2022) proposed a scour diagnosis method based on vehicle braking action, and constructed a scour indicator based on the correlation of dynamic response.

In summary, vehicle-induced vibration response of bridges is widely used to extract scour indicator such as frequency and mode shape. Most of the existing studies are based on laboratory tests or numerical simulation, and there is a lack of field tests on the vibration characteristics of piers under the action of moving vehicles. In addition, the passing vehicle and bridge

DOI: 10.1201/9781003483755-428

form a time-varying vibration system, and the bridge frequency is affected by the vehicle, which may affect the scour diagnostic results based on the dynamic characteristics of bridges.

In this study, a scour diagnostic method of bridge pile foundation based on structural time-varying frequency is proposed. This paper is organized as follows: In the section 2, the theoretical basis of this method is introduced. The instantaneous frequency is extracted from the vehicle-induced vibration of bridge piers based on Wavelet Synchrosqueezed Transform, and the scour indicator is defined based on statistical method. In Section 3, two field tests are used to verify the effectiveness of the proposed method. In the Section 4, a summary is given and further research suggestions are put forward.

2 THEORETICAL BASIS OF SCOUR DIAGNOSIS METHOD

2.1 *Instantaneous frequency identification of bridges based on wavelet synchrosqueezed transform*

For the vehicle-bridge interaction (VBI) system, the bridge vibration excited by the moving vehicle includes two parts (Mostafa et al. 2021), the forced vibration in the vehicle passing stage and the free attenuation response after the vehicle leaves. The passing stage is a non-stationary process, because the mass distribution of VBI system is time-dependent, so it is necessary to use time-frequency analysis methods to extract the instantaneous frequency (IF) of the VBI system. Existing studies focus on IF variation of vehicle and superstructure, but little attention has been paid to substructure.

Pier frequency is generally used to identify foundation scour. Prendergast et al. (2017) used the free attenuation signal from piers to identify frequencies, which may only be applicable to small damping structures. Since the middle pier of a continuous girder bridge is far away from the expansion joint, its free attenuation signal may be very weak. The vibration signal of bridge pier under traffic load is mainly forced vibration and contains closely spaced spectral components. It is necessary to pay attention to the time-varying dynamic characteristics of bridge pier by using time-frequency analysis tools.

Wavelet Synchrosqueezed Transform (WSST) is a novel time-frequency analysis technology (Daubechies et al. 2011), which has been proven to effectively overcome modal aliasing (Jiang, & Suter 2017) .WSST consists of continuous wavelet transform (CWT) and reallocation theory.

Firstly, CWT is used to transform the one-dimensional time signal $x(t)$ into two-dimensional wavelet coefficients:

$$W_x(a,b) = \int x(t) a^{-1/2} \Psi\left(\frac{t-a}{b}\right) \tag{1}$$

where $W_x(a,b)$ is the complex wavelet coefficient spectrum, a and b are the translation variables and scale variables respectively, $x(t)$ is the time signal, and the function$\Psi$is the mother wavelet.

Then, the IF of the signal is calculated using the following equation:

$$\omega_x(\mathrm{a},\mathrm{b}) = \frac{\frac{\partial W_x(\mathrm{a},\mathrm{b})}{\partial b}}{2\pi i W_x(\mathrm{a},\mathrm{b})} \tag{2}$$

Finally, Synchrosqueezed transformation is performed to compress and reorganize the $W_x(a,b)$ in the frequency direction:

$$T_x(\omega_l,\mathrm{b}) = (\Delta\omega_l)^{-1} \sum\nolimits_{\partial k} \mathrm{W}(a_k,\mathrm{b}) a_k^{-2/3} (\Delta a)_k \tag{3}$$

where the transformation function T_x only acts on the center$\omega_l$of the continuous interval$[\omega_l - 0.5\,\Delta\omega, \omega_l + 0.5\,\Delta\omega]$, and $\Delta a_k = a_k - a_{k-1}$, $\Delta\omega = \omega_l - \omega_{l-1}$.

The WSST compresses the wavelet coefficients to near the center frequency and refines the wavelet ridges, thus greatly improving the frequency resolution. The vehicle-induced vibration of the bridge structure often contains multiple modes, so there are multiple ridges in the time-frequency image. The modulus maximum method is used to extract the wavelet ridges and obtain the IFs of the VBI system.

2.2 *Probability estimation of instantaneous frequency*

Considering the time-varying properties of VBI system, scour-induced structural frequency changes were evaluated using statistical methods. Since the IFs distribution pattern cannot be predicted, kernel density estimation (KDE) was chosen to study the frequency distribution characteristics. KDE does not require prior knowledge and additional assumptions, and the data distribution characteristics are studied only from the sample itself.

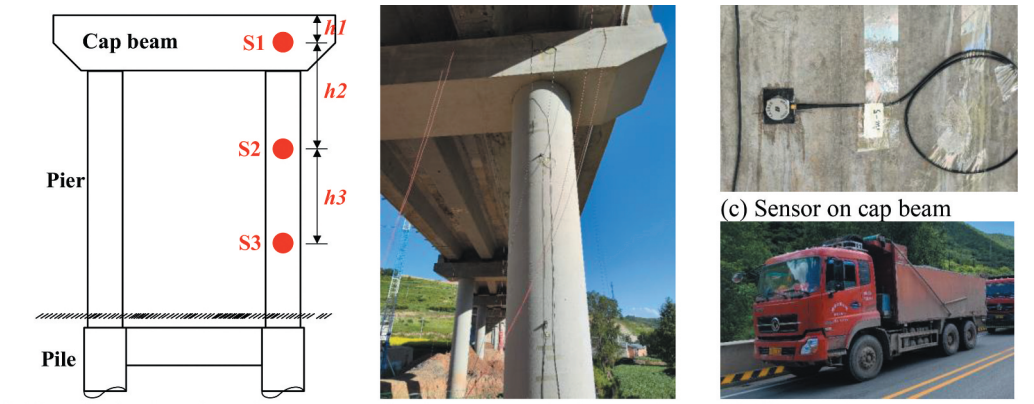
If the instantaneous frequency $\omega(t)$ is regarded as an independent and equally distributed random variable, its KDE is calculated as follows:

$$PDF(\omega) = \frac{1}{nh}\sum_{k=1}^{n} K\left(\frac{\omega - \omega(t_i)}{h}\right) \tag{4}$$

where PDF is the probability density of ω, n is the total number of samples, t_i is the i-th sampling time, h is the kernel bandwidth. Function $K(\cdot)$ is the kernel function, and the Gaussian kernel function is used in this study.

The PDF of IFs of the bridge structure has multiple peaks. In order to separate each order mode, the valley point of PDF is selected as the dividing point, and the IFs are divided into different data sets. The normal probability distribution $N(\mu, \sigma)$ was re-estimated for each data set to obtain the distribution characteristics of each order of frequency.

Finally, based on the normal probability distribution for each order frequency, a confidence interval with 70% confidence level is defined as a scour indicator SI:

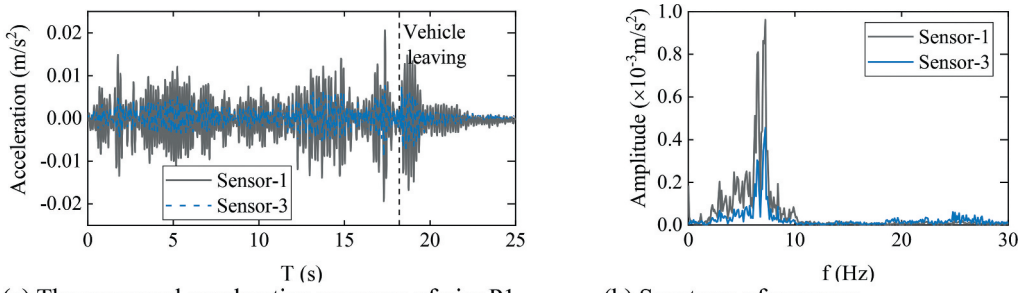


$$SI = [\mu - 0.5\sigma, \mu + 0.5\sigma] \tag{5}$$

3 FIELD TEST VERIFICATION OF SCOUR DIAGNOSIS METHOD

3.1 *Case study I- Zhangwangbao Bridge*

Zhangwangbao Bridge is a newly built concrete continuous girder bridge in Gannan, China. The test was carried out on the first four continuous spans, each span was 20m long. The bridge pier is the most common double-column bent pier among Chinese highway bridges, as shown in Figure 1(a). On-site measurement shows that the heights of piers P1 and P2 are 7.23m and 8.98m respectively, the pier diameter is 1.4m and the height of the cap beam is 1.3m. Three acceleration sensors (S1~S3) are installed on piers P1 and P2 respectively to test the longitudinal vibration, as shown in Figure 1(b). The *h1~h3* at pier P1 are 0.6m, 2.7m and 3.0m respectively, the *h1~h3* at pier P1 are 0.6m, 2.7m and 5.3m respectively. The test was conducted under closed traffic conditions and a three-axle truck weighing 45.2t passed the bridge (Figure 1(c)). Since the bridge is a curved bridge, the vehicle speed is controlled within 30km/h for safety reasons.



When the vehicle passes the bridge at a speed of 20km/h, the acceleration response of the pier P1 is shown in Figure 2(a), and the response spectrum is shown in Figure 2(b). Figure 2(a) shows that the vibration amplitude of measuring point S1 is significantly larger than that of measuring point S3, which is determined by the cantilever characteristics of the pier. The

(a) Installation location of sensors (b) Sensors installation on site (c) Sensor on cap beam (d) Three-axle truck

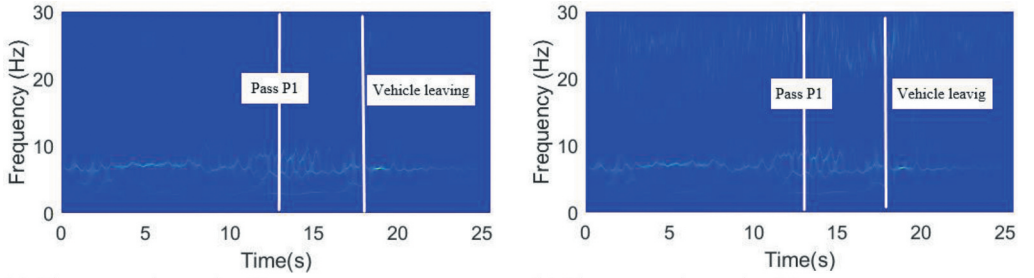


Figure 1. Overview of field test.

response of the measuring point S1 mainly contains low frequency components (0~10Hz), while the response of the measuring point S3 contains more high-frequency information (20~30Hz). This is because the low-order vibration of the pier mainly swings horizontally, and the peak of mode shape appears at the pier top, but the peak of high-order mode shape appears in the middle part of the pier.

(a) The measured acceleration response of pier P1 (b) Spectrum of response

Figure 2. Acceleration response and spectrum of pier P1.

(a) The measuring point S1 (b) The measuring point S3

Figure 3. Time-frequency representation of acceleration response at pier P1.

The acceleration response of pier P1 is analyzed using WSST, as shown in Figure 3, and the wavelet ridges can be easily observed. As the vehicle passes through the bridge, the wavelet

coefficient of the response of measuring point S1 only peaks in the low frequency band, while the peak value also appears in the high-frequency band (20~30Hz) for point S3. When the vehicle is far away from the pier P1 (0~10s), the wavelet ridge is relatively stable. When the vehicle travels near the pier P1 (10~15s), the wavelet ridge fluctuates significantly and multiple adjacent ridge appear. This is because that random wheel force acts on the adjacent spans of the pier P1 and stimulates the complex vibration mode. In the free vibration stage of the pier after the vehicle leaves (18s later), the wavelet ridge becomes stable again and gradually becomes unobservable. In addition, there is a ridge corresponding to a frequency of about 3 Hz during the vehicle passing phase, it is reasonable to speculate that this is an additional frequency caused by vehicle vibration.

The IF of piers is extracted using the dynamic response of measuring point S3 based on the method proposed in Section 2. Taking the dynamic response of pier P1 in the vehicle passing phase as an example, the extracted IFs is shown in Figure 4. The kernel density estimation is shown in Figure 5, and the normal distribution of each order frequency are shown in Figure 6.

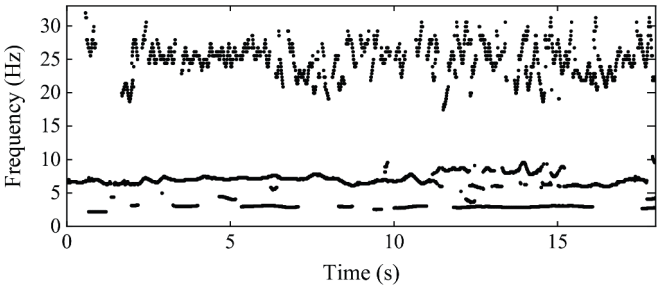

Figure 4. The IFs extracted from dynamic response of measuring point S3 in the vehicle passing phase.

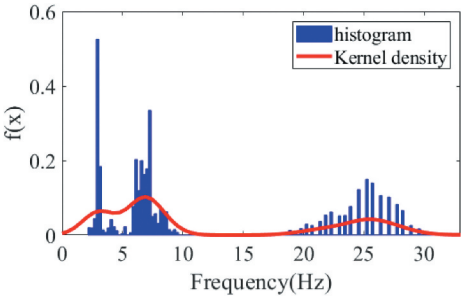

Figure 5. The kernel density estimation of Ifs.

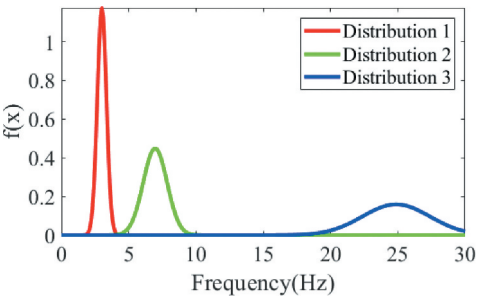

Figure 6. The normal distribution of each order IF.

The proposed scour diagnostic method can be indirectly verified using field tests on bridge piers P1 and P2. The piers of this bridge have not experienced the scour process, but the height difference between piers P1 and P2 is 1.75m. That is, pier P2 can be approximately regarded as the state after pier P1 has been scoured by 1.75m. The scour indicator *SI* is calculated using the passing phase response of measuring point S3, as shown in Table 1. Table 1 shows that the *SI* corresponding to the second-order and third-order frequencies change significantly, and the high-order frequency of the pier is more sensitive to scour. The first-order frequency is the vehicle frequency and cannot be used to identify scour, which is understandable.

Table 1. Scour indicator extracted from response during vehicle passing phase.

scour indicator	First-order frequency		Second-order frequency		Third-order frequencies	
	P1	P2	P1	P2	P1	P2
μ	3.00	3.14	6.96	6.32	24.88	19.06
μ-0.5σ	2.84	2.86	6.52	5.92	23.62	16.74
μ+0.5σ	3.17	3.42	7.41	6.73	26.13	21.38

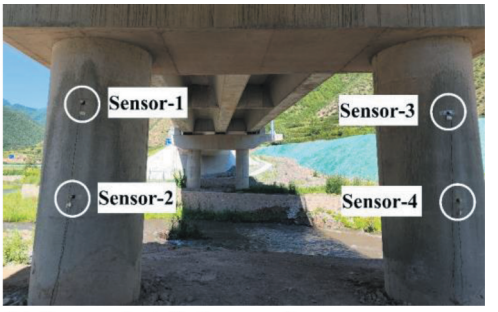
Table 2. Scour indicator extracted from attenuation response after vehicle leaving.

Scour indicator	First-order frequency		Second-order frequency		Third-order frequencies	
	P1	P2	P1	P2	P1	P2
μ	—	—	6.58	6.46	24.83	18.22
μ-0.5σ	—	—	6.47	6.30	23.26	16.37
μ+0.5σ	—	—	6.69	6.61	26.40	20.07

In order to compare the difference in pier response between the vehicle passing phase and the leaving phase, the extracted *SI* using free attenuated vibration is shown in Table 2. It can be found that in Table 2, the first-order frequency has not been identified, which again indicates that this frequency is caused by vehicles. The *SI* in Table 1 and Table 2 are not completely consistent, possibly due to random vibration of the piers and data processing errors. In addition, the change of *SI* corresponding to the second-order frequency in Table 2 is significantly smaller than that in Table 1. This may be because of the support constraints, the overall pier-beam coupled vibration accounts for the main part of the pier attenuation signal, resulting in the similarity of low-frequency vibrations for two piers.

In summary, the above results indirectly verify the effectiveness of the proposed scour diagnostic method. It should be emphasized that the mean value μ is not the exact pier frequency, but reflects the influence of foundation scour on the dynamic characteristics of the pier.

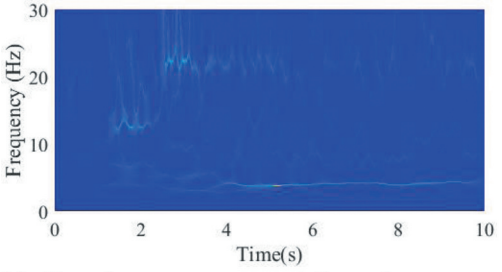
3.2 *Case study II- Yangsha Bridge*



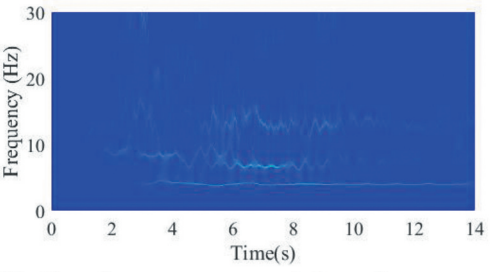
Yangsha Bridge is a new three-span concrete continuous girder bridge in Gannan, China, with each span being 30m long. The bridge piers are double-column bent piers, as shown in Figure 7(a). On-site measurement shows that the heights of piers P1 and P2 are 3.85m and 3.55m respectively, the pier diameter is 1.4m. Four acceleration sensors were installed on the piers to measure longitudinal vibration, as shown in Figure 7(b). The sensors are symmetrically installed on two columns, 1m and 2.8m away from the pier top respectively. Since there is a river between piers P1 and P2, the tests of two piers are not conducted at the same time, that is, the vibrations of the two piers are excited by different vehicles. The bridge was open to traffic during the test, and some small vehicles passed through the bridge.

The acceleration response of piers is analyzed using WSST. For piers P1 and P2, a segment of the acceleration signal when a vehicle passes through was intercepted, and its time-frequency representation are shown in Figure 8. It can be found that, except that pier P1 has an extra ridge in the frequency band near 20Hz, the ridges in Figure 8 (a) and (b) appear in similar frequency bands. This is because the heights of piers P1 and P2 are basically the same, so the dynamic characteristics also similar.

The scour indicators extracted from the above signals are listed in Table 3. Combined with Figure 8, it can be inferred that the first-order frequency is the pier-beam coupling vibration



(a) Overview of the Yangsha Bridge



(b) Sensors installation on site

Figure 7. Overview of field test.

Figure 8. Time-frequency representation of acceleration response.

frequency and is insensitive to changes in the pier state. The second and third order frequencies of pier P1 are slightly smaller than pier P2, which may be because pier P1 is 0.3m higher than pier P2. The above results show that the proposed method can better estimate the statistical characteristics of the pier's instantaneous frequency under the excitation of small vehicles, and can also accurately diagnose scour.

Table 3. Scour indicator extracted from dynamic response during vehicle passing phase.

scour indicator	First-order frequency		Second-order frequency		Third-order frequencies	
	P1	P2	P1	P2	P1	P2
μ	3.89	3.99	7.69	7.75	13.02	13.46
μ-0.5σ	3.57	3.94	7.48	7.29	12.70	12.94
μ+0.5σ	4.20	4.04	7.90	8.21	13.34	13.98

4 SUMMARY AND CONCLUSION

In this study, a scour diagnostic method of pile foundation based on time-varying frequency was proposed. Since it is difficult to observe the significant scour development in a short time and soil excavation in the field is not permitted, the proposed method was indirectly studied and verified by comparing experimental results of piers with different heights. Ignoring the difference between soil and pier properties, bridge scour mainly causes the free length of the

pier to increase, so the indirect verification method used has a certain rationality. The conclusion is as follows:

1. The scour indicator constructed based on the statistical characteristics of instantaneous frequency of the pier is very sensitive to the change of pier free length, especially the high-order frequency. The result indirectly verified the sensitivity of the proposed indicator to bridge scour.
2. For the tested continuous girder bridge, the free attenuated vibration of the pier after the vehicle leaves was controlled by the pier-girder coupled vibration mode, resulting in the low-frequency component of the pier vibration being less sensitive to scour.
3. For short and medium-span bridges, effective vibration signals can be collected through short-term field tests under the excitation of small moving vehicles.

The field cases used in this study have not experienced real scour development process, so the proposed method cannot be directly and completely verified. In the future, a refined bridge finite element model should be established to conduct in-depth research on the impact of moving vehicles on the instantaneous frequency of bridge piers, and to numerically verify the proposed method. In addition, a real field scour development case should be found to directly and completely validate the proposed method.

Nagoya Industrial Science Research Institute, Nagoya, Japan

ABSTRACT: Thickness measurement is essential to precisely assessing the condition of corroded steel structures. Ultrasonic testing method (UT) which is widely used in the current practice is not possible to measure a large area efficiently because surface treatment is necessary before the measurement. In this research, the pulsed eddy current (PEC) thickness measurement method is studied, which can measure thickness efficiently without the surface treatment since this method uses the magnetic field and induced eddy currents. The accuracy of this method is examined by measuring the thickness of a naturally corroded steel pipe pile cut out from a port facility, and compare the measured results with those by UT method and a 3D laser scanning method. As a result, it was found that PEC can identify an average thickness of a footprint area within ±10% error.

1 INTRODUCTION

1.1 *Background*

Maintenance and management of existing civil infrastructures are one of the challenging problems that civil engineers have to tackle. In Japan, there are many steel structures such as port facilities and highway bridges. In order to keep those steel structures in a healthy condition, it is important to find damage and deterioration and repair them before it becomes a severe risk.

One of the major deterioration factors in steel structures is corrosion. Since a cross sectional area of steel members will be reduced by corrosion, which leads to a decrease in load carrying capacity, a thickness measurement of steel plate is necessary for an inspection of a steel structure to identify a degree of corrosion. Currently, the ultrasonic testing method (UT) is the most popular thickness measurement method in the inspection. Although UT would yield an accurate measurement, a surface preparation to remove surface coating and rust is needed, which requires time and resources. Therefore, more efficient ways of measuring steel thickness are desired.

In this study, the pulsed eddy current testing method (PEC) (Robers and Scottini 2002, Lozev et al. 2005, Crouzen and Munns 2006, Park et al. 2013, Kitane et al. 2014, Kitane et al. 2016) is studied. Since PEC does not require the surface preparation, it may be a very efficient thickness measurement method in the inspection. PEC has been used to detect corrosion in pipelines, risers, and port structures. Since the measured thickness by PEC is considered to be an average thickness of a certain area called "footprint", it is usually used in a screening process, and a more accurate measurement is usually conducted by removing surface coating and rust if corrosion is detected by PEC.

1.2 *Objectives*

The objective of this study is to investigate the accuracy of PEC thickness measurement method by measuring the thickness of naturally corroded steel pipe pile cut out from a port facility and comparing the measured results with those by UT method and a 3D laser scanning method.

2 METHODOLOGY

2.1 *Measured pipe pile*

In this study, a 1,000 mm length of a corroded steel pipe pile as shown in Figure 1 was used, which was cut out from a port facility after 38 years of service and kept for 8 years in the laboratory. The original outer diameter and thickness of the pipe pile are 318 mm and 10.3 mm, respectively. Before the thickness measurement in this study, all corrosion products were removed by sand blasting. As shown in Figure 1, grid lines were marked at intervals of 25 mm in the height direction and 11.25 degrees in the circumferential direction.

Figure 1. Measured pipe pile.

2.2 *Pulsed eddy current testing method*

2.2.1 *Measurement principle*

PEC is a thickness measurement method by utilizing the diffusion process of eddy currents as shown in Figure 2. A measurement device consists of a probe and a data logger. A probe houses transmitter coils and receiver coils. Firstly, a pulse type current is input to the transmitter coils which creates a magnetic field. After the current is shut down, a sudden change of a magnetic field induces eddy currents on the surface of a steel plate due to the electromagnetic induction. As shown in Figure 2, eddy currents diffuse in the steel plate and infiltrate in the thickness direction as the magnitude of eddy currents attenuates over time. When eddy currents reach the back side of the steel plate, eddy currents decay significantly. The magnetic field induced by this eddy current is detected by receiver coils in the probe. A time history of the voltage signal obtained by receiver coils is shown in Figure 2, where the signal linearly attenuates as eddy currents diffuse in the thickness direction, and it is significantly reduced when eddy currents reach the bottom of the steel plate. This attenuation of the voltage signal can be expressed in Eq. (1) (SHELL Global Solutions 2004, van den Berg 2003).

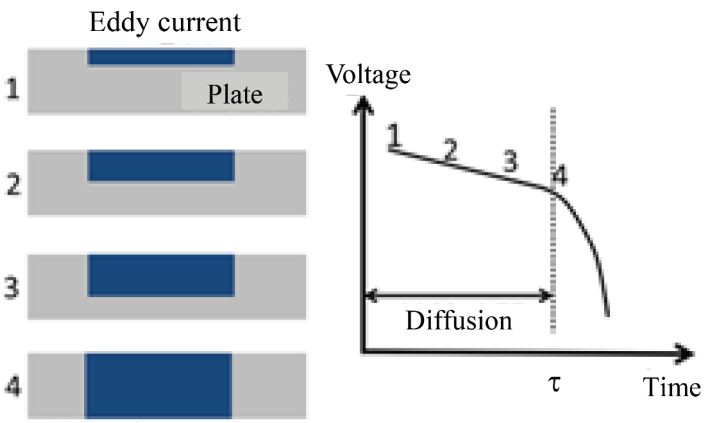
$$V(t) = A \times \begin{cases} t^{-n} & \text{for } t \le \tau \\ \tau^{-n} exp\left(-n\frac{t-\tau}{\tau}\right) & \text{for } t > \tau \end{cases} \quad (1)$$

where, A is an amplitude parameter, n is a slope parameter, t is time, and τ is the ending time of diffusion. τ can be expressed by Eq. (2).

$$\tau = \mu\sigma d^2 \quad (2)$$

where d is a thickness of steel plate, and μ and σ are permeability and conductivity of steel. Therefore, when the diffusion time τ_{ref} of a reference plate with a thickness of d_{ref} is known, a thickness of steel plate d can be estimated by using the obtained diffusion time τ as follows:

$$d = d_{ref}\sqrt{\frac{\tau}{\tau_{ref}}} \quad (3)$$



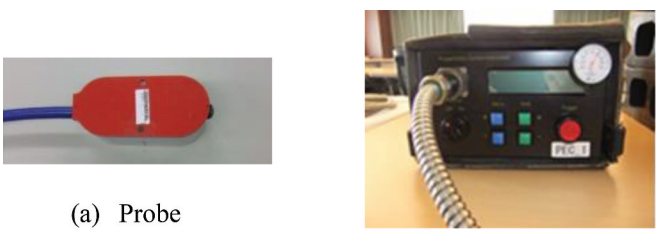


Figure 2. Diffusion process of eddy currents and induced voltage in receiver coils.

(a) Probe

(b) Data logger

Figure 3. PEC measurement device.

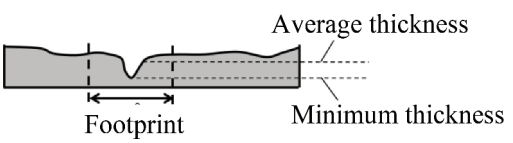

Figure 4. Average thickness of a footprint with a pitting corrosion.

Since a thickness measured by PEC is said to be an average thickness of a footprint, it is difficult to identify a deep pitting corrosion. Figure 4 shows an average thickness of a footprint with a pitting corrosion. Therefore, it is important to understand the accuracy of thickness identified by PEC when an actual corroded plate is measured.

2.2.2 *Measurement method*

In this study, a reference point where corrosion is minimal was selected and a thickness of the reference point and a diffusion time of PEC signal were identified. Thicknesses of other locations were identified by PEC by using Eq. (3). Since the footprint area is dependent on a liftoff which is a distance from the bottom of the probe to the bottom surface of steel plate, two liftoff values were used: 6 mm and 20 mm. Measurement locations of PEC are shown in Figure 5 for two different liftoffs. Figure 6 shows how PEC measurement was conducted on the corroded steel pipe pile.

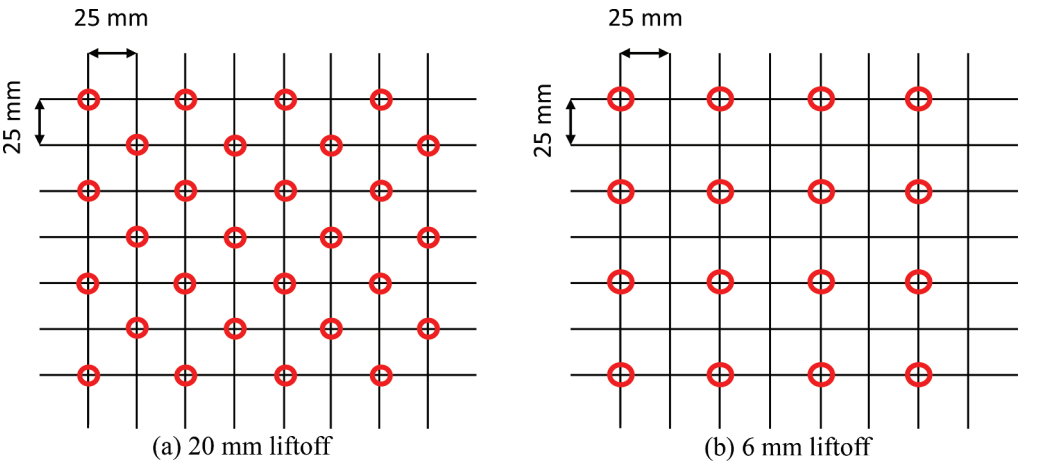

Figure 5. PEC measurement locations.

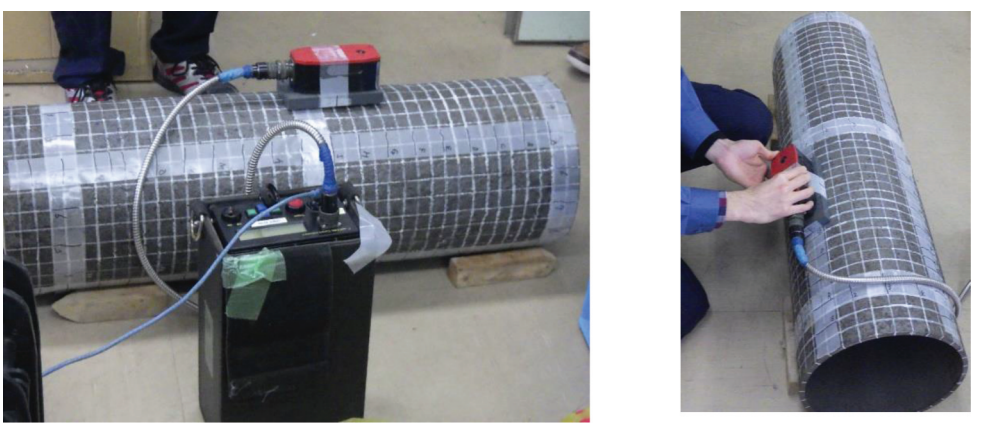

Figure 6. PEC measurement.

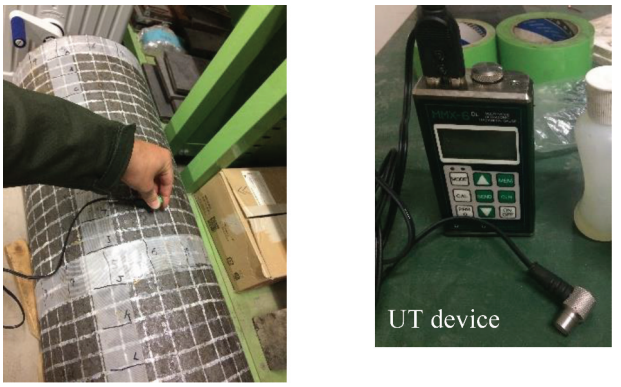
2.3 *Other thickness measurement methods*

2.3.1 *Ultrasonic testing*

Ultrasonic testing (UT) is one of the most popular method for a thickness measurement in the inspection of steel structures. In this method, a plate thickness is measured based on a travel

time of a sound pulse which travels through the thickness and reflects back from the bottom of a plate. UT can accurately measure a thickness when there is no corrosion product or coating on the surface of a plate, and the surface roughness may affect the accuracy. Therefore, surface preparation is necessary before UT thickness measurement.

In this study, UT thickness measurement was conducted by using MMX-6DL (Dakota Ultrasonics). A thickness was measured at the intersection of grid lines shown in Figure 1, and three measurements were taken at each point. Figure 7 shows UT measurement. The thickness profile by the UT measurement is shown in Figure 8(a), which shows an average thickness of three measurements at each point. The maximum, minimum, average, and standard deviation of thickness for the pipe are 10.99 mm, 5.24 mm, 9.14 mm, and 1.16 mm, respectively. In addition, Figure 8(b) shows a standard deviation of three thickness measurements at each point. The maximum and average values of standard deviations are 3.07 mm and 0.21 mm, respectively. Based on the observation, a standard deviation of three measurements is large at deep pitting corrosion. Therefore, the measurement accuracy is not high at those locations.



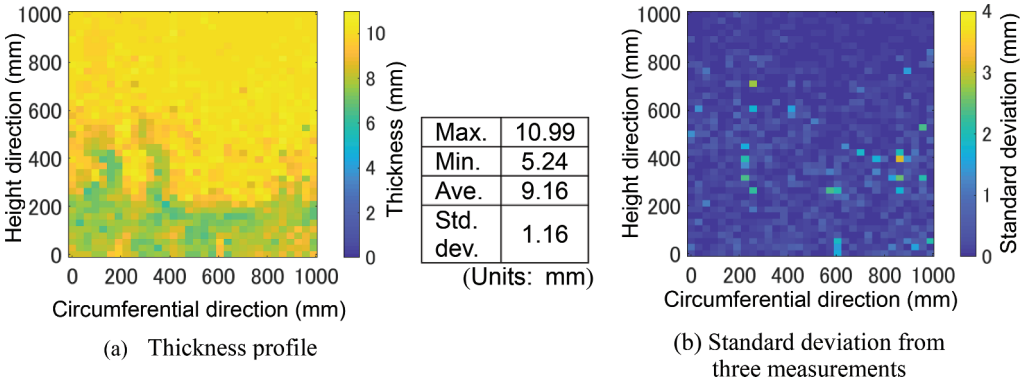


Figure 7. UT measurement.

(a) Thickness profile

(b) Standard deviation from three measurements

Figure 8. Thickness measurement results by UT.

2.3.2 *3D laser scanning*

To create an accurate 3D model, a 3D laser scanning was conducted at 0.1 mm intervals on the corroded pipe pile by using FARO Edge Scan Arm HD. The obtained 3D model is shown in Figure 9. A thickness was calculated as a distance between the outer surface and the inner surface. However, the arm of a 3D laser scanning device was not long

enough to measure the inner surface near the center of the pipe from 250 mm to 750 mm in the height direction. By examining the surface profile of the inner surface where measurement data were obtained, it was found that there is not much surface roughness by corrosion on the inner surface; therefore, the inner surface data were interpolated between 250 mm and 750 mm. In addition, the surface profile data were not obtained at some locations where surface profile changes abruptly. Examples of those locations are shown in Figure 10. In this study, thicknesses obtained by the 3D laser scanning are assumed to be the most accurate data. The identified thickness profile by the 3D laser scanning is shown in Figure 11. Based on the identified thickness data, the maximum, minimum, average, and standard deviation of thickness of the pipe are 10.56 mm, 5.08 mm, 8.56 mm, and 1.26 mm, respectively.

Ave.	8.56
Std. dev.	1.26

(Units: mm)

Figure 11. Thickness profile by 3D laser scanning.

3 RESULTS

3.1 *Thickness measurement by PEC*

Figure 12 shows thickness measurement results by PEC for both 20 mm and 6 mm liftoffs. The thickness was identified by Eq. (3), and a thickness of the reference point measured by 3D laser scanning was used. The maximum, minimum, average, and standard deviation of thickness of the pipe are 9.87 mm, 6.23 mm, 8.62 mm, and 1.07 mm, respectively for a 20 mm liftoff, and 9.95 mm, 6.19 mm, 8.77 mm, and 1.03 mm, respectively for a 6 mm liftoff.

The maximum thickness with a 6 mm liftoff was larger by 0.08 mm than that with a 20 mm liftoff, implying that the footprint of a 6 mm liftoff was smaller and the measurement with a smaller footprint can reflect surface roughness better.

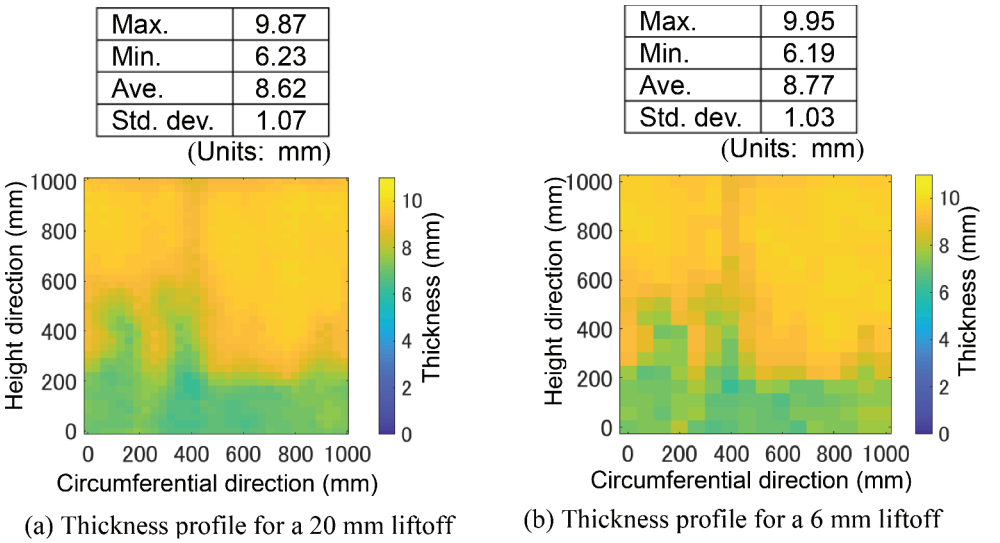

Figure 12. Thickness measurement results by PEC.

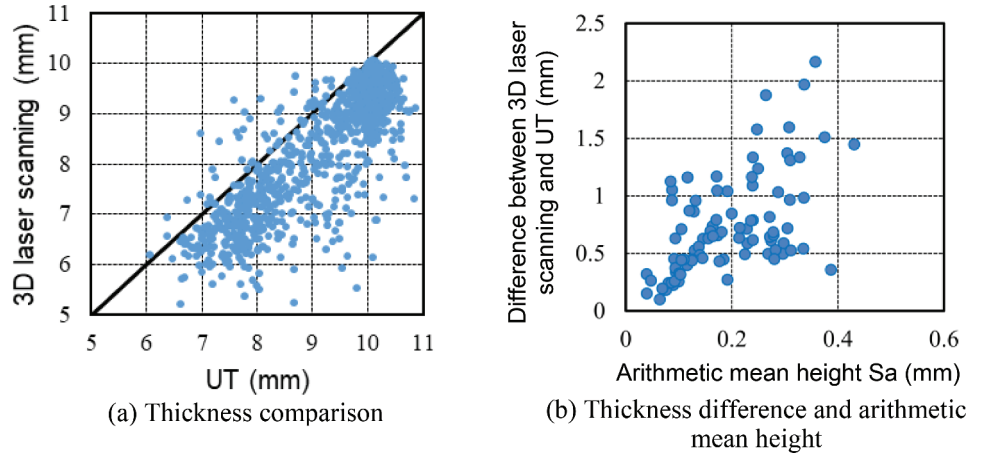
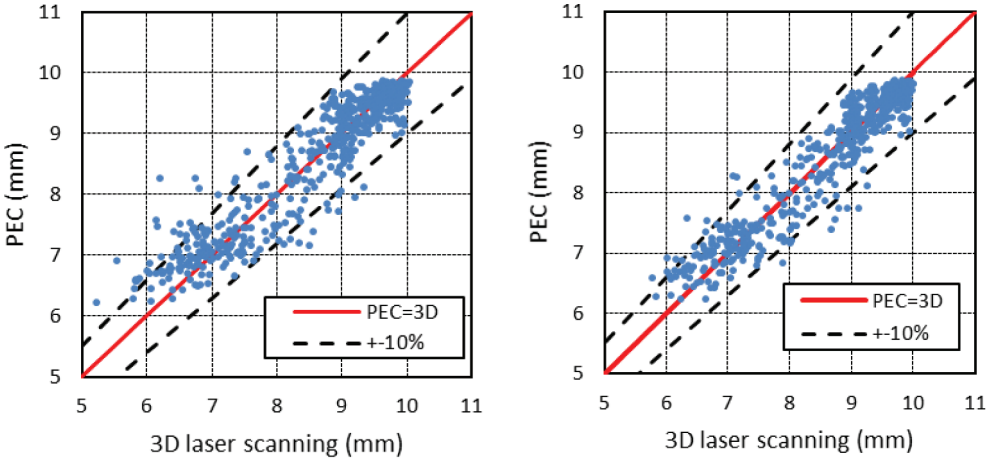


3.2 *Comparison between UT and 3D laser scanning*

A comparison of thicknesses measured by 3D laser scanning and UT is shown in Figure 13(a). It can be observed that the UT thickness is larger than the thickness by 3D laser scanning. To see the effect of surface roughness on the UT thickness measurement, a difference between 3D laser scanning thickness and UT thickness and arithmetic mean height *Sa* is compared in Figure 13(b). As can be seen in Figure 13(b), the difference becomes greater with the surface roughness, implying that UT thickness measurement will be affected by the surface roughness because a travel time of sound pulse includes both steel plate and couplant.

3.3 *Comparison between PEC and 3D laser scanning*

Empirically, a footprint size is equivalent to a distance from the bottom of probe to the bottom of steel plate (SHELL Global Solutions 2004). Figure 14(a) shows a comparison of PEC thickness with a 20 mm liftoff and 3D laser scanning thickness, where a thickness value of 3D laser scanning is an average value in the footprint assuming a circle with a diameter of 30.3 mm (20 mm liftoff + 10.3 mm). Among all measured data, 93.2% of data are within ±10% error, and the maximum and average difference are 33.8% and 3.8%, respectively.



Ando et al. (2016) examined a footprint size for a 20 mm liftoff and recommended a circle with a 100 mm diameter. Figure 14(b) shows a comparison of PEC thickness with a 20 mm liftoff and

(a) Thickness comparison

(b) Thickness difference and arithmetic mean height

Figure 13. Comparison of 3D laser scanning and UT.

(a) Thickness comparison assuming a footprint of a 30.3 mm diameter circle

(b) Thickness comparison assuming a footprint of a 100 mm diameter circle

Figure 14. Comparison of 3D laser scanning and PEC with a 20 mm liftoff.

3D laser scanning thickness, where a thickness value of 3D laser scanning is an average value in the footprint assuming a circle with a diameter of 100 mm. In this case, 96.6% of data are within ±10% error, and the maximum and average difference are 19.6% and 3.2%, respectively.

4 CONCLUSIONS

Based on a comparison PEC thickness measurement for a corroded pipe pile and UT or 3D laser scanning, characteristics of PEC thickness measurement data can be summarized as follows:

(1) UT thickness measurement results tend to be greater than thicknesses determined by 3D laser scanning when there is a surface roughness due to corrosion. The difference between UT and 3D laser scanning becomes larger with the surface roughness.

(2) By comparing PEC thickness measurement data of a corroded pipe pile with a 20 mm lift-off and average thickness values over a footprint area of circle with a 100 mm diameter based on thickness values by 3D laser scanning, it was found that 96.6% of data are within ±10% difference, and that the average difference is 3.2%. Therefore, when a 10% error is allowable, PEC thickness measurement can be a very efficient thickness measurement method in the inspection of steel structures.

Ground Penetrating Radar (GPR) for bridge inspection

Nzeeh Roumia & Claudio Mazzotti
DICAM Department, University of Bologna, Bologna, Italy

ABSTRACT: Bridge inspection plays a crucial role in providing bridge operators with an overview of their infrastructure's current condition, enabling them to extend their service life. This is even more important since a significant number of bridges were constructed after World War II with few comprehensive documents regarding their construction, for example blueprints. In such cases, non-destructive testing (NDT) methods can be employed to investigate the structure without causing damage. Among the widely utilized NDT methods, Ground Penetrating Radar (GPR) stands as one of the most widely used methods to localize reinforcement and prestressing strands, thanks to its efficient acquisition capabilities that are characterized by the speed in performing the acquisition and the instantaneous visualization of results. However, due to the inherent complexity, the use of GPR requires qualified and experienced users to obtain high-quality survey data.

To assess the capabilities and limitations of GPR, experimental reinforced concrete beams were casted to simulate real-life scenarios. Plastic and metallic tendon ducts were used, and variable spacing between stirrups was adopted. Surveys were conducted using 2GHz bipolar GPR unit, and grid scans were used to maximize the benefit of the GPR. This study presents interesting results in terms of determining the concrete cover, rebar spacings, and the position of tendon ducts accurately. These findings hold significant value for structural engineers who would like to use GPR, especially for bridge inspection applications.

1 INTRODUCTION

The early years after the World War II marked a crucial phase in the infrastructure development worldwide and in Europe particularly due to the urgent need at that time to rebuild what was destructed and to maintain what left. Therefore, extensive reconstruction campaign started to rebuild the infrastructure such as highways, railways and bridges to connect vital centers, ultimately resulting in the reconstruction of cities and towns that facilitated economic growth.

Actually, most of those infrastructures have reached the end of their service life (Invernizzi et al., 2022). Concurrently, the improper maintenance and overloading through the time accelerated the deterioration process and pushed the structures, bridges specifically, to near ultimate limit state and reduced their capacity significantly, leading to unforeseen collapses in numerous cases (Zhang et al., 2022).

Therefore, periodic visual inspection is necessary to verify the current state of bridges in addition to defining the visible defects as spalling, high humidity regions, corrosion and various other defects, together with the extension and intensity of each defect (CSLLPP, 2020). Nevertheless, relying solely on visual inspections proves insufficient for understanding what lies beneath the external surface. To gain insights into the internal structure without causing damage, it becomes important to use alternative methods. Using non-destructive testing methods (NDT) is an optimal solution in this context which could provide an overview about the subsurface (Dinh et al., 2021).

Among many different methods, Ground Penetrating Radar (GPR) demonstrate its effectiveness as a non-destructive method. Its high acquisition speed and immediate visualization of the results contribute the most to the on-site evaluation ensuring a high reliability.

DOI: 10.1201/9781003483755-430

In civil engineering, Ground Penetrating Radar is traditionally used to identifying reinforcement in slabs, beams and columns in addition to determining the spacing between rebars and concrete cover. This enables structural engineers to compare the actual project conditions with the design specifications or to reconstruct the drawings if they are not documented.

This study examines the capacity of bipolar GPR system with 2GHz central frequency in detecting commonly used components in post-tensioned bridges, for instance longitudinal rebars, stirrups and tendon ducts made of different materials like steel and plastic. Interruptions were introduced to the steel ducts body to simulate real damaged tendon ducts.

2 INSTRUMENT

The used GPR unit is bipolar unit which means that it has two distinct antennas, namely one for the shallow inspection (HH) and one for deeper inspection (VV). Both antennas have a central frequency of 2GHz, being the only difference the polarization; in other words, one of the antennas is parallel to the scanning direction and the other is perpendicular to it. The distance between the two centers is (10 cm) as depicted in Figure 1. The GPR unit is equipped with a touch screen allowing the user to customize the scanning parameters, the propagation velocity for instance, and to display the results in real time while taking measurements (IDS, 2022). Each antenna has an independent acquisition channel, providing independent results such as A-scans and B-scans which can be later merged in post-processing to provide consistent scanning outcomes.

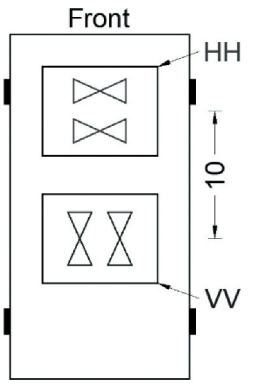

Figure 1. Antennas positioning and orientation (polarization) inside the GPR unit.

3 TESTING SAMPLES

Two different testing samples were constructed. The first reinforced concrete sample has the dimensions of 220×65×30 cm^3 (L×H×W). Plastic tendon ducts with nominal diameter of (6 cm) were used and positioned at different depths from the external surfaces. The second specimen has the dimensions of 160×65×30 cm^3 and steel tendon ducts with nominal diameter of (5.5 cm) were used. Intentional interruptions, partial and complete, were made along some tendons only in the second specimen, to simulate potential defects (strong corrosion) in the duct's structure. All the ducts were empty: no steel strands not injection mortar inside them.

The steel reinforcement cage consists of four longitudinal rebars with a diameter $\phi = 10$ mm (Ø10), while transversal reinforcement consists of stirrups with a diameter $\phi = 8$ mm (Ø8). The spacing between stirrups is not uniform, ranging from 5 to 20 cm. Figure 2 shows the blueprint of the aforementioned specimens and snapshots taken during the construction phase, showing the steel cage and the ducts. Compression tests were performed on cylindrical specimens to estimate the concrete compressive strength at 28 days, resulting $f_c' = 24.3MPa$.

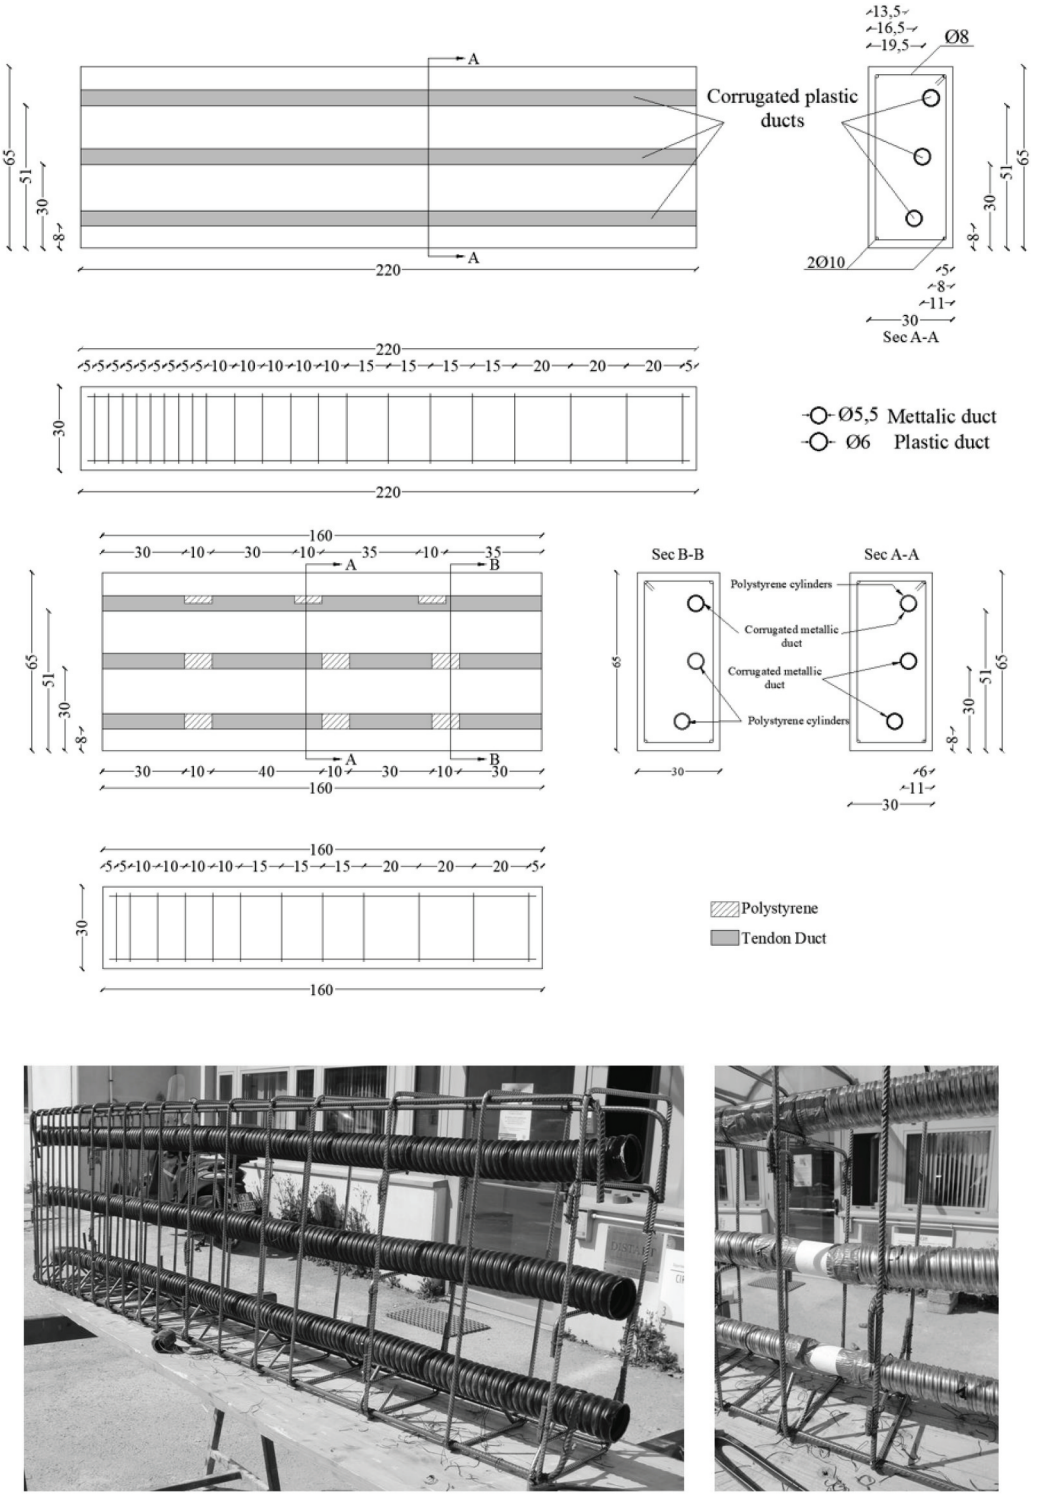

Figure 2. Reinforced concrete testing samples.

4 RESULTS

4.1 *Detection of stirrups*

Figure 3 illustrates a standard B-scan derived from the HH channel and captured along the beam length of 220 cm. It displays the direct wave as two continuous white and black strips, along with hyperbolas that depict the presence of stirrups. The apex of the hyperbola accurately corresponds to the correct location and depth of the stirrup when the velocity is appropriately calibrated. The estimated propagation velocity is determined to be 12.5 cm/ns, calibrated through synthetic hyperbola fitting. It is worth mentioning that post processing is important to enhance the image quality and reveal the deep reflectors.

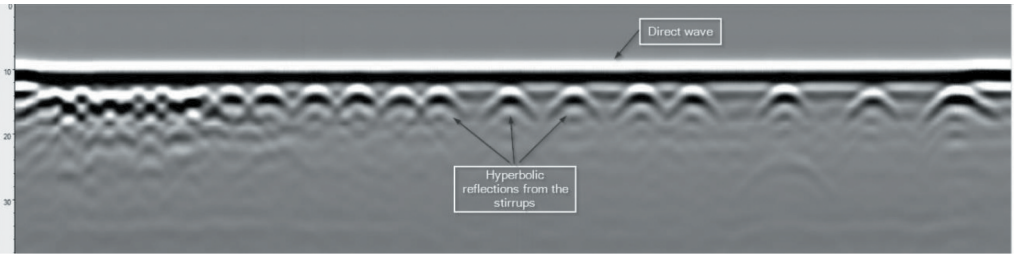

Figure 3. Typical B-scan without processing for the beam with plastic ducts.

GPR demonstrated effectiveness in identifying stirrups when the distinct spacing between two consecutive stirrups exceeded 5 cm, as illustrated on the right side of Figure 3. However, it is challenging to define a clear hyperbolic shape when the spacing is less than 5cm, leading to the stirrups appearing merged as a continuous line. The small spacing made it difficult for electromagnetic waves to penetrate, resulting in the occurrence of multiples reflections named the ringing effect. It is worth mentioning that the dimension of 5 cm (stirrups clear spacing) is less than the theoretical value of the lateral resolution of GPR. In fact, the electromagnetic wave theory leads to the following expression for the lateral resolution (Schwamborn et al., 2002):

$$\Delta x = \sqrt{2\lambda h}, \tag{1}$$

where λ is the wave length and can be calculated as the following:

$$\lambda = \frac{v}{f} = \frac{12.5}{2} = 6.25\ cm \tag{2}$$

and h is the depth of the target from the scanning surface, which is 2.2 cm in the present case. That gives a value of $\Delta x = 5.2\ cm$, making it the limit to the horizontal resolution in our case study. The theoretical value gives an insight to the limited clarity of GPR in detecting the stirrups with less than 5 cm clear spacing.

GPR signals has an oscillating nature forming positive and negative parts. each of the single scans is called A-scan or a trace. Studying each signal without considering the neighboring traces is not sufficient to understand the medium under investigation. Therefore, combining multiple A-scans into a 2D image or B-scan is commonly used to present the results offering a more comprehensive understanding. Combining B-scans gives another dimensionality obtaining 3D representation of the subsurface. Slicing the 3D data horizontally generates C-scans or time slices (Utsi, 2017).

In this study C-Scan Figure 4 is generated by merging various B-scans captured from two orthogonal directions and utilizing both antennas (HH and VV). This image offers a clearer understanding of the distribution of reinforcement and of the arrangement of the steel cage. However, it is important to note the presence of artifacts between the stirrups due to the limitation of certain postprocessing techniques such as migration, where the reflected wave energy

should ideally be focused in one point instead of being spread all over the hyperbola's length (Özdemir et al., 2014).

Therefore, it is always crucial to examine the B-scans concurrently with the C-Scans for a comprehensive assessment.

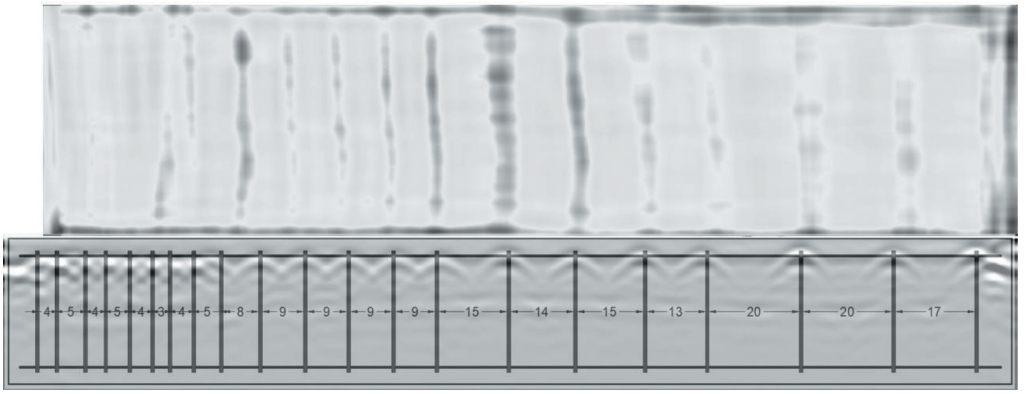

Figure 4. C-scan at the level of stirrups.

4.2 *Detection of tendon ducts*

Tendon ducts are typically located at considerable depths from the surface. Conducting a thorough inspection that involves coring at the precise locations of these ducts requires accurate information about their depth and position. Achieving this level of precision is a challenging task for traditional non-destructive methods, such as eddy currents. Therefore, the use of unconventional methods like GPR or Ultrasounds becomes essential.

Performing GPR scans along the height of the testing specimens (65 cm) successfully revealed the presence of the three tendon ducts Figure 5, Figure 6, even when having plastic ducts which is not a perfect reflector material to electromagnetic waves. Furthermore, attenuation is evident when the scans are conducted from the two accessible faces. For example, Figure 5 compares two B-scans performed on parallel scanning lines from the two opposite surfaces. In the first case, all TDs exhibit weak reflection compared to the second case because they are at greater depths. Furthermore, wider hyperbolas correspond to the first case (deep reflectors), while narrower hyperbolas correspond to the second case (shallow reflectors).

In the second testing specimen, steel empty ducts were used, which makes them perfect reflectors to EM waves due to the infinite value for the dielectric constant, while the interruptions were made by using polystyrene cylinders that have a dielectric constant ε_r = 206, making it more challenging to detect them by using GPR. Concrete dielectric constant is estimated using the following formula:

$$\varepsilon_r \cong \left(\frac{c}{v}\right)^2 = \left(\frac{30}{12.5}\right)^2 = 5.76 \tag{3}$$

Where c is the light propagation velocity in the vacuum, and v is the EM wave propagation velocity in concrete. It is worth mentioning that there is a strong correlation between ε_r and the moisture content (MC) in concrete, higher moisture content leads to higher dielectric constant and lower propagation velocity and vice versa (Soutsos et al., n.d.).

Two scans were conducted on the second specimen, as shown in Figure 6. In the first scenario, where the ducts are continuous without interruption, the corresponding B-scans shows the ducts clearly. On the other hand, polystyrene cylinders are not present in the corresponding B-scan due to the minimal difference in dielectric property between concrete and polystyrene. However, the unrepeated pattern of hyperbolas between the scans informs the inspector about the presence of the anomaly. In the case of partial interruptions, GPR could not detect the interruption.

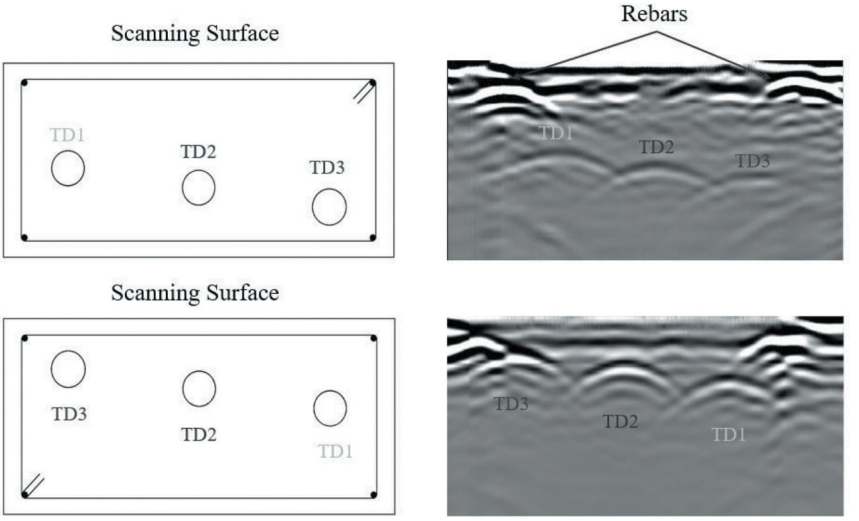

Figure 5. Typical B-Scan revealing the empty plastic tendon ducts.

Analyzing the scans performed on both specimens, it can be observed that signals from steel ducts have higher amplitudes with respect to plastic ducts, as expected. In addition, the type of wave reflected from the ducts depends on their material; in more details, for the plastic ducts, the reflected wave is made of black-white-black (B-W-B) bands; on the contrary, in the case of steel ducts, the reflection polarity is completely inverted (W-B-W). This characteristic property is an indicator to the reflector's material as metallic, such as steel tendon ducts, or non-metallic, such plastic ducts or air gaps (Kavi & Halabe, 2023). This is attributed to the different reflection factor R between the two different materials plastic and steel. R is calculated as the following simplified formula:

$$R \cong \frac{Z_2 - Z_1}{Z_2 + Z_1} \tag{4}$$

Where Z is the electromagnetic impedance of the material calculated using the simplified formula:

$$Z \cong \sqrt{\frac{1}{\varepsilon_r}} \tag{5}$$

Considering the first study case where we have plastic tendon ducts with ε_r=3, the reflection factor R=0.16. Following the same procedure for the steel reflector results in having R=-1. The negative sign from the steel refers to a change in the phase unlike the plastic or airborne reflectors.

Performing scans along the duct's length gives another perspective about the changes in the duct's structure and the duct's geometrical deformations, which might be challenging by performing scans in the orthogonal direction. Therefore, it is important to perform grid scans to obtain full awareness about what is hidden below the surface.

Figure 7 presents a comparison between HH and VV polarizations scans along the duct's length for the second specimen (steel ducts). The first observation is the misalignment in the X direction between the antennas, attributed to the physical separation between HH and VV antennas by 10 cm Figure 1. Additionally, both polarizations show the interruptions along the TD3 or the presence of the polystyrene cylinders. However, HH B-scan contains three hyperbolas corresponding to the interruption's positions while VV B-scan lacks these hyperbolas. Due to the wider illuminated area when using HH polarization, the edges of the steel duct before and after the polystyrene cylinder create half of the hyperbola. One the other hand the interruption size of 10 cm and the duct depth at 17 cm gives a lateral resolution of 14.5 cm calculated using

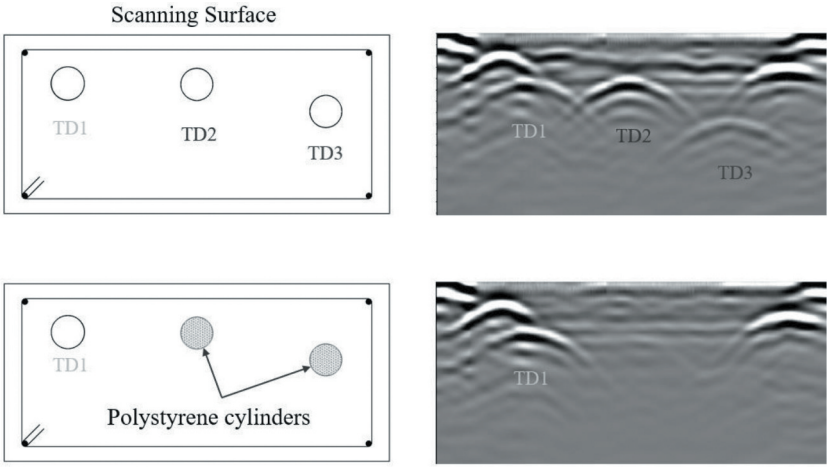

Figure 6. Comparison between B-scans showing steel ducts and polystyrene cylinders.

the equation (1), which is larger than the length of polystyrene cylinder. Consequently, the employed imaging technique combines the two parts of the hyperbola coming from two different reflectors generating one hyperbola as a strong reflector that has a reflected amplitude larger than the one coming from the steel duct itself as depicted in the right side of Figure 7.

In this case looking at the VV polarization resolves the uncertainties: there are no hyperbolas corresponding to the cylinders, as seen with the HH B-scan, and the signal phase is inverted at the position of the cylinders (change of the dielectric constant).

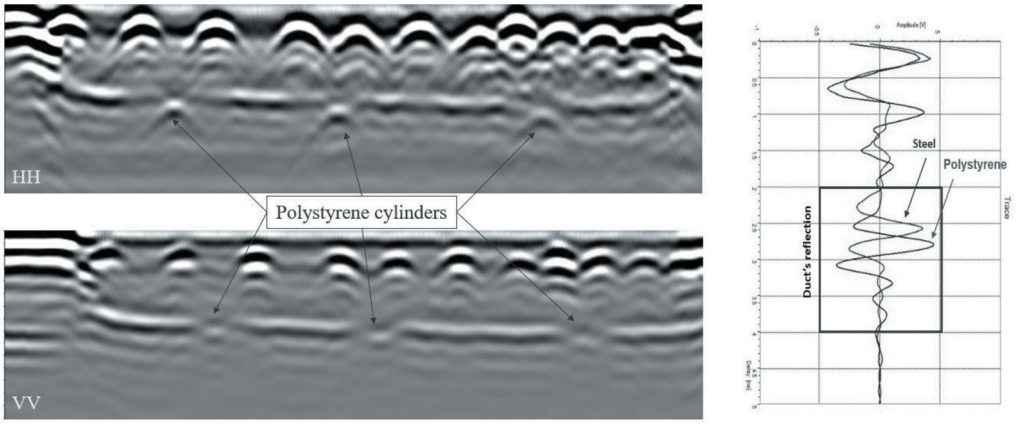

Figure 7. Comparison between HH and VV Polarizations.

5 CONCLUSION

The findings presented in this paper highlight the importance of high frequency GPR as non-destructive method in bridge inspections. The study demonstrated the capabilities of bipolar GPR unit in defining the internal composition of the testing specimens including longitudinal rebars, stirrups and tendon ducts, with high accuracy in terms of position, depth and material dielectric properties. Its high acquisition speed is a game changer onsite which gives the structural engineers an immediate overview about the scanned structural element helping to take

instant decisions. Additionally, Bipolar GPR unit saves time by conducting two scans at the same time, simultaneously collecting larger amount of information from the subsurface.

However, the challenge with GPR lies in interpreting the results as it could be misleading in certain cases. Grid scans would help in minimizing the uncertainty by providing a plan view of the scanned surface. Additionally, analyzing the B-scans from the two orthogonal directions along with C-scans is an important step to interpret the results correctly. On the other hand, better imaging techniques are needed to eliminate the artifacts. Since the electromagnetic waves cannot cross metallic reflectors such as the steel tendon ducts, filling the plastic ducts with mortar and tendons with different scenarios gives the chance to explore the GPR potentials in defects detection, which will be a continuation of the current research.

Advancements in bridges NDT: National Highways' "Structures Moonshot" – Paper No. 1

C. Mundell, C. Hendy & T. Argyle
AtkinsRealis, UK

C. George
National Highways, UK

ABSTRACT: The "Structures Moonshot" project, initiated by National Highways and led by Atkins, Jacobs, and supported by VSL, advances non-destructive testing (NDT) for highway structures, with a focus on post-tensioned bridges and half joints. Launched in late 2022 and continuing, its vision to revolutionise asset management for vulnerable bridges, enabling better and more efficient data collection, leading to self-monitoring and self-diagnosis for National Highways' most critical structures.

The project comprises two phases; The first involves testing high Technology Readiness Level (TRL) NDT technologies on bridge sections from the dismantled A14 Huntingdon Viaduct. These are compared with the as-found physical conditions after hydro-demolition. The goal is to evaluate current NDT methodologies, identify areas for improvement, and enhance efficiencies in deployment.

The second phase centers on developing low TRL NDT technologies tailored for post-tensioned bridges. This includes the use of guided wave technology, with the aims of enabling direct tendon deterioration measurements without intrusive inspections.

This paper will focus on the second aspect, being the low-TRL technologies. The Huntingdon Viaduct trials are documented in IABMAS Paper number 454.

Through the collaborative efforts involving National Highways, AtkinsRealis, Jacobs, VSL and the NDT supply chain engaged with the project, this work is leading to a better understanding of how we can determine the condition of post-tensioned bridges and half joints. The project will also provide valuable insights for future bridge inspections and structure maintenance works, enabling the development of clear training and guidance on optimal NDT deployment. This in turn will improve our overall asset management practices, ultimately leading to better safety of our structures and those using and maintaining them, and reducing disruption on our road networks.

1 INTRODUCTION

1.1 *Challenge*

Within the transport infrastructure sector, all asset owners face an ongoing challenge to both inspect, maintain and operate their asset stock, whilst maintaining the highest levels of customer service possible. These two drivers are interlinked; to provide a reliable level of service, the assets need to be well maintained and well-managed. However, this is becoming increasingly difficult; key UK bridge owner National Highways estimated that by the end of the decade, 57% of their bridge stock will be over 50 years old. This is coupled with increasing levels of traffic in terms of magnitude and vehicle weights, meaning our structures are under more stress but are also more difficult to inspect and repair due to the disruption associated

DOI: 10.1201/9781003483755-431

with road and lane closures. Whether a closure to inspect, maintain or repair a structure is planned or unplanned, the public and political impact can be substantial. For example, after routine inspections of the A52 Clifton Bridge in Nottingham, UK uncovered significant deterioration of post-tensioning strands at one location, the bridge was closed as a precautionary measure. This emergency closure lead to a spike in congestion and traffic that made it the most congested city in the world during this time (BBC News, 2020).

1.2 *Moonshot vision*

To face this challenge, National Highways have instigated a research programme they are calling their Structures 'Moonshot'. The underlying ambition of this is to maximise the benefits from advances in technology (e.g. new technologies, Artificial Intelligence and Machine Learning) to facilitate new and improved asset management approaches. The ultimate goal is to better understand the condition of our structures and facilitate interventions before deterioration has progressed to the point where major works are required.

By applying new and developing technology, the goal is to transform the management of our structures through accessing, piloting, deploying and upscaling technology. Improvements in processes and ways of working will impact on:

- Safety: minimising human intervention and improve road user safety
- Efficiency: Reducing costs from planned and unplanned closures and enabling more proactive maintenance
- Availability: minimising disruption to users and improving road user satisfaction
- Sustainability: Reducing congestion and delivering more sustainable and less intrusive asset management approaches

1.3 *Post tensioning and half joint focus*

National Highways' ambitious Moonshot project aims to consider all of the typically 'high risk' features associated with bridge structures, including post tensioning, half joints, hinge decks, scour and fatigue. In the first phase of this project, the team are investigating new approaches associated with internal post tensioning and half joints, of which there are approximately 1200 and 420 respectively within National Highways' jurisdiction in the UK (AtkinsRealis, 2023).

2 SPECIFIC CHALLENGES AND APPROACHES FOR POST TENSIONED BRIDGES

2.1 *Inspection challenges*

Both post-tensioned bridges and those with half joints provide a challenge for asset maintainers to inspect, assess and maintain. For post-tensioned bridges, this is primarily due to the primary load-bearing element typically being located within grouted ducts within the concrete volume and therefore inaccessible to most forms of inspection. For half joints, whilst the external façade of the joint can usually be inspected, the condition of the critical reinforcement along the joint length is often equally difficult to inspect without intrusive and damaging inspection.

The issue of inaccessibility is exacerbated when coupled with poor workmanship, poor detailing for water management or inferior construction techniques and materials. This can leave the tendons or half joints exposed to deterioration even in more recently-constructed structures. Whilst the failure of a half joint is usually a more ductile failure mode, failure of individual post tensioning strands can be progressive without any external warning signs and, in the worst case scenario, lead to brittle and catastrophic collapse of structures.

2.2 *Typical defects for post tensioning systems*

Ultimately, failure of a stressing system occurs if either the load within the system increases to an extent that it exceeds the limits of the undamaged strands or, more likely, when corrosion reduces the strand strength through section loss (Fisk & Armitage, 2019) whereupon failure is often brittle in nature. Many early post-tensioned bridges simply relied on infill concrete being placed around the stressed tendons to provide corrosion protection, but this has been found to offer very poor protection against water ingress. To give better protection against corrosion, post-tensioning strands are typically encased in a duct (either metallic or PVC), with the duct usually infilled with grout to prevent the ingress of moisture and/or chlorides. However, poor detailing, poor quality workmanship or inferior grouting materials can lead to a number of defects that may be present from construction:

- Voids within the ducts (most likely at high-points within the system)
- Bleed water accumulating during grout curing
- Galvanic reactions from soft grout surrounding hard grout (Fisk & Armitage, 2019)
- Incorrect placement of ducting leading to low cover
- Poor detailing of bridge joints, waterproofing or anchorage cappings

Each of the above defects in isolation may not necessarily lead to deterioration of the post-tensioning system, however in combination with each other and through general degradation of the structure, they are likely to lead to deterioration. These defects can occur in any post-tensioned bridge, but pre-cast, post-tensioned segmental structures are of the greatest concern due to increased numbers of transverse joints - potential inlets for water and chlorides (WSP, 2017).

2.3 *Current approaches to determining condition*

Determining the condition of internal post-tensioning systems is a process that is complex and often requires a mix of approaches, led by skilled and experienced engineers and specialists. In essence, this can be simplified to:

- Optical inspection methods for surface-level indications of post-tensioning deterioration
- Numerical Modelling, often including Finite Element Analysis (FEA)
- Non-Destructive Testing (NDT)
- Destructive/Intrusive Testing

Each approach has its own advantages and limitations, with current technologies unable provide a single non-destructive method for determining all required information for assessing a structure. Therefore, they must all be used to some extent, requiring an understanding of the appropriateness of each, and where it can be relied upon.

3 POST TENSIONED BRIDGE MOONSHOT - SCOPE

3.1 *Preceding work*

Following the closure of the A52 Clifton Bridge described in Section 1.1, National Highways formed a 'Tiger Team' to review their approach to managing post tensioned bridges. This included reviewing assurance processes, the relevant standards and their adoption, post tensioned experience and capabilities both internally and within the industry, risk management and the approach to inspection, data gathering and structural health monitoring. The latter aspect included a literature study on global approaches to data gathering, and in particular – a study on global approaches to NDT and the associated technologies (AtkinsRealis, 2020). This concluded there does not yet exist a clear technology that provides a bridge owner a comprehensive understanding of the internal condition; All of the systems available have inherent flaws, limitations and inaccuracies. A combination of approaches - including visual, numerical, NDT and intrusive inspections – all still have their place within the current best

practice maintenance strategy. However, there is likely a benefit to be achieved with reviewing the current usage of individual technologies, and how they can be used in parallel to better effect.

Building on the Tiger Team work, the first phase of the post-tensioned Structures Moonshot was commissioned to articulate the challenge noted in Section 1.1 of this paper and investigate the approaches that might be developed to meet these objectives. The project team - led by this paper's authors – undertook a global engagement process to appropriate institutions and sectors that might face similar challenges, and may have solutions or are undertaking research and development in a related field. This was undertaken through a 'Call for Ideas' challenge statement, which was issued to a broad range of potential research partners. This included engineering and NDT bodies and institutions, but also sought to reach out to potentially compatible institutions and companies within aeronautical, biomedical, agricultural, heavy civils (e.g. nuclear) and mining sectors. The aim was to uncover technologies, approaches or low TRL ideas that would enable the determination of:

1. Identification if the conditions for corrosion exist, and how severe they are
2. Identification if corrosion is actually occurring
3. Identification if corrosion has occurred, and if so quantification of deterioration

The statements are of increasing value to asset owners, but equally increasing in difficulty to achieve with any certainty. The aim was to identify technologies that either were already at a high enough TRL that they could be trialed and their effectiveness reviewed, or else be invested in to develop these ideas or concepts to a point at which they can be trialed and reviewed (i.e. very low TRL technologies).

Submissions were assessed and scored using a weighted scoring mechanism that considered TRL, evidence of experience in the relevant field, application of the technology (i.e. which of the three criteria above would it meet), cost and duration to develop, cost to deploy at scale and ease of applicability at scale.

At this point in the project, the A14 Huntingdon Viaduct – a post-tensioned rail bridge – was in the process of being demolished as part of a larger infrastructure scheme. The structure contained both post tensioning and half joints, with previous assessments and structural health monitoring pointing to defects in both. As will be described later in this paper, through a separate investigation led by AECOM, National Highways were able to secure three large samples of the structure to augment the scope of the moonshot project. Consequently, in addition to investing in low-TRL research, the project scope was expanded to include testing the effectiveness and applicability of higher TRL NDT technologies that are not yet in common usage.

The testing recommendations included investigating both higher and lower TRL technologies. For the former, a number of higher TRL applications were identified, including those from the agricultural sector, typically used for determining the composition of soil, high-accuracy optical strain and displacement measurements, creation of 'chloride maps' of surfaces using ground penetrating radar (GPR) and application of ultrasonic waves along the exposed tendon ends for short-distance condition mapping.

The lower TRL technologies identified included a guided wave application developed by Omnia, who – together with research partners Vallen Systeme – are well experienced in the field of acoustic monitoring techniques. Sentec's proposals included harnessing their specialisms in electronics and signal transmission to measure electrical transmission along tendons for fault finding, in addition to a variant on guided wave measurements, applied via thermal or electromagnetic means to the tendon through a surrounding concrete medium.

3.2 *Phase 2 commissioning and scope*

The first phase of the Moonshot project ended with a report recommending the trials noted above in mid 2021. In late 2022, the second phase of National Highways' Structures Moonshot was commissioned through its Specialist Professional and Technical Services (SPaTS), and funded by National Highways' designated funds for Innovation and Modernisation Fund.

The project was awarded to a Joint Venture of AtkinsRealis and Jacobs (AJJV), with the AJJV team including contractors VSL to be the Main Works Contractor, handling the management of the site activities through the project.

The main scope of this phase of the Moonshot project is split into two distinct activities; Testing of the low-TRL technologies of Omnia and Sentec (Section 4 below), and; mobilising a site compound to enable the a suite of NDT to be undertaken on the recovered samples from the A14 (Section 5 below).

4 RESEARCH AND DEVELOPMENT STUDIES

4.1 *Aims of the trials*

As part of the Moonshot project, National Highways were committed to investing in promising technologies that might enable the identification of tendon condition in existing post tensioned structures. The aim of this aspect of the project is to take early TRL technologies and ideas, and develop them to such a position that they can be deployed in a trial capacity on live structures (i.e. TRL 5). It should be noted that whilst the research is carefully assessed for alignment with the overall project goals, the investment is not linked to ownership of any developed technologies or the associated Intellectual Property (IP). National Highways are seeking the betterment of the industry through the application of new technology, rather than developing new capabilities.

Each of the R&D programmes has been split into a number of distinct phases or work packages. These are initially desk-based, using Finite Element Modelling (FEM) and small-scale testing to demonstrate the viability of the approach and the concepts involved. Follow on programmes include larger-scale testing to prove the FEM concepts, and introduce some of the real-world complexities that make these structures such a challenge to investigate. The final investment phase is to enable the construction of a prototype system that can be trialed in real-world application.

Funding and investment through the work packages/phases is dependent on a gated assessment approach. At each milestone, the project team (including National Highways and the AJJV team) review the progress to date, and the findings and outcomes compared to expectations. This provides the project team the opportunity to help steer the technology development at critical junctures, or in the case that the development is not deemed to be yielding the value required, potentially pivot to new avenues or technology investments.

4.2 *Sentec research proposals*

Technology and product developers Sentec (part of the Xylem group) supplied a number of potential NDT solutions to the Moonshot 'call for ideas', building on their experience of developing innovative sensors and smart metering for gas, water and electricity sectors. Two proposals were identified that would attempt to tackle the most challenging aspect – determining how much corrosion has occurred within a tendon. These were direct impedance measurement and Radio-frequency (RF) coupled guided ultrasound.

The direct impedance measurement involves continuous measurement of the tendon resistance and inductive/capacitive reactance, with the aim of detecting corrosion through the resistance changes within the steel. This would need to allow for changes in cable diameter and filtering out of changes in temperature and stress. It was identified from the outset that the technique may be affected by random changes in impedance due to joints and connections with reinforcement.

For the RF coupled guided ultrasound involves the remote induction of a temperature gradient within the tendon via pulsed radio frequency. The induced temperature gradient is used to generate a high-power guided ultrasonic wave within the tendon, which is then measured by multiple receivers along the length of a section (from the surface of the concrete).

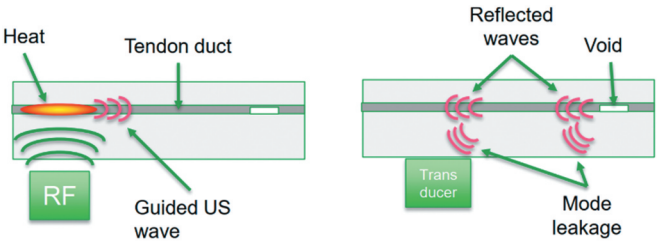

Figure 1. Sentec RF Coupled Guided Ultrasound.

4.2.1 *Progress to date – Direct impedance*

At the time of writing, the direct impedance methodology has been proven through a series of small scale tests and numerical modelling. Validated and compared against numerical modelling, the team constructed a 1m long grouted line, which was then injected with an 80 MHz bandwidth pulse, which was drilled with a 1cm hole (simulating a defect). The system was able to measure a demonstrable difference and change in signal between wet and dry conditions.

Demonstrating initial promise, the system does currently have a number of limitations and assumptions. These are namely:

- Changes in condition are best measured as variations from a baseline, and as such generation of a baseline is required for optimum results
- A direct electrical connection to the duct and strands is required to induce the signal into the system (with potential to use a current loop to couple a signal into the strand remotely at a later date)
- Instances of connections between the tendon and metallic ducts, and further connections between duct and reinforcement will lead to a 'short' in the circuit and currently prevents further interpretation of the signal at this point

4.2.2 *Progress to date – RF coupled guided ultrasound*

The initial approach for this methodology was to attempt to induce a guided wave using an RF source, however it was determined through the course of the research that for situations where a duct is metallic, the power was predominantly absorbed by the duct. As such, the technology developed to trialing near field coupling via a magnetic field induced by a coil.

With the revised methodology, the Sentec team were able to induce and detect a generated ultrasound signal from a standoff of 300mm. Through numerical studies, this was progressed to observing wave propagation through water-filled voids within a duct, with a number of possible mechanisms for detecting and measuring the void.

4.2.3 *Omnia research proposal*

Omnia Integrity is a company specialising in non-intrusive methods for asset inspections, with a focus on wave mechanics (guided wave and acoustic emission). The proposal team included partners with ARCES (Bologna University) and Vallen Systeme, specialists in guided wave mechanics and acoustic emission inspections respectively.

The Omnia proposal harnesses their teams' expertise in acoustic monitoring, and utilizing the same apparatus, to induce guided waves that can assess condition in addition to detecting wire breaks.

4.2.4 *Progress to date*

The Omnia-headed team have been commissioned to undertake two phases of development to date; a numerical study with small scale testing, and; larger scale testing to validate numerical concepts and theory.

The initial phase of finite element modelling involved incremental increases in modelling complexity, moving from detecting responses in a 2D, single plain bar through to a 3D-modelled concrete-encased 7-wire wound strand. At each stage of testing, the team have been careful to test multiple frequencies and wave forms and ensure full understanding of the wave

propagation and the associated response before moving onto subsequent stages, including identification of defect patterns such as breaks or section loss. The technology has shown promise that defects within grouted tendons can be identified up to a range of (currently) approximately 4m when utilising an excitation source connected directly to a strand.

At the time of writing, Omnia are undertaking large scale testing to validate the numerical studies, having constructed a 9m beam with stressed tendons encased in concrete. A number of 'windows' have been cast into the beam to allow the connection of excitation devices, in addition to control defects to be detected by the system. Trials are ongoing, with positive results indicating that the hypotheses of the numerical studies are borne out in practical application.

4.3 *Next steps*

Next steps for these technologies have been mapped out, but each technology must next be evaluated on its own merits and assessed with respect to those criteria set out in the initial moonshot 'call for ideas'. Likelihood of successful development through to a deployable technology will be key considerations, along with scalability and impact; to secure further investment the project team must be satisfied that a suitable return on investment will be achieved in the form of a high-impact technology that will lead to a step change in current asset management approaches.

5 NON DESTRUCTIVE TESTING – TECHNOLOGY APPRAISAL TRIALS

5.1 *Aims of the trial*

As discussed in previous sections, through preceding work, National Highways have secured a number of sections of the A14 Huntingdon Viaduct - including two sections with half joints – with the intention of undertaking blind trials of various forms of higher-TRL NDT technologies. The overall approach is to deploy these technologies across the three sections, followed by controlled hydrodemolition of the sections and extraction of key features (e.g. PT ducts and anchorages). By comparing the NDT results with as-found condition, the project team will be able to determine the effectiveness of various technologies and identify particular strengths and limitations. These findings will be used to develop improved approaches and process maps for asset investigations, laying different technologies together to complement each other and respond to the specific challenges faced on a structure-by-structure basis.

The trial does not just consider technology – gathering good data is a combination of people, process and technology; Having the appropriate equipment for a situation can be rendered ineffective if it is deployed in a sub-optimal arrangement, or used by insufficiently trained teams. This study therefore captures what 'best practice' looks like, and also includes duplication of specific pieces of equipment to attempt to distinguish differences in quality through different applications.

Finally, through the reach of the Phase 1 'call for ideas', the trials have included a number of cross-sector technologies. In particular, as will be detailed later in this paper, technologies from the agriculture sector – typically used for soil composition analysis – have been adopted.

6 PROGRAMME AND NEXT STEPS

6.1 *Programme and broader moonshot objectives*

This phase of the Structures Moonshot is scheduled to run until the end of 2024 or early 2025, by which point the planned R&D being undertaken by Sentec and Omnia will have reached the intended conclusions and the NDT on the A14 samples will have been assessed and documented. As noted in this document, National Highways' current aspiration is that this work is continued to consider other 'high priority' areas and structure types; this will likely be informed by the success and direction of these initial phases and the value delivered.

A key objective of the project is around knowledge sharing and dissemination. In addition to publication of key findings, part of the project scope is to host an industry conference at the end of the project, inviting the wider industry to attend and explore the findings and their implications, including asset owners, consultants, contractors, NDT providers and technology developers.

6.2 *Data collection, BIM approach and harness of artificial intelligence*

Throughout the NDT trials of the A14 sections, data has been captured in such a way that it can be considered holistically; The aim is to be able to draw conclusions and identify relationships between the findings of different techniques and approaches, tied to the as-found condition of the samples. This is founded on a clear and simple referencing system for the NDT specialists to adhere to, and will be augmented by transposing these data into a single federated 3D model, providing a 'Digital Twin' of the samples. Using typical BIM products such as Autodesk Revit, Navisworks and Bentley BIMTrack, the samples have been recreated as 3D models, upon which the NDT defects can be layered, along with the physical findings. Over and above this, the project team have been carrying out Lidar scans of the samples throughout the hydrodemolition process, providing 3D meshes of the exposed tendons in-situ, which can also be layered into the digital twin and explored in parallel to the NDT findings.

In addition to the exploration of the data by the project team, the goal is to be able to harness new approaches to data review such as Machine Learning and Artificial Intelligence, with the digital twin described above will be a key building block for this work. As noted, industry engagement is a key tenet of the project, and it is intended that further 'Open Invites' may be launched to expose the gathered data to industry AI and ML specialists, allowing the data to be much more broadly explored and different approaches tested.

7 SUMMARY AND CONCLUSIONS

Although still in progress, the project has already yielded significant insights and progress. The low TRL technologies explored by Omnia and Sentec are each pushing boundaries of what is achievable, particularly in the field of guided waves. In this aspect of the project, progression of the technologies will now start moving from what is theoretically possible to the practicalities of deployment in a real situation, and the relative value derived from its application.

Again, with respect to the NDT trials of the A14, although the data collation and assessment is still underway, a number of interesting observations and avenues have already been identified, and a broad suite of NDT techniques deployed. The industry engagement has also been very strong, with the NDT providers engaged being both collaborative and inquisitive, which has allowed the collation of information to be much broader than initially anticipated, which will in turn yield greater insights as the project turns to the data assessment.

ACKNOWLEDGEMENTS

The Authors would like to thank all of the parties involved in this project to date. These include the client and project sponsors National Highways (and the funding by National Highways' designated funds for Innovation and Modernisation Fund), the AtkinsRealis and Jacobs joint venture project team, Main works contractor VSL, R&D partners Sentec (supported by Lucy Electric) and Omnia (supported by Vallen Systeme and ARCES) and NDT specialists Mistras, Bridgology, CTS, Allied Associates, Screening Eagle, the Royal Agricultural University (supported by the University of Bristol and Pro-Lite Technology), Hausbots, Hilti, GScan and IFDB.

Advancements in Bridges NDT: National Highways' "Structures Moonshot" – Paper No. 2

C. Mundell, C. Hendy & T. Argyle
AtkinsRealis, UK

C. George
National Highways, UK

ABSTRACT: The "Structures Moonshot" project, initiated by National Highways and led by Atkins, Jacobs, and supported by VSL, advances non-destructive testing (NDT) for highway structures, with a focus on post-tensioned bridges and half joints. Launched in late 2022 and continuing, its vision to revolutionise asset management for vulnerable bridges, enabling better and more efficient data collection, leading to self-monitoring and self-diagnosis for National Highways' most critical structures.

The project comprises two phases; The first involves testing high Technology Readiness Level (TRL) NDT technologies on bridge sections from the dismantled A14 Huntingdon Viaduct. These are compared with the as-found physical conditions after hydro-demolition. The goal is to evaluate current NDT methodologies, identify areas for improvement, and enhance efficiencies in deployment.

The second phase centers on developing low TRL NDT technologies tailored for post-tensioned bridges. This includes the use of guided wave technology, with the aims of enabling direct tendon deterioration measurements without intrusive inspections.

This paper will focus on the first aspect, being the Huntingdon Viaduct trials. The low-TRL technology developments are documented in IABMAS Paper number 452.

1 INTRODUCTION

As discussed in IABMAS paper No. 452, through preceding work, National Highways have secured a number of sections of the A14 Huntingdon Viaduct - including two sections with half joints – with the intention of undertaking blind trials of various forms of higher-TRL NDT technologies. The overall approach is to deploy these technologies across the three sections, followed by controlled hydrodemolition of the sections and extraction of key features (e.g. PT ducts and anchorages). By comparing the NDT results with as-found condition, the project team will be able to determine the effectiveness of various technologies and identify particular strengths and limitations. These findings will be used to develop improved approaches and process maps for asset investigations, laying different technologies together to complement each other and respond to the specific challenges faced on a structure-by-structure basis.

The trial does not just consider technology – gathering good data is a combination of people, process and technology; Having the appropriate equipment for a situation can be rendered ineffective if it is deployed in a sub-optimal arrangement, or used by insufficiently trained teams. This study therefore captures what 'best practice' looks like, and also includes duplication of specific pieces of equipment to attempt to distinguish differences in quality through different applications.

DOI: 10.1201/9781003483755-432

Finally, through the reach of the Phase 1 'call for ideas', the trials have included a number of cross-sector technologies. In particular, as will be detailed later in this paper, technologies from the agriculture sector – typically used for soil composition analysis – have been adopted.

2 NON DESTRUCTIVE TESTING – TECHNOLOGY APPRAISAL TRIALS

2.1 *Sample details & history*

The A14 Huntingdon Railway Viaduct (HRV) was constructed in 1975, carrying four lanes of traffic over six spans and crossing both local distributor roads and the East Coast Main Line (rail link). In December 2019, new routes were opened which rendered the structure obsolete.

The main span consists of a main drop-in span formed of simply-supported precast beams (with transverse post tensioning and an in-situ deck slab), supported on longitudinally post-tensioned cantilever sections. The support and articulation for the precast main span elements are via half joints at the end of the precast cantilevers.

Over the course of 20 years, the structure has been subject to a number of detailed structural assessments, supported by testing and continuous monitoring (e.g. via Acoustic Emission Monitoring, or AEM). Due to a low assessed capacity and observed increases in re-entrant cracking of the half joints, a number of repair and remedial measures have been carried out, including regrouting of PT ducts and providing a secondary support structure to negate the risk of sudden half-joint failure. It should be noted that over the course of the 20 year period of AEM, a total of 52 wire breaks were recorded within the PT ducts, with a number concentrated in the section of the structure that was removed as part of this project and identified as 'Sample 3′ (AECOM, 2021). In 2020, during the demolition of the full structure, three number samples were removed by wire cutting from the north monolith, as shown in Figure 1.

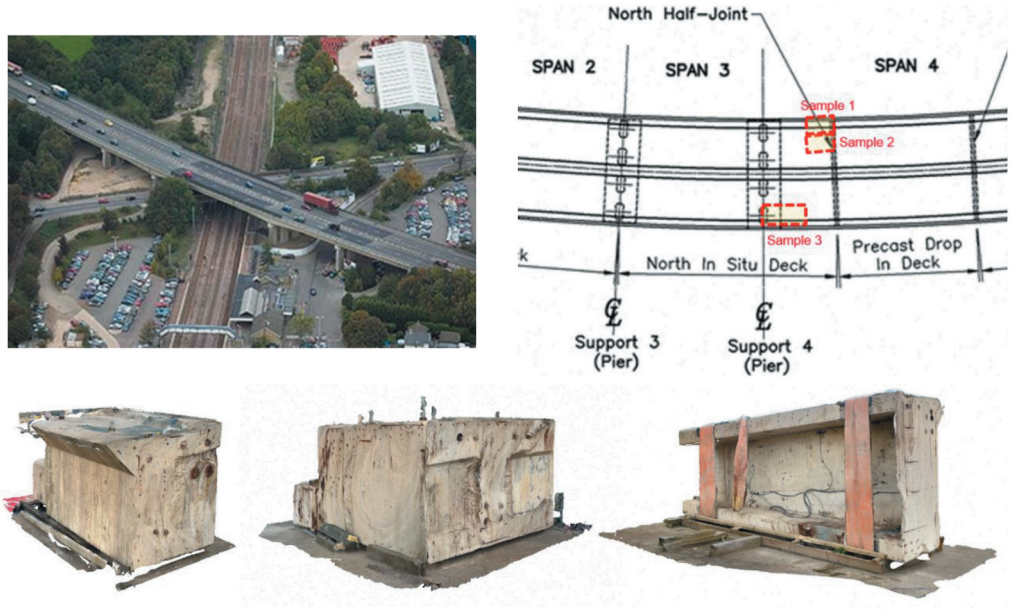

Figure 1. Top left – Huntingdon Viaduct; Top right – Sample locations; Bottom (left to right) – samples 1, 2 and 3.

Samples 1 and 2 have been extracted from the end of the cantilever, being two adjacent sections containing half joints and PT ducts. The PT ducts all terminate within either the half joint nibs or immediately behind within the full-height section of the structure, meaning that

all PT ducts within these samples also contain anchorages (5 number in sample 1, 8 number in Sample 2). The samples vary in size between 2m to 3m in length and width, weighing 16 and 24 tonnes respectively. Sample 1, being the outermost section, also includes the parapet beam support and a patterned finish to the external-facing elevation.

Sample 3 has been removed from the opposite side of the same cantilever monolith, starting at the pier support diaphragm and extending 6m along the cantilever section, being 4m tall at the highest (diaphragm) end. The section has been taken from part of the outermost cell, and as such contains part of the top and bottom flanges of the cell, along with the web. The external façade of the web is patterned and contains a diagonal nib to support the parapet beam (as per Sample 1). This section contains 7 number PT strands, of which one terminates within the section web. Images of the 3 samples are shown in Figure 4.

2.2 *NDT technologies and open invite*

The initial plan included engaging with some of the industries most established NDT suppliers to provide a suite of NDT techniques. This included optical/spectral inspections, electromagnetic sensors, mechanical wave induction and electrochemical tests. Testing providers initially included VSL (also acting at the main works contractors) Bridgology, Mistras, CTS, Allied Associates and the Royal Agricultural University (RAU). Many of the techniques were commonplace; Ground penetrating radar (GPR), covermeter surveys, ultrasonic tomography, half cell potential surveys and impact echo, but a number were also less common; Hyperspectral imagery, FTIR gas monitoring, magnetic flux leakage, chloride mapping via GPR and ultrasonic guided wave testing.

In addition to the planned NDT providers and technologies, the project team undertook a further 'call for ideas' from the wider industry (akin to the phase 1 moonshot call out). This was specifically seeking to understand if additional technologies and approaches had come to the market since the first phase, or had been missed in the first instance. Using National Highways' competitions page, coupled with social media outlets, the project and the opportunity to engage was opened up for several weeks while testing progressed. During this time, a number of new technologies and testing providers were brought into the project. This included Screening Eagle, bringing the latest Proseq sensors, HausBots, deploying their climbing robot, reinforcement scanning specialists Hilti and Muon tomography specialists GScan.

2.3 *Outcome focused specification*

The intention for each form of NDT is that it builds on the overall dataset which will allow structural condition to be appraised. Furthermore, the project team acknowledge that in the majority of cases, the most advantageous use of each form of NDT is best identified by the technology provider. Based on the these requirements, the project specification produced for the NDT was primarily defined by outcomes, rather than prescriptive approaches. A hierarchy of data value was established, identifying the types of defects or data measured and their relative value. Leveraging this, it was the requirement that the technology providers themselves confirm the deployment methodology and which of the desired outcomes that they hoped to meet.

With the nature of this project being aspirational, each provider was challenged to aim to achieve the maximum level of data and interpretation possible, even where the confidence of the data gathered may be lower. To capture this, the specification allows for individual tests to differentiate between when there are strong indications that defects are present, or conversely where there may only be a suggestion of potential for defects or the conditions for deterioration. As such, when capturing data from surveys, where defects are identified, these are coupled with a 'Level of Confidence' indication by the testing provider, scored as high, medium or low depending on the definition of the observation and potential for misinterpretation.

Finally, to enable a holistic review of the NDT data and actual condition data post-demolition, a detailed co-ordinate and referencing system has been established, catering for the different types of NDT and how they will capture data. This includes a 3D local co-ordinate system for each sample, individual identification of sample faces, duct numbering and chainage system and strand and wire numbering. Each NDT provider provides their findings in a standardised format where appropriate, allowing the project team to consolidate defects and findings and look for trends and linked observations.

2.4 *NDT key outcomes to date*

At the time of writing, detailed NDT findings are still pending, however an initial collaboration session with the NDT providers has yielded outline results and initial findings as noted within this Section.

2.4.1 *Half cell resistivity*

Detailed electro-potential readings, dust sampling and chloride content testing carried out immediately prior to demolition (of the samples) are yet to be provided, however initial resistivity testing of the exposed faces results have typically been found to show low likelihood of deterioration in the near surface reinforcement and concrete, with some areas of hotspots, such as the re-entrant corners of the half joints of Samples 1 and 2.

2.4.2 *Ultrasonic pulse echo*

Ultrasonic Pulse Echo testing has been independently undertaken by a number of NDT providers, including Mistras, Screening Eagle and Allied Associates. Focus of testing has been on Sample 3 where the suspected wire breaks are located. This testing has identified a number of suspected voids within the tendon ducts, particularly within the web of the sample, as shown by Figure 5 below. This would indicate that at several points along the length of the tendons there is a lack of grout within the ducts, which would in turn provide an elevated risk of tendon deterioration.

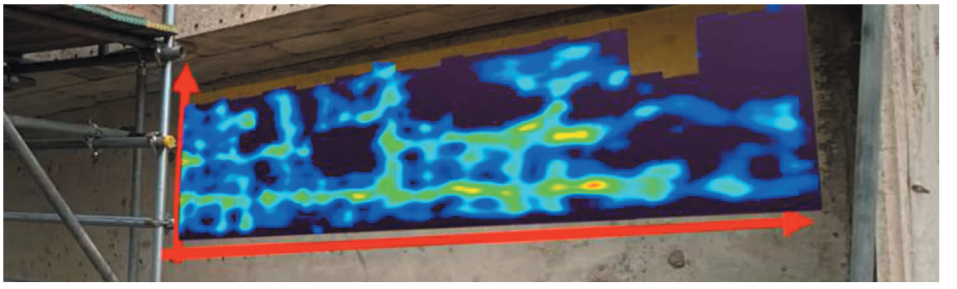

Figure 2. Ultrasonic pulse echo testing examples.

2.4.3 *Impact echo*

Similar to the ultrasonic tomography, impact echo testing has focused on Sample 3 for the most part, and has again found a number of areas where there are strong indications that there is voiding within the sample and the ducts at a number of locations.

2.4.4 *Ultrasonic testing of wires*

Using a probe mounted to the exposed ends of the strands, a signal is induced to the individual wires within the tendons, with Mistras proprietary software analysing the signal for approximately 1m along the length of the tendon. As shown in Figure 3, the system has identified a number of tendons where there is a strong indication of corrosion along the length tested, although this test is limited to those locations where the tendon end can be cleanly accessed.

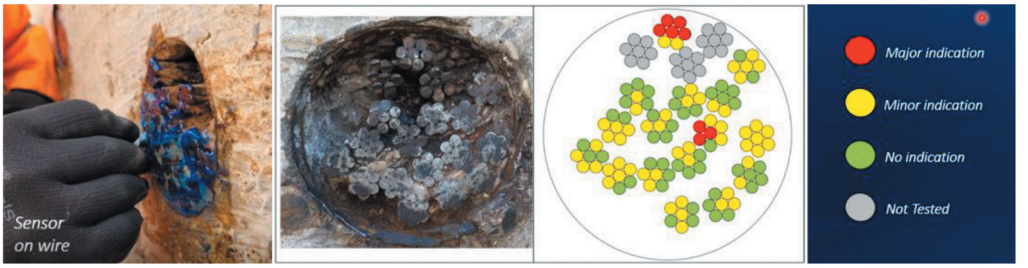

Figure 3. Ultrasonic tendon testing example data.

2.4.5 *Acoustic emission testing*
AEM is normally a passive system that is installed to measure potential tendon breaks over time; for the purposes of these NDT tests, a number of sensors were installed along the length of the samples, with signals induced by a 13cm spring loaded centre punch and a Schmidt hammer. The system measures signal attenuation and amplitude along the length of the sample, looking for breaks and potential indicators for wire breaks.

2.4.6 *Ground Penetrating Radar (GPR)*
GPR has been undertaken using a number of different devices and by a number of different providers, producing detailed coverage of all samples. Although a relatively simple and quick test to undertake, the latest GPR systems have proved effective at locating reinforcement and PT ducts, with multiple scans unlocking 3D images.

This technology has been effectively paired with the ultrasonic pulse echo technology, with both complementing the other in detecting voids and moisture. Following the workshop noted above, further tests were commissioned to attempt to use GPR to specifically identify duct deterioration; results from these tests are pending.

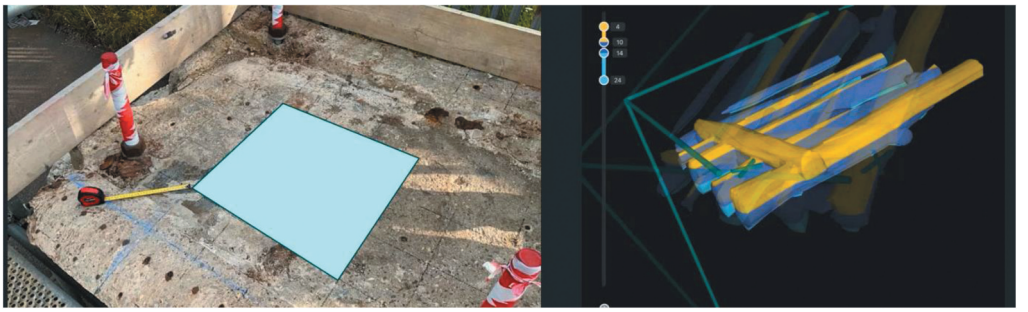

Figure 4. GPR testing data.

2.4.7 *Portable X-Ray Flourescence (pXRF)*
pXRF is a technique used to identifying elemental composition within a sample, and can be applied via a hand-held device directly to a surface. The technique can detect many different impurities in the materials (e.g. sulfur, silicon or zinc), but the team focused on identifying corrosion accelerants such as chlorides, which were found to be most abundant in the duct areas. High concentrations of Sulphur were also identified specifically in the duct areas, which is also currently being reviewed further.

2.4.8 *Fourier Transform Infra-Red (FTIR) Spectroscopy*
FTIR Spectroscopy is a gas-sampling approach which uses a Gasmet device through two different applications; either a chamber attached to the surface of the samples, which is sealed and made a vacuum (or as close as possible), or via a 'sniffer' which can be inserted into bore

holes and cracks. The device then analyses the gases to identify specific variances in gases that are being emitted directly by the sample (compared against baseline readings).

In the case of the moonshot tests, over a 10 minute timeframe, there were increases in Methane, Carbon Monoxide and Carbon Dioxide. Methane in particular was measured consistently across all of the samples at the time of the testing, potentially indicating some aspect of biological action. This is being further explored, including repeat testing and consideration of additional testing such as DNA testing of samples following demolition and sample extraction.

2.4.9 *Field Spectroradiometry and Hyperspectral Imaging*

Using field and laboratory spectroradiomters (ranging in the 280 to 2500nm spectra) in addition to a Raman spectroscopy device using an active light source (a monochromatic laser), further measurements of chemical composition can be remotely undertaken. Additional spectral analyses was carried out using a Specim IQ camera, recording in the 400 to 1000nm range.

Although full data processing has not yet been concluded, to date there have been no significant or noteworthy findings from the data obtained via these methods.

2.4.10 *GPR Chloride Mapping*

Using GPR data, Bridgology are able to develop a 'heat map' of chlorides and corrosion risk in a surface. In this case, the technology has used the Proseq GP8000 GPR scan, undertaken in scans 100mm apart and along two perpendicular directions (i.e. forming a grid of data). As shown in Figure 5 below, the technique has found some indicators of elevated risk of corrosion, particularly focused around the re-entrant corner of the half joints. This is of particular interest, and is not unexpected due to the known cracking along this location and historical deterioration of the structure.

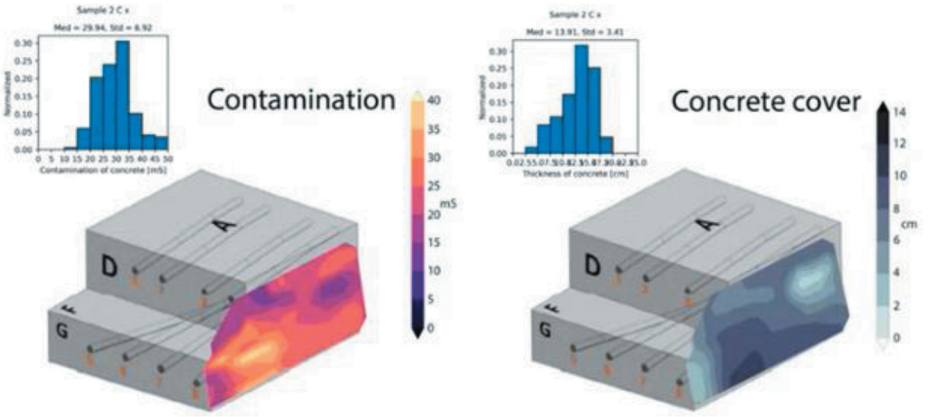

Figure 5. Chloride and concrete cover 'Heat Maps' developed through GPR Surveys.

2.4.11 *Magnetic Flux Leakage (MFL)*

German-based company IFDB were engaged to deploy MFL testing, which involves remotely magnetizing the tendon from the sample surface and then measuring the magnetic flux density along the tendon path using magnetic sensors

Due to the specifics around the magnetization and interference/reflection from cut ends, the MFL technology is most suited to large, planar surfaces or long lengths of beams. As such, there were limited areas of applicability for MFL within the A14 samples. However, it was successfully used on Sample 3, both on the top surface and the exposed web. The team were successfully able to obtain signals from 5 of the 7 ducts within Sample 3, however there was no clear evidence from this technology of wire breaks within the strands.

2.4.12 *Muon tomography*

The final technique tested uses an emerging technology called Muon Tomography. Muons are sub-atomic particles – similar to electrons - that are formed when cosmic radiation hits the earth's atmosphere. Muons are harmless to life, and have very high levels of penetration, which make them ideal for inspecting through dense structures such as a bridge elements. There are a number of methods for tracking the passage of the muons, however the method deployed by specialists GScan for the Moonshot project use high-technology materials such as Plastic Scintillating Fibers and Silicon Photo-multipliers, allowing the path of individual muons to be measured. By measuring over a long period of time (several weeks), the deviations of the muons due to changes in medium (e.g. where they pass from concrete into a metallic duct) can be detected, allowing an image or model of the area in front of the scanning plates. The technology promises to provide not just an image/model showing the various key elements (e.g. duct, tendons, reinforcement), but also the chemical composition of the materials, potentially showing deterioration and the presence of rust. The key limitation for this technology at present is the infrequent nature of the passage of muons; In order to build up a picture that shows defects at the scale required (i.e. millimeter precision), the scanning devices need several weeks left in situ, with the area under observation therefore limited to the size of the scanning plates. In addition, a continuous power supply – although not large – is currently required for the system, which may add logistical complexity for in-situ bridges.

For the purposes of the Moonshot trials, two number sensors were used, one above and one below the concrete flange of Sample 3, and left for a total length of five weeks. The arrangement was locally moved after 2 weeks, with the intention of the second position enabling a 3D image. At the time of publication, the images and data obtained are still under development, with further trials under discussion.

2.5 *Hydrodemolition*

This aspect of the project has now moved into the final phase of work, being the controlled demolition of the samples and extraction of key elements such at the tendon and ducts, samples of concrete in areas of interest and key reinforcement bars for further testing (e.g. reinforcement critical to the half joint strength).

The PT ducts are the key elements of interest, which have been cut into 1m to 2m sections, and will be transported to a more controlled environment for opening and inspection. At this time, the ducts will first be inspected, photographed and measured, before being carefully cut and peeled from the grout and tendon. Again, the grout and any exposed tendon will be inspected and documented, with samples of the grout taken for compositional testing. The locations of any identified voids in the grout will be identified for comparison with the NDT findings. Finally, the grout will be mechanically and chemically removed, exposing the individual strands for inspection and testing, again for comparison with specific NDT findings.

The majority of the ducts have not yet been opened and inspected, however some exploratory work has already been undertaken, particularly with the ducts extracted from Sample 1 (Figure 6). An immediate observation was that the majority of the ducts have suffered deterioration to some extent, and in some cases the ducts were almost entirely non-existent along large lengths of the exposed ducts. Furthermore, the mortar was found to be missing or of very poor quality. Where the ducts were intact with grout present, a small number were cut and opened to expose the tendons and grout. In these cases, the grout was found to be of uniformly low strength, extremely soft and friable, and purely the removal of the duct was enough to cause the mortar to disintegrate and peel away from both strands and duct. This will be key area for further study, including the chemical composition of the grout and its remaining strength.

3 PROGRAMME AND NEXT STEPS

3.1 *Programme and broader moonshot objectives*

This phase of the Structures Moonshot is scheduled to run until the end of 2024 or early 2025, by which point the planned R&D being undertaken by Sentec and Omnia will have reached

Figure 6. Chloride and concrete cover 'Heat Maps' developed through GPR surveys.

the intended conclusions and the NDT on the A14 samples will have been assessed and documented. As noted in this document, National Highways' current aspiration is that this work is continued to consider other 'high priority' areas and structure types; this will likely be informed by the success and direction of these initial phases and the value delivered.

A key objective of the project is around knowledge sharing and dissemination. In addition to publication of key findings, part of the project scope is to host an industry conference at the end of the project, inviting the wider industry to attend and explore the findings and their implications, including asset owners, consultants, contractors, NDT providers and technology developers.

3.2 *Data collection, BIM approach and harness of artificial intelligence*

Throughout the NDT trials of the A14 sections, data has been captured in such a way that it can be considered holistically; The aim is to be able to draw conclusions and identify relationships between the findings of different techniques and approaches, tied to the as-found condition of the samples. This is founded on a clear and simple referencing system for the NDT specialists to adhere to, and will be augmented by transposing these data into a single federated 3D model, providing a 'Digital Twin' of the samples. Using typical BIM products such as Autodesk Revit, Navisworks and Bentley BIMTrack, the samples have been recreated as 3D models, upon which the NDT defects can be layered, along with the physical findings. Over and above this, the project team have been carrying out Lidar scans of the samples throughout the hydrodemolition process, providing 3D meshes of the exposed tendons in-situ, which can also be layered into the digital twin and explored in parallel to the NDT findings.

In addition to the exploration of the data by the project team, the goal is to be able to harness new approaches to data review such as Machine Learning and Artificial Intelligence, with the digital twin described above will be a key building block for this work. As noted, industry engagement is a key tenet of the project, and it is intended that further 'Open Invites' may be launched to expose the gathered data to industry AI and ML specialists, allowing the data to be much more broadly explored and different approaches tested.

4 SUMMARY AND CONCLUSIONS

Again, with respect to the NDT trials of the A14, although the data collation and assessment is still underway, a number of interesting observations and avenues have already been

identified, and a broad suite of NDT techniques deployed. The industry engagement has also been very strong, with the NDT providers engaged being both collaborative and inquisitive, which has allowed the collation of information to be much broader than initially anticipated, which will in turn yield greater insights as the project turns to the data assessment.

ACKNOWLEDGEMENTS

The Authors would like to thank all of the parties involved in this project to date. These include the client and project sponsors National Highways (and the funding by National Highways' designated funds for Innovation and Modernisation Fund), the AtkinsRealis and Jacobs joint venture project team, Main works contractor VSL, R&D partners Sentec (supported by Lucy Electric) and Omnia (supported by Vallen Systeme and ARCES) and NDT specialists Mistras, Bridgology, CTS, Allied Associates, Screening Eagle, the Royal Agricultural University (supported by the University of Bristol and Pro-Lite Technology), Hausbots, Hilti, GScan and IFDB.

Advancements in Structural Health Monitoring (SHM): Deformation Area Difference (DAD) method and model updating

T. Čamo
Department of Engineering, University of Luxembourg, Luxembourg

E. Apostolidi & D. Waldmann-Diederich
Institute for Solid Structures, Technical University Darmstadt, Germany

ABSTRACT: As the global population continues to urbanize and rely on essential infrastructure for safe transportation, trade, and everyday life, the significance of SHM of existing structures becomes increasingly evident. Bridges in particular, are the lifelines of transportation networks, connecting communities, facilitating economic activities, and supporting the flow of goods and services. They are subjected to a complex interplay of environmental factors, traffic loads, and aging, making them susceptible to various forms of deterioration and damage over time. Ensuring the structural integrity of bridges is paramount to public safety, environmental sustainability, and economic prosperity. This research focuses on the refinement and enhancement of the DAD method, coupled with a parametric analysis, to investigate the influence of various parameters, including the position of damage within their cross-section. Additionally, the integration of generative design tools in the commercial software Grasshopper enables the determination of damage levels within bridge structures. This integration allows for an additional level of SHM in determining the extent of damage using the DAD method, leading to more precise and actionable results for bridge maintenance and safety management. To validate the proposed methodology, in-situ experiments were conducted on a demonstrator bridge. These experiments employed state-of-the-art technologies, including photogrammetry and Unmanned Aerial Vehicles (UAVs), to capture high-precision deformation on the bridge structures. The combination of these cutting-edge technologies and the refined DAD method with Model Updating ensures a robust and comprehensive approach to bridge health assessment.

1 INTRODUCTION

Infrastructure forms the backbone of the global economy, with bridges standing as pivotal components. However, the combination of aging structures and increasing transportation demands has led to deteriorating conditions in many bridges. To avoid financial and life-threatening risks, many structures need to be assessed. As bridges age, their structural integrity decreases. In Europe concrete bridges are experiencing corrosion issues due to the use of de-icing salt during cold weather(Matos *et al.*, 2023). Moreover, changes in design codes over the years have led to the need for reassessment of many bridges in Europe to determine their load carrying capacity under present loading conditions (Tilly, 1990). Despite these assessments, the focus remains primarily on visual inspection, neglecting the inner structural condition of the bridges.

With an increasing importance for reliable structural evaluation of bridges, various recent studies deal with condition assessment methods. These topics can be divided in two main approaches based on dynamic and static measurements. For instance, (MacLeod and Arjomandi, 2023) present a novel dynamic parametric Bridge Weigh-In-Motion (BWIM) method utilizing experimentally estimated modal parameters for simulating the response of a bridge structure to moving loads. Although validated in a case study, its applicability to different

DOI: 10.1201/9781003483755-433

bridge types is limited and depends on the calibration quality. (Li, Lan and Lin, 2023) are proposing an indirect approach to localize and quantify bridge damage using sensing and parked vehicles. The study presents equations for back calculating residual contact-point responses of the sensing vehicle with suspension and tire damping and sensor-installing errors are deduced to eliminate self-frequencies and suppress the negative effects of road roughness. A novel modal assurance criterion-based objective function using indirectly identified frequencies is proposed to enhance the robustness of damage detection. Despite offering a novel method, challenges persist due to factors, such as road conditions and vehicle properties.

While dynamic methods provide insights into the structural response, they may not capture the full range of behavior exhibited under static loads. (Grandić and Grandić, 2017) propose a damage estimation technique based on the Grey Relation Coefficient (GRC) and curvature of displacement influence lines in beams, requiring sparse measurements. Numerical simulations were conducted to validate the effectiveness of the proposed procedure and experimental validation also confirmed its effectiveness. However, its reliance on a high number of static load experiments increases the experimental effort of the method. Similarly, (Ha and Fukada, 2017) developed an estimation method that utilizes only displacement data for detecting structural damage by introduction of the Displacement Assurance Criterion (DAC) and the Displacement-Based Index (DBI). DAC can properly indicate the occurrence of degradation in structures and DBI can be utilized as a suitable pointer for damage localization, albeit the method is not able to identify the damage severity.

Model updating emerges as a crucial tool, enabling the estimation and quantification of damage extent, crucial for decision-making before retrofitting or rehabilitation. (Jahangiri and Hadianfard, 2019) introduce a Vibration-based Structural Health Monitoring (VSHM) and proposes a Holistic Objective Function (HOF) demonstrating a high accuracy in damage extent and location. Yet, being a dynamic method, VSHM remains sensitive to environmental factors such as temperature, humidity, and noise, potentially impacting results' reliability.

The integration of Drones in bridge assessment has improved data consistency, efficiency, safety, and cost-effectiveness. (Kim *et al.*, 2022) developed an Unmanned Arial Systems-based Bridge Management System for government bridge management and decision-making tasks, while (Jiang, Jáuregui and White, 2008) highlighted the efficacy of close-range photogrammetry for bridge deformation monitoring and geometry measurement. Combining UAVs with close-range photogrammetry enables high precision measurements for hard-to-reach bridge structures and allows for a continuous displacement line.

The Deformation Area Difference (DAD) method, analyzing area differences between the curvature lines of measured and reference models, shows promising results in detecting the presence and location of damage (Erdenebat, Waldmann and Teferle, 2019). With the DAD method only one measurement using a continuous deformation line is sufficient for damage detection, proving the DAD method efficient for existing bridge structures. However, it falls short in assessing the level of damage.

This paper introduces a novel method that incorporates model updating for damage level assessment adding a new level of SHM to the DAD method. Additionally, this paper investigates the influence of a local damage on the assessment, using the DAD method across various positions transversal to the bridge cross-section. The study presents findings from a detailed numerical analysis involving two different bridge structures: a hollow-box-prestressed concrete structure and a multi-girder steel structure. Furthermore, it applies the DAD method and the damage level assessment on a real-bridge experiment.

2 DEFORMATION AREA DIFFERENCE METHOD

The Deformation Area Difference (DAD) method, as presented in Figure 1 as example of a girder bridge with changing cross-section, aims to identify local damage in bridge structures by comparing measured deflections $w_d(x)$ with those from a reference system $w_t(x)$. As shown in Figure 1, the deflection line of a damaged bridge structure is measured under a known loading. The method involves creating a linear finite element model of the bridge structure as

reference system, ensuring a continuous deformation curve considering however stiffness changes due to variations in the cross-section. If available, also an initial measurement could serve as a reference but as usually bridge structures do not have an initial measurement, a FE numerical model is used alternately. The method calculates the inclination angle curves of the structure from measured deflection curves $\varphi_d(x)$ and from the reference model $\varphi_t(x)$ by derivation of the deflection line (equations (1)).

$$w'(x) = \frac{\partial w(x)}{\partial (x)} = \varphi(x) \tag{1}$$

For minor deflections, the second derivative of the deflection curve reflects the structure's curvature (equations (2)). The curvature of the structure, denoted as $\kappa(x)$, can be represented as the ratio of the bending moment M(x) to the stiffness EI(x) (equations (3)). In this equation, the curvature, derived as the second derivative of the deflection curve, and the bending moment from the applied load are known parameters. Consequently, any alteration in stiffness EI(x) should be detectable by analyzing changes in the curvature line.

$$w''(x) = \varphi'(x) \cong k(x) \tag{2}$$

$$\kappa(x) = -\frac{M(x)}{EI(x)} \tag{3}$$

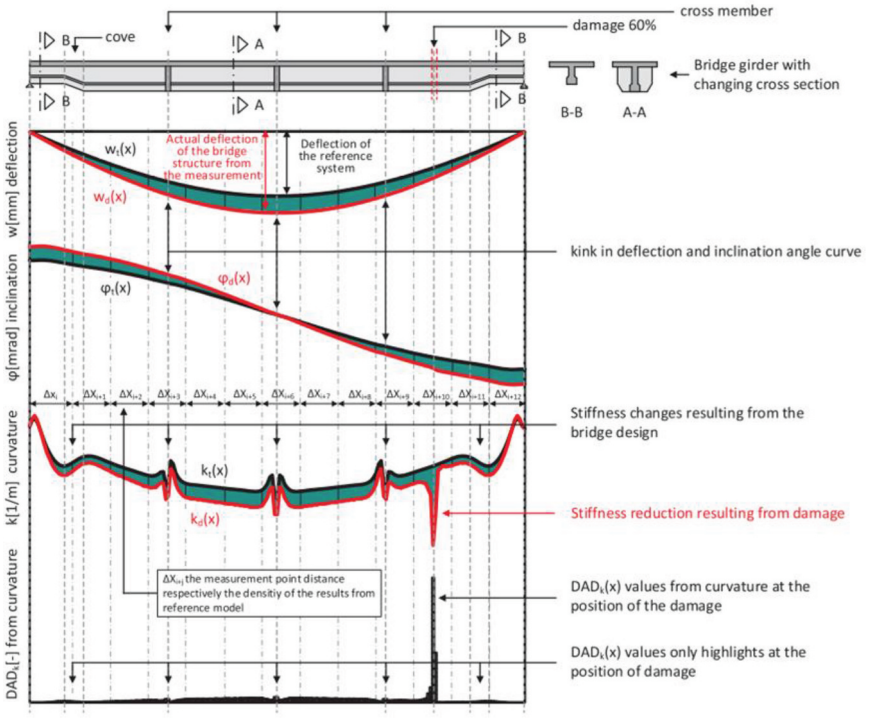

Figure 1. Principle of the Deformation Area Difference (DAD) method (Erdenebat and Waldmann, 2020).

The area between the two curvature lines is divided in discrete elements (ΔX_i). The area of every element is squared to reinforce the effect and divided through the whole area for normalization. This has the advantage that the model does not need to be calibrated, and small deviations of the model from the real structure do not lead to wrong conclusions, as planned stiffness changes are taken into account in the model. By analyzing differences in the area between the theoretical and experimental curvature curves, the DAD method highlights areas

of damage with increased values, filtering out known stiffness-changing elements from the reference model. It is noteworthy that global damage will not be detected with the DAD method. For example, if the support is lowered and a loss of support occurs, the entire static system will change. This results in a continuous deflection change. However, the DAD values indicate stiffness differences between discrete elements. So the DAD values would probably show some irregularities, but not as if there was local damage.

3 DAMAGE LEVEL ASSESSMENT WITH MODEL-UPDATING

The DAD method has demonstrated its reliability in detecting and localizing damage with a single measurement (Erdenebat *et al.*, 2018; Erdenebat, Waldmann and Teferle, 2019; Erdenebat and Waldmann, 2020), serving as the first two level of SHM according to (Rytter, 1993) However, while efficient in localizing damage, the DAD method lacks the capability to assess damage severity, as its values are normalized and result in identical outcomes for varying damage levels. Introducing an additional level of SHM involves implementing an algorithm to estimate the damage level.

Following successful damage localization through the DAD method, a model updating process is initiated (Figure 2). Due to the normalization of DAD values, they prove unsuitable as a fitness function. However, without normalization, the curvature area between the measured and reference system curvature lines can be used as a potential fitness function in the new algorithm. This new algorithm has the function to update the reference model by adjusting the stiffness of individual discrete elements in the locations the DAD revealed to be damaged. The

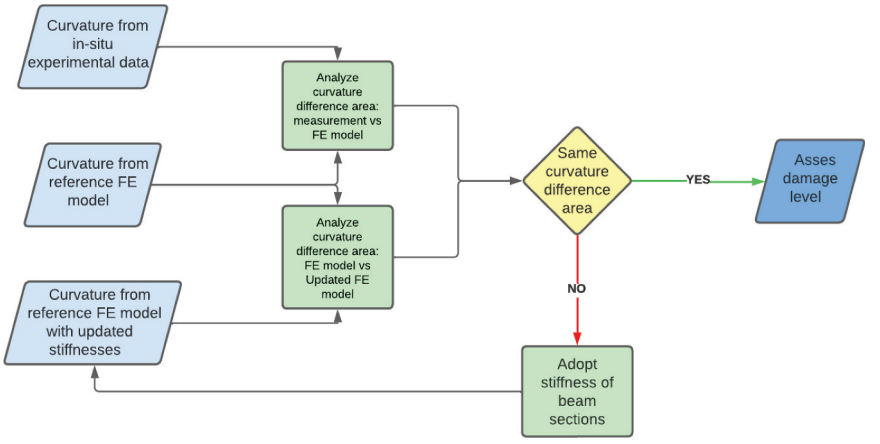

Figure 2. Flowchart of model updating method for damage level assessment.

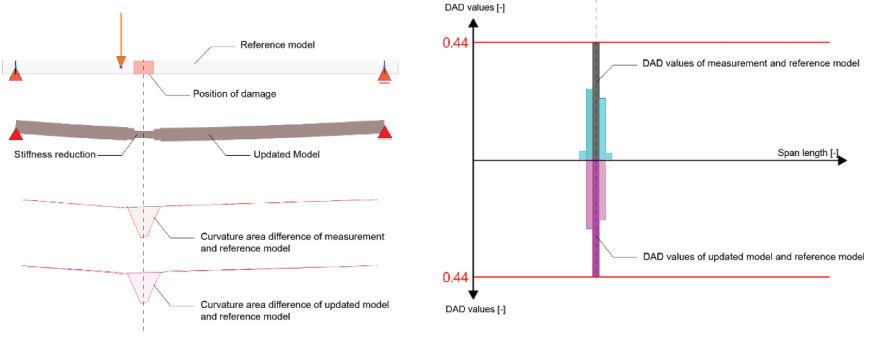

Figure 3. Damage level assessment example for a reinforced concrete beam.

algorithm iterates by modifying the stiffness of the reference model until the area between the curvature lines of the updated and reference models aligns with the area between the curvature line based on the measured deflection line and the one of the reference model. Figure 3 illustrates the reference model, pinpointing the damage location, while the updated model reflects a stiffness reduction at the damage site.

The curvature difference area of measurement and reference model and updated model and reference model are shown resulting to DAD values localizing both the damage position.

4 DAMAGE LEVEL ASSESSMENT WITH MODEL-UPDATING PARAMETRICAL NUMERICAL ANALYSIS

To better understand the influence of local damage to the entire cross section and enhance the in-situ experimental set-up, an extensive parametric analysis is carried out. This paper presents the model of a hollow-box prestressed reinforced concrete structure (Figure 4) and the model of multi girder steel bridge (Figure 5), with both bridges being based on real bridge structures in Luxembourg. The hollow box bridge structure has three spans, a total length of 150 m and a width of 10,50 m, while the steel bridge is a single span bridge with a length of 30 m and a width of 10 m. Local damages (D1 to D4 in Figure 4) are introduced to the numerical model and the DAD method is assessed using an undamaged reference model and the damaged numerical model at different axes of the cross-sections. For the hollow-box bridge the investigated damage positions are presented in Figure 4 as red areas and the measurement axes for the application of the DAD method is shown with numbers. For the steel bridge each girder is damaged individually, and the DAD method is carried out with deflections of all different girders. Local damage is simulated for both models with a 30% reduction of the bending stiffness within the predefined damage area.

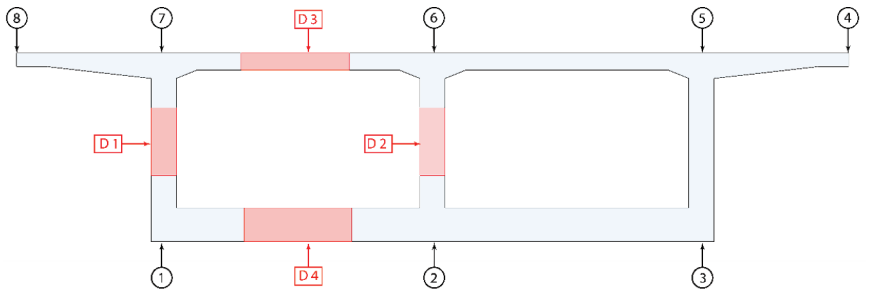

Figure 4. Cross section of hollow box prestressed concrete bridge structure.

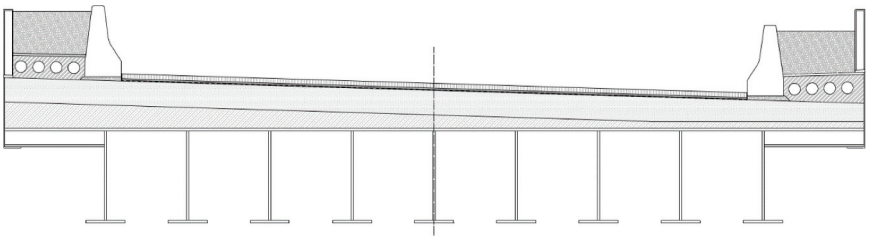

Figure 5. Cross-section of multi girder steel bridge.

Figure 6 shows exemplary the DAD values as a bar graphs in all 8 measurement axes for the second span of the hollow box prestressed concrete bridge, resulting from damage in mid-span in the lower slab (D4 in Figure 4). Figure 7 visualized the DAD values of all girders for

a damage of the second girder at midspan (red area) for the multi girder steel bridge. The DAD values are not of interest here, only the course of the bar graphs is important to highlight the influence. While the local damage of the hollow-box structure leads to successful location in six of eight measurement axes (which are shown as numbers in Figure 4), the damage of the steel structure can be only located with the DAD values based on the deflection line of this same girder. So, the curvature line of the different girders behaves more independent from each girder for the steel bridge, leading to very small influence of local damage to the neighboring girders. In return, it can be stated, that the influence of local damage on neighboring areas is higher for cross-sections with a compact structural behavior. Consequently, less measurement axes are necessary for more compact cross-sections (e.g., hollow box) to detect local damage.

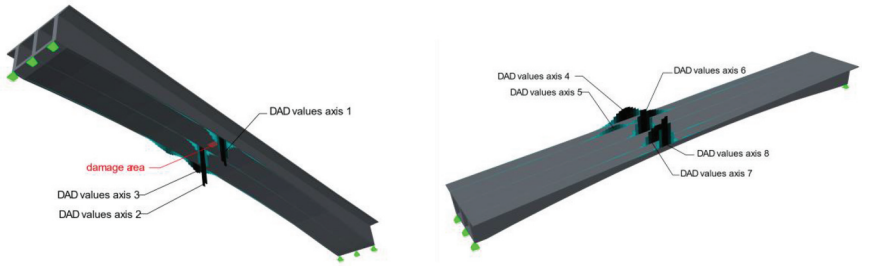

Figure 6. DAD values as bar graphs at different measurement positions; 3D bottom (left) and top view (right) of a hollow box prestressed concrete bridge.

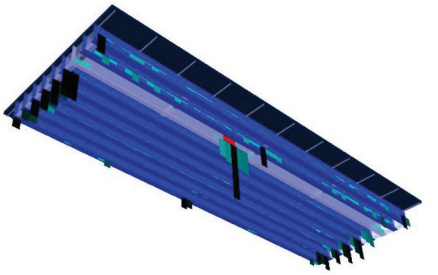

Figure 7. DAD values as bar graphs at different measurement positions; 3D bottom view of a multi girder steel bridge.

5 IN-SITU EXPERIMENT

While the DAD method has been proven in laboratory tests (Erdenebat, Waldmann and Teferle, 2019), a real bridge experiment in Altrier (Luxembourg) (Erdenebat and Waldmann, 2020) affirmed its applicability. However, further studies are necessary to validate its efficiency for damaged bridges.

In this study, the DAD method is applied to a previously parametrically analyzed steel bridge, as described in Section 4 (Figure 5). The static load deflection measurement employed photogrammetry, using targets installed on the girder for continuous deflection measurement (Figure 8) using a programmed UAV. The photogrammetric targets ensure a very high accuracy, around 0.11 mm (Erdenebat and Waldmann, 2020), as high accuracy is required for the DAD method. Since the parametric study revealed that local damage might not impact the curvature of other girders, only one girder is investigated here due to time and budget constraints. Reference targets on the abutments serve as a scale and coordinate system. Two measurements, unloaded and loaded, were conducted, with six heavy trucks as loading.

Subtracting the measured deflection line generated for the unloaded system from the one from the loaded system, a continuous displacement line is provided. The obtained curve is compared with that of a reference FE model analyzed under the same load conditions.

Using the collected data, the DAD method is applied. Figure 9 presents the DAD values in a bar graph, with darker shades indicating higher values. Damage is considered when the value exceeds a predefined boundary (Erdenebat and Waldmann, 2020). In this analysis, no DAD value surpasses the outlier boundary, suggesting no definitive damage detection. However, the highest value hints a potential damaged area. Comparison with the bridge's condition reveals significant corrosion in the girder and cross girder at the DAD method identified point.

The subsequent damage level assessment estimated a 13% reduction in bending stiffness, but it's noteworthy that smaller damages are susceptible to greater noise influence. As the ratio between curvature areas from small damages to noise diminishes, it tends to over- or underestimate damage levels. Further investigations are needed to comprehend and address this discrepancy.

Figure 8. Measurement of deflection using a UAV for a steel bridge structure in Soleuvre, Luxembourg (left); located damage position indicating corroded girder and cross beam (right).

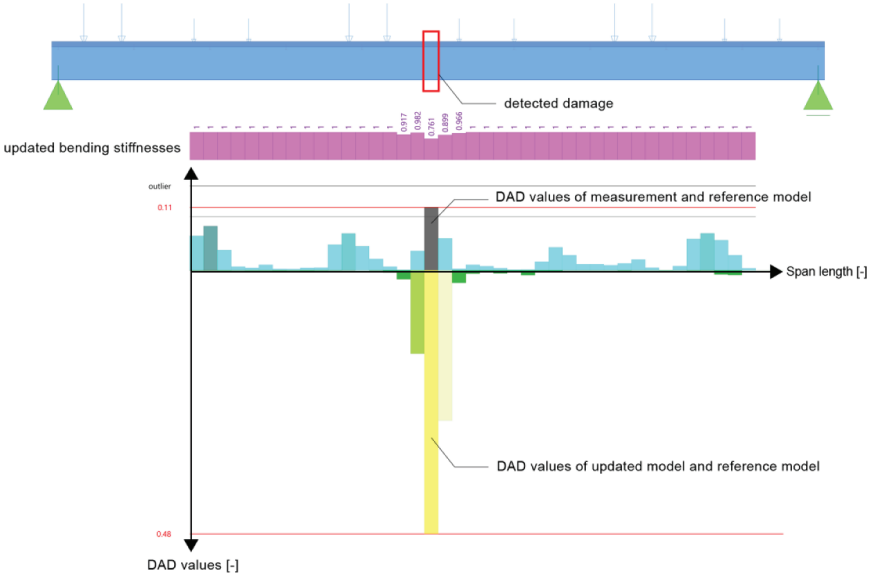

Figure 9. Localized damage & damage level estimation of a steel bridge structure in Soleuvre, Luxembourg.

6 CONCLUSIONS

The present work introduces a novel method using model updating for assessing damage levels. An extensive parametric numerical model illustrates the impact of local damage on the overall

structure. The quantity of measurements needed decreases with a more compact cross-section. The DAD method can detect damage along various measurement axes in a compact hollow box cross-section. However, in a multi-girder steel bridge, the DAD method only identifies damage within the affected girder, with the remaining girders showing no damage indication. A real bridge experiment confirmed localized damage with visual evidence. The novel damage level assessment method estimates a 13% reduction in the structure's bending stiffness due to the damage.

ACKNOWLEDGMENTS

The authors would like to express their gratitude to the "Administration des Ponts et Chaussées" of Luxembourg for providing the opportunity to carry out experiments on a real bridge. Further gratitude is expressed to Mr. Harald Krause, PMS Photo Mess Systeme AG for his professional advice and support on close-range photogrammetry. We are also very thankful to our support engineers of the FSTM Cédric Bruyere and Vincente Reis-Adonis for measuring the reference points.

A study on hammering inspection for unreinforced concrete based on wearable microphone measurement

K. Takeya, S. Kobayashi, A. Akutsu, Y. Ito & E. Sasaki
Civil and Environmental Engineering, Tokyo Institute of Technology

ABSTRACT: In this study, the hammering method for concrete structures using wearable devices was investigated. First, comparative studies of several wearable microphones revealed that the response varied depending on where the microphones were attached. As a result, the helmet type demonstrated the best performance. Next, features of sound pressure and input force waveforms were calculated and evaluated for their importance in defect detection. Then, a fully connected neural network was constructed and the evaluated features were selected as input parameters. Cross-validation was performed using the dataset obtained from a concrete wall with various artificial voids. As a result, the defect detection rate was around 94%, including voids at 10 cm depth at maximum.

1 INTRODUCTION

Initial inspections of concrete structures mainly involve visual inspection. However, since it is necessary to detect defects inside concrete that cannot be confirmed by visual inspection, the hammering method, ultrasonic method, or thermal infrared method are used for destructive inspection. A hammering test has been used in practice for a long time because it can be easily carried out using only a hammer as the specified instrument. The hammering method is widely used in concrete structures to perform periodic inspections (Asakura et al. 2003). However, skilled inspectors are in short supply due to the aging population. In addition, the result of human-based inspection varies even by skilled inspectors because of the human auditory characteristics (Yasuda 2023). Personnel and skills become more difficult to secure and demands for the automation technology of the hammering method that anyone can perform, regardless of their skill level are increasing. Therefore, research has been carried out to automate the detection of defects in concrete structures by measuring hammering sound responses with sensors.

On the other hand, the movement to utilize artificial intelligence (AI) in the civil engineering field is remarkable, and various approaches have been proposed (McMillan et al. 2022). Emoto et al. (2020) conducted a comparative study of AI methods that are effective in determining hammering sound response. Learning and identification were performed using seven AI methods such as logistic regression and decision trees, using the frequency domain obtained by FFT as a feature quantity. Takeya et al. (2021) applied fully connected neural networks to detect void failures in the concrete wall. However, these methods have limitations in measurement, fixing the microphone on a tripod, or controlling the distance from the striking position.

In recent years, fully automated inspection methods by robotics technology have been studied (Menendez et al. 2018). However, it is difficult to introduce robotics technology due to the introduction and operation costs for local governments that manage various civil engineering structures. Because of flexibility in the various fields, human-based inspection will continue to be a common method.

DOI: 10.1201/9781003483755-434

In this study, the wearable microphone measurements for the hammering inspection were investigated as a premise of the human-based inspection. The targets were void defects in concrete walls up to approximately 10 cm in depth that are difficult to detect even by experienced inspectors. By comparing body mounts to attach a microphone to the human body, their characteristics were investigated experimentally. Finally, a neural network for defect detection was proposed, and cross-validation tests examined its accuracy.

2 COMPARISON OF WEARABLE METHODS

2.1 *Attachment methods of a microphone to the human body*

With multiple proposals of wearable device measurement methods, the response characteristics were compared by measurement experiments. Two objectives were focused on considering the wearable method. First, weight reduction was prioritized over high functionality since inspectors are not used to increasing instrument weight. Second, it was important to ensure workability to avoid contact between the arm and the microphone when hammering sounds were measured. The five different mount types are shown in Figure 1. Table 1 shows the specification of measurement equipment. The impact load was measured by an impact hammer (Model: 086C03, 2.25 mV/N) and sound pressure was measured by a microphone (Model: 378B02, 50 mV/Pa). The microphone was attached to the body through a shock-absorbing mount (Figure 1). The sampling frequency was 50 kHz.

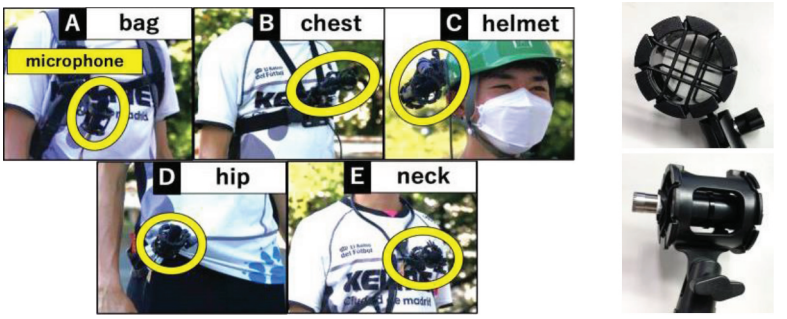

Figure 1. Proposed mount types and the shock-absorbing mount of the microphone.

Table 1. Specification of measurement equipment.

Microphone	378B02 (PCB)	Impact hammer	086C03 (PCB)
Sensitivity	50 [mV/Pa]	Sensitivity	2.25 [mV/N]
Frequency range	3.75 ~ 20000 [Hz]	Head weight	0.16 [kg]

2.2 *Outline of comparison measurement*

Measurements were made on the concrete wall as shown in Figure 2. The hammer was struck 10 times each in the case of hitting the area above the shoulder (high) and the case of hitting the area below the shoulder (low). The sound pressure data were obtained with each mount type of microphone. The left figure in Figure 2 shows an example of measured sound pressure data. The sound pressure response of each impact was extracted from the measurement data, and the feature values were calculated. The time-domain features are listed in Table 2.

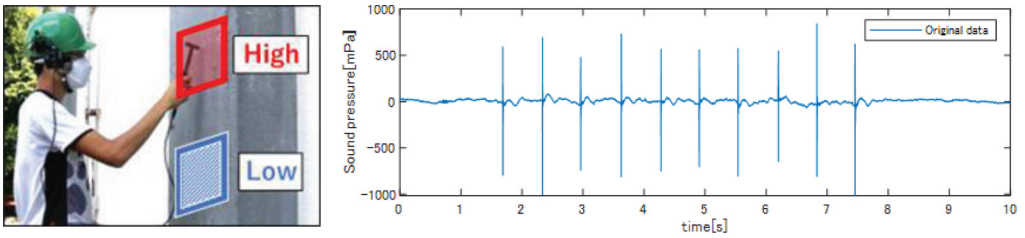

Figure 2. Example of sound pressure data. (Mount type: Helmet, hitting area: high.).

Table 2. Time-domain features of sound pressure.

Features in time-domain	Unit	Notation
Absolute area of sound pressure	mPa.sec	p_area
Absolute maximum of sound pressure	mPa	p_absmax
Absolute of first peak of sound pressure	mPa	p_peak

2.3 *Results and discussion*

The sound pressure response depends on the magnitude of the impact load. Therefore, we proceeded with the discussion hereafter using values normalized by dividing the sound pressure feature by the maximum value of the impact load. To perform a relative evaluation, the ratios to the average value of all methods (value divided by the average value of all methods) were calculated as shown in Table 3. If the ratio is smaller than 1, it indicates a smaller response compared to others.

The difference in sound pressure response was caused by the directivity of the microphone. The microphone's sound collection direction is the same for the helmet and hip mount type. (Figure 3). The bag, chest, and neck mount types have a microphone between the high and low impact points and are oriented in the middle so that it is not biased toward either side (Figure 4). As a result, the microphone was oriented halfway, and it is thought that there were places where the response could not be picked up properly.

There were no significant differences in frequency characteristics between the methods. However, a peculiar frequency peak was observed in the case of neck mount and hip mount as shown in Figure 5. It is thought that the neck mount was loosely constrained to the body, and the hip mount was likely to transmit body vibrations to the microphone when hitting low positions.

Table 4 shows a summary of the differences in the wearable methods of the microphone. The closer the distance between the strike positions and the microphone, the easier it was to obtain a response. However, even when the distance was close, the response was small. This was thought to be an effect of the directivity of the microphone. Therefore, it is necessary to consider the positional relationship between the striking positions and the microphone to obtain appropriate responses. On the other hand, there was no significant difference in the frequency response. However, when the microphone fixation was loose, the effect of noise due to body vibration was considered to appear in the frequency distribution. As a result, the helmet mount type was selected.

Table 3. Normalized values of time-domain features (ratio to the average value of all methods).

	Bag		Chest		Helmet		Hip		Neck		
Mount type position	high	low	high	low	high	low	high	low	high	low	mean
p_area	0.94	0.96	0.95	0.84	0.88	1.19	0.72	1.25	1.33	0.93	1.00

3 DEFECT CLASSIFICATION WITH A WEARABLE MICROPHONE

The wearable device was used to measure and discriminate defects using neural networks (NNs). Based on the classification results, the effects of advantage (large sound pressure response) and disadvantage (disorder caused by wearables) due to wearables on the classification were discussed.

3.1 *The concrete wall specimen with void failures and measurement of data sets*

The equipment was similar in Table 1. The specification of the impact hammer used (Type: 086D05, 0.23 mV/N) in the experiment is shown in Table 5. The head size of the impact hammer increased to improve the S/N ratio. Figure 6 shows the power spectrum density of the sound pressure response by two impact hammers (086C03 and 086D05). The microphone was fixed at a position 30 cm from the impact position, and the sound pressure was measured for 60 seconds each. The large hammer can induce higher sound pressure responses at around the 2000 to 3000 Hz frequency range. Although it is necessary to select a hammer by considering a frequency band that is easy to distinguish depending on the type of defect, in this study we decided to use a larger hammer (086D05) while considering the magnitude of the impact load.

Table 5. Specification of the impact hammers.

Impact hammer	086C02 (PCB)	086D05 (PCB)
Sensitivity	2.25 [mV/N]	0.23 [mV/N]
Head weight	0.16 [kg]	0.32 [kg]
Resonant Frequency	>22 [kHz]	>22 [kHz]

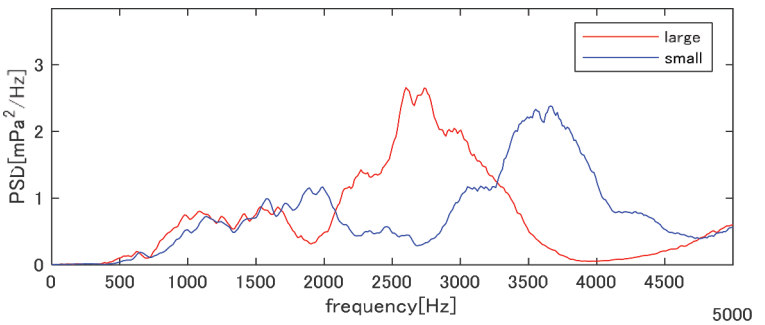

Figure 6. Power spectrum density of the sound pressure response by different impact hammers.

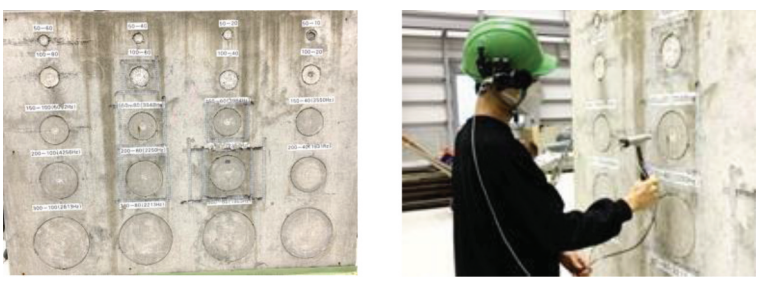

Figure 7. The concrete wall specimen with various artificial voids and example of measurement process. (Mount type: helmet, target: R15-d08.).

The concrete wall specimen used in the experiment was the circular defect model used by Takeya et al.(2021). Figure 7 (left) shows the concrete wall specimen. The specimen had artificial voids in which a disk-shaped Styrofoam (thickness: 25 mm) was embedded, and each had a different depth and diameter. The maximum depth was 10 cm which was difficult to detect even by expert inspectors.

The 18 defect areas were struck for 20 seconds each, and the 12 sound areas were struck for 30 seconds each, so the total number of data was similar, as shown in Table 6. 'R' means diameter (cm), and 'd' means depth (cm) of defects. For example, R20-d08 indicates that a void with diameter R = 20 cm is embedded at depth d = 8 cm. Figure 7 (right) shows a photo of the measurement process.

Table 6. A list of void failures and number of data samples.

Voids	Num. samples	Void	Num. samples
R05_d02	40	R15_d08	59
R05_d04	47	R15_d10	56
R05_d06	56	R20_d04	56

R15_d04	55	R30_d08	55
R15_d06	66	R30_d10	55
Total number of samples of void defect areas			1007 samples
Total number of samples of sound areas			880 samples

3.2 *Evaluation of feature values*

The time-domain features are shown in Table 7. The frequency-domain features are calculated from the power spectrum density (PSD). The spectrum was divided into frequency bands of 500 Hz, and features were calculated in each frequency band (0~500Hz, 500~1000Hz, . . ., 4500~ 5000Hz). The correspondence tables of frequency-domain features and their frequency bands are shown in Table 8. For example, the average amplitude of PSD in the frequency band 1000 ~ 1500 Hz is expressed as "p_freq_mean_3".

Table 7. Correspondence table for time-domain feature notation.

features	Unit	Notation	features	Unit	Notation
Absolute of first peak	mPa	p_peak	Average force	kN	f_mean
Absolute area	mPa.ms	p_area	Impulse force	kN.s	f_impulse
Absolute maximum	mPa	p_absmax	Duration of impact force	ms	f_duration
Maximum force	kN	f_peak	Distance from impact point	m	distance

Table 8. Correspondence table for frequency domain feature notation and their frequency bands.

Features of PSD	Unit	Notation
Maximum amplitude	(mPa)2/Hz	p_freq_max
Average amplitude	(mPa)2/Hz	p_freq_mean
Area	(mPa)2	p_freq_area
Average peak frequency	Hz	p_freq_pmean
Peak centroid frequency	Hz	p_freq_pcentroid
Area centroid frequency	Hz	p_freq_acentroid

No.	Freq. band	No.	Freq. band
1	0.0~0.5 kHz	5	2.0~2.5 kHz

$13^{th} \sim 15^{th}$	p_freq mean 3	p_freq area 3	p_freq max 1	> 0.47
$16^{th} \sim 18^{th}$	p_freq pcentroid 2	p_freq acentroid 3	p_freq area 4	> 0.40
$19^{th} \sim 21^{st}$	p_freq mean 4	p_freq pcentroid 4	p_freq pmean 1	> 0.38
$22^{nd} \sim 24^{th}$	p_freq pmean 7	p_absmax	p_freq acentroid 6	> 0.36

The time-domain features and frequency-domain features were evaluated in terms of their importance for detecting void defects. The feature evaluation was based on the method of Takeya et al.(2021). The importance scores or weights were calculated using the chi-square test, Minimum Redundancy Maximum Relevance (MRMR), ReliefF, Nearest neighbor analysis. The delta thresholds for linear discriminant analysis models and the predictor importance for ensemble classification of decision trees were also calculated. Table 9 shows an overview of the six feature selection algorithms used to score the features. The evaluation values of each algorithm are normalized by dividing them by their maximum value to integrate the evaluation. The top 24 features are shown in Table 10. As a result, the features of impact load (average, impulse, maximum, and duration of impact force) were evaluated with high importance. The frequency-domain features in lower frequency bands by 2 kHz were also ranked high.

3.3 *Defect detection using a fully connected neural network*

Figure 8 and Table 11 show the configuration and structure of the neural network (NN) used for defect detection. The number of input features was decided by trial and error, and the top 24 features were used. The number of hidden layers was two to prevent over-learning.

Cross-validation was performed to obtain the percentage of correct classifications. In screening tests for defects inside concrete using hammering tests, the priority is to detect all defects, so recall is more important than precision. The defect detection rate has the same meaning as the recall rate. Recall rates for each target void are shown in Table 11. No defect was overlooked if the recall rate was 100 %. The recall rate was high even for deep voids (d08 and d10). This indicates that it is possible to detect defects at the same level as experienced inspectors. The average recall rate was 94.2 %. On the other hand, the total accuracy was 86.7%. This fact shows that the trained neural network performed a safe diagnosis for defect detection. The recall rate was low, especially in the case R30-d06 where the defect diameter is large at 30 cm and the depth is 6 cm, the hammering sound response tends to be different from the sound part. It is supposed that it is difficult for neural networks to predict defects that deviate from the training data. The defect detection accuracy will improve by collecting a wide range of training data.

4 CONCLUSIONS

In this study, to propose the hammering method with wearable device measurements, experimental studies were conducted considering the difference in hammering sound response measurement by mount type. The effective feature values were considered, and the defect detection method was proposed by using the neural network. The findings are summarized as follows.

A comparative study of five mount types was conducted. It was shown that the hammering sound response varies depending on the attachment method and position of the microphone by comparing the feature values. If the microphone was not facing the direction of the strike, the response tended to be small even if the microphone was close. As a result, the helmet mount type has an advantage for measuring the hammering sound response.

The time-domain and frequency-domain features were proposed, and the effective feature values were considered by combining the results of six feature selection algorithms. The impact force

features such as impulse, maximum value, and duration showed high importance. The frequency-domain features in the low-frequency band by 2kHz seemed effective for defect detection.

The fully connected neural network was proposed and learned using the measured data at the concrete wall specimen with various artificial voids. As a result of cross-validation, it can be said the average recall rate of defect detection was around 94 %, including voids at 10 cm depth in maximum. On the other hand, the recall rate decreased for defects with diameters and depths that could not be interpolated using the learned defect data. There is room to improve the classification accuracy by collecting various training data including deeper void than 10 cm for example.

Input / hidden / output layers	1 input / 2 hidden / 1 output layers
Input data	24 features
Output results	defect or sound

Simulation of cylinder impact damage by peridynamics

J.J. Zhang, Z.C. Pan & H.C. Chang
Tongji University, Shanghai, China

ABSTRACT: Impact damage to bridges may lead to immense economic losses and significant environmental impacts. Traditional continuum mechanics is in some ways ill-suited to the solving of discontinuity problems in impact damage. The peridynamics (PD) theory has been regarded as a promising method for predicting impact damage. PD has been attractive to researchers as it is a non-local formulation in an integral form, unlike the local differential form of classical continuum mechanics. The hypervelocity impact of cylinders on a rigid boundary test is a classic example to validate the accuracy of the simulation method. In this study, a PD-based 3D discrete particle model of the cylinder impact on a rigid boundary is developed to simulate the process of impact damage. The predictions concerning the damage growth of the cylinder are compared with the previous experiments. The results of the proposed method agree well with the previous experiments.

1 INTRODUCTION

Recently, bridges have been subjected to an increasing frequency of impact loads, often resulting in serious consequences. Impact on bridge components can lead to concrete spalling and reduced load-bearing capacity. However, predicting material damage under high-speed impact has always been challenging. Therefore, it is necessary to study numerical simulation methods for material impact damage. In this paper, peridynamics has been used to simulate high-speed impact models to demonstrate the potential of this method in predicting bridge impact damage.

On the basis of traditional continuum mechanics, various numerical methods have been proposed to analyze the mechanical properties of materials (Fang et al. 2023, Zeng & Liu 2018, Vu-Bac et al. 2013). However, the presence of discontinuities is inconsistent with the continuity assumption and limits their application. Peridynamicss (Silling & Askari 2005, Silling et al. 2007, Silling 2000) (PD) transforms the differential equations of traditional continuum mechanics into integral forms for solution, allowing for the description of natural material damage. Peridynamicss has been widely used to predict and analyze failure behavior in various fields, such as fluid–structure interaction (Chang et al. 2023, Chang et al. 2022), quasi-static, impact failure (Liu et al. 2017, Baber et al. 2018), corrosion and fatigue damage, and multi-field coupling.

The cylinder impact on a rigid boundary problem is a classic case used to verify the accuracy of numerical simulations. However, the numerical simulation of the Taylor impact test for a cylinder impact on a rigid boundary was initially proposed by Taylor (1948) to determine the effect of impact velocity on the material's dynamic yield stress. In the past few decades, this type of test has been used to probe the response and damage of metals and alloys under high-speed impact. The constitutive model of materials under high-speed impact becomes very complex, and the Taylor test is particularly suitable for studying the dynamic failure of materials and validating damage models. Therefore, the Taylor test is widely used to assess the accuracy of numerical simulation methods and various constitutive models.

Currently, peridynamics has not been applied to the numerical simulation of the Taylor impact test. This paper uses conventional state-based peridynamics to numerically simulate the Taylor impact experiment, predicting the impact damage on the cylinder at different impact velocities and comparing the results with previous experimental data.

2 METHODOLOGY

2.1 *Ordinary state-based peridynamics theory*

Peridynamics first discretizes the object into a series of material points, with each material point interacting with other material points within a certain range. The governing equation (Silling et al. 2007) for material point **x** as follows:

$$\rho\ddot{\mathrm{u}}(\mathrm{x},\ t)=\int_{H_{\mathrm{X}}}\{\underline{\mathbf{T}}[\mathbf{x},t]\langle x'-\mathbf{x}\rangle-\underline{\mathbf{T}}[\mathbf{x}',\ t]\langle\mathbf{x}-\mathbf{x}'\rangle\}\mathrm{d}V_{\mathrm{X}'}+b(\mathbf{x},t) \tag{1}$$

Where ρ is the material density, ü is the acceleration of material pointx, $\boldsymbol{b}$ is the body force density of the external load. $\underline{\mathbf{T}}[\mathbf{x},t]$ and $\underline{\mathbf{T}}[\mathbf{x}',t]$ are force vector states of material points **x** and **x'**. $dV_{\mathrm{x}'}$ denotes the volume for material point x'. The integral domain H_{x} is defined as $H_{\mathrm{x}}=\{0<|\mathbf{x}'-\mathbf{x}|<\delta\}$, where δ is called the horizon size.

In the context of the Ordinary State-Based Peridynamicss (OSB-PD), the force state can be defined as:

$$\underline{\mathbf{T}}\ =\ \underline{t}\ \underline{\mathbf{M}} \tag{2}$$

Where t is called the scalar force state, $\mathbf{M}$ is the direction of force state $\mathbf{M}=\mathbf{Y}/|\mathbf{Y}|,\mathbf{Y}=\ y(\mathbf{x},\ t)-y(\mathbf{x}',\ t),y(\mathbf{x}',\ t)$ and $y(\mathbf{x},t)$ represent the positions of $\boldsymbol{x}'$ and $\boldsymbol{x}$.

The strain energy density is defined as:

$$W\left(\theta,\underline{e}^{d}\right)=\frac{k\theta^{2}}{2}+\frac{\alpha}{2}\left(\underline{\omega}\ \underline{e}^{d}\right)\cdot\underline{e}^{d} \tag{3}$$

Where k and α are positive constants, θ is referred to as the dilatation, and $\underline{e}^{d}$ is the deviatoric part of the extension scalar state $\underline{e}$.

$$\underline{e}=\underline{y}-\underline{x} \tag{4}$$

$$\underline{y}\ =|\underline{\mathbf{Y}}| \tag{5}$$

$$\underline{x}\ =|\underline{\mathbf{X}}| \tag{6}$$

$$\underline{e}^{i}=\frac{\theta x}{3} \tag{7}$$

$$\underline{e}^{d}=\underline{e}-\underline{e}^{i} \tag{8}$$

$$\theta(\underline{e})=\frac{3}{m}(\underline{\omega x})\cdot\underline{e} \tag{9}$$

Where m represents the weighted volume

$$m=(\underline{\omega}\ \underline{x})\cdot\underline{x} \tag{10}$$

From Equation (3), the scalar force state value is:

$$\begin{aligned}\underline{t}&=\underline{t}^{i}+\underline{t}^{d}\\&=\frac{\partial W}{\partial\underline{e}^{i}}+\frac{\partial W}{\partial\underline{e}^{i}}\\&=\frac{3k\theta}{m}\underline{\omega}\ \underline{x}+\alpha\underline{\omega}\ \underline{e}^{d}\end{aligned} \tag{11}$$

2.2 *Elastoplastic peridynamics model*

In Mitchell (2011), W in the elastoplastic model is rewritten by:

$$W\left(\theta,\underline{e}^{d},\underline{e}^{dp}\right)=\frac{k\theta^{2}}{2}+\frac{\alpha}{2}\left(\underline{e}^{d}-\underline{e}^{dp}\right)\cdot\omega\left(\underline{e}^{d}-\underline{e}^{dp}\right) \tag{12}$$

According to the above equation, the force state can be rewritten as:

$$\begin{aligned} \underline{t} &= \underline{t}^{i} + \underline{t}^{d} \\ &= -\frac{3P}{2}\underline{\omega}\,\underline{x} + \alpha\underline{\omega}\left(\underline{e}^{d} - \underline{e}^{dp}\right) \end{aligned} \tag{13}$$

Where $P = k\theta$ is the peridynamics pressure.

The yield surface and plastic flow for the peridynamics elastoplastic model are defined here (Vogler & Lammi 2014):

$$f = \frac{\left\|\underline{t}^{d}\right\|^{2}}{2} - \beta P - \varphi_0 \leq 0 \tag{14}$$

$$\dot{\underline{e}}\, dp = \lambda \nabla^{d} f \tag{15}$$

$$\lambda \geq 0, f\left(\underline{t}^{d}\right) \leq 0, \lambda f\left(\underline{t}^{d}\right) = 0 \tag{16}$$

Where $\nabla^{d} f$ and λ denotes a Frechet derivative and consistency parameter.

2.3 *Peridynamics failure criterion*

In peridynamics, damage to a material is often characterized by the breaking of bonds and describes the extension of cracks in the material. A common type of bond breaking criterion is the critical stretching criterion proposed by Silling & Askari (2005). This criterion states that when the stretching of a bond between material points exceeds a critical value, the bond irrecoverably breaks. The stretching of a bond is defined as follows:

$$\underline{s} = \frac{\underline{e}}{\underline{x}} = \frac{\underline{y} - \underline{x}}{\underline{x}} \tag{17}$$

$$d = \begin{cases} 1 & \underline{s} < s_0 \\ 0 & \text{otherwise} \end{cases} \tag{18}$$

$$D(\mathbf{x}, t) = 1 - \frac{\int_{H_{\mathrm{X}}} d\, \mathrm{d}v_{\mathrm{X}'}}{\int_{H_{\mathrm{X}}} \mathrm{d}v_{\mathrm{X}'}} \tag{19}$$

Where s_0 is the critical stretch, d is used to mark whether the bond is broken. Once the bond fails, the internal force between the material points is no longer effective, and the damage degree of material points is obtained by counting the ratio of number of failed bonds to the number of total bonds.

2.4 *Contact model*

In peridynamics, the contact model is used to describe the contact behavior between different Blocks. A typical contact model is a short-range force model (Macek & Silling 2007), in which the interaction of material points occurs when the distance between material points is less than the contact radius. The short-range force is defined as:

$$N_S = c_S \frac{\left(d_s - \left|y_p - y_i\right|\right)}{\delta} \frac{y_p - y_i}{\left|y_p - y_i\right|} \tag{20}$$

where c_S is the spring constant, and it is usually chosen to be a multiple of micromodule coefficient. d_s is the contact radius.

3 SIMULATION MODEL OF CYLINDER IMPACT

As the Figure 1 show, in this paper, a three-dimensional peridynamics model is built in the Cartesian coordinate system to analyze impact damage in the cylinder. The size of the rigid boundary is 0.0005m×0.03m×0.03m. The radius of the cylinder is 0.00381m and the length of the cylinder is 0.02347m. The mesh size should be as fine as possible and the mesh size no coarser than 0.000300256m. The rigid boundary has been meshed into 4900 elements, and the cylinder has been meshed into 15510 elements. The radius of the horizon is 3.015 times the mesh size.

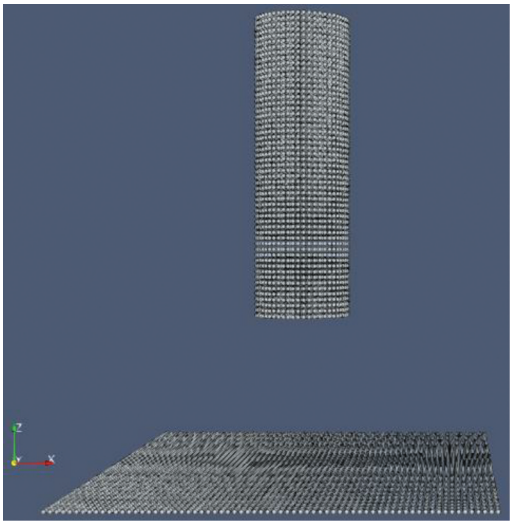

Figure 1. Three-dimensional perdynamic moedl for cylinder impact rigid boundary.

This article uses the material parameters used by Wilkins & Guinan (2003). Table 1 lists the values of the parameters of the cylinder. The cylinder uses an elastic-plastic model, and Poisson's ratio and Young's modulus can be deduced from the given Bulk Modulus and Shear Modulus. The formulas are as follows (Ma et al. 2022):

$$E = G\left(3 - \frac{G}{K}\right) \tag{21}$$

$$\nu = \frac{1}{2} - \frac{G}{2K} \tag{22}$$

Table 1. Material properties.

Material	1090 steel
Density (kg/m^3)	7850
Bulk Modulus(GPa)	190
Shear Modulus(GPa)	80
Yield Stress(MPa)	1200

4 MODEL VERIFICATION

In this section, the proposed computational model is compared with the numerical simulation results of Wilkins & Guinan (2003) with the test results to determine the accuracy of the model.

The model accuracy is calibrated from a qualitative comparison of the shape of the cylinder after impact with a quantitative comparison based on the metric, which is the ratio of the length L_f of the cylinder after it has undergone the impact test to the original length of the cylinder L_0.

The shape of the cylinder after the test is shown in Figure 2(a) (Wilkins & Guinan 2003) The shape of the cylinder in the peridynamics numerical simulation results is shown in Figure 2(b). It can be seen that the post-impact shape of the cylinder in the peridynamics model is similar to the experimental results. The results of numerical simulation compared to the results of the experiment have smaller plastic deformation in the region of contact with the rigid surface. This is due to the fact that in the peridynamics model, when the cylinder is in contact with the rigid surface, it will generate a hoop force on the cylinder, which restricts the deformation of the cylinder.

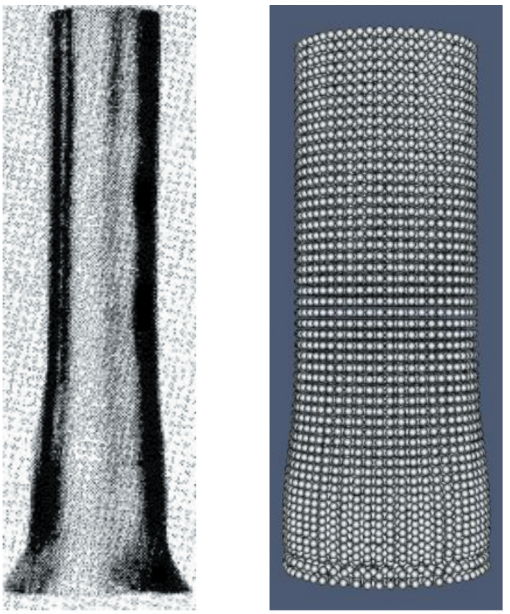

Figure 2. The shape of 1090 steel cylinders impacts on a rigid boundary (Wilkins & Guinan 2003).

As shown in Figure 3, the proposed peridynamics model can get quite similar results to that of a finite element model and experiment data in terms of cylinder impacts on the rigid boundary. The action range of interfacial force in the proposed model is called the horizon, and its influence on calculation results needs to be analyzed. Three horizons are chosen to be $\delta=2.0015\Delta x$, $\delta=3.0015\Delta x$, and $\delta=4.0015\Delta x$. Figure 4 shows the deformation pattern of steel cylinder specimens with different horizons. With the increases of horizons, the deformation patterns of the 1090 steel cylinders are more similar to the data of the experimental. When $\delta = 4.0015\Delta x$, the peridynamics model deformation pattern is consistent with the experimental data. Figure 5 displays the error curves under different horizons. The peridynamics results are consistent with experimental data in terms of the deformation of 1090 steel cylinders. Based on the experiment (Wilkins & Guinan 2003), the calculation error of the peridynamics model is within 4.5%. These findings show that the peridynamics can correctly characterize the 1090 steel cylinders' impacts on the rigid boundary. Moreover, the interface horizon affects the deformation pattern of steel cylinders. When the horizons increase, the deformation mode and deformation amount of the peridynamics are more consistent with the experimental data.

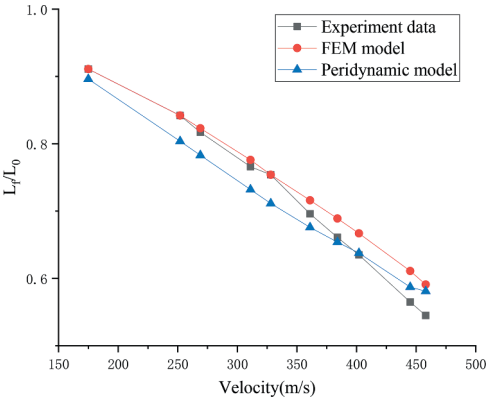

Figure 3. Calculation results of cylinders impacts on a rigid boundary.

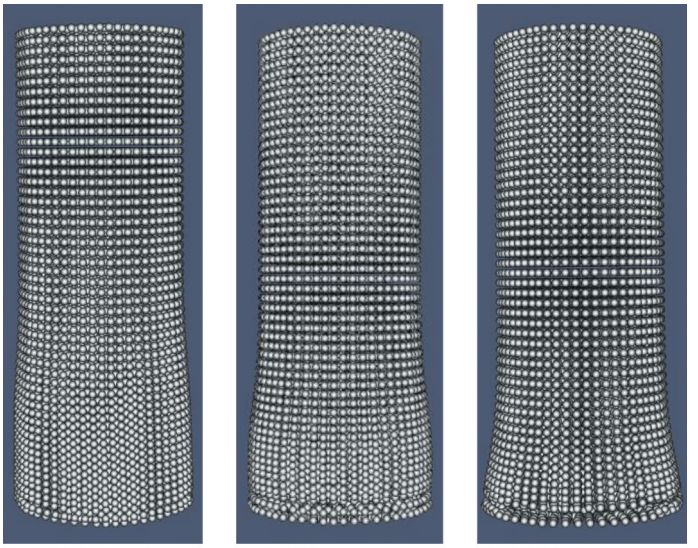

Figure 4. Deformation of 1090 steel cylinders computed by peridynamics with different δ.

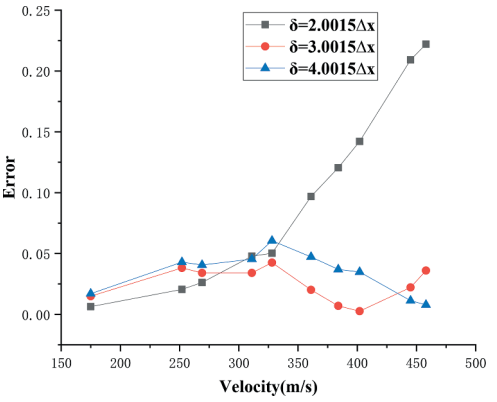

Figure 5. Calculation results of cylinders impacts on a rigid boundary.

5 CONCLUSIONS

Based on ordinary state-based peridynamics theory, a 3D peridynamics model was established to investigate the damage of cylinder impact rigid boundary. The elastic-plasticity model and the short-range force contact model have been used to build peridynamics model. The proposed model is validated by the shape of the cylinder after impact and the L_f/L_0 values of the cylinder after impact. Good agreements have been achieved not only in comparison with the finite element model but also in comparison with the experimental results. The results show that the peridynamics model based on ordinary state-based peridynamics theory is able to simulate the impact damage of the material well and peridynamics has potential in predicting bridge impact damage. The deformation pattern of steel cylinders can be affected by the size of the interface horizon. However, in order to better simulate the morphology of the cylinder after impact, the contact force model of the peridynamics needs to be modified in subsequent work.

Analytical evaluation of DBTT in Charpy impact test for structural steels

A. Jamil, H. Tamura, H. Katsuchi & C. He
Yokohama National University, Yokohama, Japan

ABSTRACT: The Charpy impact test is a widely accepted method for the measurement of material's fracture toughness and facilitates the investigation on the temperature related ductile-brittle transition phenomena. In order to study the structural steel behavior under different conditions such as the effect of pre-strains and the residual stresses etc., the experimental procedure of impact test becomes laborious and expensive. The ability to reproduce experimental results analytically from a limited set of material parameters may reduce the cost and allow assessment of the various behaviors of target steel from few tested samples. In this study, efforts were made to simulate the Charpy impact test to measure the brittleness of steel based on the modified Weibull stress (MWS). To deal with strong non-linearity and reproduction of elasto-plastic deformation phenomena under impact, an explicit-dynamic analysis was performed employing penalty contact method. The fracture occurrence probability at different temperatures was evaluated based on MWS, while internal energy from the analysis was decided at 95% fracture probability. The ductile-brittle transition temperature (DBTT) was estimated from the ductile-brittle transition curve for two Japanese structural steels i.e., SM570Q and SM490YB. To validate the analytical results, laboratory experiments were performed under similar conditions. The internal energy from MWS calculations was compared with the experimental absorbed energy from the Charpy impact tests. It was found that the analytical values and the experimental values are in good agreement in the low-temperature region where brittle fracture dominates. Based on the outcomes of this study, it was concluded that MWS calculations can be applied to evaluate the brittle fracture occurrence during Charpy impact tests.

1 INTRODUCTION

In standard Charpy impact testing, the fracture toughness is characterized on the basis of quantity of energy absorbed. For steel, low energy absorption occurs at low temperatures and a significant amount of energy is absorbed at higher temperatures. Due to BCC (body-centered cubic) structure, steel is vulnerable to failing under brittle fracture at low temperatures. Therefore, determination of transition from lower shelf (brittle behavior) to the upper shelf (ductile behavior) is really important.

For long-term operation of many important structures like pressure vessels, submarines, nuclear power plants, DBTT determination of structural materials play a vital role (Bruchhausen et al. 2016). Charpy testing technique has been widely applicable for the assessment of ductile-to-brittle transition temperature (DBTT) for previous century by finding the absorbed energy corresponding to different testing temperature. For a dual-phase steel, (Chao et al. 2007) successfully evaluated the DBTT using the Charpy impact testing and speculated the splitting in all impact specimens due to the fabrication process. (Haušild et al.2005) modelled Charpy impact test for a porous metal in the range of DBTT and confirmed that stress level around the notch increased after the initiation of ductile crack. For a Charpy specimen, the effect of inertia near the V-notch was investigated using 3D FE-analysis and provided the solution of contact issues between the hammer and the specimen (Takashima et al. 2017).

For the past few decades, cleavage fracture has become a common failure in structural steels and occurs at low temperatures without any prior warning. This study focused on the estimation in the region of brittle fracture.

DOI: 10.1201/9781003483755-436

2 SIMULATION OF CHARPY IMPACT TEST

2.1 *Explicit dynamic analysis*

Stress changes and elasto-plastic deformation of Charpy impact analytical model was reproduced.

By using a 3-dimensional finite element model on Abaqus/Explicit, analysis was performed. Explicit dynamic analysis was performed to check the sudden deformation phenomena. The equation of motion in explicit dynamic analysis is solved on the basis of explicit central-difference integration rule.

$$\ddot{u}_{(i)}^{N} = \left(M^{NJ}\right)^{-1}\left(P_{(i)}^{J} - I_{(i)}^{J}\right) \tag{1}$$

In the equation (1), $\ddot{u}$ represents the acceleration vector, M^{NJ} is the mass matrix, P^{J} is the applied load vector, and I^{J} is the internal force vector. In the model, increment number has been represented by the subscript i, whereas n shows the number of degrees of freedom (Smith 2009). During analysis, the Courant-Friedrichs-Lewy condition was satisfied by using smaller time increment than the stability limit. In accordance with JIS Z 2242 (Japanese standards association 2018), Figure 1 shows the standard geometry of V-notched Charpy impact specimen with a notch depth of 2 mm and a notch root radius of 0.25 mm, having notch angle of 45°. As the Charpy specimen is symmetric in shape, only one-quarter specimen was modelled analytically to save time and calculation cost. In Figure 2, the Charpy impact analytical quarter-model is presented where the hammer, specimen and anvil were modelled using 3D solid elements. The contact surface was provided using the penalty contact method which forbids energy dissipation due to impact and also restricts the penetration of nodes between different surfaces.

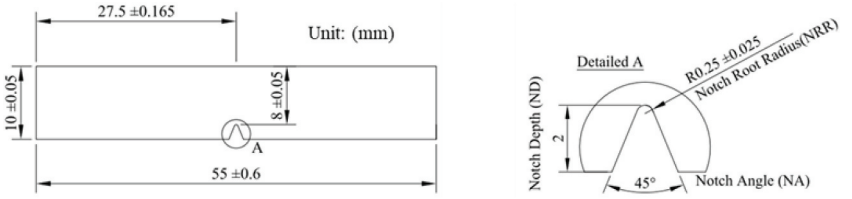

Figure 1. V-notched Charpy impact specimen.

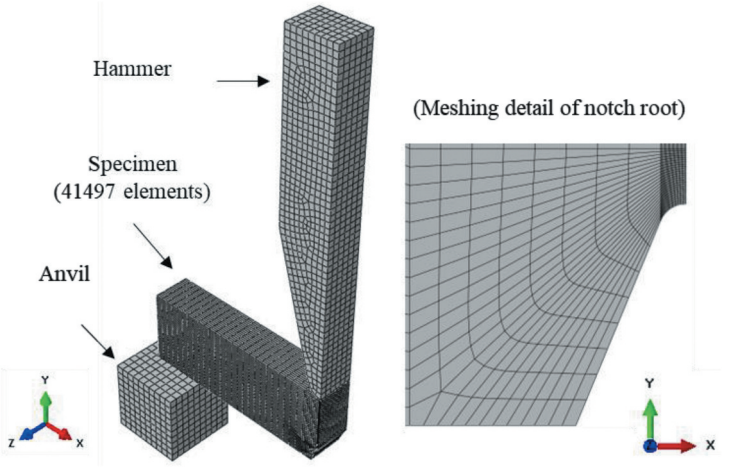

Figure 2. Charpy impact quarter-model for finite element analysis.

During the analysis, impact velocity of the hammer has a great influence on the kinetic energy (Yasuhito et al. 2017). Therefore, to replicate the experimental results, an impact load and velocity for hammer was given according to the specifications of Charpy impact testing machine as given in Table 1. The tests were conducted using two testing machines having 150 J and 600 J potential energy. The boundary condition for support was completely fixed and the hammer allows displacement merely in the translational direction. As quarter-model was reproduced in the analysis, symmetric boundary conditions about plane X (XSYMM) and along the Z-axis (ZSYMM) were also provided. For the specimen, the elemental division was divided into smaller parts near the notch where stress concentration occurs, and the minimum element size was set to be 20 μm. The analysis was performed for two Japanese structural steels and at different temperatures as listed in Table 2. For SM490YB steel, tests were performed by using 600 J Charpy impact tester at –100 °C, –80 °C and –60 °C as highlighted by blue color in Table 1 and Table 2 respectively.

Table 1. Charpy impact testing machine specifications.

Testing machine	Hammer weight, W (N)	Distance from the center of rotation axis to the center of gravity of the hammer, R (m)	Hammer lifting angle, θ_0 (°)
150 J	152.43	0.523	151
600 J	407.29	0.850	137

Table 2. Temperature for various steel material.

Steel type	Temperature (°C)
SM570Q	–80, –60, –50, –40, –20, 0
SM490YB	–196, –100, –80, –60

2.2 *Material properties for analysis*

For material properties, values for the Poison's ratio and the Young's modulus were set to be as 0.3 and 200 GPa. In order to imitate the changes in the material properties of the steel due to the effects of temperature and strain rate, the yield stress estimation formula provided by the Japan Welding Engineering Society standard WES2808 was used (Takashima et al. 2016). For SM570Q steel, Figure 3 represents the stress-strain relationships at various strain rates. The stress increases at lower temperature as compared to the higher temperature as illustrated in Figure 3a and Figure 3b respectively. Similarly, Figure 4a and Figure 4b shows the stress-strain relationships at two different temperatures for SM490YB steel. The outcome depicts that yield stress increases at higher strain rates and lower temperatures as presented in Figure 3 and Figure 4 for two different structural steels. As cleavage fracture in steel arises catastrophically and at a very high speed (Chen and Cao 2015), hence, for precise analytical calculations, the strain rate varied between 0 to 2000 /sec up to 4 mm/mm plastic strain values.

2.3 *Energy balance in explicit analysis*

In explicit analysis, energy output is an important parameter because comparison of various components of energy represented in Table 3 may assist to evaluate the appropriate response of analysis. For the whole model, an energy balance is shown in Equation (2) (Smith 2008). For Charpy analytical model, the input was provided in the form of inertia and initial velocity to the hammer hence, kinetic energy (ALLKE) can be regarded as the input energy. The reproducibility of the analysis has been represented in Figure 5, in which the input energy (ALLKE) and all the other remaining energy components are compared at –80°C and –100°C for SM570Q and SM490YB respectively. In this research, the internal energy (ALLIE) hereafter known as the analytical

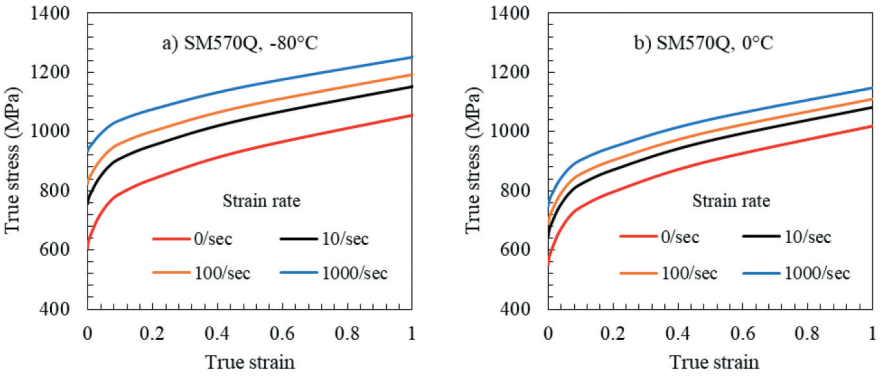

Figure 3. Stress-strain relationships for SM570Q steel at a) –80°C and b) 0°C.

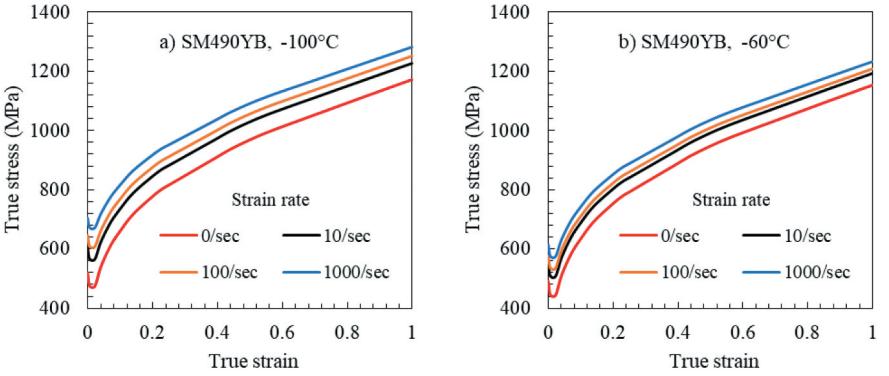

Figure 4. Stress-strain relationships for SM490YB steel at a) –100°C and b) –60°C.

energy is used for comparing the experimental absorbed energy from Charpy impact testing. The analytical energy (ALLIE) includes two major energy components, i.e., the elastic strain energy which can be recovered and also the non-recoverable or dissipated energy from the inelastic processes such as plasticity.

Table 3. Various energy components for the explicit analysis.

Abbreviation	Definition
ALLKE	Kinetic energy
ALLIE	Internal energy
ALLVD	Viscous energy dissipated
ALLFD	Frictional energy dissipated
ALLWK	Work done by the externally applied loads
Total energy	Sum of all the energy components

$$\mathrm{ALLIE} + \mathrm{ALLVD} + \mathrm{ALLFD} + \mathrm{ALLKE} - \mathrm{ALLWK} = \mathrm{Total\,energy} = \mathrm{constant} \qquad (2)$$

2.4 *MWS calculations for analytical results*

From the Charpy impact analytical results, MWS was calculated based on the formula from (Tamura et al., 2018) using the Weibull parameters i.e., shape parameter (m), scale parameter ($\sigma_u{}^*$) and the threshold stress (σ_{th}) as listed in Table 4. The output from analysis i.e., equivalent

stress (SMISES), maximum principal stress (SMAX), equivalent plastic strain (PEEQ) and the element volume (EVOL) were used as an input for MWS calculations. The calculations were performed for elements around the notch root having substantial distribution of SMISES, SMAX and PEEQ as represented in Figure 6 for center-line section of a quarter-model.

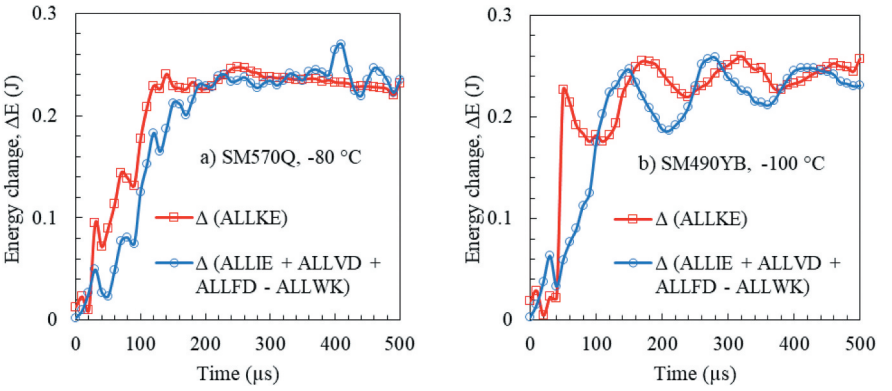

Figure 5. Reproducibility of Charpy analytical model for SM570Q and SM490YB.

Table 4. Weibull parameters and the threshold stress.

Steel type	Shape parameter, m	Scale parameter, σ_u^* (MPa)	Threshold stress, σ_{th} (MPa)
SM570Q	21.35	976	1960
SM490YB	36.04	1320	1275

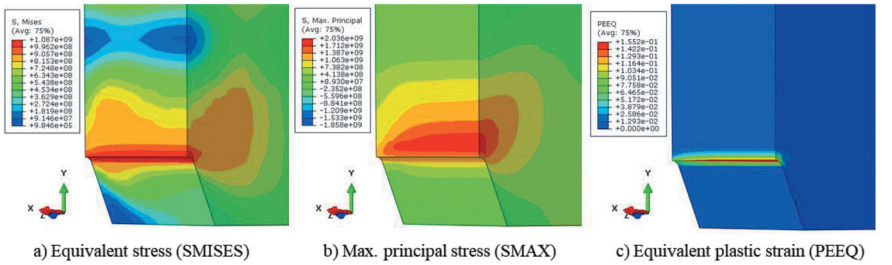

Figure 6. Distribution of stress and strain around the notch root for SM570Q at –80°C.

For SM570Q steel, Figure 7 represents the time-histories of modified Weibull stress (MWS) and fracture probability (P_f) showing that 100% P_f achieves earlier for lower temperatures as compared to the higher temperatures. In Figure 7, the plots of MWS and P_f at –40°C shows a relatively small increment between 300 to 500 μs as compared to other temperatures. The reason is for analysis at DBTT, insignificant number of elements have maximum principal stress greater than the threshold stress, hence restricting the continuous increase in modified Weibull stress and fracture probability. The results of MWS, P_f and ALLIE at –20°C and 0°C are almost the same because the modified Weibull stress calculations couldn't predict material's behavior after the DBTT. In statistics, the fracture probability is usually considered as 95% (Stienstra et al. 1990), along with other fracture probabilities like 90% (Ruggieri and Dodds 1998) or 80% (Zhang and Qian 2016). According to Figure 8a, at lower temperatures different fracture probabilities are approximately similar, therefore, in this research, the analytical energy is considered on the step time at which 95% fracture probability is reached as illustrated in Figure 8b.

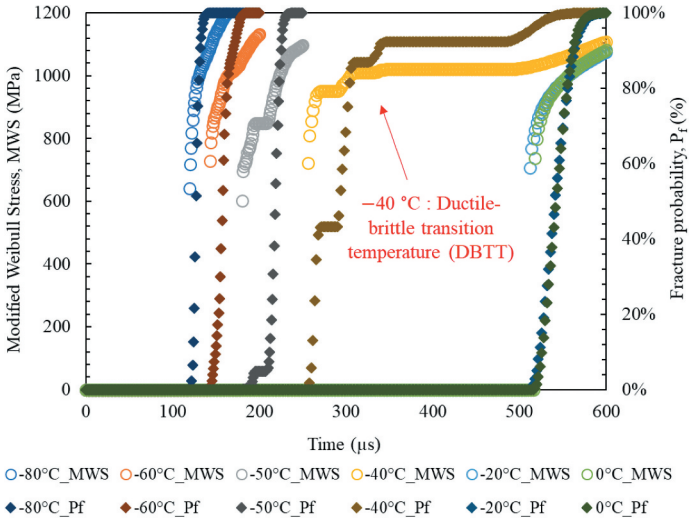

Figure 7. Time-histories of modified Weibull stress (MWS) and fracture probability (P_f) for SM570Q.

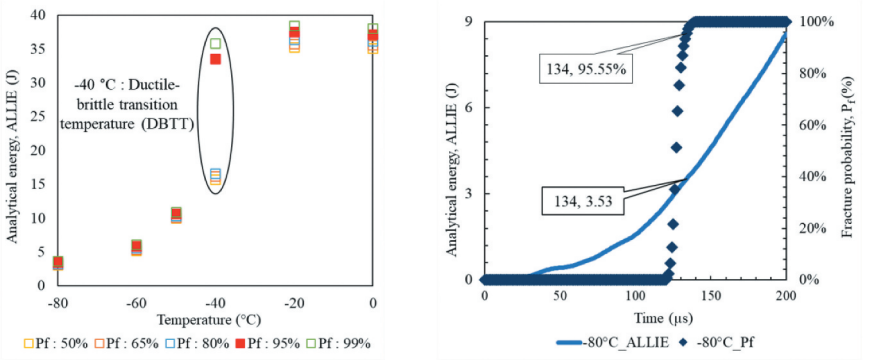

Figure 8. Analytical energy (ALLIE) for SM570Q.

3 CHARPY IMPACT EXPERIMENTATION

To validate the concept of estimating DBTT through Charpy impact analysis, experiments were performed on SM570Q and SM490YB using two Charpy impact testing machines and at various temperatures as mentioned earlier in Table 1 and Table 2 respectively. The mechanical properties at room temperature and the chemical composition have been listed in Table 5. For testing at temperatures lower than –80 °C, the testing specimens were cooled by placing in liquid nitrogen while, for temperature higher than –80 °C, mixture of ethanol and liquid nitrogen was used as a cooling liquid solution. Before testing, the specimens remained in the cooling liquid solution for at least 10 minutes at ±2 °C, and three specimens were tested at each temperature. While testing, the temperature of cooling liquid was measured by using a K-thermocouple type thermometer.

The test results for absorbed energy (E_a) at various temperatures represented in Figure 9 shows that higher amount of energy was absorbed by the specimens at higher temperatures. The amount of absorbed energy is more for SM490YB steel as compared to SM570Q showing higher material's toughness (Kim et al. 2002) and lower DBTT of –100 °C comparative to –40 °C

Table 5. Mechanical properties and composition of SM570Q and SM490YB structural steel.

				C	Si	Mn	P	S
Steel type	Yield stress (MPa)	Tensile stress (MPa)	Uniform elongation (%)	Mass (%)				
SM570Q	593	664	36	0.1	0.23	1.53	0.008	0.002
SM490YB	431	537	26	0.13	0.27	1.28	0.011	0.003

for SM570Q steel. Experimental curve was fitted by performing a regression analysis (Oldfield 1979) and are represented on 95% confidence levels. The comparison of analytical energy (ALLIE) and absorbed energy (E_a) for SM570Q and SM490YB structural steels depicted the applicability of Charpy analytical model for the determination of ductile-brittle transition temperature. Analytical and experimental values are in good agreement in the low-temperature range where the brittle fracture dominates. This analysis is unable to regenerate the ductile fracture phenomena, as the energy loss by crack propagation is significant when fracture occurred as ductile fracture. On the contrary, in case of brittle fracture the energy loss is small making it possible to predict the brittle fracture by using MWS calculations. Generally, the Charpy impact test is used to guarantee the quality of steel for construction, but this article presented the validity of MWS approach through Charpy impact analytical model. For various steel grades or even for a single grade the values of material property vary a lot. This model has been developed for the clarification of such complications for steel showing cleavage fracture.

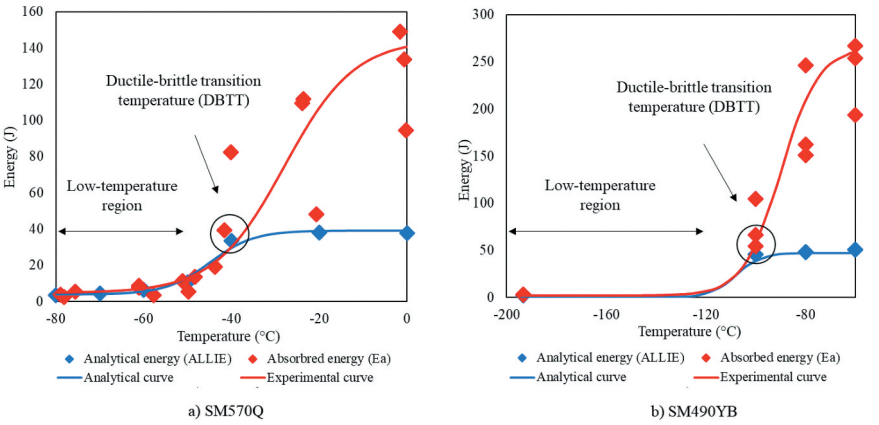

Figure 9. Comparison of analytical and experimental absorbed energy for SM570Q and SM490YB.

4 CONCLUSION

In order to rationalize the testing effort and cost for studying various behaviors of steel, modelling of Charpy impact test was performed using dynamic-explicit analysis and the Charpy's analytical energy was evaluated based on MWS calculations. The analysis was performed for two steel types and at various temperatures. The time-histories of MWS and P_f evaluated the DBTT for SM570Q and SM490YB as –40 °C and –100 °C respectively. The analytical energy was calculated from the MWS at a global fracture probability of 95% and compared with the experimental results. The results showed a good correlation at lower-temperature region before the DBTT. By using the Charpy analytical model proposed in this article, we can improve the experimental conditions for Charpy impact testing for the estimation of the modified Weibull parameters.

Department of Bridge Engineering, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: The tower of a cable-stayed bridge adopts the steel-concrete composite structure, which gives full play to the advantages of steel and concrete. In order to study the elastic-plastic bearing capacity of the steel-concrete composite bridge tower, ABAQUS was used to establish the finite simulation models of the tower section considering material nonlinearity. The elastic-plastic bearing capacity of the tower column was calculated and analyzed. Meanwhile, the influence of structural parameters such as the thickness of steel panels, the diameter of vertical bar, and the concrete strength on the bearing capacity of the tower column was discussed. The results show that the concrete and the steel are subjected to the joint force in the elastic stage. The structural design of the composite tower column has sufficient reservation on loading capacity, which can meet the requirements of the bearing capacity in the elastic stage. The optimization suggestions can improve the technical economy and construction efficiency

1 INTRODUCTION

With the increase of span and traffic load grade of long-span cable supported bridges, higher requirements are being placed on the bearing capacity of bridge structures. As the main load-bearing component of long-span cable supported bridges, the bridge tower will endure significant compressive and bending loads throughout its construction and operation (Xiang et al. 2001). The steel-concrete composite bridge tower has been gradually applied to the construction of long-span cable supported bridges due to its excellent structural performance, durability, economy and construction convenience. The steel-concrete composite bridge tower is a bridge tower that is loaded by two materials: steel and concrete, both of which have the same section. The bearing capacity of the composite bridge tower varies depending on the cross-section structures and steel-concrete connection forms.

Currently, extensive research has been conducted on the mechanical properties of steel-concrete composite tower in the field of bridge engineering. Wang et al. conducted an axial compression test on a steel and high-performance concrete composite bridge tower segment, and obtained the ultimate bearing capacity and failure mode of the composite tower column. Based on the test results, a calculation method of the bearing capacity of the composite bridge tower was proposed(Wang et al. 2023). By conducting model tests and finite element analysis, Wang et al. investigated the mechanical performance of a composite tower consisting of steel-encased hol-low concrete columns under axial compression loads, and found that the composite tower columns effectively utilize the bearing capacity of both concrete and steel, resulting in improved deformation capacity (Wang et al. 2017). Zhang et al. conducted a study on the impact of various parameters, including concrete strength, steel plate thickness, and connector type, on the axial compression performance of a model. This was done through axial

DOI: 10.1201/9781003483755-437

compression testing and finite element analysis of a hollow outer wall steel plate-concrete composite bridge tower column model. It has been found that increasing the strength of concrete and steel plate, as well as increasing the thickness of the steel plate, can enhance the bearing capacity of the composite tower column (Zang et al. 2018). Through the model test, Gao found that the multi-element section of the composite bridge tower has better mechanical properties than the double steel section (Gao et al. 2023). At present, research on steel-concrete composite tower columns primarily focuses on the use of a simple steel box filled with concrete as a composite column. The steel-concrete composite structure of the bridge tower is used in long-span cable-supported bridges to ensure the synergistic force between steel and concrete, thereby improving the overall mechanical performance. Connectors or stud structures are placed between the steel wall plate and the filled con-crete. This creates a tenon structure that enhances the overall bearing capacity by reinforcing the steel box opening stiffeners with steel bars and concrete (Fan et al. 2023, Zhu et al. 2018).

Currently, there are few studies on the bearing capacity of steel plate-concrete composite bridge towers. In this paper, the numerical analysis of the elastic-plastic bearing capacity of the steel plate-concrete composite bridge tower column is carried out. The analysis is based on the design of the double steel plate-concrete composite bridge tower column used in a cable-stayed bridge. The influence of structural parameters such as steel plate thickness, vertical steel bar diameter and concrete strength on the bearing capacity of the tower column is analyzed and discussed, which provides a reference for the engineering application of the steel plate-concrete composite structure in the long-span cable supported bridge tower.

2 STANDARD SECTION OF COMPOSITE BRIDGE TOWER

The steel structure of the composite tower column of a cable-stayed bridge consists of inner and outer steel panels, partition plates, vertical stiffeners, horizontal stiffeners and welding studs (Figure 1). The steel structure material is Q355D, and the filled concrete is C50 concrete. The cross section is divided into twelve bins. The inner and outer panels are secured with welding nails.

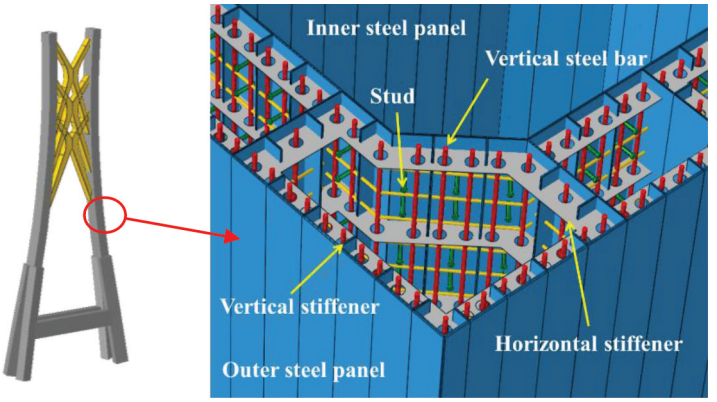

Figure 1. Steel-concrete composite bridge tower structure.

3 FINITE ELEMENT MODEL

3.1 *Establishment of FE model*

The ABAQUS finite element model was established as shown in Figure 2. The solid element (C3D8R) was used for steel plate, concrete, the shell element (S4R) was used for steel plate, and the truss element (T3D2) was used for rebars.

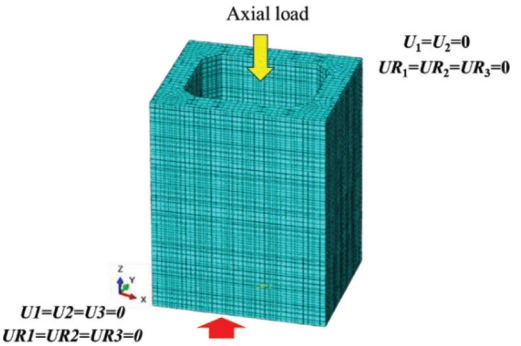

Figure 2. Finite element model of composite bridge tower segment.

When defining the material properties of steel plate and steel bar, the elastic properties and plastic properties are defined at the same time. The constitutive relationship of steel plate is simplified by multi-fold line model. In order to improve the convergence of model calculation and save calculation time, the uniaxial stress-strain curve of steel bar and stud is simulated by double-fold line model. Concrete adopts the concrete damage plastic model (CDP). When external load is applied to the concrete, it deforms. However, the presence of the external steel pipe provides lateral restraint to the concrete, thereby enhancing its strength. Based on the model proposed in (Liu et al. 2005), the compressive constitutive relation of concrete filled in a steel box of a tower column was determined, including the elastic modulus, peak compressive strain and compressive strength of concrete.

3.2 *Verification of FE model*

In order to study the rationality and validity of the numerical model, the concrete-filled square steel tube composite tower column was used as the verification object. The section size is 300mm × 420mm, the tower height is 1260mm, the wall thickness is 6mm, the size of the stiffener is 1260mm × 55mm, and the thickness is 4mm. The size of the combined column model is shown in Figure 3.

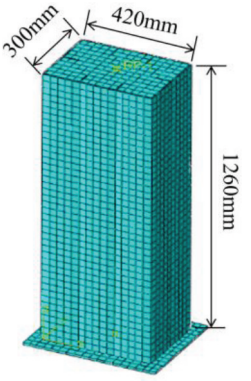

Figure 3. Finite element verification model.

Using the modeling method proposed in section 3.1, the finite element model is established and verified as shown in Figure 4 (b). From the comparison of the failure modes (Figure 4), it can be seen that the failure mode of the specimen is the yield bulging of the steel plate in the middle of the tower column, which was similar to the test's failure mode. The comparison between the axial compression curve obtained through finite element calculation and the

curve obtained from the test is shown in Figure 5. Prior to reaching the peak load, the stiffness of the finite element simulation is found to be excessively high due to initial defects in the components and the presence of testing errors. However, it has been confirmed that the numerical model provides an accurate overall simulation of the composite tower column text, as the yield section and limit point of the curve align well. The relative error of the ultimate bearing capacity of the two is within 2%. It can be seen that the numerical model accurately reflects the elastic-plastic bearing capacity of the composite tower column model.

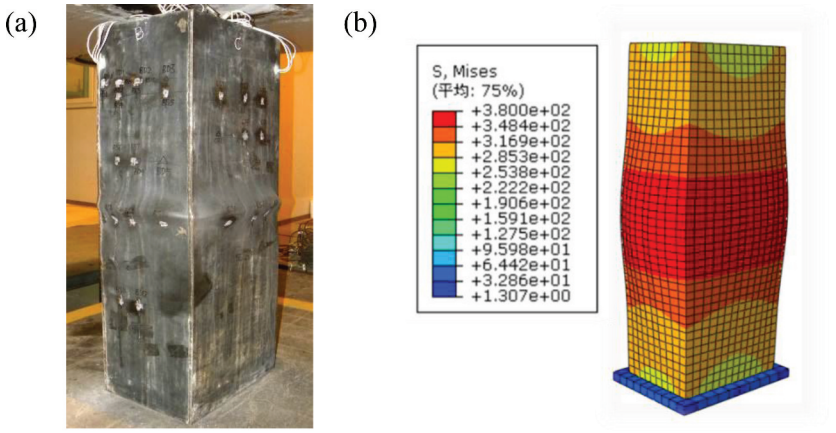

Figure 4. Comparison of failure forms: (a) test model; (b) numerical model.

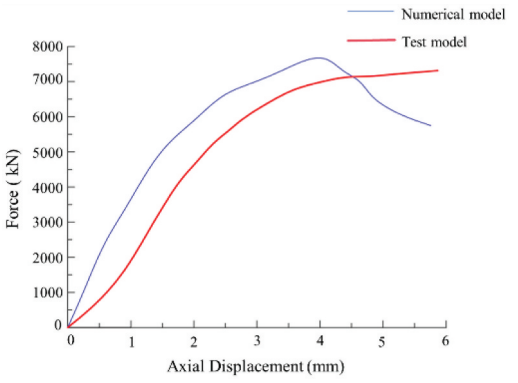

Figure 5. Axial compression load displacement curve.

4 NUMERICAL ANALYSIS RESULTS

4.1 *Structural parameters*

The height of the finite element model of the composite bridge tower is 8m. The thickness of the outer steel plate is 16 mm, while the thickness of the inner steel plate is 12 mm. The thickness of the transverse bridge partition plate is 10 mm. A vertical stiffener is set at a transverse interval of 300 mm inside the cross-section warehouse, and a transverse rib is set at a vertical height interval of 600 mm. The vertical main bar is 40 mm in diameter, and the horizontal spacing is 150 mm. The transverse steel bar is 22 mm in diameter and the vertical spacing is 200 mm. The inner and outer wall plates are set with welding studs, the horizontal spacing is 300 mm, and the specification of welding studs is Φ22 × 150 mm. The structural optimization analysis was carried out for the main structural parameters such as the thickness of the outer

steel panel, the diameter of the steel bar, and the concrete strength. Six groups of finite element models were established by simulating the original parameters and variable parameters.

Table 1. Model parameter table.

Numbering	The thickness of the outer panel(mm)	The thickness of the inner panel(mm)	The diameter of vertical steel bar(mm)	Materials	
				The steel panel and the stiffeners	The concrete
Model 1	16	12	40	Q355D	C50
Model 2	12		40		
Model 3	16		32		
Model 4	16		25		
Model 5	16		40		C40
Model 6	16		40		C60

4.2 *Elastic-plastic bearing capacity analysis*

4.2.1 *Influence of steel outer panel thickness*

Figure 6 shows the load-displacement curves of composite tower columns with outer plate thicknesses of 16 mm and 12 mm respectively. When the thickness of the outer plate of the composite bridge tower is reduced from 16 mm to 12 mm, it can be seen from Figure 6 that the increase of the thickness of the outer plate has little effect on the initial stiffness of the composite bridge tower. The ultimate bearing capacity is reduced from 1.19×10^6kN to 1.16×10^6kN.

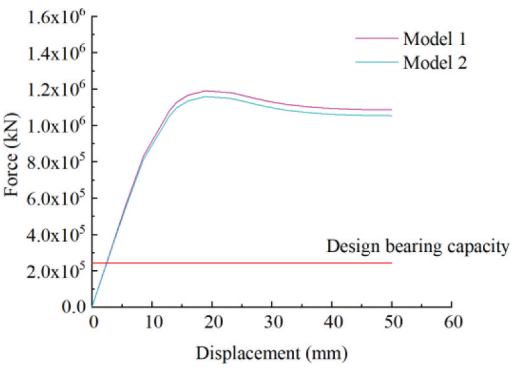

Figure 6. Load displacement curves of composite tower under different steel outer panel thickness.

4.2.2 *Influence of vertical steel bar diameter*

Figure 7 shows the load displacement curves of steel plate concrete composite bridge towers with vertical steel bar diameters of 40mm, 32mm, and 25mm respectively. According to Figure 7, the ultimate bearing capacity of the steel plate-concrete composite tower column is 1.19×10^6kN, 1.14×10^6kN and 1.11×10^6kN when the vertical steel bar diameters are 40mm, 32mm, and 25mm respectively. Compared with the vertical steel bar diameter of 40mm, the tower column's bearing capacity decreased by 4.2% and 6.7% when using 32mm and 25mm respectively.

4.2.3 *Influence of concrete strength*

When using different strength grades of concrete such as C40, C50, C60, the ultimate bearing capacity of the composite tower column is 1.15×10^6kN, 1.19×10^6kN and 1.42×10^6kN respectively. Figure 8 shows the load displacement curve of a steel plate-concrete composite tower column with concrete strength grade of C40, C50 and C60 respectively. From Figure 8, it can be seen that the initial stiffness of the composite bridge tower increases with the increase in concrete strength grade.

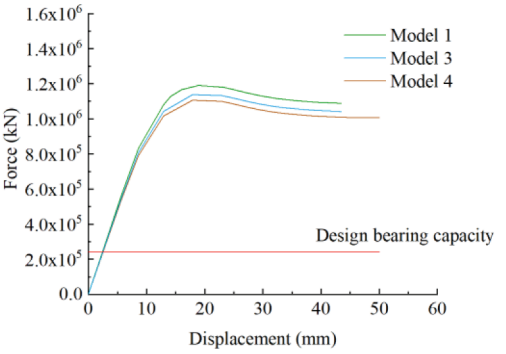

Figure 7. Load displacement curves of composite tower under different vertical steel bar diameter.

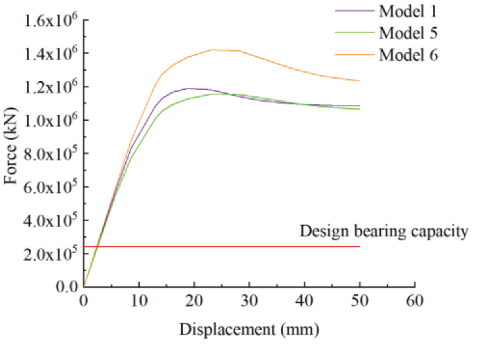

Figure 8. Load displacement curves of composite tower under different concrete strengths.

4.2.4 *Failure mode*

Combined with the corresponding relationship between the load displacement curve in the elastic-plastic stage and the deformation cloud diagram of the tower column, it is found that the steel and concrete of the composite tower column are jointly stressed in the elastic stage. After entering the plastic stage, the overall bulging phenomenon occurs in the standard section due to the compression of the core concrete. After the lateral displacement of the continuous loading model reaches the limit state, the load no longer increases and enters the descending section. The overall deformation of the segment model is shown in Figure 9.

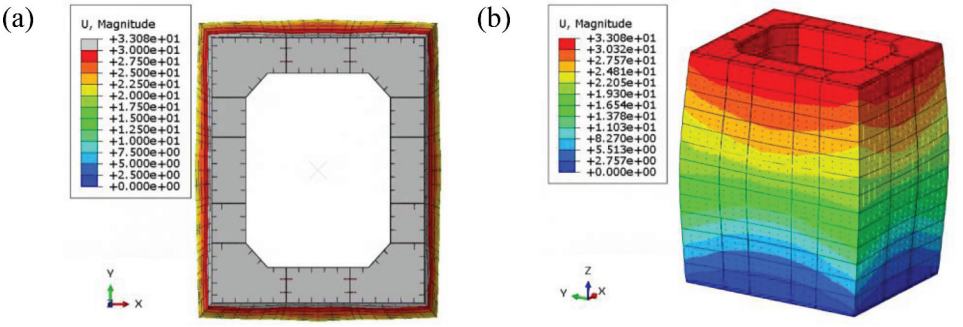

Figure 9. Comparison of failure forms: (a) plan; (b) elevation.

4.2.5 *Comprehensive comparison*

Table 2 presents the axial compression ultimate bearing capacity of the six groups of models in both the elastic and plastic stages. It also compares the bearing capacity of the model after parameter optimization with that of model 1. It has been found that the strength of the concrete has a significant impact on the bearing capacity of the composite tower column. The plastic ultimate bearing capacity is increased by 19.3 % compared to the original design. The thickness of the steel plate and the diameter of the vertical steel bar will also affect the bearing capacity of the composite tower. As the thickness of the steel plate and the diameter of the steel bar decrease, the elastic-plastic ultimate bearing capacity of the composite tower decreases.

Table 2. Comparison of elastic-plastic ultimate bearing capacity.

		Elastic-plastic bearing capacity			
Numbering	Variable parameter	Elastic stage (kN)	The ratio of decline-(increase) compared with the original design	Plastic stage (kN)	The ratio of decline compared with the original design
Model 1	Original design	8.30×10^5	/	1.19×10^6	/
Model 2	The thickness of the outer panel 16mm→12mm	8.12×10^5	-2.2%	1.16×10^6	-2.5%
Model 3	The diameter of vertical steel bar 40mm→32mm	8.07×10^5	-2.8%	1.14×10^6	-4.2%
Model 4	The diameter of vertical steel bar 40mm→25mm	7.91×10^5	-4.7%	1.11×10^6	-6.7%
Model 5	The concrete strength C50→C40	7.73×10^5	-6.9%	1.15×10^6	-3.4%
Model 6	The concrete strength C50→C60	8.77×10^5	+5.7%	1.42×10^6	+19.3%

4.3 *Design force performance analysis*

4.3.1 *Load condition*

The design stress performance of Model 1 was analyzed. The design force loading condition adopts the combined loading mode of concentrated force and bending moment. The specific loading condition is set as shown in Table 3. The P and M increased in turn when the loading increase ratio was set to 0.1,0.2,0.3,0.4,0.6,0.8,1,2,4 times. P and M are the maximum design axial force and bending moment respectively under the most unfavorable axial force conditions.

Table 3. Design force loading conditions.

Numbering	Load condition	loading method
Model 1	Condition 1	Maintain the design bending moment unchanged and increase the axial force proportionally.
	Condition 2	Maintain the axial force unchanged and proportionally increase the longitudinal bending moment of the bridge.
	Condition 3	Maintain the axial force unchanged and proportionally increase the transverse bending moment of the bridge.

4.3.2 *Result analysis*

The numerical analysis of the design force loading condition of the standard section of the composite tower column was carried out. In order to characterize the calculation results, the model section area is divided as shown in Figure 10. The height of the top, middle, and bottom parts is divided from top to bottom along the height direction of the tower column.

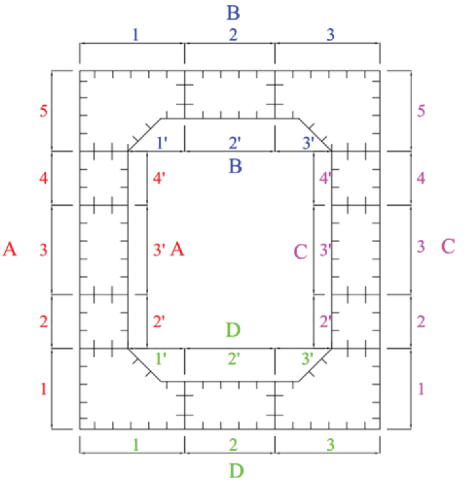

Figure 10. Division of section area for composite tower.

The stress calculation results of each component of the composite tower column model are shown in Table 4. The maximum value of Mises stress in the steel box occurs at the top of the standard section. The maximum compressive stress in the concrete also occurs at the top of the standard section. Additionally, the vertical bar stress in the top area of the standard section is the highest. When the axial force, longitudinal bending moment, and transverse bending moment of the bridge reach the design force loading condition, the maximum mises stress of the steel box is 93.8 MPa. The maximum vertical compressive stress of the concrete is 15.7 MPa, and the steel mesh and bolts are in the elastic stage.

Table 4. Stress calculation results of combined tower column.

		Steel box stress		Vertical stress of concrete		Reinforcement mesh stress	
Load condition	Loading Steps	Maximum (MPa)	Location of occurrence	Maximum (MPa)	Location of occurrence	Maximum (MPa)	Location of occurrence
1	0.6P	62.1	A1 top	-10.4	A1 top	56.9	D1 top
	P	93.8	A1 top	-15.7	A1 top	86.5	D1 top

Note: In table, P represents the maximum design axial force under the most unfavorable axial force conditions, M represents the maximum design bending moment under the most unfavorable axial force conditions.

5 CONCLUSION

In this paper, a finite element numerical analysis was conducted on the axial compression of the steel plate-concrete composite tower column of a cable-stayed bridge. The elastic-plastic bearing performance and the mechanical performance of each component under the design force were studied. The results are as follows.

(1) The ultimate bearing capacity of the steel-concrete composite bridge tower in the original design is 8.3×10^5kN in the elastic stage, and 1.19×10^6kN in the plastic stage. These values are significantly higher than the maximum design bearing capacity.

(2) Increasing the thickness of the steel plate surrounding the tower column, the diameter of the vertical steel bar, and the concrete strength grade can enhance the bearing capacity of the steel plate-concrete composite tower column. Among these factors, improving the concrete strength grade has the most significant impact.
(3) The failure mode of the composite bridge tower model is the joint force between the steel and concrete during the elastic stage. After entering the plastic stage, the standard section bulges out as a whole. After reaching the limit state, the load no longer increases, and the bearing capacity begins to decrease.
(4) When the axial force, longitudinal bending moment, and transverse bending moment of the bridge reach the design force loading condition, the maximum mises stress of the steel box is 93.8 MPa, the maximum vertical compressive stress of the concrete is 15.7 MPa, and the steel mesh and bolts remain in the elastic stage.

ABSTRACT: The composite girder cable-stayed bridge has been widely used in engineering for its advantages of light weight and large spanning ability. However, most of the current research mainly focused on the thickness of concrete bridge decks ranging from 25 cm to 30 cm, and there is a lack of research on the mechanical properties of thick concrete decks at side span of long-span cable-stayed bridges. Therefore, this study was carried out to solve the above existing problems. Based on a composite truss girder cable-stayed bridge with a main span of 930 m, the stress performance and reasonable structure of the concrete deck at side span of 46.8cm are studied. First, in order to determine the most unfavorable position of the side span, a multi-scale model was established. Then, considered the dead load and live load effect, the refined analysis framework was developed. The results shown the longitudinal stress in the concrete deck is uneven along the transverse direction, especially in the cable anchorage section, and a small tensile stress appears on the upper surface of concrete deck near the auxiliary pier. In addition, the transverse stress is the smallest at the upper chords on both sides along the width direction Along the thickness direction, the stress on the upper surface of concrete deck is the most unfavorable, the stress is gradually decreasing from top to bottom surface.

1 INTRODUCTION

In recent years, the combination structure of steel and concrete has been increasingly widely used in large-span cable-stayed bridges due to its advantages such as good stress performance and light weight (Karoumi. 1999, Su et al. 2016, Xiang et al. 2000). The composite girder cable-stayed bridge combines the characteristics of both composite girder bridge and cable-stayed bridge. This type of bridge uses concrete deck instead of orthotropic steel bridge decks, which not only saves steel but also improves the stiffness and stability of the structure, avoiding the problem of fatigue cracking in orthotropic steel bridge decks (Xin et al. 2014).

The main beam of a composite cable-stayed bridge is generally prestressed concrete or steel, and the concrete deck is usually prefabricated. Shear connection keys are arranged on the above of the steel main beam and transverse connection structure, and integrating precast concrete deck with steel girder through cast-in-place wet joints. Based on in-situ testing and finite element analysis for a composite girder cable-stayed bridge, Wang et al. (Wang et al. 2023, Zhang et al. 2023) conducted a study on the longitudinal stress distribution in concrete deck at different construction stages. Meng et al. (Meng et al. 2022) studied the cracking problem of concrete bridge deck in the anchorage zone of composite girder cable-stayed bridges. The standard thickness of concrete decks is 28 cm. They analyzed the stress distribution characteristics, cracking mechanism, and crack morphology of the cables anchorage zone, and provided some crack resistance measures and reinforcement suggestions. Some scholars have conducted

DOI: 10.1201/9781003483755-438

systematic research on the effects of cable-stayed arrangement, and different connection methods between towers and steel truss girder. Walther (Walther 1999) have taken a three span cable-stayed bridge with a main span of 200 m as an example, obtained the influence of the above parameters on the static behavior of the cable-stayed bridge. Compared to the stiffness changes of the main beam or bridge tower, the overall stiffness and internal force distribution of cable-stayed bridge structures are more significantly affected by the arrangement of cable-stayed cables and the connection methods between towers and beams. In addition, other studies have conducted to investigate the concrete deck response and stress state of a composite truss cable-stayed bridge under dynamic loads (Du et al. 2010).

In summary, there is relatively little research on stress behavior of composite girder cable-stayed bridge with a thick concrete deck exceeding 40 cm. Therefore, this article is based on a large-span composite truss cable-stayed bridge with thick concrete deck for the side span, the stress performance of thick concrete deck is studied. What's more, the influence of concrete bridge deck thickness on the longitudinal and transverse stress distribution of the main load-bearing components of the structure was analysed.

2 BRIDGE INFORMATION

The composite beam cable-stayed bridge with a total length of 1779.5 m, as shown in Figure 1. The overall width of the bridge deck is 29.8 m, with tow lanes in both directions. There are two forms of bridge deck, the main span and side span are located within a range of 30 m near the main tower, with a total length of 990 m both adopt an orthotropic steel bridge deck. For the remaining length of the side spans, a composite structure of thick concrete bridge deck and steel truss is adopted, and the concrete bridge deck thickness is 468 mm.

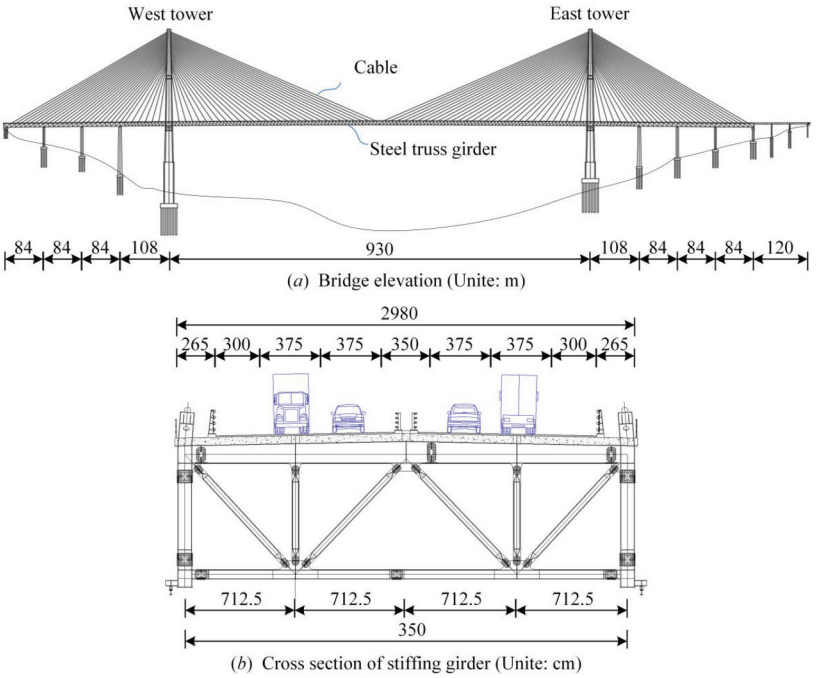

Figure 1. Sketch of a real composite truss cable-stayed bridge.

3 FINITE ELEMENT ANALYSIS

3.1 *Multi-scale bridge model*

Based on the pre-calculated results of the full-bridge model, it can be concluded that the negative moments of auxiliary pier at the side span is relatively large. Therefore, the auxiliary pier section of the side span was selected for analysing. If the entire bridge model uses solid elements, the computational workload is too large to solve. In order to balance computational efficiency and accuracy, a multi-scale finite element model is established, as shown in Figure 2. The local steel truss girder is simulated by shell element (S4R), and the concrete deck is simulated by solid element (C3D8R), the remaining parts of the main girder and concrete tower are simulated by girder element (B31). The cables and steel fabric are simulated by truss element (T3D2). To ensure stress and displacement coordination between interfaces of different scale elements, it is necessary to reasonably set the interaction and boundary conditions between different scale element. The concrete tower and cable are connected through MPC Tie, while the cable and steel truss are connected through a shared node. The sliding action between the steel truss and the concrete deck slab is not considered, so they are connected by binding constraints. The steel mesh is directly embedded in the concrete.

FE model boundary conditions are set as same as the actual bridge boundary conditions, as shown in Figure 2. Fixed constraints are applied at the bottom of the bridge tower, and Two translational degrees of freedom and one torsional degree of freedom of the constrained are used on the support node at the auxiliary pier on both sides (U_x=U_z=R_z=0). On one side of the end of the main beam, one direction of translational freedom and one direction of torsional freedom was constrained (U_x=R_z=0). on the other side of the end of the main beam, the translational degrees of freedom in two directions and the torsional degrees of freedom in one direction was constrained (Ux=Uy=Rz=0).

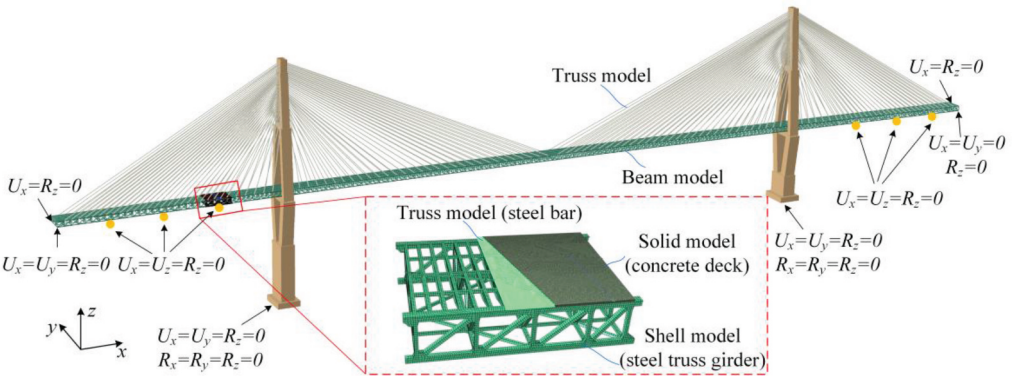

Figure 2. Multi-scale finite element model.

3.2 *Loading scheme*

For the composite cable-stayed bridge, the dead load occupies a large proportion in the total load of the bridge, and the vehicle loads directly on the bridge deck, which affects the stress state of the concrete deck, so the structural response of the thick concrete deck under the dead load and vehicle load is considered. When calculating the stress performance of the bridge structure, the vehicle load effect is loaded using lane load I recommend in standard (Ministry of Transport of the People's Republic of China. 2015), the lane load I consists of a concentrated force and a uniform load, where the uniform load value is 10.5 kN/m and the concentrated force value is 360 kN. As multi-lane loading conditional, it is necessary to carry out longitudinal and transverse reductions. Considering lane load I loading in all lanes, the reduced factor of transverse and longitudinal was set as 0.67 and 0.94 respectively.

4 MAJOR RESULTS AND DISCUSSION

4.1 *Stress analysis of thick concrete deck*

In the composite truss girder cable-stayed bridge, the concrete deck and the steel truss girder both bears the dead load and live load. Under the various loads such as tension cable force, self-weight, and vehicle load, the stress situation of concrete deck and steel truss girder is complicated. Therefore, four typical cross-sections including cable anchorage section (H1), cross section without crossbeam (H2), cross section with crossbeam(H3), and cross section at the top of auxiliary pier (H4) are selected to study the distribution of longitudinal stress in the concrete deck, as shown in Figure 3(a). Since the main girders are symmetrical along the center line of the bridge deck, only half of the bridge deck is selected for analyzing the distribution pattern of transverse stress in thick concrete deck. In order to compare the transverse stress distribution at different cross-section locations along the width of the bridge deck, the cross-section located at the top chord (Z1), the cross-section between the small longitudinal beams (Z2), and the cross-section at the position of the small longitudinal beams (Z3, Z5) were selected for analysis. Due to the thicker of the concrete deck, the distribution law of longitudinal stress and transverse stress along the concrete thickness direction are worth paying attention. To study the distribution law of longitudinal and transverse stress along the concrete deck thickness direction at the position of auxiliary pier, three typical sections of the concrete deck are selected, such as the top, bottom and middle surface of the concrete deck.

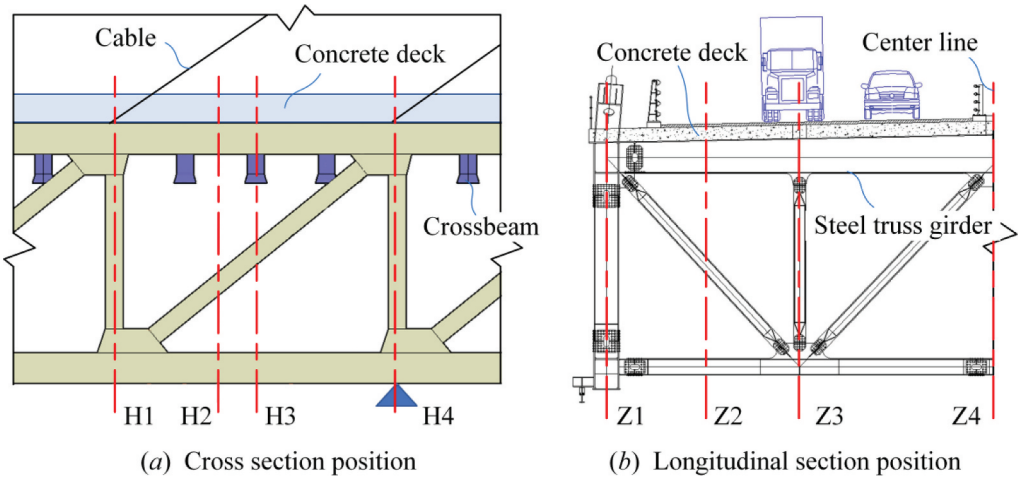

Figure 3. Concerned section position of concrete deck.

4.1.1 *Longitudinal stress*

Figure 4 shows the longitudinal stress calculation results for four typical sections of concrete bridge deck under the dead load and live load. It can be seen from Figure 4 that at different cross-section locations, the longitudinal stress in the concrete deck is dominated by compressive stress, and the longitudinal compressive stress in the concrete deck gradually decrease along the thickness direction. While along the width direction of the concrete deck, the stress changes significantly at the small longitudinal beams, and the stress distribution at the bottom surface of the concrete deck is most affected by the small longitudinal beams. For cross-section with and without cross-section, the longitudinal stress distribution is not uniform, and the closer to the two sides of the top chord section, the smaller the longitudinal stress. For the cross-section at the location of the auxiliary pier, there are tensile stresses observed on the top surface of the concrete deck, while the bottom surface of the concrete deck continues to bear compressive stress. The reason for the tensile stress on the top surface of the concrete deck may be due to the negative bending moment at the top of the pier.

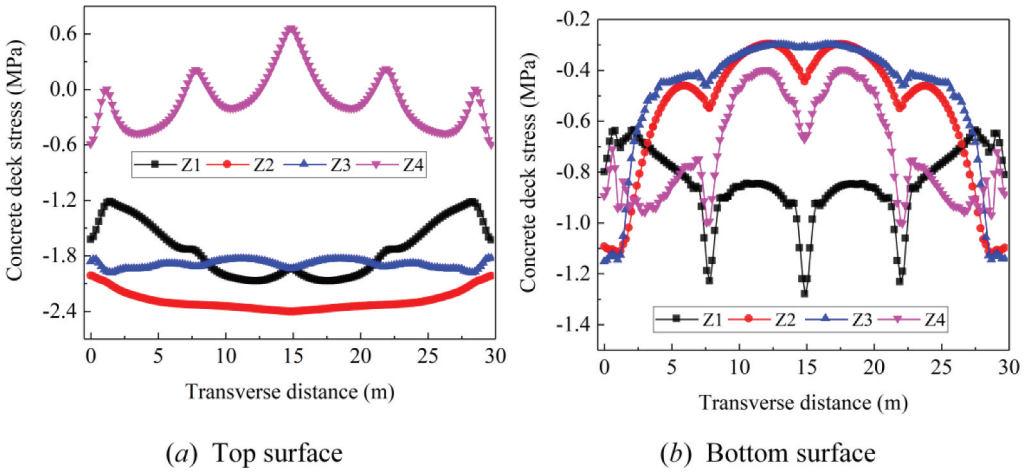

Figure 4. Longitudinal stress along the considered cross-section of concrete deck.

4.1.2 *Transverse stress*

The transverse stress calculation results for four key cross-sections of the concrete bridge deck at the pier are illustrated in Figure 5, with the coordinate origin located at the cable anchorage section on the side away from the tower. Based on the calculation results in Figure 5, it can be observed that the transverse stress along the longitudinal distribution of the Z1 section fluctuates relatively less compared to other sections. However, the overall transverse stress level is relatively low, and there is not significant variation in stress along the thickness direction. For the Z2 to Z4 sections, the transverse stress significantly fluctuated, particularly near the small longitudinal beams. This indicates that the small longitudinal beams influence the distribution of transverse stress. Comparative analysis of transverse and longitudinal stress distributions across several sections, the transverse stress in the concrete deck is generally lower than the longitudinal stress except for the section position where the concentrated force of lane load acts. Moreover, the closer to the top chord position, the smaller the transverse stress in the concrete deck.

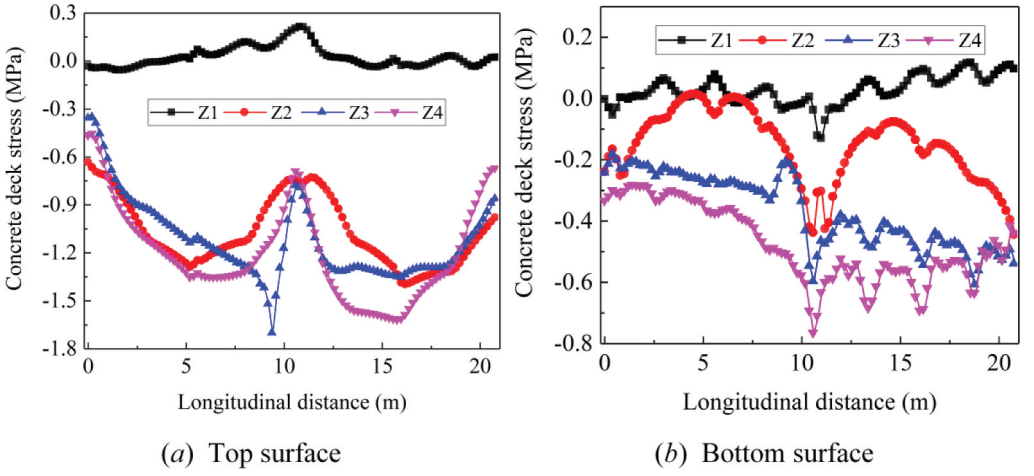

Figure 5. Transverse stress along the considered cross-section of concrete deck.

4.2 *Stress analysis of steel truss girder*

Figure 6 shows the longitudinal and transverse stress calculation results for the upper and lower chords of the steel truss girder at the auxiliary pier. It can be seen from Figure 6 (*a*) that the upper and lower chords of the main truss are mainly subjected to longitudinal forces. From Figure 6(b), it can be observed that the transverse stress in the upper chord of the main crossbeam is mainly compressive stress. Specially, there is a significant variation in transverse stress at the location of the small longitudinal beams. The lower chords of the main transverse truss primarily experience transverse forces. Near the sides of the upper chords, the transverse stress is compressive, while between the lateral longitudinal beams, the transverse stress in the lower chords changes from compressive to tensile.

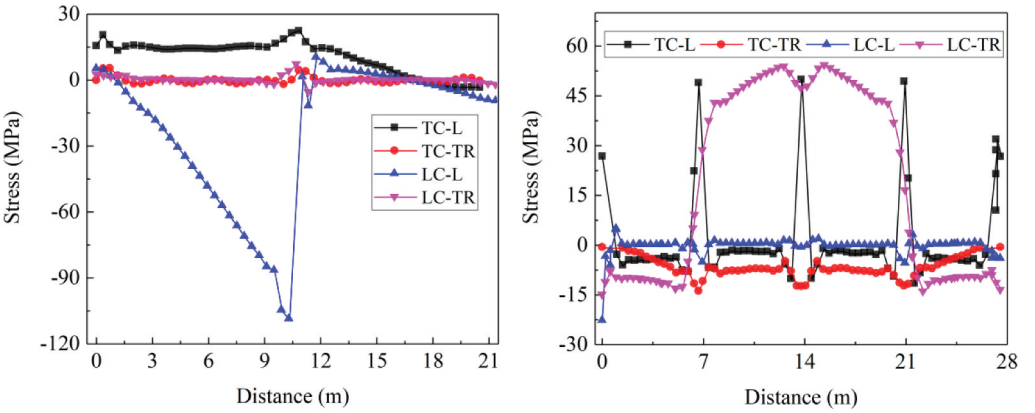

Figure 6. Stress along the considered cross-section of steel truss girder.

4.3 *Influence of concrete deck thickness*

A parametric analysis was conducted to investigate the influence of concrete deck thickness on the distribution of longitudinal and transverse stresses in the concrete deck and steel truss girder,. The concrete deck thickness was set as 300 mm, 350 mm, 400 mm, 500 mm, 550 mm, and 600 mm, respectively, the width of the concrete deck remained unchanged

4.3.1 *Stress distribution law of concrete deck*

From the calculation results in Section 4.1.1, it is evident that tensile stresses appear on the top surface of the concrete deck near the auxiliary pier, which could potentially lead to concrete deck cracking. Consequently, the cross-section of the concrete bridge deck at the auxiliary pier (H4) was selected to analyze the influence of concrete deck thickness on stress distribution in the concrete deck. Figure 7 shows the longitudinal stress distribution in concrete bridge deck of different thicknesses. According to the calculation results in Figure 7, it can be seen that, the smaller the thickness of the concrete bridge, the greater the longitudinal stress. With the increase of the concrete deck thickness, the longitudinal stress across the concrete deck section decrease, and the distribution of longitudinal stress becomes more uniform. Additionally, the concrete bridge deck above the upper chord changes from compressive stress to tensile stress. The reason for this phenomenon may be that as the thickness of the concrete bridge deck increases, it leads to an increase in the stiffness of the structure.

4.3.2 *Stress distribution law of steel truss*

For steel materials, the commonly accepted yield criterion is the von Mises yield criterion. When the equivalent stress exceeds the yield stress of the material, the structure will undergo plastic deformation. The von Mises stress in the members of the main truss and main

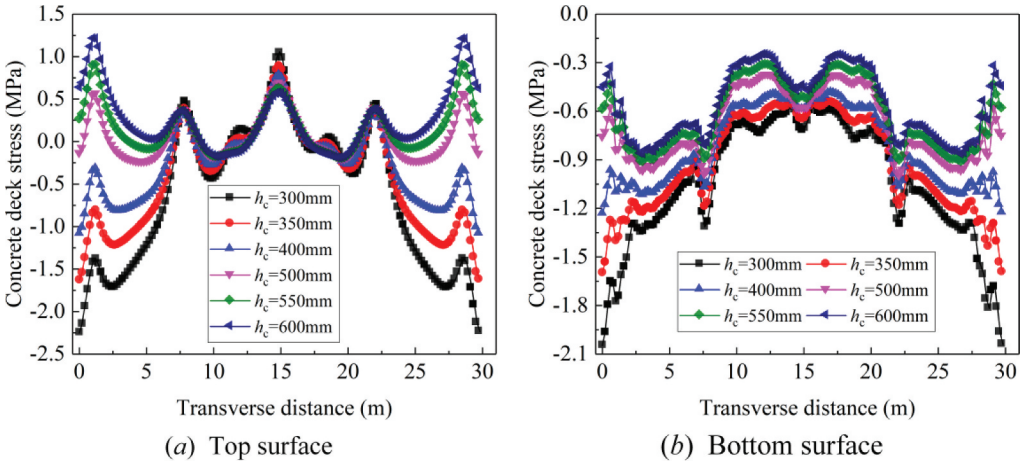

Figure 7. The longitudinal stress distribution law of concrete deck.

transverse truss are illustrated in Figure 8. It can be seen in Figure 8, as the thickness of the concrete deck increases from 300 mm to 600 mm, the von Mises stress in the members of the main truss initial decrease and gradually increase. As for the members of the main transverse truss, von Mises stress gradually increased. Through analysis, it is determined that the components with less favorable stress are diagonal web members and lower chord members. For the main transverse truss, the components with less favorable stress are the upper chord and diagonal web members.

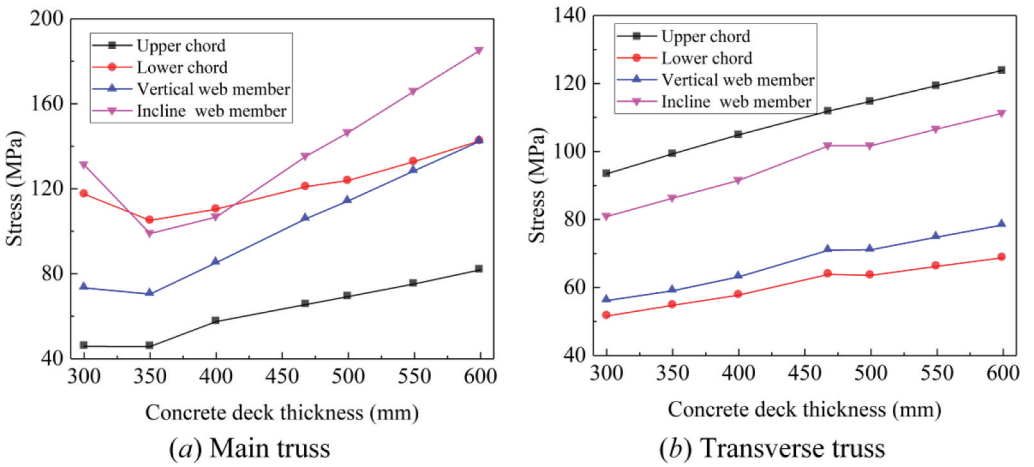

Figure 8. The influence of concrete deck thickness on the steel truss girder.

5 CONCLUSIONS

This article analyzed the stress distribution law of thick concrete bridge deck at the auxiliary pier of the side span under dead load and live load. On this basis, a parameter analysis was conducted to investigate the influence of concrete deck thickness on the distribution of longitudinal and transverse stresses in the concrete deck and steel truss girder. The main conclusions are as follows:

(1) The main direction of stress on the thick concrete bridge deck is the longitudinal direction of the bridge, indicating that the thick concrete deck is a one-way slab.
(2) The main truss is primarily subjected to longitudinal stress, while the transverse truss mainly bears transverse stress. For the main truss, the most unfavorable members are the inclined web and the lower chord. Conversely, for the transverse truss, the most unfavorable members are the upper chord and inclined web.
(3) As the thickness of the concrete bridge deck increases, the longitudinal stress distribution in the concrete bridge deck becomes more uniform, while the transverse stress increases with the increase of thickness. The longitudinal stress and transverse stress in the main truss and main transverse truss gradually increase with the thickness of the concrete bridge deck.
(4) Taking into account the stress distribution law of concrete deck and steel truss girder, the thickness of concrete deck is recommended as 400 mm to 500 mm for composite cable-stayed bridges with small side to span ratios and side span that require weight compression.

ABSTRACT: Based on the previous research of structural performance of composite truss girder with thick concrete deck in cable-stayed bridge, the reasonable degree of shear connection for such bridge was carried out here. Considering the material and geometric nonlinearity, a local finite element model was established to study the mechanical performance of the composite truss girder with thick concrete deck of the cable-stayed bridge. The influence of the shear connection degree on the mechanical performance of the composite truss girder is studied. Moreover, the shear lag effect of thick concrete deck of composite cable-stayed bridge is analyzed. The results indicate that the maximum relative slip of the interface occurs at the anchorage of the cable, and the relative slip of the interface increases obviously under the vehicle load. The degree of shear connection has a great influence on the stress of thick concrete deck, steel truss girder as well as studs. In addition, the closer to the auxiliary pier, the effective distribution width of thick concrete deck is gradually decreased, and it will increase with the thickness of concrete deck. On the above research results, the reasonable layout scheme of shear connection is obtained.

1 INTRODUCTION

The cable-stayed bridge is mainly composed of three basic components: the main beam, cables, and cable towers. Based on the research by domestic and foreign, composite beam cable-stayed bridges are more competitive than other types of bridges when the span is between 400m and 700m. Composite truss girder is a new type of composite structure developed on the basis of traditional composite girder. The concrete bridge deck is connected to the upper chord, small longitudinal beam, and crossbeam through shear connection studs. In composite steel truss girder, the concrete plays a role in transmitting vehicle loads, while also improving the stiffness and stability of the structure (Zhang et al. 2012).

At present, many researchers have conducted research on the complex stress state and design methods of the composite girder cable-stayed bridge, including the internal force distribution relationship between steel main girder and concrete deck, shear lag effect and shrinkage creep effect of concrete deck (Chen et al. 2019). Pedro et al. (Pedro et al. 2010) established a finite element model of a composite girder cable-stayed bridge with a concrete deck thickness of 25 cm, analyzing the mechanical properties of the structure during construction, while considering the effects of nonlinearity and concrete shrinkage and creep. Wei et al. (Wei et al. 2013) conducted elastic and elastic-plastic analysis on composite cable-stayed bridge through finite element numerical simulation. The thickness of the concrete bridge deck was 26 cm, and a segment experiment model was established to study the distribution of stress along the beam height. The load distribution relationship between the concrete bridge deck and the steel girder was obtained.

DOI: 10.1201/9781003483755-439

The shear connection stud is important component in composite girders, which connecting concrete and steel into a whole to coordinate and deform under external load, the bearing capacity of the composite girder will be affected once slippage and compression deformation occur between the shear connection stud and the concrete. In composite structures, due to the influence of shear deformation on the distribution of bending stress, there is a shear lag phenomenon in concrete deck, and the longitudinal stress is unevenly distributed along the width direction. What's more, the shear lag phenomenon is more significant in wide slabs (Zhu et al. 2015). As the span of the cable-stayed bridge increases, the width of the bridge deck also increases, and there is a significant shear lag effect in the concrete bridge deck, which is worthy of attention (Wang et al. 2023, Zhang et al. 2023). Tian et al. (Tian et al. 2005) used a simplified analytical method to study the shear lag effect of concrete flange plate in steel-concrete composite beams under different forms of loads. Based on the thin plate theory, strain and deflection differential equations were established, and the calculated shear lag coefficient was close to the numerical calculation results, indicating that the calculation method has high accuracy. The parameter analysis results indicate that the width to span ratio and load form have a significant impact on the shear lag effect. Wang et al. (Wang et al. 2022) conducted a series of studies on the shear lag effect in a concrete bridge deck of a double steel composite beam cable-stayed bridge. By considering multiple load conditions in model tests, the distribution of longitudinal stress in concrete was analyzed, under the combined effects of positive and negative bending moments, axial forces, and shear forces.

In summary, research on the structural form of composite truss cable-stayed bridges is still insufficient, and current regulations also lack relevant provisions. Therefore, this article is based on a large-span composite truss cable-stayed bridge with thick concrete deck. The shear lag effect of thick concrete bridge deck of the composite truss cable-stayed bridge is analyzed, and the effective width coefficient of different section positions is calculated. In addition, the influence of interface relative slip, shear connection degree, and width span ratio on the effective width coefficient of thick concrete bridge deck is analyzed.

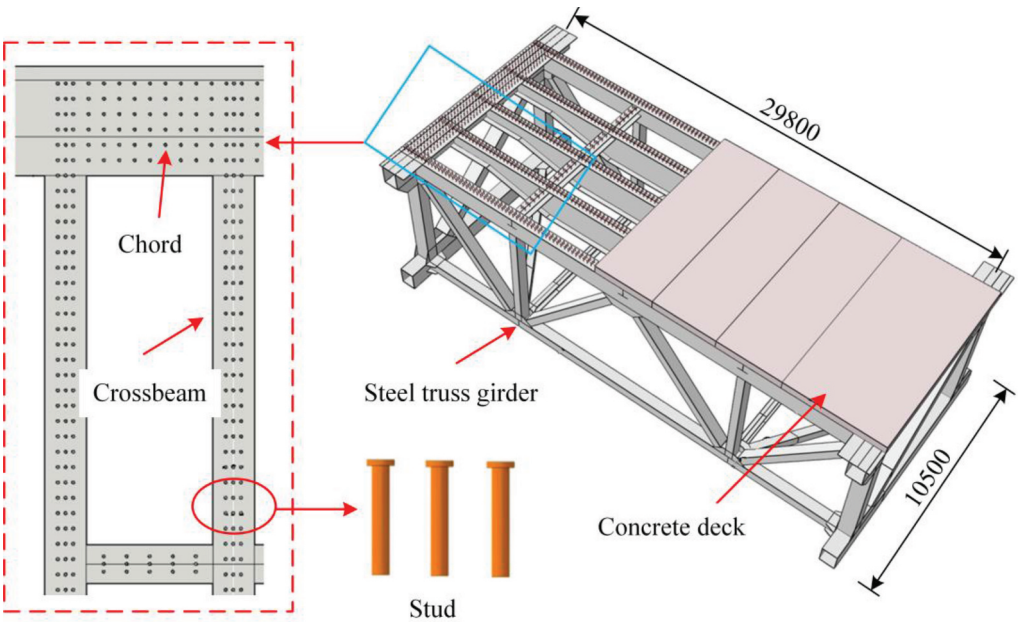

Figure 1. Layout of the typical segment (Unit: mm).

2 CASE STUDY

The puzhehei bridge is a spatial double cable plane composite truss cable-stayed bridge with a main span of 930 m. The main span is a slab truss composite steel truss girder, and the side span is a concrete bridge deck steel truss composite girder with a concrete bridge deck thickness of 468 mm. The concrete deck has a full width of 29.8 m and the bridge is arranged in a two-way four lane layout. The standard segment of the side span is shown in Figure 1.

3 FINITE ELEMENT ANALYSIS

3.1 *Local refinement finite element model*

In general, the steel truss and concrete bridge deck are connected by shear connection studs, and the connection between the two determines the overall stress performance of the composite girder. In order to study the stress performance of composite truss girder under relative interface sliding, a local refined segment model of the composite truss girder was established, as shown in Figure 2. In the segmented numerical model, both concrete and studs are use C3D8R three-dimensional hexahedral elements, and the steel truss girder is simulated using S4R elements. Based on the specification (National Standard of the People's Republic of China GB50010. 2010.), the concrete material properties are obtained. To accurately simulate the connection between concrete deck and steel truss girder, the normal interaction between concrete deck and steel truss girder is set as hard contact, and the tangential interaction adopts penalty friction, with a friction coefficient of 0.4. Studs are embedded into concrete bridge decks, the bottom surface of the steel truss girder and studs is bound together through MPC-Tie. According to relevant literature, a simply supported boundary is adopted in the FEM.

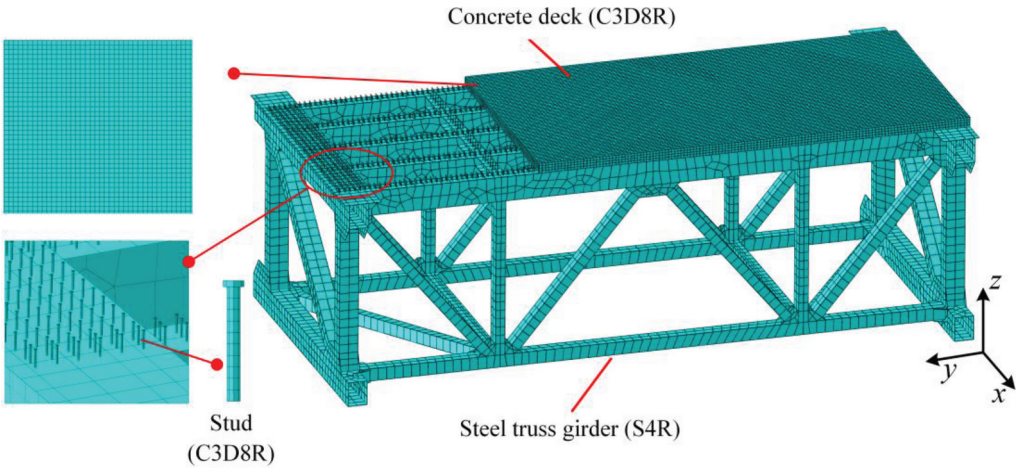

Figure 2. Local refined finite element model.

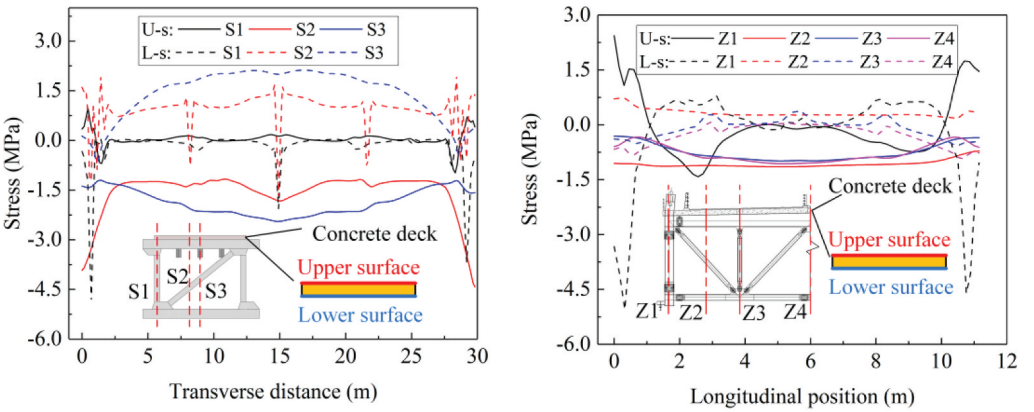

3.2 *Loading case*

When calculating and analysing the overall stress performance of the structure, the vehicle lane load I was selected as recommended in specification (Ministry of Transport of the People's Republic of China. 2015.). The Lane load I consists of concentrated forces and uniformly distributed loads, with a uniformly distributed load of 10.5 kN/m and a concentrated force of 360 kN. The load condition is set to deploy vehicle lane load I on all lanes, and the longitudinal and transverse reductions on vehicle lane load I was considered. The load effect of cables is simulated by applying axial and vertical forces.

4 FE RESULTS

4.1 *Stress distribution law of concrete bridge deck*

To study the stress distribution in concrete bridge decks under live load and dead load, the FEM was calculated according to the load arrangement in section 3.2. Figure 3 shows the longitudinal stress distribution of some key sections in concrete deck under constant and vehicle loads. It can be seen from Figure 3 that for concrete deck, the longitudinal stress at the cross-section with crossbeams is generally greater than that of other cross-sections, and the longitudinal stress shows a symmetrical distribution pattern along the width direction of the concrete deck. For transverse stress in concrete deck, the section between the small longitudinal beams is generally greater than that of the other sections. Furthermore, there is a sudden change in the distribution of longitudinal and transverse stresses in the concrete deck, the current mutation is mainly located at the location where the concentrated force of the vehicle load. This indicates that the concentrated force of vehicle load has a certain impact on the stress distribution of the bridge deck.

(*a*) Longitudinal stress (*b*) Transverse stress

Figure. 3. Stress analysis of concrete deck.

4.2 *Effective width coefficient of concrete deck*

There is a longitudinal shear force at the interface between steel and concrete in composite girder. Under the influence of longitudinal shear force transmission, the stress distribution in concrete shows significant non-uniformity, resulting in the phenomenon of shear lag. Due to the thickness of the concrete deck reaching 468 mm in this study, the distribution of stress along the thickness direction must be considered when calculating the effective width, as shown in Equation 1. The effective width coefficient that characterizes the shear lag effect can be calculated according to the Equation 2 (Ministry of Transport of the People's Republic of China. 2015.).

$$b_e = \frac{\int_0^{h_c}\int_0^{b}\sigma(x,y,z)\mathrm{d}y\mathrm{d}z}{|\sigma_{max}|h_c} \tag{1}$$

$$\eta = \frac{b_e}{b} \tag{2}$$

Where b_e is the effective width of the concrete deck; x, y, z represent the longitudinal, transverse, and vertical directions of concrete deck, respectively; $\sigma(x, y, z)$ is the longitudinal stress in concrete deck; σ_{max} is he maximum normal stress in concrete deck; h_c is the thickness of the concrete deck; b is the actual width of concrete deck; η is the effective width coefficient.

The value of effective width coefficient of concrete bridge deck was obtained, as shown in Table 1., it can be seen the average value of effective width coefficient of the concrete deck is 0.60 in the side span, and the maximum effective distribution width coefficient of the concrete bridge deck near the auxiliary pier is 0.78. In addition, the closer to the auxiliary pier, the smaller the effective distribution width of the section, which may be due to the large negative bending moment of the section at the auxiliary pier.

Table 1. Effective width coefficient value of concrete deck.

Section Position	Support position of side span	Middle position of side span	Auxiliary pier
S1	0.46	0.41	0.31
S2	0.78	0.60	0.71
S3	0.73	0.58	0.72

5 PARAMETRIC STUDY

5.1 *The influence of stress distribution law on concrete deck*

In order to study the stress response of concrete deck under different degrees of shear connection, variable parameter analysis was conducted on the shear connection degrees at the top chord, transverse truss, and transverse beam, respectively. The number of studs per unit length of the upper chord n_1 is set as 17, 25, 34, 38, 46, and 59, respectively. The number of studs per unit length range at the transverse truss and crossbeam n_2 is set as 10, 11, 12, 13, 14, and 15, respectively. Figure 4 shows the variation of maximum longitudinal and transverse stress in the concrete deck when different degrees of shear connection are used between the steel truss girder and the thick concrete deck. It can be concluded that as the number of studs per unit length of the upper chord increases, the longitudinal tensile stress of concrete deck gradually decreases and then increases, and then remains basically unchanged. In summary, the influence of the number of studs per unit length of the crossbeam on the longitudinal compressive stress of the concrete bridge deck can be ignored.

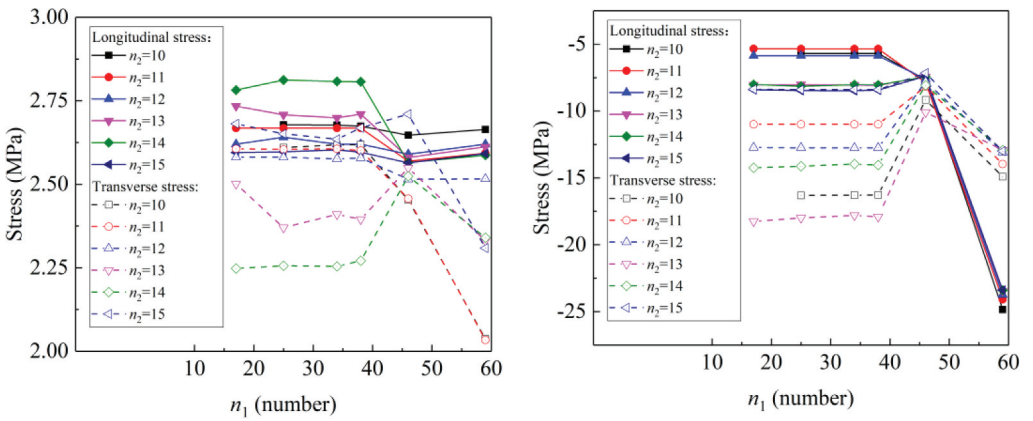

Figure 4. The influence of shear connection degree on the stress performance of concrete deck.

As the number of studs per unit length of the upper chord increases, the transverse tensile stress of the concrete deck gradually decreases and then increases, and then gradually decreases. However, the transverse tensile stress of concrete deck initially remains basically unchanged, and then shows a trend of increasing and then decreasing. When the number of studs per unit length

of the upper chord is less than or equal to 46, as the number of studs per unit length of the crossbeam increases, the stress of the concrete bridge deck shows a trend of increasing and then decreasing.

5.2 *Variations of effective distribution width coefficient*

5.2.1 *Influence of shear connection degree*

The effective width coefficient value of concrete deck with different degrees of shear connection were obtained. Due to spatial limitations, only the calculation results for n_1 equal to 38 and 46 are listed, as shown in Figure 5. Through calculation and analysis, it was found that n_1 less than or equal 38, the change in the degree of shear connection of the upper chord had little effect on the effective width coefficient of the concrete deck. As the value of n_1 greater than or equal 46, The effective width coefficient of the cross-section is significantly reduced. When the degree of shear connection at the crossbeam increases, the effective width coefficient of the section significantly decreases. As the value of n_2 is equal to 11, the effective width coefficient of the concrete deck is the highest.

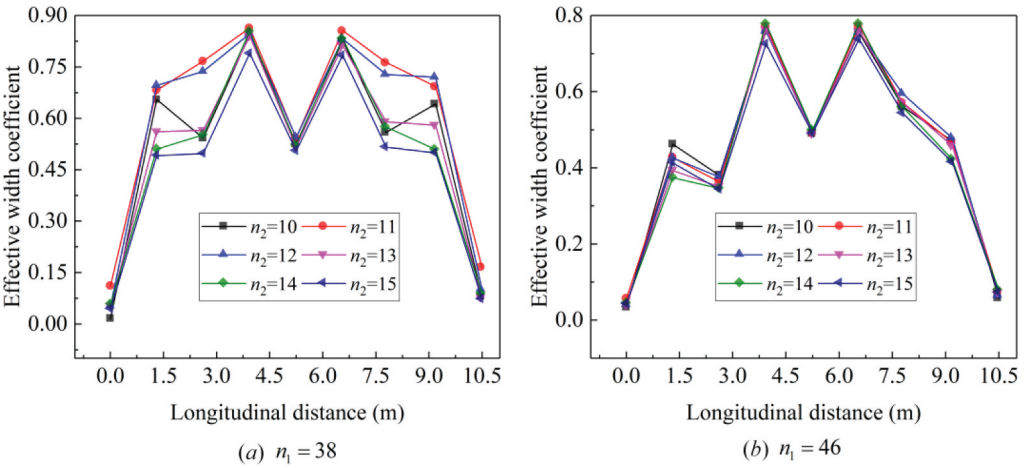

Figure 5. The influence of shear connection degree on the value of effective width coefficient.

5.2.2 *Influence of concrete deck thickness*

When the thickness of the concrete deck is 300 mm, 350 mm, 400 mm, 468 mm, 500 mm, 550 mm, and 600 mm respectively, the effective width coefficients of each key section of the concrete deck are shown in Figure 6 (a). It can be seen for the cable anchorage section, as the concrete thickness increases from 300 mm to 400 mm, the effective width coefficient gradually increases. As the thickness continues to increase, the effective width coefficient gradually decreases. In the middle non-cable anchorage section, as the thickness of concrete increases, the effective width coefficient of the concrete deck gradually increases. The reason for this phenomenon may be that as the thickness of the concrete deck increases, the section stiffness increases, resulting in the stress distribution on the concrete deck section more uniform.

5.2.3 *Influence of width to span ratio (b/L)*

When the length of the concrete segment increases to three intervals, the b/L value decreases. In order to improve the computational efficiency and convergence of the model, studs are only arranged on the surface of the concerned area. Figure 6 (b) shows the variation of the effective width coefficient of each key section with the width to span ratio. It can be concluded that when the b/L decreases, the effective width coefficient of the cable anchorage section significantly increases. This is may be the attention section is further away from the boundary conditions.

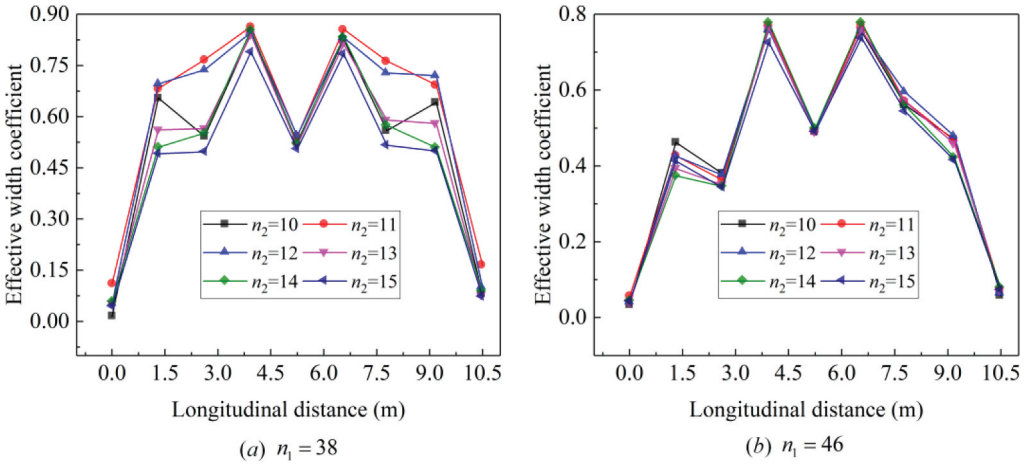

Figure 6. The distribution of effective width coefficient.

Further analysis revealed that the effective width coefficient of L/8 and 7L/8 section is smaller than other cross-sections. The effective width coefficients of 3L/8 section, 5L/8 section, and mid span section all increase as the pan ratio decreases. This indicates that when the width to span ratio decreases, the stress distribution in the mid span concrete bridge deck will be more uniform.

6 CONCLUSIONS

This article establishes a local refined numerical model to study the stress distribution in thick concrete bridge decks under dead and live loads. The influence of shear connection degree on the stress performance of concrete deck is analyzed, and the main conclusions are as follows:

(1) Considering the longitudinal and transverse stress of the concrete deck, it is recommended to use 46 studs per unit length of the upper chord and 11 studs per unit length of the transverse truss and crossbeam. The recommended height of stud for thick concrete deck should exceed half of the concrete deck thickness by 2 to 5 cm, and it is recommended to take a stud height of 28 cm.
(2) Through FEM analysis, it was found that there is a significant shear lag phenomenon in the concrete deck, and the effective width of the section decreases as it approaches the auxiliary pier position.
(3) Properly reduce the degree of shear connection and utilize slight relative slip at the interface to make the stress distribution of the concrete bridge deck more uniform. The thicker the concrete bridge deck, the greater the effective width coefficient. As the width to span ratio decreases, the effective width coefficient increases.

ABSTRACT: This paper describes tests on a new connection between a precast abutment wall and a cast-in-place foundation suitable for rapid construction in seismic regions. The primary goal of this study is to reduce on-site construction time. Its features include both speed and simplicity of erection, as well as generous tolerances. The foundation concept is termed a 'wet socket' connection. Abutment wall elements are precast without exposed reinforcement and feature strategically placed ducts to allow the foundation´s top mat reinforcement to pass through the wall unimpeded. Two scaled specimens were constructed and tested as part of this research. The first specimen served as a reference and was detailed according to current standards in Iceland. The second specimen included the new socket connection. Lateral-load tests on the new connection were completed in 2022. Overall, the performance of the new connection was quite satisfactory and comparable to the reference specimen. The new connection will be implemented in an upcoming road reconstruction and bridge project in North-Iceland.

1 INTRODUCTION

The construction of bridges often results in traffic delays, translating to measurable costs in terms of time, money, and wasted fuel. Therefore, road administrations are actively exploring methods to expedite construction processes, commonly referred to as Accelerated Bridge Construction (ABC). Several strategies for ABC use administrative techniques and/or incorporate inventive financial incentives, while others have relied on new building practices to minimize the duration of on-site work. The use of precast concrete represents a promising technology for ABC demonstrating successful applications in bridge piers within both non-seismic (Matsumoto et al., 2001) and seismic regions (Pang et al., 2010; Haraldsson et al., 2013; Khaleghi et al., 2012; Mashal et al., 2016) For structures in seismic regions, those interfaces represent the locations of high-bending moments and shears. Designing connections for both ease of construction and seismic resistance poses a formidable challenge.

While limited research has been published on ABC technology for bridge abutments, several state agencies in the United States have developed systems to expedite abutment construction (Culmo, 2011). This paper describes a new connection between a precast abutment wall and

DOI: 10.1201/9781003483755-440

a cast-in-place foundation. Two specimens were fabricated and tested. The first specimen was detailed to the current standard in Iceland. The second specimen was detailed with the new connection.

2 CONNECTION CONCEPT

The 'wet socket' connection concept is illustrated in Figure 1. The construction sequence involves fabricating a precast wall element in a controlled environment. The precast wall is equipped with wide horizontal ducts at the bottom, facilitating the passage of top-mat reinforcement from the foundation through the wall to ensure ample moment resistance. The outer surface of the ducts is intentionally roughened to enhance the bond between the precast wall and the cast-in-place concrete. Furthermore, the bottom section of the wall which will be embedded in the foundation is manufactured with roughened surface to increase the binding between the wall and the foundation.

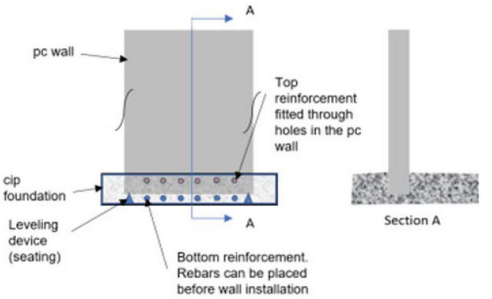

Figure 1. Wet socket wall connection concept.

The proposed construction sequence is as follows: Initially, the wall elements are precast; subsequently, the foundation is excavated, and formwork is constructed. The precast wall elements are then positioned, ensuring proper alignment, leveled, and braced. Following this, foundation reinforcement is installed, and the foundation is cast.

With the new connection, the abutment is constructed in the same amount of time as it takes to construct a foundation alone, using the standard cast-in-place method. In standard practice, the foundation reinforcement is placed in molds and cast with wall reinforcements protruding up from the foundation; then the work with the wall formwork can begin and the wall is cast a few days later. This system's primary advantage over conventional cast-in-place construction is its accelerated speed. Additional benefits include mitigating challenges associated with fitting

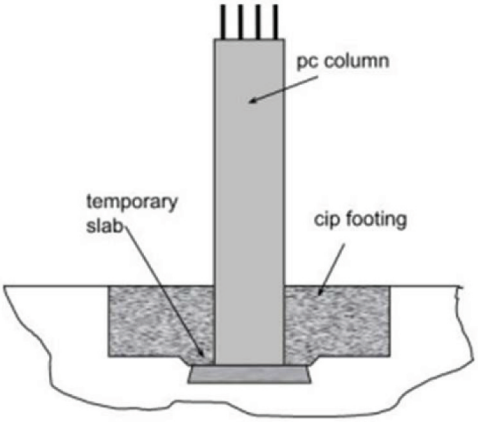

Figure 2. Wet socket column connection concept.

bars in vertical sleeves or ducts, often encountered when placing a precast element on top of a cast-in-place foundation with starter bars. Moreover, the absence of protruding reinforcements on the precast wall during transport and erection minimizes vulnerability.

The concept of the new connection is derived from an established socket connection between a precast column and a cast-in-place footing developed by Haraldsson et al. (2013) and is illustrated in Figure 2. Similarly, the precast column is manufactured with a roughened surface at the bottom, intended for embedding in the spread footing. In this connection, there are no bars extending from the footing into the column. This connection detail was successfully implemented in a bridge replacement project over I-5 in Washington State (Khaleghi et al., 2012).

3 TESTING

The research aimed to assess the connection's ability to withstand out-of-plane moments without causing substantial damage to the foundation while confirming its constructability. Two scaled (63%) test specimens were constructed and subjected to quasi-static, displacement-controlled, one-sided lateral loads to assess their behavior.

The first specimen, designated as 'Cast-in-place Wall,' served as a reference and was detailed according to current standards (e.g., Eurocode, and Icelandic Road and Coastal Administration Bridge Design Manual [Vegagerðin, 2018]). The second specimen, representing the new proposed connection, was detailed in alignment with the same standards and designated as 'Precast Wall'. Throughout the rest of this paper, the Cast-in-place and Precast wall specimens will be denoted as CIP and PC, respectively. Both specimens had the same foundation dimensions, with the length, width and thickness being 1190 mm, 900 mm and 290 mm, respectively. As specimen PC involves embedding the precast wall into the foundation, adjustments to PC specimens wall dimensions were necessary. In line with previous research by Haraldsson et al. (2013), the target was to achieve an embedment depth 1.1 times the wall thickness. Post-embedding, both walls shared identical dimensions, with a length, width, and thickness of 1000 mm, 650 mm, and 190 mm, respectively. Building the full-scale height of the walls was deemed unnecessary since the point load equivalent from the on-site earth load acts at a height of 1/3 times the wall height. The specimen´s design is discussed in more detail in a master´s thesis by the first author (Sigurjónsson, 2023).

The design concrete strength for both walls and foundations were C35/45, and the reinforcement conformed to BN500C. The specimens were cast in two stages, with the first stage involving casting the footing of Specimen CIP and the wall of PC. In the second stage, the wall of CIP and the foundation of PC were cast. The measured wall concrete strength on test day in CIP and PC walls were 70 MPa and 61 MPa, respectively.

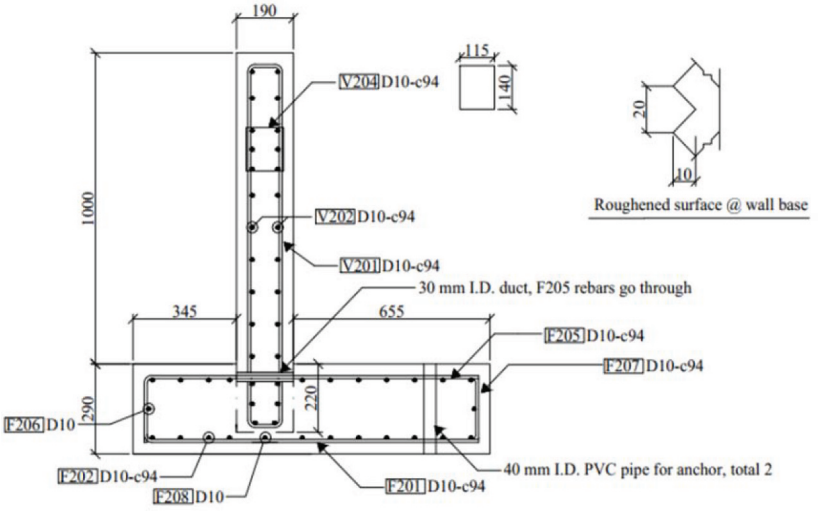

Figure 3. Cross section of PC design (Sigurjónsson, 2023).

3.1 *Setup*

The specimens were tested at the University of Iceland Structural Laboratory. The setup can be seen in Figure 4. Each specimen underwent testing under a unidirectional slow rate cyclic displacement history. Lateral displacements were induced using an Instron displacement-controlled actuator positioned 730 mm above the interface, with a maximum force capacity of 100 kN. The loading protocol comprised 11 peak displacements derived from the lateral load protocol utilized by Haraldsson et al. (2013). The procedure involved applying force until reaching the maximum displacement in 20 seconds, maintaining the constant maximum displacement while mapping new cracks, measuring crack widths, and capturing photos. Afterward, the load was released, completing one cycle.

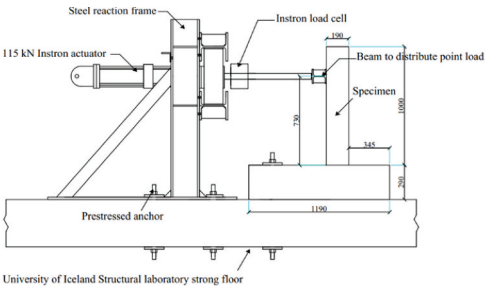

Figure 4. Test setup.

3.2 *Results*

Both CIP and PC completed the loading protocol of 11 peak displacements. Both specimens experienced wall failure, while the foundations remained undamaged throughout the testing. Specimen CIP developed a plastic hinge at the interface between the foundation and the wall, while PC experienced a combination of moment and shear failure. The maximum base moments of the two specimens differed, with the measured maximum moment in CIP at 75.7 kNm and in PC at 66.2 kNm.

The differences in both strength and failure modes prompted post-test examinations, during which the specimens were cut apart and wall thickness measurements were taken. Results indicated that the average wall thickness in the plastic hinge region of Specimen CIP was approximately 200 mm, while Specimen PC measured 190 mm. This distinction can be attributed to the vertical casting of Specimen CIP, inducing pressure in the formwork, and resulting in concrete bulging. In contrast, Specimen PC, cast horizontally, exhibited a more consistent thickness. Additionally, the measured concrete strengths on test day were 70 MPa for CIP and 61

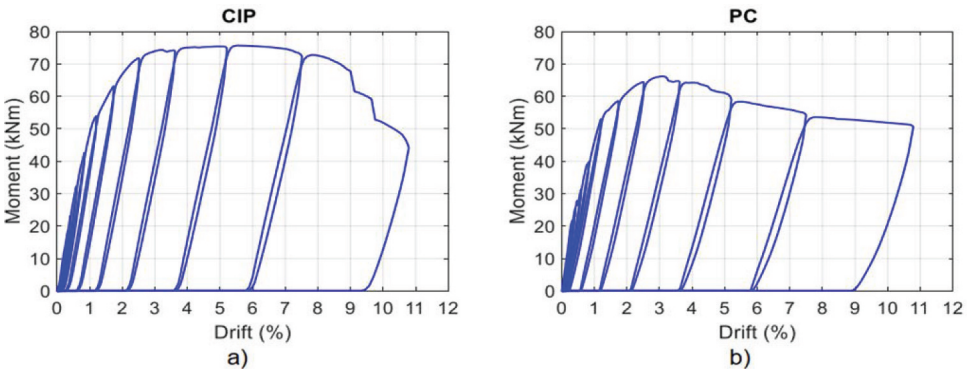

Figure 5. Moment-Drift comparison of both walls, CIP (left) and PC (right).

MPa for PC, further influencing the observed differences. Notably, the foundation's concrete strength measured at 59 MPa was lower than that of the CIP wall. Hairline cracks in the foundation closed upon unloading the test specimen. In Specimen PC, the measured concrete strength was 67 MPa, and the foundation remained undamaged, mirroring the condition of Specimen CIP. Figure 5 shows the moment-drift response of both specimens.

4 IMPLEMENTATION

In Bárðardalur area, located in North-Iceland, a road reconstruction project includes building a compliant new bridge due to the non-conformity of the existing structure with current bridge standards. The new bridge is designed as a single span, measuring 9 meters in length and 10 meters in width. To expedite construction, the design team opted for the new abutment connection, dividing the sizable front- and wing walls for easy transport and on-site assembly through an 'in-situ stitch.' Figure 6 displays plan and front views of the separated abutment elements.

The 300-mm-thick wall elements will be embedded 360 mm into the foundation, influenced by both the U-bar depth, determined in testing, and the concrete cover. Similar to the test specimen discussed in Section 3, the wall section embedded in the foundation will have a textured or roughened surface. Figure 7 shows the cross-section of a front wall element post-segmentation. Figure 8 illustrates the frontal view with corrugated ducts on the left and a cross-section with reinforcement bars protruding on the right. All dimensions are in millimeters.

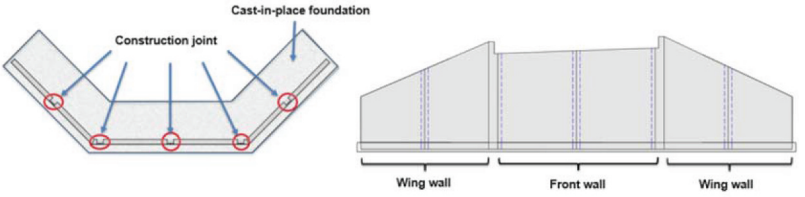

Figure 6. Abutment plan view (left) and front view (right).

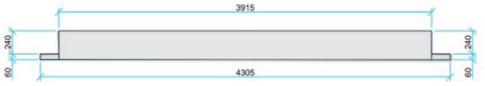

Figure 7. Typical cross section of a precast wall element.

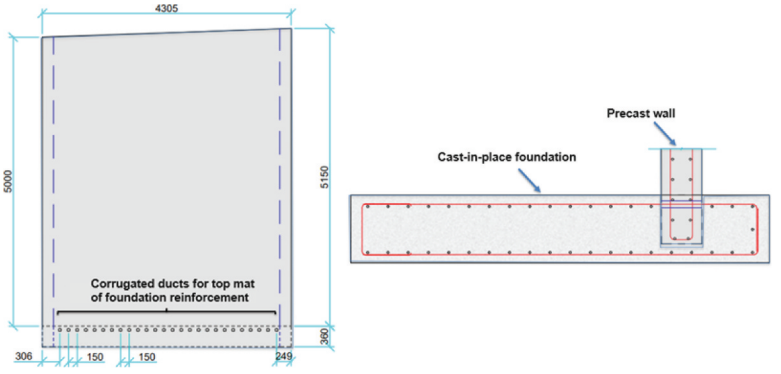

Figure 8. Typical elevation of a precast wall element (left) and connection cross section between precast wall and cast-in-place foundation.

5 CONCLUSIONS

A new 'wet-socket' connection between an abutment wall and a cast-in-place foundation is introduced that is both conceptually straightforward and rapid to construct. This connection concept is derived from an established connection method between a precast column and a cast-in-place spread footing.

Two scaled (63%) test specimens were constructed and subjected to out-of-plane testing under quasi-static, displacement-controlled, one-sided lateral loads. The first specimen, serving as a reference, adhered to current standards (e.g., Eurocode, and the IRCA Bridge Design Manual). The second specimen represented the new connection and was detailed according to the same standards. The following conclusions are drawn:

1. The socket wall connection effectively transmitted loads from the abutment wall to the foundation. As observed in the reference specimen, a failure occurred in the wall, while the foundation remained undamaged.
2. Maximum strength and failure mode varied between specimens. Specimen CIP exhibited a plastic hinge at the construction joint between the foundation and the wall, while Specimen PC underwent a combined moment and shear failure in the wall segment just above the foundation. Further investigation post-testing revealed a wall thickness of 200 mm for CIP, exceeding the prescribed 190 mm. Additionally, the measured wall concrete strengths differed, with CIP at 70 MPa and PC at 61 MPa, impacting both strength and failure mode.
3. The construction of the socket connection suggested that on-site implementation would be simple.

In 2023 two new details of the construction joint between the foundation and the wall were designed and then tested in January 2024. The data is being processed and the results will be presented later.

ACKNOWLEDGEMENTS

NDT for damage detection in FRP reinforced/strengthened concrete elements

Armin B. Mehrabi, Seyed Saman Khedmatgozar Dolati & Pranit Malla
Department of Civil and Environmental Engineering, Florida International University, Miami, FL, USA

Jesus Ortiz Polanco & Antonio Nanni
Department of Civil and Environmental Engineering, University of Miami, Coral Gables, FL, USA

ABSTRACT: The application of Fiber Reinforced Polymer (FRP) materials in concrete structures has been rising due to their several advantages, including lightweight, high tensile strength, ease of installation, and corrosion resistance. They have been mostly implemented for strengthening and repairing existing structures in the form of an externally bonded system, i.e., sheet, jacket, near surface mounted. Furthermore, they have been recently utilized as internal reinforcement of concrete elements in the form of strands, bars, tendons, etc. Although higher durability and performance are associated with the FRP material compared to steel, concerns remain regarding potential damages and defects in this material, many of which are related to their unique features. Importantly, debonding of FRP materials from concrete is a potential issue resulting deterioration of the structural performance. Therefore, as for any other type of material or elements, concrete elements strengthened or reinforced with FRP materials have to be also inspected periodically. This study first determines all possible or potential damages and anomalies attributed to FRP reinforced/strengthened concrete (FRP-RSC) elements. It then investigates Non-Destructive Testing (NDT) methods that can be applicable to the inspection of FRP-RSC elements from a literature survey of past studies, applications, and research projects. Finally, it proposes the most promising methods for detecting FRP and their damage/defects in FRP-RSC elements. By providing the inspection community with more clarity in the application of NDT to FRP, the results of this study offer means for verifying the performance and, therefore, help the proliferation of FRP materials in concrete structures.

1 INTRODUCTION

1.1 *FRP composites*

The 2021 American Society of Civil Engineers (ASCE) infrastructure report card (ASCE, 2021) scored America's infrastructures a low grade of C- and its bridges a low grade of C. In the context of bridges, 42% of the nation's 617,084 highway bridges are over 50 years old and as time passes, an ever-increasing number of bridges will be near the end of their service time and will need some kind of rehabilitation or replacement. Fiber-reinforced polymer (FRP) composites have gained popularity in meeting challenges with durability, for building new civil structures or for maintaining the existing ones. FRPs are composite materials composed of polymeric resins reinforced with fibers. The fibers can be made of glass (GFRP), carbon (CFRP), aramid (AFRP), and basalt (BFRP). They provide several benefits over the conventional construction materials that include but are not limited to corrosion resistance, higher strength to weight ratio, superior durability, and ease of construction (Dolati and Mehrabi, 2022, 2023). Thus, FRP composites have been increasingly used as externally bonded system with the application of FRP sheet, laminates, jacket and near surface mounted (NSM) bars for strengthening and

DOI: 10.1201/9781003483755-441

repairing existing structures. Additionally, their use as internal reinforcements for concrete structures in the form of FRP bars and strands/tendons have been increasing.

1.2 *FRP strengthened concrete (FRP-SC) elements*

FRP composites are primarily utilized for repair, rehabilitation and strengthening of structures when design defects are noticed, the load-bearing capacity of an in-service structure is modified, deterioration of materials has begun, or after damages due to extreme events (seismic or fire events). This is generally achieved by externally bonding FRP systems to the reinforced concrete (RC) elements which is termed as FRP strengthened concrete (FRP-SC) elements in this paper. The external FRP systems can enhance the flexural, axial, shear, and torsional strength. In seismic zones, FRP wraps can be used for columns to increase their ductility due to the induced confinement of the concrete. Apart from the advantages of higher tensile strength with lighter weight, the ease of installation, and suitability for irregular surfaces of FRP composites have contributed to their popularity as a strengthening technique.

1.3 *FRP reinforced concrete (FRP-RC) elements*

Corrosion is one of the major issues that can severely impair the serviceability and safety of conventional steel reinforced/prestressed concrete structures. However, internal FRP reinforcements such as FRP bars and strands are resistant to all the elements that lead to corrosion in steel RC structures, such as reduction of pH of the concrete from carbonation, chloride contamination of the concrete and diffusion of halides and chemicals (Mohamed and Benmokrane, 2014; Benmokrane *et al.*, 2021). Application of FRP reinforcement is one of the most promising alternative available to completely eliminate the issue of corrosion (Benmokrane *et al.*, 2006; Dolati and Mehrabi, 2022; Khedmatgozar Dolati and Mehrabi, 2022b, 2022a; Mehrabi and Khedmatgozar Dolati, 2022) compared to application of corrosion protection measures to carbon steel such as cathodic protection, epoxy-coating and galvanizing that only delay corrosion rather than eradicating it (Wang, 2017). Hence, the application of FRP reinforced concrete (FRP-RC) structures is strongly justified for locations where corrosion of traditional steel reinforcement is an economic and safety concern. The mechanical performance and durability of the FRP composites further make them suitable for these conditions. When compared to carbon steel rebars, FRP bars have higher tensile strength, lower density, and can achieve a longer service life. Although the initial cost of FRP rebars is frequently highlighted as a drawback to its implementation, it has changed significantly due to the growth of the FRP rebar market.

1.4 *FRP reinforced/strengthened concrete (FRP-RSC) elements*

The next phase of development in the application of FRPs in concrete structures could culminate in elements possessing both internal and external FRP systems simultaneously. Future scenarios may include strengthening structures that are originally reinforced with FRP bars and tendons. Further, with the advancements in the application of FRP in civil engineering, it is conceivable that the use of FRP in certain aggressive and hostile environments, such as coastal areas, becomes prevalent. Thus, this paper takes into consideration both the FRP-RC and/or FRP-SC elements to set a foundation for the most promising construction materials of the future.

2 DAMAGES IN FRP REINFORCED/STRENGTHENED CONCRETE (FRP-RSC) ELEMENTS

2.1 *Damages in FRP-SC elements*

FRP strengthened concrete (FRP-SC) elements are generally comprised of three materials: internal reinforcement (typically steel rebars, with the potential for future adoption of FRP rebars), concrete and FRP composites. Defects associated with FRP-SC elements can occur within either of the three materials or at the interface between them (Malla, Khedmatgozar Dolati, Jesus D Ortiz, *et al.*, 2023). Examining the rebar, concrete, FRP system, and interface

separately enables a focused approach to identify and address the potential damages in FRP-SC elements. Hence, based on the locations where they occur, damages in FRP-SC elements typically fall into three distinct groups: 1) Defects in FRP Composites (i.e., FRP Composites Defects); 2) Bond Defects (i.e., FRP-Adhesive Interface, Adhesive, and Adhesive-Concrete Interface Defects); and 3) Defects in Concrete (i.e., Concrete (C) and Concrete-Steel Rebar Interface Defects) (Malla, Khedmatgozar Dolati, Jesus D Ortiz, *et al.*, 2023). Figure 1 illustrates the location and identification of the most likely defects in FRP-SC concrete elements.

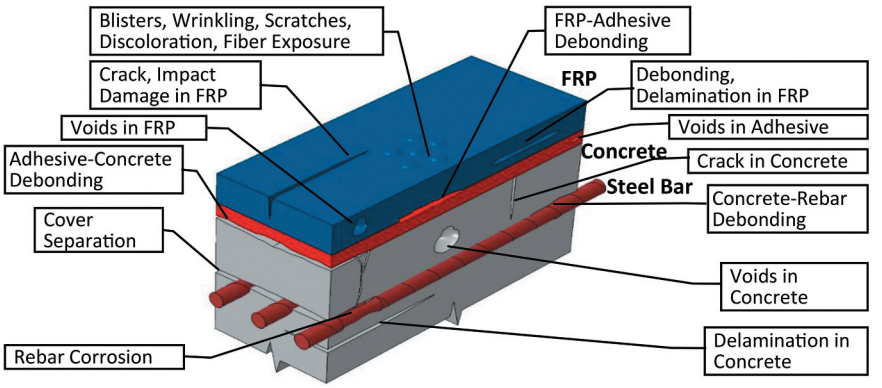

Figure 1. Damages and defects in FRP-SC elements.

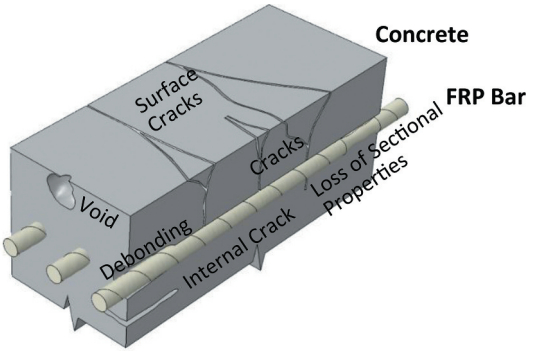
2.2 *Damages in FRP-RC elements*

FRP bars exhibit enhanced durability and performance in certain respects compared to steel. Nevertheless, there are concerns regarding potential damages and defects in FRP bars and FRP-RC elements. Unlike conventional steel-RC elements, FRP-RC elements may not be vulnerable to serviceability issues such as cracking, permeability, carbonation, chloride penetration, and concrete cover requirements. However, FRP bars and FRP-RC elements are susceptible to a distinct set of defects compared to their steel-reinforced counterparts. As an example, the bond behavior at the FRP bar-concrete interface is different from the bond characteristics of steel bars embedded in concrete (Zhao *et al.*, 2021). The bond failure in FRP-RC elements can also occur internally within the FRP bars themselves, a phenomenon not typically observed in steel bars (Hossain, Ametrano and Lachemi, 2014; Kim and Lee, 2019). Similarly, another divergent characteristic of FRP bars compared to steel is their lower modulus of elasticity which results in the formation of relatively more cracks in FRP-RC elements. A research conducted by Valentine (2015) indicated that cracking is the most reported defect in FRP-reinforced bridge decks, as observed by bridge inspectors. However, as FRPs are resistant to corrosion, the formation of cracks in FRP-RC elements does not present



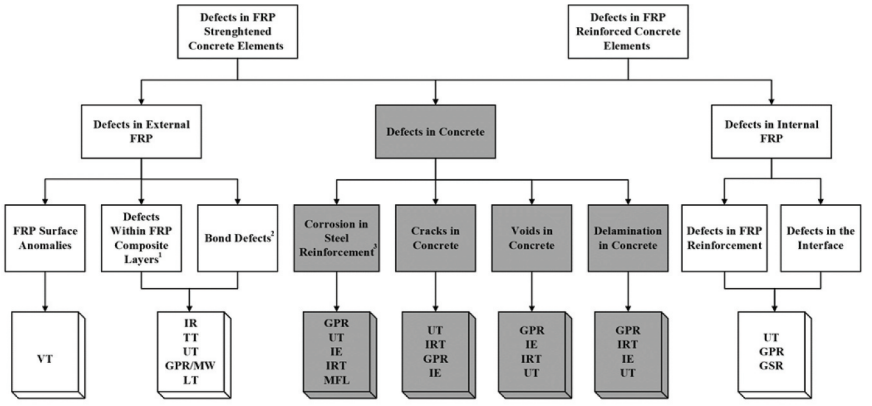


Figure 2. Damages and defects in FRP-RC elements.

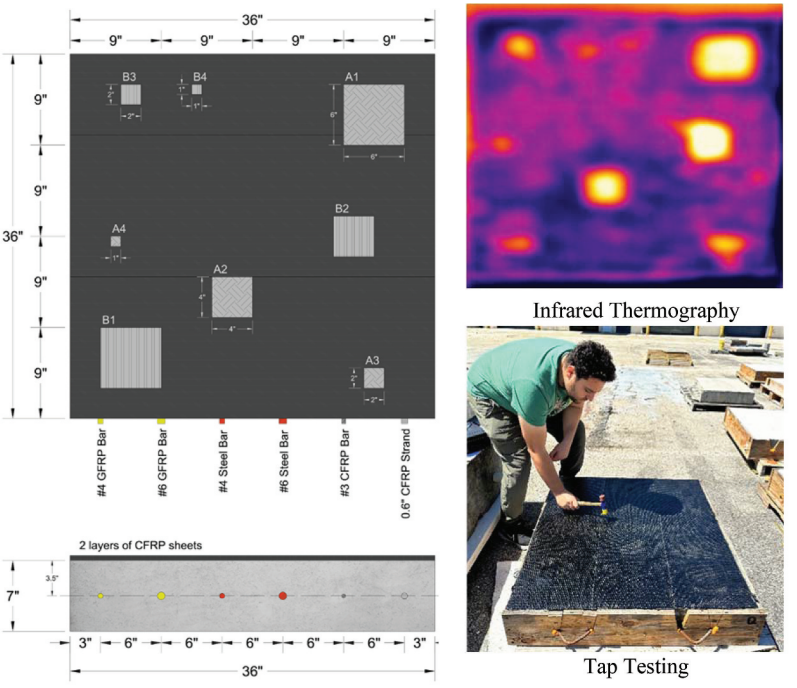
a significant concern as long as the cracks are not severe. Unlike steel bars where corrosion is the obvious damage to be expected, there is very limited information on damages that are possible on FRP bars, a relatively new corrosion resistant construction material. Hence, to contribute to the gap in the knowledge, the authors have listed "potential defects" that could occur in FRP bars and FRP-RC elements as shown in Figure 2.

3 NON-DESTRUCTIVE TESTING (NDT) METHODS FOR THE INSPECTION OF FRP-RSC ELEMENTS

Although substantial research efforts have been dedicated to the application of Non-Destructive Testing (NDT) and inspection techniques for traditional steel-RC elements, research pertaining to NDT of FRP-RSC elements remains comparatively underdeveloped. There exists an absence of definitive guidelines regarding the application of various NDT methods for the detection and assessment of damage in FRP-RSC structures. To address this research gap, for the study reported in this paper a comprehensive examination was conducted on all NDT methods potentially applicable for the evaluation of FRP-RSC elements through literature review of past studies.

The comprehensive literature review identified Ground Penetrating Radar (GPR) and Ultrasonic Testing (UT, including Phased Array Ultrasonic Testing, PAU) as the most effective Non-Destructive Testing (NDT) methods for identifying the presence of damage in FRP-RC elements. These methods are also most commonly employed in the evaluation of steel-RC elements. Additionally, visual inspection (VT), tap testing (TT), and infrared thermography (IR) were recognized as particularly relevant NDT techniques for the examination of FRP-SC structures. Figure 3 shows the flowchart for the selection of NDT methods applicable for the inspection of concrete elements reinforced or strengthened with FRP based on the literature review. This has been described in detail in (Dolati *et al.*, 2023; Malla, Khedmatgozar Dolati, Jesus D. Ortiz, Mehrabi and Nanni, 2023). In addition to VT, TT, GPR, UT, and IR, the NDT methods considered include IE (Impact Echo), MW (Microwave), LT (Laser Testing), IRT (Impulse Response Testing), MFL (Magnetic Flux Leakage), and GSR (Global Structural Response Testing). The flowchart also suggests the order of priority of various NDT methods, type of damages, and type of applications. To further validate the applicability of these selected NDT methods in inspection of FRP-RSC elements, a series of experimental tests were conducted.



Notes:

1. Defects within FRP composite layers include blisters, wrinkling, scratches, discoloration, fiber exposure, voids at the fiber-matrix interface, fiber-matrix debonding, delamination between composite layers, cracks, and impact damage
2. Bond defects include debonding and voids between FRP and concrete
3. Corrosion in steel reinforcement is to be considered only when it is applicable

Figure 3. Order of priority for NDT methods suitable for each type of defect.

3.1 *Validation of selected NDT for FRP-SC elements*

To validate the applicability of the selected NDT methods for inspection of FRP-SC elements, debonding, delamination, and concrete damages such as voids and cracks were replicated in FRP-strengthened specimens. The findings indicated that GPR was less effective in identifying defects or damages for the case of externally applied CFRP and the internal targets beneath the CFRP layer (cracks and voids in concrete substrate) due to the conductive nature of CFRP. In contrast, PAU demonstrated capability in inspecting externally applied FRP including CFRP. Complementary NDT techniques, including visual inspection, tap testing, and infrared thermography, were also found to be highly effective in identifying defects or damages in externally applied FRP as shown in Figure 4. More details on the on the detection of damages on concrete elements with externally bonded FRP can be further explored in (Ortiz *et al.*, 2024)

Legends:

Defect ID	Description	Dimension

Debonding between substrate & FRP

Figure 4. Application of infrared thermography & tap testing for inspection of FRP-SC.

3.2 *Validation of selected NDT for FRP-RC elements*

To verify that GPR and PAU are applicable for inspection of FRP-RC elements, various slab specimens were fabricated with GFRP, CFRP, BFRP, and steel bars, as well as GFRP and CFRP strands. These specimens varied in depth, size, and configuration. Different damage scenarios, including bar rupture, debonding, and loss of cross-sectional properties were simulated in FRP bars/strands. Figure 5 illustrates the results for detection of damages in GFRP bars embedded in a concrete slab specimen using GPR. Furthermore, the detection of

damages within concrete, such as delamination, cracks, and voids that are same as those found in traditional steel reinforced or prestressed concrete elements were also included in the study as shown in Figure 6. It was found that GPR was effective in identifying damages in GFRP bars, CFRP strands, steel bars, and internal concrete damages. However, PAU exhibited limitations in detecting damage in GFRP and BFRP bars, but it demonstrated proficient performance in identifying damage in CFRP strands, steel bars, and concrete. Another study by the authors (Malla, *et al.*, 2024) provides in-depth information on the application of conventional NDT methods in inspection of FRP-RC elements.

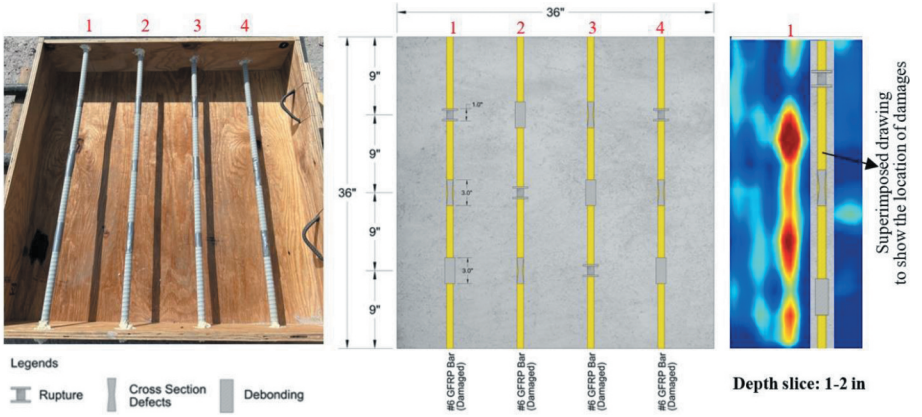

Figure 5. Application of GPR for inspection of FRP-RC specimen with defects in GFRP bars.

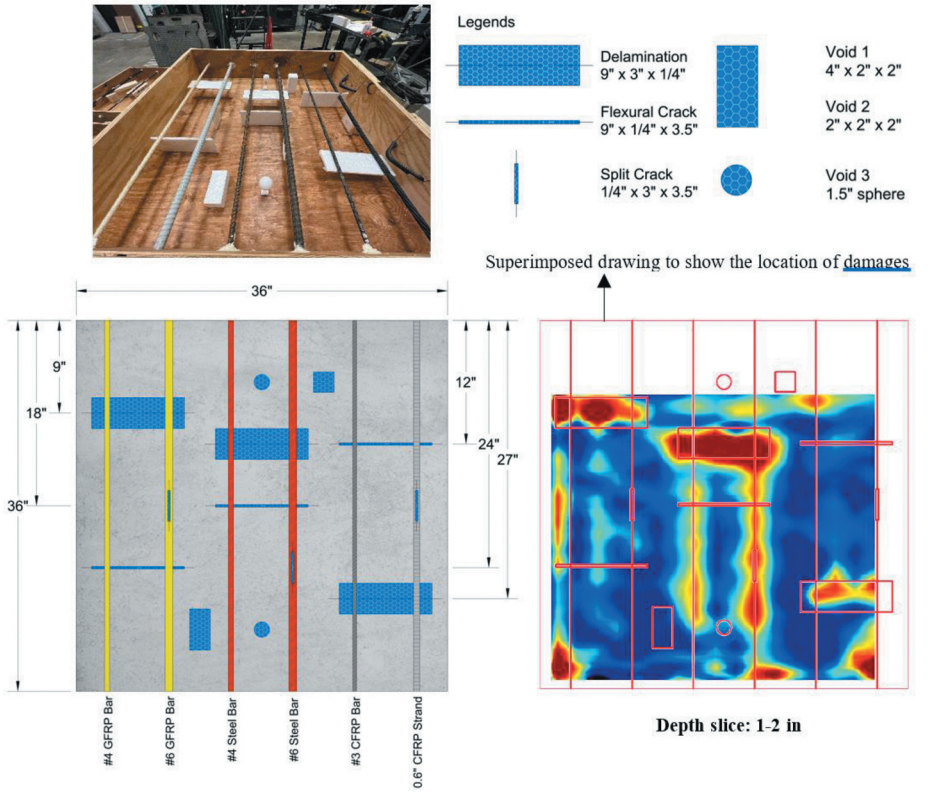

Figure 6. Application of GPR for inspection of FRP-RC specimen with defects in concrete.

4 APPROACHES TO ENHANCE THE DETECTABILITY OF EMBEDDED FRP

This study also developed two innovative approaches to enhance the detectability of embedded FRP bars and improve the identification of damages in them. The first approach involves the application of metallic particle coatings, and the second incorporates winding of wire on the surface of FRP bars. Both methods can be easily incorporated within the processes already in use for bond-enhancing of FRP bars. The efficacy of these novel techniques was validated through GPR and PAU tests on a small-scale slab specimen reinforced with modified GFRP bars as shown in Figure 7. The findings demonstrated a noteworthy enhancement in detecting embedded FRP bars and their associated damages. Further details on the method of introducing these modifications in FRP bars can be referred in the study by Malla et al. (2024).

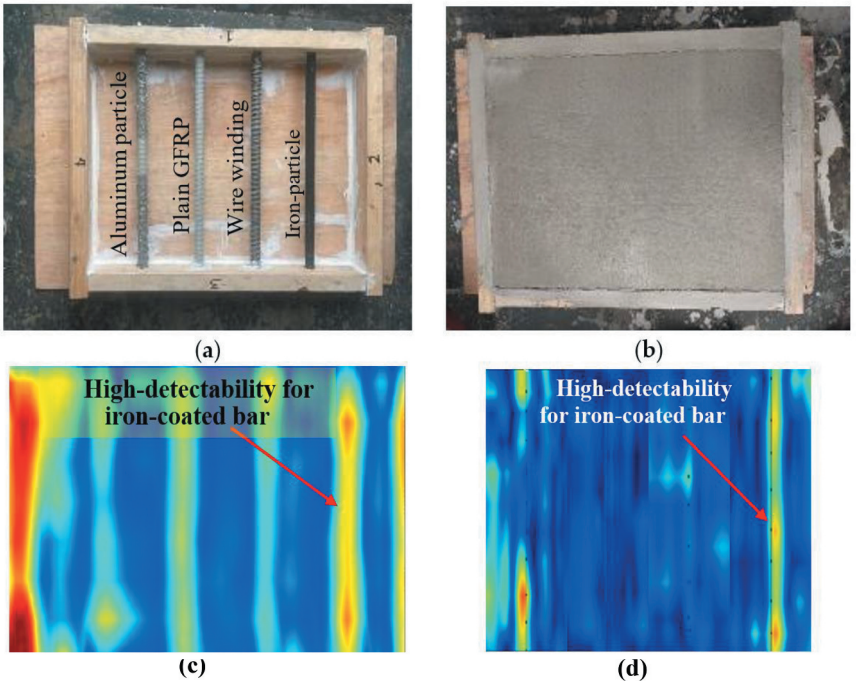

Figure 7. Slab specimen used for feasibility study for the new approaches: a) Formwork with coated & uncoated GFRP bars, b) Cast specimen, c) GPR depth slice d) PAU depth slice.

Moreover, this study found that modifying test parameters in the chosen NDT methods could enhance detectability. One notable parameter is the antenna frequency in the GPR method, which can influence the ability to detect various sizes and depths of embedded GFRP bars as further explained in Malla et al. (2023).

5 SUMMARY AND CONCLUSION

The study highlights that while FRP offers several advantages over conventional construction materials, including corrosion resistance and high strength-to-weight ratio, it also presents unique challenges in terms of detecting potential damages and defects. To address these challenges, after identifying type of damages and their sources, a thorough investigation of various NDT methods suitable for inspecting FRP-RSC elements was conducted. GPR and UT, including PAU, were identified as effective NDT methods for detecting damage in FRP-RC elements. These methods, along with visual inspection, tap testing, and infrared thermography, were found to be successful for examining FRP-SC structures. The paper also introduces two innovative approaches to enhancing the detectability of embedded FRP bars: applying metallic particle coatings and winding wire

on FRP bar surface. These novel techniques were validated through GPR and PAU tests and demonstrated significant improvements in detecting embedded FRP bars and associated damages.

In conclusion, this study provides a comprehensive overview of the application of FRP in concrete structures, the types of damages that can occur in FRP-RSC elements, and the effectiveness of various NDT methods in detecting these damages. It further contributes significantly to the field by proposing new methods to enhance the detectability of damages in FRP-RSC elements ensuring their structural integrity and extended service life.

Calibration of constitutive model parameters of bridge steels using particle swarm optimization

Yuelin Zhang
College of Civil Engineering, Tongji University, Shanghai, China

Chunbin Li & Hongwei Huo
China MCC22 Group Corporation Ltd., Tangshan, China

ABSTRACT: Conventional manual calibration of steel material constitutive model parameters is a process of trial and error, with the disadvantages of low efficiency and bad accuracy. The present work aims to propose an automatic calibration process by introducing modern optimization algorithm. Firstly, a series of Q345 and Q235 steel material property tests were conducted, to prepare the data needed to conduct the calibration. Secondly, the material property parameters were determined inversely by particle swarm optimization (PSO). It was found that after 20 times of iteration, the calibration accuracy of Q345 steel is enhanced by 18.73% to 40.44%, and corresponding improvement of Q235 steel is 12.61%-76.20%. Thirdly, the cyclic plasticity characteristics of Q345 and Q235 steels were compared, the results show that both isotropic and kinematic hardening levels of Q235 steel are greater than those of the Q345 steel. The Q-value of Q235 steel is increased by about 60.39%, compared with Q345, and the backstress (C_1/γ_1) of Q235 is 22.14% larger than that of Q345.

1 INTRODUCTION

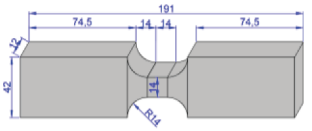
Like many other metals, the yield strength of bridge steel will increase after the loading-unloading process, which is called "hardening", and the corresponding stress-strain relationship of the material is known as constitutive relationship. The one-dimensional stress-strain relationship curve of steel material was generally defined as bilinear or trilinear model [1], but the above models are not very accurate in the mechanical behavior simulation of steel material under cyclic loading, and the calculated curve may be quite different from the actual one. To satisfy practical requirement and convene engineering application, researchers proposed a series of calculation models for steel materials to simulate their constitutive relationship under cyclic loading or other extreme loading conditions [2-10]. Ramberg [11] recommended a three-parameter model to describe the cyclic loading skeleton curve of metals; Krawinkler and Nathaniel [2, 4] proposed a mathematical expression to describe the cyclic behavior of steel material based on elastic-plastic mechanics method, concepts including hardening, softening, and average stress were defined; Chaboche et al. [12-15] proposed cyclic constitutive models of steel material that comprehensively consider isotropic hardening and kinematic hardening characteristics, and specific determination methods of model parameters were given; Atkan [6] and Wang et al. [5] gave the constitutive model of reinforcement under cyclic loads, which also has reference significance for steel material; On the basis of multi-surface model proposed by Dafalias and Popov et al. [9, 10], Shen and Usami [7, 8] proposed a double yield surface model, which accurately described the cyclic performance of steel structures. Among these constitutive models, Voce-Chaboche (VC) combined hardening model is widely used [16]. However, in order to apply the

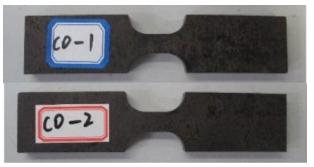
DOI: 10.1201/9781003483755-442

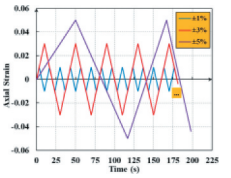
model to practical analysis, there must be corresponding finite element calculation methods and programs, and model parameters must be reasonably determined, and there are several parameters to be determined in this model. Since these highly nonlinear mathematical expressions can describe some much complex mechanical responses of materials, they are somewhat sensitive to integral algorithm of parameters. Therefore, determination methods of parameters in elastic-plastic models now have already drawn researchers' attention gradually, and a lot of investigations have been done [17].

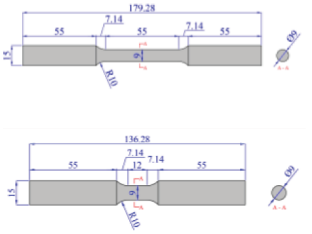
The commonly used parameter optimization methods include Gauss Newton method, CO rolling gradient method and least square method (LSM), these traditional optimization methods have the characteristics of fast convergence speed and high calculation accuracy, but all of them are localized extremum algorithm, the solution given by these methods are localized optimal one, rather than global optimal one [18]. As a typical random searching algorithm, particle swarm optimization (PSO) was first proposed by Kennedy and Eberhart [19], it is a computational model established to simulate the predation behavior of birds. The researchers found that the behavior of birds in flight is unpredictable, for example, birds may suddenly disperse, gather or change flying direction, but some consistency is still kept, i.e., individuals maintain the most suitable distance to avoid collision phenomenon. It was found that there is an information sharing mechanism in biological population through conducting investigation on the behaviors of similar biological population. In PSO, each particle represents a possible solution in the searching space, the population is the set of potential solutions of the problem. The initial population is usually randomly generated. In the simulation of birds' predation gathering process, each particle in the swarm constantly searches and evolves in the solution space, and during the searching process, each particle records its own optimal value, and simultaneously learns from other particles. Through the personalized learning of particles and the cooperative interaction between them, the whole search group constantly approaches the optimal solution of the problem. As a bionic heuristic algorithm, PSO algorithm model is simple, convenient to be operated, easy to be realized, robust, and has deep intelligent characteristic, its advantage is apparent. Currently, PSO has been widely used in various areas [20-24]. As a development and application of PSO, calibration of the combined hardening constitutive model parameters of bridge steels will be carried out using PSO in this paper.

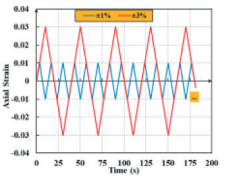
2 DATA PREPARATION











2.1 *Experimental setup*

The subjects to be tested include two kinds of dog-bone material property coupon, one is Q345 flat plate coupon, with a total number of two. The other is Q235 round bar coupon, with the total number of five. The Q345 coupons are labelled as C0-1 and C0-2, where±1% and ±3% strain amplitude loading tests were conducted on Specimen C0-1 and C0-2, respectively. Q235 coupons are labelled as t1, t2, Q235-1#, Q235-2#, and Q235-3#, where monotonic tensile tests were conducted on Specimen t1 and t2, while±1%, ±3%, and ±5% strain amplitude cyclic loadings were applied on Specimens Q235-1#, Q235-2#, and Q235-3#, respectively. Detailed geometrical dimensions, photos, and loading protocols of the coupons are summarized in Table 1. The tests were carried out at Experimental Center of Engineering Mechanics, The School of Naval Architecture, Ocean & Civil Engineering (NAOCE), Shanghai Jiao Tong University. An MTS fatigue testing machine with the capacity of 500kN was used to conduct the cyclic loading experiments. Loading rate was 0.035/s, an extensometer with the gauge length of 8mm was used to measure strain data, which were shown in Figure 1. Data collection frequency was 40Hz.

2.2 *Experimental results*

After testing, photos of the Q235 round bar coupons are illustrated in Figure 2, it can be found that the cracks are basically located within the gauged length region. First two cycle stress-strain curves of the five cyclic loaded specimens were plotted in Figure 3 (a), (b), and (d)-(f), and complete stress-strain curves of the two monotonic loaded coupons are depicted in

Table 1. Information of the coupons and corresponding loading protocols.

Material	Coupon dimension	Coupon schematic	Loading protocol
Q345			
Q235			Monotonic tension 

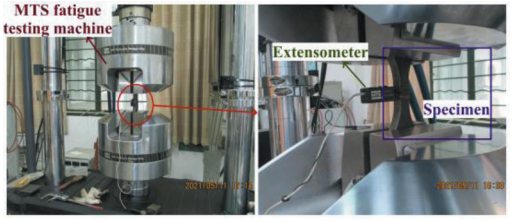


Figure 1. Experimental setup.

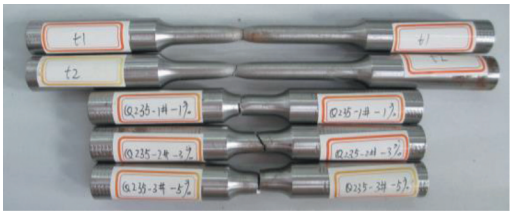

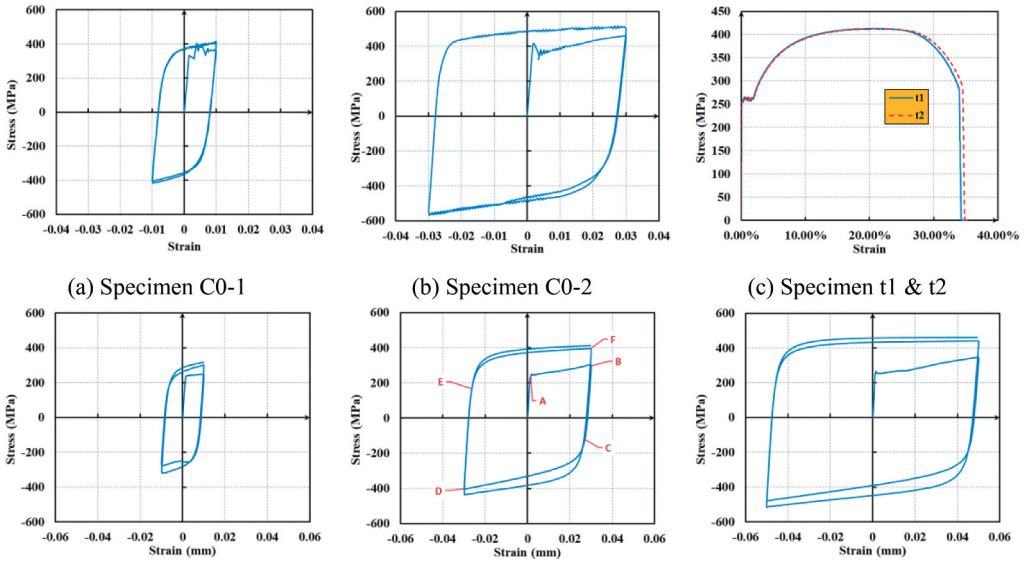

Figure 2. Photo of the Q235 round bar coupons after testing.

Figure 3 (c), where the stress is the average stress of the gauged cross-section, and the value is the ratio of the load of the testing machine to the cross-sectional area, while strain data was read directly from the extensometer. It can be found that the first and the second hysteretic loop of Q345 low-alloy steel almost overlap with each other, indicating that the steel is a cyclic stabilization material. While for Q235 carbon steel, the stress of the second cycle is a little larger than that of the first cycle, implying that the material shows a slight degree of cyclic hardening. Table 2 summarized the basic mechanical property parameters of Q235 steel by aforementioned two monotonic tensile coupons, i.e., t1 and t2.

3 PERTINENT THEORIES

Taking Specimen Q235-2# for example, point A in Figure 3(e) is the initial yield point of the material, point B is the ultimate stress of the monotonic cycle, point C is the yield point of

(a) Specimen C0-1 (b) Specimen C0-2 (c) Specimen t1 & t2

(d) Specimen Q235-1# (e) Specimen Q235-2# (f) Specimen Q235-3#

Figure 3. Stress-strain curves of the seven specimens.

Table 2. Summary of monotonic tensile test results

Specimen No.	Young's modulus (MPa)	Yield stress (MPa)	Ultimate tensile stress (uts, MPa)	Fracture strain	Elongation after fracture
t1	1.98E+05	258.02	412.38	21.43%	33.75%
t2	1.88E+05	251.42	412.10	20.39%	34.95%
Average value	1.93E+05	254.72	412.24	20.91%	34.35%

negative direction, point D is the ultimate point of the negative direction, point E is the yield point of the first cycle, and point F is the ultimate point of the first cycle. The stress-strain curve can be regarded as a piecewise function of stress varying with strain, in which OA section is an elastic section, and the stress-strain relationship follows Hooke's Law:

$$\sigma = E\varepsilon \tag{1}$$

where E is Young's modulus.

For section AB, according to Mises yielding criterion:

$$\sigma = \alpha + \sigma^0 \tag{2}$$

where α is backstress, which is used to describe the characteristic of kinematic hardening. Generally, α consists of 1~4 component(s):

$$\alpha = \sum_{k=1}^{n} \alpha_k, n = 1, 2, 3, 4 \tag{3}$$

For the purpose of simplification, only one component is used in this paper:

$$\alpha_1 = \frac{C_1}{\gamma_1}\left(1 - e^{-r_1 \varepsilon^{pl}}\right) \tag{4}$$

where α_1 is Chaboche exponential term, C_1 and γ_1 are parameters to be calibrated, ε^{pl} is equivalent plastic strain. σ° in Formula (2) is isotropic stress, according to Voce isotropic hardening law [25]:

$$\sigma^0 = \sigma|_0 + Q_\infty\left(1 - e^{-b\bar{\varepsilon}^{pl}}\right) \tag{5}$$

where $\sigma|_0$ is the initial yield stress of the material, Q_∞ reflects the expansion degree of yield surface, while b reflects the expansion rate of yield surface.

Section BC is elastic unloading section:

$$\sigma{=}E\left(\varepsilon - \left|\varepsilon|_{\sigma=0}\right|\right) \tag{6}$$

where $\varepsilon|_{\sigma=0}$ is the strain value at the intersection of stress-strain curve and x-axis.

For section CD:

$$\sigma{=}\alpha - \sigma^0$$

$$\alpha_1 = -\frac{C_1}{\gamma_1} + \left(\alpha_C + \frac{C_1}{\gamma_1}\right)e^{-r_1\left(\varepsilon^{pl} - \varepsilon_C^{pl}\right)} \tag{7}$$

where α_C is the backstress at point C, ε_C^{pl} is the equivalent plastic strain at point C. According to the characteristics of the functions mentioned above, C_1/γ_1, C_2, $\sigma|_0$, and Q_∞ determine the value of peak stress together, the peak stress increases with the increase of these parameters, and the peak stress decreases in contrast. γ_1 governs the shape of hysteretic cycle, a larger γ_1 leads to a plumper hysteretic loop, on the contrary, the hysteresis loop is flatter.

For section DE:

$$\sigma{=}E\left(\varepsilon + \left|\varepsilon|_{\sigma=0}\right|\right) \tag{8}$$

For section EF:

$$\alpha_1 = \frac{C_1}{\gamma_1} + \left(\alpha_E - \frac{C_1}{\gamma_1}\right)e^{-r_1\left(\varepsilon^{pl} - \varepsilon_E^{pl}\right)} \tag{9}$$

where α_E is the backstress at point E, ε_E^{pl} is the equivalent plastic strain at point E.

4 PSO-BASED REVERSE CALIBRATION OF CONSTITUTIVE MODEL PARAMETERS

4.1 *Working procedure*

As mentioned above, there are several parameters, such as Young's modulus, initial yield stress, isotropic hardening parameters, and kinematic hardening parameters, to be calibrated in the above-mentioned constitutive model. In contrast to traditional calibration method, which is essentially a trial and error process, inverse calibration is gaining increasing popularity [26-29]. The first step of inverse calibration is to create an FE model and generate an inp. file, and then Matlab software is used to call Abaqus software to run the inp. file, so that a result post-processing file with odb. format is generated. The next step is to read the load-displacement data from the result post-processing file, and then the load-displacement data is converted to average stress-strain data of the gauged region, so that the calculated stresses can be compared with the tested ones. To address the problem of unmatched simulated and experimental data, the test and simulated curves are interpolated into two new curves with the same abscissa. The comparison result of the simulated value and tested value should be quantified through an error function (also called as objective function or fitness function). To

reduce the amount of calculation, residual sum of squares (RSS) is adopted as the fitness function in this paper:

$$F_{error} = \sum_{i=1}^{N} \left(\sigma_i^{\exp} - \sigma_i^{\text{model}}\right)^2 \tag{10}$$

After the definition of error function, PSO algorithm can be adopted. The basic principle of PSO [19] is to make use of the sharing of information by individuals in a group, so as to make the movement of the whole group produce an evolutionary process from disorder to order in the problem-solving space, and then the optimal solution of the problem can be obtained. In PSO, each solution of an optimization problem can be regarded as a bird in the searching space, and is referred to as a particle, and the optimal solution of the problem corresponds to the corn field that the birds search for. Every particle has a position vector (the position of the particle in the solution space) and a velocity vector (to determine the direction and velocity of the next flight), and the fitness value of the current position can be calculated according to an objective function, in which the fitness value can be understood as the distance from the corn field. In each iteration, a particle in the group can learn from its own experience (historical position), as well as the experience of the optimal particle, so as to determine how to adjust and change the flying direction and velocity in the next iteration. In this way, the particles in the whole group will tend to optimal solutions gradually. The detailed working procedure of PSO can be found in the author's previous work [29].The iteration procedure of PSO, as well as the whole calibration procedure is demonstrated in Figure 4.

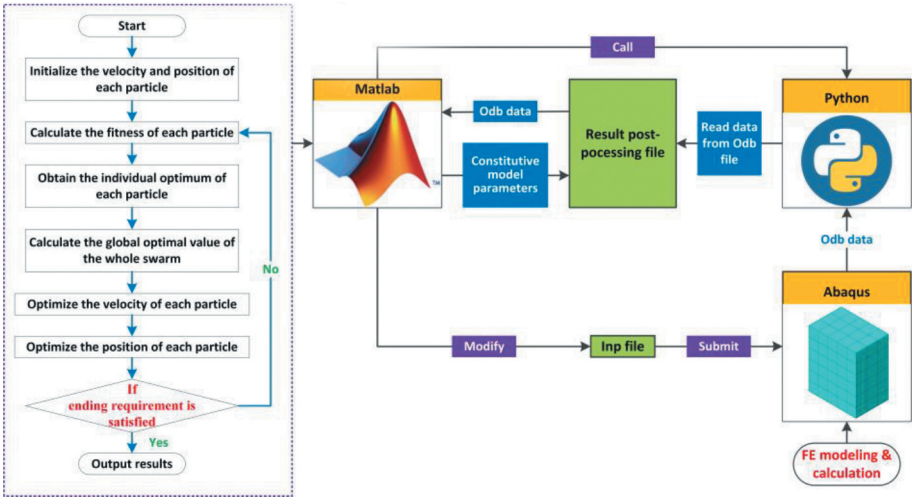

Figure 4. Flow chart of inverse calibration procedure.

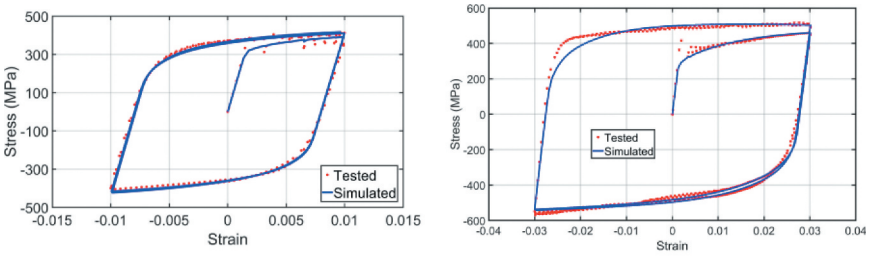
For the process of finite element (FE) modeling, only the gauged region was modeled, to improve calculation efficiency. Both ends of the gauged region were coupled to two reference points (RPs), so that loads and boundary conditions can be applied to the RPs. The element type is commonly used C3D8R, and the loading displacement amplitudes were set in accordance with those in experimental scenarios (The last column in Table 1).



4.2 *Optimized results*

The necessary model parameters after optimization are listed in Table 3, and comparisons of the gauged regions' average stress-strain curves calculated by the parameters and experimental curves are demonstrated in Figure 5 and Figure 6. It can be found that the simulated curves agree well with experimental ones. The fitness function values calculated by original model

parameters are further compared with those calculated by optimized model parameters in Figure 7. It can be found that after 20 times of iteration, the calculation accuracies are improved by about 18.73% and 40.44% under ±1% and ±3% strain amplitude loads, respectively, for the Q345 coupons. While for Q235 steel, the calculation accuracies are enhanced by 12.61%-76.20%.

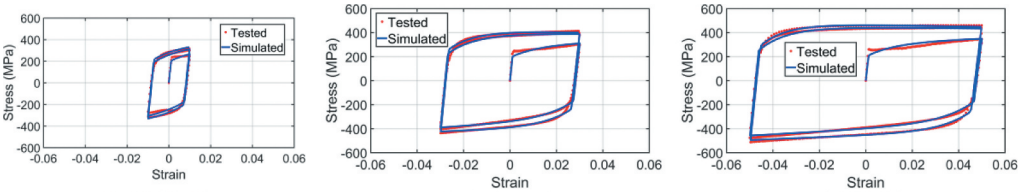


Table 3. Calibrated constitutive model parameters.

Parameter	Unit	Q345 ±1%	±3%	Average	Q235 ±1%	±3%	±5%	Average	Comparison
E	MPa	1.92E+05	1.93E+05	1.93E+05	191429	193161	185348.09	1.90E+05	-1.31%

5 DISCUSSION

The last column of Table 3 shows the difference between the constitutive model parameters of Q345 and Q235 steels. It can be found that Young's modulus of the two steels are very close to each other, and the yield strength of Q235 steel is about 15.26% smaller than that of the Q345 steel. The isotopic hardening degree of Q235 steel is much larger than that of the Q345 steel, since the Q-value of Q235 steel is increased by about 60.39%, compared with Q345. While the isotropic hardening rate (b) of Q235 is 19.06% slower than that of Q 345 steel, implying that Q345 is more like cyclic stabilization material, while Q235 shows a certain degree of cyclic hardening. The two steels show similar stiffnesses after yielding (second-order stiffness), since their C values are very similar to each other. Q235 is also larger in kinematic hardening degree, and the backstress (C_1/γ_1) is 22.14% larger than that of the Q345 steel. As a summary, both isotropic and kinematic hardening levels of Q235 steel are greater than those of the Q345 steel.

6 CONCLUSIONS

In this paper, cyclic loading tests were conducted on Q345 steel flat plate coupons and Q235 round bar coupons. Based on testing data, cyclic plasticity constitutive model parameters of the two steels are inversely calibrated by particle swarm optimization (PSO). According to the results obtained, following main conclusions can be drawn:

(1) Using PSO inversely calibrated constitutive model parameters to conduct finite element (FE) calculation can greatly improve calculation accuracy. For Q345 coupons, the calculation accuracies are improved by about 18.73% and 40.44% under ±1% and ±3% strain amplitude loads, respectively. While for Q235 steel, the calculation accuracies are enhanced by 12.61%-76.20%.
(2) Both isotropic and kinematic hardening levels of Q235 steel are greater than those of the Q345 steel. The Q-value of Q235 steel is increased by about 60.39%, compared with Q345, and the backstress (C_1/γ_1) of Q235 is 22.14% larger than that of Q345.

Modal identification for rapid assessment of short span reinforced concrete bridges

S.L. Leiva-Maldonado
Universidad de la Salle, Bogota, Colombia

F. Consuegra
INGETEC S.A., Bogota, Colombia

ABSTRACT: Structural condition assessment of bridges is the combination of multiple activities such as visual inspections, field and lab testing, structural modeling among others. Therefore, it implies not only structural resistance and static analyses but also dynamic behavior. Dynamic testing techniques as a non-destructive structural assessment is commonly used in bridge engineering. However, different challenges arise when mathematical modeling is involved for rapid evaluation, including modes and frequency validation. The vibration record is a procedure that allows the evaluation of the real behavior of a structure without affecting its own operation. Calibrating numerical models from field data allows to know the real structural behavior during operation. This investigation focuses on the difference between the real behavior and the idealized numerical model built with field structural data in terms of natural frequency and mode shapes. For this study, forty-five simply supported bridges located in Colombia were instrumented and modeled. Visual inspections and proper photographic records were available for all bridges. Different mathematical models were examined including single beam elements, beam elements in conjunction with shell elements and only shell elements. Flexural frequencies and mode shapes were compared using field data and mathematical models. Results suggest that the consideration of the dynamic modulus of elasticity instead of the static modulus in numerical analysis led to more accurate results compared with those obtained from analysis of field data.

1 INTRODUCTION

Dynamic monitoring of structures is a common practice since late 70´s. Those records commonly had been used to estimate the real behavior of a structure such as fatigue analyses observed from dynamic parameters (Doebling et al., 1996) among others. In many cases, researchers focus on the comparison between the real response of the structure (identified in the dynamic records) and the simulated response through numerical models.

This investigation was focused on the study of a simply supported reinforced concrete bridge located in Colombia and part of the main road system. There were two reasons for choosing those structures: Firstly, the huge importance of this type of configuration for the developing of the Colombian infrastructure. Secondly, the potential contribution to the modeling of bridges and their accurate response compared with the real behavior. In addition, the particularity of those structures is that are constantly forced to dynamic forces like the transit of vehicles, characteristic that makes feasible the dynamic characterization with field acceleration records.

Starting from the available field inspections of bridges, numerical models had been created. Additionally, field acceleration records had been used to identify the dynamic behavior of the structure during operation. Comparisons of both results allow to identify the differences between both behaviors. All data including pictures, field inspections (visual and field tests) structural drawings, concrete compression resistance and acceleration records were supplied by INGETEC S.A. – Ingenieros Consultores –.

DOI: 10.1201/9781003483755-443

This method is commonly known as bridge modal identification (BMI) and has been implemented by different authors. For example, Sadeghi Eshkevari et al., (2020) and Talebi-Kalaleh & Mei, (2023) implemented the method in long-span simply supported bridges, focused on the accurate dynamic response. Other researchers like Li et al., (2022) examined BMI in long-span cable stayed bridges. Finally, Consuegra & Santos, (2015) presents an alternative method to investigate structural condition based on a non-linear elastic mathematic representation of the structure based on BMI. Hence, the current research efforts are focused on complex methods to be used in detailed analyses. Consequently, alternative rapid assessments for dynamic bridge responses could be useful for practitioners and inspectors as an initial tool of analysis and preliminary structural behavior. The analysis aims to determine a rapid relationship between the numerical model and the operation response through the modulus of elasticity of the concrete.

The elastic modulus of elasticity is the relationship between the normal stress and longitudinal strain of any given material under axial load (Neville, 2011). The elastic modulus of elasticity is given by the slope of the stress-strain curve of a given material due to a pseudo-static test; however, this curve is not strictly linear for the concrete behavior (Serrano-Guzmán & Pérez-Ruiz, 2010). The dynamic modulus of elasticity corresponding to a very small instantaneous strain is approximately given by the initial tangential modulus which is the tangent modulus for the line drawn from the origin. It is generally 20, 30 and 40 percent higher than the static modulus of elasticity for high, medium, and low strength concretes respectively (Serrano-Guzmán & Pérez-Ruiz, 2010).

Equation 1 shows the numerical expression used by "Norma Colombiana de Diseno de Puentes (CCP14)" which is the official normative used for the analysis and design of bridges in Colombia. This equation stablishes a relationship between the compressive resistance of the concrete ($f'c$) and the value of the elastic modulus of elasticity.

$$E_c = 4800(f'c)^{0.5}\ [MPa] \tag{1}$$

Several attempts have been made to correlate static (E_c) and dynamic (E_d) moduli of elasticity for concrete. The simplest of these empirical relations was given by Lydon & Balendran, (1986), and it is presented in equation (2):

$$E_c = 0.83E_d\ [MPa] \tag{2}$$

Therefore, it can be determined that the dynamic modulus of elasticity for concretes above 18.00MPa (considered as structural concrete) is 1.20 times higher than the elastic modulus of elasticity. Additionally, and as specified by Serrano-Guzmán & Pérez-Ruiz, (2010), for lower compressive strengths, it could be 1.40 times larger.

2 DESCRIPTION OF BRIDGE DATABASE AND FIELD INSTRUMENTATION

All the bridges analyzed can be comprised in the following superstructure categorization: 35 reinforced concrete beam bridges (RC), 1 reinforced concrete beams bridge with external post-tensioning (RC-ET), and 9 prestressed concrete beams bridges (PC). There are 37 bridges with one simply supported span, 5 with two simply supported spans and 1 with three simply supported spans; it means that there are 50 different acceleration records. Geometrically there are bridges with 3 to 9 principal beams, widths from 8.00m to 14.70m including the handrails, and lengths between 5.00m to 42.20m. Average values of concrete compression strength varies between 7.85MPa to 31.90 MPa.

A simply supported reinforced concrete beams bridge is presented for the explanation of the method. The geometry of the structure is presented in Figure 1. The bridge is 11.02m long (10.00m between supports), 8.57m wide, the superstructure is composed of four main 0.41x0.82m beams with principal reinforcement of 2 layers of 8#8 plain reinforcing steel. Reinforced steel distribution and concrete compressive strength (11.80MPa) were obtained from non-destructive testing, visual inspections and extracted concrete core samples.

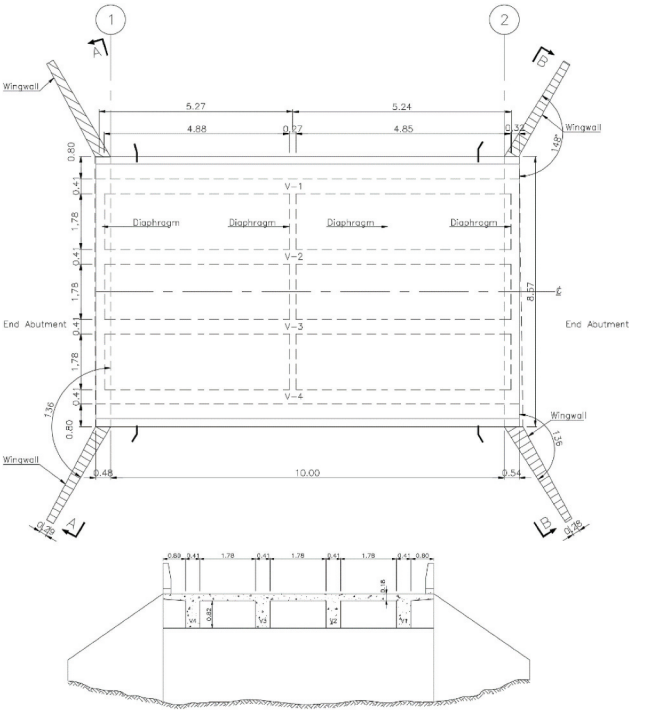

Figure 1. Reinforced concrete bridge geometry.

All field records were made with 3 accelerometers located at the extreme points of the external beams of the bridge in a straight parallel line to the longitudinal direction. Accelerometers #1 and #3 were installed in the end quarters of the total bridge length, and accelerometer #2 in the midspan as shown in Figure 2. Data was recorded at 2,000sps for a maximum period of 3 minutes. Data were collected with micro-vibration accelerometers with a scale range of ±0.50g, and an acquisition equip of 24bits. Measurements were collected at both sides of the

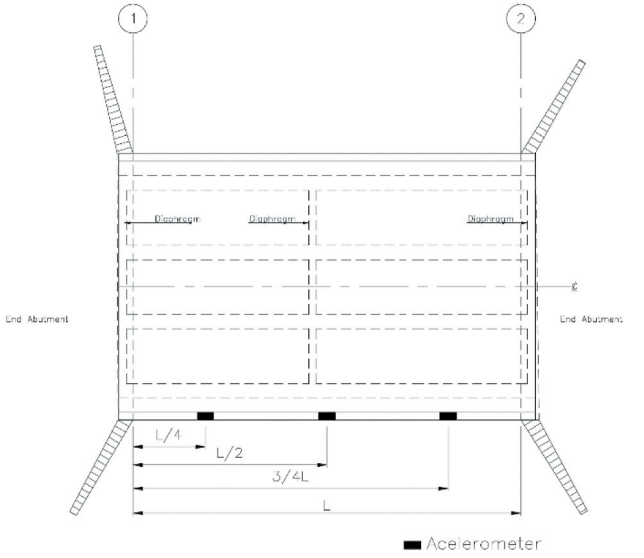

Figure 2. Accelerometer location for dynamic monitoring.

bridge independently. There are no records of the type and periodicity of the traffic, however, all tests were made during operation.

3 ANALYSIS OF FIELD RECORDS

Vibrations inherently are time-domain data, however, for engineering purposes, frequency-domain data are preferable. Hence, the fast Fourier transform (FFT), understood as a computational tool to transform time-domain data to frequency-domain outputs, is a feasible method to analyze acceleration field records. Complementary, flexural, and torsional frequencies were found using the "Peak-Pick" method, filtering the original signal as proposed by other authors (F. Consuegra & Irfanoglu, 2012; Bindi et al., 2015; Naderpour & Fakharian, 2016; Jin et al., 2021). For this study Chevychev type I filter was used due to the frequency attenuations of records higher than the filter frequency parameter established. To identify and compare the vibration modal shapes due to flexion and torsion, an acceleration normalization was used, taking as the norm the maximum value among the accelerations filtered.

Moreover, due to the nature of the acceleration records, the response shown in the acceleration spectrum is highly influenced by interpretation. The most common challenge faced in these analyses is the frequency picking among multiple peaks close together. Figure 4 (b) shows the frequency spectrum of an acceleration record test (a). As can be seen, there are multiple identifiable frequency peaks that could be interpreted as flexural or torsional frequencies. Therefore, filters for each peak were performed for all the accelerometers positioned (c, e and g) and the modal shapes identified from the filtered signals (d, f and h). Hence, the modal shape that best fits the flexural or torsional expected modal shape (verified with the numerical model) was selected as the frequency for each phenomenon. The definitive frequency used for the comparison with the numerical model is the mean of the frequency values obtained for all the acceleration tests available for each bridge.

4 NUMERICAL MODELATION

Based on the geometry, material properties and visual inspections made for all the bridge database, 3D models using only shell elements were constructed using SAP2000® software (see Figure 3). In addition, other models were considered, including 2D single-frame models, 3D

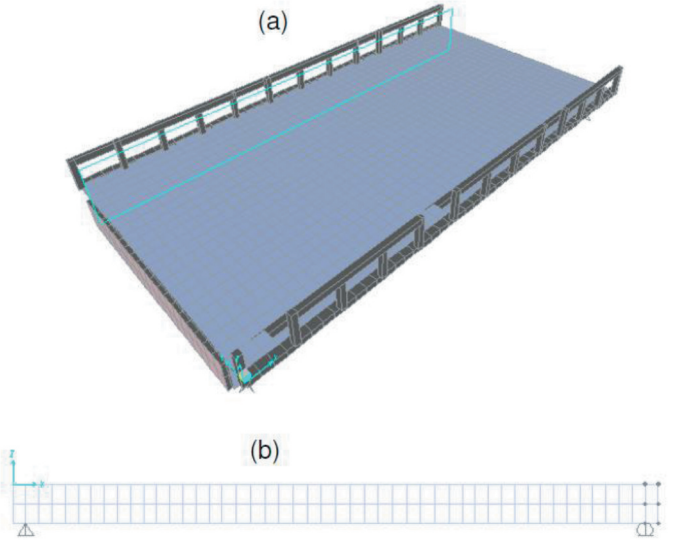

Figure 3. 3D shell only model. (a) Isometric general view. (b) General profile.

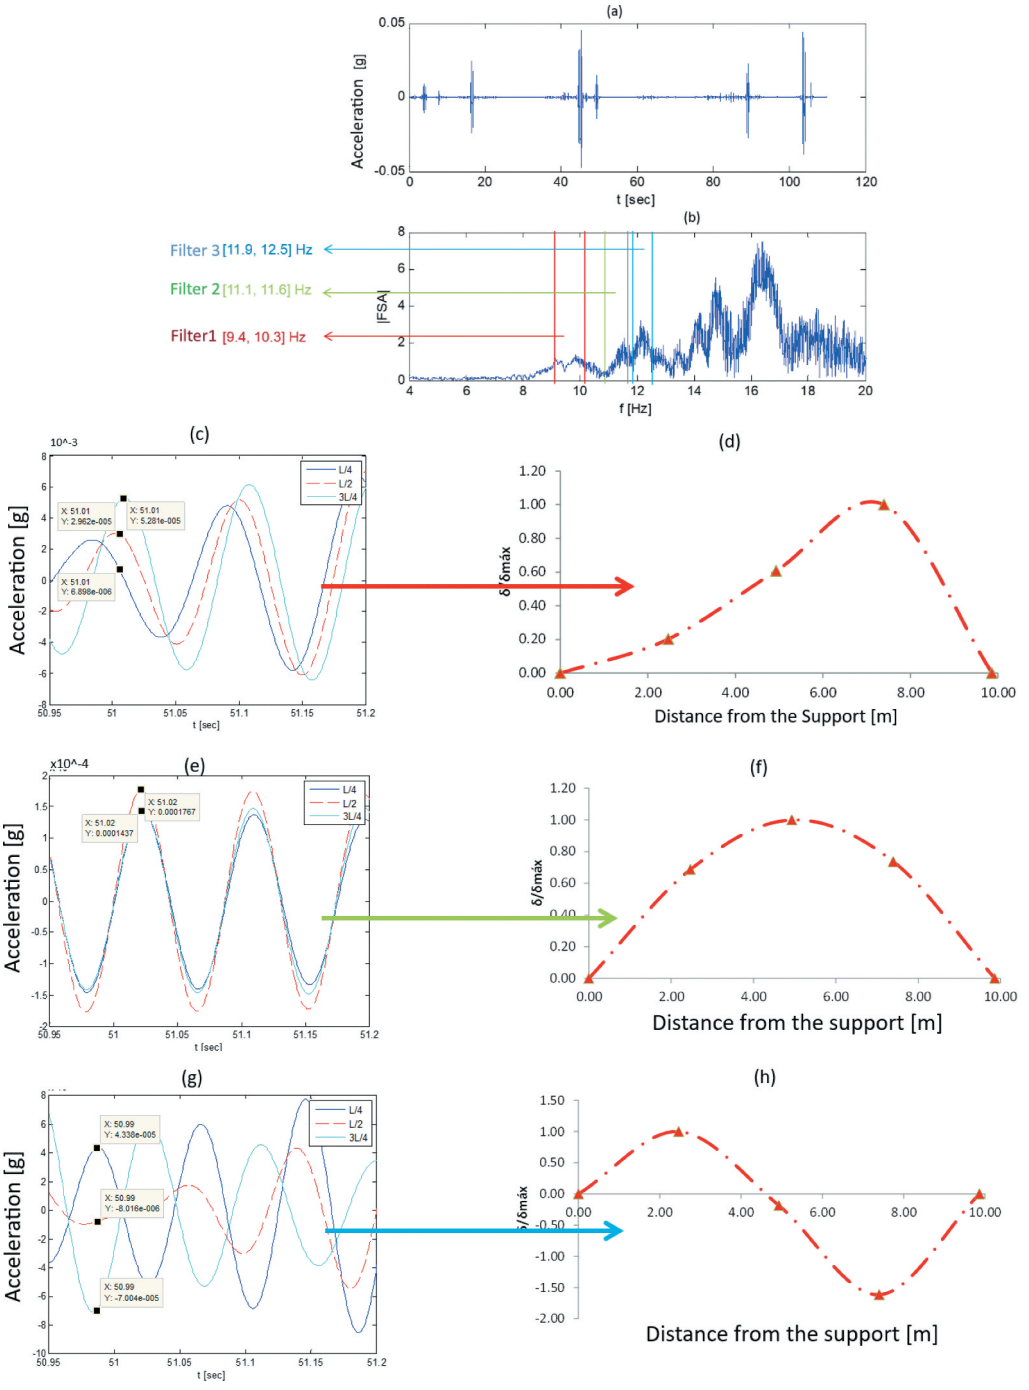

Figure 4. Signal processing. (a) Acceleration record. (b) Frequency spectrum. (c) Filtered signal (Filter 1). (d) Modal shape filtered signal (filter 1). (e) Filtered signal (Filter 2). (f) Modal shape filtered signal (filter 2). (g) Filtered signal (Filter 3). (h) Modal shape filtered signal (filter 3).

shell-frame models with wearing surfaces and barriers (as additional masses), and mathematical expressions for flexural and torsional frequencies based on Euler-Bernoulli beam vibrations theory. Nevertheless, contemplating the feasibility of the model development for rapid

assessment, 3D shell models are commonly used in the analysis of bridges, and therefore, chosen for this study. Non-linearity of materials cracked cross sections or additional support stiffness were not included in the numerical models, to simplify the application of this procedure.

Once the model is analyzed, modal shapes and frequencies for both flexural and torsional behavior can be obtained, as shown in Figure 5.

5 ANALYSIS OF RESULTS

As derived from the Euler-Bernoulli vibration theory, frequencies are dependent on variables such as modulus of inertia, element length, cross sectional area, density, and modulus of elasticity. Since all geometrical properties are constant, frequencies are directly correlated with the square root of the modulus of elasticity. Therefore, the relationship between experimental and numerical model frequencies can be expressed in terms of the modulus of elasticity ratio of the experimental and numerical models as described in Equation (3) for the flexural behavior.

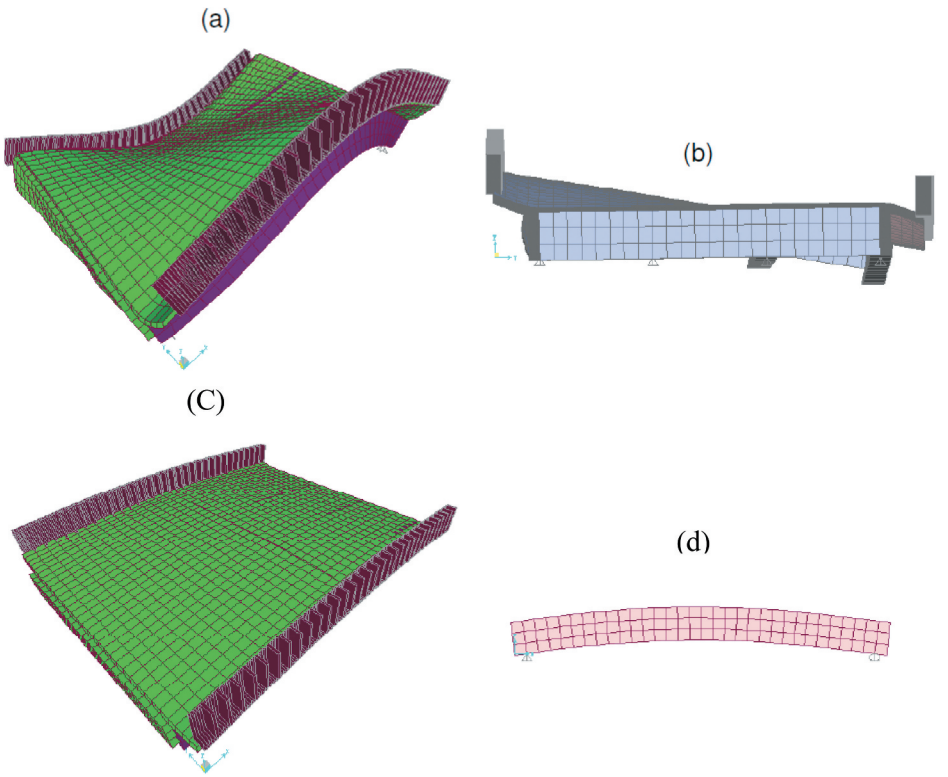

Figure 5. Modal Shapes. (a) and (b) Flexural modal shape. (c) and (d) Torsional modal shape.

$$f_F = \frac{\pi}{2L^2}\sqrt{\frac{EI}{\rho A}} : \{\pi\ L\ A\ I\ \rho\} = const. \therefore f_F \propto \sqrt{E}$$
$$\frac{f_F Exp}{f_F Mod} = \frac{\sqrt{E_{Exp}}}{\sqrt{E_{Mod}}} = \sqrt{\frac{E_{Exp}}{E_{Mod}}} \therefore \left(\frac{f_F Exp}{f_F Mod}\right)^2 = \frac{E_{Exp}}{E_{Mod}} \rightarrow E_{Exp} = E_{Mod}\left(\frac{f_F Exp}{f_F Mod}\right)^2 \quad (3)$$

Thus, the frequency ratio squared could be related to the ratio between the elastic and the dynamic modulus of elasticity presented in Equation (2). As described before, that relationship depending on the compressive strength of the concrete could vary from 1.20 to 1.40 for high and low strength concretes respectively. Figure 6 Shows the frequency ratios results for all the bridge database, specifying the average ratio and the maximum and minimum extreme values. Taking the average value as the contrast value (ratio=1.10), the final relationship understood as the ratio squared is 1.21, which is consistent with the ratio between modulus of elasticity for structural concrete. Therefore, the inclusion of the dynamic modulus of elasticity in the numerical model for the dynamic analysis of vibrations results in the accurate structural response of the structure analyzed.

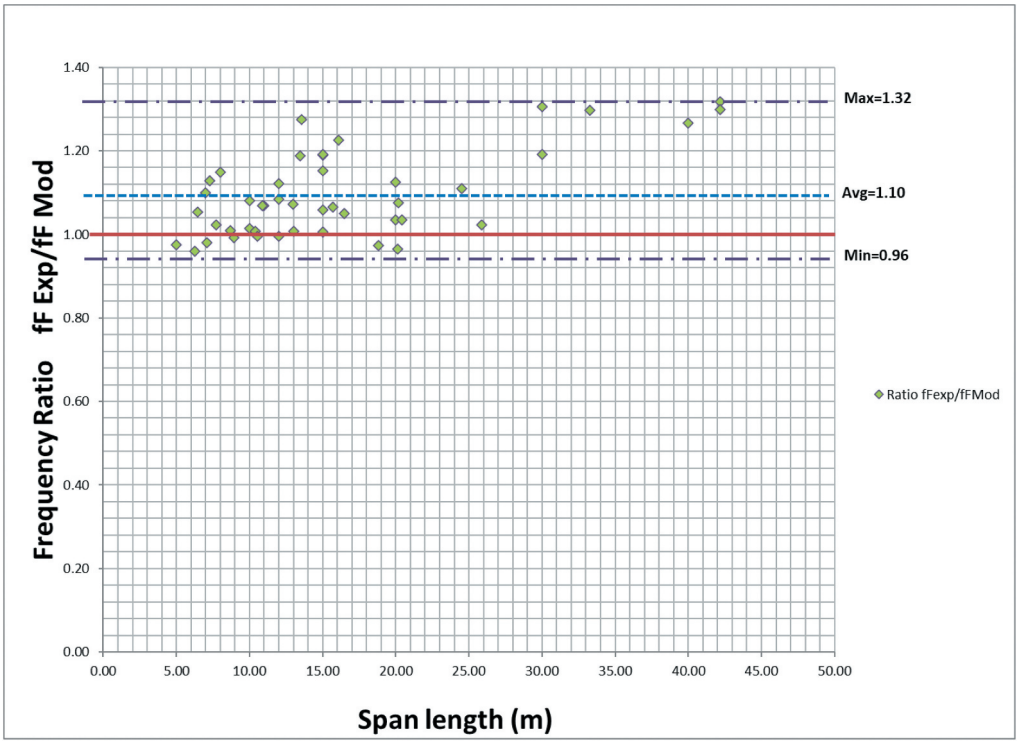

Figure 6. Frequency flexural ratios for different span lengths.

6 CONCLUSIONS

A rapid approach for dynamic analysis and characterization was proposed comparing numerical 3D models and acceleration records from a Colombian bridge database part of the main road system, provided by INGETEC S.A. The analysis suggests that for rapid assessment using acceleration records due to vibrations, a 3D shell-only model can be used, considering the dynamic modulus of elasticity instead of the regular approach which contemplates the elastic modulus. The modulus ratio (1.20) can be compared to the frequency ratio between the experimental and the numerical model squared (1.21). Consequently, findings suggest that the usage of the dynamic modulus of elasticity replicates more accurately the real behavior of the structure and could be used for practitioners and field engineers for rapid assessment. Further analyses and testing could be useful to determine an accurate relationship.

Retroreflective sheeting materials as SHM passive strain sensors

Hannah M. Power & Harry W. Shenton III
Department of Civil and Environmental Engineering, University of Delaware, Newark, Delaware, USA

ABSTRACT: Highly reflective Retroreflective sheeting materials (RRSM) are widely used today for roadway signs and markings. Retroreflectivity (RR), defined as the portion of light re-turned to the light source as measured in candelas per lux per square meter, can be measured quite easily in the field using a handheld retroreflectometer. Tests show that as load is applied to RRSM, the retroreflection changes, and for many types of RRSM, RR decreases with increasing tension and has a mostly linear relationship to the material strain. This opens the possibility for using RRSM as a passive strain sensor for structural health monitoring, whereby measured changes in RR of RRSM mounted to a structure can be correlated to changes in strain. The sensor would be low cost, practical, and innovative. Tension test results show that a yellow-green type XI material produced by one manufacturer has one of the highest material sensitivities (ratio of retroreflectivity to strain) of the many the authors have tested. The sensitivity of the material, denoted here as A-TXIFYG, decreases linearly after it is strained past approximately 1000 microstrain (με). This led to testing of the material after initial straining (pre-straining). Results show that for the material to have a similar sensitivity while mounted to that of the bare material tests, it must be externally clamped to the substrate.

1 INTRODUCTION

In the United States, bridges are only required to be visually inspected every 2 years [FHWA (2017)]. These inspections cannot identify internal damage and rely on qualitative evaluations which are susceptible to error. This has led to a desire to monitor bridges using sensing networks, which allows bridge owners to gain a more accurate and complete evaluation of a bridge. However, conventional structural health monitoring (SHM) systems can be expensive, require power and involve dedicated data acquisition [Chang, Flatau, Liu (2003)] all of which lead bridge owners to often choose to not implement them, therefore there is a need to develop passive, inexpensive sensing systems to monitor bridges that could be more easily and readily adopted by the bridge industry. This paper describes a passive strain sensor developed from retroreflective sheeting material that is inexpensive and should be easily adopted by transportation infrastructure owners.

1.1 *Retroreflective sheeting materials*

Retroreflective Sheeting Materials (RRSM) are thin flexible reflective laminate like materials that are made for various applications but are primarily used to make traffic signs and roadway markings. ASTM D4956, "Standard Specification for Retroreflective Sheeting for Traffic Control" [ASTM International (2019)] defines standards for 11 types of sheeting material. RRSMs are produced by various manufacturers [FHWA (2005)] and are comprised of several layers, including an adhesive backing so that with proper surface preparation it can be adhered to steel, aluminum, or concrete (Figure 1).

The reflecting layer of RRSMs affects the material's ability to return emitted light to the source, a measurement known as retroreflectivity (RR). Higher grade materials, with higher baseline values of retroreflectivity (RR) have a prismatic reflecting layer (Figure 1).

DOI: 10.1201/9781003483755-444

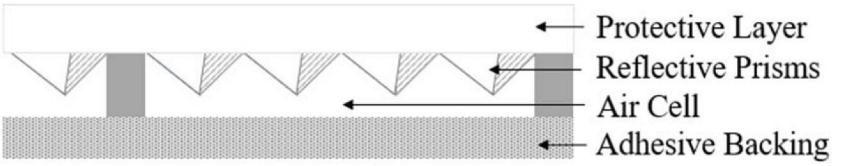

Figure 1. Prismatic retroreflective sheeting material cross-section.

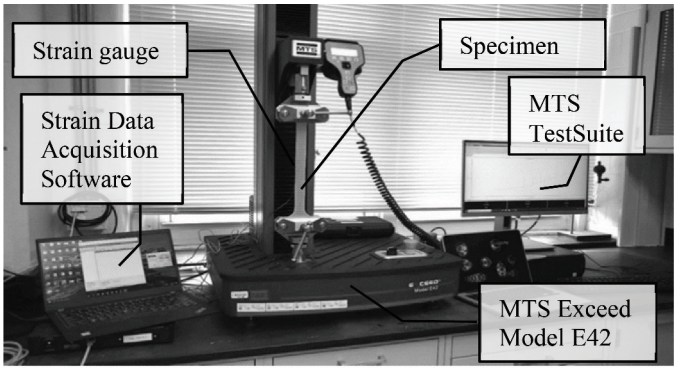
The Federal Highway Administration (FHWA) Manual on Uniform Traffic Control Devices (MUTCD) [FHWA (2012)] requires all public agencies in the United States to maintain minimum levels of sign retroreflectivity. To establish compliance, agencies can measure retroreflectivity of a sign using a handheld retroreflectometer, which when held against the material, measures the RR in candelas-per-lux-per-square meter. Many State Departments of Transportation (DOTs) make and maintain their own traffic signs and are required to periodically measure the retroreflectivity of their signs; therefore, most DOTs have access to retroreflective sheeting materials and a familiarity with retroreflectometers, i.e., the materials to fabricate a passive strain sensor and the instrument to take strain readings.

1.2 *Passive strain sensor application of RRSM*

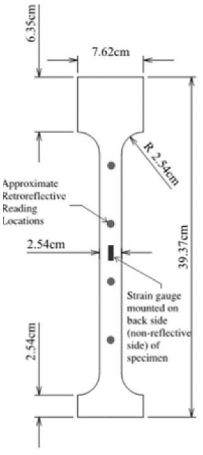
Tests conducted by the authors have demonstrated that as load is applied to RRSM the retroreflectivity changes in intensity. Consequently, there is the potential to use retroreflective sheeting material as a passive strain sensor for structural health monitoring (SHM) [Power, Shenton (2023)]. The potential applications for these sensors include monitoring dead load induced in bridge super and substructures, observing crack growth in reinforced and prestressed concrete members, residual stress measurements and other circumstances that would benefit from static strain measurements. RRSM sensors are passive, meaning they do not require power or wiring and their data acquisition is simple.

An RRSM sensor can be affixed to the tension face of any structural element, and using a handheld retroreflectometer, RR can be measured during routine inspections or after significant events. That RR value can then be compared to the material's baseline, i.e., unstrained retroreflectivity, and related to the strain in the structure based on previously determined calibration factors [Power, Shenton (2023)]. Application of RRSMs as SHM systems on bridges will allow for simple and effective monitoring.



2 RRSM BARE MATERIAL RESPONSE TO INDUCED STRAIN

Various types of RRSM made by two manufacturers have been tested in tension, measuring their RR and microstrain (με) in order to develop the RR versus strain relationship [Power, Shenton (2023)]. Many materials display a linear relationship between retroreflectivity and strain. The materials retroreflective sensitivity to induced strain (RR/με) is the most important factor when assessing RRSM's viability for use as a strain sensor. The following discusses a RRSM produced by manufacturer "A" that is standard type XI and is fluorescent yellow-green in color, denoted as A-TXIFYG. This material has high sensitivity and correlation, making it a suitable material for passive strain sensing for SHM of bridges.



2.1 *Test procedure*

Three specimens of A-TXIFYG were loaded in tension while measuring the material RR and microstrain to determine the RR-με relationship. Specimens were cut using scissors and a uniaxial strain gauge was adhered to the non-reflective side of each specimen (Figure 2b).

Tension tests were run in an MTS Exceed E42 Electromechanical Test System and strain was recorded using a Micro Measurement System 8000 data acquisition system and StrainSmart software (Figure 2a). Each specimen was loaded to approximately 4000 με and unloaded three times. The first loading and unloading cycles were paused every 4.45 N (1 lb) to record

a. Test set-up

b. Specimen dimensions

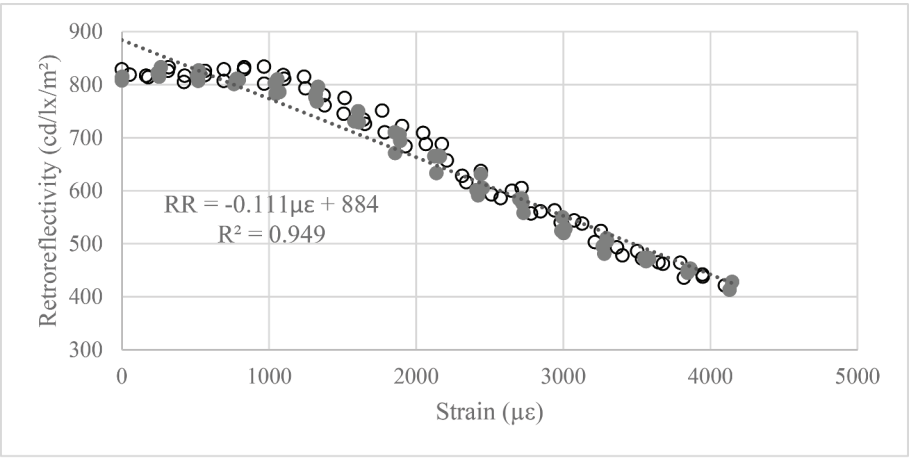


Figure 2. Bare material tension test.

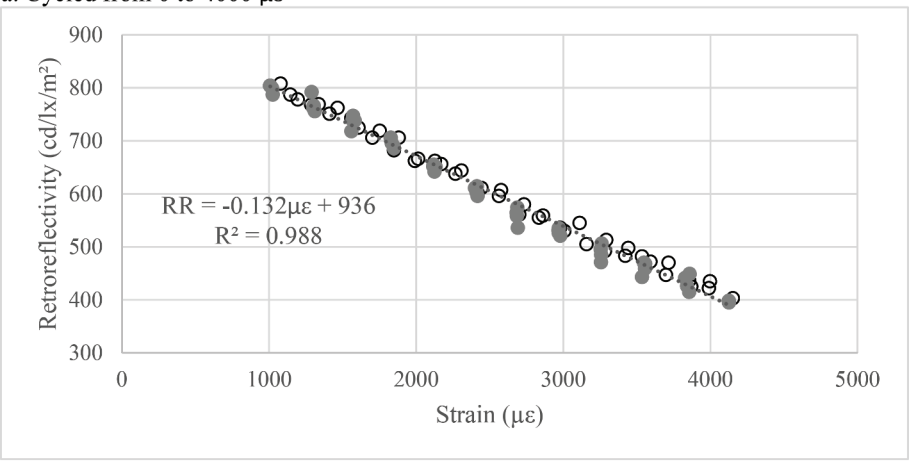
microstrain and RR. The second and third loading and unloading cycles were paused every 8.90 N (2 lb) to record strain and RR. RR has innate variability, so four readings were taken at each load step and averaged.



2.2 *Results*

The RR vs. strain response of the A-TXIFYG is shown in Figure 3a. In this figure, and all other similar plots, the first loading and unloading cycle data points are highlighted by a dark outline. A linear regression line for all cycles of the specimen is plotted along with the associated equation and R^2 value. Figure 3a clearly shows the RR dependence on the induced strain. The RR remains nearly constant for the first ~1000 με and then decreases linearly with increasing strain. From approximately 1000 to 4000 με, A-TXIFYG has a highly correlated linear retroreflective-microstrain relationship. The same specimen was tested again but first pre-strained to approximately 1000 με (i.e., pre-strained) and then cycled between 1000 and 4000 με to determine the correlation and sensitivity of the material after initial straining (Figure 3b).

The material sensitivity between 0 and 4000 με is -0.111 RR/με for this specimen with an R^2 value of 0.949. When the same specimen was pre-strained and cycled between 1000 and 4000 με, the sensitivity increased to -0.132 RR/με and the R^2 increased to 0.988. These results show that a SHM sensor made of A-TXIFYG may function best if the material is first pre-strained, and then adhered to the substrate.

3 A-TXIFYG STEEL MOUNTED TESTS

3.1 *Test procedure*

To determine material response when adhered to steel, strips of RRSM were cut and mounted to ¼" thick A36 steel "dog-bone" specimens. To prepare the surface prior to mounting the RRSM, the steel was sanded using 220 grit sandpaper and cleaned with acetone. The RRSM was cut to fit the gage width and length of the steel specimen, the backing was removed to expose the adhesive layer and the RRSM was rolled onto the steel using a rubber roller. A uniaxial strain gauge was mounted to the back of the steel dogbone specimen to measure the strain in the steel. Specimens were loaded in tension in an Instron 1331 Testing Frame to approximately 44,482 N (10,000 lb), below the yield stress of the steel, pausing every 2224 N (500 lb) to take retroreflective readings and strain in the steel. Specimens were then unloaded to 0 kg, also pausing every 2224 N (500 lb) to take RR and strain readings. This was repeated for three loading and unloading cycles, similar to the bare material test described in section 2. RR readings were recorded along the length of the specimen and those within the center region of the specimen were used to evaluate the RR-με relationship of the steel mounted material. Test set up and steel specimen dimensions are shown in Figure 4.

a. Test set-up

b. Specimen dimensions

Figure 4. Steel mounted A-TXIFYG tension test.

3.2 *Results*

Initial tests of the RRSM mounted to the steel dogbone yielded results quite different from those of the bare material. Three different specimen configurations were initially tested to determine the best methods for creating the steel mounted specimens. This included configuration (1), pre-straining the RRSM and adhering it to only the gauge length of the steel specimen. Configuration (2), pre-straining the RRSM and adhering it to the full length of the steel specimen so that the RRSM was placed in the Instron grips with the steel. And configuration (3) where the material was pre-strained, adhered to only the steel gauge length and then externally clamped before the pre-straining weights were removed. To pre-strain the A-TXIFYG prior to mounting it to the steel, weights were hung from the material so that the induced strain was approximately 4000 με. The backing film was then removed to expose the adhesive and then the RRSM was rolled onto the steel while the weight remained on the RRSM. This pre-straining procedure was used for all pre-strained steel mounted specimens.

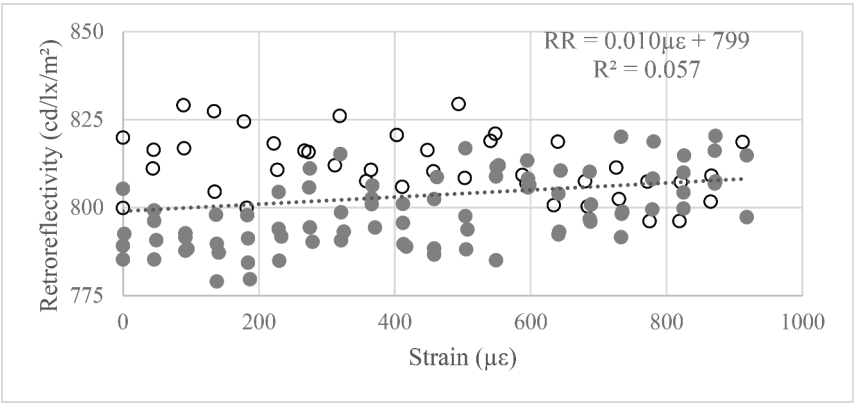

Figure 5. Pre-strained, steel mounted A-TXIFYG on gauge length test results (Configuration 1).

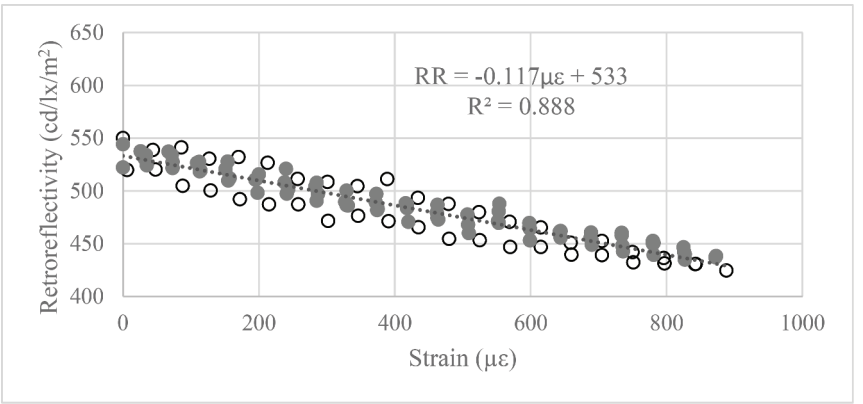

Figure 6. Pre-strained, steel mounted A-TXIFYG in instron grips test results (Configuration 2).

3.2.1 *Unclamped specimen (Configuration 1)*
Initially, specimens were pre-strained and free to relax on the surface of the steel, i.e., the RRSM material was not restrained by the Instron grips or external clamps and therefore was free to relax under load. The RR-με relationships of these specimens differed from the bare material response to induced strain. Figure 5 shows the RR-με relationship of an initial specimen of A-TXIFYG that was pre-strained and fabricated using configuration (1). These results led the authors to design specimens with configuration (2).

3.2.2 *Instron gripped specimen (Configuration 2)*
Due to the low sensitivity, poor correlation and difference compared to the bare material results, the authors decided to adhere the RRSM to the full length of the steel specimen so that the pre-strained material was restrained by the test machine grips, configuration (2). This specimen configuration led to a much higher sensitivity (-0.117 RR/με) and better linear correlation with $R^2 = 0.888$ (Figure 6).

3.2.3 *Externally clamped specimen (Configuration 3)*
The results presented in Figures 5 and 6 demonstrate that for RRSM to be used as a passive sensor for SHM, it must first be strained and then clamped. To achieve this, an external clamping mechanism is necessary so that the sensor, consisting of pre-strained RRSM adhered and clamped to steel, can be affixed to a structure. The clamps used are front and back steel plates that are through bolted. Clamps were secured before pre-straining weights were

removed (Figure 7). Configuration (3) specimen's RR-με relationship is comparable to that of the bare material (Figure 3) and that of the specimen results prepared using configuration (2) (Figure 6). The material sensitivity is -0.104 RR/με with an R^2 of 0.925 (Figure 8).

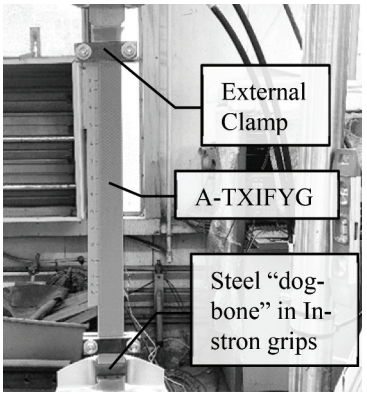

Figure 7. Pre-strained, clamped, steel mounted A-TXIFYG specimen.

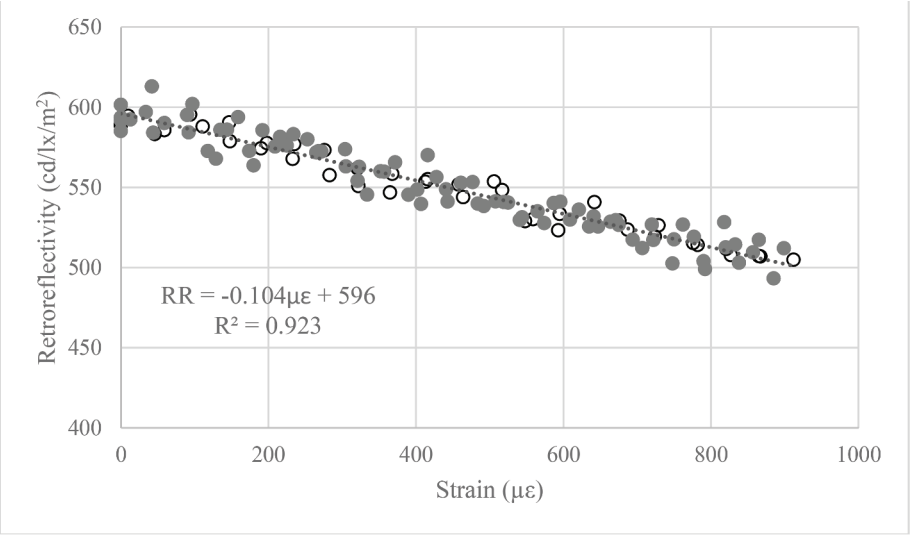

Figure 8. Pre-strained, clamped, steel mounted A-TXIFYG test results (Configuration 3).

3.3 *Discussion*

Comparing the results of the unclamped to the clamped pre-strained specimens, it is clear that for A-TXIFYG to function as a passive strain sensor, it must first be strained and clamped to a substrate. The unclamped, ungripped (configuration 1) specimen from Figure 5 has little correlation, with an R^2 value of 0.057. The material's retroreflective sensitivity to induced microstrain is +0.010 RR/με. This sensitivity is low compared to the bare material sensitivity discussed in section 2.2, and it also has the opposite sign convention, indicating that RR was not decreasing with increasing induced strain. Shear lag is suspected to be the main factor contributing to the poor behavior of the RRSM when it is not clamped/gripped to the steel substrate. That, in addition to the tremendous difference in axial stiffness between the steel and RRSM, and the fact that the reflective prisms are near the surface of the material.

When the material was pre-strained and placed in the Instron grips (configuration 2), mimicking clamping, the material sensitivity increased. The externally clamped (configuration 3)

specimen's sensitivity and R^2 values are close to that of the bare material, having percent differences of 6.3% and 2.5% respectively. These results indicate that to use A-TXIFYG as a sensor, it must first be strained and then mounted with a clamping mechanism to a steel substrate. The entire steel mounted RRSM will function as the passive strain sensor for SHM.

To use RRSM as a passive strain sensor for monitoring bridges, the material first needs to be strained, then mounted to steel and clamped to the steel. The sensor needs to be long enough so that multiple RR readings can be taken and averaged, as RRSM has innate variability. The retroreflectometer takes readings from the center of the device, therefore there needs to be enough clearance around the clamps to take the readings. To create this sensor, similar steps to those discussed in section 3.2 can be followed. First, the A-TXIFYG material is cut to shape and pre-strained. It can then be rolled onto the steel sensor. This sensor will be fabricated with backing plates for the clamping mechanism. After the RRSM is strained, the adhesive backing is used to adhere the material to the steel by using a roller. While the pre-straining weight is still on the RRSM, top clamp plates are bolted to the steel sensor using threaded bolts. After the clamps are in place, the pre-straining weights can be removed, and the sensor is ready to be adhered to the tension face of any structural element for monitoring.

4 CONCLUSIONS

In the United States, bridges are not required to be monitored with an SHM system but are only required to undergo a visual inspection every two years. These visual inspections are qualitative and can lack key information about a structure. There is a need for inexpensive and accessible SHM systems for bridge monitoring to encourage their widespread use. Bridge owners are familiar with RRSM and their measurements as they also make and maintain their traffics signs, which are also made of RRSM. This would make the technology transfer of using RRSM as a passive strain sensor on bridges simple.

RRSM has the potential to be used as a passive strain sensor for structural health monitoring of bridges as its retroreflectivity decreases with induced strain. Type XI material that is fluorescent yellow-green produced by manufacturer "A" (A-TXIFYG) has high RR sensitivity to strain and is therefore a candidate for use as a sensor. A-TXIFYG materials have little RR change for approximately the first 1000 induced microstrain as seen in tension testing of the bare material. This led to authors to strain the material before it is mounted to steel substrate. This pre-straining process only works when the material is clamped to the steel while it is being strained. When that procedure is followed, there is little difference in the bare material and mounted material sensitivity to strain. This sensor will be low cost and practical, opening the possibility for widespread monitoring of bridges.

M. Gilbert
University of Sheffield, Sheffield, UK

ABSTRACT: The development of high-speed railways brings numerous opportunities for economic growth and improved transportation networks. In the United Kingdom, the construction of the High Speed 2 (HS2) railway is a flagship project aimed at enhancing connectivity, increasing capacity and reducing travel times. However, the construction will impact existing infrastructure along the route. This paper presents an overview of the ground movement assessment conducted on eight existing masonry arch bridges in West London affected by settlement due to construction of HS2 twin bore tunnels. This work has provided valuable insights into the potential challenges and risks associated with tunnelling under a major city. The findings underscore the importance of thorough structural assessments and implementing appropriate interventions to ensure the safety and resilience of existing bridge infrastructure above new tunnel construction.

1 INTRODUCTION

High Speed 2 (HS2) is a new rail line in the United Kingdom, planned to run between London and the West Midlands. It is a government funded programme that aims to increase rail capacity, boost regional growth through better connections, and reduce carbon emissions. HS2 Phase One Lots S1 and S2 make up approximately 26km of the route, running from Euston to West Ruislip as shown in Figure 1. Within this section, the tracks will primarily run through twin-bored tunnels constructed by an Earth Pressure Balance (EPB) Tunnel Boring Machine (TBM).

Figure 1. Proposed HS2 route largely in tunnel below London (SCSJV, 2023).

While TBM construction has proved to be safe and controlled, inherent volume loss at the face can cause vertical and horizontal ground displacements along the tunnel paths. Prior to

DOI: 10.1201/9781003483755-445

the Lots S1/S2 tunnelling works, Ground Movement Assessments (GMAs) were required to assess the likely impact of the tunnelling works on existing infrastructure. These assessments are essential in preventing any unexpected adverse structural effects on existing infrastructure by identifying the need for any preventative mitigation so that it can be implemented in advance of the tunnelling. This is described in a separate paper 'Overview of assessment for bridges affected by HS2 tunnelling, London, UK' (Tsekhanskiy et al. 2024).

There are a number of bridges within the tunnelling influence zone along the HS2 tunnelling route. These structures were modelled using the Oasys XDisp software (Oasys XDisp Pro Version 20.2) to estimate the ground movement likely to be experienced by these structures under a theoretical 1% volume loss. An initial sift of the structures found that there were eight masonry arch structures likely to experience differential settlement between supports. Note that the anticipated movements were all relatively small, much smaller than those required to endanger the stability of the arch barrel. These limits were identified for bare arch ribs in previous papers (Ochsendorf 2006, Ferrero et al. 2021).

Research was undertaken to evaluate the most effective assessment method for these type of structures under the influence of tunnelling settlements. For example, a study of the effect of ground settlement on Lindsey Street Bridge, a multi-span masonry arch, concluded that the amount of pier settlement that the structure could accommodate before entering the 'Slight' damage category was proportional to the span of the arches on either side of the pier (McCarthy 2016, Burland & Wroth 1975). Although Burland and Wroth provided a method of determining the predicted level of damage to the masonry arch and crack widths that could be expected, no clear guidance could be found on the most appropriate methodology to assess the impact of the ground displacement on the arch barrel capacity. Therefore, Arup worked with Professor Matthew Gilbert, a masonry arch bridge specialist from the University of Sheffield, to develop a bespoke methodology incorporating guidance described in CIRIA C800 (Gilbert et al. 2022). This paper presents details of the assessment methodology developed, together with sample results obtained when assessing a population of masonry arch bridge structures.

The objective of the work was to assess the effects of differential settlement between supports on the load carrying capacity of the arch barrel. Anticipating such effects is an essential part of ensuring the safe construction of the tunnels, as it allows any need for mitigation measures to be identified and, if necessary, implemented prior to the tunnelling works. Another key aspect of this assessment was to determine the likely long-term impact of the tunnelling works on each arch bridge structure, seeking to ensure that there is no reduction in the lifespan of the structure through the implementation of suitable remedial works.

2 ASSESSMENT METHODOLOGY

The first step was to determine the predicted ground movements due to all excavations, tunnels, shafts and temporary dewatering works at the structure location using the software Oasys XDisp. The XDisp model included multiple interim construction stages representing the predicted ground movement as the TBMs progress underneath a given structure and the cross passages are constructed.

For the purposes of assessment, it was assumed that bridge abutments would behave rigidly and ground displacement at foundation level would be transferred directly to the springing points of the arch barrel. Differential settlement between springing points is likely to lead to deformation of the arch barrel, leading to the development of new cracks, and/or widening of existing cracks. Cracks, if left without any intervention, can result in serviceability issues and potentially reduce the lifespan of the structure. To identify the most severe impact to the arch barrel, differential settlement between supports was calculated across all construction stages to find the worst-case. Generally, the maximum differential vertical and horizontal displacement was found to occur in a transient construction stage due to the tunnelling impacting one side of the structure on approach more than the other, as can be seen in Figure 2.

To analyse the impact of the differential settlement, the analysis software LimitState:RING (LimitState Ltd 2020) was selected to undertake the assessment of the arch barrel. LimitState: RING is an interactive software tool for the analysis of masonry arch bridges. It utilises plastic

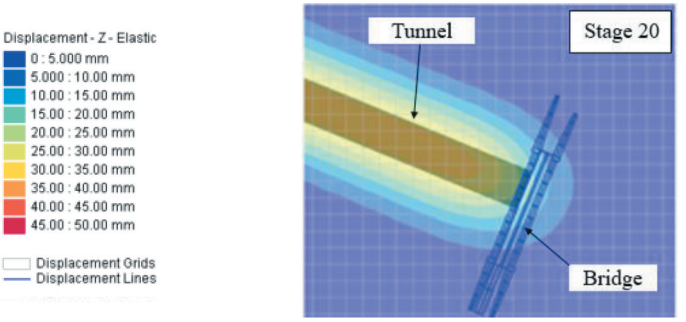

Figure 2. Vertical settlement contour taken at a transient tunnelling construction stage.

limit analysis methods using rigid block analysis, taking into account the beneficial effects of backfill, building on the mechanism method popularised by Jacques Heyman (Heyman 1982).

LimitState:RING computes the multiplier at collapse on the applied live load, termed the 'adequacy factor'. For example, if a 100kN single axle load is specified and LimitState:RING indicates a computed adequacy factor of 1.54, then the load that would cause collapse is 154kN. This software was chosen to assess the structure due to its support movement analysis functionality, whereby support movements can be applied to obtain the resulting deformed arch geometry and associated hinge points where cracks are likely to form.

The methodology that was developed for this work considers the impact of these potential new cracks induced by the HS2 tunnel construction to provide a more detailed understanding of the impact on arch bridge capacity. Following the CIRIA C800 guidance, the software was used to obtain an adequacy factor at two different limit states:

1. Ultimate Limit State (ULS):
   - The ULS represents the condition beyond which the structure no longer performs its function. The computed adequacy factor must be greater than 1.0 to satisfy ULS criteria. The ULS analysis undertaken was consistent with current asset owner standards.
2. Permissible Limit State (PLS):
   - The PLS is the point beyond which progressive load-induced degradation occurs under service loads during the intended life of the bridge (definition from CIRIA C800).
   - Degradation of the arch barrel may arise due to repeated opening and closing of cracks in the arch barrel due to cyclic live loading. This can lead to cumulative damage, resulting in loosening of or fracture/fatigue within the masonry elements.
   - PLS scenarios can be modelled by modifying the masonry and soil strength that are assumed to be mobilised at the ULS, replacing them with reduced values.
   - The adequacy factor must be greater than 1.0 to avoid the potential for cumulative damage under cyclic loading when considering PLS. If LimitState:RING indicates a computed PLS adequacy factor lower than 1.0, this means that the associated loading may lead to repeated opening and closing of joints under cyclic loading.
   - If an asset is disused or is only used for maintenance access, then PLS checks are not necessary, since the asset will not be subject to cyclic loading.

LimitState:RING models were created to quantify the effects of the deformed arch barrel geometries and cracking due to worst-case differential displacements between abutments. Six analysis cases were considered, to model each bridge in its current condition and with a combination of cracks at the intrados and extrados formed as a result of tunnelling induced settlement. This approach was chosen because it allowed informed decision making on the remedial works required to repair cracks. An overview of the analysis cases considered can be found in Table 1.

For analysis cases 4-6, where either the intrados, extrados or all cracks obtained from case 2 were not modelled, the latter cracks were assumed to be 'closed'. This could be for several reasons such as intentional repairs, or filling by loose soil/debris or closed under loading.

In reality, any cracks formed within the extrados of the arch barrel may be difficult to observe as this part of the structure is unlikely to be accessible. Under cyclic loading, extrados cracks could be filled over time if there is loose fill or debris over the arch barrel, leading to unrecoverable deformations.

Table 1. Analysis cases.

Description	Scenario	Case	Cracks modelled*	Output
Undeformed arch	Bridge in its current condition, taking into consideration any known existing cracks.	1	ULS – cracks not modelled. PLS - known existing historical cracks.	ULS & PLS adequacy factor.
Support movement analysis	Differential settlement between abutments is applied to the springing points of the undeformed arch.	2	Any known existing historical cracks.	Deformed arch geometry and associated crack locations.
Deformed arch	Bridge modelled using the deformed arch shape and a range of combinations where the cracking formed in the deflected arch is either left open or closed.	3	All cracks open.	PLS adequacy factor.
		4	Only extrados cracks repaired.	PLS adequacy factor.
		5	Only intrados cracks repaired.	PLS adequacy factor.
		6	None.	ULS & PLS adequacy factor.

* 'Intrados' and 'extrados' refer to the inner and outer surfaces of the arch barrel respectively.

Asset owner standards were used to determine input parameters such as live load, material strength and load distribution through fill (known as effective width). Across the studied masonry arch structures there were multiple asset owners with their own standards, which often had different input parameters. An example of this can be seen in Figure 3, which illustrates the differences in transverse load distribution between two standards used in the project.

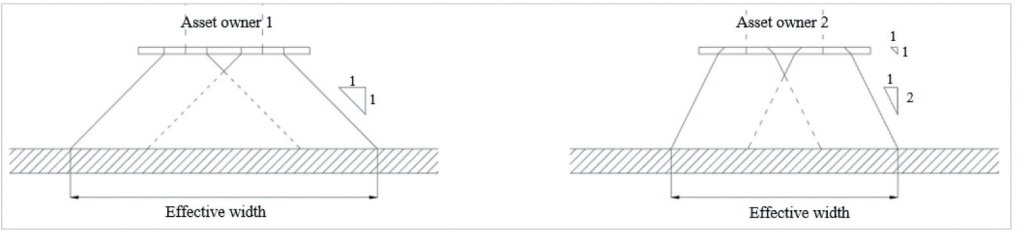

Figure 3. Transverse load distribution differences between asset owner standards.

Figure 4 provides an overview of the geometrical input parameters that are required to build the LimitState:RING models. Where possible, the geometric input parameters such as rise (f), span (l), and arch barrel thickness (s) were determined using information from topographic survey and Inspection for Assessment (IfA) reports. These parameters were verified against available historical drawings, which were also used to provide information that could not be readily obtained from inspections and surveys, such as backing height.

As with any other structural assessment, the existing condition of the structure needs to be taken into consideration when undertaking the assessment. The existing condition of a structure was determined using historical examination reports, IfA reports and topographic surveys, with photogrammetry carried out for the purpose of the assessment. Any existing cracks that were greater than 1mm were taken into consideration during the assessment. Transverse cracks were modelled by introducing mortar loss at that location, assumed to

extend to 50% of the arch barrel thickness. Longitudinal cracks were accounted for by limiting the load distribution across the arch and reducing the effective width, based on the assumption that loading could not distribute across such cracks.

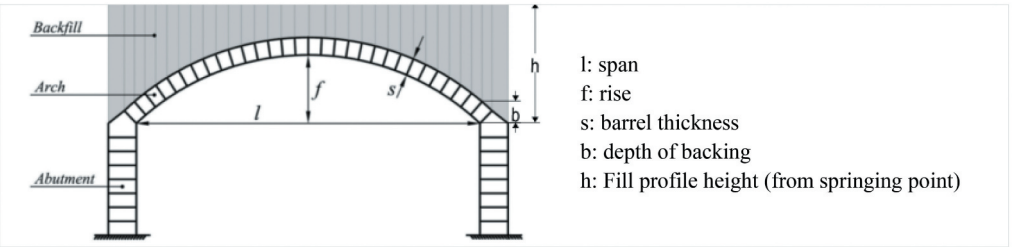

Figure 4. Geometrical input for arch analysis.

3 CHALLENGES AND LIMITATIONS

There were a number of challenges faced relating to the limited availability of historical information and the quality of available drawings. Where information was limited, the parameters were determined based on engineering judgement and upon consultation with technical experts drawn from across the project. Input parameters such as brick strength or backing height could not be verified as intrusive sampling/laboratory material tests were not included within the project scope. In the absence of this information, conservative assumptions were made for such parameters and a risk rating was given to each assumption.

Based on the modelling results obtained for the different analysis cases, it was clear that the PLS adequacy factors were significantly impacted by the presence of transverse cracks present in both the intrados and extrados of the arch. Cracking in the extrados of the arch barrel may be difficult to observe as this part of the structure is generally hard to access. These cracks can in time become evident in the intrados, through signs of visual distress such as spalling mortar and/or brickwork. However, there is risk that IfA surveys may not pick up these kinds of defects, and thus the cracks are not considered in the assessment.

The maximum vertical and horizontal displacements between springing points were often found to occur during different transient construction stages. For this project, the maximum vertical and horizontal displacements were enveloped in one analysis case. There is a possibility that there could be a more onerous arch geometry at a stage where movements are less than the maximum, but combined vertical and horizontal displacements give a worse effect. However, this was done as a pragmatic approach due to the time limitations within the project.

Although there is a level of uncertainty with the aforementioned parameters, the partial factors taken from the asset owner standards allow for uncertainty. The key objective of the analyses performed was to understand whether the ULS and PLS capacities change as a result of the tunnelling and, although there are a number of limitations in the proposed methodology, the results obtained have allowed the project to make informed decisions about how to manage these structures in a way that does not impact their capacity or longevity.

The results presented within this study are based on a live project and provide data for existing bridges being assessed for the specific loading each is likely to experience. It is a small data set with many variables changing between each example structure. Whilst some initial conclusions and trends can be drawn, more data and a further study of the impact of individual variables would allow the identification of more clear patterns and trends. A future academic study in which all variables are changed in a systematic manner might provide further useful insights.

4 OUTCOMES

The results obtained clearly demonstrated that the tunnelling settlement is likely to alter the shape of the arch profile, leading to potential changes in capacity and service life. For the

purposes of this paper, the eight arch structures considered are labelled Structure 1 to 8. Figure 5 shows an example of the support movement analysis results obtained for Structure 6 (Case 2 results). The red circles near the edges of the arch barrel indicate the locations where hinges form, which in turn will result in transverse cracks forming in the arch barrel. Figure 6 and Table 2 show PLS and ULS analysis results for all eight structures.

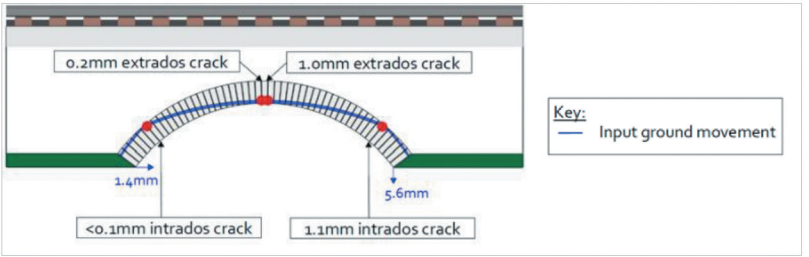

Figure 5. Example deformed arch geometry and associated cracking (Structure 6).

The results obtained suggest that the presence of cracks can significantly impact the computed PLS adequacy factor for a given structure, with these in some cases falling below 1.0. However, the analysis results also demonstrate that, in most cases, if the HS2-induced cracks are repaired, the structure in the deformed state will revert to having a computed PLS value that is close to that achieved prior to the tunnelling works. This relationship can be seen in Figure 6, which indicates how the PLS changes as a result of the tunnelling works, showing the ratio between the undeformed PLS adequacy factor and the PLS adequacy factor in the deformed analysis cases. A ratio of 1.0 represents the PLS adequacy factor being the same in both the undeformed and deformed case; a value higher than 1.0 represents an improvement in the PLS after the tunnelling works; a value below 1.0 represents a decrease in the PLS after the tunnelling works. The results obtained for Structure 2 (asset owner 1) see a dramatic increase in the PLS Case 6, as shown in Figure 6. The reason for this improvement is due to a hinge forming, as a result of the ground movement, at a location of an existing transverse crack. The analysis concluded that the existing crack was likely to widen as a result, and therefore the remedial works associated to achieve analysis case 6 would require it to be repaired. Undertaking these remedial works results in the improvement in the PLS compared to the structure's existing condition.

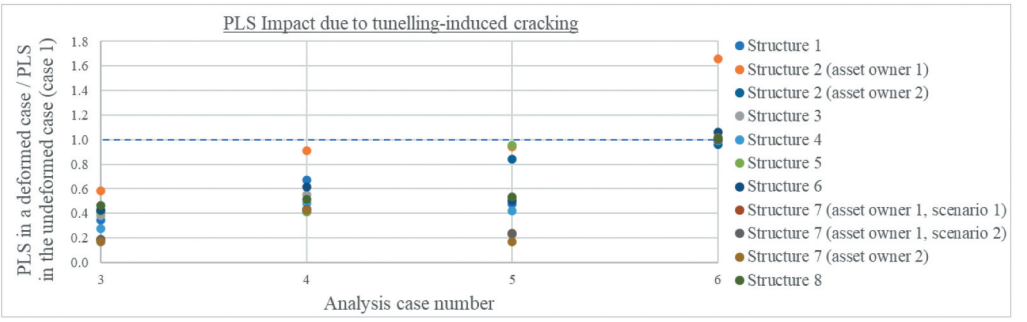

Figure 6. Graph showing the PLS impact due to tunnelling-induced cracking (where all cracks are open in case 3, but all closed in case 6).

Considering Table 2, which presents a summary of the assessment ULS and PLS results for the eight structures assessed within the project, a number of observations and patterns can be made.

Firstly, based on the assessment results, there was a clear indication that a given structure is much more vulnerable to long-term structural degradation when open cracks are present within the arch barrel. In all assessment results, a decrease in the computed PLS adequacy factor can be observed when there are open cracks are present in the intrados, extrados, or both.

Table 2. Assessment ULS and PLS results.

Structure number	Adequacy factor						
	ULS		PLS				
	Case 1	Case 6	Case 1	Case 3	Case 4	Case 5	Case 6
Structure 1	2.25	2.24	1.38	0.48	0.93	0.66	1.38
Structure 2 (asset owner 1)	4.45	4.36	1.20	0.70	1.09	1.13	1.99
Structure 2 (asset owner 2)	2.79	2.67	1.48	0.61	0.61	1.25	1.42
Structure 3	6.21	6.16	2.94	1.13	1.62	1.56	2.91
Structure 4	3.12	3.09	1.62	0.45	0.78	0.68	1.61
Structure 5	3.50	3.50	1.87	0.77	0.77	1.79	1.87
Structure 6	3.02	3.33	1.77	0.76	1.09	0.89	1.88
Structure 7 (asset owner 1, scenario 1)	1.14	1.16	0.58	0.11	0.25	0.14	0.58
Structure 7 (asset owner 1, scenario 2)	1.46	1.48	0.74	0.14	0.32	0.17	0.74
Structure 7 (asset owner 2)	1.95	2.02	1.00	0.17	0.43	0.17	1.02
Structure 8	22.00	22.10	10.30	4.80	5.30	5.50	10.40

There were some structures where the computed PLS adequacy factor did not fall below 1.0 for any of the analysis cases considered, and therefore these structures, under the predicted displacements, do not reach a stage where those cracks are opening and closing under service loads. However, over time, without preventative maintenance, age related deterioration could reduce the PLS adequacy factor further and potentially reach a point where the combined effects result in a PLS adequacy factor of less than 1.0. From an asset management perspective, this highlights the importance of performing regular inspection and maintenance.

Another observation from the results, is that the tunnelling-induced differential settlement can alter the arch geometry in such way that the arch capacity increases, and PLS adequacy factors increase if all cracks are close/repaired. Two examples of this can be seen in the results obtained for Structure 6 and Structure 8.

Structure 6 has a segmental arch profile that is anticipated to experience a slight decrease in span, by 1.4mm, and differential vertical settlement, of 5.6mm, as shown in Figure 5. The assessment results show that there is an increase in both the computed ULS and PLS adequacy factors between the undeformed (Case 1) and deformed arch geometry (Case 6). The span to rise ratio of the arch barrel geometry is considered to be relatively 'flat', meaning that the settlement and span decrease push the arch barrel into a more efficient shape.

Structure 8 has a semi-circular arch profile that is anticipated to experience a slight increase in span, by 1.3mm, and differential vertical settlement, of 5.6mm, as shown in Figure 7. The assessment results also show that there is an increase in the computed ULS and PLS adequacy factors between the undeformed (Case 1) and deformed arch geometry (Case 6). For this type of arch, it was found that the increase in span forced the arch into a more efficient shape. Therefore, it was concluded that there is likely a correlation between the arch type and its existing geometry with whether or not an increase or decrease in span allows the arch to find a more efficient shape.

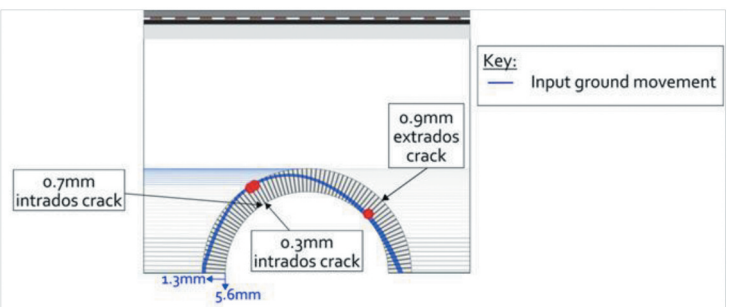

Figure 7. Structure 8 input differential settlement and support movement analysis results (Case 2).

The assessment of Structure 7 was undertaken in three parts. This was due to the presence of existing longitudinal cracks in the intrados of the arch barrel which were identified in the project surveys. The analysis for this structure was undertaken based on the assumption that loading could not distribute across a crack, as shown in Figure 8.

The assessment undertaken found the PLS adequacy factors to be below 1.0 in the undeformed state (case 1), indicating that this structure may be subject to ongoing deterioration in performance due to cyclic loading, before tunnelling activities take place. The adequacy factors dropped further for analysis Case 3, 4 and 5, before returning to a level equivalent to the undeformed structure in analysis Case 6. Thus, it is essential that any cracks that appear in both the intrados and extrados of the arch barrel are remediated. When repaired, the structure is not likely to experience any further short-term or long-term adverse effects, beyond the effects likely to be experienced as a result of its current condition.

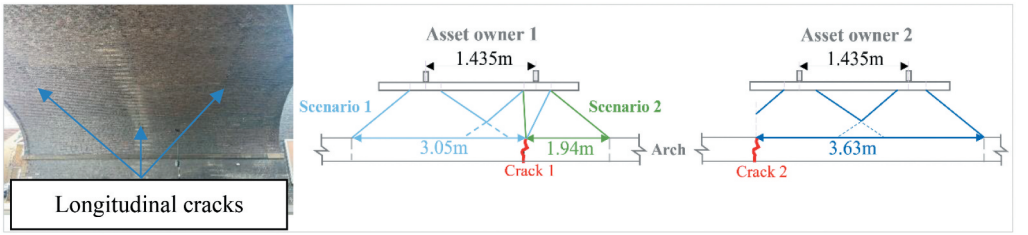

Figure 8. Longitudinal crack locations in relation to tracks (Structure 7).

Considering the ground movement assessment results obtained from a range of different bridge types across the project (Tsekhanskiy et al. 2024), arch structures appear to be able accommodate movement better than many other structure types. No significant mitigation works (such as strengthening) have been recommended for any arched structure within the project. As a result, the focus when assessing the arched structures quickly shifted to ensuring that the residual PLS after the tunnelling was not impacted, and therefore that the lifespan of the structures remained unaltered. Such an approach enables existing structures to be effectively managed, bringing sustainability benefits by maximising their lifespan through timely interventions.

5 CONCLUSIONS

The HS2 ground movement assessment project has provided valuable insights into the potential challenges and risks associated with tunnelling under a major city. The assessment methodology developed for masonry arch bridge structures provided an effective method of assessing the likely impact of ground movements on these structures at both the ultimate limit state (ULS) and permissible limit state (PLS). The findings revealed that unrepaired cracks caused by ground movements can significantly reduce the computed PLS adequacy factor for a given structure, but that undertaking repairs to both intrados and extrados cracks returns the structure to very close to that of the undeformed state, considering both the ULS and PLS. The study also showed that for some structure profiles the ground movement could result in a deformed structure profile that is more structurally efficient. Whilst some initial conclusions and trends have been drawn, a further study is recommended to study the impact of each individual variable more fully, facilitating identification of clear patterns and trends.

Overall, the assessments undertaken revealed the ability of masonry arches to accommodate settlement, and the results obtained highlighted how undertaking timely crack repairs can ensure that the lifespan of the structures is safeguarded, ensuring the safety and resilience of older bridge infrastructure.

Parametric evaluation and design of prestressed concrete beam bridges

V.N. Moraes, T.E.T. Buttignol & L.M. Trautwein
Department of Structures, University of Campinas, Brazil

ABSTRACT: Brazil faces two major challenges with respect to the construction and maintenance of the infrastructure system (bridges, railways and roadways): the continental dimensions and the lack of qualified professionals. According to the National Department of Transport Infrastructure (DNIT), the Brazilian road network has a significant number of temporary wooden bridges, constructed in precarious conditions with an imminent risk to the safety of the users. This paper is aimed to contribute to the development of the country's road infrastructure through the development of a bridge parametric design procedure. The parametric model is designed in the software Rhinoceros3D/Grasshopper and used as a standard design for the modeling and analysis of simply supported beam bridges with free spans between 10 m and 40 m. The cross-sections of the independent elements, as well as the preliminary dimensions, are dynamically determined by means of scripts elaborated in the Python programming language. The algorithm allows modeling concrete beam bridges to overcome single spans (between 10 m to 40 m) or large spans with successive supports, considering any topography. From the parametric model, a structural analysis can be carried out to obtain the acting forces and displacements. The main advantages of the described model are the possibility to simplify the structural design process and carry out an optimization procedure. An example of application of the model is presented.

1 INTRODUCTION

Beam bridges are the most widely used structural system in the state of São Paulo, Brazil. Figure 1 shows a survey with a total of 2,300 works carried by the São Paulo State Department of Roads and Highways (DER-SP), from 1940 to 1990. The structural system in beams can be subdivided in simply supported with or without overhang at the ends, and others (special, continuous or Gerber beams). Figure 1 shows that girder bridges comprise the vast majority of structures, representing 93% of the total. Frame bridges account for a smaller proportion, comprising only 5% of the structures. Arch Bridges are the least common structures, accounting for 2% of the total. Among the Beam category (Figure 1 on the right side), simply supported beams prevails, comprising around 81% of the "Beam" category.

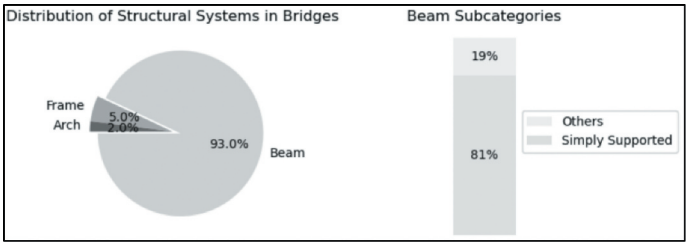

Figure 1. Bridge structural system distribution in the state of São Paulo, Brazil (DER-SP 2023).

DOI: 10.1201/9781003483755-446

Based on the survey presented in Figure 1, simply supported beam bridges were chosen to investigate the advantages of the automation design process described in this paper. This type of structure is widely known and, from a technical design point of view, there is not much new to be discovered. However, the potential for improvement lies in the quality of the materials and the optimization of the structural elements, driven by parametric modeling, algorithm-aided design and optimization techniques. The aiming of this paper is to investigate techniques that allows a more efficient design procedure and, at the same time, guarantee the expected safety and performance levels.

2 RESEARCH SIGNIFICANCE

The standard design procedure is based on the analysis of structural elements in the Ultimate (failure) and Serviceability (durability) Limit States, but does not perform a more in-depth investigation considering the global behavior (holistic engineering approach) and integrating both static and dynamic analyses. Thus, this paper is aimed to propose a design methodology that automates the design process to save valuable time and encompasses structural optimization. In this way, it is possible to optimize beams, slabs and columns, resulting in gains in terms of efficiency and performance. This approach is relevant, especially considering the number of temporary wooden bridges in Brazil and the lack of road infrastructure, which often faces significant logistical challenges and shortage of budget.

Design automation is a technical improvement that is prone to meet the growing demands of infrastructure. It includes the following advantages: i) human error reduction, guaranteeing the accuracy of calculations and drawings; ii) standardization, ensuring that all bridges comply with regulations and code standards; iii) streamlining, requiring fewer human resources to perform repetitive tasks, allowing engineers to focus on more complex and creative aspects of the project; iv) flexibility, allowing customization according to the specific needs of each project; v) quick evaluation of different scenarios, which can lead to more efficient and cost-effective solutions; vi) data integration, making it easier to access relevant information for the project; vii) cost reduction. An example of a parametric Building Information Modeling (BIM) approach to foster bridge project design and analysis can be found in (Girardet & Boton 2021, Ruiz et al 2023 and Tam et al 2017).

3 INTEGRATED BRIDGE DESIGN AND ANALYSIS SYSTEM

The so-called "Integrated Bridge Design and Analysis System" is an approach that is aimed to combine the parametric modelling and the structural analysis with optimization technologies. The integration of advanced technologies simplifies the decision-making process, allowing engineers to create more resilient, cost-effectively and environmentally friendly structures. The methodology involves the development of a 3D digital model of the bridge geometry using Rhinoceros - Grasshopper software, respectively, a computer-aided design (CAD) and algorithm-aided design (AAD). The structural analysis is performed using Karamba 3D, an addon for Grasshopper that allows static and dynamic finite element analyses. The optimization procedure is performed with the integration of Galapagos, a component of Grasshopper, which is based on genetic algorithm. Thus, the method enables a parametric optimization to find the best project configuration based on predefined criteria such as cost, performance and sustainability. Figure 2 shows the step-by-step design process.

3.1 *3D digital parametric model – preliminary analysis*

The 3D digital parametric model is constructed in Grasshopper to accurately represent the dimensions, geometry and boundary conditions of the bridge and the natural terrain. Grasshopper allows a flexible design process due to parametrization and quick adjustments/adaptations in the model.

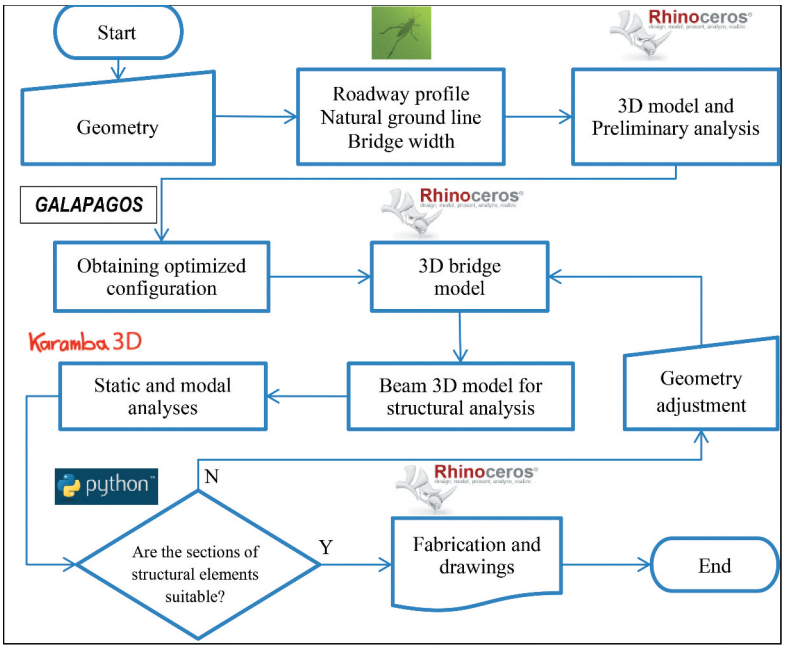

Figure 2. Workflow of the design process.

The proposed parametric model depends on two main input parameters: i) longitudinal profile, which includes the natural terrain and the bridge alignment; ii) width of the bridge. Based on these parameters, the algorithm is able to generate the preliminary 3D model of the bridge, allowing additional customizations, if needed. Figure 3 shows an example of the geometric characterization of a bridge. This example will be considered for the following analyses.

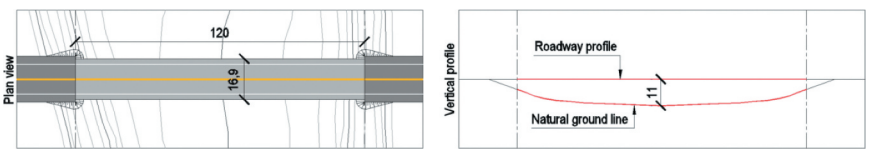

Figure 3. Geometry characterization of a bridge – plan and profile.

The 3D bridge model is generated from the given input geometric data by means of preliminary design rules implemented in the Grasshopper visual programming language. The cross-sections of the structural elements are determined dynamically using Python scripts inside Grasshopper. The prestressed concrete girders are predefined using the Brazilian historical relationship between beam height and span, as shown in Figure 4.

In Figure 4, the average height (solid blue line): represents the average height of the concrete prestressed beams in relation to the bridge span. It corresponds to the following expression: $h = 0.00025 \times L^2 + 0.02065 \times L + 0.75434$ (this expression is adopted in the parametric model). The 90% height (traced green line) represents the higher height, indicating that 90% of bridges have prestressed beams in this range or lower. The 10% height (traced dotted blue line) represents the lower height, indicating that only 10% of bridges have prestressed beams in this range or lower.

The dotted red line (girder heights) refers to the standard (DER 2015) and (DNIT 2022) recommendations.

This practical approach is derived of empirical data obtained from real bridges that have been successfully been built in Brazil. These relationships can vary based on local standards, construction site conditions, specific needs of the bridge and the specifications of the materials.

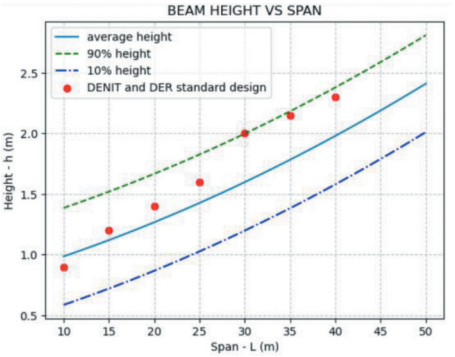

Figure 4. Bridge span-height relationship.

The preliminary design of the columns considers failure due to buckling (elastic limit) and concrete crushing (maximum allowable stress). The cross-beams should be wide enough to hold the girders. In this case, a width of 1.6 m was adopted. For the cross-beam height, the bending moment forces are determined and the neutral axis is checked, considering a limit of 40% of the effective depth. After the preliminary assessment, if the configuration of the bridge does not attend the design criteria, the process is repeated until the optimized geometry is reached. The choice of the preliminary design criteria will have a direct influence on the result.

The parametric model allows to design bridges ranging from small single spans to large multispans and adapted to different topographical conditions. It also provides adjustments, such as: i) number of supports, which impacts on the span length within specified limits; ii) number of columns per cross-beams, which influences the height of the cross section of the cross-beam and the foundation loading. Figure 5 shows an example of a 3D digital model of a multispan bridge after a preliminary assessment.

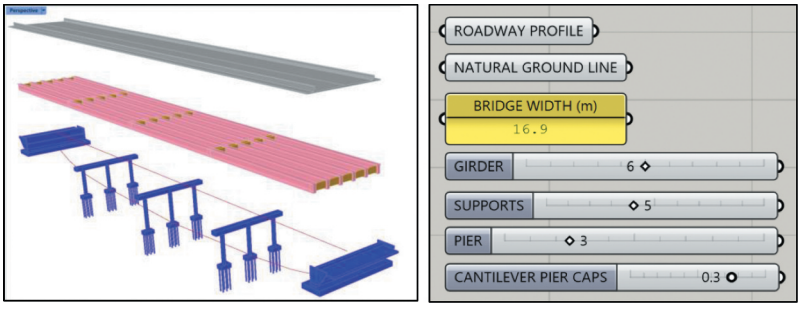

Figure 5. 3D digital model of the bridge (preliminary assessment).

3.2 *Optimization process*

The introduction of Galapagos, a genetic algorithm, into the optimization process can bring several benefits to the bridge design, especially when integrated with Grasshopper and Karamba 3D. Galapagos is a component of Grasshopper that allows the application of parametric optimization algorithms, which means it can help to find the best design parameters based on predefined (restrictions) criteria. This is an effective way to improve bridge design, making it more economical, efficient and safe, while assisting in identifying solutions that meet pre-established requirements. In this paper, as an example, Galapagos was adopted to identify the most efficient number of supports for the bridge, considering the best structural cost-benefit, as shown in Figure 6.

In the preliminary stage of the design, obtaining the optimized geometry can be challenging, since it is necessary to consider not only the volume of concrete, but also the costs of transportation, handling, assembly and environmental impact. Thus, as a simplification, a cost factor

Figure 6. Analysis in Galapagos.

(CF) was established in the analysis. This factor should be determined for each case, considering local conditions by means of a cost matrix, as shown in Table 1. One should consider the costs associated with transportion, handling, assembly and environmental impact, together with the quantity of materials employed. CF values for the case investigated are shown in Table 1. The optimized configuration of the bridge, for the adopted parameters, is shown in Table 2.

Table 1. Cost Factor (CF).

Nº of supports	Free span [m]	CF*
8	15	2.1
7	17	2.0
6	20	2.0
5	24	2.0
4	30	2.1
3	40	2.1

* CF is the cost per m^3 of the structure. This is a simplification that allows to define a single global cost to perform a preliminary optimization. The analysis was carried out in Galapagos, as shown in Figure 6.

Table 2. Main characteristics of the bridge after obtaining the optimized configuration.

Nº of supports	Free span [m]	Nº of columns	Concrete volume [m³]	Normalized cost [%]
6	20	2	1474	77

3.3 *Structural analysis*

Karamba 3D performs structural analyses by means of finite element modeling, allowing the calculation of the internal forces, stresses, strains and displacements. The software performs static and dynamic analyses and is suited to the needs of the early design phases. It can also perform modal analysis, which is important for understanding the modes of vibration of the bridge.

The analysis of the natural frequency is crucial to investigate the effects of resonance due to dynamic forces, such as wind, traffic and seismic activities. Resonance may lead to significant amplifications of displacements and forces, which can affect the safety of the users and the stability of the structure. As an example, a model analysis of the bridge is performed, as shown in Figure 7. The results are displayed in Table 3. The values should be compared with

the reference values for each region or standard. Detailed information related to dynamic analysis can be found in (Paultre 2013).

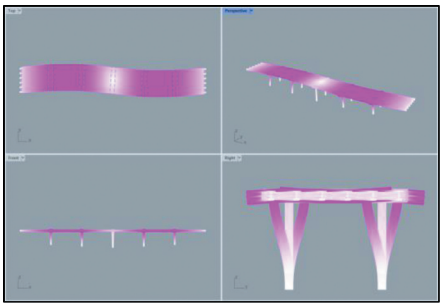

Figure 7. First mode of vibration.

Table 3. Natural frequencies - f [Hz].

Mode	Frame	Deck	Global
1	0.085	0.852	0.021
2	-	6.460	0.159
3	-	8.643	0.213
4	-	9.132	0.225

3.4 *Design of the structural elements*

The complete design of the bridge's structural system is a complex and extensive process, which is out of the scope of this work. In this case, only a summary of the bending design procedure of the concrete prestressed girders are presented, as shown in Figure 8. The design process of the other structural elements is carried out in the same way, by obtaining the forces and checking the section resistance, repeating the analysis if the section does not give satisfactory results.

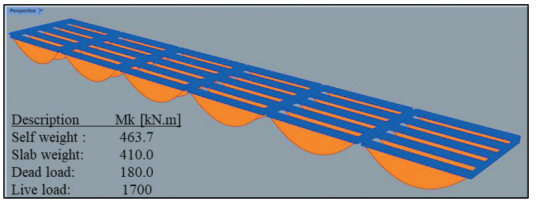

Figure 8. Bending moment diagram.

The design of the structural elements is performed to meet the safety requirements established by the local regulations. This stage ensures that the structure is capable of withstanding the load bearing capacity. It is based on an iterative step-by-step procedure. If changes on the geometry are needed, the analysis returns to the initial modeling stage (Figure 2, section 3.1) and the process is repeated until the geometry meets the established requirements.

After obtaining the maximum bending moments, the strength capacity of the cross-section is checked by computing the stresses and strains adopting the classical beam theory. The analysis takes into account the strength of the material and the influence of prestressing, which is essential for balancing the service loads. The stress diagrams are determined for each load case. The combinations are made taking into account the superposition of effects. Safety and performance criteria are applied, ensuring that the girder does not exceed the serviceability limits for cracking and deformation.

Figure 9 shows an example of the definition of the girder cross section. The stresses obtained for the predefined cross section are shown in Figure 10. The process of verification

of the girders was divided in 3 stages, as follows: i) stage 1 – immediate prestressing, considering the self-weight; ii) stage 2 – immediate prestressing, considering assembly and construction, self-weight and slab loading (including immediate and time-dependent prestress losses); iii) stage 3 – time-dependent prestressing, considering permanent and live loads. Detailed description of the prestressed design can be found in (Naaman 2012, El Debs 2021).

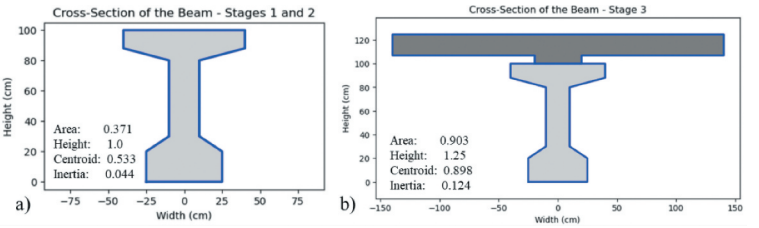

Figure 9. Cross section of the girders: a) Stages 1 and 2; b) Stage 3.

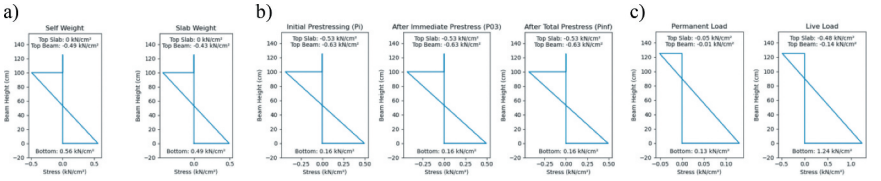

Figure 10. Cross section stresses considering different load cases: a) stage 1; b) stage 2; c) stage 3.

4 RESULTS AND DISCUSSION

The integrated design procedure described in Figure 2 provides an efficient procedure for the preliminary assessment of the prestressed girder bridges, optimizing the use of natural resources and reducing the overall cost. Firstly, an analysis was performed to obtain the best choice for the number of bridge supports, based on the preliminary design criteria adopted. After that, the girders were optimized and the model reprocessed to obtain the optimized solution. Figures 11a and 11b show, for the concrete beam bridge investigated, the optimum free span that results, respectively, in the lowest concrete volume and cost of the girders. Values in grey corresponds to the initial values determined in the preliminary assessment. Values in blue corresponds to the final value after the structural analyses.

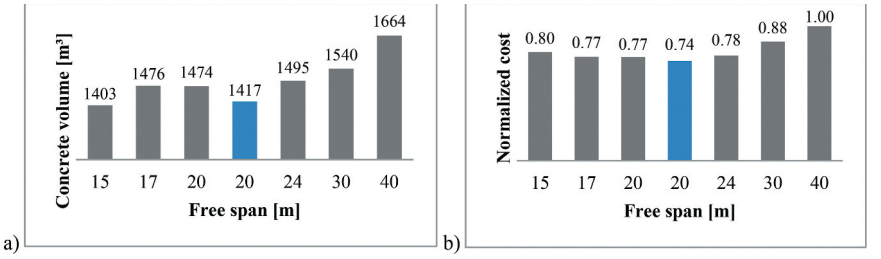

Figure 11. Results: a) Free span vs. concrete volume; b) Free span vs. normalized cost.

The results demonstrate a reduction of approximately 4% in the concrete volume of the cross section in relation to the initial values determined in the preliminary analysis. It is worth mentioning that the initial values also met the service and resistance requirements at the design stage. After the completion of the process, the prestressed girders are ready to be manufactured and built. The final configuration of the beam bridge after optimization, is shown in Figure 12.

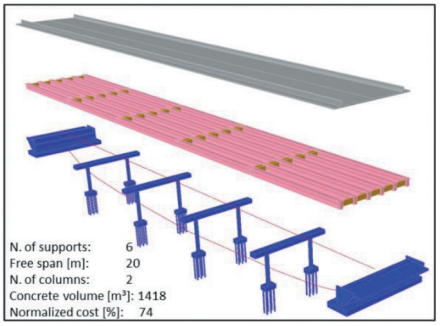

Figure 12. Final configuration of the bridge.

5 CONCLUSIONS

This paper explored the potential of the modern tools to create innovative and efficient solutions. It highlighted the main advantages of an automation design process, which is based on an integrated design procedure buttressed on parametric modelling and structural optimization procedures. The design automation comes in hand as a response to the current challenges in structural design, aiming to save time, reduce costs and improve the sustainability. This approach represents a technical advance and a feasible solution to meet the demands of infrastructure, offering benefits such as error reduction, standardization and rationalization of resources.

The implementation of the Integrated Bridge Design and Analysis System, using tools such as Rhinoceros-Grasshopper, Karamba 3D and Galapagos, is an evolution in the structural engineering design process. The example described in this paper demonstrated that the automation design procedure of concrete prestressed girders is able to reduce the cost and the concrete volume, contributing to improve the construction sustainability. This methodology can be extended to other structural elements to provide a holistic analysis of the structure.

ABSTRACT: Current state-of-the-art deterioration forecasting models such as the stochastic Markov hazard model require relatively large sample data to meet accuracy requirements. Small zones e.g., small cities and countries have a few infrastructure assets including bridges to manage hence their inspection data is incomplete. Also, the interdependence between structural deterioration and chemical attack has not been fully investigated. Chemicals e.g., CO_2 and Cl accelerate reinforced concrete (RC) deterioration by ingressing through RC pores which facilitates rebar corrosion leading to cracking, delamination and spalling that terminates in structural failure in case of no intervention. Additionally, worse RC structural state results in more severe chemical attack as more chemicals ingress into RC. This study proposes a composite Markov hazard model that captures these compounding processes and examines the influence of chemical attack on RC bridge deterioration rate, and vice versa, to aid proactive interventions. The study applies multiple imputation to generate more complete data to address small zone data incompleteness and shows empirical model applicability.

1 INTRODUCTION

1.1 *Bridge deterioration under chemical attack*

Bridges are important transportation systems constructed mainly using reinforced concrete (RC) that combines steel and concrete for high tensile and compressive strength. RC deterioration is accelerated by inadequate designs, poor initial construction and workmanship (i.e., compaction and curing), seismic activity and chemicals e.g., CO_2 and Cl that facilitate reinforcement bar (rebar) corrosion producing rust that is larger than steel generating internal stresses in RC resulting in cracking. RC bridges in critical structural condition are more exposed to chemicals that ingress through concrete orifices and hence experience more severe chemical attack (Kobayashi 2006, Akiyama et al. 2011, Cui et al. 2021). These compounding RC deterioration processes require timely intervention to avert costly failures. Deterioration graphs of two RC bridges (B=1,2), with B=2 under significant chemical attack, follow different trends requiring different actions A (Figure 1).

DOI: 10.1201/9781003483755-447

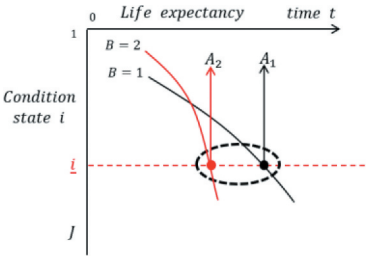

Figure 1. Life expectancy of two bridges (B=1,2); with B=2 under significant chemical attack.

Rebars are protected by a passivisity layer that inhibits chemical progression. CO_2 reacts with $Ca(OH)_2$ in cement to form $CaCO_3$, an acid, destroying this layer. Chlorine, introduced into RC through admixtures, airborne chlorides and de-icing salts, reacts with rebars to form hydrated iron (III) oxide (rust), catalyzed in acidic conditions (Neville 1995).

RC condition can be determined through visual inspection and non-destructive tests (NDTs) such as the rebound hammer, and RC chemical state can be quantified through laboratory analysis on samples obtained by semi-destructive tests (SDTs). NDTs do not affect bridge structural performance, functionality and serviceability yet offer simplicity and rapidity (Bakamwesiga et al. 2014a). On the other hand, SDTs are costly and are not carried out as regularly as NDTs hence RC condition and chemical state may not be known concurrently.

RC chemical attack has been modeled as two distinct successive phases; i.e., initiation characterized by chemical ingress into RC and propagation where visible cracks develop (Roelfstra et al. 2004, Lethanh et al. 2017). Kaito et al. (2021) modeled bridge member deterioration and its effects on another considering steel girder end corrosion using a regime switching Markov model. This study explores the composite Markov model developed by Kobayashi and Kaito (2016) to model the transition of pavement surface condition and load bearing capacity that are equally nonconcurent as RC chemical and structural condition.

1.2 *Incompleteness of small zone data*

Small zones including small cities and countries have a few infrastructure assets e.g., bridges that span shorter lengths and hence generate incomplete structural monitoring data which complicates the application of current state-of-the-art deterioration forecasting models such as the stochastic Markov hazard model that requires relatively large sample data to meet accuracy requirements (Tsuda et al. 2006). Data incompleteness has been handled through improving models or scientifically augmenting data. Lethanh and Adey (2012) built a hidden Markov model, Kobayashi et al. (2012) developed a Bayesian estimation method and Kobayashi et al. (2019) applied multiple imputation (MI) (Rubin 1976, 1987, Schafer and Graham 2002) to handle incomplete data.

To apply MI, data missingness types need to be identified. There are generally three missingness types; i.e., Missing Completely at Random (MCAR) where missingness has no dependency on any sample variable (observed or missing), Missing at Random (MAR) for which missingness depends strictly on observed data, and Missing not at Random (MNAR) where missingness depends on other observed or missing variables. Unobserved small zone data may be considered as MCAR.

1.3 *Study objectives*

This research models bridge structural deterioration and chemical attack as processes that compound each other using a composite Markov deterioration model. The objectives are

1) Model RC bridge deterioration and chemical attack using a composite Markov model and examine the interdependency between these processes.
2) Develop a mechanism to generate more complete monitoring data for small zones using MI.
3) Show the empirical applicability of the model.

2 COMPOSITE MARKOV MODEL

2.1 *Model definition*

Consider discrete time (t = 0, 1, 2, …) in which discrete bridge condition states i(i = 1, …, J) with condition J as the absorbing state deteriorate if there is no renewal. This degradation is exacerbated by chemical attack defined using discrete chemical states c(c = 1, …, D) with D as the worst state, and vice versa. States i and c are obtained at different times because chemical tests are more rigorous and time consuming. The discrete survey time is defined as (t_{is} = 0, 1, 2, …, T_{is}) and (t_{cs} = 0, 1, 2, …, T_{cs}) with survey interval (r_{is} = 0, 1, 2, …, R_{is}) and (r_{cs} = 0, 1, 2, …, R_{cs}); and state variable $h(t_{is})$ and $g(t_{cs})$ where subscripts 'is' and 'cs' specify condition and chemical state, respectively.

2.2 *Deterioration of structural condition*

The Markov Transition Probability (MTP), expressing condition state $h(t_{is}) = i$ changing to $h(t_{is} + r_{is}) = j$ given chemical state $g(t_{cs}) = c$ (Tsuda et al. 2006, Kobayashi and Kaito 2016)

$$Prob[h(t_{is} + r_{is}) = j | h(t_{is}) = i, g(t_{cs}) = c\ ] = \pi_{ij}(c) \tag{1}$$

To identify the closest influential chemical state, the discrete time t_{cs} must satisfy conditions

$$\left.\begin{array}{c} \underset{t_{cs}}{argmin}\ |t_{is} - t_{cs}|\ \ \forall t_{cs} \\ t_{cs} \le t_{is} \end{array}\right\} \tag{2}$$

The MTP from i to j given that there was no repair

$$\pi_{ij}(c) = \sum_{\tilde{k}=i}^{j} \prod_{\tilde{m}=i}^{\tilde{k}-1} \frac{\varphi_{\tilde{m}}(c)}{\varphi_{\tilde{m}}(c) - \varphi_{\tilde{k}}(c)} \prod_{\tilde{m}=\tilde{k}}^{j-1} \frac{\varphi_{\tilde{m}}(c)}{\varphi_{\tilde{m}+1}(c) - \varphi_{\tilde{k}}(c)} \exp\left(-\varphi_{\tilde{k}}(c) r_{is}\right) \qquad i \le \tilde{k} \le \tilde{m} \le j \tag{3}$$

where $\varphi_i(c)$ = hazard rate and; $\tilde{k}$ and $\tilde{m}$ = indices.

The hazard rate $\varphi_i(c)$ is expressed in exponential form

$$\varphi_i(c) = \beta_c^0 exp\left(\boldsymbol{x}\boldsymbol{\beta}_{\boldsymbol{i}}^{'}\right) \qquad (i = 1, \ldots, J-1) \tag{4}$$

where $\boldsymbol{\beta_i} = \left(\beta_{i,1}, \ldots, \beta_{i,M}\right)$ = row vector of unknown parameters with symbol [′] showing transpose; $\boldsymbol{x}$ = row vector of explanatory variables; and β_c^0 $(c = 1, \ldots, D-1)$ = heterogeneity scale parameter showing the influence of chemical state c on RC structural condition. $\beta_{c=1}^0$ is standardized to 1.

For a set (i = 1, …, J), the MTP matrix $\Pi(c)$ can be defined between each (i, j) pair

$$\Pi(c) = \begin{bmatrix} \pi_{11}(c) & \cdots & \pi_{1J}(c) \\ \vdots & \ddots & \vdots \\ 0 & \cdots & \pi_{JJ}(c) \end{bmatrix} \tag{5}$$

To satisfy MTP properties and pavement deterioration considering no repair

$$\left.\begin{array}{c} \pi_{ij}(c) \ge 0 \\ \pi_{ij}\ (c) = 0\ (when\ i > j) \\ \sum_{j=1}^{J} \pi_{ij}(c) = 1 \end{array}\right\} \tag{6}$$

Life expectancy ($RMD_i(c)$) and its average $ET_i(c)$ from start of RC bridge life are (Lancaster 1990)

$$RMD_i(c) = \frac{1}{\varphi_i(c)} \tag{7}$$

$$ET_i(c) = \sum_{i=1}^{j} \frac{1}{\varphi_i(c)} \tag{8}$$

2.3 *Progression of chemical attack*

Similarly, MTP defining change from chemical state $g(t_{cs}) = c$ to $g(t_{cs} + r_{cs}) = d$ given condition state $h(t_{is}) = i$

$$Prob[g(t_{cs} + r_{cs}) = d | g(t_{cs}) = c, h(t_{is}) = i\ ] = p_{cd}(i) \tag{9}$$

With discrete time t_{is} satisfying

$$\left.\begin{array}{c} \underset{t_{is}}{argmin} \; |t_{cs} - t_{is}| \; \forall t_{is} \\ t_{is} \le t_{cs} \end{array}\right\} \tag{10}$$

The MTP from c to d given no intervention

$$p_{cd}(i) = \sum_{\tilde{k}=c}^{d} \prod_{\tilde{m}=c}^{\tilde{k}-1} \frac{\lambda_{\tilde{m}}(i)}{\lambda_{\tilde{m}}(i) - \lambda_{\tilde{k}}(i)} \prod_{\tilde{m}=\tilde{k}}^{d-1} \frac{\lambda_{\tilde{m}}(i)}{\lambda_{\tilde{m}+1}(i) - \lambda_{\tilde{k}}(i)} \exp\left(-\lambda_{\tilde{k}}(i) r_{cs}\right) \tag{11}$$
$$c \le \tilde{k} \le \tilde{m} \le d$$

The hazard rate $\lambda_c(i)$ in exponential form

$$\begin{array}{c} \lambda_c(i) = \gamma_i^0 exp\left(\mathbf{y}\boldsymbol{\gamma}_c^{'}\right) \\ (c = 1, \ldots, D-1) \end{array} \tag{12}$$

where $\boldsymbol{\gamma}_c = \left(\gamma_{c,1}, \ldots, \gamma_{c,M}\right)$ = row vector of unknown parameters; $\mathbf{y}$ = row vector of explanatory variables; and $\gamma_i^0 (i = 1, ..., J-1)$ = heterogeneity scale parameter showing the effect of condition state i on RC chemical state. Also, $\gamma_{i=1}^0$ is standardized to 1.

The MTP matrix $P(i)$ can be defined between each (c, d) pair

$$P(i) = \begin{bmatrix} p_{11}(i) & \cdots & p_{1D}(i) \\ \vdots & \ddots & \vdots \\ 0 & \cdots & p_{DD}(i) \end{bmatrix} \tag{13}$$

Again, all MTP properties considering no action must be met and $RMD_c(i)$ and $ET_c(i)$ estimated.

2.4 *Composite deterioration model*

Chemical attack compounds RC structural deterioration, and vice versa. Composite deterioration condition $\eta(t) = \eta(\eta = 1, \ldots, \Omega)$ with $\Omega = J \times D$. The composite $\eta(t)$ corresponds to $(1, 1), \ldots, (1, D), (2, 1), \ldots, (2, D), (3, 1), \ldots, (J, D)$ and is specified as $\eta(t) = \{h(t), g(t)\}$. The elements of the $\Omega \times \Omega$ composite probability matrix Δ are (Kobayashi and Kaito 2016)

$$\omega_{ic}^{jd} = p_{cd} \times \pi_{ij} \tag{14}$$

The Δ matrix must also follow MTP rules. The composite deterioration process of RC bridge structural elements considering no improvement

$$H(t) = H(0) \times \Delta \tag{15}$$

where $H(0)$ = initial composite state vector and; $H(t)$ = composite vector at time t.

2.5 *Tests for the composite deterioration process*

The modeled composite deterioration process was based on the assumption that chemical attack accelerates RC structural deterioration and that heavily deteriorated RC bridges experience more severe chemical attack. This compounding process can be tested using two hypotheses; i.e, structural deterioration acceleration due to chemical attack using Hypothesis I and increased chemical attack due to structural degradation using Hypothesis II.

To test Hypothesis I, the null hypothesis H_0^c $(c = 2, \ldots, D-1)$, and the alternative hypothesis H_1^c $(c = 2, \ldots, D-1)$, are specified as

$$\begin{cases} H_0^c : \beta_c^0 > 1 \\ H_1^c : \beta_c^0 \leq 1 \end{cases} \tag{16}$$

If H_0^c is rejected, then the alternative H_1^c may be supported. Otherwise, if H_0^c is not rejected, then H_1^c cannot be supported. When Hypothesis I is not rejected, it implies that structural condition deterioration could be accelerated by chemical state c (c = 2, . . ., D − 1) compared to c = 1. The null hypothesis can be tested in the confidence interval $\left[\beta_{c,\alpha}^0, \infty\right]$ for a significance level α.

Similarly, to test Hypothesis II, the null hypothesis H_0^i $(i = 2, \ldots, J-1)$, and the alternative hypothesis H_1^i $(i = 2, \ldots, J-1)$, are specified as

$$\begin{cases} H_0^i : \gamma_i^0 > 1 \\ H_1^i : \gamma_i^0 \leq 1 \end{cases} \tag{17}$$

When Hypothesis II is not rejected, it implies that the worsening of the chemical state may be quickened in condition state i (i = 2, . . ., J − 1) compared to i = 1. The null hypothesis can be tested in the confidence interval $\left[\gamma_{i,\alpha}^0, \infty\right]$ for a significance level α.

3 MULTIPLE IMPUTATION (MI)

3.1 *Handling missingness using MI*

MI can be applied to generate more complete small zone data while maintaining incomplete data attributes. Consider complete data X_{com} with an observed part X_{obs} and missing part X_{mis} with R as the distribution of missingness. Missingness types based on distributions Φ are defined as

$\phi(R|X_{com}) = \phi(R|X_{obs})$ for MAR
$\phi(R|X_{com}) = \phi(R)$ for MCAR
$\phi(R|X_{com}) = \phi(R|X_{mis}, X_{obs})$ for MNAR.

A multivariate condition and explanatory data matrix, Mx with an observed part X_n (n = 1, …, n) and a missing part X_n (n = n + 1, …, N) is formulated as

$$M_x = \begin{bmatrix} i & j & r & x_1 & \cdots & x_a \\ i_1 & j_1 & r_1 & x_{11} & \cdots & x_{a1} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ i_n & j_n & r_n & x_{1n} & \cdots & x_{an} \\ i_{n+1} & j_{n+1} & r_{n+1} & x_{1n+1} & \cdots & x_{an+1} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ i_N & j_N & r_N & x_{1N} & \cdots & x_{aN} \end{bmatrix} \tag{18}$$

where x = covariate; $(1, \ldots, n, n+1, \ldots, N)$ and $(1, \ldots, a)$ = integers.

For univariate complete data j_{com} $(j_1, \ldots, j_N)$ with an observed part j_{obs} $(j_1, \ldots, j_n)$ and a missing part j_{mis} $(j_{n+1}, \ldots, j_N)$ with j_{obs} and j_{mis} independent and identically distributed (i.i.d), MI can be applied to simulate approximate j_{mis} using Bayesian methods ensuring that the imputed data retains similar attributes to the incomplete data (Rubin 1976, 1987, Schafer and Graham 2002).

3.2 *Approximate Bayesian Bootstrap (ABB)*

ABB, detailed by Rubin (1987), enables non-parametric imputation for MCAR data by sampling with replacement to generate m imputations of j_{mis} following these steps.

i) Create a new data pool j^*_{obs} by resampling n values from j_{obs} $(j_1, \ldots, j_n)$ with replacement.
ii) Generate an imputed data set j^*_{mis} by resampling $N - n$ values from j^*_{obs} also with replacement.

ABB produces approximate draws from $\Phi(j_{mis} \mid j_{obs})$ in j_{obs}. The resampling of j^*_{obs} from j_{obs} approximates a draw of multinomial probabilities from their observed-data posterior under a Dirichlet prior. For the covariates $x_{1n}, \ldots, x_{an}$ $(n = n+1, \ldots, N)$, the sample values can be partitioned into cells based on unique patterns of each cell and ABB carried out within each cell. Imputation within cells reduces bias and distortion of estimates for quantities such as means.

4 MODEL APPLICATION

4.1 *Surveyed Ugandan bridges*

Bakamwesiga et al. (2014a) assessed the extent of structural damage and chemical attack on 22 RC bridges along 5 major highways in Uganda (Figure 2). Information on bridge age, inventory, structural strength, location, extent of chemical attack (i.e., carbonation and chloride) was collected in 2013. Traffic loading on the 5 routes in Equivalent Standard Axel Loads (ESALs) was obtained from Obunguta and Matsushima (2020) assuming stagnant traffic from 2013 to 2017.

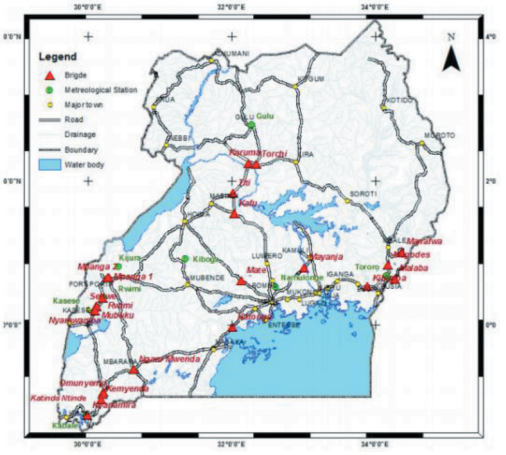

Figure 2. Study bridges (Bakamwesiga et al. 2014a).

4.2 *Strength and chemical tests on Ugandan bridges*

RC strength was obtained using the NDT Proceq N-34 Schmidt hammer on bridge piers, abutments and decks by striking perpendicular to the concrete surface to obtain a rebound number. A minimum of 3 test areas were chosen for every bridge element with a maximum of 10-12 readings obtained at each area, care taken to avoid striking the same point to minimize local aggregate influence. The results were then averaged and the compressive strength (CS) derived (Bakamwesiga et al. 2014b).

SDTs were carried out to test for carbonation and chlorination for the surveyed bridges by Bakamwesiga et al. (2014a). Phenolphthalein was sprayed on exposed concrete which turns purple in alkaline (uncarbonated) and remains clear in acidic (carbonated) environments. A powdered concrete sample was collected and taken for laboratory analysis to determine *Cl* concentration (*mg/l*).

4.3 *MI for Ugandan bridge data*

Ugandan bridge data was incomplete with a MCAR missingness type for which ABB was applied considering i.i.d data variables. MI was done by generating 3000 imputes (imp) with iterations set at 1000 for a sample with greater than 90% missingness. MI results for quantitative data showed relatively small bias between observed and imputed data means μ and variances σ^2 (Table 1). Figure 3 shows Kernel density plots for the quantitative data showing similar trends. Imputed qualitative data (element location, carbonation) had similar proportions to observed data.

Table 1. MI results for quantitative data.

	CS (MPa)		*Cl* (*mg/l*)		Age (years)		Traffic ('000 ESALs)	
Parameter	obs	imp	obs	imp	obs	imp	obs	imp
μ	42.42	42.34	9.24	9.23	36.05	35.94	6.19	6.21
σ^2	67.16	67.30	30.83	30.71	284.54	284.55	23.79	23.76

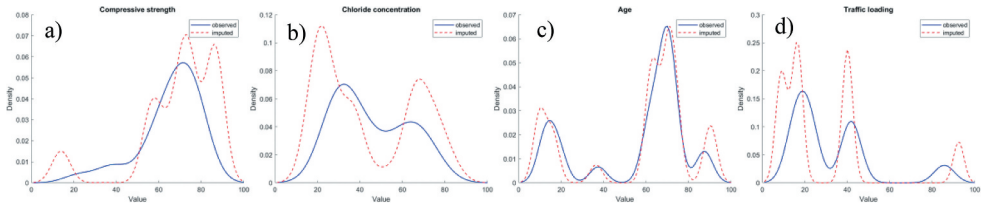

Figure 3. Kernel density plots for quantitative data; CS (a), *Cl* (b), Age (c) and Traffic (d).

4.4 *Discretization of the continuous chemical and structural condition values*

To apply the stochastic composite model, the continous condition values were discretized. Assigning accurate CS ranges to define RC condition states is complex because of different materials, construction methods and environments. The British Standard (BS) 5400 and Ugandan road design manual specify initial RC CS and material composition for specific live and dead loads (MoWT 2010). RC CS is low just after casting and gradually increases to the highest level after curing from where it decreases. CS also increases over time based on curing methods, components (e.g., water/ cement content) and carbonation. Carbonation reduces RC porosity as the produced $CaCO_3$ occupies greater volume than $Ca(OH)_2$ leading to increased hardness.

Past research defined bridge condition under chemical attack following the initiation and propagation stages. Roelfstra et al. (2004) defined propagation based on rebar section loss, whereas Lethanh et al. (2017) defined it using crack width. Both studies classified initiation according to *Cl* concentration. This study defined RC chemical state in both stages using *Cl* concentration and carbonation and set RC condition state using CS-age relationships (Al-Khaiat and Fattuhi 2001, Roelfstra et al. 2004, Rizkalla et al. 2009 and Yet et al. 2012) shown in Table 2.

Table 2. Definition of RC bridge condition and chemical states.

State	Condition data				Chemical data		
	Imputed (%)	Description	CS (MPa)	Age (years)	Imputed (%)	*Cl* (*mg/l*)	Carbonation
1	21.43	No visible damage and bridge is new or nearly new.	[0, 35] > 35	[0, 5] (5, 20]	31.73	< 7	Absent
2	5.03	Local spalling, micro cracks, and insignificant structural damage.	[0, 35] > 20 > 35	(5, 10] (20, 30] (30, 35]	25.23	< 7 (7, 14]	Present Absent
3	57.07	Significant spalling, cracks, and/or humid zones.	[0, 20] [0, 35] > 20	(20, 30] (30, 35] (35, 50]	33.73	(7, 14] (14, 28]	Present Absent
4	16.47	Heavy spalling with visible rebars, macro cracks and/or humid zones. Structure in danger of failure.	[0, 20] > 20	> 35 > 50	9.30	(14, 28] > 28	Present Absent/ Present

4.5 *Estimation of Ugandan bridge deterioration rate*

4.5.1 *Definition of hazard rates*

Deterioration rate was estimated considering chemical attack effects on structural degradation, and vice versa, using the composite Markov model. Hazard rates for the condition and chemical state transitions were specified as

$$\varphi_i(c) = \beta_c^0 exp\left(\beta_{0,i} + \beta_{1,i} x_1\right) \tag{19}$$

$$\lambda_c(i) = \gamma_i^0 exp\left(\gamma_{0,i} + \gamma_{1,i} \bar{y}\right) \tag{20}$$

$$\bar{y} = \begin{cases} 1 & for\ substructure \\ 0 & for\ substructure \end{cases} \tag{21}$$

Inuagral condition was estimated from bridge age with best state at age zero. Traffic loading x_1 was normalized to [0, 1] and considered to only affect bridge structural condition. Dummy variable $\bar{y}$ differentiated element location as the substructure (abutments and piers) is more exposed to chemical agents such as moisture compared to the superstructure (decks). The Markov Chain Monte Carlo (MCMC) methods and Metropolis Hastings (MH) algorithm were used to predict the unknown parameters and their 95% confidence intervals using MATLAB for a 15,000 run with a 5,000 burnin eliminated due to poor initial convergence. Parameter convergence was tested using the *Geweke* diagnostic with values falling within [–1.96, 1.96] limits where 0 shows perfect convergence.

4.5.2 *Estimated condition and chemical degradation*

Estimated β and γ values, average hazard rates and life expectancies are shown in Table 3. The positive β values show that traffic loading increase leads to faster deterioration in condition state 1 and 3. Positive γ values show that the substructure has a reduced life expectancy attributable to higher chemical exposure. Chemical degradation was prevalent from state 2 onwards.

Predicted condition and chemical state life expectancies (19.94 and 19.03 years, respectively) were similar. However, state transition 1 to 2 to 3 was more rapid for condition compared to chemical degradation probably due to the more significant effects of chemical attack in condition 1 and 2.

Table 3. Estimated parameters and life expectancy.

	Absolute	Traffic	Absolute	Element	Hazard rate		Life expectancy	
State	β_0	β_1	γ_0	γ_1	$\varphi_i(c)$	$\lambda_c(i)$	$RMD_i(c)$	$RMD_c(i)$
1	–0.7802 [–1.0511, –0.5402] (0.3297)	0.0920 [–0.1121, 0.2957] (0.9363)	–1.6754 [–1.9659, –1.4029] (–1.1503)	-	0.4688	0.1872	2.1347	5.3409
2	–0.1430 [–0.4340, 0.1325] (–0.0227)	-	–1.1208 [–1.4249, –0.7984] (–1.3277)	0.0557 [–0.1029, 0.2121] (1.3522)	0.8702	0.3384	1.1492	2.9565
3	–2.8397 [–3.1416, –2.5690] (1.5308)	0.1146 [–0.2083, 0.4210] (–1.8602)	–2.4843 [–2.8359, –2.1295] (–0.2764)	0.1713 [–0.1015, 0.4451] (–0.4759)	0.0601	0.0937	16.6527	10.734

Note: The 95% confidence interval is shown in square brackets and *Geweke* diagnostic in parentheses.

4.5.3 *Hypothesis testing for the compounding process*

The heterogeneity scale parameters with influence of chemical state β_c^0 and condition state γ_i^0 are shown in Table 4. Standardized $\gamma_i^0 > 1$ for $i = 3,\ 4$ and for $i = 2,\ 3,\ 4$ at 95% confidence interval suggest that more deteriorated bridges experienced accelerated chemical attack supporting hypothesis II. Standardized $\beta_c^0 > 1$ for $c = 2$, and for $c = 2,\ 3,\ 4$ at 95% confidence interval show that chemical attack speeds up structural degradation supporting hypothesis I. Chemical attack shrinks rebar area reducing RC tensile strength and expansive rust causes cracking.

Table 4. Scale parameters.

	Condition deterioration		Chemical degradation	
State	Scale parameter β_c^0	Standardized β_c^0	Scale parameter γ_i^0	Standardized γ_i^0
1	0.1715 [0.1355, 0.2145] (–1.7128)	1.000	0.1683 [0.1257, 0.2202] (0.9554)	1.000
2	0.1725 [0.1382, 0.2191] (–0.1978)	1.006 [0.806, 1.278]	0.1521 [0.1073, 0.2172] (–0.2093)	0.904 [0.638, 1.290]
3	0.1698 [0.1330, 0.2215] (–1.6175)	0.990 [0.776, 1.292]	0.1729 [0.1336, 0.2198] (–0.9105)	1.027 [0.794, 1.306]
4	0.1658 [0.1283, 0.2136] (–1.6083)	0.967 [0.748, 1.245]	0.1808 [0.1296, 0.2444] (0.9848)	1.074 [0.770, 1.452]

5 CONCLUSIONS

This study built a composite Markov hazard model capable of examining the influence of chemical attack on RC bridge structural deterioration, and vice versa. MI was applied to generate more complete small zone data to enable area specific infrastructure performance evaluation instead of relying on wider area averages that may not reflect local conditions. An empirical application was carried out using imputed Ugandan bridge data. The results showed an increase in RC bridge structural deterioration due to chemical attack and worsening chemical state for heavily deteriorated structures. These results can be used to improve existing standards for more resilient bridge design. Existing RC

standards such as the Eurocode EN 206–1:2000 restrict the maximum water content, minimum strength, cement and air content for different chemical exposure levels, however, chemical progression rates can inform RC design standard improvement in specific environments.

For the engineering construction practice, the study draws important implications including increasing the initial RC bridge construction quality and monitoring to ensure that construction follows design specifications. For instance, RC cover depth should strictly be constructed as designed. If structural monitoring uncovers defects in existing bridges, then preventive maintenance such as applying sealants to RC with low cover depth should be immediately carried out.

National Highways, Guildford, UK

ABSTRACT: This paper considers the effect of inadequate or damaged anchorage regions on the shear strength of bridge beams. This research is motivated by the occurrence of theoretical deficiencies in the assessed shear capacity of existing reinforced concrete bridges. The provisions for dealing with damaged or non-standard RC details as prescribed in CS455 (2020) can be conservative, as such low shear strength assessed capacities may lead to expensive and potentially unnecessary repairs. The aim is to identify if changes are needed to the provisions currently adopted in the UK for the assessment of shear capacity for beams with non-standard anchorage. The paper presents preliminary results from a series of off-set 3-point tests on beam specimens specifically constructed to replicate the types of anchorage defects commonly found in aging UK infrastructure. This includes the effects of insufficient anchorage length, prior slip in the longitudinal reinforcement and corrosion affecting longitudinal bars, links and concrete cover. A unique two-stage beam casting system has been implemented to produce specimens with known prior anchorage slip and corrosion. Beams with either plain or deformed bars and both with and without stirrups, have been tested, representative of typical bridge reinforcement detailing within the UK infrastructure. CS455 (2020) does not provide full guidance on RC elements affected by prior anchorage slip, the higher-than-expected resistances obtained to date (particularly for deformed bars) seem to suggest that the current limited provisions may lead to overconservative assumptions. However, further study is needed for beams containing plain bars, which are expected to exhibit significantly much lower bond capacities.

1 INTRODUCTION

As reinforced concrete (RC) structures age over time and are exposed to deterioration, they can become affected by a series of defects. For RC bridges, anchorage zones are amongst the most sensitive areas where aging and deterioration can worsen the impact of pre-existing sub-standard details or expose new defects. Deficiencies in the anchorage zones for RC bridge beams and slabs can influence the shear capacity (Shave et al., 2007, Coronelli et al., 2019, Han et al. 2020) and may require expensive repair interventions and interim measures. Although authors have proposed methods to assess the shear capacity of RC elements with short anchorage lengths (Shave et al. 2007) and for elements affected by corrosion (Coronelli et al. 2019), there is still no standardized approach to deal with the assessment of the shear capacity of RC members with insufficient or damaged anchorage and no guidance was found in case of prior slip of the longitudinal reinforcement.

DOI: 10.1201/9781003483755-448

Assessment standards in the UK do not currently provide full guidance to deal with the deterioration of the anchorage bond behaviour that may be caused by corrosion or by a previously happened failure in the reinforcement anchorage (commonly referred to as prior anchorage slip).

In the UK some existing RC bridges present short anchorage lengths of the longitudinal reinforcement which appear to have slipped and/or show signs of corrosion. To investigate the effects of prior anchorage slip and corrosion of short anchorage lengths on the shear capacity of RC bridge elements a series of tests adopting a two-stage beam casting has been planned and partly performed to date.

In addition, the specimens have been intentionally designed with identical characteristics to those used Shave et al. (2007) to be able to directly compare the results, particularly for the pre-slipped and corroded specimens which were not included in Shave et al. (2007).

2 TESTING PROGRAMME

2.1 *Test specimens*

As part of an ongoing project, a preliminary study of 9 beams presenting either deformed or plain bars with anchorage lengths ranging from zero up to twenty bar diameters are presented. In addition to anchorage length, other parameters such as presence or absence of links, link spacing, the influence of prior slip of the longitudinal reinforcement or of corrosion were investigated.

Within this initial study two main section types have been utilised: one with no links (for which the naming convention B1 was adopted) and another one with the same longitudinal reinforcement but with links (namely B4 section type). Variations on section code B4 (i.e., B4.1, B4.2 and B4.3) have been tested to investigate the influence of links density, concrete cover and corrosion. The various section codes with their characteristics are presented in Figure 1.

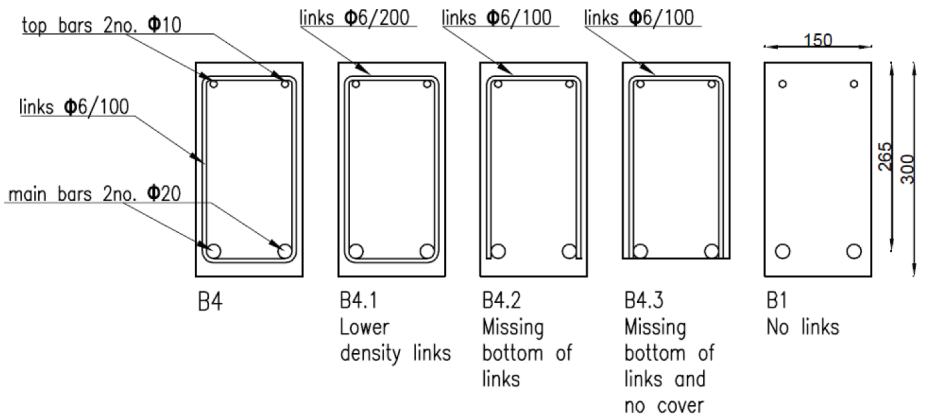

Figure 1. Beam specimens section types, geometry, and reinforcement.

With the exception of section type B4.3, all sections have the same nominal geometry, concrete cover (25mm to main bars) and reinforcement arrangement. Sections B4.2 and B4.3 present U-shaped links (as shown in Figure 1) only in the anchorage zone, and closed links along the shear and back spans. These two sections belong to the group of corroded specimens. The missing bottom leg in B4.2 as well as the missing concrete cover in B4.3 simulate a moderately high level of corrosion replicating typical defects observed in existing RC bridge beams in the UK.

The choice of the two values adopted for the link spacing for section types B4 and B4.1 was based on the knowledge that the beneficial effect upon the bond strength provided by a links density of approximately 0.5-0.6d is generally sufficient. A further increase in the density only provides marginal improvements, whilst for lower densities a gradual worsening of the bond behaviour is observed, as remarked by Koulouris and Apostolopoulos (2020).

The specimens have been designed in accordance with CS455 (2020) to assess the expected type of failure to ensure they failed in shear or by exceeding the bond strength in the anchorage zone. In this way, the risk of accidental bending failures was also minimised as much as possible.

The anchorage length was measured from the centreline of the bearing and varied from zero up to 20 bar diameters (400mm). As indicated in Figure 2 the clear span of the beams is 2000mm resulting in a full length of 2.8m including the allowance for the anchorage length on both ends.

To investigate the effect of prior anchorage slip and corrosion, most of the specimens have been cast in two stages.

The first stage includes casting only the anchorage zone of the specimen up to the centre line of the bearing, which is assumed to be the end 400mm of the specimen, but which could be varied depending on the anchorage length being investigated. The reinforcement extends beyond the end of the concrete in this stage as shown in Figure 2a. The prior anchorage slip was achieved through a bond test carried out by pulling all of the bottom extending bars in turn using jacks, whilst measuring the slip (from the end of the bar which was intentionally left sticking out from the back of the specimen of a few centimeters during stage 1 casting operations), to a value of slip in the range of 2mm that is sufficient to exceed the slip corresponding to the peak bond stress. For specimens where the effect of corrosion was investigated, the stage 1 specimens were immersed in salt water and corroded in the anchorage zone.

In stage 2, the shear links are installed where required and the remainder of the specimen is cast. The specimens were tested adopting an off-set 3-point load test at least 14 days after stage 2 casting. Most of the tests have been performed with a shear span $a_v = 3d$.

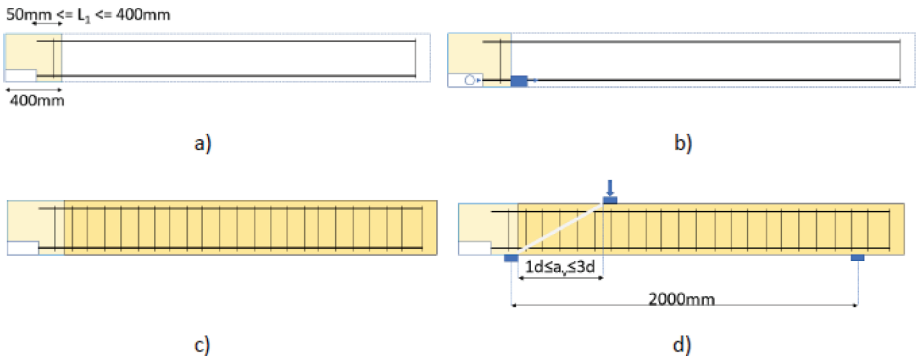

Figure 2. a) Stage 1 casting of specimen b) pre-slip test; c) Stage 2 casting of specimens; d) Stage 2 shear test.

2.2 *Accelerated corrosion*

The effect of corrosion on the main reinforcement was obtained immersing the anchorage parts cast in stage 1 (see Figure 2) in a 10% salt water solution and a constant current induced in the main reinforcement that worked as anode whilst a immersed stainless steel cage surrounding the concrete was used as a cathode. Faraday's law (Equation 1) was adopted to evaluate the current intensity for the target mass loss.

$$I = \frac{\Delta m z F}{M t} \tag{1}$$

In the equation shown, Δm is the mass loss of the reinforcement (g); M is the atomic weight of the metal (56g/mol); I is the electric current (A); z is the ionic charge (equal to 2.0) and F is the Faraday's constant (equal to 96500A/s). The accelerated corrosion was performed with a calculated current density of approximately 1360μA/cm^2. This value of current density is not too dissimilar from the one adopted by Han et al. (2020), that was 1000μA /cm^2.

2.3 *Three-point load test set-up*

The layout of the 3-point load test is as shown in Figure 3. Various transducers have been placed along the shear span and displacement transducers have also been located at the ends of the main bars which stick out of the concrete. Two transducers can be seen on the top of the beam along the shear span in Figure 3, whilst two additional transducers are installed on the back of the beam and can be seen on the left of Figure 3. Load cells have been placed under both supports and at the load point. In addition, the shear span and the relative anchorage length have been painted to enable future use of Digital Image Correlation techniques (DIC). The load was applied using a lever beam to ease the positioning of the specimen and avoid clashes between the DIC images and the press' structure. The lever beam transferred the load on the shear span and was supported by a frame that was directly supported by the strong floor in the back span (hence not touching the beam at all). Prior to casting, one strain gauge was also installed on each of the main bars in the shear span at approximately 50mm from the front face of the support.

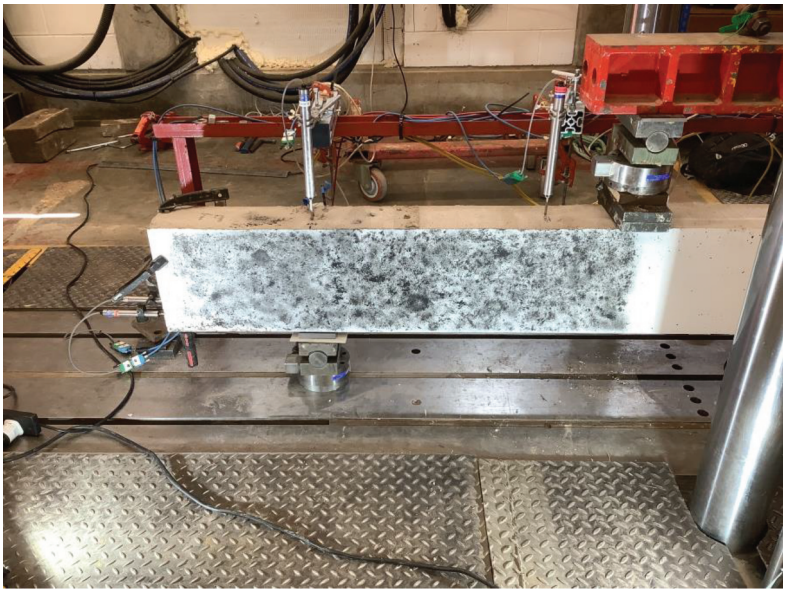

Figure 3. Some details of the shear span side for the setup of the beam 3-point load test.

2.4 *Naming convention*

A total of 9 specimens are presented in this paper, as listed in Table 1. To allow for the correct identification of each specimen and its associated characteristics the following naming convention has been implemented:

- Section Type (B1, B4, B4.1, B4.2 or B4.3 as shown in Figure 1)
- Bar Type ("d" for deformed bars, "p" for plain bars)
- Anchorage length (number of bar dia. followed by capital L)
- Shear span (expressed as number of effective depths, e.g., 3d)
- Status of the specimen ("s" if pre-slipped, "c" if corroded, empty if none of the two).

The naming convention can be read as follows: Specimen B4.1d6L3d, has section type B4.1 (low density link), deformed bars as main reinforcement, an anchorage length of 6 bar diameters and was tested across a shear span of 3d and was not slipped or corroded.

As shown in Table 1, a set of 6 beams with deformed bars including pre-slipped and non-pre-slipped specimens, dense, less dense and without links were tested at 3d with 6 bars diameters anchorage lengths alongside a further set of 3 beams with plain bars. The latter include

beams with dense stirrups only with a control non-slipped specimen and the equivalent pre-slipped one both having 6 bar dia. anchorage lengths and an additional pre-slipped specimen with 12 bar dia. anchorage length.

Additionally, one of the plain specimens included in the results was tested at a shear span of 2d. This choice was taken after the equivalent control non-slipped specimen failed in bending with a vertical crack.

3 TEST RESULTS

3.1 *Full beams test results*

The recorded load-deflection plots for beams with deformed and plain bars are presented in Figure 4 and Figure 5 respectively. For each beam the Ultimate load, Mode of failure and cube strength is provided in Table 1.

It is worth highlighting that whilst all the beams with deformed bars failed in shear, this was not the case for all plain bars. For beams with plain bars, failure modes were a result of bond failure of the longitudinal bars, leading to formation of one large flexural crack (B4p6L3d), or inclined shear/flexural cracks (e.g., B4p6L2ds).

Table 1. Three-point load tests results summary

Specimen	Ultimate load P_u [kN]	$P_u/P_{assessment}$ [%]	Prevalent failure mode	Concrete cube strength [MPa]	Load at first slip P_{slip} [kN]	Slip at P_u, s_u [mm]
B4d6L3d	184.74	119	Shear	28.0	107.87	0.204
B4p6L3d	55.56	46	Flexure + Bond	28.0	54.77	0.045
B1d6L3d	68.68	185	Shear	28.0	44.53	0
B4.1d6L3d	124.15	113	Shear	28.0	78.09	0.39
B4d6L3ds	203.48	142	Shear	37.7	110.05	1.25
B4p6L2ds	65.54	69	Flexure + Shear	37.7	64.39	0.014
B1d6L3ds	85.77	250	Shear	37.7	77.77	0
B4.1d6L3ds	140.12	138	Shear	37.0	105.77	0.216
B4p12L3ds	90.14	55	Shear	33.0	88.84	0.069
B4.2d6L3dc	178.11	238	Shear	33.0	148.91	0.004
B4.2p6L3dc	109.83	197	Shear	33.0	98.19	0.3
B1d6L3dc	78.81	244	Shear	33.0	25.78	0

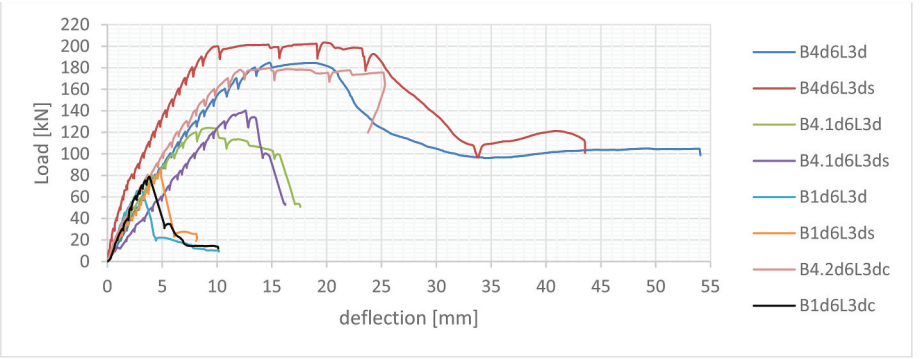

Figure 4. Load-deflection plots for beam specimens with deformed bars.

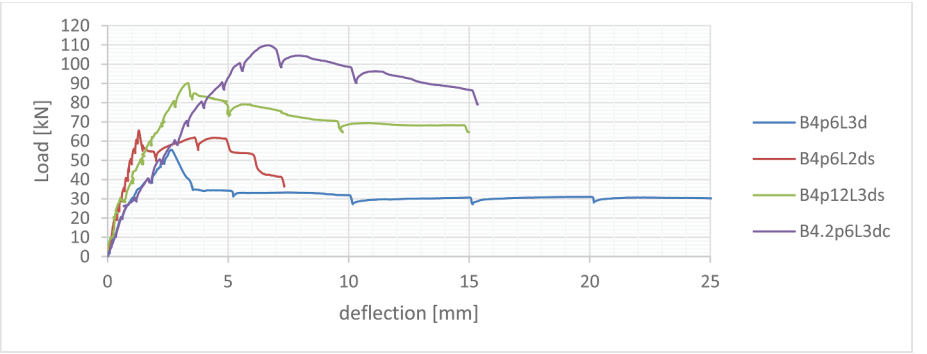

Figure 5. Load-deflection plots for beam specimens with plain bars.

3.2 *Pre-slip tests results*

During the pre-slip tests, the load-slip behaviour was recorded, with the load being converted to an average bond stress along the anchorage length. Typical behaviour of deformed and plain bars has been observed with the latter presenting lower peak and residual bond strength compared to deformed bars and a steeper descending branch after the peak bond was exceeded. Prior to performing the pull-out tests, the expected bond strength of the various specimens has been calculated in accordance with CS455 (2020). Whilst the deformed bars have shown bond characteristics in line with the expected values, plain bars underperformed as also shown in Table 2.

Table 2. Results of pull-out slipping tests for the selected specimens.

Specimen	Expected bond strength $f_{ub,exp}$ [MPa]	Recorded bond strength $f_{ub,rec}$ [MPa]	$f_{ub,rec}/f_{ub,exp}$ [%]
B4d6L3ds	4.08	4.79	118
B4p6L2ds	2.27	0.78	34
B1d6L3ds	2.51	3.18	127
B4.1d6L3ds	4.08	3.31	81
B4p12L3ds	2.62	1.15	44

The poor performance of plain bars is significantly below the expected values, such a reduction in bond strength would not be covered by the partial factors γ_{mb} provided in Section 2 of CS455 (2020) (which is either 1.4 or 1.25). It seems probable that the extremely smooth surface of the cold-drawn plain bars had a significant impact on the bond behaviour The variation in bond strength between the two plain bars specimens presented (B4p6L2ds 34% and B4p12L3ds 44% of the expected values respectively) may also be due to the fact the bars used within B4p12L3ds had been left exposed to develop a degree of surface rust in the environment for a period thereby roughening the surface finish.

3.3 *Accelerated corrosion results*

The results obtained to date have provided levels of mass loss which resulted in a fraction of the targeted 10%. The two specimens included in this paper reached approximately 2% for the one with links and 5% for the one with no links. As a consequence, the results of the shear tests on corroded specimens are not going to be presented in this paper as further testing with different and higher levels of corrosion is needed.

Similarly, to what has been observed by Han et al. (2020), one of the reasons that could have caused the lower than expected levels of corrosion, may be due to the formation of a corrosion cell between the stirrups, the top reinforcement and the stainless steel even if insulation was applied to isolate the main bars from the remaining steel. Additionally, as also suggested by

Imperatore et al. (2019), it may be good practice to immerse the concrete to be corroded in the saltwater solution for a conditioning period prior to starting the actual accelerated corrosion process. This would allow the salt to penetrate the concrete and should reduce the delay of the start of the corrosion process. Although, also after conditioning the specimens, a correction factor (α) for the Faraday's law may be used when corroding bars embedded in concrete (Han et al. 2020, Imperatore et al. 2019). Additionally, it would be preferable to continue the corrosion process until the formation of longitudinal corrosion cracks as these may be the fundamental indicator of loss of bond due to corrosion, as also suggested by Mak and Lees (2021).

3.4 *Discussion of the results*

The third column in Table 1 provides the ratio between the experimentally determined ultimate load P_u and the value $P_{assessment}$ determined in accordance with CS455 (2020).

As shown in Table 1 all the beams with plain bars underperformed compared to the expected maximum load calculated in accordance with CS455 (2020), reaching 50% to 70% of the expected load. Preliminary analysis of the results provided in Tables 1 & 2 indicates that bond strength and the resulting bond force that can be resisted by the anchored bars (F_{ub}) offers the most significant influence on the mode of failure. Specimens that experienced flexural failure were those for which bond characteristics were poorer or the maximum bond force (F_{ub}) was smaller. For example, specimen B4p12L3ds, which failed in shear, had a longer anchorage length of 12 bar dia, compared to B4p6L2ds which had a 6 bar. dia. anchorage, and hence able to develop a higher bond force, but also showed a slightly better bond behaviour during the slipping operations as it can be seen in Table 2. The fact that bond characteristics of longitudinal reinforcement have a significant influence on the shear resistance is also confirmed in the Fib Bulletin 85 as shown in the study performed by Muttoni et al. (2018).

Further comparison of the results shown in Tables 1 and 2, indicates that pre-slipping the main reinforcement in the anchorage zone has little impact on the overall shear capacity of the beam element.

It is hypothesized that the confining effect provided by the support reaction may enhance the bond characteristics at and near support partially or fully restoring the residual bond strength for pre-slipped anchorages. The impact of this confining effect may be more significant for plain bars for which the residual bond strength is significantly lower than the peak. Deformed bars did not show a significant descending branch of the bond-slip curve, so the post slip bond stress remains approximately constant, at least for the range of pre-slip applied.

An alternative hypothesis is that the small amounts of prior slip used in the pre-slipping operations, typically in the range of 2mm, do not have a severe effect on the resistance of the beam. It is recommended that the effect of prior slip should be investigated further in the next phases of the testing.

From the load-deflection plots presented in Figure 4 and Figure 5, it is clear how the specimens with deformed bars reach the peak load at higher values of deflection. Additionally, from the correspondent load-slip plots recorded during the 3-point load tests, it was possible to notice that for specimens with stirrups the slip reaches higher values for plain bars for a given value of the deflection if compared to beams with deformed bars.

The last two columns of Table 1indicate the value of the external load at which initial slip happened in the main reinforcement (P_{slip}) and the value of the slip correspondent to the peak external load (s_u). All the specimens with links with either deformed or plain bars, slipped or not, corroded or not, experienced slip of the main reinforcement prior to reaching the ultimate load. On the other hand, although all the three specimens without links (i.e., B1 section type) reached the peak load (P_u) without signs of slip in the main reinforcement, this happened almost concurrently with the shear failure and in a sudden manner, in line with the typical behaviour of unconfined bars subject to tension.

The load-deflection plots of Figure 4 and Figure 5 also highlight a different stiffness of the various specimens. In Figure 5 for example, the stiffness of B4p6L2ds may be slightly higher than the other three specimens because it has been tested at 2d instead of 3d. From Figure 4, the stiffer response is provided by B4d6L3ds (so a pre-slipped specimen) which also presents

an f_{cu} of 37.7MPa hence approximately 30% higher than the correspondent non slipped specimen (B4d6L3d). On the other hand, for the two specimens with a lower density of the links (B4.1d6L3d and B4.1d6L3ds), the non-slipped one provides a stiffer response despite f_{cu} being 30% lower. As a consequence, it is difficult to draw conclusions on whether or not the prior slip has an influence on the response of the beam as well as if the behaviour is due to the concrete elastic modulus or to slight differences that occurred during the setting up of the test.

4 CONCLUSIONS

From the results obtained it is possible to draw some initial conclusions on some of the main parameters investigated.

The effect of prior anchorage slip in the beams tested, seems to have negligible to no effect on the shear resistance. It is possible that the pressure exerted by the support when the beam is loaded has a significant influence on enhancing the bond behaviour of reinforcement affected by prior slip. This is evidenced by the results obtained for the peak resistances during the 3-points load tests. This requires further investigation.

The beams with plain bars, offer a very low resistance to failure, due to premature slip of the bars at low stress levels, resulting in bond/flexural failures. The surface roughness of plain bars has a significant impact on the bond strength and as a direct consequence on the overall resistance of the beam and on its failure mode and warrant further investigation.

The accelerated corrosion methodology adopted did not provide the target value mass losses expected. A combination of factors including the formation of unexpected corrosion cells and a delay in the start of the corrosion of the main reinforcement, may have been attributed to this finding. For these reasons, in the next testing phases, the concrete end parts will be conditioned in salt water for a period of time (likely in the range of 5-7 days due to time constraints) prior to starting the accelerated corrosion.

ACKNOWLEDGEMENTS

The authors of the paper would like to thank National Highways for sponsoring the research project on the realistic shear assessment of reinforced concrete bridges and WSP and the University of Bath to support the research project. Special thanks also to the technicians William Bazeley and Angus Tillotson of the Structures Laboratory at the Department of Architecture and Civil Engineering of the University of Bath whose contribution for setting up and carrying out the tests has been fundamental.

Deep learning for evaluation of girder rotation during bridge deck construction

Li Hui

ABSTRACT: During bridge deck construction, overhang brackets are commonly utilized to resist the weight of fresh concrete and the loads from heavy construction equipment. These loads transfer through the overhang bracket to the bridge's girder system, resulting in significant torsional moments, particularly on the exterior girder. Under certain circumstances, such torsional moments have been observed to induce excessive transverse rotation in bridge exterior girders. This rotation can potentially give rise to safety and maintenance concerns throughout the entire bridge's service life. A detailed finite element analysis is typically recommended to mitigate these isto evaluate torsional effects on bridge girders during deck construction. However, this analysis, though thorough and comprehensive, can be tedious and time-consuming. In this study, several deep-learning models were developed to accurately predict the maximum rotation of the exterior girder. Over 10,000 finite element models were generated using SAP2000 to gather enough data to develop these deep learning models. The accuracy of these deep learning models was also scrutinized and compared. The results suggest that deep learning-based prediction models can effectively and efficiently assess the rotation of the exterior girder during bridge deck construction, thereby providing a powerful tool for engineers and construction professionals in the bridge design and construction field.

1 INSTRUCTION

In bridge construction across the United States, it is common practice to distribute a series of girders evenly beneath the deck slab to manage costs effectively (J.D. Fasl, 2008). These girders are evenly spaced, and the bridge's deck slab extends beyond the outer girders, forming a cantilevered overhang. As shown in Figure 1, the construction of bridge decks often incorporates overhang brackets. These brackets provide the necessary support for the formwork, the weight of the fresh concrete, and the load imposed by construction machinery like deck finishing machines, which span the bridge's full width (shown in Figure 2). The force introduced by these machines, especially at the edges of the overhangs, can cause considerable torsional moments and excessive rotation in the exterior girders (Ashiquzzaman et al., 2016; Clifton and Bayrak, 2008; Yang et al., 2009). Figure 3 shows the exterior girder rotation during bridge deck construction. If not properly managed, this can lead to significant safety and maintenance challenges, including uneven deck thickness and compromised stability, which could precipitate a bridge collapse during both construction and use (Ashiquzzaman et al., 2021; Hraib et al., 2019; Hui et al., 2019a, 2019b).

To mitigate these risks, state transportation departments in the U.S. have established guidelines for the maximum permissible width of the overhang to control the transverse rotation of bridge girders during deck construction. For instance, Illinois sets limits on girder rotation by specifying the maximum deflection of the overhang (Illinois Department of Transportation,

DOI: 10.1201/9781003483755-449

2012). Kansas dictates that the girder rotation must not exceed one degree during construction and that the overhang width should be determined according to the torsional forces applied to the girder (Roddis et al., 1999). Methods to limit girder rotation include implementing both permanent and temporary lateral bracing systems, which can compromise their intended function (Ashiquzzaman et al., 2016; Faress Hraib, 2020). However, these temporary rotation prevention systems are often installed during the bridge deck construction phase without thorough analysis, sometimes diminishing their effectiveness (Hui et al., 2019b).

Figure 1. Overhang bracket during bridge deck construction.

Figure 2. Bridge deck finishing machine.

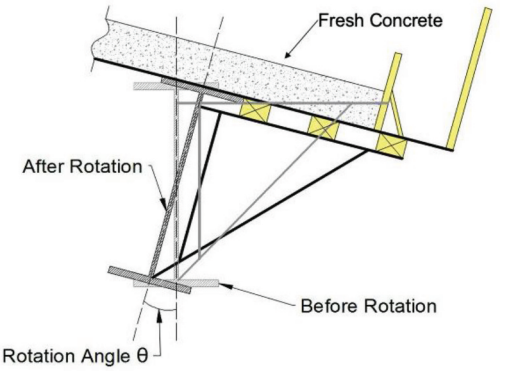

Figure 3. Exterior girder rotation during bridge deck construction.

One of the most significant and complex challenges in designing lateral bracing systems for bridges is the precise prediction of girder rotation. This aspect of bridge engineering is critical, as inaccuracies in predicting girder rotation can lead to substantial structural inefficiencies, which may manifest as compromised durability or even pose safety risks. The AASHTO LRFD Bridge Design Specifications provide a framework for this analysis, recommending the use of sophisticated 3-D finite element analysis (FEA) techniques (American Association of State Highway and Transportation Officials, 2017). These techniques are crucial for a detailed examination of the torsional effects that can arise, particularly from the loads imposed by overhang brackets during construction. Nonetheless, the process of conducting finite element (FE) analysis is complex, involving intricate modeling that demands considerable time and effort, and necessitates a thorough understanding of numerical simulation principles.

In recent years, deep learning applications have surged in civil engineering, with research utilizing these methods for predicting various structural behaviors, such as concrete strength and member deflection. Dutta and Barai conducted research to predict concrete compressive strength using artificial neural networks (Dutta and Barai, 2019). Besides, several researchers used deep learning to predict the deflection of structural members. Tadesse et al. successfully predicted the middle-span displacement of six composite bridges by using a deep learning model, which was developed using data generated from computer simulation and experimental results (Tadesse et al., 2012). However, no study has been conducted to evaluate the bridge torsional behaviors using the deep learning algorithm, and the applications for assessing bridge torsional responses remain unexplored.

This study aims to develop a deep-learning model to forecast the maximum rotation of exterior bridge girders during deck construction. A substantial dataset for model training was generated through finite element analysis using a MATLAB program created for this research. Feature selection techniques were employed to refine the variables and avoid overfitting, ultimately selecting five key bridge geometry parameters to predict girder rotation through an artificial neural network model.

2 FINITE ELEMENT MODELING AND DATA GENERATION

2.1 *Finite element modeling*

To develop a comprehensive dataset for the training of the deep learning model, finite element (FE) analysis was undertaken utilizing the SAP2000 software suite. The FE models were validated in previous research (Hui et al., 2019b). An example of such a model, which is instrumental for data generation, is shown in Figure 4. Given that the rotation of the exterior girders is affected by many factors, the development of the FE models took into account a variety of parameters, including construction loads, material properties, and the intricacies of bridge design.

During bridge deck construction, it is a common practice to employ a deck finishing machine to ensure the deck's surface is both even and smooth. Typically, this machinery is maneuvered along the edge of the overhang formwork, spanning the full width of the bridge, thereby exerting substantial loads on the overhang of the bridge. For the purposes of this study, a standard Bidwell-3600 deck finishing machine was utilized as the basis. Consequently, the force exerted by the finishing machine is modeled as discrete concentrated loads, with each wheel imparting a load of 3,336 N (750 lbs.).

Given that the concrete deck lacks the rigidity to contribute to structural support during construction, it is modeled in the FE simulations as a series of distributed loads along the length of the bridge girders. Table 1 consolidates the fundamental considerations of the loads and material properties that are typically accounted for in the construction of bridge decks.

2.2 *Data generation*

In determining the variables that influence the rotation of exterior girders during the construction of bridge decks, several parameters were identified for initial consideration. These include

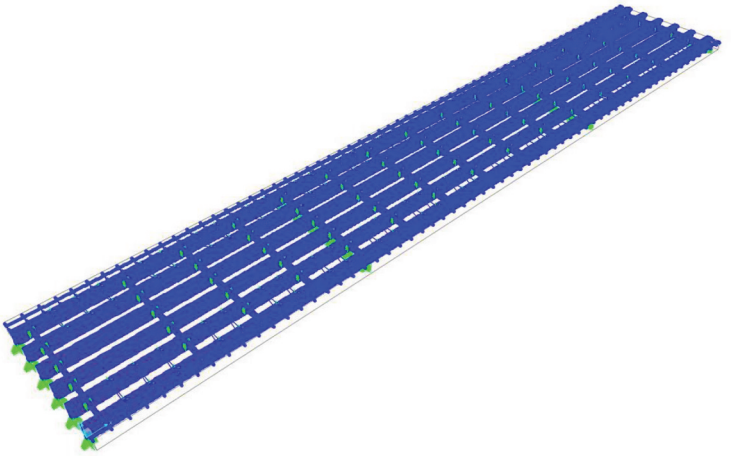

Figure 4. Typical finite element model for data generation.

Table 1. Material properties and loads during bridge deck construction.

Items	Values
Deck Thickness	20.32 cm (8 in)
Concrete Unit Weight	23.56 kN/m^3 (150 lb/ft^3)
Deck Finishing Machine Loads	3,336 N (750 lb) per wheel
Elastic Modulus of Steel	200 GPa (29,000 ksi)
Elastic Modulus of Concrete	26.43 GPa (3,834 ksi)

the span length of the bridge, the cross-sectional profile of the girders, the distance between girders, the width of the deck overhang, the total number of girders used, and the specifications of the diaphragms. According to the data presented in Table 2, the selection of girder sections was guided by the ASIC section database (American Institute of Steel Construction, 2017), encompassing a variety from W27 to W44. Span lengths were considered within a scope extending from 9.14 m (30 ft) to 33.53 m (110 ft) and included diaphragms spaced no less than 3 m (10 ft) apart. The parameters for overhang width and girder spacing were determined by guidelines from the Illinois Bridge Manual, which advises that the width of the overhang should not exceed half the distance of the girder spacing. The inclusion of additional parameters followed recommendations from the Illinois Bridge Manual alongside established general design practices.

Table 2. Geometric parameters for data generation.

Parameters	Ranges
Girder Depth	W27 to W44
Diaphragm Section	W12 to W21
Span	9.14 m to 33.53 m (30 ft to 110 ft)
Girder Spacing	1.8 m to 3 m (6 ft to 10 ft)
Overhang	36.8 cm to 118.9 cm (14.5 in to 46.8 in)
Number of Girders	3 to 6
Number of Diaphragms	2 to 10
Slab Thickness	8
Concrete Unit Weight	23.56 kN/m^3 (150 lb/ft^3)
Elastic Modulus of Steel	200 GPa (29,000 ksi)
Skew	0

Utilizing the input parameters, a computer program was developed to automatically generate the FE models. This program calculates and assembles essential data points such as nodal coordinates, element configurations, material characteristics, cross-sectional dimensions, and boundary conditions. This compiled data is then formatted into an input file compatible with the SAP2000 structural analysis program. The integration between MATLAB and SAP2000 is facilitated by using SAP2000's application programming interface (API) functions, which allow for the seamless transfer of FE analysis results back into MATLAB for further processing.

A comprehensive set of 10,267 finite element (FE) models was constructed using the computer program developed in this study. Each model documented an array of bridge parameters along with their corresponding maximum girder rotation values for subsequent analysis. The physical properties of the girder and diaphragm sections were assessed based on section depth and weight, ensuring consistency with structural norms. In addition, based on the findings of recent research by Ashiquzzaman et. al. in 2021 (Ashiquzzaman et al., 2021), which highlighted the ratio of the braced length to the girder depth (B/D ratio) as a critical factor in gauging exterior girder rotation, the B/D ratio was incorporated into the dataset for each bridge model. The range of the B/D ratio spanned from 2.7 to 11.1, exhibiting consistent mean and median values, thereby providing a reliable basis for evaluation.

2.3 *Feature selection*

Eight dependent variables were identified for potential inclusion in the preliminary stages of developing the deep learning model. However, incorporating extraneous predictors can often contaminate the model with noise, muddling the estimation of truly impactful variables and potentially leading to an overfitting issue. Overfitting is characterized by the model's excessive acclimation to the training data, to the extent that it impairs its generality and performance on new datasets.

To circumvent the inclusion of such redundant predictors and to distill the subset that would enable the most effective deep learning model, a comprehensive feature selection process was undertaken. This process was conducted by assessing correlation metrics to determine the statistical significance of each variable, thereby identifying the subset that most accurately conforms to the regression model's requirements. Furthermore, the study acknowledged the nonlinear correlations between the desired rotation outcomes and the bridge's geometric configurations. To navigate this, logarithmic transformations were applied—but only to the rotation values—to preserve the model's straightforwardness and operational efficiency.

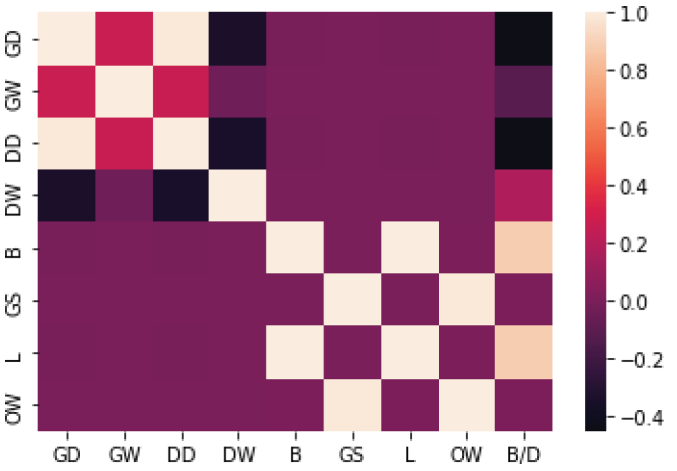

Figure 5. Correlation heatmap.

As detailed in Figure 5, the analysis of correlation among all variables led to the exclusion of four variables—namely diaphragm depth, girder spacing, span length, and unbraced length—from the final selection. These variables were highly related to other variables and thus were not carried forward into the deep learning modeling phase.

2.4 *Deep learning model*

The architecture of the artificial neural network (ANN)—a prevalent form of artificial intelligence in predictive modeling—was selected for developing this deep learning model. To ensure the model operates at peak efficiency, the dataset underwent a standard normalization process as a preliminary step, which scales the data to a common range without distorting differences in the ranges of values. Subsequently, the dataset was divided into two distinct subsets for training and testing purposes. The training subset was instrumental in developing the ANN model, serving as the basis upon which the model learned to make predictions. Meanwhile, the testing subset was essential for evaluating the model's accuracy and reliability in predicting unseen data.

The ANN architecture designed for this study is shown in Figure 6. It features a network with five input nodes corresponding to the input parameters, two hidden layers—each consisting of 64 nodes to capture complex patterns and relationships within the data—and a singular output layer that yields the predicted value of girder rotation. This structured approach to the ANN design facilitates a robust learning process, enabling the model to accurately capture the intricate dynamics governing bridge construction.

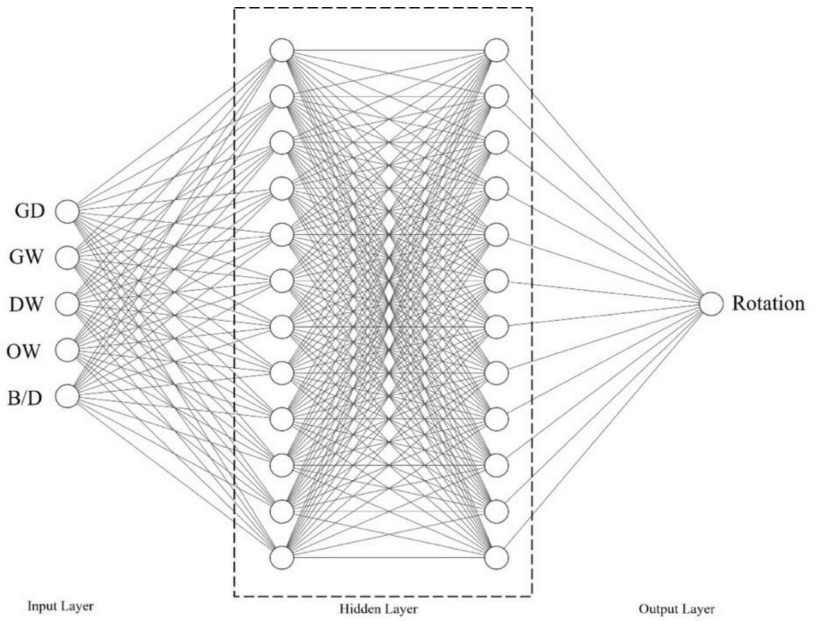

Figure 6. ANN deep learning model.

The performance of the ANN model was quantitatively assessed using mean square error (MSE) and the coefficient of determination (R^2). For the evaluation, the dataset was randomly split into a training set, comprising 80% of the data to train the model, and a testing set, constituting the remaining 20% to test its predictive accuracy. After training over fifty epochs, the ANN model demonstrated a minimum MSE of 0.008 and an R^2 value of 94% for the training set, indicating high accuracy and a strong ability to predict girder rotation. These metrics were mirrored closely by the testing set results, confirming the model's robust performance and generalization capabilities. Figure 7 shows the MSE during the ANN training process.

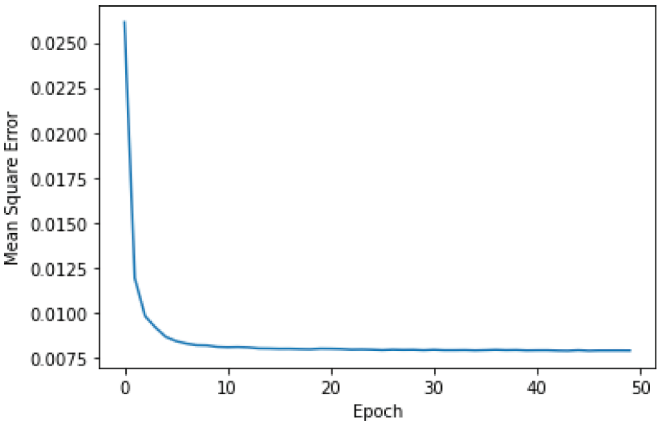

Figure 7. Mean Square Error (MSE) over ANN trainingBottom of form.

3 VALIDATION

The accuracy of the deep learning model developed for this research was evaluated through comparisons with results from FE analysis. One bridge in Illinois was chosen as a case study to test the accuracy of the artificial neural network (ANN) model. This bridge incorporated W30×124 wide flange beam sections for the girders and W12×25 sections for the diaphragms, with an overhang width of 94 cm (37 in) and a maximum braced length of around 6 m (20 ft). The bridge uses pipe-tie systems as the rotation prevention system during construction, resulting in the bridge's B/D ratio of 3.75. The detailed bridge parameters that will be used in the ANN model are shown in Table 3.

Table 3. Bridge configuration for ANN model validation

Item	Value
Girder depth	76.2 cm (30 in)
Girder weight	168 N/m (124 lb/ft)
Diaphragm weight	34 N/m (25 lb/ft)
Overhang width	94 cm (37 in)
B/D Ratio	3.75

The comparison result is shown in Table 4. The FE result indicated a maximum rotation value of 0.208 degrees at the mid-span location. The ANN model shows a very similar value compared with the field data. The results demonstrated that the ANN model developed in this study can accurately predict the maximum exterior girder rotation during bridge deck construction, with a difference of less than 1% for the selected bridge.

Table 4. Comparison of maximum rotation between FE and ANN models

	FE Model	ANN Model
Maximum Rotation	0.2080	0.2096

4 CONCLUSION

The essence of this research was to forge a deep learning model adept at forecasting the maximum rotation of exterior girders during the construction phase of bridge decks. In pursuit of

this goal, an extensive dataset consisting of over 10,000 finite element (FE) models was generated. The complexity of the model was streamlined through feature selection, leveraging P-Values and Pearson's correlation coefficients to mitigate overfitting. The selected parameters for the artificial neural network (ANN) model included girder depth, girder weight, diaphragm weight, overhang width, and the B/D ratio. Validation was performed using field-monitored data from a bridge located in Illinois, and the findings corroborated the model's ability to estimate the maximum exterior girder rotation precisely, bypassing the need for intricate FE modeling. The following conclusion can be drawn based on the findings of this study:

- The B/D ratio emerged as a robust predictor, allowing for the omission of braced length in analyses.
- The conventional weights of the girders, diaphragms, and the overhang width were identified as significant factors influencing exterior girder rotation.
- Variables such as diaphragm depth, girder spacing, and span length were deemed to have minimal effect.
- Consequently, the ANN model devised herein is a potent tool, enabling bridge engineers to assess girder rotation with greater efficacy and expedience.

ABSTRACT: Railway noise barriers should provide excellent sound insulation and sufficient load-bearing capacity. High-speed railway noise barriers experience significant and transient aerodynamic loads from passing trains, resulting in noticeable dynamic responses. In this study, three simplified load models were applied to a noise barrier to compare the dynamic responses to those obtained under a reference load from cfd simulations. Results show that the natural frequency of target noise barriers exceeds 10 hz, significantly surpassing the excitation frequency of the train-induced aerodynamic load, thereby minimizing the likelihood of resonance. The displacement or stress evolution closely correlates with the variation in pressure over time. Along the longitudinal direction of the noise barrier, the stress range initially increases, stabilizes, and eventually decreases, reaching its maximum at the penultimate post. Compared to the two simplified rectangular load models, the triangular load model with a distribution load length of 12 m better represents the detailed time-varying aerodynamic load.

1 INTRODUCTION

Railway noise barriers are essential infrastructure in mitigating noise generated by passing trains, particularly along high-speed railway (HSR) lines. The rapid development of HSR and the increase in train speed not only contribute to the increase in railway noise pollution (King, 1996), but also amplify the train-induced aerodynamic effects (Baker, 2010). Hence, besides offering good sound insulation, railway noise barriers must also be able to withstand the external aerodynamic forces generated by passing trains. The rapid shift of train-induced aerodynamic load, from positive to negative pressure in a short period of time, induces a strong dynamic response on the noise barrier alongside the tracks (Zbieć, 2021). Consequently, it becomes necessary to analyze the dynamic behaviors of noise barriers under train-induced aerodynamic loads.

The speed of the train plays a crucial role in influencing the dynamic responses of noise barriers. At speeds below 200 km/h, the impact of train-induced aerodynamic load on the dynamic behavior of noise barriers is limited. However, as train speeds increase, particularly for tall concrete noise barriers with low natural frequencies (approximately 3 – 5 Hz), the maximum strain response escalates significantly. This increase is attributed to the coupling effect of resonance and tail pulse overlap (Tokunaga et al., 2016). A reduction in the distance between the noise barrier and the track center also amplifies the dynamic response of the noise barrier. However, the extent of increase in dynamic response is greater than that of the

DOI: 10.1201/9781003483755-450

pressure magnitude acting on the noise barrier (Olaszek et al., 2020). Additionally, Luo et al. (2016) highlighted that increasing the distance between steel posts significantly intensifies the dynamic responses of noise barriers, resulting in multiple peak values and affecting the overall structural stability of the noise barrier.

In addition, the distribution of train-induced aerodynamic loads also affects the dynamic responses of railway noise barriers. Various calculation models exist for train-induced aerodynamic loads on vertical noise barriers. For instance, the Eurocode EN 14067-4 (CEN European Standard, 2013) offers a rectangular load model with a width of 5 m, while Tokunaga et al. (2016) proposed a triangular load model. Sturt et al. (2022) recommended an adjustment to the Eurocode load model, suggesting an increase in the along-track length of pressure pulses to 12.5 m to align closer with real load curves. Therefore, based on a finite element analysis (FEA) conducted using Abaqus® commercial software, this study compares the dynamic responses under three load models with those obtained from the detailed load curve derived in computational fluid dynamics (CFD) simulations. The purpose is to evaluate the effect of the distribution shape of train-induced aerodynamic load on the dynamic behavior of noise barriers and to determine a simplified load model that can effectively represent the detailed aerodynamic load.

2 FINITE ELEMENT MODELING

2.1 *Railway noise barrier model*

In Sweden, the most common type of railway noise barrier is the steel-post wood-panel structure, depicted in Figure 1. The wooden panels, with an average thickness of 104 mm, are attached to

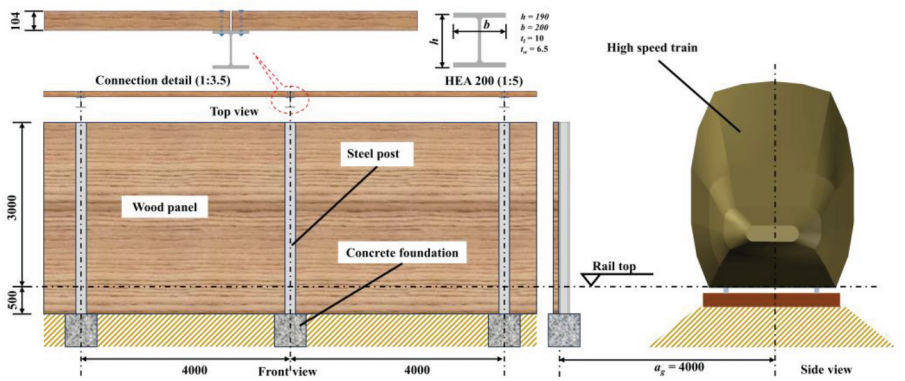

Figure 1. Typical Swedish steel-post wood-panel noise barrier (unit: mm).

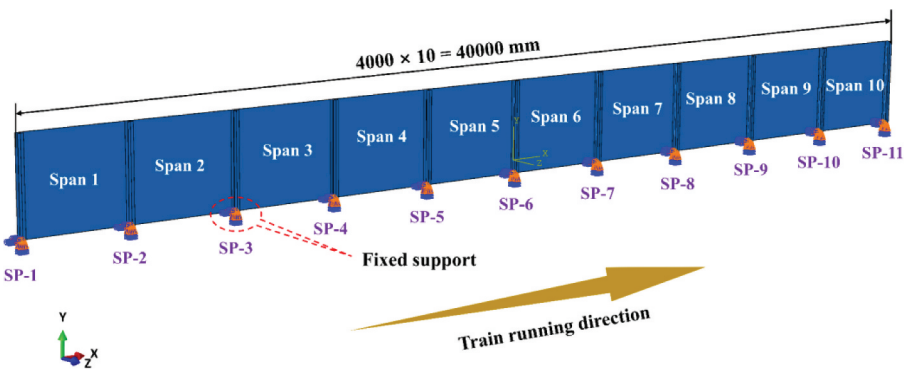

Figure 2. Three-dimensional model of steel-post wood-panel noise barrier in FEA.

Table 1. Material properties of noise barriers.

Components	Materials	Density (kg/m^3)	Elastic modulus (GPa)	Possion's ratio
HEA 200 post	Carbon steel	7850	200	0.29
Wood panel	Larch	500	10	0.40

the steel posts using extended stem bolts. These steel posts are HEA 200 with the cross-sectional dimensions shown in Figure 1, and the wood panels are made of finely sawn larch; their material properties are shown in Table 1. The 3D model employed for FEA is shown in Figure 2. In this study, the target noise barrier spans 40 m, with steel posts placed at 4-m intervals. The assumption made is that the steel posts are securely anchored to the concrete foundations.

2.2 *Train-induced aerodynamic load*

The aerodynamic load induced by passing trains on noise barriers depends on several factors, such as the distance between the noise barrier and the track centre, the speed and type of the high-speed train, etc. In this study, the scenario assumes that the SJ high-speed train X2000 in Sweden is traveling at 80 m/s (288 km/h), passing a 40-m-long single-side noise barrier situated 4 m from the track centre. The train itself is 50 meters in length.

The results obtained from the preliminary CFD simulations indicate that the maximum aerodynamic pressure corresponds to a positive pressure equal to 432 Pa observed at the train nose. The load-time varying curve derived from the CFD simulation is presented in Figure 3-(a). It should be noted that some minor pressure variations at the connections between carriages were not accounted for due to the simplification of the train model in CFD simulations. Therefore, the pressure in the middle train carriages was assumed to be zero.

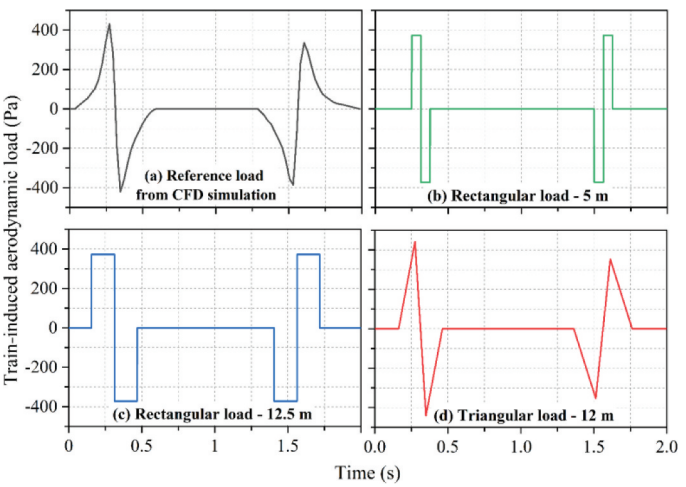

Figure 3. Four time-varying aerodynamic load curves used in this study.

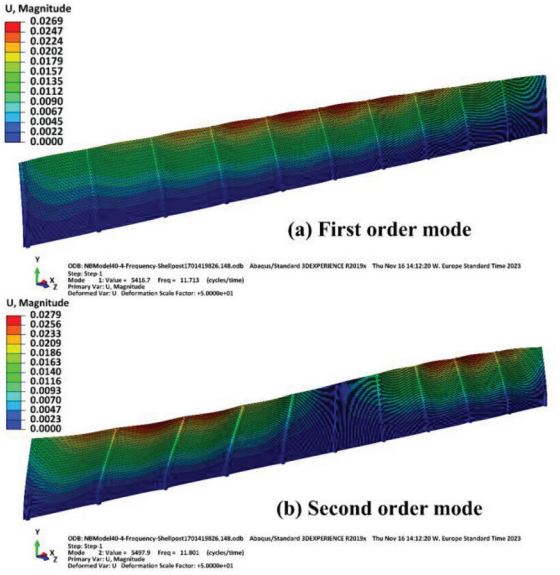
Two rectangular load forms were used with a peak pressure of 373 Pa, calculated using the Eurocode load calculation model, as shown in Equation (1) (CEN European Standard, 2013). This value is lower than the pressure value obtained from CFD simulations, indicating that the Eurocode calculation underestimates the aerodynamic load caused by the SJ high-speed train X2000.

$$P = 0.5 \times \rho \times \mathrm{v}_{\mathrm{tr}}^2 \times k_1 \times \left(\left(2.5/\left(a_g + 0.25\right)^2 \right) + 0.02 \right) \quad (1)$$

where P is the aerodynamic load (MPa); ρ is the air density, 1.225 kg/m^3; v_{tr} is the train speed (m/s); k_1 is the shape coefficient of the train, which is 0.6 for high-speed train; a_{g} is the distance to the track center (m). The peak pressure at the train tail is considered equivalent to that at

the train nose. The main difference between the two rectangular load models lies in the length of load distribution, with the one being 5 m and another one being 12.5 m, as shown in Figure 3(b) and (c). The last one, as shown in Figure 3(d), adopts a triangular load shape with a distribution length of 12 m, as described in Tokunaga et al. (2016). In this triangular model, the maximum load corresponds to the peak value at the train nose obtained from CFD simulations. However, the peak pressure at the train tail amounts to 80% of that at the train nose. Across the three simplified models, each negative pressure peak corresponds to the peak value of the corresponding positive pressure peak. All models considered pressure reduction in the vertical direction, utilizing the pressure height coefficient depicted in Equation (2).

$$C_z = 10.5 \times (z/h)^3 \tag{2}$$



where C_z is the pressure height coefficient; z is the elevation (m); and h is the height of the noise barrier above the rail top (m). The comparison of the four different load models is shown in Figure 3. It is important to note that the aerodynamic load derived from the CFD simulations serves as the reference load model for evaluating the impact of load distribution shapes on dynamic results.

2.3 *Dynamic analysis*

The implicit dynamics analysis method was used to obtain the dynamic responses of the noise barrier under train-induced aerodynamic load. The spatial and temporal distribution of aerodynamic loads on the noise barrier was considered when inputting the loads. The total analysis duration is 4 s, with a time step of 0.000625 s. Shell elements were used for both the steel posts and the wood barrier panels, assuming full connectivity between them. Rayleigh damping coefficients were determined using the first two natural frequencies, as shown in Equations (3) and (4) (Huang et al., 2022).

$$\alpha = 2 \times \xi \times \frac{\omega_1 \omega_2}{\omega_1 + \omega_2} \tag{3}$$

$$\beta = 2 \times \xi \times \frac{1}{\omega_1 + \omega_2} \tag{4}$$

(c) The first ten natural frequencies of noise barriers

Order	Frequency (Hz)
1	11.713
2	11.801
3	11.980
4	12.276
5	12.707
6	13.274

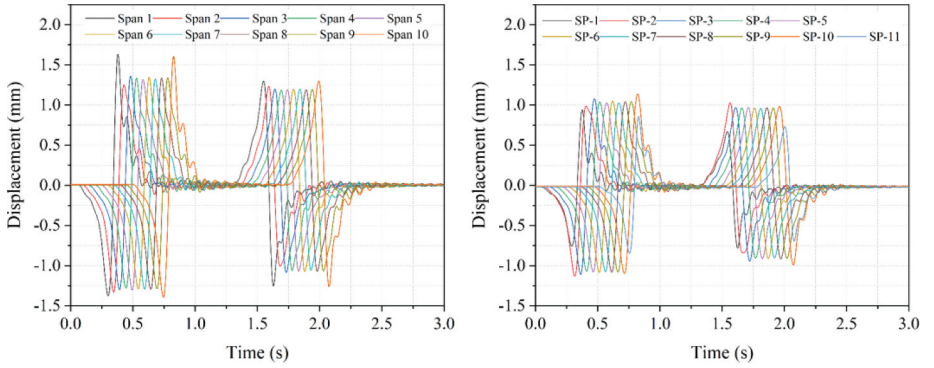
where, α and β are the Rayleigh damping coefficients; ξ is the damping ratio, which is 1% in this study (Tokunaga et al. 2016); ω_1 and ω_1 are the first two natural frequencies.

3 RESULTS AND DISCUSSIONS



3.1 *Mode analysis of noise barrier*

Before conducting the dynamic analysis, a frequency analysis of the noise barrier was initially performed. This was aimed to assess the potential for resonance effects by comparing the natural frequency with the excitation frequency of the train-induced aerodynamic loads. As illustrated in Figure 4, the first natural frequency measures 11.713 Hz, which is significantly higher than the excitation frequency of train-induced aerodynamic loads, generally remaining below 5 Hz (Liu et al., 2023). Consequently, this indicates that resonance effects are unlikely to occur within this noise barrier structure. Moreover, based on the results of the first two natural frequencies, two Rayleigh damping coefficients for use in the Finite Element Method (FEM) dynamic analysis were determined: 0.1176 and 0.0008, respectively, using Equations (3) and (4).

3.2 *Dynamic responses of noise barrier*

The dynamic responses of the noise barrier under train-induced aerodynamic load (reference load) – including displacement and stress – are shown in Figure 5 and Figure 6. In Figure 5(a), the graph shows the time-varying displacement at the top of the mid-span of each noise barrier panel (Span 1 to 10). The evolution of displacement over time closely mirrors the pressure variation illustrated in Figure 3. The prominent peaks in displacement coincide with the passage of the train's nose and tail through the noise barriers. Damping property of the structure causes the amplitude of dynamic responses to gradually decrease after the train's nose passes, resulting in minimal response fluctuations as the middle car passes through the noise barrier.

The noise barrier panel experiences the greatest displacement at the mid-span of the two end panels, while the displacement at the mid-span of the middle panels does not show a significant difference. This is attributed to the fact that the two end panels are less constrained than the middle panels. Due to their greater stiffness compared to the barrier panels, the displacement at the top of each steel post (SP1 – 11) is smaller than that of the barrier panels, as illustrated in Figure 5(b). Furthermore, in comparison to the middle steel posts, the two end steel posts experience less displacement. Along the longitudinal direction of the noise barrier, the displacement response peaks at the penultimate post. Under the train-induced aerodynamic load, the highest stress is observed at the base of the steel post. Figure 6 illustrates the stress time history for different steel posts. Like the displacement, a notable stress peak occurs as the train's nose

(a) At the mid-span of the wood panels (b) At the top of the steel posts

Figure 5. Displacement time history of noise barrier.

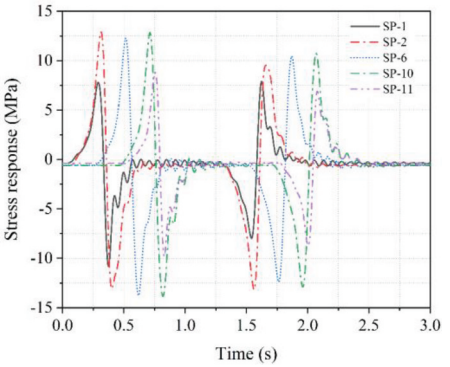


Figure 6. Stress time history at the steel posts of noise barrier.

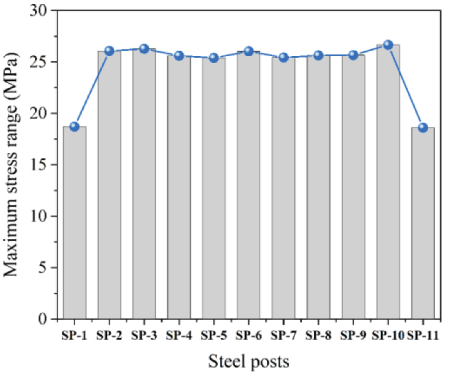

Figure 7. Maximum stress range at the steel posts of noise barrier.

and tail pass through the steel posts. Along the longitudinal direction of the noise barrier, the stress range (i.e., the difference between the maximum and minimum stress), initially increases, stabilizes for a period, and then gradually decreases, as shown in Figure 7. The maximum stress peak among these steel posts is found at the penultimate post.

3.3 *Comparison of dynamic response under different load forms*

The differences in the dynamic responses of noise barriers under the three simplified load models, in comparison to the reference load, are illustrated in Figure 8 and Figure 9. The two rectangular load models induce higher displacement responses at the mid-span of barrier panel Span-5, in contrast to the reference load. Specifically, both rectangular load models with load distribution lengths of 5 m and 12.5 m increase the peak values by 9.28% and 12.31%, respectively, as shown in Table 2. Furthermore, the longer distribution length of the rectangular load with a load distribution length of 12.5 m prolongs the zone of high displacement response. Because it is assumed that the magnitude of the load at the train tail for the two rectangular load models is equal to that of the train nose, the maximum displacement caused by tail wave notably increases. In practical scenarios, the pressure magnitude at the train tail is generally lower than at the train nose. Interestingly, the rectangular load model with a load distribution length of 5 m decreases the stress magnitude at the bottom of the steel post – SP-6. This is because the total moment caused by the rectangular load with a length of 5 m is smaller than the total moment caused by the reference load. Conversely, the second rectangular load model, with a distribution length of 12.5 m, amplifies the stress peak caused by the nose wave, resulting in a 10.52% deviation in stress range compared to the reference load.

In comparison to the rectangular load models, the simplified triangular load more accurately represents the reference load. Table 2 shows that the absolute relative errors for five indicators between the triangular load and the reference load are all below 5%. However, this load model results in a slight decrease in the dynamic responses of the noise barrier. This could be attributed to the shorter length of load distribution in the simplified triangular load model, which is smaller than the actual load distribution length.

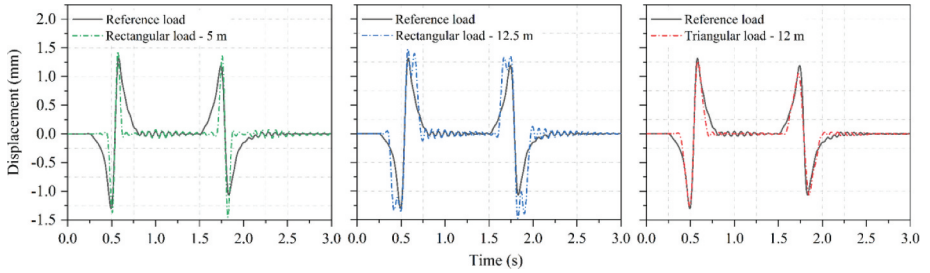

Figure 8. Comparison in displacement time history of Span-5 between different load forms.

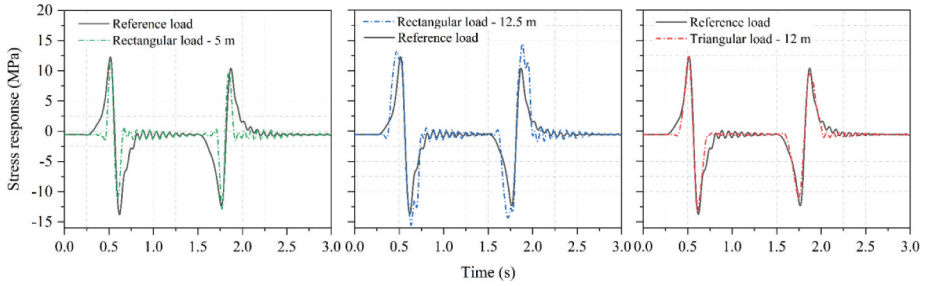

Figure 9. Comparison in stress time history of SP-6 between different load forms.

* Relative error with the value of reference load.

4 CONCLUSIONS

This study conducts a dynamic analysis of high-speed railway noise barriers under train-induced aerodynamic loads using the FEA method. Four distinct load models were employed to investigate the influence of load distribution form on dynamic responses, leading to the following conclusions:

(1) Frequency analysis revealed that the natural frequency of the target noise barrier—steel-post wood-panel noise barrier—is significantly higher than the excitation frequency of train-induced aerodynamic loads, indicating a low likelihood of resonance effects.
(2) The temporal changes in displacement and stress in the noise barrier correspond to the variation in aerodynamic load over time. In the longitudinal direction, stress peaks at the bottom of steel posts initially increase, exhibit minor fluctuations among the middle posts, and eventually decrease, reaching a peak at the penultimate post.
(3) Both rectangular load models, one with a distribution length of 5 m and the other with 12.5 m, induce greater displacements at the mid-span of barrier panels compared to the reference load. The 5 m rectangular distribution model reduces the stress range at the bottom of steel column SP-6 with an absolute relative error of 13.39% compared to the results caused by the reference load, whereas the 12.5 m distribution model increases the stress range, showing an absolute relative error of 10.52%. Conversely, the triangular load model with a 12 m distribution length more accurately represents the reference time-varying load curve compared to the simplified rectangular load models. It exhibits absolute relative errors of below 5% for both displacement and stress ranges.

Analytical evaluation of Hybrid Deck Bulb Tee for superstructure replacement

P. Agüero-Barrantes
LanammeUCR, Universidad de Costa Rica, San Pedro, Costa Rica

A. Hain
Civil and Environmental Engineering Department, University of Connecticut, Storrs, USA

ABSTRACT: Around 7.5% of bridges in the United States are considered structurally deficient, and the existing backlog for bridge repair costs has reached $125 billion. Looking ahead, there is a growing demand for the replacement of bridges, along with advancements in construction methods and materials to enhance the longevity of these crucial infrastructure assets. To address the shortcomings of traditional prestressed concrete bridge girders, a new hybrid beam element, the Hybrid Deck Bulb Tee (HDBT) is presented. The HDBT utilizes staged fabrication, in which the bottom flange is cast with Ultra High-Performance Concrete (UHPC) and prestressed prior to casting the web and top flange with High Performance Concrete (HPC). The purpose of this study is to analytically evaluate the structural performance of HDBT elements for bridge structures. Three HDBT bridges were designed following the state-of-the-art criteria in regards of UHPC bridge design.

1 INTRODUCTION

Around 7.5% of bridges in the United States are considered structurally deficient, and the existing backlog for bridge repair costs has reached $125 billion (ASCE, 2023). Looking ahead, there is a growing demand for the replacement of bridges, along with advancements in construction methods and materials to enhance the longevity of these crucial infrastructure assets.

Prestressed concrete beams account for more than 40% of bridges spanning over 10 meters (30 feet) (USDOT, 2023). Despite their widespread use, there have been limited advancements in the design and construction of prestressed concrete structures over the past five decades. One instance is the Decked Bulb Tee (DBT) girder, which has been in use since the 1980s with minimal progress in materials and production techniques (Grace et al, 2015).

The fabrication processes of traditional prestressed concrete girder superstructures present four notable drawbacks (Graybeal & Tanesi, 2007; PCI, 2014; Torres et al, 2020): (1) Durability Concerns: Existing prestressed concrete structures exhibit suboptimal durability when exposed to corrosive environments, as evidenced by the pronounced corrosion observed on in-service bridges. (2) Tensile Stress Generation: Standard fabrication methods for prestressed concrete beams unintentionally generate tensile stress at the endzone or result in bursting forces as a consequential effect. (3) Design Limitations: The current design method is constrained by the maximum allowable tensile stress at the extreme fiber of the top flange near both ends, imposing restrictions on the overall structural design. (4) Camber Variations: Variations in the camber of prestressed concrete beams may necessitate substantial corrective measures in the field, introducing challenges in maintaining uniformity during construction.

Recent advancements in cementitious materials present opportunities for advancing both beam design and fabrication procedures, addressing existing constraints in prestressed concrete bridge beams. Notably, the emergence of Ultra High-Performance Concrete (UHPC)

DOI: 10.1201/9781003483755-451

stands out as a significant breakthrough in cement technology over recent decades. UHPC offers notable improvements in tensile strength, compressive strength, permeability resistance, and overall durability when compared to conventional or High-Performance Concrete (HPC) (Graybeal 2011, 2014). Researchers are actively exploring the performance of bridge girders constructed entirely from UHPC (Binard, 2017; El-Helou & Graybeal, 2019). However, it's worth noting that the production of full UHPC girders using standard fabrication methods does not completely address the previously mentioned issues associated with prestressed beams, such as tension in the top flange and unpredictable camber. Sim et al. (2020) specifically discusses the persistent challenge of unpredictable camber in the design of precast, prestressed UHPC elements. Moreover, the existing body of research on prestressed UHPC girders tends to be predominantly focused on long-span bridges exceeding 76.2 meters (250 feet) (El-Helou & Graybeal, 2019; Sim et al., 2020). This focus, however, may not align with the reality that over 95% of girder bridges in the United States have spans under 45.7 meters (150 feet), according to USDOT (2022). Within this span range, there are over 40,000 girder bridges with superstructures considered in fair condition (rating of 5.0) or structurally deficient (rating 4.0 or below). This large number makes them promising candidates for superstructure replacement, highlighting the potential applicability of UHPC in addressing the maintenance and structural needs of a substantial portion of the existing bridge infrastructure.

Another significant consideration arises when comparing superstructures utilizing prestressed High-Performance Concrete (HPC) girders with steel girder superstructures. HPC girders cannot compete with steel girders in terms of dead load and vertical clearance. Therefore, it is currently not always possible to replace steel girder superstructures with prestressed concrete girders. In response to this challenge and the limitations in traditional prestressed beam fabrication, the Hybrid Deck Bulb Tee (HDBT) emerges as a potential solution. The HDBT, a novel hybrid beam element, undergoes a multi-stage fabrication process. Initially, the bottom flange is cast with Ultra High-Performance Concrete (UHPC) and prestressed. Subsequently, the web and top flange are cast with High-Performance Concrete (HPC). The innovative design of the HDBT introduces several advantages: (A) Staged Fabrication for Camber Control: The staged fabrication process enables precise control over camber and the differential camber between units. This control has the potential to eliminate the need for corrective measures in the field, enhancing efficiency and accuracy during construction. (B) Selective Prestressing: Prestressing is selectively induced in the bottom flange, avoiding the development of tension in the top flange and mitigating the risk of cracking in the end zone. This contributes to the structural integrity and longevity of the superstructure. (C) Cost-Effective Material Allocation: The use of UHPC in critical regions and HPC for the web and flange contributes to cost reduction. This strategic material allocation maximizes the benefits of UHPC where its superior properties are most crucial, while maintaining cost-effectiveness through the use of HPC in less demanding areas.

The introduction of the HDBT represents a promising step forward, addressing not only the challenges associated with steel girder replacement but also offering innovative solutions to enhance performance, durability, and cost-effectiveness in the realm of prestressed concrete bridge construction. This research aims to provide an analytical evaluation for the HDBT to show its feasibility for further analysis and experimentation moving forward. The analytical model accounts for the differences in HPC and UHPC materials such as modulus of elasticity, shrinkage and creep behaviors.

2 CONSTRUCION PROCESS OF THE HDBT

The fabrication of the HDBT involves a staged process, shown below in Figure 1. It includes:

- Assemble UHPC Bottom Flange Form: Begin by assembling the form for the Ultra High-Performance Concrete (UHPC) bottom flange.
- Place Steel Reinforcement and Strands: Strategically place steel reinforcement and strands in a manner that ensures the resultant force aligns with the cross-section centroid of the bottom flange (Figure 1a).

- Apply Tension to Strands: Apply tension to the strands to achieve the desired prestress, a crucial step in reinforcing the structure (Figure 1b).
- Cast and Cure UHPC: Pour and cure the UHPC, creating a robust foundation for the bottom flange (Figure 1c).
- Prepare Top Surface of UHPC: Prep the top surface of the UHPC to establish a strong bond with the subsequently applied High-Performance Concrete (HPC).
- Release Strands in Bottom Flange: Once the specified compressive strength is attained, release the strands in the bottom flange. This induces compression to fortify the UHPC bottom flange.
- Shore the Bottom Flange: As camber is not anticipated, shore the bottom flange to set it to the required profile, ensuring structural uniformity (Figure 1d).
- Assemble Web and Top Flange Form: Proceed to assemble the form for the web and top flange, incorporating crack control reinforcement and deck reinforcement (Figure 1e).
- Cast and Cure HPC: Pour and cure the High-Performance Concrete (HPC) to complete the structure, leveraging the superior properties of HPC in specified areas (Figure 1f).
- Remove Forms: Once the HPC reaches the specified strength, remove the forms, revealing the final Hybrid Deck Bulb Tee (HDBT) structure. For a general view, refer to Figure 2a) below, illustrating the schematic of the completed HDBT element.

This planned process ensures the integration of UHPC and HPC components, optimizing the structural performance and durability of the final prestressed concrete element.

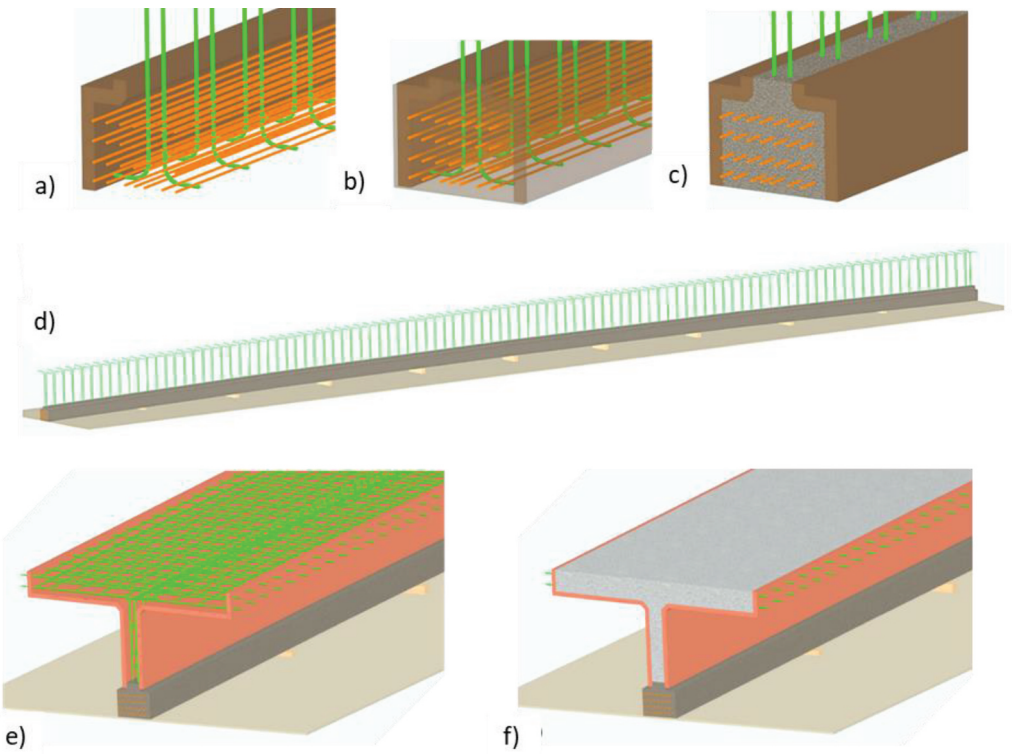

Figure 1. Steps in HDBT fabrication including a) placing reinforcement and strands in form, b) applying tension to strands, and c) casting and curing UHCP bottom flange, d) shoring UHPC bottom flange to set the desired camber, e) assembling forms and placing reinforcement and f) casting the web and top flange with HPC.

3 DESIGN AND ANALYSIS OF THE HDBT

The design process of the HDBT was iterative using CSiBridge (CSI, 2019). An overall view of the completed HDBT is shown in Figure-2a and 2-c. Figure-2b shows a general view of the finite element model. The analysis included all phases of the stage fabrication to capture stress accumulation and strain compatibility between stages. The UHPC bottom flange was modeled with frame elements and included the prestressing strand group that was modeled with a single tendon element with an equivalent area located at the center of gravity of the strand pattern. The HPC web and top flange were modeled with shell elements. The support conditions were defined as a pin-roller condition.

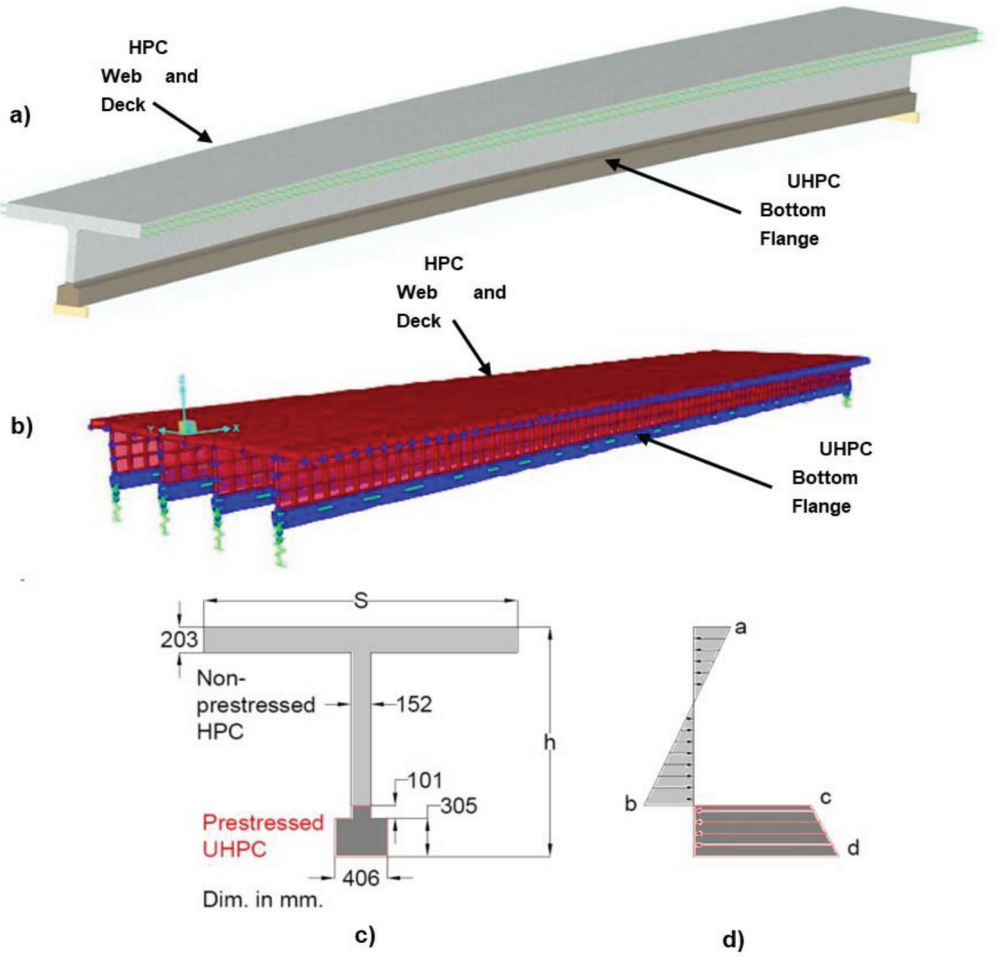

Figure 2. a) Schematic showing final view of HDBT element after form removal; b) 3-D view of model from analysis showing full single span four-beam bridge with HDBT elements; c) interior HDBT beam dimensions shown in millimeters; and d) corresponding flexural stress distribution for service loads.

Strength assessments were conducted utilizing standard design properties for HPC. The moment capacity was established in compliance with the AASHTO LRFD Bridge Design Specifications Section 5.6.3.2. This section details the procedure for calculating the ultimate flexural capacity of a reinforced concrete section, considering the contributions of the compression block in UHPC and the prestressed strands. Shear and interface shear (between different concrete layers) capacities were determined according to Sections 5.7.3.3 and 5.7.4.3

of the AASHTO LRFD, respectively. These provisions set forth guidelines for calculating the necessary vertical reinforcement to resist shear forces and to ensure the integrity of the interface between concrete layers under shear stress.

The modulus of elasticity for both HPC and UHPC was calculated using the formula provided in AASHTO LRFD C5.4.2.4-1. This formula is recommended for accurately predicting the elastic properties of concrete, taking into account factors such as aggregate type and concrete density. The research by El-Helou et al. (2022) supports the use of this equation for both types of concrete, emphasizing its relevance for materials with advanced mechanical properties.

For the distribution of live loads to the superstructure girders, the AASHTO LRFD Bridge Design Specifications Section 4.6.2.2.2 was applied. This section offers a methodology for calculating how live loads are distributed across multiple girders, considering the girders to function collectively as a unit. This approach is crucial for accurately estimating load effects on each girder and ensuring the design accounts for realistic loading scenarios.

Serviceability limit states, including deflection and cracking, were verified following general AASHTO LRFD guidelines applicable to HPC materials. This ensures that the structure maintains its functionality and appearance over time without compromising safety or performance.

Time-dependent losses in UHPC, such as creep and shrinkage, were estimated using the methodology developed by Mohebbi and Graybeal (2022). These factors are critical for long-term performance, as they can significantly affect the prestress forces and, consequently, the structural integrity and serviceability of the bridge.

For the compression stress limits in UHPC, AASHTO LRFD's specifications for conventional concrete were adapted, following the specific recommendations by El-Helou and Graybeal (2022). The tensile stress limit was defined as a fraction of this compression stress limit, incorporating a safety reduction factor of 0.85 to account for the uncertainties associated with material behavior under tensile loading.

A key aspect of the hybrid double-beam technology (HDBT) design is managing the tension stress at the HPC-UHPC interface, particularly at the critical location identified in the study (point b in Figure-2d). The design flexural cracking stress for this interface was assessed according to AASHTO LRFD Section 5.9.5.4.4c, equivalent to the modulus of rupture (Section 5.4.2.6) with a reduction factor of 0.85. This approach allows for a conservative estimation of the tension stress capacity of the HPC web, ensuring that it remains within acceptable limits under service conditions.

To address tensile stresses effectively, the construction process incorporates distributed reinforcement in alignment with AASHTO LRFD Section 5.6.7. This strategy enables bridge owners to define an acceptable level of cracking, thus establishing a specific design criterion that contributes to the long-term structural integrity and performance of the HDBT. While the AASHTO reference sections are for design checks in the United States, similar national codes may be used to extend the design to other countries.

4 EXAMPLE

The following section details a sample design for a 30.5 m (100 ft) single-span bridge. The cross section is composed of four HDBT beams spaced 2.44 m (8 ft). The external beam overhang is 3.5 (1.07m). Therefore, the interior girder width is 2.44 m (8 ft), and the exterior girder width is 7.5 ft in (2.29 m). The web thickness is 152 mm (6 in). The bottom flange is 406 mm (16 in) width and 305 mm (12 in) depth. The total height (labeled as h in Figure 1c) of the section is 1.60 m (63 in). The bridge is designed for AASHTO's HL-93 live load (2020). A 75-mm (3 in) wearing surface and a 7.3 kN/m (0.50 kips/ft) barrier are included as dead load. Regarding the barrier, 50% of the load is applied to the external beam and the remainder to the next internal beam. The deck thickness is 203 mm (8 in), and a 13 mm (0.5 in) asphalt wearing surface is included. The final section geometry is shown below in Figure-2c above.

The wearing surface and parapets are defined as area loads and line loads, respectively. The compressive strength of the UHPC was defined as 100 MPa (14 ksi) at strand release with a 28-day strength of 150 MPa (22 ksi). The UHPC effective cracking stress is assumed as 6.7

MPa (1 ksi). The specified HPC com-pressive strength is 70 MPa (10 ksi). Both concrete materials are normal weight concrete. The strands are grade 1850 MPa (270 ksi). The pre-stressing stress 1388 MPa (202.5 ksi). The relative humidity for losses calculation is 70%.

The PCI Bridge Design Manual (PCI, 2014) was chosen as reference given the availability of multiple preliminary designs, based on AASHTO LRFD Specification 2010 (AASHTO, 2010). Despite the differences between 2010 and 2020 AASHTO Specifications, the PCI Manual is a good reference point. Figure 3 shows the comparison of the total weight of the beam and deck for the different designs, between PCI Manual's preliminary designs (grey bars) and HDBT (blue bars), for both exterior and interior beams (labeled as Ext. and Int. respectively). Regarding dead load, the HDBT is the most efficient design, with a 12 and 16% reduction compared to the next lightest design for interior and exterior beam, respectively. This dead weight can be reduced using lightweight HPC.

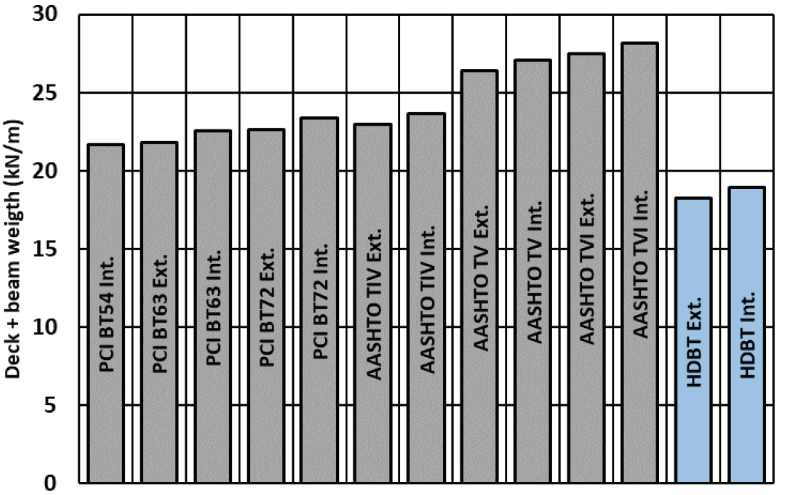

Figure 3. Comparison of beam weights for 30.5-m (100-ft) single span PCI Manual preliminary designs and HDBT preliminary designs for exterior (Ext.) and interior (Int.) beams. Note that barrier, haunch, and wearing weights are not included. PCI BT = PCI Bulb Tee standard section, AASHTO = AASHTO standard section.

5 CONCLUSIONS

This paper introduces a novel prestressed concrete alternative designed for short- and mid-span superstructure replacement projects, presenting a compelling contender to steel girders in terms of weight and section depth. Notably, the fabrication process of the HDBT tackles various challenges associated with existing prestressed concrete girders. By strategically incorporating Ultra UHPC in critical regions and HPC for the web and flange, cost reduction is achieved. This approach ensures a design characterized by predictable camber and the absence of tension in the top flange.

The analytical study conducted for the HDBT demonstrates the structural viability of the proposed design and construction methodology. Notably, it successfully reduces dead load by up to 16% compared to preliminary designs outlined in the PCI Bridge Design Manual. This research provides compelling evidence supporting the feasibility of the HDBT as an effective approach for bridge repair and replacement. With its potential to address current structural deficiencies within the U.S. bridge network, the HDBT emerges as a promising solution for enhancing the overall performance and longevity of bridge structures. As the use of composite and fully UHPC bridge girders increases in prevalence, additional experimental and analytical work is needed to update current design and inspection practices.

PCA-based technique to assess the modal properties of the Itacaiúnas bridge during flooding

R. Lopes & J. Weyl
Universidade Federal do Pará, Belém, Pará, Brazil

V. Barros & T. Bittencourt
Universidade de São Paulo, São Paulo, Brazil

ABSTRACT: The monitoring of bridges is important to ensure structural safety throughout the life-cycle of the enterprise. Environmental effects such as increased water volume in rivers can cause considerable changes in the data provided by instrumentation, sometimes making it challenging to identify whether the structure is exhibiting a damage pattern or just indicating a change in structural behavior due to an environmental component. In some regions of the state of Pará/Brazil, rivers can rise up to 10 meters during flood periods. This characteristic makes bridges in these regions good candidates for testing classification and damage pattern recognition algorithms. Techniques for detecting damage in large structures have been successfully applied in several case studies. Works based on principal component analysis (PCA) have been widely performed due to the ease of implementation of the algorithm and the efficiency in extracting patterns that are important in structural response. In this work, PCA, T^2-statistic and Q-statistic were used to evaluate the influence of the effect of floods on the modal properties of the bridge over the Itacaiúnas River. The acceleration data for this structure was obtained at two times: flood period in 2018 and dry period in 2021. The results indicate that the increase in river level causes a decrease in frequencies in the vibration modes of the structure. Furthermore, the use of PCA proved capable of discriminating characteristics from environmental effects.

1 INTRODUCTION

The monitoring of large bridges is generally costly and time-consuming process. Procedures to increase the efficiency of detecting changes in structural behavior have improved over the years, allowing extraction of important features without the need for extensive tests. Most of these techniques focus on detecting damage using vibration responses, but they can also be used to evaluate variations in the load effecting structures. According to Turrisi (2022), one of the major technical challenges faced by SHM when dealing with real-world structures under operational conditions is the significant impact of external factors on measured signals, commonly referred to as environmental and operational variables. According to Mujica (2010), any damage will change this vibration response, as well as the transient caused by a wave propagating through the structure. In addition to structural damage, the dynamic characteristics of structures are also affected by typical environmental variations, Sen (2019). However, environmental variations that inevitably occur during different data acquisition time periods also cause changes in vibration features, Yan (2005). Some loads can change the boundary conditions, resulting in changes to the structure's stiffness. This change does not indicate damage but results in a variation in vibration response, which can be detected by damage detection algorithms. In this paper explains how to use PCA to define indices capable of detecting variations in the structural responses of the Itacaiúnas Bridge.

DOI: 10.1201/9781003483755-452

2 PRINCIPAL COMPONENT ANALYSIS

PCA is used to estimate principal directions where maximum variability exists and redundance is minimal. These directions are obtained by transforming the original data set into a new coordinate system where the variables are uncorrelated. The eigenvector used to transform the data are sorted in descending order of their associated eigenvalues. The eigenvectors with the highest eigenvalues are chosen to represent most of the system's variability, allowing for the reduction of data dimension by selecting a few principal components. The techniques to applying PCA are described below.

Firstly, the data collected was arranged in a matrix $\mathbf{X}_{n\times m}$, where each row vector represents measurements of the sensors, and each column represents measurements from different experiment trials. If the data set has measurements with different magnitudes and scales is important to normalize the data set before analysis. Then the covariance matrix $\mathbf{C}_X$ is defined and the eigenvalues and eigenvectors are determined.

$$C_X \mathrm{P} = \mathrm{P}\Lambda \tag{1}$$

where **P** = eigenvectors; and Λ = eigenvalues

Matrix **P** is used to determine matrix **T**, that contain the original data transformed over the direction of the principal components.

$$T = XP \tag{2}$$

After applying the dimension reduction is not possible to recover completely **X**, but a matrix projected onto the principal components can be found:

$$\hat{X} = TP^T \tag{3}$$

Then the original data **X** can be represented as a sum of the matrix $\hat{X}$ and the projection on the residual left components $\bar{X}$:

$$X = \hat{X} + \bar{X} \tag{4}$$

3 DETECTING CHANGES IN STRUCTURAL BEHAVIOR

In this work were used two indices to detect chances in data collected: Q-statistic and T^2-statistic. The first one is based on analyzing the residual data matrix $\bar{X}$ to represent the variability of the data projection in the residual subspace. The second method is based in analyzing the score matrix **T** to check the variability of the projected data in the new space of the principal components, Mujica (2010)

The T^2-statistic indicate an abnormal behavior within the normal subspace and is defined in the form:

$$T_i^2 = t_{si}\Lambda^{-1}t_{si}^T \tag{5}$$

where $\boldsymbol{t_{si}}$ is a projection of the ith trial; and Λ^{-1} is the inverse of the diagonal matrix composed of eigenvalues.

The Q-statistic is measure of the difference between the sample and its projection onto the principal components retained in the model.

$$Q = \bar{x}_i\bar{x}_i^T \tag{6}$$

4 METHODOLOGY

In this study, a training set was created using the power spectrum density (PSD) from acceleration data collected during 9 trials in 2021. This dataset was considered normal condition as the monitoring period was outside the flood season in the region. After applying PCA, a baseline was built with the projection matrix. The monitoring was performed positioning accelerometers on both sides of the deck section and acquiring signal at a frequency of 100 Hz for 20 minutes. The acquisition points were varied at intervals of 30 meters for the central span and 35 meters for the other spans.

The principal components from the baseline model were used to project the data collected in 2018 (flood season in the region). This test set was obtained under the same conditions as 2021 (PSD from 9 experiments). For the two datasets (training and test), the T^2-statistic e Q-statistic were calculated and then compared. Figure 1 shows the power spectrum densities from the accelerations acquired in 2021 (Training Set)

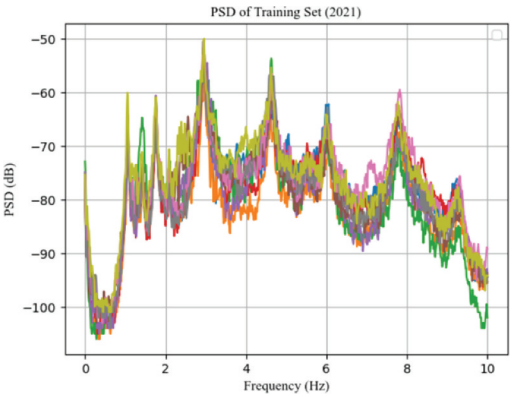

Figure 1. PSD from acceleration collected In 2021.

5 CASE STUDY: ITACAIÚNAS BRIDGE

The Itacaiúnas Bridge is located in the city of Marabá, in the state of Pará, Brazil. The structure consists of 3 spans, with a central span of 120 m and the others of 70 m. The structure was monitored with accelerometers in 2018 (river level ≈ 13.60 m) and 2021 (river level ≈ 3.10 m). Figures 2–3 shows the geometric characteristics of the Itacaiúnas bridge. Figure 4 shows the equipment used to collect celebrations.

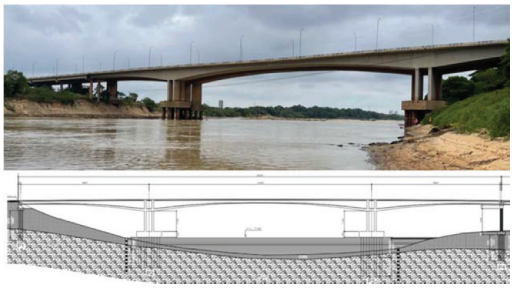

Figure 2. Itacaiúnas bridge.

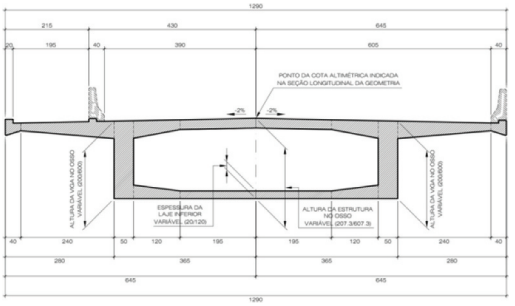

Figure 3. Cross section in mid of central span.

Figure 4. Accelerometer used in each experiment.

6 RESULTS

The vibration frequency of the bridge was estimated based on acceleration data collected in 2018 and 2021. The magnitude of the frequencies indicates that there is different structural behavior occurring between the training and test set. Table 1 shows that the difference between the frequencies in different years is small. Figure 5 also shows how small the difference between the frequencies is.

Table 1. Frequency under operational vibration.

Mode number	Training Set Frequency (Hz)	Test Set Frequency (Hz)
1	1.06	1.04
2	1.41	1.41
3	1.760	1.73
4	2.10	2.08
5	2.94	2.90
6	4.62	4.58

Due to the difficulty in distinguishing the change in structural behavior, the T^2-statistic and the Q-statistic were plotted to verify their ability to indicate any abnormality. Figure 6 shows that the Q-statistic was not sufficient to differentiate the behaviors between training and test set.

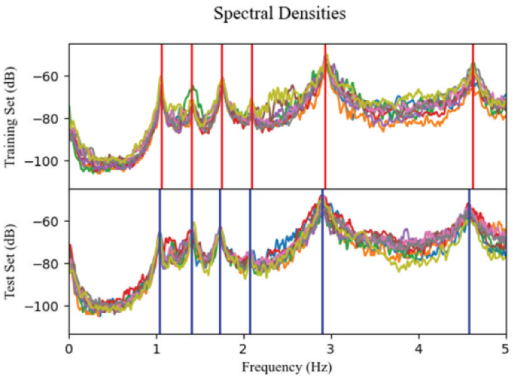

Figure 5. Vibration frequencies in training and test set.

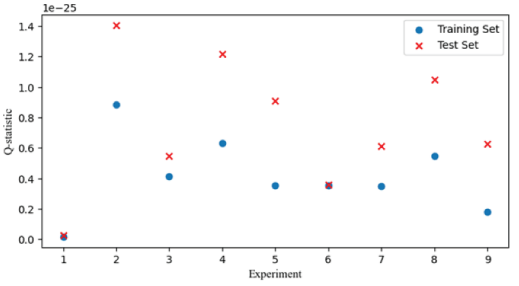

Figure 6. Q-statistic for each experiment.

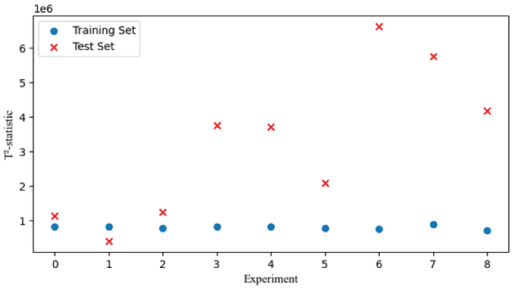

Figure 7. T²-statistic for each experiment.

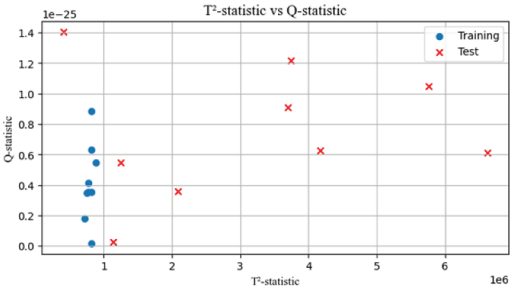

Figure 8. Match of the q-statistic and T²-statistic.

Figure 7 Shows that the T^2-statistic provides better conditions for distinguishing changes in structural behavior. The training set has almost the same magnitude in each experiment, while the test set has larger differences in each experiment. Figure 8 shows that the best way to detect a change in the structural behavior due to the flood in the river is to match the Q-statistic and T^2- statistic indices in the same plot. It is clearly visible that the training set is concentrated in the left side of the plot, while the test set is scattered on the right side of the plot.

7 CONCLUSION

This study shows an application of PCA and Q-statistic and T^2-statistic indices to detect changes in structural behavior due to increases of river level. The results show that matching both indices in the same plot is a good way to identify abnormal behaviors. This methodology is an alternative when the frequency magnitude of different monitoring is too close to detect variations in the load acting on the structure.

More experiments in different levels of the river would be important to test the capability of the methodology to be applied in larger structures. The structure will be monitored continuously during the next two years and then the proposed indices will be updated.

The influence of the temperature effects was not evaluated because average temperatures in north Brazil do not vary throughout the year.

ABSTRACT: To mitigate environmental impact and societal costs, there is a need to extend the lifetime of existing transportation infrastructure. Research has shown that many structures, such as bridges, have a substantial inherent load-carrying capacity that is often not fully utilized. In the research presented, it was shown how non-linear numerical analysis can be used to show higher performance and longer lifetime than with conventional engineering methods. Comprehensive recommendations for use in engineering practice have been developed for the structural assessment of reinforced concrete slabs using the finite element method. A multi-level structural assessment strategy was developed to provide a framework for successively improved and more advanced analysis. For the more advanced levels, non-linear FE analysis is used, adopting a global safety format and incorporating the effects of deterioration. With such analyses, the structural behaviour can be more accurately described and higher, yet conservative load-carrying capacities can generally be demonstrated.

1 INTRODUCTION

To reduce environmental impact and carbon emissions, and to optimise the utilization of the society´s resources, it is of outermost importance that the huge investments in transportation infrastructure are well managed. It is imperative that existing structures must be utilized during their entire lifetime with respect to function and safety, and their capacity must be fully used to meet higher demands from the transportation industry. When assessing existing structures, many of these shows insufficient load-carrying capacity, often accompanied by uncertainties regarding the structural behaviour. However, tests on real structures as well as experience with advanced assessment methods shows that existing structures often have substantially higher intrinsic capacity and a more complex structural response than shown with conventional assessment methods, see e.g. Bagge at al. (2018).

For design and assessment of reinforced concrete structures, simplified analysis methods and code provisions are commonly used. For structural analysis, the linear finite element (FE) method is common. However, for the assessment of existing structures, a greater effort with more advanced methods for structural analysis is often motivated. Research as well as experience from engineering practice has shown that non-linear FE analysis provides great possibilities of achieving a better understanding of the structural response, and have demonstrated the potential to reveal higher load-carrying capacity, see e.g. Shu et al. (2018) and Bagge et al. (2019).

DOI: 10.1201/9781003483755-453

Today, non-linear FE analysis is a standard method within research, but it is still sparsely used in engineering practice. This is partly because the method is more demanding, but also because it includes many uncertainties regarding in-data, modelling choices and result interpretation. There has also been concerns regarding the safety format since the partial factor method, normally used in design, may be questioned in the context of non-linear analyses.

The goal of the work presented was to develop detailed recommendations for how non-linear FE analysis can be utilized for structural assessment of reinforced concrete structures in engineering practice. The work focused on reinforced concrete (RC) slabs, but the principles, strategies and many of the methods developed are generally applicable. The objectives of the work were to (1) develop a methodology for incorporating non-linear FE analysis in successively improved structural assessment, (2) develop analysis methods for different levels of assessment of RC slabs and (3) through examples demonstrate and show the potential of the recommended approach. The research methods used included literature studies, laboratory tests, analytical and numerical analyses as well as parameter studies. In addition, the methodology and recommendations presented are founded in the authors' own long experience of non-linear analysis and structural assessment, within research as well as in engineering practice.

2 A MULTI-LEVEL ASSESSMENT STRATEGY

The assessment strategy is based on a stepwise approach where the structural assessment is made with successively more sophisticated methods for evaluation, see e.g. Sustainable Bridges (2007). These can consist of more advanced structural analysis methods, improved knowledge of the structure and its condition, and with safety formats suitable for the analysis methods employed. In Figure 1, a principal flow diagram for the assessment process is shown.

A Multi-Level Assessment Strategy was proposed in Plos et al. (2017) to facilitate enhanced assessment through successively improved structural analysis and resistance evaluation. The framework also provided a structured approach to the use of non-linear FE analysis for structural assessment of RC slabs. Five different assessment levels were proposed, see Figure 2. The assessment starts with traditional simplified analysis methods (Level I), followed by the currently dominating linear FE analysis method (Level II). The higher levels (Levels III – V) involves non-linear FE analysis on different levels of detailing.

A non-linear FE analysis simulates the response of the structure. It resembles the structural behaviour under successively increased loads, possibly up to and beyond the failure of the structure. This means that the load-carrying capacity can be evaluated from the non-linear analysis directly, provided it is sufficiently detailed to reflect the governing failure mode. If all possible failure modes of interest are not reflected in the analysis, the related action effects from the analysis must instead be compared to local resistances for these failure modes, similarly as in standard design methods. This is the case for some of the failure modes at Levels III and IV, see Figure 2.

While the common resistance models from e.g. Eurocode 2 (2004) are used at Levels I and II, higher Level-of-Approximation resistance models from Model Code 2010, fib (2013), are proposed for Levels III and IV. The five assessment levels are briefly described below.

- Level I: Simplified analysis methods: 2D linear beam or frame analysis, tabulated solutions or plasticity-based analysis like the strip method or the yield line method.
- Level II: 3D linear FE analysis: Generally shell element analysis. Modelling and redistribution of stress concentrations according to e.g. Pacoste et al. (2012).
- Level III: 3D non-linear shell FE analysis: Non-linear material properties of concrete and reinforcement, including concrete cracking and crushing and reinforcement yielding, Perfect reinforcement-concrete bond is assumed. Bending failures are reflected in the global analysis, while shear type and anchorage failures are checked separately.
- Level IV: 3D non-linear FE analysis with continuum elements: Here also shear type failures, including punching, can be reflected with sufficiently dense element mesh.
- Level V: 3D non-linear FE analysis with continuum elements including reinforcement-concrete bond-slip: With even finer mesh resolution also anchorage failure and realistic crack distribution can be reflected. No major failure modes are checked separately.

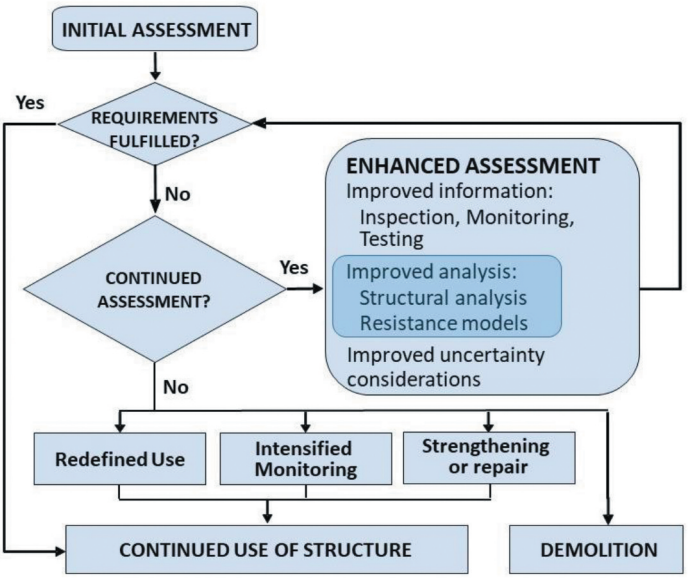

Figure 1. Flow diagram for successively improved structural assessment. Based on Plos et al. (2021).

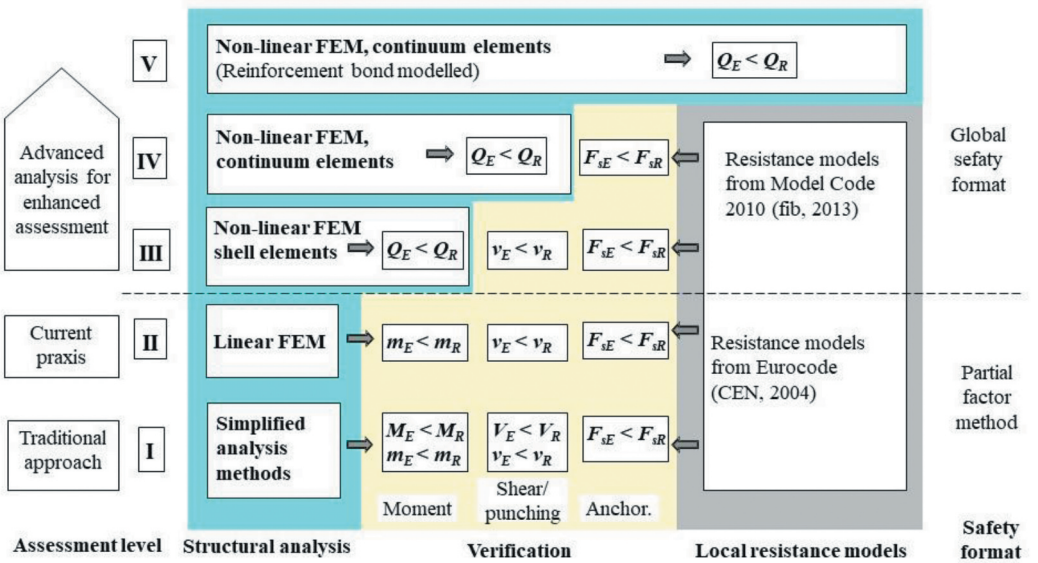

Figure 2. Illustration of the Multi-Level Assessment Strategy for RC slabs. From Plos et al. (2017, 2021).

It must be emphasized that in practical terms, it is necessary to start the assessment with analyses on the lower load levels, i.e. Levels I or II. With such an analysis, the structure can be assessed for a great number of load combinations and load positions. As the analysis progresses to non-linear stages, the response becomes history-dependent and load effects from different loads cannot be combined. Instead, a separate non-linear analysis must be made for each combination of loads studied. Since it is comparably more time consuming and computationally demanding to do a non-linear analysis, such analyses are recommended for evaluating a limited number of critical load combinations, previously identified on lower assessment levels.

For analysis with simplified methods or linear FE analysis according to current standards (Levels I & II), the partial factor method is used to meet the safety demands. However, a non-linear FE analysis simulates the response of a structure during successive loading to failure for a specific load combination. It can be seen as a virtual testing of the existing structure as a whole and is by its nature always a global type of assessment. Consequently, global safety factor methods are recommended for use in combination with non-linear finite analyses for assessment on Levels III, IV and V. In Plos et al. (2021), detailed recommendations are given for their application.

3 NON-LINEAR FE ANALYSIS

For analysis on different levels of detailing, structural analysis methods were developed and proven feasible for the assessment of existing concrete slabs, see Shu et al. (2015, 2016, 2017). The analysis methods were verified through comparison with laboratory tests. Sensitivity studies of modelling choice were made for slabs subjected to bending as well as shear type failures. Detailed recommendations for application of the analysis methods on the different assessment levels are given in Plos et al. (2021). In particular, detailed recommendations regarding modelling, analysis and evaluation for non-linear FEM is given for analysis with shell elements (Level III) and continuum elements (Level IV and V). How the global safety format and the resistance models from Model Code 2010, fib (2013), can be applied on each level is described, in combination with the non-linear analyses.

In addition to the detailed recommendations for RC slabs, general recommendations for modelling and analysis of concrete structures with non-linear FEM are given in Plos et al. (2021) . Many of the challenges and questions that a practicing structural engineer is facing when performing this kind of analysis are addressed and recommendations are given regarding modelling choices and application of the methods. Detailed guidelines are provided regarding determination of material parameters and other in-data for the analyses. Advices are given for quality check and interpretation of analysis results.

The response in a non-linear analysis is history dependent. The order in which the loads are applied may therefore be important. It can influence the response during loading, but also the interpretation of the obtained failure load. Since detailed rules on this are not available in standards or codes, recommendations are given for the load application in non-linear analysis.

When the structure is deteriorated due to, for instance, reinforcement corrosion or frost damage, the structural effect of the deterioration needs to be counted for in the structural analysis or in local resistance models, see e.g. Zandi (2010). For different levels of assessment, recommendations are given in Plos et al. (2021) on how the effect of such deteriorations can be included as a change in material properties, cross-sectional area of the concrete and reinforcement, and bond properties between reinforcement and concrete.

4 EXAMPLES

The feasibility and potential of the assessment strategy and the analysis methods were shown through applications to laboratory tests as well as real structures, see Shu et al. (2015, 2016, 2017, 2018, 2019). In Plos et al. (2021), they are demonstrated in three examples. In two of the examples, concrete slabs previously tested in laboratory by Fall et al. (2014) and Vaz Rodrigues (2007) were studied. In Figure 3, the analyses on different levels are illustrated. The potential to demonstrate higher load-carrying capacity was demonstrated through comparison between test results and analyses on different levels. In the third example, the strategy was demonstrated on an existing bridge with future (hypothetical) deterioration from reinforcement corrosion and frost, including the application of the global safety format. Figure 4 summarises the load-carrying capacities possible to demonstrate through analyses on the different assessment levels. For the slabs tested in laboratory, the load-carrying capacity relates to the measured failure load. For the composite bridge deck slab, it relates to the capacity demonstrated with non-linear FEM on level IV.

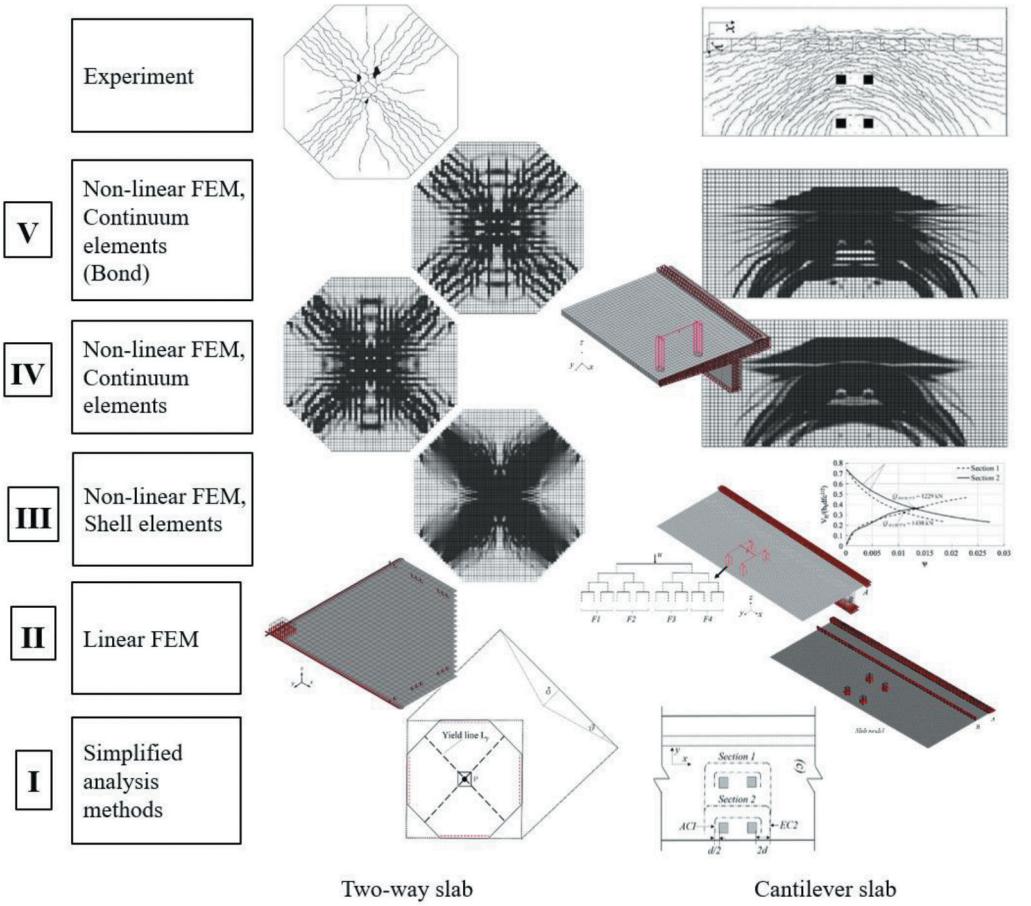

Figure 3. Illustration of analyses on different levels of accuracy, for slabs tested in laboratory. From Plos et al. (2021). Test performed by Fall et al. (2014) and Vaz Rodrigues (2007).

5 CONCLUSIONS

To facilitate the use of advanced analysis methods in engineering practice, recommendations were developed for structural assessment of RC slabs, Plos et al. (2021). A methodology for successively improved assessment, and analysis methods for different levels of assessment were developed. The methods recommended are intended for use in engineering practice and follows current standards and established handbooks such as CEN (2004) and fib (2013). They are intended to give conservative estimates of the load-carrying capacity, fulfilling the required safety level. While the recommendations are formulated for RC slabs, the underlying principles are universal and many of the recommendations are relevant also for other type of structures. Plos et al. (2021) provides a clear framework for structural assessment of RC structures, gives detailed recommendations for analyses on different levels of detailing and includes examples showing the application.

In the examples, it was demonstrated how more accurate assessment can be made using non-linear FE analysis for cases where simplified analysis cannot demonstrate sufficient load-carrying capacity. A substantially higher part of the intrinsic capacity of the structure could be demonstrated using more advanced analyses.

Non-linear analysis with shell elements in combination with resistance models from Model Code 2010, fib (2013), (Level III) are judged to be useful for practical engineering work. They are more demanding than traditional analysis methods but are powerful when a higher load-

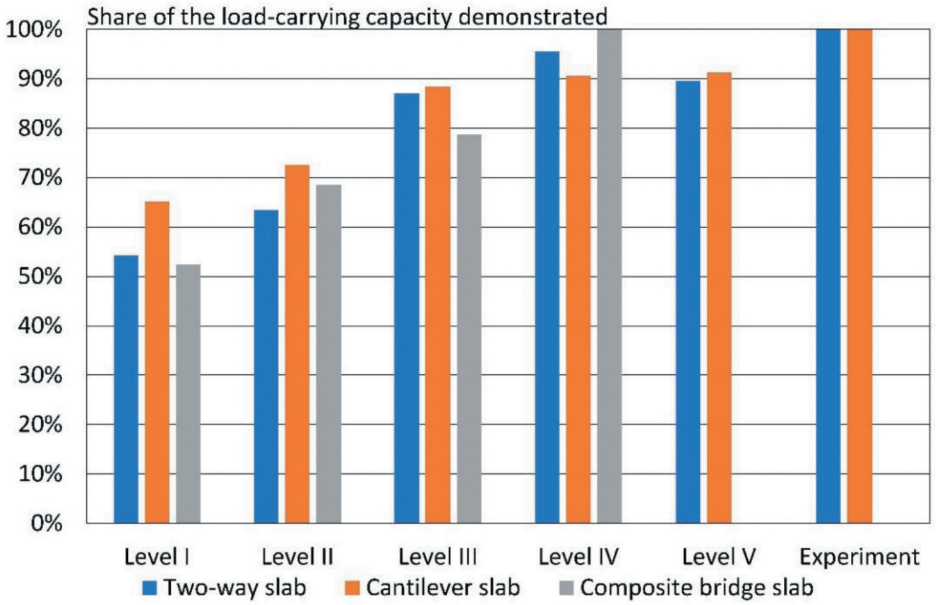

Figure 4. Demonstrated load-carrying capacity with assessment on different levels of accuracy, for the examples in Plos et al. (2021).

carrying capacity needs to be demonstrated. It was shown through examples that assessment with such an analysis can result in 15% to 35% higher capacity compared to assessment according to current praxis using linear analysis.

Non-linear analysis with continuum elements (Level IV and V) can be very helpful to provide a better understanding of the structural behaviour. However, this kind of analysis is considerably more demanding. Furthermore, there are still doubts regarding the modelling uncertainty which, in practice, makes it difficult to prove additional capacity with such analyses.

ACKNOWLEDGEMENT

The research presented was mainly funded by the Swedish Transport Administration (Trafikverket) and conducted at Chalmers University of Technology, Sweden.

Behaviour & management of pre-tensioned girder halving joints

ABSTRACT: The root cause of several worldwide bridge collapses in the past 20 years has been identified as resulting from the poor performance of structural details known as halving joints. Concrete halving joints are renowned for their low redundancy, potentially brittle failure characteristic (if not detailed correctly), and high stress concentration zones. Best practice management of these details involves both structural assessment and inspection with information from both contributing to the overall assessment. This research presents the results of the analysis of the strand development length effect on the behaviour of halving joints on pre-tensioned girders. A conventional strut-tie analysis of these joint revealed that their capacity is controlled by the development characteristics of the pre-tensioned strand. Based on this analysis, the most vulnerable bridge on the network was identified. Non-linear advanced finite element analysis demonstrated that the strand development did severely limit the halving joint capacity and that this mode of failure had not been anticipated by the designers. This knowledge allowed the management of these bridges to be improved by modifying inspection regimes to include the likely crack locations for this failure mode.

1 INTRODUCTION

"Halving Joints" or "Half Joints" (Figure 1) describe the intersection of the two components (superstructure and substructure) that are overlapped. They typically feature cantilever superstructure and suspended span/drop in spans. They facilitate a beneficial reduction to the overall height of the structural system while maintaining clearance over roads/railways or other assets. Catastrophic failure of structures triggered by failure of these key details had occurred in recent years (eg, Lecco, Italy and De La Concorde, Canada). A knowledge of these failures motivated the Queensland Department of Transport and Main Road's (QTMR) to develop a deeper understanding of concrete halving joint bridges on Queensland network and provide appropriate risk management and assurance in relation to the performance of these bridges.

The largest cohort of QTMR halving joint bridges consists of pre-tensioned T girder bridges supported on inverted T reinforced concrete headstocks constructed in between circa 1990 and 2010. The Subject bridge is a 5-span bridge and had the lowest ratio of available halving joint capacity to required capacity for this cohort of bridges based on a preliminary assessment. This paper summarises detailed investigations into the Subject bridge halving joint behaviour and illustrates how advanced analysis can inform better management of such assets.

1.1 *Context and background*

The physical configuration of half joint introduces a significant change in cross-section stiffness and strength. The joints are positioned in the structure so that there is no primary moment at the joint. However, there is typically significant cross-section shear, leading to

DOI: 10.1201/9781003483755-454

localised shear and bending resulting from the joint configuration. Reduced cross-section stiffness and strength combined with complex localised bending and shear makes them vulnerable to failure, often exacerbated by other factors. Ultimately typical failure of concrete half joints occurs as illustrated in Figure 2, often with limited warning.

Key factors exacerbating halving joint vulnerability include poor reinforcement detailing and/or lack of appropriate reinforcement. In addition, these joints are difficult to inspect and maintain, and are often positioned near deck joints resulting in increased environmental exposure (water leakage) leading to localised material deterioration. These factors combined with their potentially brittle failure nature and (often) limited alternative load paths (low system redundancy) pose significant risks.

Figure 1. Typical QTMR half joint – inverted "T" headstock and super "T" girders.

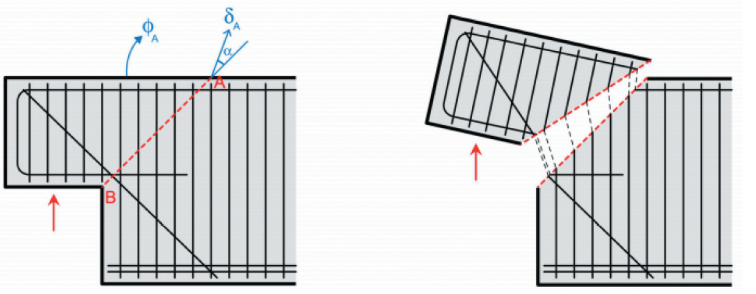

Figure 2. Half joint failure (after CS466 risk management and structural assessment of concrete half joint deck structures).

1.2 *Objectives*

The objective of this investigation is to better understand the behaviour of halving joints in this cohort of pre-tensioned girders to identify improved management opportunities. This paper highlights an example of how pre-tensioning can modify halving joint behaviour, creating issues but also opportunities for the management of these structures.

2 SUMMARY OF PRE-TENSIONED SUPER "T" GIRDER BEHAVIOUR

The general arrangement plan and elevation is shown in Figure 3. A notable feature is the 45° skew on this bridge that also has both girder and headstock with halving joints. The concerns identified are in the girder halving joints, particularly those on the Span 4 (39 m) which is significantly longer than the other spans (31.5 and 29 m).

The strut and tie assessment of the halving joint predicted a capacity of 1210 kN representing only 66% and 90% of the capacity required for the external and internal girders respectively,

based on a preliminary loading analysis. According to the strut and tie models the halving joint capacity was limited by the force that could be developed in the prestressing strand at the bottom of the girder. This was because there were only 14 bonded strands at the ends of the girder. De-bonded strands can be found to varying extents for other QTMR T girder bridges.

The strut and tie model that used for the preliminary assessment (Figure 4) is based on the geometry along the girder centre line and so does not specifically take into account the high skew on the bridge and the effect that might have on the location of some bars. It predicts a halving joint capacity of 1210 kN with a co-existing horizontal tension of 121 kN.

Figure 5 shows the details of the struts and ties at the bottom chord which represents the not de-bonded 14 strands. Also shows a plot of the force development in the bottom chord, and the maximum force that can be developed in the strand based on the AS 5100 (Bridge Design Code) requirements. The vertical component of the diagonal shear force that can transferred up to the top of the girder by the ligatures and the diagonal bars is limited by the capacity of the bottom chord to resist the horizontal components of those forces.

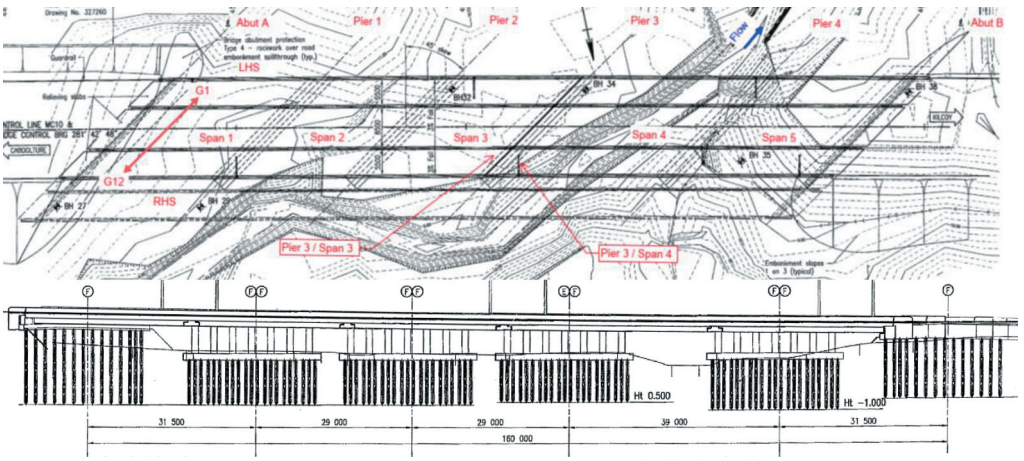

Figure 3. General arrangement of the subject bridge.

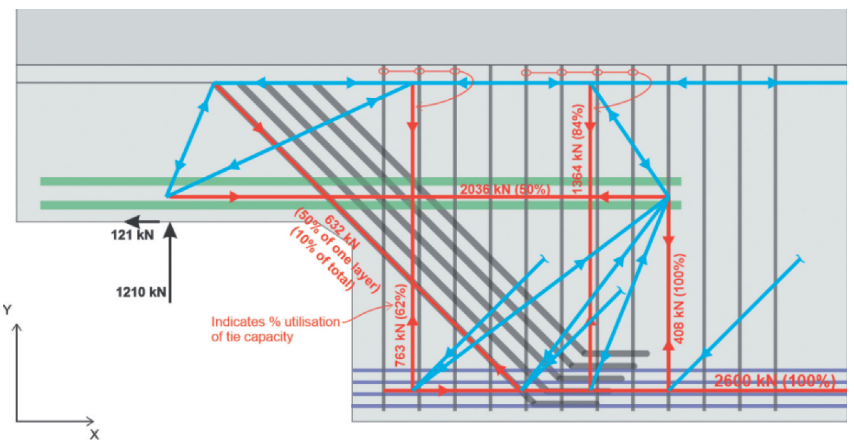

Figure 4. The subject girder halving joint strut and tie model from preliminary assessment.

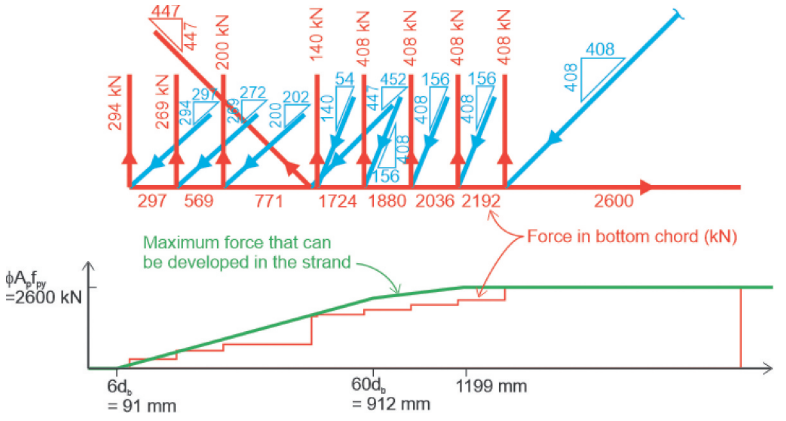

Figure 5. Detail of force development in the bottom chord of the strut and tie model.

The capacity of the strand representing the bottom chord is 100% utilised. However, the ligatures, horizontal bars, and diagonal bars adjacent to the re-entrant corner are only 62%, 50%, and 10% utilised, respectively. It is clear that in the design of the HJ a lot attention was paid to preventing failure by a diagonal crack starting at the re-entrant corner, but insufficient attention was paid into how the forces in the bars preventing that failure were to be transferred into the rest of the girder.

3 FINITE ELEMENT ANALYSIS

VecTor2 finite element software (Wong et al, 2013) was selected as the tool for a more detailed investigation of the structural behaviour. Vector2 software is a two-dimensional plane stress formulation and so the analysis will represent average conditions across the girder which needs to be considered when interpreting results. A full description of modelling is beyond the scope of this paper but suffice to advise that the development of an appropriate modelling rationale required careful consideration. Figure 6 shows the Vector2 FE model. The right-hand edge of the model is fully restrained. The load increment is applied as nodal loads over the width of the bearing plate. To allow for braking forces and/or horizontal frictional loads due to temperature or live load

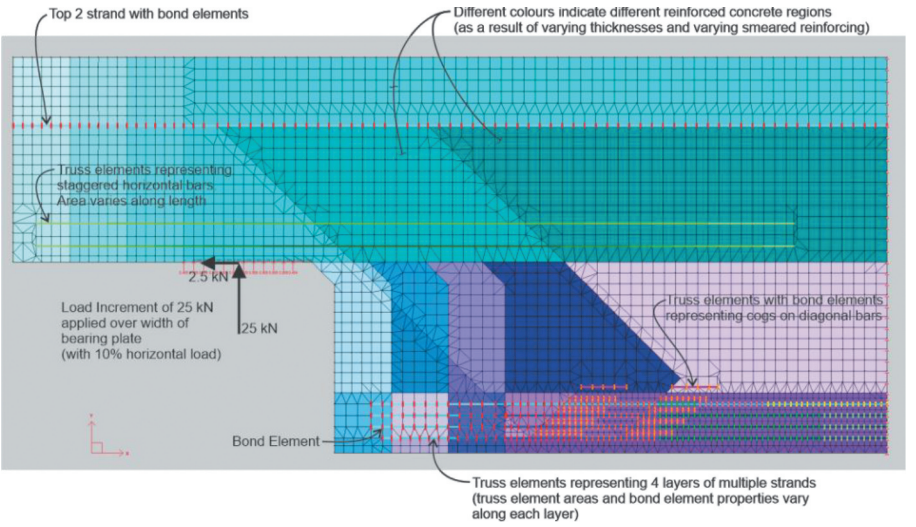

Figure 6. The VecTor2 FEA model mesh.

deformations, a horizontal tension load of 10% of the vertical load was applied which is consistent with the preliminary strut and tie model.

The first step in the analysis has zero load applied. It is effectively equivalent to the step of releasing the strands in the stressing bed, so that the strand slips near the end of the girder, activating the bond elements and developing the force profile at the ends of the strands. As the strand forces develop, corresponding stresses due to the prestress develop in the girder. Subsequent load steps applied an increasing bearing reaction in increments of 25 kN. The bearing load was increased until satisfactory convergence could no longer be achieved.

The adopted bond stress -slip relationship for strand is shown in Figure 7. The maximum value (3.6 MPa) varies along the length of the strand to achieve an overall force development profile which matches the AS 5100 values. This relationship is a key determinant of overall HJ behaviour. The slip values (S_1, S_2, and S_3) that were adopted were consistent with the findings of Lee (2017) and are much larger than those for deformed reinforcing bars. These larger slip values were essential to be able model bond consistent with the AS5100 development length requirements for strands.

Several different analyses were undertaken with varying parameters. The following section contains a detailed discussion of the results for an analysis with realistic parameters. The results discussed are for the analysis which used the strand bond model described above and the default concrete tensile strength which is 2.33 MPa. No capacity reduction factors were included. This analysis should provide a good representation of the likely behaviour and failure load. However, it is not code compliant or consistent with the strut and tie model as it includes capacity that relies on the concrete tensile strength and does not include capacity reduction factors.

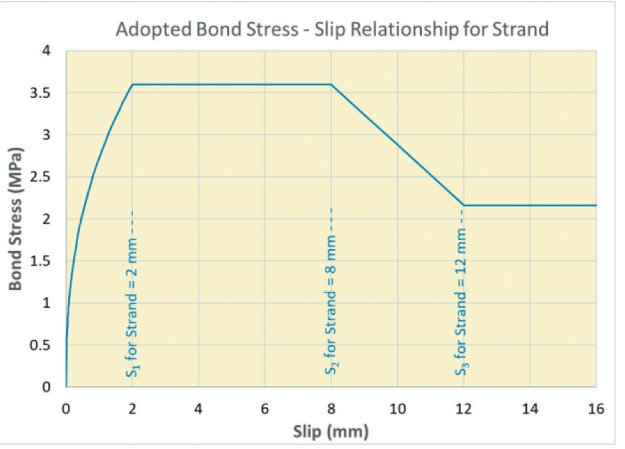

Figure 7. Adopted bond stress slip relationship for strand and the VecTor2 default relationship.

3.1 *Deformed shapes and cracking*

Figure 8 (a) to (c) shows the deformed shape and the extent of cracking at varying levels of the estimated design loading and for the predicted failure load. At the SLS Permanent Effects plus Traffic loading of 1250 kN (Case (a)), the extent of cracking around the re-entrant corner has developed and the maximum crack width at the surface is 0.47 mm. There is widespread cracking through the region of the diagonal reinforcing although the crack widths away from the surface are small (~ 0.1 mm). At this loading the first cracking in predicted in the diagonal bar – strand anchorage zone. This is a region where the horizontal component of the force in the diagonal bars has to be transferred into the strand, via the concrete.

At the estimated ULS Permanent Effects plus Traffic loading of 1825 kN (Case (b)) cracking is widespread. There is an increased amount of cracking in the diagonal bar – strand anchorage zone, although these cracks still are relatively small at about 0.4 mm. Flexural cracking at the extent of the model is now also predicted.

The predicted failure load was 2025 kN. This is the last load step at which convergence could be achieved. At this load (Case (c)), the deformed shape shows a failure crack immediately behind the diagonal bars. This has been allowed to open by the strands on the left of the crack slipping.

At the failure load the stresses in the diagonal bars (204 MPa) and the horizontal bars (124 MPa) near the re-entrant corner are still very low. The capacity of the halving joint is completely controlled by the development of force in the strand.

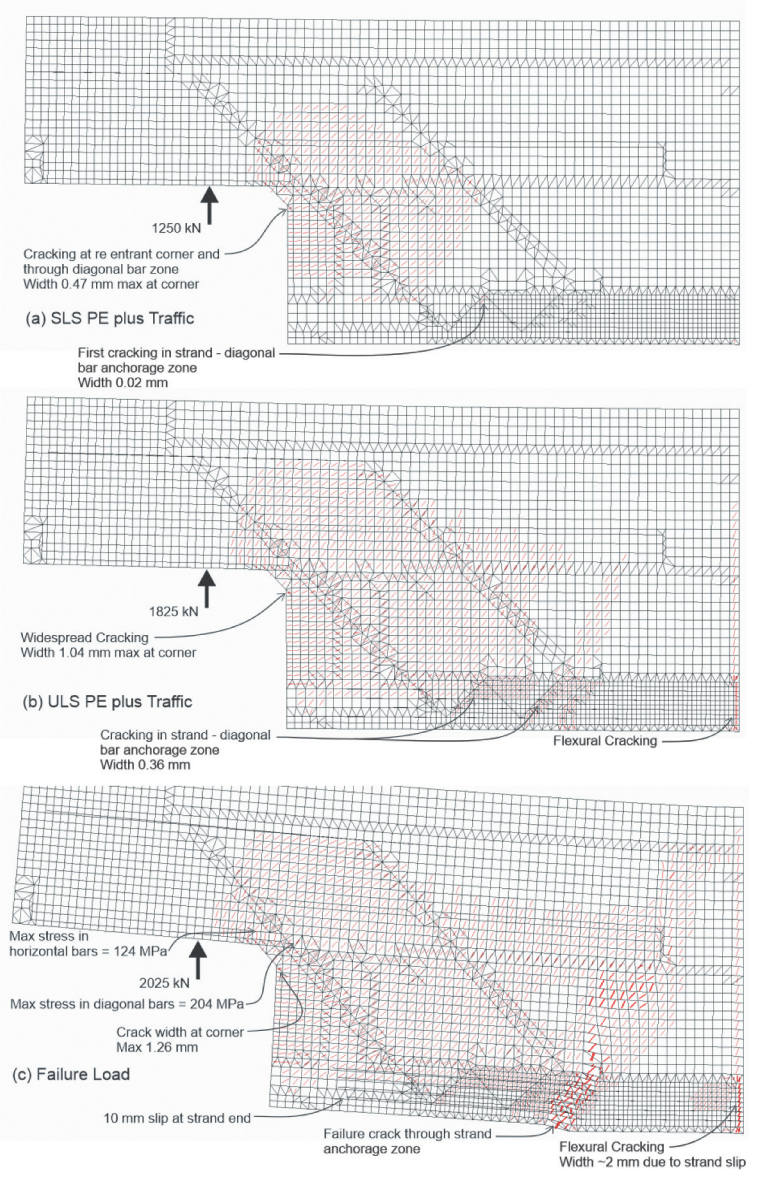

Figure 8. Deformed shape and cracking extent from analysis.

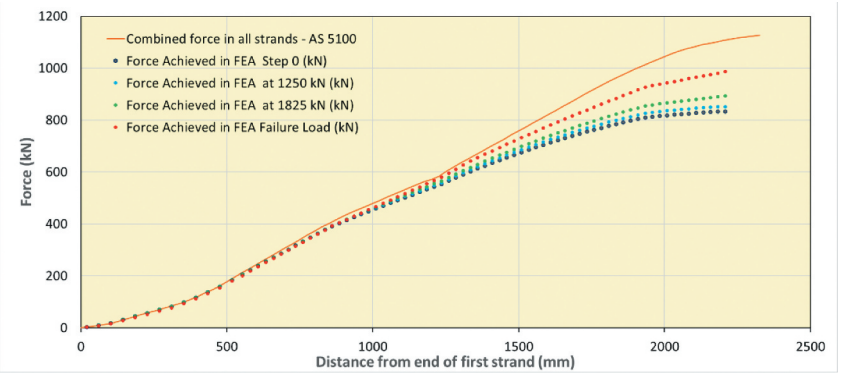

Figure 9. Force development in strand at various load levels compared with AS 5100 requirements (bottom strand layer).

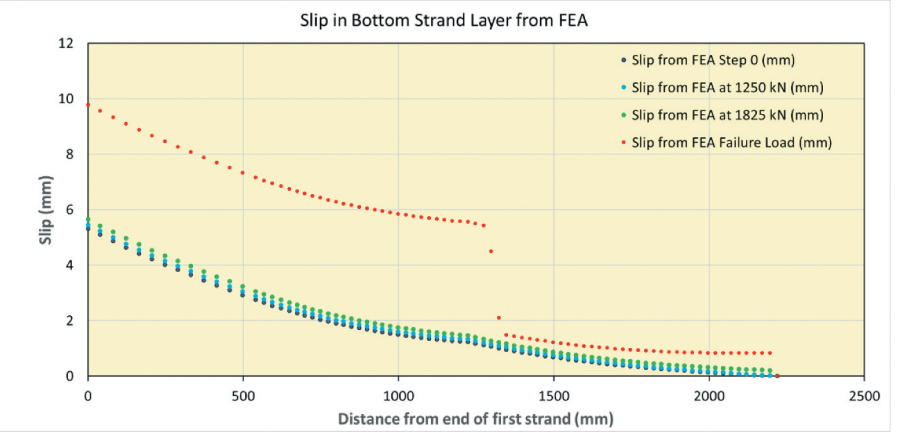

Figure 10. Slip along strand at various load levels.

3.2 *Strand force development and slip*

Figure 9 shows the force in the bottom layer of strands from the FEA analysis at various load levels. This is compared with the theoretical values from superposition of the AS 5100 stress development profiles for the six tendons with the staggered starting points. Figure 10 shows the slip along the bottom layer of strand at various load levels. For the lower load levels the force in the strand closely matches the AS 5100 curve for 800 mm and then slowly falls below it. This is because the additional force in the strand is not required at these load levels. The slip in the strand beyond about 800 mm from the end is still less than 2 mm and so there is further bond capacity that can be activated by slightly increasing the slip. This happens as the load increases. The slip increases slightly and the force development beyond 800 mm moves closer the AS 5100 line.

As the failure load is approached the force in the strand increases until it closely matches the AS 5100 line. At this load, the slip is above S_1 (refer to Figure 7) at all locations to the left of the failure crack. Slips near the start of the strand are increasing above S_2 (8 mm), which means that the bond capacity starts to reduce. At this point, the maximum force that can be developed also starts to reduce, resulting in failure.

These plots show that the model has achieved the goal of the selection of properties for a single line of truss and bond elements which represents the behaviour of multiple staggered strands with force development characteristics consistent with the AS 5100 requirements. Hence the predicted failure load is consistent with the AS 5100 stress development requirements.

Figure 11 shows the deflection at the centre line of the bearing from the analysis. This is the deflection measured relative to a tangent to the girder soffit on the right-hand side of the model.

Deflections are small until the failure crack starts to open due to slip of the strand. Over the final 10% of the theoretical failure load, the deflections increase rapidly due to opening of the failure crack.

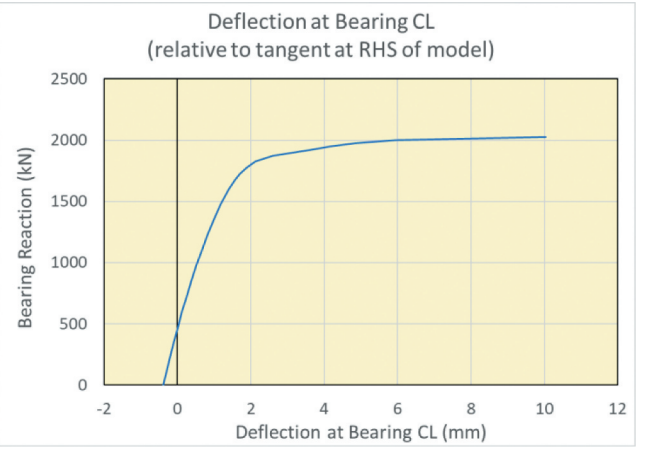

Figure 11. Deflection at bearing centre line for loads up to the failure load.

3.3 *Results for code compliant assessments*

The analysis described above included concrete tensile strength and did not include material capacity reduction factors. Further analyses were completed with these assumptions changed.

If capacity reduction factors are included and the concrete tensile strength ignored, then the analysis consistent with the AS5100 design code requirements and the assumptions of the Strut and Tie assessment. The result for these assumptions was a predicted capacity of 1525 kN. This is higher than the result of the strut and tie assessment (1210 kN). The reason is mainly related to the longer average strand development length in the FEA when the girder end skew was properly taken into account.

While including the concrete tensile strength is not consistent with a strut and tie model, it is consistent with code-based shear capacity assessments where the adoption of a V_{uc} term is essentially equivalent to including an average tensile stress in the concrete and checking that it can be transferred across the cracks by shear on the crack faces. The VecTor2 software includes these checks and so the predicted capacity including the concrete tensile strength is consistent with the AS5100 shear requirements. When the VecTor2 default concrete tensile strength of $0.33\sqrt{f'c}$ was included, the predicted capacity increased to 1650 kN.

4 IMPLICATIONS FOR MANAGEMENT OF HALVING JOINTS

Best practice halving joint management (Highways England, 2020) requires both the assessment and inspection of halving joints and is typically focussed on cracking behaviour in the vicinity of the re-entrant corner as illustrated in Figure 2. The analysis described above indicates that while re-entrant corner cracking will occur (and has been observed) at the re-entrant corner, it is not always the controlling failure mode when the complexities of pre-tensioned concrete are introduced into halving joint behaviour. In this case the conventional reinforcing steel has only reached approximately half of its capacity when failure initiates as a result of slip of the pre-tensioned strand. The above predicted behaviour is sensitive to strand development characteristics, so QTMR is progressing further research to gain a better understanding of actual strand development characteristics. These results will be used to update the VecTor2

model to improve understanding of the behaviour and capacity of the The Subject bridge halving joints. All QTMRs super T halving joints bridges are controlled by strand development based on strut-tie assessment. The findings from this research will be used to better inform the management of the whole bridge co-hort. Halving joint inspection focus has been extended to include seeking evidence of girder soffit cracking in the region between 1 and 2 m from the end of the girders. While this is only anticipated to occur at very high load levels, this tendon slip failure mechanism is expected to give little warning of collapse, so such cracking would be a significant escalation trigger should it be observed.

5 CONCLUSIONS

The behaviour described above illustrates the need to understand the expected behaviour of concrete halving joint bridges in detail, particularly when pre-stressing is coincident with the halving joint design. Current best practice halving joint management uses evidence from observed cracks to assist in understanding and managing the risk associated with operating halving joint bridges on the network. While the strut-tie analysis was sufficient to identify the issue (behaviour and capacity controlled by strand development length), it was not possible to gain a detailed understanding of structural behaviour. Finite element analysis (in this case using VecTor2 software) allowed a much more detailed understanding of behaviour, including identification of how failure associated with the controlling mechanism might progress, and provides revised focus for halving joint inspections.

ABSTRACT: Structures with concrete halving joints lack redundancy and are prone to potential brittle failures, particularly with poor detailing and high stress concentration areas. In recent years, several bridge collapses have been attributed to inadequate halving joint performance. A network-level approach has identified specific issues requiring deeper comprehension for improved structural assessment and inspection protocols. This paper investigates the impact of post-tensioning on girder halving joint behavior, with a focus on post-tensioned girders on inverted T headstocks, a common network detail. "I" girders, a significant subcategory, showed structural assessment ratios below 1.0, despite limited evidence of associated cracking. This study aims to understand this anomaly and presents numerical modeling results for a post-tensioned I girder, revealing modifications to known failure mechanisms due to post tensioning and introducing an additional failure mechanism. The result of the advanced analysis creates opportunities for more optimised management of these structures.

1 INTRODUCTION

A bridge with halving joints consists of suspended spans with dapped ends supported on the nibs of abutments or adjacent cantilevered girders. The physical configuration of the joint introduces a sudden change in geometry, resulting in significant variation in the stiffness and strength within the joint section. The joints are positioned and configured in the structure so that there is no/minimal global bending moment in the joint. However, there is typically significant cross-section shear, leading to localised shear and bending resulting from the joint configuration. Reduced cross-section stiffness and strength, combined with complex localised bending and shear, makes them vulnerable to failure, often exacerbated by other factors.

Many of the halving joints in Queensland Department of Transport and Main Roads (QTMR) network are located on the Subject Bridge in Brisbane which was built in the 70's. A preliminary assessment of a typical halving joint on the post-tensioned I-Girders on this bridge involved finite element analysis of several spans of the structure to determine halving joint loads, and Strut and Tie analysis of the headstock and girder halving joints to determine halving joint capacities, resulting in tolerable Structural Assessment Ratios (SARs) of 0.85 to 1.00 at several locations. However, the I-Girder halving joints had lower SARs (0.73 to 0.90), raising concerns.

Inspections on those HJs revealed minimal cracking, inconsistent with calculated SARs. There was a concern that the low level of cracking was due to the relatively high level of prestress in the post tensioned girders, and that a situation might exist where the failure load was not much above the cracking load. This would be undesirable because inspections showing a lack of cracking would not necessarily mean a low failure risk. This discrepancy combined

DOI: 10.1201/9781003483755-455

with the significance of the asset to the QTMR network, motivated further investigation, with the aim of developing a better understanding of the behaviour and adequacy of the I girder halving joints in this Expressway.

2 I GIRDER HALVING JOINT

Figure 1 and Figure 2 show the halving joint geometry and reinforcing details of the I girder analysed. The results from the previous assessment (Stevens, 2020) relevant to this more detailed investigation are also summarised below. The loads in Table 1 are the highest reactions obtained for a typical pier for service and ultimate limit states (SLS and ULS). Two halving joint capacities were estimated (Table 2); one considering optimistic assumptions regarding the anchorage of key reinforcing bars, and other considering conservative assumptions. The uncertainty that leads to those assumptions is whether all the bars which cross the crack can be properly anchored by struts and ties in the regions above and below the crack.

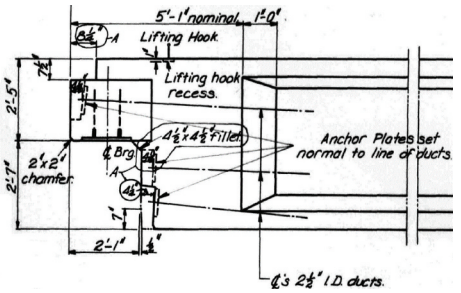

Table 1. I girder HJ loads.

Loading	SLS Reactions	ULS Reactions
PE only	479 kN	620 kN
PE+LL (1G*)	918 kN	1496 kN
PE+LL (T&D**)	898 kN	1456 kN

* GML Semi Trailer 42.5 t
** Truck and Dog 50.5 t

Figure 1. I girder halving joint geometry.

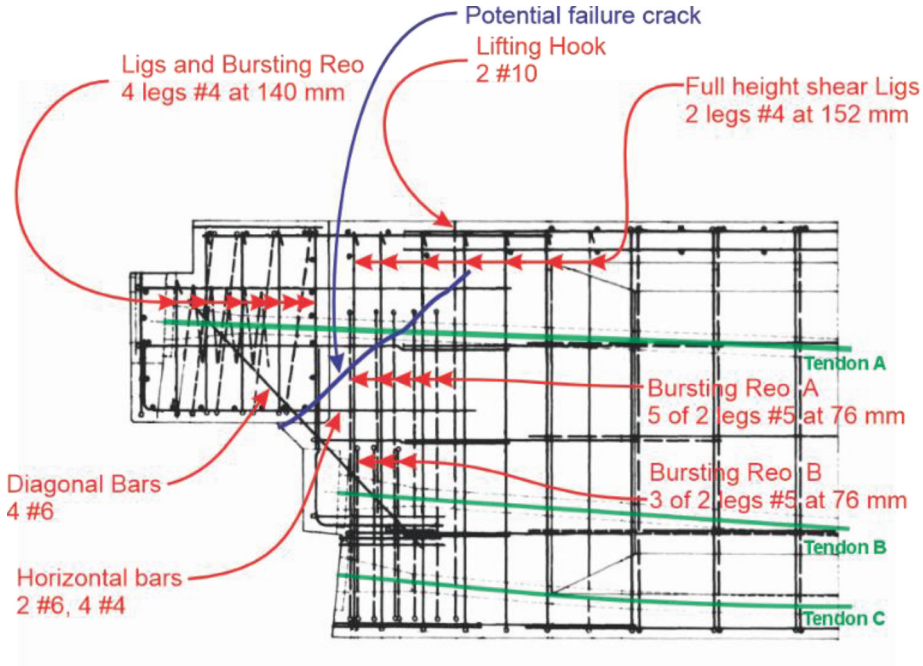

Figure 2. Reinforcing details at the I Girder halving joint.

Table 2. Strut and tie predicted capacities for the I girder halving joint.

Case	Reliable capacity ΦV_u (kN)
Optimistic – assuming all bars can be fully developed except Lifting Hook at 50% developed	1360
Appropriately conservative – reduced capacity of bars with inadequate development length	1035

3 FINITE ELEMENT MODEL

The Finite Element Analysis (FEA) model of the I girder halving joint was developed in VecTor2 software (Wong et al, 2013). VecTor2 allows a bond element to be defined connecting the main reinforcing bars to the concrete, allowing the effect of the inadequate development length of some bars in the halving joint capacity to be investigated. A snapshot of the model is shown in Figure 3 where the various colors in the model represent different materials, determined by parameters like thickness, concrete and steel properties, and horizontal and vertical reinforcing percentages.

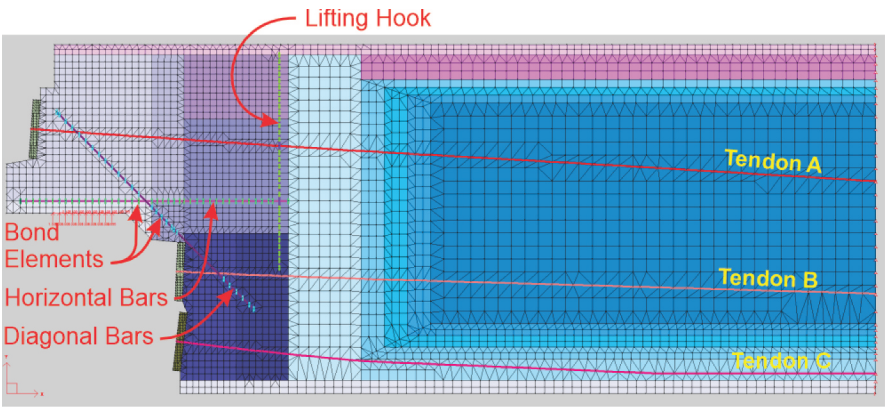

Figure 3. Vector 2 finite element model of the I girder halving joint.

The ligatures and bursting reinforcing (Figure 2) are modelled as distributed reinforcing as well as the small amount of horizontal face reinforcing. So, the material properties in the regions behind the tendon anchorages are different because some regions include one or both bursting reinforcing types as well as the full height shear ligatures.

The tendons, the lifting hook bars, the diagonal bars, and the horizontal bars (Figure 2) are modelled as concentrated reinforcing elements. The tendons assume perfect bond, given their positive anchorages preventing slip. However, the other bars are connected to the concrete through bond elements that permit slip, and the resistance to this slip is determined using a bond model, which is explained more later in the paper.

The loading is applied as a series of nodal loads across the bearing width, with the center of action aligning with the bearing centre. A horizontal tension load equal to 10% of the vertical load is applied at the bearing. This is in line with strut and tie models and serves as an allowance for braking or frictional forces due to temperature or live load deformations. No other loads are added to allow a fair comparison with strut and tie results. However, this approach is conservative when compared to the maximum reactions calculated in the previous FEA, as the maximum shear at the failure crack location is expected to be slightly lower than the maximum bearing reaction.

3.1 *Material properties*

3.1.1 *Concrete*

The specified concrete compressive strength is 41 MPa. Young's Modulus for the concrete is 33,000 MPa in accordance with AS 5100 (Standards Australia, 2017). The concrete tensile strength was varied as a parameter to investigate its effect on the predicted halving joint capacity. Table 3 shows the values considered.

Concrete contributes to shear strength by allowing average tensile stress to exist between cracks due to shear on the crack face and a local reserve of capacity in the reinforcing at the cracks. In VecTor2, this is modeled using Modified Compression Field Theory - MCFT (Vecchio & Collins, 1986), in contrast to strut and tie models that do not account for such tensile stresses. Models incorporating average tension in the concrete are likely to predict higher capacities compared to strut and tie models.

Table 3. Values for the concrete tensile strength.

Average tension in the concrete (f'_{ct})	Comment
0.1 MPa	Essentially zero, to allow a fair comparison with strut and tie model predictions
$0.33\sqrt{f'_c} = 2.11$ MPa	This is the default value for VecTor2 and MCFT. It provides a shear strength prediction including a concrete component consistent with the AS 5100.
$0.6\sqrt{f'_c} = 3.84$ MPa	Since the initial cracking was likely to be in a small zone at the re-entrant corner, the code specified characteristic flexural tensile strength might be more appropriate for predicting observed cracking patterns

Note: For analyses including the concrete capacity reduction factor (φ_c), these values are reduced by $\varphi_c = 0.65$.

3.1.2 *Reinforced and prestressing steel*

Structural steel is modelled in VecTor2 as a linear-elastic material up to the point of yielding, after which plastic deformation and strain hardening occur, providing realistic predictions of the steel's behaviour. However, to obtain a capacity prediction consistent with code requirements it is necessary to enforce a true yield plateau for both reinforcing and prestressing steels. This is particularly conservative for the prestressing steels which do not have a yield plateau. Table 4 shows the prestressing and reinforcing steel properties.

Table 4. Steel properties.

	Yield stress	Comment
Prestressing steel	$0.82\, f_{pb} = 1525$ MPa	In accordance with AS 5100.5 and $f_{pb} = 1860$ MPa
Reinforcing steel	410 MPa	Cold worked deformed bars

Note: For analyses including capacity reduction factors, these values of yield stress are reduced by the capacity reductions factors of 0.9 for prestressing steel and 0.85 for reinforcing steel.

3.1.3 *Bond-slip relationship for strand*

The bond material properties are essentially an expression of the relationship between the bond stress on the bars and the bar slip relative to the surrounding concrete. Figure 4 shows the typical bond-stress relationship used in VecTor2, which was proposed by Eligehausen et al (1983).

In Figure 5, the maximum bond stress from the Eligehausen model is compared with the bond stress used in AS 5100 for different ratios of (c/d) where c is the minimum of the concrete cover and half of the bar spacing and d is the bar diameter. It clearly shows that Eligehausen bond stresses are generally much higher than those implied by the AS5100 development length

requirements. It is only for the very low c/d ratio of around 1 that the splitting bond stress approaches the AS 5100.5 values. The pullout bond stress is much higher than the splitting values for low c/d ratios and the code values. However, for high c/d ratios the Eligehausen splitting bond stress can get as high as the pullout stress. The bond pullout values are only applicable in the presence of a confining pressure σ. VecTor2 uses a parameter β to interpolate between the splitting and pullout values for the bond stress. In most cases β is zero and the splitting value will be used, however in the girder model the diagonal bars are anchored behind the prestress anchorages therefore some confining pressure would be applicable.

In the present analysis, two bond levels were considered: Code bond and High bond (Table 5).

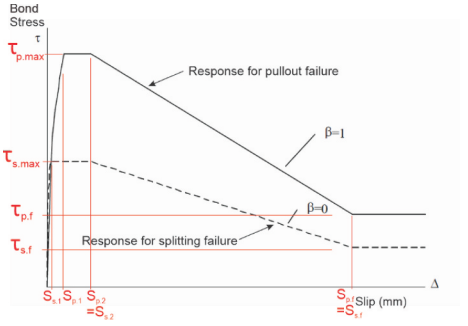

Figure 4. Bond-slip relationship in Vector 2. τ_p - pullout stress, τ_S - splitting stress and β - confinement pressure factor.

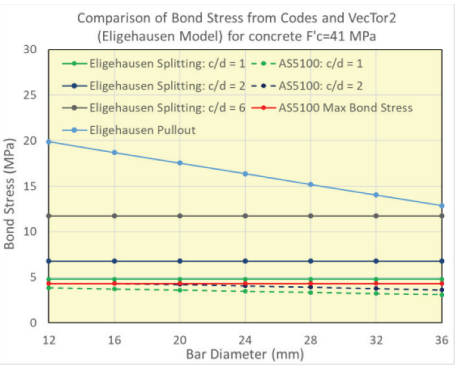

Figure 5. Comparison of AS5100 and Vector 2 bond stress (Eligehausen model) for concrete F'c=41 MPa.

Table 5. Bond levels.

Bond level	
Code bond	Input parameters to VecTor2 were manipulated to force the software to adopt a value for $\tau_{max} = 4.31\ MPa$ which is the maximum value allowed by the codes.
High bond	Applicable confining pressures and actual clear cover values were input, and the software calculated the values for τ_{max}

Note: AS 5100.5 does not apply a capacity reduction factor in calculating development lengths, the values adopted for "Code bond" were the same irrespective of whether capacity reduction factors were used in the analysis. However, High bond is affected when capacity reduction factors were included in the analysis.

4 RESULTS DISCUSSION

Table 6 summarises some of the key results for the analyses. These results can be compared with previous results in Table 1 and Table 2.

Analysis A1, has essentially zero concrete tension and so is based on assumptions consistent with a strut and tie model and a comparison of the results is instructive. Differences in the assumptions are the degree to which the diagonal bars, horizontal bars and lifting hook bars participate in carrying the load across the diagonal failure crack. Also, the strut and tie model does not include any contribution from the Bursting Reinforcing A. Based on the crack directions at the maximum load, which essentially align with the principal compressive stress direction, and so can be thought as compressive strut directions, it was observed that vertical bars of Bursting Reinforcing A are carrying high stress and consequently are participating in the load path. When the load in the three ligatures of Bursting Reinforcing A is added into the strut and

tie solution the predicted capacity increases to 1465 kN, which is comparable to the VecTor2 predicted capacity of 1425 kN. The point of this comparison is to show that the VecTor2 solution with no concrete tension is transparent. The load paths can be identified with strut and tie considerations, and the predicted capacity is consistent with a strut and tie model.

Analysis A2 includes concrete tension, and so essentially includes a small concrete shear component, consistent with MCFT and the code shear provisions. Including the concrete tensile strength also improved the anchorage of the bars that were modelled discretely resulting in higher stresses in these bars. As expected, the results are similar to that for A1. The maximum load was slightly higher.

Analysis A3 and A4 were similar to the first two analyses except that the more realistic bond properties in VecTor2 were used. This change further increased the predicted capacities by allowing higher forces in the discretely modelled bars.

Analysis A5 and A6 did not include capacity reduction factors and so, gave higher failure predictions. These analyses were included to give a more realistic estimate of the actual capacity, and a more realistic prediction of the actual behaviour in terms of what cracking might be expected at SLS and ULS loadings, which is key information for maintenance inspections. The following comparison of cracking patterns is done based on these two analyses.

Table 6. Summary of key Vector 2 analysis results.

						Yield indexes					
Analyses	Bond level	f'_{ct} (MPa)	Capacity reduction	R* (kN)	Defl.** (mm)	Diagonal	Horizontal Bars	LH Bars	Burst Reo A (top)	Top tendon	Failure mode***

* R – Maximum Halving Joint reaction. ** Defl. – Deflection at centreline of bearing at Maximum reaction

*** Failure modes: A - Crushing in region just above Bursting Reo A, B - Rapid crack growth and yielding in region above bursting reinforcement.

4.1 *Comparison of cracking patterns*

The key focus of these analyses lies in assessing the extent of cracking at different load levels, offering valuable insight into the interpretation and significance of observed cracks on the girders.

Understanding the software's crack direction output is essential before comparing results. The VecTor2 software and its theory doesn't predict individual cracks but rather smears or averages them over elements. So, if an element is nominally cracked, it means that there will be cracking in that region. Even if many elements are shown as cracked, there may only be one or two actual cracks.

The predicted cracking patterns for analyses A5 and A6 are discussed below. These analyses do not include capacity reduction factors and so are more realistic in terms of likely cracking levels. The difference between the two analyses is the concrete tensile strength. Analysis A5 uses the default concrete tensile strength of 2.11 MPa, while Analysis A6 uses 3.84 MPa.

Each analysis considered all load levels from zero up to the predicted capacity. For loads up to about 900 kN which is the SLS loading, there is only a small amount of cracking predicted at the re-entrant corner.

Figure 6 shows the cracking pattern at the ULS loading (permanent & traffic) and at the predicted failure loads.

For ULS loading (Figure 6.a&b), the crack widths are very wide near the corner but reduce quickly. Significant cracks at some distance from the corner indicate yielding of the vertical reinforcing. Figure 6.b shows cracking confined to a narrow band extending about 600 mm from the corner indicating that there might only be one or two cracks. In case A5 (Figure 6.a), the vertical reinforcing strength (at a crack) is higher than the concrete cracking strength and once the reinforcing crossing the main diagonal crack reaches a high enough stress, additional cracks will form above and below the main crack. This results in the cracking spreading upwards into the zone above the bursting reinforcing, where the amount of vertical reinforcing is much less.

For the failure loads (Figure 6.c&d) the maximum crack widths at the surface are similar and extremely wide. The extent of cracking is much greater for the A5 case for the reasons noted above. For this case there is widespread cracking in the region above the bursting reinforcing and the cracks in this location are very wide (4 mm). There are also other regions away from the corner with very wide cracks. This is different from the higher f_{ct} case, which even at a higher load has a much narrower band of cracking, and the cracks away from the corner are a maximum of about 1 mm. This is still wide, and an indication of moderate yielding but not an indication of imminent failure. This difference in failure characteristics is discussed in 4.2.

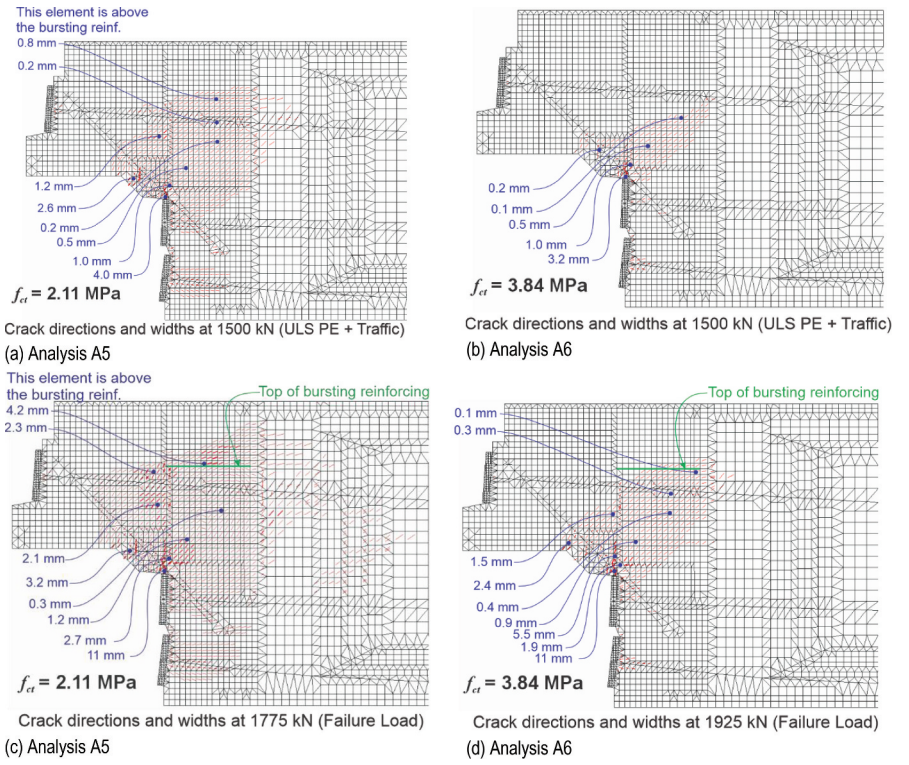

Figure 6. Cracking pattern for three different loading levels and for analyses cases A5 and A6(Table 6).

4.2 *Comparison of failure modes*

In the default f_{ct} model (Figure 6.c), wide cracking occurs in some areas due to extensive yielding and very large strains (5 mε to 10 mε). The final failure was caused by crushing of the concrete in the region above the bursting reinforcing. The higher f_{ct} model (Figure 6.d) has a different failure mode, but failure occurs at a higher load. As the load increases, the band of cracking stays relatively narrow and progresses past the large lifting hook bars. These large bars transfer enough load into the concrete above the bursting reinforcing to cause the

cracking to spread into this region. Figure 6.d shows that cracking has spread through most of the region above the bursting reinforcing. Since this region has much less vertical reinforcing than the region below it, once it cracks, the capacity would be less than the current load, and the failure would be rapid. So, in this case, considered to be the more realistic of the two, there is only moderate reinforcing yielding and moderate width (~1 mm) cracks away from the corner (in the context of failure being imminent) until failure occurs, which would be rapid. This issue occurs because of the particular pattern of reinforcing in this design. If the bursting reinforcing, which in the end is being partly relied on for the halving joint capacity, extended all the way to the top of the girder then a sudden failure would not occur. Note that the predicted capacity is about 25% above that required for the ULS loading so the risk of such a failure occurring is extremely low. Also, the solution does not include strain hardening of either the reinforcing or the prestressing strand which likely would further increase the predicted capacity and reducing the risk of a rapid failure.

5 CONCLUSION AND IMPLICATIONS FOR THE HJ MANAGEMENT

Uncertainties regarding the capacity of the post-tensioned I girders halving joints motivated this investigation. From the preceding discussion, the contribution of nominally inadequate bars has been appropriately included in the VecTor2, with an optimised strut-tie model identified in the process. Some cracking is anticipated although reduced when compared to typical reinforced concrete sections, with minor or no cracking from permanent effects and minimal observable cracking under normal operational loads, primarily at the re-entrant corner. Cracking from conventional halving joint failure mechanisms is expected to be ductile, but concrete crushing above the bursting steel can lead to a loss of structural integrity. Small deflections associated with the halving joints makes load redistribution challenging, emphasizing the need to prevent individual halving joint failure.

The halving joint capacity (1425 kN) is slightly below the demand (1496 kN), but additional capacity may exist when considering the concrete contribution. However, it's essential to consider the following context: 1) The assessment focuses on one HJ at one pier, although considered a typical scenario, there are numerous other HJ in the Expressway. 2) The Live Load Factor (LLF) of 2 may overestimate real traffic loads (Pape et.al, 2022), particularly given the primary commuter duty of this bridge and also it is needed to understand the live load scenarios. 3) Ductility (area under the load-deflection curve) appears to decrease in Table 6, with deflection at bearing centreline reducing by approximately half between A1 and A6; while ductility is a concern in relation to halving joints, a specific methodology would need to be developed to quantify it.

While the I girder HJ under investigation have yet to be extensively inspected, early observations have shown that no significant cracks have been detected. This is consistent with the discussion in Section 4. A summary of the expected defects which may be observable in the field based on the VecTor2 analysis is given in Figure 7, with small, inclined cracking likely to be observed first (1). Vertical cracking (2) may become more prominent as load increases,

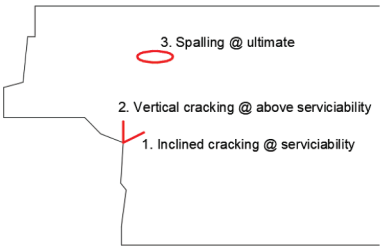

Figure 7. Likely sequence of anticipated cracking potentially observable.

with spalling to be observed near the ultimate capacity of the joint (3). While further inspection of the halving joints is required, it is likely that few re-entrant corner cracks will be identified based on observations to date. Evidence of cracking or spalling above the bursting reinforcement should also be checked, and while not anticipated, should be considered a serious defect if it is observed. Assuming that no significant defects are discovered, the I girder HJ are considered to meet QTMR requirements.

Fatigue behaviour of reinforced concrete inverted T headstock halving joints

N. Stevens

National Transport Research Organisation, Brisbane, Australia

ABSTRACT: The root cause of several worldwide bridge collapses in the past 20 years has been identified as resulting from the poor performance of structural details known as halving joints. Concrete halving joints are renowned for their low redundancy, potentially brittle failure characteristic (if not detailed correctly), and high stress concentration zones. Following safety concerns related to a halving joint bridge, an extensive program of structural health monitoring was conducted spanning nearly 2 years. The monitoring data combined with the finite element modelling allowed an investigation of the fatigue risk associated with reinforced concrete halving joint headstocks. This paper presents the results of the investigation into the potential for fatigue to adversely influence the halving joint performance. Despite the obvious issues with the bridge, it was found that the fatigue risk in the headstock halving joints was low.

1 INTRODUCTION

1.1 *Context and background*

Halving joints or Half joints (Figure 1) describe the intersection of the two components (superstructure and substructure) that are overlapped. They typically feature cantilever superstructure and suspended span/drop in spans. They facilitate a beneficial reduction to the overall height of the structural system while maintaining clearance over roads/railways or other assets. Catastrophic failure of structures triggered by failure of these key details had occurred in recent years (eg, Lecco, Italy and De La Concorde, Canada). A knowledge of these failures motivated the Queensland Department of Transport and Main Road's (QTMR) to develop a deeper understanding of concrete halving joint bridges on the Queensland network and provide appropriate risk management and assurance in relation to the performance of these bridges.

A strategically important bridge on the national highway was identified to have significant halving joint performance concerns in 2019. Most QTMRs halving joint bridges have headstock configurations similar to this bridge. An extensive program of structural health monitoring was conducted spanning nearly 2 years to support management and remediation of the bridge. The monitoring data combined with the finite element modelling allowed an investigation of the fatigue risk associated with reinforced concrete halving joint headstocks in the specific case. This paper presents the results of the investigation into the potential for fatigue to adversely influence the halving joint performance. The investigation results also have implications for the management of similar assets.

The physical configuration of half joint introduces a significant change in cross-section stiffness and strength. The joints are positioned in the structure so that there is no primary moment

DOI: 10.1201/9781003483755-456

at the joint. However, there is typically significant cross-section shear, leading to localised shear and bending resulting from the joint configuration. Reduced cross-section stiffness and strength combined with complex localised bending and shear makes them vulnerable to failure, often exacerbated by other factors. Ultimately typical failure of concrete half joints occurs as illustrated in Figure 2, often with limited warning. Key factors exacerbating halving joint vulnerability include poor reinforcement detailing and/or lack of appropriate reinforcement. In addition, these joints are difficult to inspect and maintain, and are often positioned near deck joints resulting in increased environmental exposure (water leakage) leading to localised material deterioration. These factors combined with their potentially brittle failure nature and (often) limited alternative load paths (low system redundancy) pose significant risks.

Figure 1. Typical QTMR half joint – inverted "T" headstock and super "T" girders.

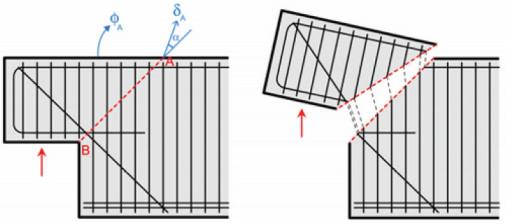

Figure 2. Half joint failure (after CS466 Risk management and structural assessment of concrete half joint deck structures).

1.2 *Objective*

The objective of this investigation was to better understand the fatigue behaviour of reinforced concrete halving joint headstocks. While fatigue risks were substantially mitigated by intervention for the bridge in question, there was an opportunity to better understand fatigue performance of many similar components on the network. The objective of this paper is to summarise the outcomes of the reinforced concrete fatigue investigation.

2 BRIDGE CONFIGURATION

The Subject Bridge is a 5-span post tensioned concrete girder bridge carrying northbound highway traffic. Figure 3 shows the general arrangement of the bridge. The road centre line has a 303.5 m radius. There is a large radius vertical curve and a 5% crossfall. Figure 4 shows a typical cross section through the girders, and typical elevation at the piers.

There are five spans in total, four with overall lengths of 28 to 29 m and one longer span. As a result of variations in the headstock widths, these four spans have essentially identical bearing-to-bearing girder lengths (27.29 m for central girder). Span 4 has a 35 m overall span and longer girders (32.59 m bearing-to-bearing for the central girder).

As shown in Figure 4, the underside of the headstock is at the same level as the underside of the girders. To achieve this, the girder/headstock connection incorporates a halving joint, with the half depth end of each girder sitting on bearing shelves which essentially cantilever from each side of the headstock.

An engineering inspection of the bridge in June 2019 determined that there was structural cracking in the pier headstock and girder halving joints. This cracking indicated that the halving joints were potentially operating under some degree of structural distress. Subsequent detailed engineering analyses determined that the halving joints were operating at reduced margins compared to those in Australian Standards for as-of-right freight vehicles (including B-Doubles). The structure was observed to have significant cracking at the corners of the headstock halving joints. Subsequently an interim Structure Management Plan (SMP) was put

in place, the bridge was instrumented to monitor cracking in the pier headstocks and Heavy Vehicle Travel Restrictions were implemented (September 2019). Ensuing capacity assessments showed the headstock halving joint capacity to be deficient (based on a code compliant assessment) for vehicles that were currently using the structure.

Strengthening of the headstock halving joints was undertaken, and completed by January 2021. The objective of the strengthening works was to safely and efficiently remove the travel restrictions for Class 2 vehicles operating under notice (as-of-right freight vehicles) and reduce the risk associated with the passage of Class 1 heavy vehicles (indivisible loads). Travel restrictions remain for some vehicles requiring a permit to operate, and a Structure Management Plan (SMP) remains in place (QTMR, 2023a). The load monitoring has continued since the strengthening was completed and the freight load restrictions lifted.

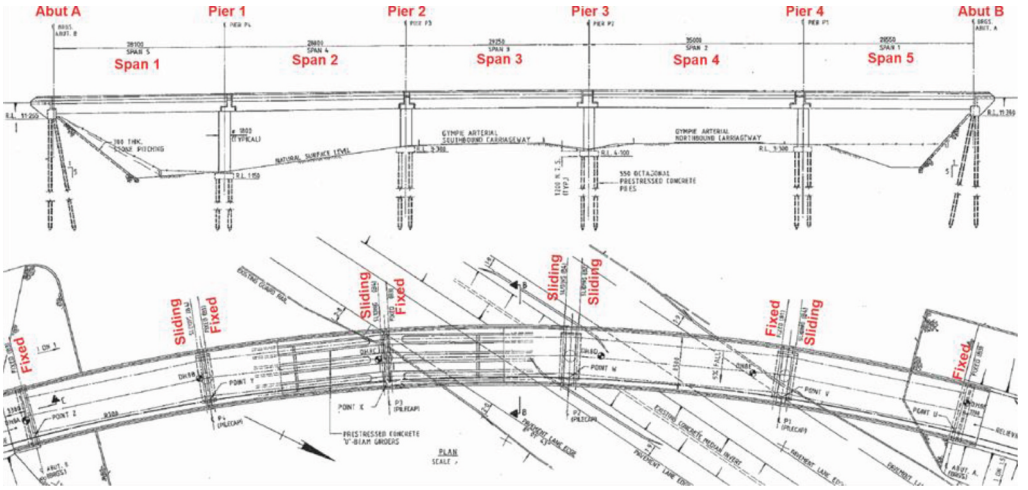

Figure 3. General arrangement of the subject bridge.

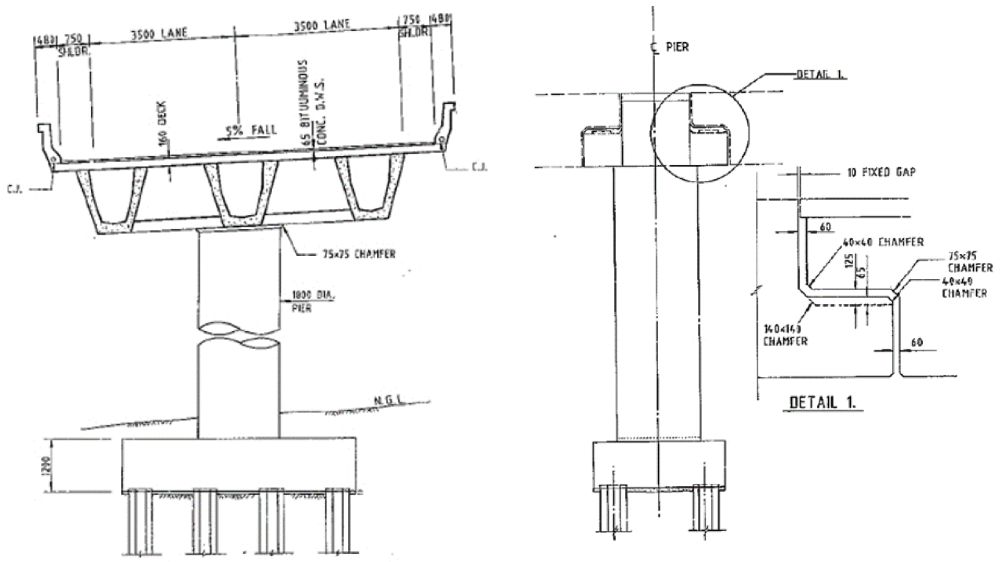

Figure 4. Typical elevation at pier showing halving joints.

A Bridge Specific Live Load Model (BSLLM 2020) was developed in October 2020 to inform decisions relating to the interim management of the superstructure including the girder halving joints which remain unstrengthened. The BSLLM provided a better understanding of the vehicles accessing the structure and the live loads they impose with an update report issued in May 2023 (QTMR, 2023b). The data used to generate the BSLLM was made available to investigate the potential fatigue issues in inverted "T" headstocks.

2.1 *The opportunity to investigate fatigue in halving joints*

When considering the management of halving joints in concrete bridges the question arises as to whether fatigue is likely to be an issue. The question arises because it is not uncommon for there to be significant cracks emanating from the joint re-entrant corner, which, if measured, will be found to be opening and closing with the passage of every heavy vehicle. This scenario was identified in 2019 during early Subject Bridge technical investigations.

While the fatigue risk in the Subject Bridge headstocks no longer exists due to the strengthening, the question of whether fatigue would have been an issue is still relevant because it can help guide future management decisions on other bridges. Essentially, if there ever was going to be a case where fatigue could be an issue on QTMR halving joint bridges, then it would be on this bridge. It is very heavily trafficked, with deficient headstock halving joints, and obvious working cracks. The availability of comprehensive loading data over a period of almost 2 years provided a unique opportunity to investigate whether fatigue would have been an issue in the headstocks of the Subject Bridge. This investigation only addresses the potential for fatigue in the headstocks.

3 ANALYSIS METHODOLOGY

A full discussion of analysis methodology is beyond the scope of this paper. In summary:

- Finite Element Analysis (FEA) and health monitoring results were used to define the characteristic bearing reactions under ambient loading.
- Separate FEA was used to determine the characteristic opening/closing of one of the cracks for which monitoring data was available and predict bar stress ranges.
- Contemporary fatigue assessment of both steel and concrete elements was then undertake based on FEA results.

Some of the more pertinent aspects of this approach are discussed in this Section.

The loading data that are available for each heavy vehicle and useful for the fatigue assessment are the midspan girder strains. This was recorded for every heavy vehicle. A threshold girder strain for classification as a heavy vehicle was set at 25 microstrain in any girder. If the threshold was exceeded the event was classified as a heavy vehicle and the peak girder strains and other data was recorded and saved.

The data available covers the period from 16 December 2020 to 31 May 2022, a period of 531 days. Over this period there were 287432 heavy vehicle events.

If a threshold girder strain of 48 microstrain was exceeded, then the event was classified as a very heavy vehicle and the waveform of the response and photographs of the vehicle were also recorded. There were 5576 very heavy vehicle events over the recording period. Many of these vehicles could be classified (eg as 4 axle cranes, 6 axle low loaders etc). This allowed a more careful assessment of the fatigue effects of these to be undertaken.

Influence line results from FEA of the structure were used to predict girder strains and bearing reactions for various vehicle types. These results were in turn used as follows:

- The difference in girder peak strains between Girder 1 and Girder 3 (the outer two girders) was shown to be able to predict the drive line (relative to the bridge centre line) for a vehicle. These results were used to estimate the drive lines of all the heavy vehicles based on the recorded maximum girder strains.
- The load range at the outside bearing on Pier 2 was shown to be very sensitive to drive line. For various vehicle types the relationship between the bearing reaction range, the sum of

the girder strains (a measure of vehicle mass) and the drive line eccentricity (relative to the centre line) was established. This, combined with a FEA system model allowed the bearing load range to be calculated for each event.

Separate FEA of the Pier 2 headstock allows the stress range in the reinforcing in the headstock to be calculated based on the live load reaction range on the outer bearing. Full details of this FEA are beyond the scope of this paper, but some features are relevant. Illustrations of the models are provided in Figure 5.

The right-hand side of the model is at the face of the pier column and is fixed. The concrete in the model is "pre-cracked" into 5 distinct blocks. The 'crack' locations match observed cracking. The interfaces between the blocks have no tensile capacity and no friction when the cracks are open, but very high friction when the cracks are closed. The green block shown in Figure 5 supports the bearing loads (applied to the red squares). Once permanent load has been applied, the green block is supported only by reinforcing crossing the pre-existing cracks. When an additional live load is applied, the reinforcing resists all of the additional load. This methodology was used to ensure that the calculated stress ranges in the reinforcing due to the vehicle loads was conservative.

An unforeseen feature of this model was that bending deformations in the headstock produced slip on the crack faces once they were open and hence frictionless (No Crack Friction model). This resulted in local bending stresses in the reinforcing where it crossed the cracks. These stresses were in some cases higher than the axial stresses and would reduce the predicted fatigue life by orders of magnitude. A more realistic estimation of the local bending stresses was arrived at by introducing some friction (or shear stress) on open, but narrow, cracks (Friction on Crack model). Even for this model, the reinforcing stress ranges due to local bending are very significant.

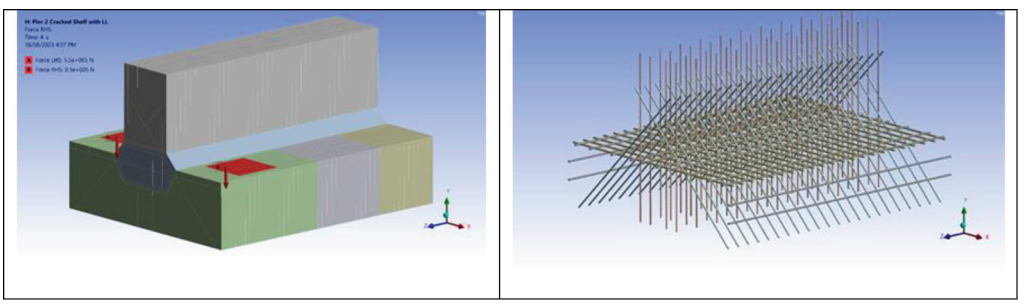

Figure 5. Illustration of separate FEA models of concrete and reinforcing.

The calculated reinforcing steel stress range for every vehicle was used to calculate the fatigue damage for each vehicle. This is then summed over all the vehicles to calculate the fatigue damage over the known monitoring period. This can then be used to calculate total fatigue damage over a required design life.

4 STEEL FATIGUE ASSESSMENT

The fatigue assessment was undertaken in accordance with Section 18 of AS 3600:2018 (Standards Australia, 2018). This is a new section in AS 3600 but is almost identical to the fatigue provisions of the CEB-FIP Model Codes (2010). A similar section has not yet been added to AS 5100 (Standards Australia, 2017). The fatigue assessment requires that for each heavy vehicle event, i, the fatigue life N_i cycles be calculated based on the reinforcing steel stress range $\Delta\sigma_i$ for that event. The formula for this is given in Eq. 1.

$$N_i = \left(\frac{\varphi_{s,fat}\Delta\sigma_{Rsk}}{\gamma_F\Delta\sigma_i}\right)^m N_{Rsk} \tag{1}$$

Where N_i is the fatigue life in cycles, $\varphi_{s,fat} = 0.85$ is the capacity reduction factor for fatigue, $\gamma_F = 1.1$ is the load factor for fatigue, $\Delta\sigma_{Rsk} = 210MPa$ for straight N16 bars, $N_{Rsk} = 10^6$ cycles, $m = 5$ for $\gamma_F\Delta\sigma_i > \varphi_{s,fat}\Delta\sigma_{Rsk}$ or 9 otherwise, $\Delta\sigma_i$ is the reinforcing stress range and i is the event.

The fractin of the fatigue life used, or the fatigue damage, for each event is 1/Ni. The total fatigue damage (D) is calculated by summing the damage for each event over all events, Eq. (2).

$$D = \sum_i \frac{1}{N_i} \tag{2}$$

Note that these code-specified fatigue lives are by their nature conservative. They are based on characteristic fatigue S-N curves which have only a low probability of not being exceeded, and then have capacity reduction factors applied to them. The probability of fatigue cracking existing when the fatigue life has been reached is still very low.

4.1 *Steel fatigue assessment - results*

In the first instance, the results are based on the higher reinforcing stresses from the No Crack Friction model.

The total fatigue damage for the 287432 heavy vehicle events which occurred over 531 days was 0.0265. Assuming this rate of fatigue damage remains constant then the fatigue life would be 55 years (37.7 cycles of 531 days). The total fatigue damage for the 5576 very heavy vehicle events (classified) which occurred over 531 days was 0.0057.

The 5576 classified very heavy vehicle events will essentially be the same as the highest 5576 events in the unclassified data as determined by the G1 girder strain. The fatigue damage for these events calculated using the unclassified methodology was 0.0067 which is slightly higher than that calculated using the classified event methodology. This is expected because the unclassified data was treated as if it was all from the most severe vehicle type. Significantly these 5576 events represent only 1.9% of the heavy vehicles but caused 25% of the fatigue damage.

Conversely the events with Girder 1 strains less than 25 με, which only just exceeded the threshold for inclusion, represent 15% of the total events, but only caused $1.17\text{x}10^{-7}$ of the fatigue damage. So, it can be concluded that the fatigue damage due to all of the loadings which were not recorded was negligible.

If the reinforcing stress ranges use the more realistic local bending stress from the Friction on Crack model, then the fatigue damage due to all of the heavy vehicle events was only 0.00115. This corresponds to a fatigue life of 1265 years.

4.2 *Discussion – steel fatigue assessment*

The stress ranges using the reduced local bending stresses are still considered to be conservative. Most methods of analysis would not have even considered local bending stresses.

The dramatic effect of stress levels on the fatigue life is due to the exponent $m = 9$ used in the fatigue life calculations. The value $\Delta\sigma_{Rsk} = 210$ MPa is effectively a fatigue cut off limit. Stress ranges below this (after including capacity reduction factors and load factors) cause very little fatigue damage.

Consideration should be given to any non-conservative aspects of the assessment. Particularly, it is noted that the Girder 1 strain predictions were about 5% low for the calibration vehicles. If the predicted bearing reaction ranges were increased by 5% to account for this, this would in turn reduce the fatigue life by a factor of about $0.95^9 = 0.63$. While significant, the predicted fatigue life is still very high.

The assessment has only considered Pier 2. Piers 3 and 4 of the bridge support Span 4 which is longer. From previous assessments the bearing reactions for the HML B-double on this span are about 8% higher than those on Pier 2. The headstock design is different with more reinforcing, but as a worst case if the headstock design was the same as Pier 2, then the predicted fatigue life (including the 5% assessment error) would be factored by $(0.95/1.08)^9 = 0.31$. This equates to 399 years which is clearly still adequate.

It is concluded that despite the excessive cracking in the headstocks, the fact that they had insufficient ultimate capacity, and the high traffic loads, premature failure due to fatigue in the reinforcing steel was not likely.

The assessment did not consider the effects of corrosion on the reinforcing bars, which is appropriate for this bridge. However, the presence of corrosion on the reinforcing in a halving joint would greatly reduce the fatigue resistance.

5 CONCRETE FATIGUE ASSESSMENT

There are two types of fatigue in the concrete that require consideration. The first is conventional concrete fatigue from cycles of compressive stress. The second is local fatigue in the concrete surrounding the reinforcing bars due to bond stress resisting slip. This will be referred to as bond fatigue.

5.1 *Concrete fatigue*

Based on the headstock FEA, the maximum compressive stress which occurred in the headstock under the maximum calculated bearing load (from all recorded events) was 12.5 MPa. After taking into account the stress gradient factor, this stress was less than the threshold defined in Clause 18.2 of AS 3600 and therefore no further fatigue assessment for concrete in compression was required. Hence failure due to fatigue from cyclic compression in the concrete was not considered to be a risk.

5.2 *Bond fatigue*

Bond fatigue refers to a gradual reduction in the bond stress between the bars and the concrete under conditions of repetitive loading cycles. Initially the bond stress is highest immediately adjacent to a crack. If the stress in the reinforcing at the crack is high, then the bond capacity might locally be exceeded resulting in a small amount of local slip near the crack. This effectively allows the crack to open.

The concern is that this region of locally exceeded bond capacity will extend along the bar if the cyclic stress range in the bar is very high. The particular concern was with the horizontal bars in the bearing shelf which are straight, and are not anchored at each end with hooks or cogs. If the local bond breakdown did continue to grow along the bar, then ultimately bar pullout and failure might occur.

There are no requirements relating to bond fatigue in AS 3600 or the CEB FIP model concrete code.

A number a fundamental bond fatigue tests were undertaken by Balazs (1991). In brief, the test results showed that the nature of fatigue behaviour depended on the embedment length:

- If the embedment length is short so that slip occurs over the entire length of a bar that is pulled from one end, then the fatigue life is finite and relatively short (depending on load level and many other factors)
- If the embedment length is long enough so that there is no movement at the unloaded end, then the fatigue life is essentially infinite. The slip increases with load cycles initially and then stabilizes.

All of the bars except the horizontal bars have development lengths in excess of the code requirements for the development of the bar yield stress of 410 MPa. Given that the maximum bar stress under the highest recorded bearing load was 280 MPa (for the vertical bars), slip at the unloaded end will not occur and the bond fatigue life should be infinite.

For the horizontal bars, the length of the bar beyond the crack is 610 mm which is less than the development length of 745 mm for these Y24 bars. Hence the available length could develop a stress of 610/745 x 410 MPa = 336 MPa in the bar. The maximum stress in the horizontal bar at the crack was 103 MPa. This should be easily developed by the available length,

and so slip at the unloaded end will not occur and the bond fatigue life for this bar should also be infinite.

A further indicator that bond fatigue is not an issue is the results of the monitoring of the crack movement. If bond degradation is occurring, and bar slip near the crack increasing, then an increase in the crack opening movement will occur. The results of the monitoring (QTMR 2023b) showed that, while early results seemed to indicate increasing crack opening, this proved to be a seasonal effect and over the full monitoring period there was no trend of increasing crack movement.

It was concluded that failure due to bond fatigue is not considered to be a risk.

6 CONCLUSIONS

Discovery of active cracks on the Subject Bridge halving joints in 2019 was a significant concern given the strategic significance of the route and its heavy vehicle duty. The scope of concerns spanned both ultimate and serviceability limit states, with significant concerns associated with the potential for fatigue deterioration over time, particularly for the reinforced concrete headstock. A range of interventions were implemented including structural health monitoring.

While permanent interventions on the bridge eliminated the consequences associated with this risk, the opportunity was identified to better understand and quantify the nature of fatigue risks in reinforced concrete halving joints based on structural health monitoring data gathered as part of interim intervention.

The results of the investigation showed that for a heavily trafficked halving joint with compromised ultimate capacity, fatigue in the joint due to repeated ambient loading was confirmed to be unlikely. The department's existing operational and inspection regime for the bridge is considered adequate. This also provided valuable information for assessing the likely fatigue risks in other reinforced concrete halving joints in the QTMR network.

Note that these findings are somewhat dependent on the traffic mix using the QTMR network. Further, they would not be applicable to halving joints with corroded reinforcing.

Enhancing safety on timber bridges: Feasibility and risk assessment of bridge barrier implementation

B. Wiggins
Queensland Department of Transport and Main Roads, Queensland, Australia

ABSTRACT: The Queensland Department of Transport and Main Roads (TMR) manages 286 timber bridges, some of which do not have bridge barriers or are substandard. Whilst the current Australian Standard indicates that bridge barriers are not required in certain road scenarios, the enhancement and elevation of safety measures remains a factor to consider. This project investigated the feasibility and prioritisation of installing bridge barriers on timber bridges. First, a literature review was conducted, followed by the identification of. barrier installation options as well as commercially available proprietary systems. A risk-based multi-criteria analysis was developed to identify suitable bridge barrier candidates on low-volume roads. This methodology was used to quantify crash risks and calculate a risk score for each location. The analysis identified 138 sites that are recommended to be investigated for safety barrier installation. This process can be extended to bridge networks across Australia.

1 INTRODUCTION

Bridge barriers are crucial for preventing errant vehicles from leaving the bridge deck or colliding with hazards adjacent to or on the immediate approach to the structure. To align with the Australian Government's Vision Zero principle (Commonwealth of Australia, 2021), which aims to create a road transport system with no fatalities or serious injuries, it is essential to enhance safety at locations with a high risk of fatal and serious crashes.

Currently, many timber bridges within the Queensland Department of Transport and Main Roads (TMR) network are without bridge barriers. Timber bridges are typically found on low-traffic roads in Queensland. Despite lower traffic volumes, these roads often experience run-off-road and head-on crashes at rates equal to or higher than major freeways (Milling et al., 2023). The risk of serious or fatal injury crashes on low-volume roads and bridges does not decrease with lower traffic volumes. The presence of non-frangible hazards on the bridge approach, adjacent to the bridge and in the ravine; the presence of water in the ravine; and drop heights from a bridge deck substantially elevate crash risks. Bridges without adequate safety barrier lengths on the bridge approach, or without bridge barriers on the bridge deck, fail to protect errant vehicles from these hazards.

This project was established to develop technical guidance to evaluate the feasibility of installing bridge barriers on timber bridges. It also established a method for identifying timber bridges where the addition of a bridge/approach barrier would improve road user safety.

2 LITERATURE REVIEW

2.1 *Barrier system feasibility*

Barrier systems work by transferring forces through the barrier railings to the post, into the deck and then the bridge substructure where they dissipate. These forces can potentially cause damage or failure to the deck under collision loads at the point where the post is attached to the deck. In the consideration of safety and damage minimisation, AS 5100.2 (Standards Australia, 2017) requires bridge barriers be designed as progressive strength systems, with barriers being the first to fail, then connections and finally supporting elements. This is achieved by applying an ultimate load factor of 1.0 to the design of bridge barriers, 1.05 to the connection bolts and reinforcement and 1.10 to the bridge deck design ultimate capacity. To ensure proper performance of a barrier system on a bridge, the bridge deck must be assessed to ensure sufficient strength to transfer the barrier forces without causing damage to the substructure. This assessment is particularly critical for installing barriers on timber bridges since the attachment of the barrier posts to the bridge deck and the ability of the timber superstructure to resist the applied barrier loads may often be the controlling parameters (Ritter et al. 1999). AS 5100.8 (Standards Australia, 2017) allows for a lower performance level barrier to be selected if the bridge's structural capacity is inadequate and replacing or strengthening the bridge is not an option.

For bridges susceptible to flooding, the installation of barriers introduces additional loads on the bridge superstructure during flood conditions. Flooding events can significantly alter the hydraulic conditions around a bridge, resulting in increased water pressure, debris impact and hydrodynamic forces. The presence of a barrier will impose additional hydrodynamic loads on the bridge, leading to increased forces on the piers and abutments. The additional load effects can elevate stress levels and potentially compromise the structural integrity of the bridge.

In addition, the provision of barriers can prevent the passage of debris. Debris jams at the barriers can cause an increase in the upstream water levels (known as afflux) and create a backwater effect, thus posing an additional flood hazard to nearby areas. Stranded wood debris also intensifies the hydrodynamic actions, exacerbating the situation.

The hydraulic performance of a bridge barrier system is dependent on factors such as height, size, shape and open space within the rail face. According to TMR's *Design Criteria for Bridges and Other Structures* (Queensland Department of Transport and Main Roads, 2021), post and rail traffic barriers are suggested to reduce upstream afflux, indicating that steel post and rail bridge traffic barriers are suitable in scenarios where controlling afflux is crucial. When installing bridge barriers, it is important to weigh both their crash resistance and hydraulic performance. Hydraulically, larger openings allow greater passage of water to reduce upstream flooding effects.

Barrier deflection is also an important consideration for timber bridges as it is common to have a narrow horizontal clearance beyond the edge of the traffic lane which limits the allowable dynamic deflection of the barrier, potentially leading to inadequate containment of vehicles during a collision. Austroads (Austroads, 2013) requires rigid (i.e. in situ concrete) or semi-rigid (i.e. horizontal steel beams) barriers when the envelope for deflection is too small to accommodate the dynamic deflection distances specified in the guideline. It is noted that 'low' performance barriers are generally designed to deform during a collision, rather than remaining rigid (Queensland Department of Transport and Main Roads, 2021).

2.2 *Bridge barrier system selection criteria*

AS 5100.1 (Standards Australia, 2017) establishes various performance levels for providing 'Road Traffic Barriers', these include Low, Regular, Medium and Special, as well as the option for no barrier in certain circumstances. These performance levels are adopted as guidelines in all Australian and New Zealand jurisdictions. Both the Austroads (Austroads, 2013) guide and AS 5100.1 (Standards Australia, 2017) provide procedures for assessing the risk associated with bridge barriers and determining the appropriate performance levels.

To assist in selecting the right performance level, Austroads (Austroads, 2013) introduces a site condition category system. AS 5100.1 (Standards Australia, 2017) largely follows these recommendations from Austroads (Austroads, 2013) in its performance level selection procedures,

including chart-based risk assessments and benefit-cost analyses for special performance level barriers. It is also important to note that timber bridges often have narrow widths, decks with limited strength and other factors that can complicate the retrofitting of bridge barrier systems.

AS 5100.8 (Standards Australia, 2017) suggests that if the achievable barrier performance level does not meet the requirements identified in the risk assessment, alternative remedial actions should be explored. These alternatives may include measures like lowering speed limits or installing warning signs to mitigate the identified risks.

For timber bridges on low-volume roads with an annual average daily traffic (AADT) less than 500 vehicles/day and speed limits up to 100 km/h, a low-performance level barrier typically complies with AS 5100.1 (Standards Australia, 2017) requirements. However, a detailed risk assessment is necessary to confirm the performance level required for barriers installed on bridges.

2.3 *Determine the need for bridge barriers on low-volume roads*

Safety barriers (approach and bridge barriers) (Figure 1), are provided to reduce the crash severity of an errant vehicle from the approach to a bridge and on the bridge deck. The criteria to provide a bridge barrier in AS 5100 (Standards Australia, 2017) does not consider the quantification of crash risk (likelihood, exposure, severity) to determine or prioritise the need to provide a bridge barrier.

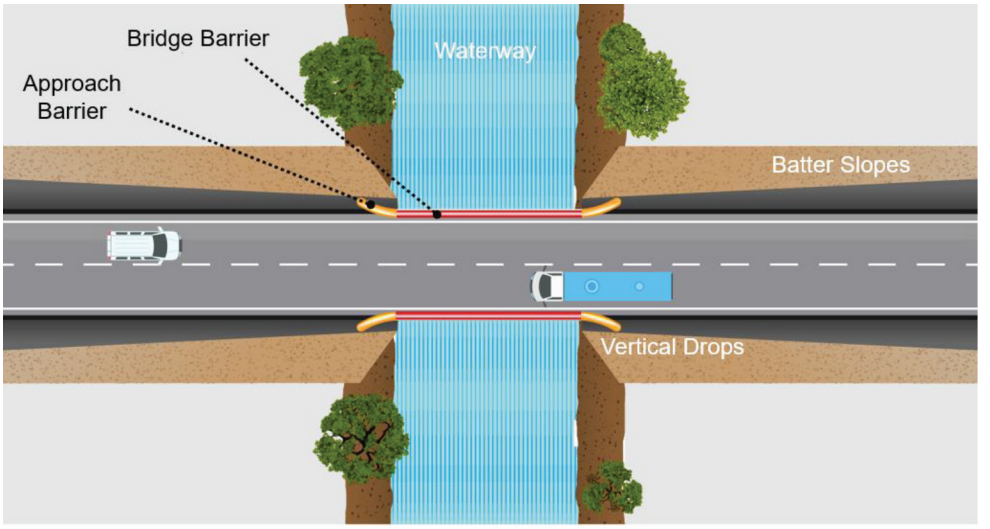

Figure 1. General arrangement of a bridge with approach barriers.

Technical guidance developed in '*NACOE R70 Addressing Sub-optimal Road and Safety Barriers at Bridge Approaches*' (Milling et al., 2023) provided a basis to develop a method to quantify crash risk to determine the need of a bridge barrier and prioritise multiple structures for further investigation across a road network.

3 BARRIER SYSTEMS FOR TIMBER BRIDGES

The structural capacity of timber bridges is a key constraint when selecting a suitable barrier system, as highlighted in the Section 2. The horizontal clearance beyond the edge of the traffic lane determines whether a barrier can be top mounted on the bridge deck or is required to be side mounted. This influences which bridge element(s) will be connected to the barrier system. The individual structural capacity of each bridge element should be evaluated according to the requirements set in AS 5100 (Standards Australia, 2017). The type of barrier selected greatly influences

the structural capacity required of bridge elements, with rigid barriers requiring the highest capacity to resist bending moments, followed by semi-rigid barriers and low-stress barrier systems.

To assist designers and asset owners with the selection of barrier systems for timber bridges, a list of concept arrangements and proprietary products is compiled in Section 3.1. As identified in the Section 2, the requisite highest performance level for barrier systems on these bridges aligns with the low performance level for timber bridges on low-volume roads (AADT < 500 veh/day and speed limit < 100 km/h).

3.1 *Concept barrier arrangements*

There are multiple barrier arrangements available to designers and asset owners that may be suitable for timber bridge applications. A deck-mounted post configuration (Figure 2a) can be considered if the bridge deck has sufficient structural capacity. If the structural capacity of the bridge deck is not considered adequate, the barrier can be side mounted to the outer girder (Figure 2b); however, this arrangement can introduce challenges such as inadequate bearing support due to the round shape of the girder and unsuitable attachment points. If additional structural capacity is still required, steel cross girders with backstays can be installed below the bridge deck (Figure 2c) to provide structural capacity from multiple bridge girders. In the event the entire bridge does not have sufficient structural capacity, the barrier system can be anchored to the bridge abutment and act structurally independent of the bridge. This arrangement is limited by the maximum span of the barrier solution and only relevant for short span bridges or where the barrier system can be fixed to bridge piers. Proprietary products such as the CrocGuard® system (Figure 2d) are available in the market for this application.

If it is not feasible to install barrier systems on a timber bridge, a road safety audit can be beneficial. This audit can help pinpoint appropriate countermeasures to enhance the safety of those using the bridge.

There are a few proprietary systems on the market that are appropriate for low-volume timber bridges. Products such as the Ezy-Guard Bridge Barrier System, CrocGuard® Barrier System and DOLR N232 provide a range of relevant features such as load transfer minimisation to the bridge superstructure, connection to the bridge abutments and minimisation of hydraulic effects during flood events.

(a) Concept arrangement of deck mounted (Source: Adapted from Polivka et al., 2002), (b) Concept arrangement of side-mounted posts to outer girder, (c) Concept arrangement of a barrier attached to superstructure using cross girders and backstays, (d) CrocGuard® barrier system anchored to bridge abutments.

4 ASSESSMENT AND PRIORITISATION OF BARRIER SYSTEMS IN QUEENSLAND

A method for identifying the need to provide a barrier system on a bridge on a low-volume road was developed by adapting the methodology from *NACOE R70 Addressing Road and Safety Barriers at Bridge Approaches* (Milling et al., 2023) whilst considering AS 5100.1 (Standards Australia, 2017). The NACOE R70 method, in line with widely accepted standards, quantifies risk through the calculation of a combined risk score. This method was adopted from the Austroads *Guide to Road Design Part 6* (Austroads, 2022). The combined risk score (CRS) is used to quantify potential improvement to road user safety by providing a barrier system on a timber bridge. The approach in AS 5100.1 (Standards Australia, 2017), Clause 14.5 Road Traffic Barriers Performance levels is based on a site-specific risk assessment and does not calculate a risk score.

This methodology was applied to TMR asset inventory data and TMR's Digital Video Road (DVR) to quantify the potential improvement to the CRS by providing a bridge barrier or safety barrier on the bridge approach.

4.1 *Assessment process*

The process to determine the need for a bridge barrier on a low volume is shown in Figure 3.

The decision to install barriers on bridges is guided by an evaluation process. This process includes a pass/fail assessment based on stopping sight distance (SSD), a numerical computation of the CRS and a comparative study of the CRS values for scenarios with and without a bridge barrier. The CRS with and without a bridge barrier is considered in parallel with the network CRS intervention level (Network Roadside Risk Intervention Threshold (NRRIT)), the crash history and in some situations a road safety audit. A bridge-specific structural assessment is also required to determine if it is technically feasible to install a barrier system as a measure to improve road user safety.

4.2 *Calculation of CRS*

The CRS is calculated by considering the local road attributes and bridge scenarios shown in Figure 4. The calculation of the CRS is based on the method in Austroads *Guide to Road Design Part 6* (Austroads, 2022) and TMR's supplement *Road Planning and Design Manual Edition 2, Volume 3, Supplement to Austroads Guide to Road Design Part 6: Roadside Design, Safety and Barriers* (Queensland Department of Transport and Main Roads, 2023).

Table 1 shows the CRS inputs for evaluating the need to provide a bridge barrier.

4.3 *Assessment and prioritisation of investigation of TMR's bridge stock*

The database revealed that TMR owns and manages 296 timber bridges, with 167 identified as being on low-volume roads (Low-volume roads were defined as a road with an AADT less than 500). Among these, 96 (57%) have an existing bridge barrier (recorded presence only, no confirmation of being compliant or functional).

TMR's Bridge Asset Database and attributes collected via TMRs DVR were used to calculate CRSs for all timber bridges on low-volume roads. This was inclusive of identifying the crash risk on the approach to a bridge and on the bridge deck. This allowed for crash risk for each timber bridge to be quantified, thus allowing for the sites to be prioritised for further investigation. All sites were assessed with the assumption that the existing safety barrier on the approach or bridge barrier on the deck was inadequate. This allowed for the crash risk at each site to be identified; the adequacy of any existing barrier treatments would be determined in site-specific investigations.

The safety risk assessment methodology calculated a CRS for the following at each of the 167 structures:

- a vehicle leaving a bridge deck and to quantify the need to provide a bridge barrier
- a vehicle striking a hazard behind a bridge approach and to quantify the need to provide a safety barrier on the approach to a bridge.

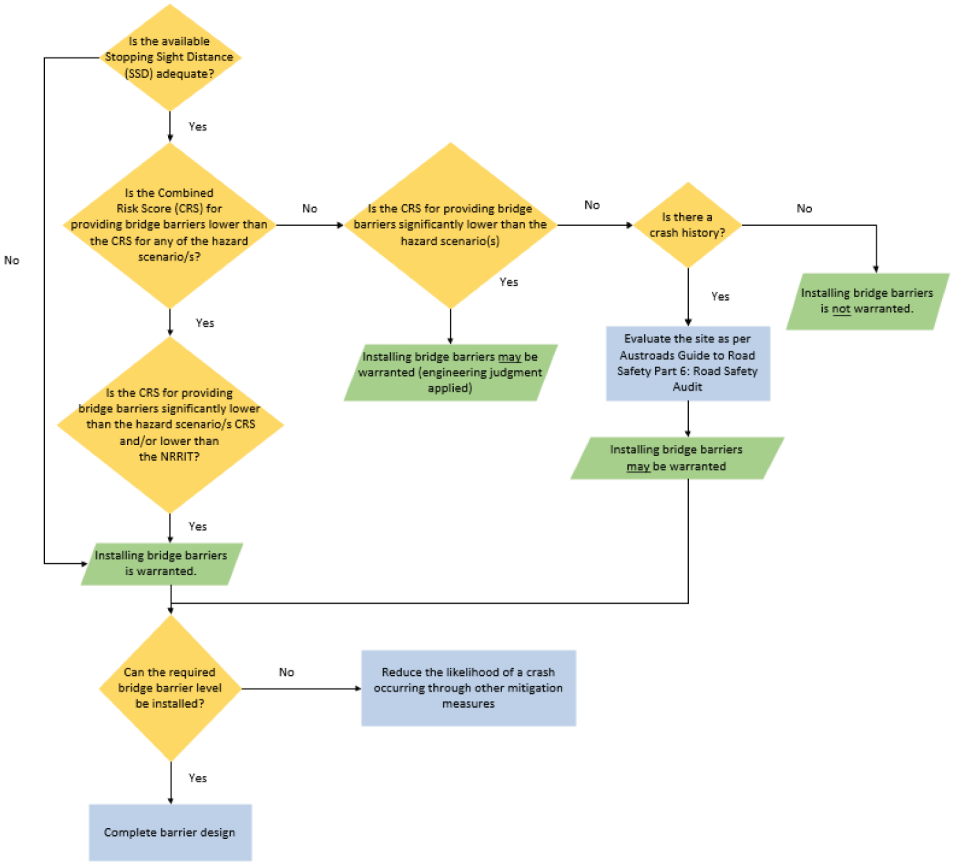

Figure 3. Assessment process to determine the need for bridge barriers.

The assessment identified that 138 of 167 bridges had a CRS higher than the TMR NRRIT of 0.6. This indicates that the risk of a vehicle running off the road or striking a hazard behind the bridge approach is higher than the risk threshold for intervention set by TMR. These bridges may benefit from the installation of barrier systems subject to an onsite assessment. Of these bridges, 47 had a CRS higher than 0.6 for both the approach safety barrier and the bridge barrier. This means the risk of a vehicle running off the road and the risk of striking a hazard behind the bridge approach are both higher than the NRRIT. The other 91 bridges had a CRS higher than 0.6 for the bridge barrier only, meaning the risk of a vehicle leaving the bridge deck is higher than the NRRIT.

5 CONCLUSION

Barrier systems are a key contributing element to road user safety on bridges. However, special consideration must be applied when selecting a suitable barrier system for a timber bridge, particularly those which may have limited structural capacity. Key findings from this report include:

- Low performance barriers typically meet the requirements in AS 5100 (Standards Australia, 2017) for timber bridges on low-volume roads in Queensland (AADT < 500veh/day and speed limit < 100 km/h).
- The existing structural capacity of a timber bridge is a key limitation when selecting a barrier system. AS 5100 (Standards Australia, 2017) requires a hierarchy of failure with

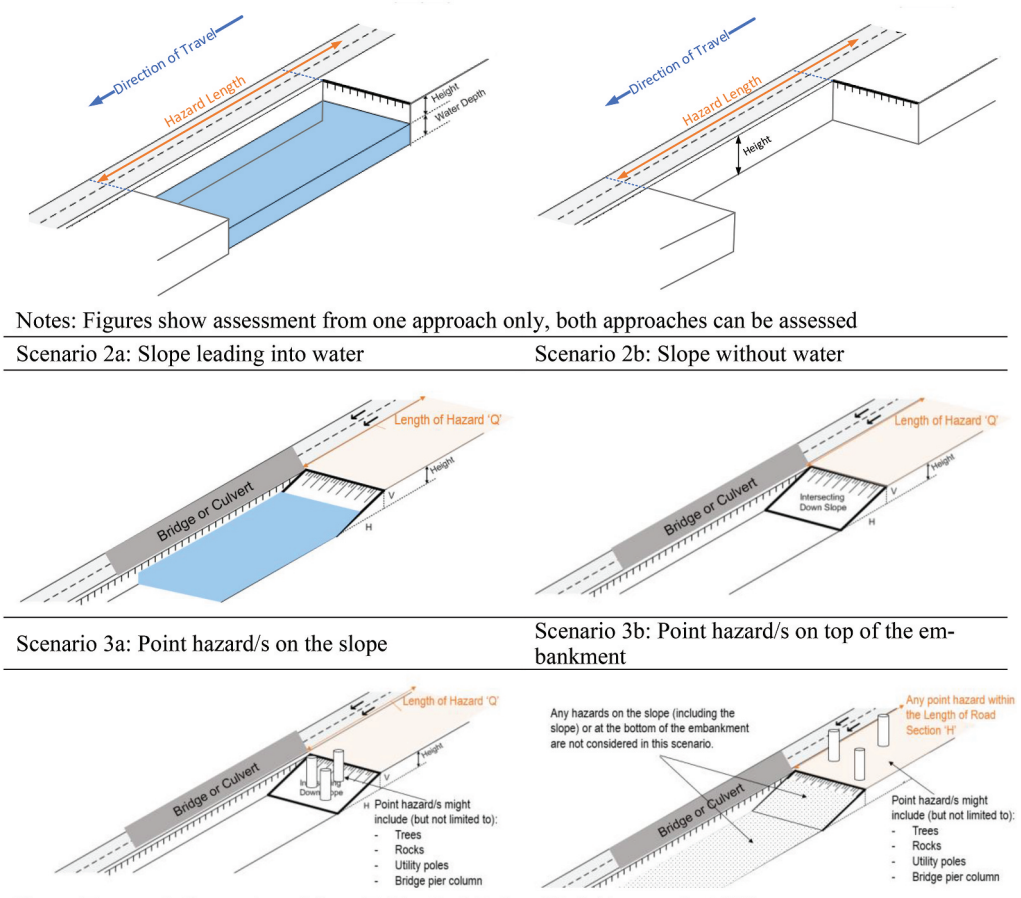

Figure 4. Isolated hazard scenarios: bridge deck and bridge approach.

the barrier to fail first, followed by the connection and finally the bridge superstructure. There are multiple barrier concept arrangements available for selection with connections made to one or a combination of bridge elements.

- Hydraulic effects are an important consideration for bridges at risk of flooding. These effects can be minimised by providing sufficiently large voids in the barrier to allow water and debris to pass through, such as rail and post traffic barriers.
- A risk-based assessment methodology was developed to assist TMR in the prioritisation of investigations for bridge barrier installations.
- An analysis of the TMR Bridge Asset Database found that 138 of the 167 timber bridges on low-volume roads have a CRS greater than TMR's NNRRIT. This analysis can support TMR effectively target structures which would most benefit from intervention.
- Barrier systems may not be a feasible solution for timber bridges, and in these cases, a road safety audit should be performed to identify measures that can be applied to improve road user safety.

By leveraging the insights gained from this project, TMR is now able to equip decision-makers with the necessary knowledge to prioritise the timber bridges that would benefit most from a barrier system with available funding. This crucial assessment can lead to significant enhancements in road user safety.

Table 1. Combined risk score inputs.

Group	Measure	Hazard scenario/s	Bridge barrier
General road characteristics	Length of road segment (m)	Greater of 200 m or the length for the hazard scenario.	Greater of 200 m or the length for the hazard scenario.
	Lane width (m)	Same measurement for hazard scenario and bridge barrier.	Same measurement for hazard scenario and bridge barrier.
Background hazard characteristics	Description	Background hazards are not considered when assessing a vehicle departing a bridge as the hazard.	Background hazards are not considered when assessing a vehicle departing a bridge as the hazard.

ABSTRACT: Bridge datasets in the UK lack geometric data needed to estimate the flood vulnerability of bridges. Therefore, flood quantitative risk assessment (QRA) of these portfolios is impaired. This paper developed design curves to derive arch rise and arch thickness for masonry arch bridges given their maximum span length. The span length was found in all surveyed bridge datasets. The masonry arch bridge type presents the higher flood risk in the UK. This work involved: (i) a search process to identify studies that addressed the lack of bridge data; (ii) the collection of publicly available bridge data for masonry arch bridges over UK rivers; (iii) the fitting of design curves to the collected data; and (iv) the model validation of design curves. Seen statistics metrics, the design curve of arch thickness may supply bridge data. Regarding design curves of arch rise, collected data is too sparse, thus better pre-processing is needed.

1 INTRODUCTION

Bridges are crucial in supporting our society. Flood actions are the leading cause of bridge damage around the world (Degan Di Dieco et al. 2022). The frequency of flooding is expected to increase, thus more riverine bridges are expected to fail (Wang et al. 2021).

There are about 150.000 bridges in the UK, among them, half are masonry arch bridges (MABs) and have short-length span, and in many cases are more than 100 years old (Solan et al. 2020). One MAB is expected to collapse every three years in the UK (Lamb et al. 2019).

To prevent failures, bridge capacities are designed to withstand effects of load demands, given a bridge geometry in input. The bridge geometry can be used either in numerical analyses (Tubaldi et al. 2018) or in analytical expressions (Degan Di Dieco et al. 2023) for "probabilistic reliability-based assessments" (NH 2022). Probabilistic reliability-based assessments express the likelihood that assets at risk will sustain varying degrees of damage conditioned upon hazard intensity. Probabilistic reliability-based assessments that estimate the expected level of asset direct damage are called "fragility functions" (Galasso et al. 2021), which is the term used herein. To define reliable fragility functions, it is necessary to identify the bridge geometry. In this study, variables underpinning the bridge geometry, such as span length, pier dimensions, are referred as "bridge attributes" (Pregnolato 2019). To use geometry-based fragility functions, specific bridge attributes are needed, such as arch rise, arch thickness, aspect ratios of pier and abutment (George & Menon 2021). However, bridge datasets of UK infrastructure owners do not generally report arch rise and thickness (Degan Di Dieco et al. 2022), thus limiting quantitative risk assessment (QRA) of bridge portfolios at risk of scour and/or flooding (Li et al., 2021). The present study estimates missing attributes from those that are commonly available, such as span length, by developing design relationships for arch thickness and arch rise as a function of span length.

Section 2 presents the literature review of studies which addressed the lack of bridge attributes. Section 3 shows methodologies proposed for data collection, model development, data

fitting and model validation. Section 4 shows results of data fitting and model validation. In Section 5, strengths and weakness of the proposed models are discussed, and future directions are given. Section 6 summarises paper findings.

2 LITERATURE REVIEW

For QRA of bridge portfolios via fragility functions, scholars typically: (i) extract bridge attributes from databases; (ii) carry out statistical analysis on bridge attributes; (iii) classify bridges into classes; and (iv) develop fragility functions for each class.

Lack of bridge attributes may occur when dealing with databases; in this case, it is common practice to use surveyed real-life bridge attributes to characterize missing ones via preliminary design relationships, which are referred as "design curves" in this study (da Porto et al. 2016). Major attributes for the characterization of a MAB are arch thickness to span length ratio t/L and arch rise to span length ratio r/L (Proske & van Gelder 2009).

A few works proposed design curves for MABs and provided results of statistical fitting. Design curves are developed as part of national scale QRA (Medina-Cetina et al. 2020). The literature review of this study is based on a searching process that used the keywords "bridge inventory" and "bridge portfolio" via Scopus and Google Scholar: 120 studies were found. Of these, only 13 studies were retained, with 11 studies related to MABs and two studies to reinforced concrete bridges. These 13 studies have been summarised in Table 1 by load(s), bridge location(s), design curve(s) used to fit arch rise and arch thickness. The main gap of these studies is the lack of goodness of fit to bridge attributes, therefore reliable design curves for masonry arch thickness and arch rise are missing in the literature. This paper aims to estimate attributes for MABs needed for vulnerability assessments by developing new design curves for arch rise and arch thickness. To fulfil the aim, this study develops design curves using a publicly available database for 74 MABs in the UK (Wu 2010). Once developed, the design curves are validated against a second publicly available dataset for MABs in the UK (Robinson 2000). The two datasets are totally independent.

Table 1. Summary of the selected studies proposing design curves for masonry arch bridges (in alphabetical order). Legend: NA = not applicable, r = arch rise, t = arch thickness, L = span length.

3 METHODOLOGY

For QRA of bridge portfolios, fragility functions are crucial to estimate direct damages. However, UK available bridge datasets do not contain bridge attributes commonly needed for applying existing fragility functions (e.g. George & Menon 2021), so QRA is impaired. This lack of bridge attributes is common in QRA for other natural hazards (da Porto et al. 2016). Several approaches are possible in order to answer this data lacking. In particular, Zelaschi et al. (2016) suggests identifying lower and upper bounds of bridge attributes and assigning a probability distribution to each attribute; subsequently, the distribution can be sampled to derive a certain number of bridge samples. However, this procedure is statistically expensive and associated with different epistemic uncertainties. A less complex methodology is proposed by da Porto et al. (2016), which suggests using design curves based on fitting functions of available bridge attributes; by doing so, statistical uncertainties. Therefore, design curves are used in this study to derive missing bridge attributes. The current work was conducted in different steps, the flowchart shown in Figure 1 presents the needed steps for building the design curves.

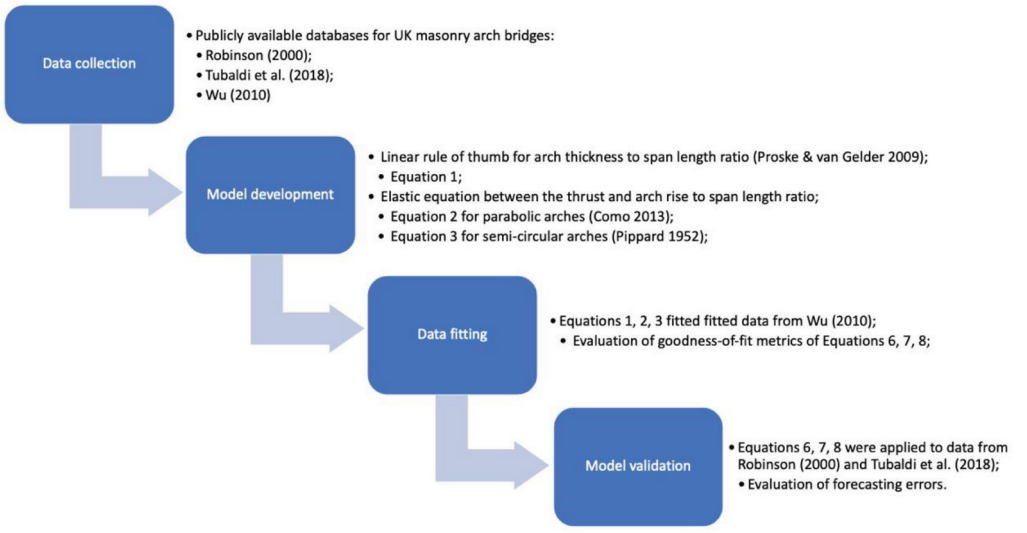

Figure 1. Flowchart of the steps needed to develop and validate proposed design curves.

3.1 *Data collection*

Publicly available geometry data for MABs was searched via Scopus and Google Scholar using the keywords "bridge portfolio" and "bridge inventory". The first dataset for MABs is from Wu (2010) and is used as the fitting dataset. Among bridges investigated by Wu (2010), 74 bridges are related to the UK. Therefore, these 74 bridges were selected by this study for curve fitting. Further geometry data was found in Robinson (2000). Robinson (2000) collected geometry data of 99 MABs in the UK, from which nine bridges were randomly considered to carry out the model validation; a further case study for model validation was retrieved by Tubaldi et al. (2018), for a total of ten bridges. The datasets used in this study are totally independent.

3.2 *Model development*

From the literature review, two approaches were identified to identify design curves: (i) application of regressions to available attributes (Proske & van Gelder 2009); (ii) use of theoretical relations which map the axial force in the arch at the crown to available attributes (Como 2013).

From Table 1, it can be seen that t is a linear function with span length L in 8 of the 13 reviewed studies. Therefore, in this study, a general linear function (Equation 1) is used for fitting

the t/L ratio data of Wu (2010). The r/L ratio data is a function of arch shape (Como 2013), thus fitted with the theoretical relation between the axial force, called thrust, and arch rise for two kinds of arch shapes, parabolic arch (Equation 2) and semi-circular arch (Equation 3).

A linear function between arch thickness t and span length L suitable for most arch shapes can be expressed as (Proske & van Gelder 2009):

$$t' = \frac{t}{L} = \frac{c_1}{L} + c_2 \tag{1}$$

where c_1 is a length, c_2 is dimensionless, both are constants and greater than zero. In this study, t represents the arch thickness at the arch crown, or key, and this value is kept constant along the arch line, i.e. arch thickness at crown is equal to arch thickness at springing.

In the elastic theory, the thrust H in a parabolic arch is given by $H = pL^2/8r$ (Como 2013), where p is the uniform load, L is the span length, r is the arch rise. Therefore, the arch rise to span length ratio r/L can be obtained via arranging the terms:

$$r_p' = \frac{r}{L} = \frac{pH}{8} \cdot L = c_3 \cdot L + c_4 \tag{2}$$

where c_3 and c_4 are both constant, c_3 is opposite of a length while c_4 is dimensionless.

In the elastic theory, the thrust H in a semi-circular arch is given by $H = 4pr/3\pi$ (Pippard 1952), where p is the uniform load, r is the arch rise. Because the arch is semi-circular, $L = 2 \cdot r$, r/L can be obtained via arranging the terms:

$$r_p' = \frac{r}{L} = \frac{3\pi H}{4p} \cdot \frac{1}{L} = \frac{c_5}{L} + c_6 \tag{3}$$

where c_5 and c_6 are both constant, c_5 is a length while c_6 is dimensionless.

3.3 *Data fitting*

The fitting of t/L and r/L data is carried out by using the MATLAB Curve Fitting Toolbox (MathWorks 2023). The data is first plotted via scatter plots, on which fits are performed. The performance of the fitted models is evaluated via two goodness of fit metrics, R^2 and Root Mean Square Error ($RMSE$). R^2 is the coefficient of determination in statistics (Motulsky 1995), while $RMSE$ of forecasted values $\widehat{Y}_i$ is computed as the square root of the mean of the squares of deviations (Kutner et al. 2005). Alexander et al. (2015) proposed two criteria for a forecasting model to be useful: (i) high R^2, e.g., $R^2 > 0.6$; (ii) low $RMSE$ of test set forecasts. The two indicators are both considered in this study.

3.4 *Model validation*

The model validation methodology used in this study is proposed by Kutner et al. (2005). This methodology proposes to compare R^2, $RMSE$, and the mean absolute error (MAE). The MAE is another measure of errors between paired observations expressing the same phenomenon, such as actual value and fitted value, and it is computed as:

$$MAE = \frac{1}{n}\sum\nolimits_{i=1}^{n} \left| Y_i - \widehat{Y}_i \right| \tag{4}$$

where n is the number of cases in the test dataset, Y_i is the actual value and $\widehat{Y}_i$ is the fitted value at the ith validation case. In addition, the mean absolute percentage error ($MAPE$) has been used to validate the prediction accuracy of a design curve (De Myttenaere et al. 2016):

$$MAPE = \frac{100\%}{n}\sum\nolimits_{i=1}^{n} \left| \frac{Y_i - \widehat{Y}_i}{Y_i} \right| \tag{5}$$

4 RESULTS

4.1 *Data collection*

The scatter plot of t/L ratio and r/L ratio data of 74 UK masonry arch bridges publicly available from Wu (2010) was plotted in Figure 2a and Figure 2b, respectively. These figures shows that the span length of these 74 bridges is mostly concentrated between 0 and 20 m, among which, the t/L ratio is mostly concentrated between 0.02 and 0.1, while the r/L ratio is evenly distributed between 0.1 and 0.5. Furthermore, the r/L ratio data is very sparse and seemingly clustered in various groups for values of span length less than 20 m. The developed design curves cannot be used to extrapolate values of t/L or r/L outside of the highlighted bounds.

4.2 *Model development*

4.2.1 *Data fitting*

The following design curve for t' was obtained, see the blue curve in Figure 3:

$$t' = \frac{t}{L} = \frac{c_1}{L} + c_2 = \frac{0.2757\text{m}}{L} + 0.0268 \tag{6}$$

R^2 resulted to be equal to 0.2987, while $RMSE$ is equal to 0.02176. The value of R^2 is less than ideal, i.e. 0.6. The value of $RMSE$ is low. The two goodness of fit metrics preliminarily indicate that this design curve has certain predictive ability, but the accuracy may not be ideal. To test the equation accuracy, the difference between actual arch thickness values and estimated ones, called "residuals", were calculated and shown in Figure 5.

Subsequently, by applying Equation 2 to the data shown in Figure 2b, the design curve for r_p' was obtained, see the blue curve in Figure 4a:

$$r_p' = \frac{r}{L} = c_3 \cdot L + c_4 = -\frac{0.003292}{m} \cdot L + 0.3546 \tag{7}$$

For r_p', R^2 is equal to 0.09926, while $RMSE$ is equal to 0.1075. This value of R^2 is too small when compared with 0.6, which indicates of the design curve fitting extremely poorly. Although, the value of $RMSE$ is low. The two goodness of fit metrics preliminarily indicate that this design curve has not predictive ability. Residuals for actual arch rise values and estimated ones are shown in Figure 6a. Then, by applying Equation 3 to the data shown in Figure 2b, the design curve for r_p' was obtained, see the blue curve in Figure 4b:

$$r_p' = \frac{r}{L} = \frac{c_5}{L} + c_6 = \frac{0.4894}{L} + 0.2594 \tag{8}$$

For r_p', R^2 is equal to 0.04953, while $RMSE$ is equal to 0.1104. This value of R^2 is too small when compared with 0.6, which indicates of the design curve fitting extremely poorly.

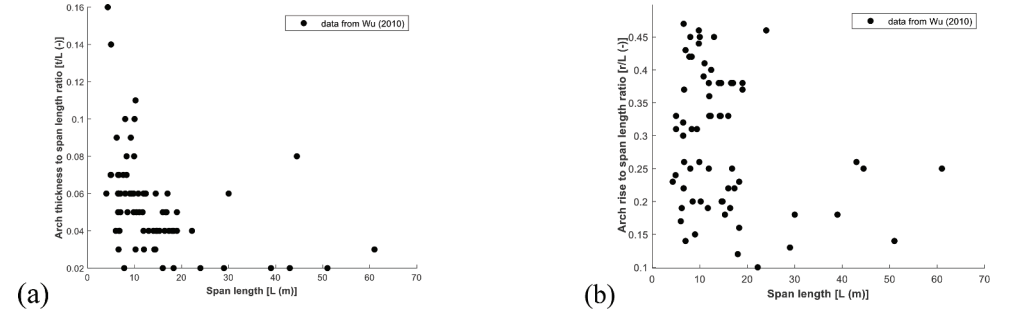

Figure 2. (a) Scatter plot of arch thickness to span length ratio data for masonry arch bridges of the UK; (b) Scatter plot of arch rise to span length ratio data for masonry arch bridges of the UK.

Although, the value of *RMSE* is low. The two goodness of fit metrics preliminarily indicate that this design curve has not predictive ability. Residuals for actual arch rise values and estimated ones are shown in Figure 6b.

4.2.2 *Residual plot analysis*

Plots of the residuals, i.e. the difference between the observed value and the estimated value of the quantity of interest, are helpful to study whether a regression function is appropriate or not (Kutner et al. 2005). Since bridge attributes in the fitting dataset are mostly concentrated between 0 and 20 *m*, only the data distribution between 0 and 20 *m* is analysed.

As shown in Figure 5, the distribution of residuals for t/L tends to converge, displaying no systematic tendencies to be positive or negative. With the longer span of masonry arch bridge, the distribution of residual points becomes smaller and closer to the centre line, i.e. tending to zero residual. This indicates that the span length of a bridge is correlated with the t/L ratio, but there may be other variables affecting the t/L ratio, such as the service type of a bridge, such presenting higher piers and abutments.

The residuals for r/L of a parabolic arch are shown in Figure 6a, and they fall evenly in the band area with zero as the centre and plus or minus 0.2 as the upper and lower boundary, displaying no systematic tendencies to be positive or negative. However, the width of this band area is wider, indicating that the prediction accuracy of this design curve is low.

The distribution of residuals of r/L of a semi-circular arch are shown in Figure 6b. This latter distribution is similar to the case of Figure 6a.

Validation analysis of developed design curves is then carried out to check their practical use.

4.3 *Model validation*

As a proof of concept, the developed design curves were firstly applied to the case study by Tubaldi et al. (2018) pretending to have arch thickness and arch rise as unknown, see Figure 7; (ii) then, to nine further bridge geometries from Robinson (2000).

In Tubaldi et al. (2018), the two arches are segmented and symmetric; the span length (from the left abutment to the central pier) is 9.26 *m*; arch rise is 3.45 *m* and arch thickness is 0.50 *m*, which are pretended to be unknown. In particular, arch thickness and arch rise were first forecasted by Equation 6 and Equation 8, respectively, and then compared with the actual values. The forecasted arch thickness value is 0.524 *m*, while the forecasted arch rise value for the semi-circular arch is 2.891 *m*. When comparing forecasted values with actual values for arch thickness, it is found that the absolute of residual is 0.024 *m*, which shows that the two values are very close. When comparing modelled values with actual values for arch rise of semi-circular arch, it is found that the absolute of residual is 0.559 *m*, which shows that the two values are not very close. Considering the ten validation case studies, the *MAE* is 0.075 *m* for arch thickness forecast, 0.728 *m* for parabolic arch rise forecast and 0.723 *m* for semi-circular arch rise forecast, which means higher accuracy for arch thickness and low accuracy for arch rise. The MAPE of arch thickness is 13.6%, 28.9% for the parabolic arch rise and 29% for the semi-circular arch rise.

5 DISCUSSION AND FUTURE RESEARCH

Three design curves were obtained and validated by fitting publicly available datasets of MABs.

The first design curve for t/L ratio presents $R^2 = 0.3$, $RMSE = 0.022$. The second design curve for r/L ratio of parabolic arches presents $R^2 = 0.1$, $RMSE = 0.108$. The third curve for r/L ratio of semi-circular arches presents $R^2 = 0.05$, $RMSE = 0.11$. Although the R^2 of the design curve of arch thickness is less than 0.6, it has good *RMSE*. It also performs well in the model validation section. Therefore, Equation 6 can be used as an acceptable design curve for preliminary estimates. The values of R^2 of the Equation 7 and Equation 8 are very close to zero, and the value *RMSE* is high. These indicators suggest that they are two poor design curves.

The residual plots of the three design curves tell that fitting results are not very ideal.

Regarding the model validation, the *MAE* for arch thickness forecast is 0.075 *m*, while it is 0.728 *m*/0.723 *m* for parabolic/semi-circular arch. The *MAPE* of arch thickness is 13.6%, 28.9% for the parabolic arch rise and 29% for the semi-circular arch rise, which indicates that only the design curve of the arch thickness has certain forecast accuracy and can be used as a forecasting model, but further validation is needed.

Future work can filter input data by arch shape and bridge service type, and fit new design curves for arch rise.

The developed curves could be used by scholars for rapidly obtain attributes of MABs, without in-situ commuting, thus enabling QRA of bridge portfolios.

6 CONCLUSIONS

UK bridge datasets lack attributes necessary for QRA of bridge portfolios. Therefore, this paper proposed new design curves to forecast arch thickness and arch rise for MABs. To fulfil the aim, this work first fitted rule of thumbs and theoretical relations for arch thickness and arch rise to publicly available bridge data (Wu 2010), which was filtered to UK MABs. Then, the developed design curves were validated using a second public available bridge dataset (Robinson 2000, Tubaldi et al. 2018). It was found that the developed design curves do not have a high R^2, although the design curve of arch thickness well performs in the validation section with the randomly selected bridges. For design curves of arch rise, they did not get a good goodness of fit, and they did not perform well in the model validation either.

This paper proposed one possible design curve for arch thickness and two design curves for arch rise as a function of span length. The design curve of arch thickness, given by Equation 6, may be applied to derive missing arch thickness data. This work can be improved by filtering fitting data according to arch shapes, thus improving arch rise design curves.

ABSTRACT: In this study, the seismic performance of typical multi-span simply supported deck bridges with single shaft Reinforced Concrete (RC) piers with corroded rebars is examined through extensive NonLinear Static Analysis (NLSA). Six different bridge configurations, differing in pier layout (Constant, Ramp and V-type) and number of spans are investigated, considering different deterioration scenarios, characterized by different deterioration patterns (over the cross-section of the pier) and severity of corrosion of steel rebars. The influence of corrosion on the seismic vulnerability of the bridge is evaluated in terms of ratio between the maximum earthquake intensity level (from NLSA) that the structure can withstand before collapse and the code-conforming (Italian Technical Standards) intensity level that would be used for the verification of the Collapse Limit State of a new structure.

1 INTRODUCTION

Ageing and deterioration of RC bridges can significantly increase their seismic vulnerability and have a significant impact on expected economic losses. Among the different deterioration mechanisms that bridge structures may experience, chloride-induced corrosion of steel rebars represent the most critical one. Indeed, depending on the severity, extension and location, corrosion of steel rebars may lead to significant loss of structural strength and poor seismic performance of bridge piers which often represent the most vulnerable element of a bridge.

The starting point of this study is represented by a set of force-displacement skeleton curves, in the as-built and degraded conditions, obtained through pushover analyses of accurate 'fiber' models of single-shaft rectangular-hollow piers. Piers with different height (from 5 to 35m) and different section aspect ratio (1 to 3) have been examined. In addition, two different construction ages have been considered (referred to as pre-74 and post-74), differing in terms of construction details (quantities of longitudinal reinforcement, stirrup spacing, etc.) and mechanical characteristics of the materials. Reference to (Bernardini et al. 2022) can be made for more details on the structural characteristics and mechanical properties of the selected piers.

Piers have been analyzed considering different deterioration patterns, as well as different intensity levels of corrosion and height extensions, as described in (Bernardini et al., 2022). In all cases, however, corrosion was concentrated at the base of the pier where plastic deformations are expected to develop under earthquakes. Five in-plane corrosion patterns were assumed, clearly identified with the letters A, B, C, D and E in Figure 1. In the same figure, the intensity level of corrosion is identified by a number ranging from 0 (as built) to 6 for the degradation pattern associated with the higher percentage of mass loss. The values of mass loss (valid for both longitudinal and transverse steel bars) and crack width (cover concrete) reported in Figure 1 have been used to define the effective diameter of corroded bars and the

DOI: 10.1201/9781003483755-459

constitutive laws of corroded steel and cracked concrete based on the semi-empirical relationships proposed by (Imperatore et al. 2017) and (Coronelli & Gambarova 2004), respectively.

According to the Italian Technical Standards for Constructions (NTC 2018), pier collapse was assumed to occur when the first of the following events occurred: (i) attainment of a strain of 4% in the first longitudinal steel bar, (ii) 15% drop in the peak lateral resistance on the degrading branch of the force-displacement skeleton curve of the pier, (iv) shear failure, calculating the shear strength with the formula reported in the NTC18 for existing RC structures. In accordance with the NTC18, a safety factor equal to 1.5 for ductile mechanisms and 1.25 for brittle mechanisms was applied to derive the performance points at collapse.

Seismic analyses were carried out assuming the viaducts located in two different sites (L'Aquila and Naples) featuring high and medium seismic hazard for Italy. Soil type C (deep deposits of dense or medium-dense sand, gravel or stiff clay with thickness from several tens to many hundreds of meters) has been assumed in both the cases.

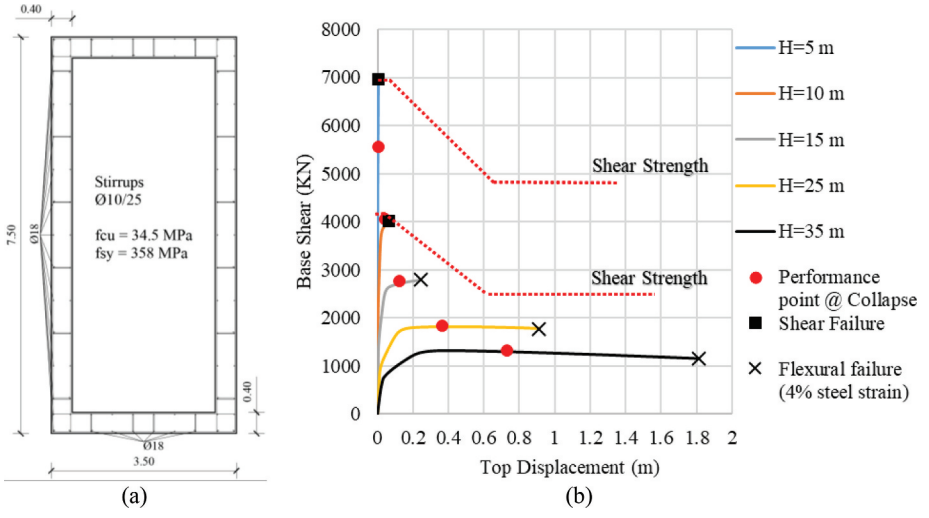

Figure 2. (a) Pier cross-section dimensions and (b) typical pushover curves in the as-built configuration for pre-74 piers (weak direction) featuring different heights and failure modes.

For brevity, in this paper the attention is focused on the viaducts located in L'Aquila only. Similarly, only pre-74 piers with cross-section aspect ratio equal to 2 and corrosion pattern type E (5%H height extension) (see Figure 1) are considered.

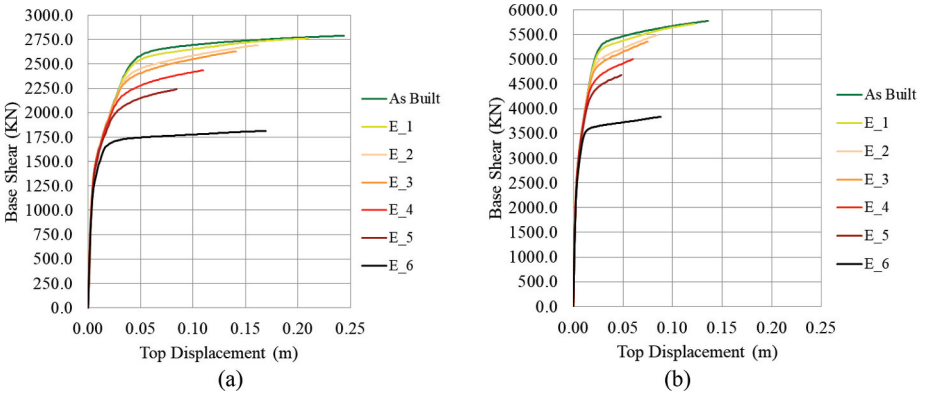

Figure 3. Comparison of as-built and degraded pushover curves for the 15m height pre-74 pier in the (a) weak and (b) strong direction.

2 METHODOLOGY

Figure 2(a) shows the dimensions of the pier cross-section with the amount of longitudinal and transverse reinforcement and the mean values of concrete compression strength and steel yielding stress assumed in the analysis. Figure 2(b) shows some typical pushover curves in the as-built configuration for pre-74 piers (weak direction) featuring different heights and failure modes. Ductile piers include those with height ranging from 15m to 35m. Piers with height between 7.5m and 12.5m exhibit a hybrid failure mode in which shear failure affect flexural ductility anticipating pier collapse. Piers with 5m height exhibit an elastic fragile behavior. In the latter case, corrosion produces limited effects, causing a reduction in the shear strength not exceeding 15-18%. It should be noted, indeed, that pre-74 piers were poorly reinforced against shear (stirrups not well anchored in the concrete core and with large spacing). Therefore, the effects of stirrup corrosion on concrete confinement and shear strength are quite low.

Figure 3 shows some typical pushover curves for the 15m height pre-74 pier featuring different corrosion degradation scenarios. As can be seen, corrosion of steel rebars strongly affect the ultimate displacement capacity of ductile piers with reductions up to 65-70% in the worst situations (see E_5 curves). Also the lateral strength is significantly influenced by corrosion, with reductions up to 35% in the worst case (see E_6 curves).

Pushover curves have been converted into an equivalent bilinear force-displacement relationships (see Figure 4) following the instructions reported in the NTC18 (effective initial stiffness taken as the secant stiffness at the actual yield displacement; post-yield slope determined by a line segment that passes through the curve at the actual ultimate displacement and that approximately balance the area above and below the curve).

Figure 5 shows the bridge layouts examined in this study. They include three different pier profiles (C: Constant, R: Ramp-type and V: V-type) by two different lengths (S: Short with 3-spans and L: Long with 7-spans). In Figure 5, the height of each pier is reported, as well as the average value of the ρ-parameter measuring the level of irregularity of the bridge. The ρ-parameter is expressed as the ratio between the maximum and the minimum ratio between the shear at the base of the i-th pier at the performance point and the corresponding ultimate lateral resistance.

The seismic performance of the bridge has been assessed through Nonlinear Static Analysis. Among others, the Inverse Adaptive Capacity Spectrum Method (IACSM) described in (Cardone et al. 2011) has been adopted in this study. Within this method, pushover analysis was carried

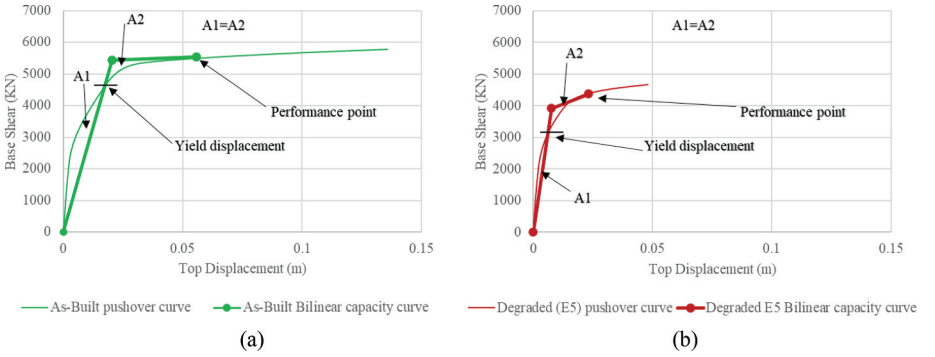

Figure 4. Conversion of pushover curve into an equivalent bilinear capacity curve for the (a) as-built and (b) degraded (E5) 15m height pre-74 pier.

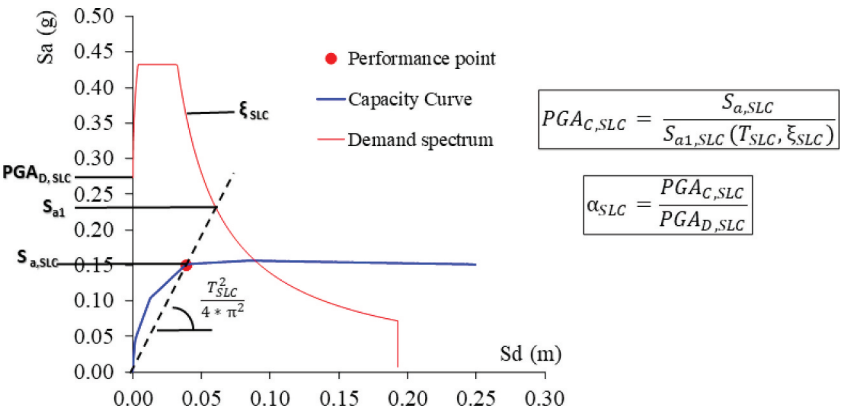

Figure 6. Inverse Adaptive Capacity Spectrum Method (IACSM).

using a uniform force pattern in the longitudinal direction and a first mode force pattern in the transverse direction. The IACSM converts the pushover curve of the MDOF bridge into the Capacity Curve of an equivalent SDOF system by computing the displacement ($S_{d,k}$) and the acceleration ($S_{a,k}$) of the equivalent SDOF system based on the actual deformed shape of the bridge at each (k-th) step of analysis (Cardone et al. 2011). The Demand Spectrum is represented by a high-damping elastic response spectrum. The equivalent viscous damping of the bridge is estimated through a suitable combination of the effective damping ratios of each component (pier, bearings, etc.) based on the displacement and force levels acting in each component at the selected

performance point. Indeed, the main objective of the IACSM is to evaluate the seismic intensity (e.g. the PGA) of the expected ground motions corresponding to the attainment of a given damage state (e.g. collapse) of the structure, identified by a given performance point on the capacity curve of the bridge (see Figure 6). The earthquake intensity level corresponding to the attainment of the performance point represents, to some extent, the seismic capacity of the structure. The ratio (α) between the seismic collapse capacity of the structure ($PGA_{C,SLC}$ in Figure 6) and the seismic demand prescribed by the Code for the verification of collapse limit state for code-conforming structures ($PGA_{D,SLC}$ in Figure 6) provides an estimate of the seismic risk of the bridge. In this study, the effects of degradation due to corrosion have evaluated in terms of changes in the α-index.

The definition of the degradation scenario is a complex operation at the level of single pier and even more at the level of entire viaduct. As mentioned before, a simplified approach, based on the assumption of schematic degradation patterns differing in corrosion severity and extension (see Figure 1), has been adopted at the level of single pier. A heuristic approach has been followed to define several alternative degradation patterns at the level of entire viaduct. It is based on the assumption that tall piers are in principle more subject to degradation from corrosion close to the base as they are less protected by the "umbrella" effect of the deck in the event of windy rain and splashes of salt water from the joints and curb edge. Similarly, it is more likely that a tall pier is located in the middle of a valley and then exposed to strong winds or in a riverbed and then subjected to continuous dry-wet cycles. Consequently, for the type E degradation pattern (see Figure 1), referable to piers in riverbed or piers exposed to wind-rain along the entire base perimeter, the hypothesis was that taller piers (e.g. all those with height greater than the average pier height over the entire bridge) could reach the maximum intensity of degradation due to corrosion (intensity 6 of Figure 1), while lower piers (e.g. all those with height less than the average pier height over the entire bridge) could not exceed certain levels of corrosion (e.g. intensity 3 of Figure 1). On the basis of such hypotheses, the worst scenarios were defined (first row of Figure 7). Then, others were derived by progressively reducing the intensity of degradation up to the as-built configuration (rows 2 to 6 in Figure 7). Finally, some additional scenarios were considered to maximize the effects of corrosion on the α-index. They are characterized by degradation at the maximum intensity concentrated only on the critical pier from the analysis on the as-built configuration (rows 7 and 8 in Figure 7).

3 RESULTS

Figure 8 reports the values of the α-index obtained for each analysis case (six different bridge layouts by nine different degradation patterns). The values of the α-index are reported separately for both directions (longitudinal and transverse). The critical pier of the bridge is also identified.

Based on the results reported in Figure 8, the following considerations can be made:

- Degradation due to corrosion, when concentrated in the critical areas of the piers (e.g. at the base of the pier for single shaft piers), can significantly worsen the seismic performance of RC viaducts;
- When the critical element coincides with a short pier (subjected to shear failure) the reduction of the α-index is limited (see configurations S_V2, L_R and L_V2 in the longitudinal direction) because the degradation slightly affects only the lateral resistance of the pier. On the other hand, when the collapse is due to the failure of a ductile pier (as always happens in the transverse direction and in the longitudinal direction for the configurations S_C, S_V1 and L_V1) the degradation due to corrosion causes a strong reduction in the ultimate displacement capacity of the piers (see Figure 3) and consequently a significant reduction of the α-index;
- The longitudinal direction turns out to be always the critical direction of the bridge, due to the strong interaction between decks as a consequence of the reduced width of the internal joints;
- The critical element does not change as the intensity of degradation in the structure varies.

It is worth noting that, in some rare cases, the values of the α-index in degraded conditions are higher than those in the pristine (as-built) conditions. This can be ascribed to the

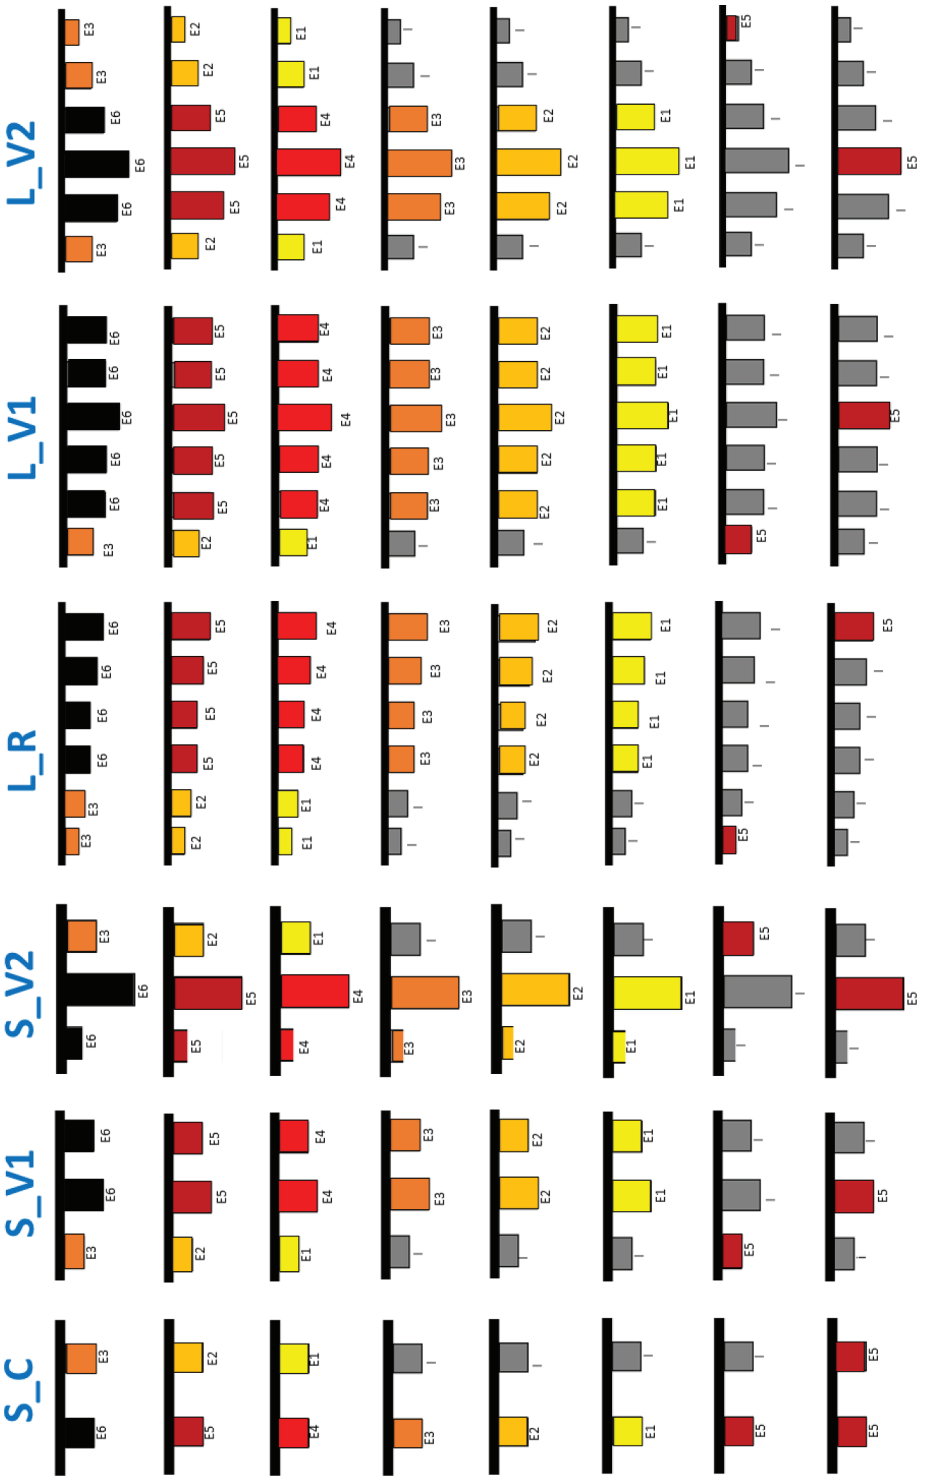

Figure 7. Degradation patterns considered (ref. to Figure 1 for the meaning of labels and colors).

bilinearization criterion adopted (see Figure 4) which, in presence of a remarkable reduction in ductility, provides a slight increase in the initial stiffness for slender piers.

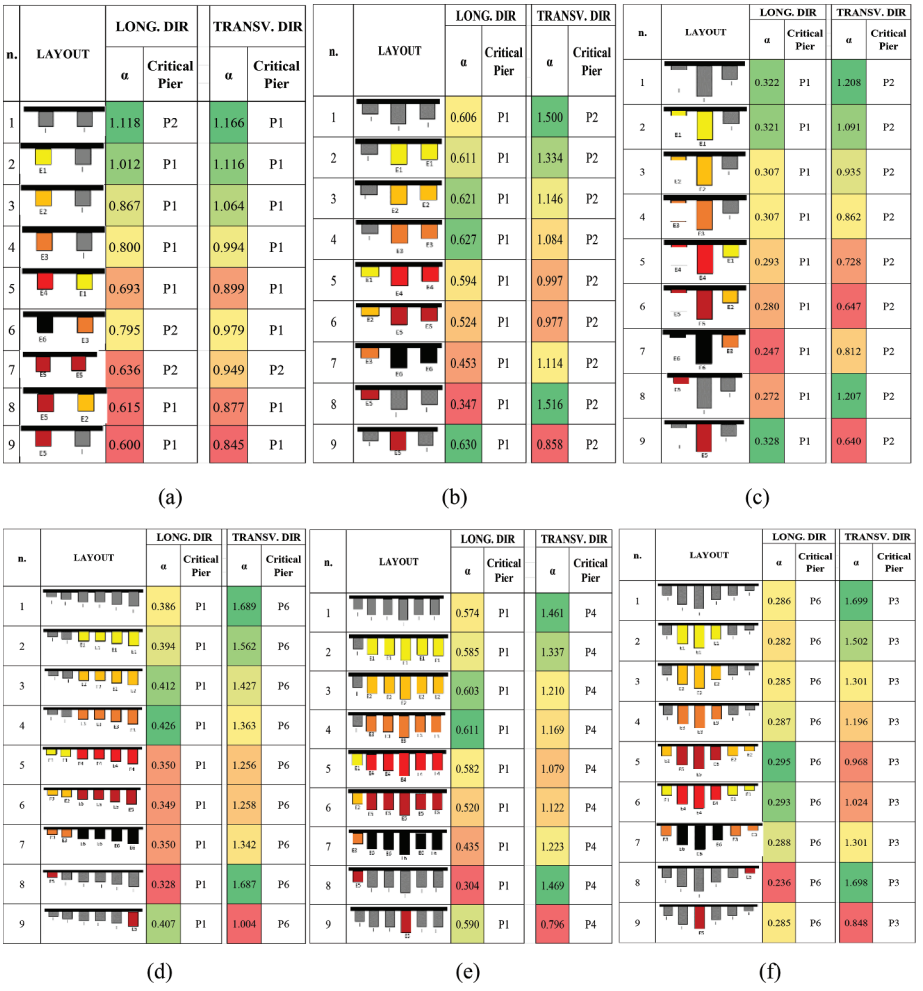

Figure 8. Values of the a-index for different degradation patterns and bridge layouts.

Examining the trend of the α-index reported in Figure 9, the following observations can be done:

- The maximum reduction in the α-index is of the order of 50% in both directions. This reduction is observed when corrosion degradation involves, with its highest level of intensity, the critical pier of the bridge (see bridge layouts n. 8 and 9 of Figure 8 in the longitudinal and transverse direction, respectively);
- When the critical pier coincides with a short pier subjected to shear failure (ref. to bridge layouts S_V1, S_V2, L_R and L_V2 in the longitudinal direction) the reduction of the α-index does not exceed 20%. This is because, for brittle piers, corrosion produces only a slight reduction (15-20%) in the lateral strength of the pier;
- In the transverse direction, the modal force distribution adopted in pushover analysis leads to the failure of the highest piers. In this case, the reduction of the α-index is proportional to the reduction in the displacement capacity of the highest pier.

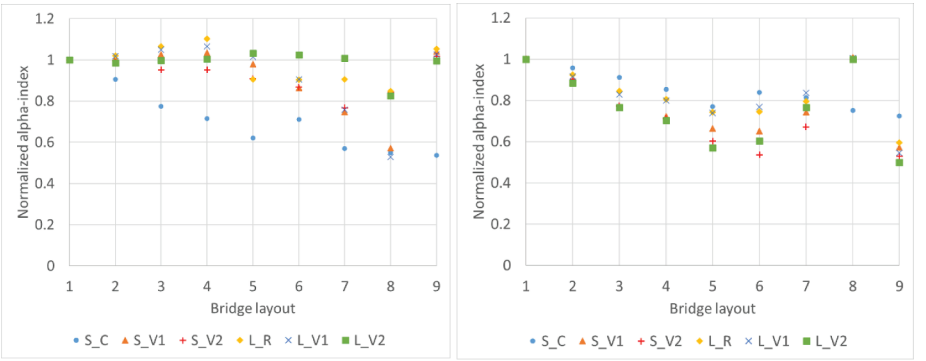

Figure 9. Normalized α indexes (degraded vs. pristine) in the (a) longitudinal and (b) transverse direction (ref. to Figure 7 for the numbering of the degradation patterns).

4 CONCLUSIONS

The seismic performance of typical multi-span simply supported deck bridges with single shaft RC piers with corroded rebars has been examined through NonLinear Static Analysis (NLSA). The influence of corrosion on the seismic performance of the bridge has been evaluated in terms of the α-index, that is the ratio between the maximum earthquake intensity level (from NLSA) that the structure can withstand before collapse and the code-conforming (NTC18) intensity level that would be used for the verification of the Collapse Limit State of a new structure.

Based on the results obtained so far, it can be stated that degradation due to corrosion can significantly influence the seismic performance of RC viaducts when it occurs in the critical areas (for seismic purposes) of ductile piers at the maximum levels of severity and extension observed in the practice (mass losses of the longitudinal reinforcements of the order of 40% along the entire perimeter of the cross section). As a matter of fact, the seismic risk of the bridge can even double in the worst case in which the degradation affects the critical pier of the bridge. Further analyses, varying the seismic hazard of the site, the mechanical characteristics of the piers (as a function of the era of construction of the bridge) and the in-plane and in-elevation degradation pattern of the pier, are underway to draw more robust conclusions.

Identification of governing structural safety criterion for existing bridges considering costs, occupancy and conditional fatality probability

F. Liljefors & J. Köhler
Department of Structural Engineering, Norwegian University of Science and Technology (NTNU), Trondheim, Norway

ABSTRACT: Assessing existing bridges requires balancing the risk of failure and mitigation costs. Economic and human safety aspects are considered when deriving an optimal or acceptable level of safety. Additionally, an absolute human safety criterion may provide an upper risk limit, and this study aims to clarify its role and criticality. Although human safety is included in the marginal life-saving criteria through the life quality index and the societal willingness to pay for one additional saved life, this does not guarantee the safety of individuals. The rationale behind this is that even though it would be worthwhile to sacrifice human safety because the average expected risk to humans is low compared to the cost of mitigating the risk, exposing individuals to adverse risks is not ethical. With this contribution, we discuss the relation between individual risk and structural risk and identify factors contributing to the relative importance of the absolute human safety criterion compared to the cost-benefit and marginal life-saving criteria for existing road bridges. From these factors, we derive classes of cases for which the absolute human safety criterion can safely be ignored and cases when it governs the assessment. The results are useful for future reliability- and risk-based assessments of bridges.

1 INTRODUCTION

1.1 *Structural safety as a societal concern*

The fundamental requirement on structures such as bridges is structural safety. This requirement can be quantified as the ability of the structure to withstand loading with a specified probability during a specified time (ISO 2394, 2015), either implicitly by the partial factor method or explicitly by structural reliability analysis. The criterion that specifies the acceptable level of structural safety is typically derived from historical design codes or risk analysis and is commonly given as a reliability index or a probability of failure.

Criteria for structural safety are relevant for the design of new structures and for the assessment of existing ones. This study focuses on the latter, as there is usually a larger urge to adjust the safety criteria for existing structures. This is because the uncertainties are different for an existing structure, more information can be retrieved, and it is more costly to increase the safety of a built structure than in the design stage.

With structural risk assessment based on structural reliability analysis, a proper level of safety that balances the risk of failure with the cost of increasing safety can be determined. As structural safety is not only about purely economic consequences but also involves human life, several complementary criteria need to be assessed. For the criteria involving human life, there is a reluctance to assess human life in monetary value, and the concepts are often cryptically described so as not to provoke people.

Structures expose the public to involuntary risks and are not a private business but a societal concern. Hence, we find the lack of transparency problematic and argue that society has the right to know how structural risk is dealt with. Explicitly addressing the trade-off

DOI: 10.1201/9781003483755-460

between human safety and money enables prioritisation of risk mitigation measures to reduce the structural risk efficiently with limited resources. Transparency is also essential for further developing the risk criteria to ensure they work as intended.

One important distinction in this discussion is whether risk assessments and their criteria should be descriptive or prescriptive, i.e. describing what is done or dictating what should be done. For the standardisation of structural risk, we favour the latter to ensure that standards take a rational and objective approach from a societal perspective. It is not meaningful that the industry that sets society at risk determines the criteria themselves, as they have no incentive to adopt stricter criteria than what is optimal for them, as argued by Abrahamsen & Aven (2012).

The approaches we investigate further in this paper are economic optimisation, marginal life safety, and absolute life safety. We omit societal risk, a variant of the absolute life safety approach that values fatalities in a single event differently from the same number of fatalities in multiple events. Taking the prescriptive approach to these matters described above, we think the societal risk approach is neither ethical nor rational.

1.2 *Aim to investigate the relation between the multiple criteria*

The most straightforward approach of the three criteria is economic optimisation. This criterion aims to minimise the expected total costs, assessing the value of human life according to the decision-maker's preferences in line with other costs. The marginal life safety also weighs the human loss against investment costs, with the difference that other failure costs than human loss are not considered, and the value of human life is quantified to a predetermined value for the societal willingness to pay (SWTP) for saving an additional life. The absolute life safety is fundamentally different as it specifies an absolute limit for the risk of life and limb of any person passing the bridge, independent of investment and failure costs.

As apparent from this introduction to the topic, assessing structural risk is complex. This was confirmed at a recent workshop on risk acceptance criteria organised by JCSS and IABMAS in Trondheim in June 2023. This workshop gathered professionals from academia and industry to establish a common understanding of the gap between the current practice and the goal of consistently regulating the level of safety throughout different fields and countries. The basic principles were agreed upon, such as the trade-off between safety and cost, the need for an upper-risk limit and the problem of risk aversion and avoidance. However, even this well-informed group of risk experts had different understandings of some aspects discussed.

With this contribution, risk acceptance criteria for the specific domain of structural assessment of existing bridges are further investigated. We explore how the three criteria for structural risk assessment relate to each other in different situations. This is done by identifying the important parameters, parameterising them at a reasonable range, and determining the governing criterion for the possible combinations. With consistent criteria based on a decent rationale, sufficient levels of safety of existing bridges can be assured that align with society's preferences. More accurate treatment of these criteria will lead to more accurate and precise risk assessments of individual structures and improvements in code calibration of the simpler reliability and semi-probabilistic assessment formats.

2 CRITERIA FOR ASSESSMENT

2.1 *Overview*

In this section, we present details for the three approaches which are supported by ISO 2394 (2015): Economic optimisation, marginal life safety and absolute life safety. The main influencing parameters are given, and the specific models for calculating the criteria for the yearly probability of failure used in this study are presented.

2.2 *Economic optimisation*

The continuous renewal assumption for assessment gives the total present expected costs for infinite time as the sum of intervention (risk mitigation) costs and expected failure costs:

$$E[C_{tot}(\boldsymbol{p})] = E[C_{intervention}(\boldsymbol{p})]\left(1+\frac{\omega}{\gamma}\right) + E\left[C_{failure}\frac{P_f(\boldsymbol{p})}{\gamma}\right] \tag{1}$$

where ω is the intervention rate, γ is the discount rate, P_f is the yearly probability of failure and $\boldsymbol{p}$ is the decision parameter, i.e. the set of mitigation options. By minimizing $E[C_{tot}(\boldsymbol{p})]$, the limit for cost-efficient interventions for discrete interventions is:

$$P_{f,ec} = \frac{C_{intervention,p}(\gamma+\omega)}{C_{failure}} + P_{f,intervention,p} \tag{2}$$

By assuming that an intervention will have a significant effect on the failure probability, $P_{f,intervention,p} \ll P_{f,ec}$, and:

$$P_{f,ec} \approx \frac{C_{intervention,p}(\gamma+\omega)}{C_{failure}} \tag{3}$$

Choosing a yearly reference period for the intervention, $\gamma + \omega \approx 1$, and:

$$P_{f,ec} \approx \frac{C_{intervention,p}}{C_{failure}} \tag{4}$$

2.3 *Marginal life safety*

The marginal life safety criterion takes a similar form as the economic optimisation criterion, with the difference that the failure costs are pure loss of human life:

$$P_{f,marg} \approx \frac{C_{intervention,p}}{P_{d|f} \cdot occ \cdot SWTP} \tag{5}$$

where $P_{d\,|\,f}$ is the conditional fatality probability, i.e. the probability of dying given structural failure and being exposed. Further, occ is the occupancy or the average number of people at risk close to the bridge, and $SWTP$ is the societal willingness to pay for saving an additional life. The occupancy can be calculated as:

$$occ = AADT \cdot t \cdot n_p \tag{6}$$

where $AADT$ is the annual average daily traffic, t is the time one vehicle is exposed (on or close to the bridge), and n_p is the average number of people in one vehicle. If the bridge crosses another road, the exposure for this road should be added.

2.4 *Absolute life safety*

The absolute life safety (or individual risk) criterion is preferably given in the metric "expected value of the number of deaths per person-year" to be transferable between different activities and domains. For structural risk, it is expressed as:

$$P_{f,abs} = \frac{IR_{crit}}{P_{d|f}} \tag{7}$$

where IR_{crit} is the criterion for the expected number of fatalities per person-year and $P_{d|f}$ is the conditional fatality probability.

The absolute limit for life safety is subject to issues regarding system definition in time and space and arbitrariness. It is argued that it is not the risk for one specific person that is regulated but rather the risk for a statistical person involved in an activity (Faber et al., 2015). It is, however, not obvious how the activity should be defined. For instance, the activity of driving across one specific bridge is different from the general activity of driving over bridges. These matters of risk transfer and averaging risks are common issues in more traditional risk fields but may be considered odd and lack broad acceptance among structural engineers.

2.5 *Governing criteria*

The governing criterion is:

$$P_{f,gov} = min\{P_{f,ec},\ P_{f,marg},\ P_{f,abs}\} \tag{8}$$

The values for the societal willingness to pay $SWTP$ and the individual risk criterion IR_{crit} are considered to be constant for a given decision-maker, and four parameters remain: The costs of intervention and failure, the occupancy, and the conditional fatality probability. The effect of combinations of these parameters on the governing criteria is explored in the following.

3 DEMONSTRATION

3.1 *Aim and approach*

This investigation aims to assess the necessity of three different criteria in the structural risk assessment of existing bridges. The hypothesis is that it may be fruitful to identify the governing criterion for ranges of cases to direct the risk assessment for individual assessments to the important criterion. A better understanding of the governing criterion would also improve the basis for code calibration of simpler safety formats.

3.2 *Parametrisation*

The input parameters with the selected ranges are given in Table 1. The failure cost is given as a one-time cost, and the intervention cost is given as a yearly net present cost. The upper limit for the conditional fatality probability is firm, as a probability cannot be larger than one, while the other limits are chosen arbitrarily. They are believed to cover all relevant combinations for bridge maintenance of public roads in Norway. The occupancy ranges from exposing 0.001 people, which corresponds roughly to ten vehicles per day, to 100 people, which is a number that is hard to imagine even on the largest and busiest bridges in Norway. Fixed values for $SWTP$ (Norway, 2023's value) and absolute safety criteria IR_{crit} were adopted as 50 MNOK and 10^{-4}.

Table 1. Ranges of parameters studied.

	Description	Range
C_{int}	Yearly intervention cost [MNOK]	10^{-4}–10^{2}
C_{fail}	One-time failure cost [MNOK]	0.1–1000
OCC	Occupancy, average number of people exposed	10^{-4}–10^{2}
$P_{d\|f}$	Fatality probability given exposure and failure	0.001–1

4 RESULTS AND DISCUSSION

For every case, the three criteria were calculated and compared. With fixed values for two of the four parameters, the results take the form of three heatmaps and the identification of the governing criterion in Figure 1. The colour of the heatmaps gives the criterion in probability of failure, where blue is less strict and red is more strict. For this figure, failure costs and the conditional fatality probability are fixed at 10 MNOK and 0.1, whereas intervention cost and occupancy are varied. The upper-left figure illustrates that high occupancy and low cost for intervention result in strict (red) criteria for the marginal life safety approach. The economic optimisation is not affected by the occupancy, and the absolute criterion is constant over occupancy and cost of intervention.

When the three criteria are compared, the absolute criterion is the governing one for most of the cases, indicated with black in the lower-right figure. The economic criterion (marked with grey) only governs for cheap interventions where $C_{int}/C_{fail} < 10^{-3}$. The marginal life

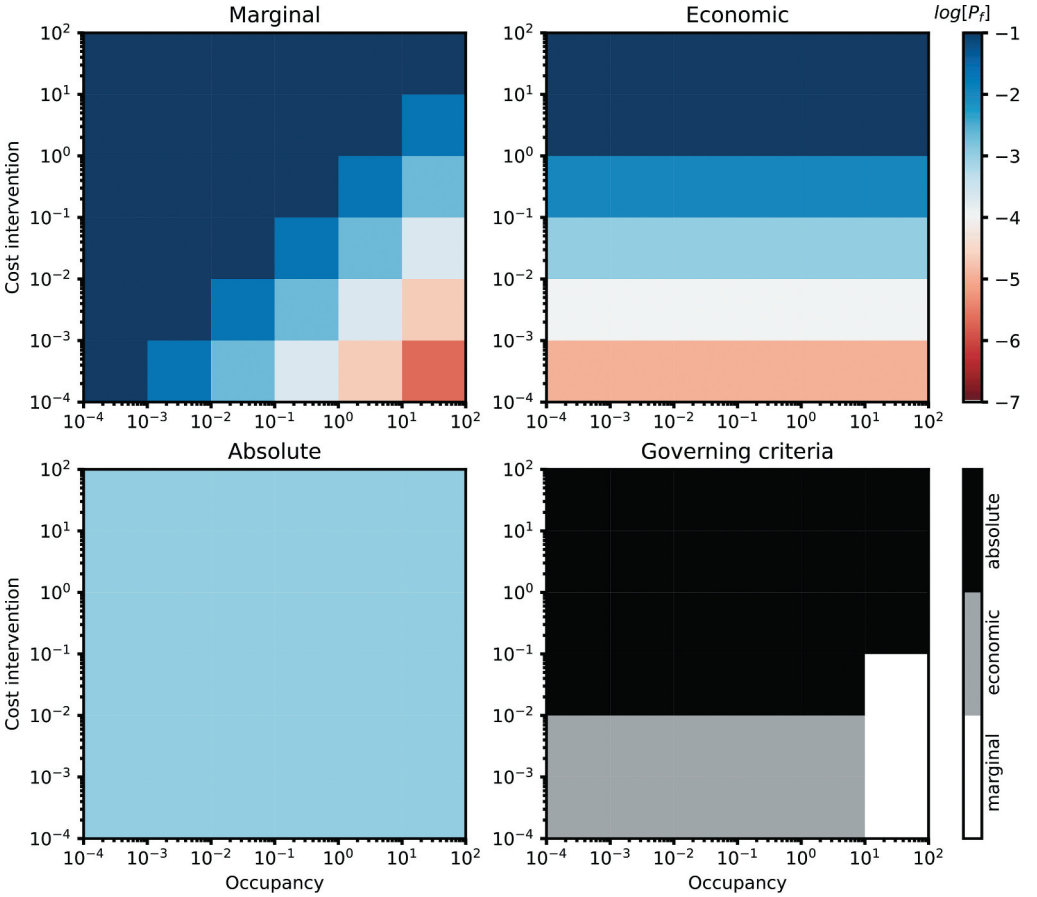

Figure 1. The criteria for the yearly probability of failure for economic optimisation and marginal and absolute life safety, parameterised by intervention cost and occupancy. C_{fail} = 10 MNOK and $P_{d\,|\,f} = 0.1$, red values indicate stricter criterion and the governing criterion is presented in the lower right plot.

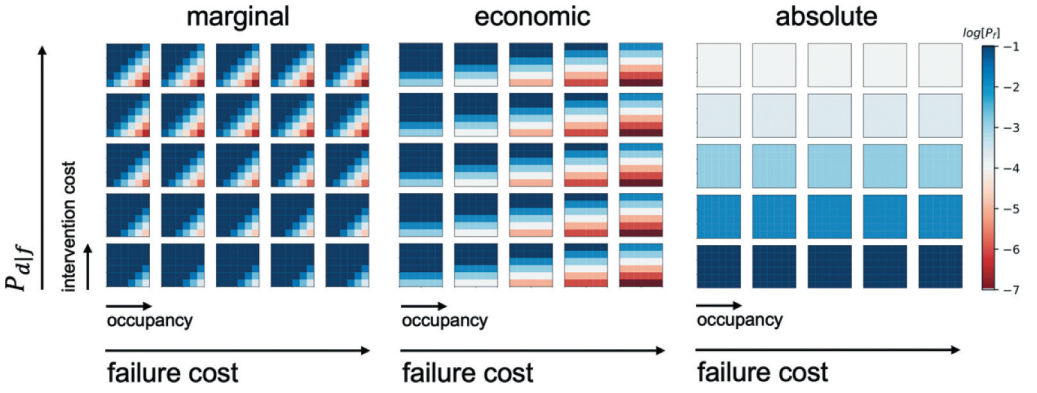

Figure 2. This figure shows results as in Figure 1 for a range of parameters C_{fail} and $P_{d\,|\,f}$.

safety criterion is the critical criterion for combinations of very high occupancy and low cost for intervention, as indicated with white colour.

Expanding the variety of the two fixed criteria, failure cost and conditional fatality probability, results in a range of plots in Figure 2. Here, we see the criteria for all four parameters

in one figure. The middle plot in all three five-by-five plots is identical to Figure 1, and the rest are results of varying failure costs and conditional fatality probability. The three criteria have distinct patterns, illustrating the impact of the different parameters. Comparing them and identifying the strictest one results in Figure 3, which is the main outcome of this study. This figure illustrates the governing criteria for all four parameters at once. The governing criterion for the reference case presented in Figure 1 is found in the middle of Figure 3. With a higher conditional fatality probability and lower failure costs (the upper left plots), the economic criterion has less influence compared to the reference case. On the contrary, with a lower conditional fatality probability and higher failure costs (the lower right plots), the economic criterion is more important. Two case studies in earlier work by Liljefors & Köhler (2024) are given as reference points, one which is governed by the absolute criterion and one by the economic criterion.

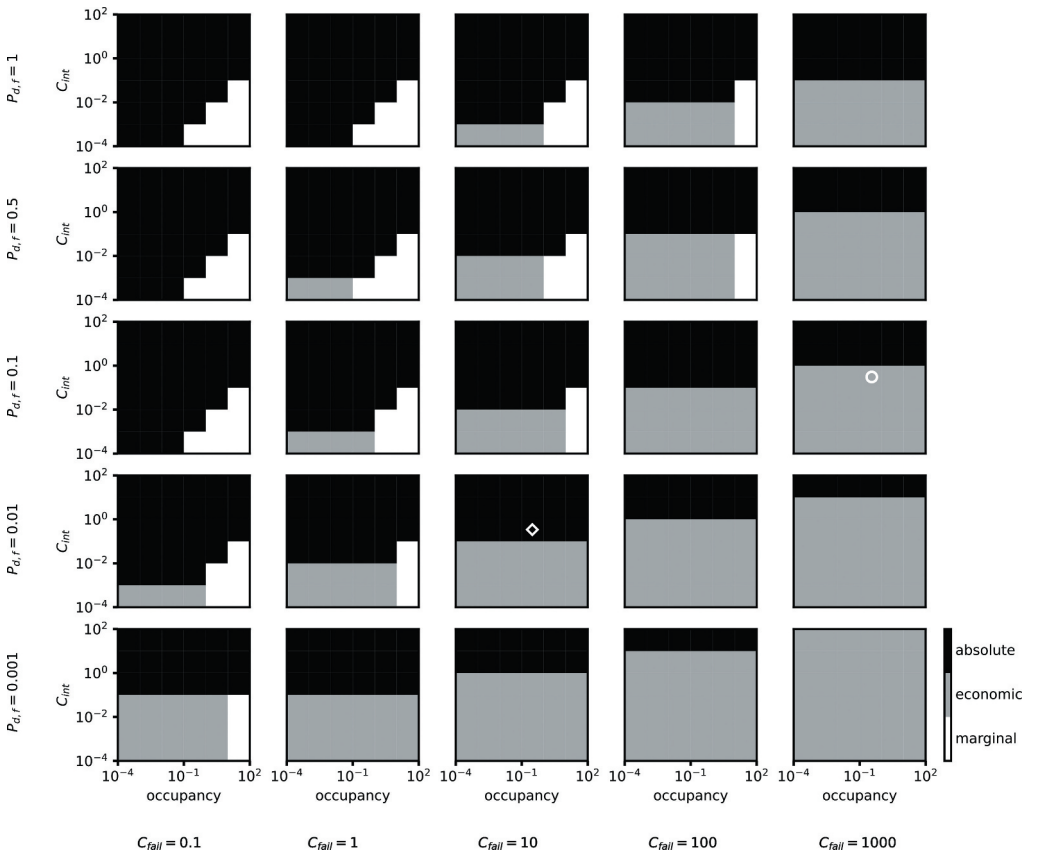

Figure 3. The governing criteria for the parameter study. The circle and diamond refer to case studies Herøysund and Osvold in Liljefors & Köhler (2024).

Repeating the calculations with a stricter absolute life safety criterion of 10^{-5} results in a shift of one magnitude favouring the absolute criterion (black covers a larger area, not shown here). This indicates that the absolute safety criterion may be governing for a majority of cases, and further investigation into this criterion is recommended. When doing so, one should remember that strict absolute criteria are costly and may waste resources that could be better utilised in society, i.e. they should not be conservatively assigned.

The assumption that the failure cost is independent of the occupancy and the conditional fatality probability is questionable. They both affect the expected number of fatalities, which impacts the failure costs as each fatality is quantified by a compensation cost, e.g. the

statistical value of a saved life *SVSL*. This means that the results are only valid when the costs for fatalities are a minor part of the total failure costs. In addition, some of the combinations may not be feasible and are therefore meaningless and can be ignored. This selection of practically reasonable parameters is left to the decision-maker. The range of occupancy in this study may be further restricted. Instead, a higher resolution for the areas where the criteria are similarly important may be interesting to study.

In this investigation, we compared three different criteria with little focus on the actual numbers. The values for the criteria are sensitive to the input parameters, but the relative comparison of the criteria is less sensitive. The study is meant as a qualitative overview that illustrates the behaviour of the different criteria. However, the numbers may provide some insight. The strictest criteria are in magnitude 10^{-7}, corresponding to the highest reliability class 3 in Eurocode for a yearly reference period. This would mean that, in any case, the highest safety level of the Eurocode is safe enough for assessment of existing structures (in case of no deterioration or other deviations). The least strict criteria are in magnitude $10^{-1} - 10^{-2}$, values that are considerably lower than any criteria in the Eurocode. This is promising, as it indicates that it may be justifiable to decrease the safety requirements for existing structures, which is commonly argued. However, this should be done with utmost caution, bearing in mind that, for example, deterioration or increased traffic load may violate this reasoning.

5 CONCLUSION

Establishing consistent safety criteria is fundamental for efficient and sustainable maintenance of existing bridges. In this study, we derived criteria in the form of failure probabilities from three approaches: Economic optimisation, marginal life safety and absolute life safety. The input variables were parameterised, and the governing criterion for each combination was identified. The study revealed ranges for which each approach is clearly governing the assessment and areas where the approaches are equally important. The large variation of governing criteria at reasonable ranges justifies the use of multiple criteria as it enables a more uniform safety level.

A review of design and assessment methods for skew concrete slabs

Alessandro Lipari
ENEA Italian National Agency for New Technologies, Energy and Sustainable Economic Development

ABSTRACT: Concrete slabs are often used for short-span bridges where it is required to limit the deck construction depth. Alongside, skew decks are helpful when there are space constraints in the bridge construction area, e.g., in urban areas, thus they are not uncommon. Nonetheless, skew slabs are not as much investigated as straight slabs and comprehensive guidance on their design or assessment is generally lacking. This is particularly the case for the shear behaviour of skew concrete slabs, which exhibit significant load concentrations around the obtuse corners with observed failure modes that are intermediate between the traditional cases of one-way and two-way (punching) shear. A reliable estimation of the shear strength is beneficial for both design and assessment: in fact, if shear strength is over-estimated, it may lead to undesired brittle failures, whereas if it is under-estimated, it may lead to inefficient design or unnecessary interventions to existing structures.

This paper reviews the provisions of three codes of practice on shear design (Eurocode 2, the Swiss SIA 262, and fib Model Code 2010), as well as main research on skew slabs. Procedures for extending the code provisions to skew slabs are presented and then applied to a case study. Some scatter is found across different codes of practice, broadly reflecting their complexity. The findings may be useful to practitioners with the design and assessment of skew concrete slabs.

1 INTRODUCTION

A slab can be defined as an element whose minimum panel dimension is not less than 5 times the overall slab thickness (European Committee for Standardization, 2004). Slabs can be considered *one-way spanning* if they possess two free unsupported and sensibly parallel edges and are subjected to dominantly uniformly distributed loads (European Committee for Standardization, 2004). Otherwise, slabs are said to be *two-way spanning*: this is mostly the case of bridge decks, as they are often not subjected to dominantly uniformly distributed loads.

Concrete slabs are often used for short-span bridges where it is required to limit the deck construction depth, as they provide more headroom than a typical beam-and-slab arrangement. Alongside, skew slabs are most suitable when there are space constraints, e.g., in urban areas.

Several established methods are available to analyse the flexural behaviour of concrete slabs, traditionally based on the theory of plasticity. In contrast, the shear behaviour is not as much established. Even for the simpler case of beams, there is no universal agreement on a single approach to predict the shear strength, particularly when no shear reinforcement is provided, that is the most typical case for slabs. Interestingly, slabs under concentrated loads close to supports exhibit an intermediate behaviour between the two traditional cases of one-way and two-way shear (Vaz Rodrigues et al., 2008, Lantsoght et al., 2013).

This paper reviews the provisions of three codes of practice on shear design (Eurocode 2, SIA 262, fib Model Code 2010), as well as main research on the shear behaviour of skew concrete slabs. As these codes do not generally have specific provisions for the calculation of shear in skew slabs, practical procedures are presented to extend their principles to skew slabs. The codes of practice are then applied to the case study of a skew railway bridge deck.

DOI: 10.1201/9781003483755-461

2 FLEXURAL BEHAVIOUR

Traditional methods to analyse the flexural behaviour of slabs are based on either the lower or upper bound analysis from the theory of plasticity, such as the *strip method* (Hillerborg, 1960, Wood & Armer, 1968), mainly used for design, or the *yield line theory* (Johansen, 1972), mainly used for assessment. These methods have the advantage of requiring relatively simple calculations and considering the plastic strength reserve of the material. However, in design, a linear elastic analysis may be required for SLS checks. Nowadays, the application of such traditional methods to skew decks is generally limited, as the use of Finite Element Method (FEM) has become widespread. A *grillage analysis*, in which the slab is idealized as a mesh of beams, may not be accurate for areas of high concentrated loads; therefore, it is advisable to use two-dimensional elements.

From a structural 2-D analysis of a slab, two shear forces per unit breadth are obtained along the x- and y-axes, v_x and v_y, as well as three moments per unit breadth: the bending moments m_x and m_y, and the twisting moment m_{xy} (Figure 1). Applied axial forces are generally not significant in non-prestressed slabs.

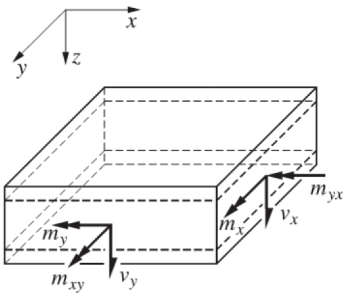

Figure 1. Shear forces and moments acting on a slab.

In slabs, it is useful to compute the bending moment m_n in any direction n forming an angle θ from the x-axis, which can be found from equilibrium considerations:

$$m_n(\theta) = m_x \cos^2\theta + m_y \sin^2\theta + 2m_{xy}\cos\theta \sin\theta \tag{1}$$

The *Field of Moments* method has been widely applied both for design and assessment purposes. The method uses the *normal moment yield criterion* and is valid for under-reinforced sections. No axial or shear forces are considered. The applied moment field is derived from the structural analysis, and it is checked that moment capacities are not exceeded anywhere, i.e., for all values of θ.

In design, as a derivation of the Field of Moments method, the Wood-Armer equations are often used to size the reinforcement by defining the required moment capacities for an orthogonal reinforcement grid (Wood, 1968, Armer, 1968):

$$\begin{cases} m^*_x = m_{Ed,x} \pm k \left| m_{Ed,xy} \right| \\ m^*_y = m_{Ed,y} \pm \frac{1}{k} \left| m_{Ed,xy} \right| \end{cases} \tag{2}$$

in which the sign + is valid for sagging moments (bottom reinforcement) and the sign – for hogging moments (top reinforcement); k is typically taken equal to 1, thus ensuring the least amount of reinforcement is required, although different values may be selected. In skew slabs, if the reinforcement grid is not placed along the x- and y-axes, the applied moments along the reinforcement directions can be derived from Equation 1.

However, some flaws have been noted in Equation 2 (Denton & Burgoyne, 1996, OBrien & O'Dwyer, 2015) affecting its application to assessment, as well as to the uncommon cases of anticlastic bending, i.e. bending moments of opposite sign, and skewed heavy reinforcement (Denton et al., 2010).

In assessment, both the applied and resisting moments are known, and the *excess capacity* is of interest, sometimes expressed in terms of a safety factor. The resisting moments due to multiple reinforcement layers i placed at angles α_i from the x-axis can be found as follows:

$$\begin{cases} m_{R,x} = \sum_i m_{R,\alpha_i} \cos^2\alpha_i \\ m_{R,y} = \sum_i m_{R,\alpha_i} \sin^2\alpha_i \\ m_{R,xy} = \sum_i m_{R,\alpha_i} \sin\alpha_i \cos\alpha_i \end{cases} \quad (3)$$

in which $m_{R,\alpha i}$ = resisting moment in the direction of the i-th reinforcement layer, which can be obtained from the classical flexural design theory of concrete beams. Inserting Equation 3 into Equation 1 gives the resisting moment in any direction n forming an angle θ from the x-axis:

$$m_{R,n}(\theta) = m_{Rd,x}\cos^2\theta + m_{Rd,y}\sin^2\theta + 2m_{Rd,xy}\cos\theta\sin\theta \quad (4)$$

3 SHEAR BEHAVIOUR

Traditionally, shear failure in slabs has been divided into two failure modes:

- *One-way* shear failure (often simply referred to as shear), associated with distributed or line loads and linear supports. In this case, the behaviour of a slab at failure is comparable with that of a wide beam.
- *Two-way* shear failure, associated with the local introduction of heavy concentrated loads, such as wheel loads. Two-way shear often refers to the case of punching shear, where failure occurs as the load roughly creates a truncated cone.

In reality, slabs may exhibit an intermediate case between the two failure modes when subjected to concentrated loads close to the supports (Vaz Rodrigues et al., 2008, Lantsoght et al., 2013). In such cases, two-way shear becomes prevalent over one-way shear, but with a flow of inner forces different from that of the punching shear case.

The shear behaviour of skew slabs has not been much investigated. Cope (1985) performed nine tests to failure on slab models with skew of 30°, 45° and 60° subjected to dead weights and concentrated loads: the 30° and 45° skew models failed in shear with cracks in proximity of the concentrated loads and/or the support line, whereas the 60° skew model failed in punching shear; it was also shown that an increasing skew angle considerably decreases the shear capacity. Morrison & Weich (1987) tested a model of a 50° skew decommissioned concrete slab deck, which failed in punching shear exhibiting ductility. Miller et al. (1994) tested a 30° skew decommissioned concrete slab bridge to destruction, which failed abruptly in punching shear. Théoret et al. (2012) proposed bending moment and shear force factors to design skew slab bridges using the equivalent beam method. For a comprehensive review refer to Lipari (2020).

In analysis, thick plates should be used, as they are able to capture the shear concentrations in the obtuse corners typical of skew slabs. However, supports are best modelled with springs and, when point supports are used, a fine mesh around them may lead to unrealistic shear forces. This typically affects shear forces within a deck depth from the support (OBrien et al., 2015).

3.1 *Principal shear force*

The concept of principal shear force is crucial to analyse the shear behaviour of slabs. The applied shear force acting on any direction forming an angle θ from the x-axis can be found from equilibrium considerations:

$$v(\theta) = v_x\cos\theta + v_y\sin\theta \quad (5)$$

The principal shear force can be represented by its magnitude, v_0, and direction forming an angle φ_0 from the x-axis:

$$v_0 = \sqrt{{v_x}^2 + {v_y}^2} \quad (6)$$

$$\varphi_0 = arctan\left(\frac{v_y}{v_x}\right) \tag{7}$$

The principal shear action occurs on a plane perpendicular to the direction of the principal shear force. Close to the supports of skew slabs, φ_0 is expected to be comparable to the skew, as it is typically perpendicular to the support line. In general, it suffices to perform the shear resistance check along φ_0, but there may be uncommon cases where other directions should be checked (Lipari, 2020).

3.2 *Equivalent reinforcement ratio*

When the longitudinal reinforcement is not placed perpendicularly to the support line, the direction of the principal shear force typically differs from the direction of the main flexural reinforcement. The concept of *equivalent area of reinforcement* is useful to compute the effects of the reinforcement along any directions. The area of flexural reinforcement $A_{s,\alpha}$ placed at angle α from the x-axis may be resolved for any direction forming an angle θ from the x-axis as follows:

$$A_{s,\alpha}(\theta) = A_{s,\alpha} cos^2(\theta - \alpha) \tag{8}$$

The $\cos^2$ function accounts for the increase in bar spacing and the decrease in effective reinforcement area with increasing angle θ. Dividing both terms for the effective area $b{\cdot}d$, where b = width of the section, and d = effective depth, and considering multiple reinforcement layers i, Equation 8 can be rewritten with reference to the reinforcement ratio ρ:

$$\rho(\theta) = \sum\nolimits_i \rho_{\alpha_i} cos^2(\theta - \alpha_i) \tag{9}$$

In the case of reinforcement placed along the x-y axes, and in the direction of the principal shear force ($\theta = \varphi_0$), Equation 9 simplifies as $\rho_0 = \rho_x cos^2\varphi_0 + \rho_y sin^2\varphi_0$.

Note that Equations 8-9 represent mere *geometric* equivalences, giving an *equivalent reinforcement ratio*, as if an unreinforced direction had reinforcement along it. In fact, when using Equation 8 for the calculation of reinforcement forces, an implicit assumption of yielded reinforcement is made.

Alternatively, an expression based on the theory of elasticity may be used, in which the reinforcement strains (and associated stresses) are taken into account (Clark, 1983):

$$A_{s,\alpha}(\theta) = A_{s,\alpha} cos^4(\theta - \alpha) \tag{10}$$

When using the $\cos^4$ function for the calculation of reinforcement forces, it is then implied that the flexural reinforcement remains elastic. Equation 10 may be regarded as an effective *mechanical* equivalence, as it allows to compute the force that a fictitious reinforcement along an unreinforced direction would exercise when yielding is not achieved (Denton et al., 2010).

Following a similar development to that of Equation 9, the equivalent reinforcement ratio for multiple reinforcement layers i can be rewritten as follows:

$$\rho(\theta) = \sum\nolimits_i \rho_{\alpha_i} cos^4(\theta - \alpha_i) \tag{11}$$

In the case of reinforcement placed along the x-y axes, and with $\theta = \varphi_0$, Equation 11 simplifies as $\rho_0 = \rho_x cos^4\varphi_0 + \rho_y sin^4\varphi_0$.

It is always on the safe side to use Equation 11, rather than Equation 9.

4 CODES OF PRACTICE

This section outlines provisions of three codes of practice about shear design without shear reinforcement: Eurocode 2 (in the following EC2), which is the standard in most European

countries and is based on a statistical analysis of experimental data; the Swiss code SIA 262 *Concrete Structures* (SIA262) and the *fib Model Code for Concrete Structures 2010* (MC2010), which are based on two different strain-based mechanical approaches. For a full description of the methods, the reader is referred to the codes and Lipari (2020).

4.1 *Eurocode 2*

Annex LL in Eurocode 2 part 2 (European Committee for Standardization, 2005) deals with the design of shell elements with a *sandwich model*, in which the outer layers (*cover*) resist membrane forces, such as axial forces and moments, and the inner layer (*core*) resists the shear forces. In fact, a slab can be considered as a case of a shell element.

For the design of the inner layer, the principal shear force should be computed according to Equations 6-7. In the direction of the principal shear force, the shell element behaves like a beam and Eurocode 2 part 1 applies (European Committee for Standardization, 2004).

Lipari (2020) proposed an extension for skew slabs introducing the equivalent reinforcement ratio $\rho(\theta)$ into the EC2-1 formulation expressed in terms of design shear resistance per unit breadth:

$$v_{Rd,c}(\theta) = C_{Rd,c} \cdot k \cdot \sqrt[3]{100 \cdot \rho(\theta) \cdot f_{ck}} \cdot d_m \geq v_{min} \cdot d_m \tag{12}$$

in which d_m = average effective depth; f_{ck} = characteristic concrete strength; and $\rho \leq 0.02$ as for beams. Although Annex LL uses the $\cos^2$ function to reduce the effectiveness of the reinforcement (Eq. 9), the use of the more conservative $\cos^4$ is recommended. It is then checked that the design shear resistance $v_{Rd,c}$ with $\theta = \varphi_0$ (Eq. 12) is greater than the design principal shear force $v_{Ed,0}$ (Eq. 6). If not, in design, shear reinforcement can be provided.

EC2 allows shear forces due to loads applied on the upper side within a distance $0.5d \leq a_v \leq 2d$ from the edge of a support to be reduced by a factor $\beta = a_v/2d$, in which a_v = distance between the edge of the load and the support edge; for $a_v \leq 0.5d$, $\beta = 0.25$.

4.2 *SIA 262*

The Swiss Code SIA 262 (SIA, 2013) endorses a simplified version of the *Critical Shear Crack Theory* (CSCT) (Muttoni & Fernández Ruiz, 2008). The shear resistance of slabs without shear reinforcement is determined for a control section at a distance $d/2$ from the edge of a support or from the point of application of a concentrated load.

The design shear resistance $v_{Rd,c}$ strongly depends on the reinforcement strain ε_s. This increases the design effort compared to EC2; however, as an approximation suitable for outline design or preliminary assessment, it can be conservatively assumed that the flexural reinforcement is yielded, thus substantially reducing the computational effort. In such case, SIA262 provisions are readily applicable to skew slabs.

On the other hand, if the flexural reinforcement remains elastic, the bending utilization in the direction of the principal shear force, $m_{Ed,0}/m_{Rd,0}$, needs to be found at the control section to calculate ε_s. The design applied moment per unit breadth, $m_{Ed,0}$, is found by means of Equation 1 with $\theta = \varphi_0$. Consistently, the design resisting moment per unit breadth, $m_{Rd,0}$, is calculated according to Equation 4 with $\theta = \varphi_0$.

Notably, a factor $1/[\sin^4(\varphi_0 - \alpha_l) + \cos^4(\varphi_0 - \alpha_l)]$ has to be applied to ε_s to consider the case when the direction of the principal shear force φ_0 significantly deviates from that of the main reinforcement α_l (Muttoni & Fernández Ruiz, 2008).

4.3 *Fib Model Code 2010*

The *fib Model Code for Concrete Structures 2010* (International Federation for Concrete Structures, 2013) provides equations for the shear resistance of web of beams and core layers of slabs, as per the sandwich model mentioned in Section 4.1. It also gives different *Levels of Approximation* (LoA): the higher the level, the greater the effort, but the more accurate the results.

The design shear force must in general be determined for control sections at a location d from the face of supports and from discontinuities of geometry or applied loads. Notably, MC2010 includes the case of concentrated loads applied to a slab near a support line. In this case, the slab capacity must be checked both for punching at the control perimeter around the loaded area and for shear at a control section taken parallel to the support line.

The MC2010 provisions for members without shear reinforcement are based on the Simplified Modified Compression Field Theory (SMCFT) (Bentz et al., 2006). Two levels of approximation are provided. LoA I is readily applicable to skew slabs, as the only inputs required are the concrete strength f_{ck} and the effective shear depth z, and it may be used for outline design or preliminary assessment. In LoA II the shear resistance $V_{Rd,c}$ depends on the longitudinal strain at the mid-depth of the effective shear depth ε_x, which in turn depends on the design applied shear force V_{Ed}, thus making the check an iterative process, as well as on the design applied moment M_{Ed} and the area of reinforcement A_s. It is not stated how to deal with the cases when the direction of the principal shear force differs from that of the main reinforcement; therefore, the following recommendations are made for the calculation of ε_x in skew slabs:

- the design moment M_{Ed} is taken per unit breadth and resolved for $\theta = \varphi_0$, $m_{Ed,0}$ (Eq. 1);
- the design shear force V_{Ed} is taken as the design principal shear force per unit breadth, $v_{Ed,0}$ (Eq. 6);
- the area of longitudinal reinforcement A_s is taken as the equivalent area of reinforcement per unit breadth along φ_0, $a_{s,0}$, based on the more conservative Equation 10.

Note that, although MC2010 states to neglect any transverse reinforcement, this assumption seems over-conservative when applied to significantly skew slabs.

5 CASE STUDY

Underbridge DSN1/14 at Eaglescliffe (United Kingdom) is a pre-cast concrete solid slab with two upstands, constructed in 2016 to replace an older deck. The bridge carries one ballasted railway track.

Table 1 resumes main information on deck geometry and material properties. In spite of its short span, the concrete deck is quite slender, with a span-to-depth ratio of 14.5:1. The supports (10x200 mm^2 unreinforced elastomeric strips) are modelled by means of distributed

Table 1. Main data.

Description	Value
Skew span between supports	4.35 m
Slab depth	0.3 m
Slab width (right angle)	3.7 m
Skew	26.5°
Concrete strength class	C40/50
Maximum aggregate diameter	20 mm
Nominal cover	45 mm
Modulus of elasticity of steel	200 GPa
Longitudinal reinforcement ratio (midspan)	2.16%
Longitudinal reinforcement ratio (supports)	1.08%
Transverse reinforcement ratio	0.61%

linear springs with stiffness 14,000 MN/m^3. The orthogonal reinforcement grid has the longitudinal reinforcement parallel to the free edges.

The material partial safety factors for concrete and steel are respectively $\gamma_c = 1.5$ and $\gamma_s = 1.15$. The applied train load is the Load Model 71 (LM71) (European Committee for Standardization, 2003). The design axle load at ULS Q_v is 822.9 kN. Considering each individual wheel load and the longitudinal distribution between sleepers, the design point load is 205.7

kN. The LM71 is positioned so that the nearest point load lies at a minimum distance of $2d$ from the support edge ($a_v \geq 2d$); as such, there is no need to consider the EC2 factor β.

To enable a comparison among the three codes of practice, the design applied shear forces v_{Ed} are all taken at a distance d from the support edge. For MC2010, the design applied bending moment m_{Ed} is taken at a distance d from the support edge, whereas for SIA262 the design bending moments m_{Ed} and m_{Rd} are taken at a distance $d/2$ from the point of application of the loads, as a greater bending utilization is achieved there.

Figure 2 shows the shear forces along the x-axis under the worst train load position, which is in proximity of the bottom obtuse corner.

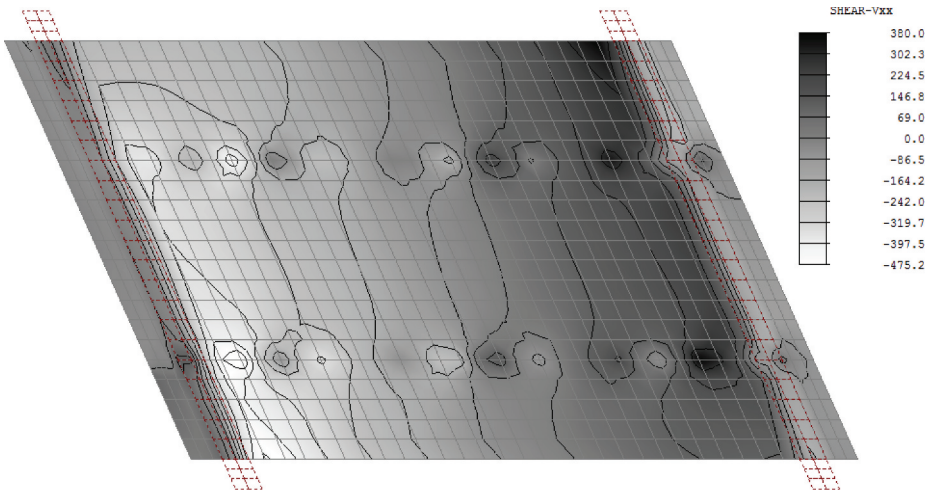

Figure 2. ULS design shear forces along x-axis [kN/m] (area below upstands is excluded).

Table 2. Design shear forces and moments, and shear strengths.

Shear force or moment (*distance of control section from support edge*)	Value
Shear force, ($v_{Ed,x}$, $v_{Ed,y}$) [kN/m] (d)	(-475.2, -215.2)
Principal shear force, $v_{Ed,0}$ [kN/m] (d)	521.4
Direction of principal shear force, φ_0 [°] (d)	24.4
Bending and twisting moments, ($m_{Ed,x}$, $m_{Ed,y}$, $m_{Ed,xy}$) [kNm/m] (d)	(61.9, 55.6, 38.5)
Moment along direction of principal shear force, $m_{Ed,0}$ [kNm/m] (d)	89.8
Bending and twisting moments, ($m_{Ed,x}$, $m_{Ed,y}$, $m_{Ed,xy}$) [kNm/m] ($3d/2$)	(134.6, 90.1, 50.8)
Moment along direction of principal shear force, $m_{Ed,0}$ [kNm/m] ($3d/2$)	165.2
Resisting moment along direction of principal shear force, $m_{Rd,0}$ [kNm/m] ($3d/2$)	216.6
Shear strength according to EC2 [kN/m]	172.5
Shear strength according to SIA262 (plastic reinforcement) [kN/m]	123.9
Shear strength according to SIA262 (elastic reinforcement) [kN/m]	174.9
Shear strength according to MC2010 (LoA I) [kN/m]	129.5
Shear strength according to MC2010 (LoA II) [kN/m]	133.9

Table 2 reports the design values of forces and moments at the control sections, as well as the design shear strengths calculated according to Section 4. Note that, as expected, φ_0 is close to the skew.

Based on the results presented, the following observations can be made:

– the loss of accuracy when using the simple LoA I of MC2010 compared to the more accurate LoA II is quite small (-3.3%), due to relatively high strains ε_x;
– MC2010 LoA II provides lower shear strength values than EC2 or SIA262 with elastic reinforcement, mostly due to the high shear forces v_{Ed}, which affect the shear strength;
– SIA262 provides the greatest shear strength when assuming that the flexural reinforcement remains elastic, otherwise it returns the lowest strength; in the former case, the difference is substantial when compared to MC2010 (+30.6%) and minimal when compared to EC2 (+2.4%).

Note that the deck needed shear reinforcement, regardless of the code applied, due to its slenderness and the high shear forces.

6 CONCLUSIONS

Skew concrete slabs are not uncommon in bridge engineering. While their flexural behaviour is quite established, their shear behaviour has not been much investigated. Indeed, skew slabs exhibit significant load concentrations around the obtuse corners, with observed failure modes that are intermediate between the traditional cases of one-way and two-way (punching) shear. Furthermore, guidance on their design and assessment is not comprehensive.

The provisions of three codes of practice on the shear design without shear reinforcement (the empirical Eurocode 2 and the strain-based SIA 262 and fib Model Code 2010) are presented here, along with procedures to extend them to skew slabs. The codes are then applied to the case study of a skew railway deck. Significant scatter is found, broadly reflecting their complexity: the quicker MC2010 LoA I and SIA262 with an assumption of plastic reinforcement expectedly return the lower estimates, which may be used for preliminary calculations, whereas EC2 and SIA262 with an assumption of elastic reinforcement return significantly greater estimates than MC2010 LoA II.

C. Popescu
Sintef AS and Invator AB

M. Holmqvist
Invator AB

ABSTRACT: The Herøysunds bridge on the west-coast in Nordland Fylke in Norway had undergone concrete repair works with focus on reinforcement corrosion. During these actions, it was discovered that the tendon ducts had loss of injection. To ensure the safety of the bridge it was decided to map voids and defects in the ducts. Several risk areas were pointed out by the constructor and a non-destructive test (NDT) was carried out. A methodology with combination of different NDT methods were used; cover meter, GPR, UPE, IE and Videoscope. The results from the NDT investigate shows that the suggested approach was successful, and it was possible with high accuracy to detect voids in the ducts. The methodology forms a basis for the procedure recommended by the Norwegian Public Roads Administration.

1 INTRODUCTION

Herøysundet Bridge is a beam bridge, constructed on-site with varying height. The bridge has 6 spans consisting of 5 pillars and two abutments (Figure 1). The total length of the bridge is 154 meters, it has one traffic lane, as well as sidewalks on both sides, and the largest overall width is 5.30 meters. The largest span, which is the navigational channel, is located in span 4 and has a length of 60 meters. Pillars and abutments are founded on rock. The Herøysund Bridge, situated in Nordland County, is a post-tensioned bridge. Recent inspections have revealed corrosion in the tendons of its post-tension system. Plans are in place for the replacement of the bridge, followed by the demolition of the old structure. This scenario serves as an excellent case study (Popescu et al. 2023) to enhance current engineering practices in the assessment of existing structures by incorporating the latest scientific advancements. Nordland County, in collaboration with the Norwegian Public Roads Administration (Statens Vegvesen), sees significant value in conducting a comprehensive assessment of this bridge. Such an evaluation can provide valuable insights, enhancing our comprehension of the structure's condition, degradation processes, and overall structural integrity (Karlsson et al. 2021). This paper presents the planning and implementation of non-destructive testing (NDT) for the Heroy Bridge, encompassing the assessment and recommendation of testing methodologies to detect voids in the ducts. Detecting defects and deterioration of the prestressed tendons is a complex task due to inaccessibility. Exploratory openings (e.g. coring) would offer limited results to localized areas. Non-destructive methods should be preferred for minimum disturbance to the structure – i.e. coring done for validation only.

In non-destructive testing, the planning of the inspection is an important part for a successful end result. During the planning, a testing procedure is established where the overall problems of the construction are first mapped and then suitable NDT methods are selected,

DOI: 10.1201/9781003483755-462

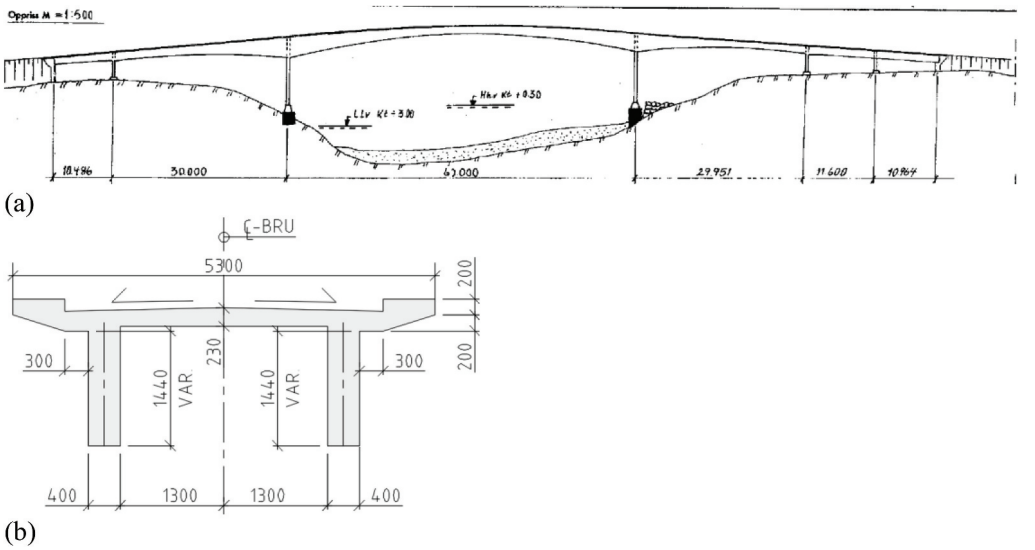

Figure 1. Heröysund Bridge: (a) elevation; and (b) cross-section.

in which order they should be carried out and which construction areas should be prioritized in the investigation. When establishing the testing procedure, drawings, previous inspection reports and photos are reviewed – process known as desk study. With this as a basis, the inspection can be placed on the construction parts that are most relevant and where the greatest risk of serious damage exists (Woodward, 2001; Matt et al. 2000).

While the focus lies on examining external post-tensioned (PT) tendons, some non-destructive testing (NDT) methods outlined by Im et al. (2010) may also prove relevant for internal tendon inspection. Among these are the Shearwave Tomography, Impact Echo, and Ultrasonic. Additionally, the Ground Penetrating Radar and Infrared Thermography are worth considering as alternative methods.

2 NON-DESTRUCTIVE TESTING APPROACH

The inspection task was carried out by using the following NDT systems:

- Covermeter
- Ground penetrating radar (GPR)
- MIRA ultrasound 3D (UPE)
- Impact echo
- Videoscope

In addition, cores were extracted at select locations to provide access to the tendon ducts followed by drilling to provide ground truth information and validation.

The inspection process included the following actions:

1. Desk study where potential focus areas were defined.
2. Locate the areas to be inspected based on the original planning and adapt based on local conditions. Deviations may exist due to local unevenness of the concrete surface making the data collection difficult.
3. On the areas marked in step 2, use ground penetrating radar to locate the ordinary reinforcement and prestressed reinforcement.
4. Mark the position of the prestressed reinforcement directly on the concrete surface and divide the profile line into 10 cm segments.
5. Use MIRA instrument to capture 2D slices at every 10 cm segment defined in step 3.

6. Combine the 2D slices within a 3D image that can be used for interpretation of the results.
7. Any detected flows on the 3D image based on MIRA measurements are further investigated using Impact echo instrument.
8. Coring/drilling is carried out in areas with potential voids inside the tendon ducts.

3 TESTING LOCATIONS

The testing locations for the Herøysund Bridge have been prearranged in consultation with the Norwegian Road Administration and Nordland County. The objective is to conduct NDT on all girders where access to tendons was feasible. It should be noted that tendons situated in the concrete deck have not undergone inspection. All test locations are illustrated in Figure 2 together with a more detailed description of section A in Figure 3. Also, the original section is presented in this figure. However, in this paper only location A, and only the North beam is going to be discussed. The approach, highlighted in Section 2, is then similar for all other locations.

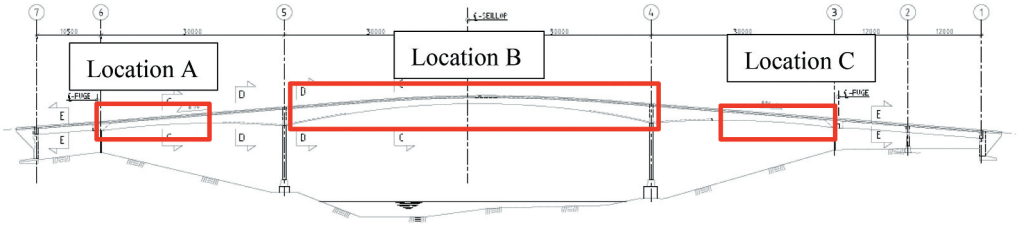

Figure 2. Testing locations.

Location A 	*Inspection of tendon ducts in the north/south girders* • *South girder (tendon ducts and length inspected)* ○ *Tendon 1SA – 10.0 m long* ○ *Tendon 2SA – 7.0 m long* ○ *Tendon 3SA – 5.0 m long* • *North girder (tendon ducts and length inspected)* ○ *Tendon 1NA – 8.0 m long* ○ *Tendon 2NA – 7.0 m long* ○ *Tendon 3NA– 5.0 m long*
	

Figure 3. Test locations and cables.

4 RESULTS

The main purpose of the investigation conducted at Herøysund Bridge was to verify the integrity of the grouting along the post tensioned tendons. Non-destructive test methods have been used to be able to check for defects. The measurements were repeated as vertical scans in the same locations as the original drawing, with this approach, the placements could be compared for the north beam in location 6, see Figure 4.

Duct number	*Placement drawing*	*Placement GPR scan*
4NA		*1050*
3NA		*850*
2NA		*540*
1NA		*300*

Figure 4. Corroborating the GPR results with as-designed drawings showing the placement of tendon ducts in north girder and a comparison with the placement.

MIRA equipment has been used in all cases to evaluate the condition of grouted post-tensioning ducts in the girders. B-scans (2D images) were collected every 10 cm along the ducts, see Figure 5. In total, around 3000 B-scans were collected throughout the bridge. The B-scans reflects the cross-section (perpendicular to the test surface) while the C-scans are obtained by combining multiple B-scans – thus, showing the reflecting interfaces on a plane parallel to the test surface. For example, tendons are shown as big dots on a B-scan together with their depth ("concrete cover") as well as the back-wall (thickness of the scanned element). On the C-scan the tendon ducts are shown as continuous lines. The lines may have a green-yellow color and indicates lower amplitude reflections from the steel tendons – meaning the duct is fully grouted. If the lines are displayed as red color, this indicates strong reflections from a discontinuity in material properties. Areas with strong interference that is characteristic of an air void will be further inspected with impact-echo instrument, see also Figure 5.

Inspection of tendon ducts started at the anchors placed in axis 6 in both north (N) and south (S) girder. The most severe locations were found on the south girder in tendon 2SA and 3SA. In the south girder two of the ducts were completely empty and had severe corrosion on the tendons.

In the north girder, duct 1NA gave indications to be lacking grout, the verification showed no presence of voids. Figure 6 shows a simplified overview of the scans, and the ultrasonic results is shown in Figure 7.

Impact echo was used in some locations to verify the results from ultrasonic scans. In order to detect ungrouted tendons two features in the frequency spectrum were of interest. First, a frequency peak in the spectrum that is associated with the thickness of the girder needs to be calculated. The frequency peak for the backwall is calculated with the actual thickness

MIRA (UPE) *Impact Echo (IE)*

Figure 5. Inspecting grouting conditions with MIRA and Impact Echo.

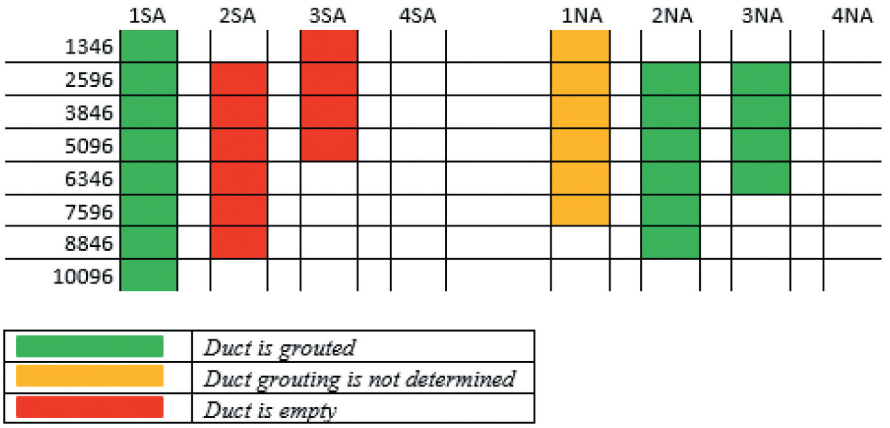

Figure 6. Grouting status according to ultrasonic results.

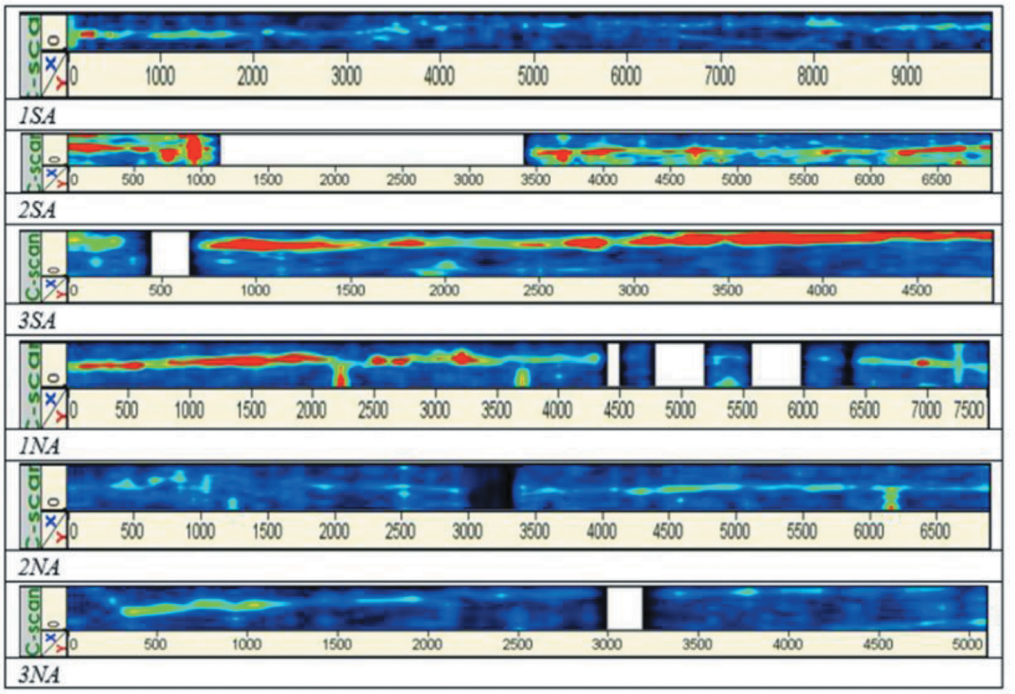

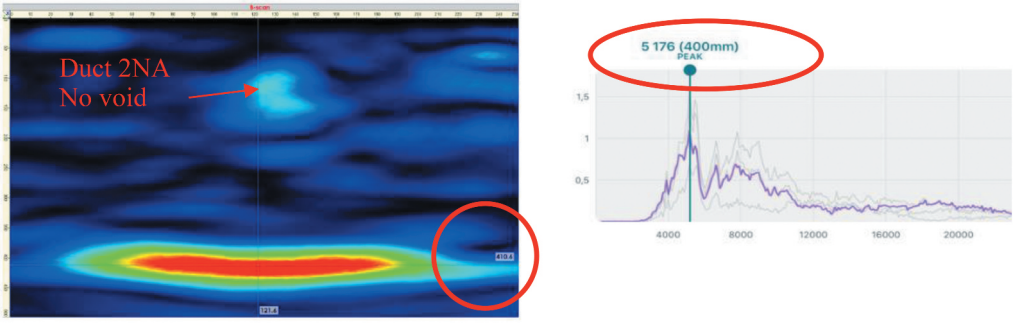

Figure 7. Ultrasonic results in south and north girder.

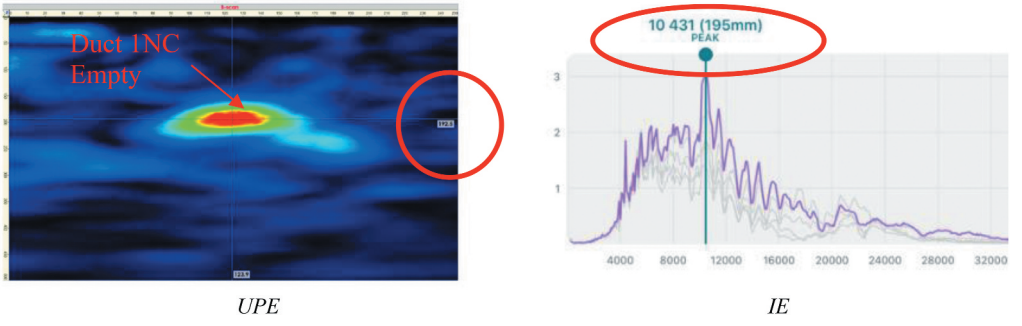
measured at the girder, $T = 400\ mm$, and the velocity measured with ultrasonic pulse, $C_p = 4140\ m/s$:



$$f = \frac{C_p}{2T} = 5.176\,kHz \tag{1}$$

The frequency peak we should look for is 5,176 kHz and if we get a peak at this frequency Impact echo shows that no voids are present in the inspected duct 2NA, see Figure 8.

UPE *IE*

Figure 8. Scan in 2NA scan 67 with no presence of voids. Backwall at 400 with both UPE and IE.

UPE *IE*

Figure 9. Void at ~200mm depth with both UPE and IE.

Figure 9 shows a scan of a duct with a void, 1NC. In this example the duct is placed with a cover of $T = 190\ mm$ and $C_p = 4140\ m/s$, a void in this duct should give a frequency peak according to the following calculation:

$$f = \frac{C_p}{2T} = 10.89\,kHz \tag{2}$$

In Figure 10 a longer grid scan with Impact echo from duct 3SC is shown, this duct is confirmed as empty in investigation made in 2020. No drilling was made during the inspection presented in this paper. The cover to the duct is around 160mm according to the GPR which means that the void could be somewhere between 160mm and 240mm. Red values show the presence of voids and the depth to the void. The green values show the thickness peak for the backwall, and the orange values show a shift in the peak which indicates a void. It should be noted that only one scan in each location was made which could mean that the impact echo missed the duct, especially the last scans were the duct was placed above the marked line on the concrete surface. This could explain the green numbers in the end. Each measurement with impact echo was made along the duct with 10 cm between, the same grid that was made with UPE.

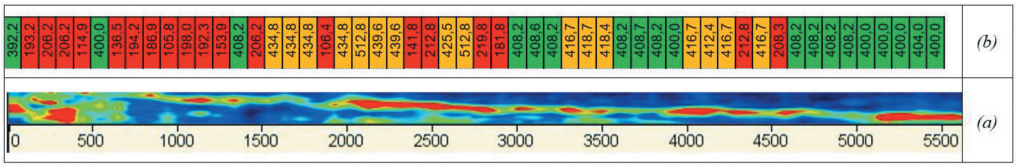


Figure 10. Empty duct with results from UPE *(a)* and Impact Echo (IE) *(b)*.

5 VERIFICATION BY CORING

To verify the results from the measurement some of the tendon ducts were opened to investigate the status of the cables and to verify voids or no voids. Caution must be exercised to ensure that the tendons are not damaged or, worse yet, severed during this process. The procedure is the following:

- Map placement of slack reinforcement – to avoid cutting reinforcement when drilling
- Map placement of ducts
- Use a hammer drill machine with ϕ16 to verify the distance to the duct
- Mount and core with ϕ80 – 100 mm depending on the depth to the duct
- Stop coring ca 15 mm outside the duct
- Carefully remove the concrete into the duct
- Open up the duct and inspect visually or in combination with videoscope
- After inspection repair the opening

The general process is shown in Figure 11 together with results from location.

6 SUMMARY AND CONCLUSIONS

The aim of the inspection was to evaluate the condition of the pretensioned tendons at Heröy Bridge. Specifically, voids in tendon ducts and consequently corrosion of the tendons has been the focus of the investigation. To achieve this, the condition of the grouting has been verified using non-destructive equipment MIRA, UPE (shear-wave tomography) and DOCter (impact echo). Careful opening of tendon ducts by coring/drilling, and subsequent visual inspection with an videoscope was carried out in suspicious areas to validate the findings.

The inspection was done in several locations starting by locating the tendons using a GPR instrument. The placement of the tendon ducts was marked on the concrete surface. The next step was to check for voids using UPE. From all measurements performed suspicious areas were detected in Section A and B. These locations were further studied using DOCter impact echo – arguably a more refined NDT method. The findings were validated using core drilling.

In section C and especially section A where the core drilling took place, the results from the NDT corresponded with the verifications.

In section A, two out of six inspected ducts were found ungrouted and verified with core drilling, 2SA and 3SA, in these two ducts we also found corrosion on the strands. Duct 1NA was found grouted on the side that was opened, despite that the ultrasonic results showed voids. Most certain, there are voids present, but on the back of the duct. In Table 1 a suggestion for probability grading is presented. The results from two girders are then summarized in Table 2. Here only the verification from these inspections is shown. We know from earlier inspection that the results in section C are verified as well.

Table 1. Grading for probability of voids.

	No voids	Probability <50%
	Minor voids	Probability > 50 %
	Major voids	Probability >75%

Table 2. Suspicious areas from ultrasound investigation with coring verification and class in south and north girders.

No.	South	UPE	Verif.	Grade	No.	North	UPE	Verif.	Grade
1	1SA				1	1NA			
2	2SA				2	2NA			
3	3SA				3	3NA			
4	1SB				4	1NB			
5	2SB				5	2NB			
6	3SB				6	3NB			
7	4SB				7	4NB			
8	1SC				8	1NC			
9	2SC				9	2NC			
10	3SC				10	3NC			

The results can be summarized:

- GPR was used to accurately locate ducts before inspecting them with MIRA and DOCter Impact echo. Ducts placed close to the re-entrant corners were more difficult to locate. A smaller GPR was used for this purpose since easier access was possible. However, this required full contact with the concrete surface (rather than relying on wheels) which in some areas posed difficulties due to unevenness of the concrete surface.

- The result from ultrasonic scanning shows that there where voids inside the ducts, this was confirmed with core drilling. In section A, south girder, 2 out of 3 ducts was completely empty, the tendons had severe corrosion and we also found a wire breakage in duct 2SA
- The amount of grouting and corrosion differs a lot inside the same duct. Duct 3SA was completely empty 4,3m from the anchor point with and there where corrosion on all the strands. Closer towards the anchor the bottom half of the duct was grouted, and corrosion could only be found in the top half of the duct. In duct 2SA there was a big difference in corrosion degree only 20 cm between two openings. Therefore, it is important to trust the equipment and put some effort in the openings to make sure that the voids are located.
- Although no defects to the grouting (i.e. voids) were found in 1NA when opening up the metallic ducts, it cannot be ruled-out the risk of voids on the other side of the duct or on the other side of the tendons in the duct. Change in material properties of the grouting mixture along the duct may also be an explanation for the suspicious areas obtained by MIRA. However, the effect of the grouting mixture has not been mentioned in the literature and thus additional research is needed. Nevertheless, despite that it was sometime difficult to detect voids, the process developed has proven to work and that it can with certain probability detect voids in the ducts which then can be a potential indicator for corrosion in the tendons.

7 FUTURE WORK

The future plans entails the development of a machine learning algorithm aimed at facilitating decision-making concerning voids in ducts. This algorithm will integrate raw data obtained from various non-destructive testing (NDT) technologies. The training of the machine learning model will involve both elements with known defects and those with unknown conditions, contributing to the refinement of the training procedure.

ACKNOWLEDGEMENT

We want to acknowledge the Norwegian public road administration and Nordland municipality for supporting and financing this work.

Comparison of partial factor methods for existing concrete structures: Application to a cable-stayed bridge

ABSTRACT: The assessment of existing reinforced concrete structures is currently a critical task to be dealt with by engineers and practitioners. Specifically, bridges and viaducts, composing important links in the infrastructure system, are subjected to changes in structural capacity and demand in time, e.g., due to aging and structural deterioration processes as well as the evolution of intensity and frequency of structural loadings. Moreover, climate change may have a significant impact on this evolution. In this context, partial factor methods calibrated for the design of new structures may lead to unnecessary and expansive interventions when used for the assessment of existing structures. Therefore, the exploitation of semi-probabilistic methodologies tailored for existing structural systems is necessary. In this paper, methodologies developed for the evaluation of existing structures are presented and applied to the safety assessment of a cable-stayed bridge located in France. The obtained results are eventually compared with the outcomes of the assessment performed according to the original design and the current Eurocodes regulations, with a discussion on benefits and limits of the presented methodologies.

1 INTRODUCTION

Civil engineering structures and infrastructures represent a fundamental part of the built environment. Nowadays, a large part of these systems is approaching the end of the design lifetime and needs to be re-assessed in order to evaluate the best strategy to be implemented, e.g., maintenance, reparation, or demolition (Biondini & Frangopol 2016). In particular, the safety and serviceability assessment of existing Reinforced Concrete (RC) bridges is a challenge for practitioners and engineers.

In order to assess the performance of existing structures, it is important to highlight the differences with respect to the design of new systems. Structures are subjected to an evolution in time of the structural resistance R, e.g., due to aging and deterioration processes such as corrosion (Bertolini et al. 2013), as well as the modification of the originally assumed structural demand S, e.g., due to the increase in traffic volume (Dolcemascolo et al. 2015) and to the change of climatic conditions (Retief 2022). Moreover, the remaining service life t_{ref} associated with existing structures may be significantly different from the original design service life, usually equal to 50-100 years (ISO 2394 2015), and the cost of reparation or upgrading to provide certain safety performance is higher respect to the cost of applying the same measure in the design phase of a new structure (CEN/TS 17440 2020). For these reasons, the assessment of existing structures should be

DOI: 10.1201/9781003483755-463

performed with appropriate methodologies, different from the conservative approaches tailored for the design of new structures, considering the different type of uncertainties involved and avoiding possible expensive and unnecessary repair activities (JRC 2015).

In this context, the semi-probabilistic method is a practical approach to account for uncertainties in a simplified and implicit way, providing a tool to practitioners in case of common situations in terms of uncertainties and consequences. This approach is proposed by several national and international design standards, such as the Eurocodes (CEN EN1990 2002), generally for the design of new structures. Nevertheless, this methodology may be calibrated for the assessment of existing structures (ISO 2394 2015), and over the last decade, a significant effort has been provided along these research lines (Diamantidis & Bazzurro 2007; Steenbergen & Vrouwenvelder 2010; Caspeele et al. 2013; Sykora et al. 2017). Guidance for the exploitation of semi-probabilistic approaches tailored for the assessment of existing structures can be found in the *fib* Bulletin N°80 (2016). The proposed methodologies explicitly consider the residual service life, information from in situ and laboratory tests, measurements of variable actions, and reduced target reliability levels according to both economical and human safety criteria, focusing on standard RC structures.

This paper provides basic concepts of the semi-probabilistic approach and an overview of two methodologies for the assessment of existing RC structures. The methodology used for the calibration of the Partial Safety Factors (PSF) of an existing cable-stayed RC viaduct located in France is also discussed. Finally, the results of the safety assessment, exploiting tailored methodology for existing structures, are compared, in terms of different PSF calibration, with both the original design (CCTG 1983a; CCTG 1983b) and Eurocodes prescriptions for new structures (CEN EN1990 2002; CEN EN 1991. 2005; CEN EN1992-2. 2005). The benefits and drawbacks of the presented methodologies are discussed with emphasis on possible future developments.

2 BACKGROUND ON THE SEMI-PROBABILISTIC APPROACH

The semi-probabilistic approach, also addressed as the partial factor method, relies on the satisfaction of the safety criterion stating that the design resistance R_d must be larger than the design demand E_d:

$$R_d \geq E_d \tag{1}$$

The design values are generally determined through multiplication or division of the characteristic values, e.g., R_k and E_k, by the partial safety factors γ, which are calibrated to meet the prescribed reliability requirements, usually represented by the target reliability index β_t. For ordinary structures with a lifetime of 50 years, β_t is assumed equal to 3.8 (CEN EN1990 2002). This approach is proposed by several national and international design standards, such as the Eurocodes (CEN EN1990 2002) when dealing with common situations in terms of uncertainties and consequences.

In the following, a general description of the partial factor method is provided consistently to design of new structures. Eventually, two methodologies tailored for the assessment of existing structures, i.e., the Design Value Method (DVM) (ISO 2394 2015) and the Adjusted Partial Factor Method (APFM) (Caspeele & Taerwe 2012) are introduced.

2.1 *Partial factor method for design of new structures*

The satisfaction of the criterion, defined by Equation 1, should be checked for all the significant scenarios through the evaluation of R_d and E_d for the different structural components.

The design resistance R_d may be evaluated as function of different parameters:

$$R_d = R\left\{\eta_i \frac{X_{k,i}}{\gamma_{M,i}}; a_d\right\}, i \geq 1 \tag{2}$$

where η_i are conversion factors, exploited to relate possible test results to the actual behavior of the considered member, $X_{k,i}$ are the characteristic values of the materials property, the a_d is

the value for geometrical data, and $\gamma_{M,i}$ is the partial safety factor incorporating model $\gamma_{Rd,1}$, geometrical $\gamma_{Rd,2}$ and material $\gamma_{m,i}$ uncertainties. Indeed, the factor $\gamma_{M,i}$ may be defined as:

$$\gamma_{M,i} = \gamma_{Rd,1} \cdot \gamma_{Rd,2} \cdot \gamma_{m,i} \tag{3}$$

Particularly, assuming the material strength described by a lognormal distribution, $\gamma_{m,i}$ can be defined as follows:

$$\gamma_{m,i} = \frac{X_{k,i}}{X_{d,i}} = \frac{exp(-1.645 V_{Xi})}{exp(-\alpha_R \beta_t V_{Xi})} \tag{4}$$

where V_{Xi} is the coefficient of variation of the material property X_i and the 5% quantile is considered for the characteristic values.

The design demand E_d, considering the effect of external loadings, is generally evaluated as a function of different parameters:

$$E_d = E\left\{\gamma_{G,i} G_{k,i}; \gamma_P P; \gamma_{Q,1} Q_{k,1}; \gamma_{Q,j} \psi_{0,j} Q_{k,j}\right\} \; i \geq 1; j \geq 2 \tag{5}$$

where $G_{k,i}$, P, $Q_{k,1}$ and $Q_{k,j}$ are respectively the characteristic values of permanent actions, prestressing, dominant variable loading, and non-dominant variable loadings; $\psi_{k,j}$ are the combination factors related to the selected loading configuration; eventually, $\gamma_{G,i}$, γ_P and $\gamma_{Q,j}$ are respectively the partial safety factors accounting for model, e.g., $\gamma_{Ed,G}$ and $\gamma_{Ed,Q}$, and intrinsic aleatory uncertainties for permanent actions $\gamma_{g,i}$, prestressing γ_p and variable loadings $\gamma_{q,j}$. Specifically, the factors $\gamma_{G,i}$ and $\gamma_{Q,j}$ may be defined as follows:

$$\gamma_{G,i} = \gamma_{Ed,G} \cdot \gamma_{g,i} \tag{6a}$$

$$\gamma_{Q,i} = \gamma_{Ed,Q} \cdot \gamma_{q,i} \tag{6b}$$

Particularly, assuming the partial factor for permanent loading uncertainties $\gamma_{g,i}$ following a normal distribution, it can be defined as:

$$\gamma_{g,i} = \frac{G_{d,i}}{G_{k,i}} = \frac{1 - \alpha_E \beta_t V_{Gi}}{1 - k V_{Gi}} \tag{7}$$

where V_{Gi} is the coefficient of variation of the permanent loading and value $k = 0$ is usually assumed for the permanent actions.

The partial factor for variable loading uncertainties $\gamma_{q,i}$ may be computed as follows:

$$\gamma_{Q,i} = \frac{Q_{d,i}}{Q_{k,i}} = \frac{F^{-1}_{Q,i,tref}\left[\Phi(-\alpha_E \beta_t V_{Qi})\right]}{Q_{k,i}} \tag{8}$$

where $F^{-1}_{Q,i,tref}$ is the inverse of the distribution of the maxima over the period t_{ref}, Φ is the standard normal distribution and V_{Qi} is the coefficient of variation of the variable loading.

The calculation of the partial safety factor is related to the sensitivity factors for resistance α_R and demand α_E, which are considered equal to 0.8 and -0.7 for dominant variables and to 0.32 and -0.28 for non-dominant variables respectively (CEN EN1990 2002; ISO 2394 2015).

2.2 *Target reliability for existing structures*

The definition of a reliability target β_t represents a crucial step in the semi-probabilistic approach. Indeed, the definition of the fundamental elements of the code, e.g. partial safety factors γ and combination factors ψ, are strictly dependent on the assumed reliability target. In Baravalle & Köhler (2017) and Köhler et al. (2019), a discussion regarding the selection of β_t according to different strategies, addressing the benefits and drawbacks of each methodology, is presented.

For the sake of the analysed case study, the reliability target is defined according to the formulation proposed by the *fib* Bulletin n°80 (2016), which is based on both human safety and economic considerations for bridges. The reliability target is computed according to the

Consequence Class (CC), the remaining lifetime or reference period t_{ref}, and the length of the span that may collapse S, as reported in Table 1. The Consequence Classes are conceived considering increasing consequences, from CC1 to CC3, for structural collapse at economic, social and environmental levels (CEN EN1990 2002; *fib* 2016).

Table 1. Reliability target for existing bridges considering different consequence classes (*fib* 2016).

Consequence Class	Reliability Target β_t
CC1	1.8
CC2	Max(2.3; $\beta_{t,hs}$)
CC3	Max(2.8; $\beta_{t,hs}$)

The reliability target for human safety $\beta_{t,hs}$ is defined as:

$$\beta_{t,hs} = -\Phi^{-1}\left[\frac{2.75 \cdot 10^{-5} \cdot (0.09 \cdot S)^{-2} \cdot t_{ref}}{0.055}\right] \tag{9}$$

2.2 *Design value method*

The Design Value Method is formulated to compute partial safety factors based on the available information regarding the considered structure. Indeed, based on prior experience or test results it is possible to characterize the random variables connected to the resistance and the demand, reducing the uncertainty in the evaluation. Moreover, the partial safety factors should be defined considering the reliability target β_t related to the existing structure and the expected remaining lifetime t_{ref}.

2.3 *Adjusted partial factor method*

The Adjusted Partial Factor Method proposes the definition of the partial factors related to existing structure $\gamma_{X,exist}$ multiplying the partial factors related to new structures $\gamma_{X,new}$ using an adjustment parameter ω:

$$\gamma_{X,exist} = \omega\ \gamma_{X,new} \tag{10}$$

The adjustment parameter accounts for the expected remaining lifetime t_{ref} of the considered structure, the target reliability index β_t, and possible available information from tests, measurement, and prior and new knowledge.

3 CASE STUDY OF A CABLE-STAYED BRIDGE

3.1 *Description of the bridge*

The assessed existing viaduct is a prestressed cable-stayed bridge built in 1991 in the Isère district in France. The structure consists of a five-span bridge, supported by two abutments, three piers, and one pylon. The structural typology was selected in order to overpass a gap of approximately 300 m in correspondence with the Isère River. Considering an initial design lifetime of 100 years, the remaining lifetime of the bridge is equal to 67 years at the current date.

For the specific case study, the focus is dedicated to the deck of the viaduct. The deck is composed of two types of transversal sections: the box-girder section, having the central web 30 or 45 cm thick, and the plain section, located near the abutments, specifically the first 16 m from each end. The shape of the section is triangular, adopted at the time of the design for its aerodynamic, architectural, and structural characteristics, with 21.4 m width and 2.4 m height, as reported in Figure 1. The section is built in reinforced concrete and prestressed both longitudinally and transversely. The concrete is designed to have a characteristic compressive strength f_{ck} = 40 MPa, a characteristic tensile strength f_{tk} = 3 MPa, and Young modulus E_c = 37.6 GPa, as reported in the document detailing the hypothesis of the original design.

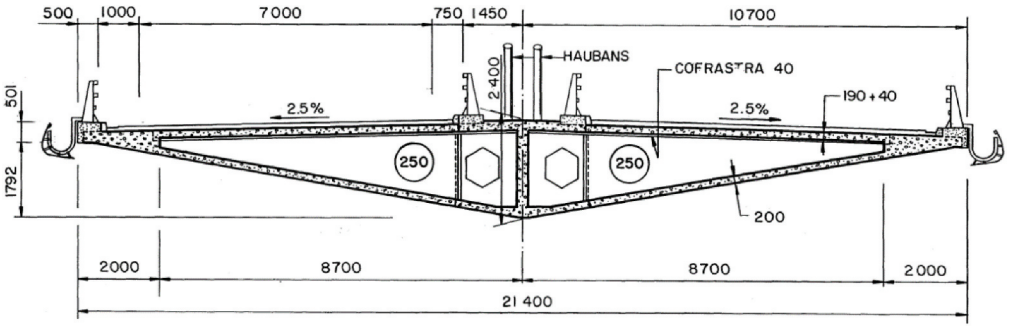

Figure 1. Cross-section of the bridge deck.

3.2 *Proposed methodology*

The methodology proposed for the assessment of the cable-stayed viaduct is based on three steps:

- Analysis of the original design;
- Assessment according to Eurocode;
- Assessment according to methodology for existing structures.

Firstly, the original design is studied in order to understand the assumption and the regulation exploited at the time of the conception of the viaduct. From the available documents, it is possible to retrieve the data about the materials and the loading considered for the bridge deck design, as well as the partial safety factors proposed by the regulations (CCTG 1983a; CCTG 1983b). The internal action and the stresses along the deck have been deduced from the original design report.

Secondly, the Eurocodes (CEN EN1990 2002; CEN EN 1991. 2005; CEN EN1992-2. 2005) are considered in order to assess the safety of the viaduct.

Eventually, the partial safety factors for the assessment of the viaduct are evaluated using two different methodologies which are tailored for the assessment of the existing structure, namely DVM, and APFM, and considering three different scenarios in terms of existing knowledge and uncertainties. Moreover, the *fib* Bulletin n°80 (2016) is exploited as guidance through the definition of the Reliability Target β_t and the partial safety factors γ.

The loadings considered for the analysis are the dead load G (self-weight and permanent actions) and the traffic load Q.

The methodology proposed for the assessment is developed considering that the Eurocodes are currently calibrated for the design of new structures instead of the assessment of existing ones, leading in some cases to over-conservative results in the case of the evaluation of existing systems.

3.3 *Reliability target and partial safety factors*

The reliability target β_t is computed according to Equation 4 and Table 1, assuming Consequence Class CC3, remaining lifetime t_{ref} = 67 years, and span length S = 148 m, which correspond to the most critical of the viaduct. Consequently, β_t = 3.55 is defined for the case study.

The sensitivity factors for resistance α_R and demand α_E are assumed to be constant and equal to the ones defined for new structures for the calculation of the partial factors according to DVM and APFM.

The values in terms of coefficient of variation V for model and geometrical uncertainties, both for the material and loading evaluations, are assumed compliant with the values suggested in *fib* Bulletin n°80 (2016). The partial factors for concrete and steel materials as well as the ones for permanent and traffic loading are evaluated according to the DVM and the APFM. Concerning the traffic load, a basic reference time of 15 years is selected.

Three different scenarios related to the existing knowledge of the structure are considered for the calculation:

1. Scenario 1 (reference scenario) is evaluated in agreement with the assumptions performed by Eurocodes (CEN EN 1991. 2005) concerning the probabilistic distributions although a different reliability target is considered.
2. Scenario 2 is conceived assuming a reduction in the uncertainties related to both loading and material and consequently reducing the coefficient of variation V considered in the reference scenario by 20%; this scenario may represent a situation in which testing and measurement led to a reduction of the uncertainties considered in the initial design.
3. Scenario 3 is conceptually opposite with respect to scenario 2, i.e., V is increased by 20% concerning considered in the reference scenario.

The results obtained in terms of partial factors (PF) are summarized in Table 2 for the DVM and Table 3 for the APFM. The results in terms of the partial safety factors for the three scenarios and considering the original design, the Eurocodes, the DVM, and the APFM are reported in Table 4.

Table 2. Partial factor according to different scenarios exploiting the DVM.

	Scenario 1		Scenario 2		Scenario 3		
	PF	V [-]	PF	V [-]	PF	V [-]	Probabilistic Distribution
γ_c [-]	1.20	0.15	1.15	0.12	1.24	0.18	Lognormal
γ_s [-]	1.06	0.05	1.05	0.04	1.07	0.06	Lognormal
γ_g [-]	1.25	0.1	1.20	0.08	1.30	0.12	Normal
γ_q [-]	1.08	0.075	1.04	0.06	1.14	0.09	Gumbel

$\gamma_{Rd,1,c} = 1.05$, $\gamma_{Rd,1,s} = 1.025$, $\gamma_{Rd,2} = 1.05$, $\gamma_{Ed,G} = 1.07$ and $\gamma_{Ed,Q} = 1.12$ (*fib* 2016).

Table 3. Partial factor according to different scenarios exploiting the APFM.

		Scenario 1		Scenario 2		Scenario 3		
	V' [-]	PF	V"/V' [-]	PF	V"/V' [-]	PF	V"/V' [-]	Probabilistic Distribution

γ_Q [-]	1.35	1.35	1.21	1.31	1.16	1.28	1.27	1.35

3.4 *Discussion*

Based on the results listed in Table 4, it is possible to observe that the partial safety factors considered in the regulations of the original design (CCTG 1983a; CCTG 1983b) and the ones related to Eurocodes (CEN EN1990 2002) are equivalent. The difference between the two regulations would be related to the possible discrepancies in the characteristic loading, which may lead to an increase in demand for structural verification.

The partial safety factors computed with the two methodologies tailored for the assessment of existing structure, i.e. DVM and APFM, are significantly different than the one used for the design of new structural systems. Firstly, considering scenario 1, the results obtained with the DVM and APFM are slightly lower than the exploited in the original design and suggested by the Eurocodes. For the examined case study, this is due to the definition of a reliability target for existing structures β_t = 3.55, which is lower than the one that should be guaranteed for a new structure. Secondly, considering scenario 2, the partial safety factors obtained by the two methodologies for existing structures are significantly lower than the results obtained for the reference scenario. This is related to the assumed reduction of the coefficient of variation, representing a case in which information on the material strength and loading would be available to properly characterize the uncertainty of the variables involved. Eventually, scenario 3 depicts an opposite case with respect to scenario 2, leading to higher partial safety factors obtained by exploiting the DVM and the APFM with respect to scenario 1, due to the increase of the uncertainties.

In general, for all the three investigated scenarios, the results obtained with APFM are more conservative than the ones retrieved exploiting the DVM considering concrete and traffic loading, due to the inherent approximation of the APFM. This aspect is highlighted in several studies, e.g., by Orcesi et al. (2021). Consequently, it is generally suggested to assess the existing structures firstly exploiting the APFM, secondly the DVM and eventually, if needed, to perform a full probabilistic verification. Furthermore, concerning the partial safety factors related to reinforcement and permanent loading, the results achieved with the two methodologies are almost equivalent.

The two approaches are both compatible with the Eurocode format, although it is observed that th DVM is more accurate in incorporating new information with respect to the APFM (Caspeele et al. 2013; Lara et al. 2021).Indeed, a recurrent Percent Deviation (PD) is observed between the results obtained with DVM and APFM for all the scenarios: the PD between the two methodologies is 8-10% for γ_C, 1% for γ_S, 1% for γ_G, and 6-10% for γ_Q. This is due to the differences in the incorporation of uncertainties between the two methodologies. Nevertheless, the obtained results highlight the importance of using appropriate methodology with proper treatment and characterization of uncertainties when dealing with the assessment of existing structures.

4 CONCLUSIONS AND FUTURE DEVELOPMENTS

Different semi-probabilistic methodologies for the assessment of existing structures have been investigated. Specifically, the definition of the partial safety factors for the evaluation of an existing reinforced concrete viaduct located in France has been firstly performed according to the original design of the structure, secondly exploiting the structural safety prescriptions according to the Eurocodes, and eventually considering two different methodologies tailored for existing structures, i.e., DVM and APFM. The results in terms of partial safety factor have been compared to the outcomes of the original design and the assessment performed according to Eurocodes, demonstrating the importance of the exploitation of appropriate methodologies for existing structures to avoid unnecessary and expensive interventions. Moreover, three different scenarios in terms of uncertainties have been defined and compared, showing the significance of a proper characterization of the structural capacity and demand.

Further investigation is necessary to properly characterize the actual information for the materials and loadings regarding the considered structure. Moreover, the same methodology may be applied for the calculation of the partial safety factors for other loadings affecting the structure, such as temperature and wind loading, and used for proper structural verification of the system. To this purpose, appropriate structural modeling at the sectional and structural level of the deck is fundamental to obtain reliable results. In addition, climate change effects are expected to significantly impact on both structural capacity and demand over time. The assumption of stationarity at the base of the current structural design codes is no longer well representing reality and this should be considered when designing or assessing the structural system. For this reason, the impact of climate change should be also integrated into the calibration of the partial safety framework. Specifically, concerning the investigated viaduct, the temperature gradient and the wind load are reported to have significant impact and their evolution due to climate change should be estimated and then incorporated into the safety assessment.

Seismic design of cable-stayed bridges in high intensity areas

B. Li, Z. Zeng, Y. He & Y. Xu
Tongji University, Shanghai, China

ABSTRACT: For the seismic design of large-span cable-stayed bridges built in high-intensity areas, it is necessary to consider the balance between internal force control and displacement control. The half-floating system is widely used in the longitudinal direction of cable-stayed bridges, which utilizes the displacement of the main beam for energy dissipation, but may result in significant relative displacement between the main beam, tower, and pier. In order to meet the needs of wind resistance, rigid constraints are often used in the transverse direction of the bridge to ensure the serviceability state, but it also leads to significant internal force response of the substructure under earthquake exaction. Therefore, it is necessary to design a reasonable damping system for large-span cable-stayed bridges to ensure the safety of the structure. This article conducts seismic calculations and seismic design for a half-floating cable-stayed bridge in a high intensity area. Hydraulic viscous dampers are used in the longitudinal direction to control the displacement of the main beam, and steel dampers are used in the transverse direction to provide energy dissipation. In this paper, the reasonable design parameters of the damping device are obtained through analysis, enabling the structure to achieve better seismic performance.

1 INTRODUCTION

The seismic response and seismic performance of large-span cable-stayed bridges are directly related to their structural systems. For longitudinal bridges, cable-stayed bridges generally adopt floating or semi floating systems (Hui, 2011), but under earthquake exaction, the displacement of pier-beams and tower-beams is relatively large, and the joints will be subjected to significant stress (Calvi et al., 2010). Therefore, it is necessary to install viscous dampers between towers and beams to control seismic displacement (Han et al., 2005).

For the transverse direction of the bridge, due to the consideration of static effects such as wind load, strong constraints need to be used at the connections between tower-beams and pier-beams to ensure that the structure has sufficient stiffness to meet wind resistance requirements (Colato et al., 2008). Currently, wind resistant bearings are commonly used to form a fixed constraint system for the transverse direction of tower-beams (Liang et al., 2013). However, rigid connections can transmit the inertia force of the upper structure to the lower structure, which may cause significant seismic internal force responses in towers, piers, foundations, etc. (Li et al., 2022) Therefore, for large-span cable-stayed bridges, it is necessary to adopt reasonable seismic systems and measures in both vertical and horizontal directions, while reducing engineering costs and ensuring structural safety (Shen et al., 2016).

This paper takes a semi floating cable-stayed bridge under construction as the research target. It is a double tower and double cable plane cable-stayed bridge with a standard width of 43m and a span arrangement of 50+85+300+85+50m, as shown in Figure 1. According to current national standards (Standardization Administration of China, 2015), the Bridge site belongs to a 7-degree zone, and the overall engineering geological conditions of the site area are ordinary, making it an area with relatively unfavorable seismic resistance. Due to the complex structure of the Bridge, existing seismic code (Ministry of Transport of the People's

DOI: 10.1201/9781003483755-464

Republic of China, 2020) is difficult to effectively guide its seismic design, it is necessary to conduct research on its seismic performance and design. The research results can not only guide the structural design of the bridge and solve the seismic safety issues of the project itself, but also provide guidance for the seismic design of similar bridge projects in the future.

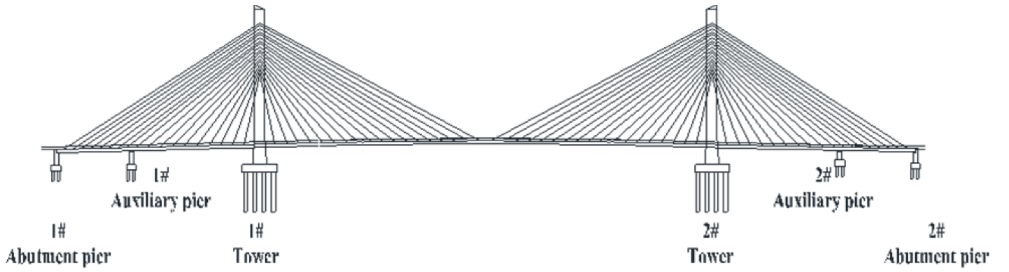

Figure 1. Schematic diagram of the bridge.

2 ANALYSIS MODEL

2.1 *Geometric model*

This paper uses the universal finite element calculation software SAP2000 for bridge modeling and dynamic analysis. This software has the characteristics of simple modeling, powerful calculation ability, and rich functionality, and has been widely used in the field of civil engineering. Based on the completed bridge state, dynamic characteristics and seismic response analysis are conducted. The main beam, bridge tower, and pier are all simulated using frame elements, while the stay cables are simulated using truss elements (rod end release bending moment and torque). The cable-stayed cable is connected to the main beam/bridge tower through master-slave constraints. The mass of the tower's pile cap and the pier's pile cap accumulates at the centroid, and the top, centroid, and bottom of the pile cap are connected by master-slave constraints. The secondary dead load and side span weight are added to the beam element in the form of linear mass and concentrated mass.

Figure 2. Basic model of dynamic calculation.

2.2 *Boundary conditions*

For conventional semi floating cable-stayed bridges, all bearings are longitudinally sliding. The bridge tower is equipped with lateral wind resistant bearings and vertical bearing bearings, the bridge pier is equipped with vertical bearing bearings, and one side is equipped with lateral limit devices, as shown in Table 1. In nonlinear time history analysis, consider the sliding friction effect of the support. In the Table 1, "0" represents freedom, "1" represents constraints, and the data in parentheses represents the constraint conditions for the support on the other side of the transverse direction.

In the seismic response analysis of bridges, the commonly used treatment method for pile foundations is to add springs in six directions at the bottom of the pile cap to simulate the

action of the pile foundation, and calculate the most unfavorable stress of a single pile using the static method (m method) based on the internal force at the bottom of the pile cap (Ministry of Transport of the People's Republic of China, 2019). The spring stiffness is determined based on the static equivalence principle according to the soil layer condition and pile arrangement, and the m value is determined from soil properties data. This treatment method is widely used in low pile cap pile foundations. This article uses a six-spring model to simulate the influence of each pile foundation group, and the data of the soil spring is shown in Table 2.

Table 1. Supporting conditions of the substructure.

Support	U_X	U_Y	U_Z	R_X	R_Y	R_Z
Tower	0	1	1	0	0	0
Auxiliary pier	0	1 (0)	1	0	0	0
Abutment pier	0	1 (0)	1	0	0	0

Table 2. Soil spring of pile foundation.

Location	X (kN/m)	Y (kN/m)	Z (kN/m)	YRX (kN/rad)	RX (kN-m/rad)	XRY (kN/rad)	RY (kN-m/rad)	RZ (kN-m/rad)
1# Tower	3.194 E7	3.194 E7	7.842 E7	1.22 E8	1.955 E10	-1.22 E8	4.565 E9	9.37 E9
1# Abutment pier	3.866 E6	4.269 E6	1.049 E7	1.597 E7	1.886 E8	-1.495 E7	1.28 E8	6.833 E7
1# Auxiliary pier	3.866 E6	3.866 E6	1.233 E7	1.496 E7	1.345 E8	-1.496 E7	1.345 E8	4.541 E7
2# Tower	3.29 E7	3.29 E7	7.557 E7	1.247 E8	1.888 E10	-1.247 E8	4.433 E9	9.649 E9
2# Abutment pier	4.063 E6	4.492 E6	1.26 E7	1.65 E7	2.089 E8	-1.543 E7	1.366 E8	7.114 E7
2# Auxiliary pier	4.061 E6	4.061 E6	1.208 E7	1.534 E7	1.34 E8	-1.534 E7	1.34 E8	4.687 E7

According to national code (Ministry of Transport of the People's Republic of China, 2020), seismic design should use the 7 seismic waves provided in the engineering site safety assessment report for calculation, and the calculation results should be taken as the average. The results of the safety assessment report indicate that the horizontal and vertical seismic

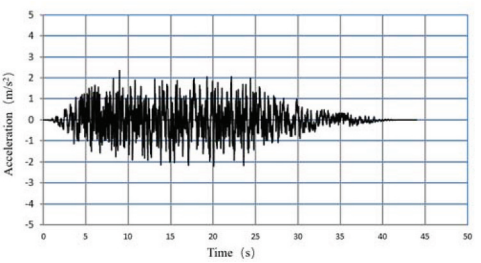

Figure 3. E1 Wave.

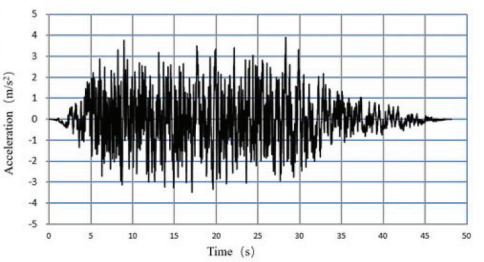

Figure 4. E2 Wave.

waves of the site are basically consistent. Figures 3 and 4 show the time history curves of one of the seismic waves under E1 and E2 working conditions.

3 DYNAMIC ANALYSIS

3.1 *Dynamic characteristics*

Analyzing and understanding the dynamic characteristics of bridge structures is the foundation for conducting seismic performance analysis (Zhang et al., 2018). Therefore, this report first uses the aforementioned basic dynamic calculation model to analyze the dynamic characteristics of the conventional system main bridge. Table 3 lists the first 10 vibration modes and corresponding periods of the Bridge.

Table 3. Structural dynamic characteristics.

Mode order	T (s)	Vibration mode description
1	4.6268	Main beam floats longitudinally and tower bends longitudinally
2	1.7212	Main beam 1st order vertical bending (symmetry)
3	1.3230	Main beam 1st order lateral bending (symmetry)
4	1.3041	Main beam 2nd order vertical bending (antisymmetry)
5	0.8648	Tower 1st reverse lateral bending
6	0.8597	Tower 2nd lateral bending
7	0.8440	Main beam 3rd order vertical bending (symmetry)
8	0.6680	Main beam 4th order vertical bending (antisymmetry)
9	0.6579	Main beam 5th order vertical bending (symmetry)
10	0.6512	Main beam 6th order vertical bending (antisymmetry)

In the pre-analysis, it was found that the bridge will experience lateral shear off of the support under the E1 exaction, resulting in changes in the dynamic characteristics of the bridge. The following are the dynamic characteristics of the bridge after considering the shear of the support, as shown in Table 4.

Table 4. Structural dynamic characteristics (support shear off).

Mode order	T (s)	Vibration mode description
1	4.6268	Main beam floats longitudinally and tower bends longitudinally
2	3.7129	Main beam 1st order lateral bending (symmetry)

3.2 *Nonlinear time history analysis*

This section conducts dynamic nonlinear time history analysis of longitudinal and transverse earthquakes and conducts seismic verification calculations on them. The aforementioned E1 and E2 seismic time histories are used as inputs, and the seismic input methods are longitudinal adds vertical and transverse adds vertical, respectively. Due to the earlier occurrence of lateral shear off of the support, the model after the support shear off was adopted for calculation.

Table 5. Locations need to be optimized.

Case	Location	Moment (kN·m)	Flexural capacity (kN·m)	Capacity-demand ratio
L+V	1# Tower-beam connection	1323274	1262000	0.95
	2# Tower-beam connection	1357435	1265000	0.93
T+V	1#Tower pile foundation	24350	15810	0.65
	2#Tower pile foundation	23801	16080	0.68

Table 5 lists the locations where the energy demand ratio is less than 1 in this seismic verification calculation. Under the longitudinal and vertical E2 earthquake exaction, the middle tower bottom section of the bridge tower does not meet the performance requirements, and its energy demand ratio is about 0.95. In addition, the bridge tower, pier, and pile foundation all meet the performance requirements. The longitudinal displacement of the main beam is approximately 800mm. Under the transverse and vertical E2 earthquake exaction, the pile foundation of the bridge tower does not meet the performance requirements, with an energy demand ratio of 0.6~0.7. In addition, the bridge tower structure itself, piers, and their pile foundations all meet the performance requirements. The relative displacement of the pier beam at the abutment pier is about 500mm, and the relative displacement of the pier beam at the auxiliary pier is about 300mm.

Therefore, the conventional structural system, whether longitudinal or transverse, cannot meet the seismic performance target under E2 earthquake exaction, and seismic reduction design needs to be carried out. The goal of a longitudinal seismic system is to reduce the longitudinal displacement of the main beam and the bending moment demand of the middle tower bottom section, while the goal of a transverse seismic system is to reduce the relative displacement between piers and beams and improve the stress on the bridge tower bottom pile foundation.

4 DAMPING DESIGN

4.1 *Longitudinal damping design*

For semi floating cable-stayed bridges, setting hydraulic viscous dampers longitudinally between the tower beams is an effective and commonly used method to control the longitudinal seismic displacement of the main beam. Therefore, this article considers setting hydraulic viscous dampers between both tower beams. The commonly used viscous dampers can be divided into linear and nonlinear viscous dampers in terms of mechanical properties. The nonlinear damping force can be represented by $F=CV^{\xi}$(Wang et al., 2005), C is the damping coefficient, and V is the relative velocity of the damper, ξ Is the speed index.

Install one viscous damper at each main tower, with the damper's velocity index ξ Taking 0.3, the damping coefficient C ranges from 1000kN/(m/s) $^{0.3}$ to 9000kN/(m/s) $^{0.3}$. By analyzing the nonlinear time-history response under E2 longitudinal earthquake exaction, the seismic responses of key parts of the structure with different parameters of viscous dampers are compared and analyzed to select appropriate damper parameters.

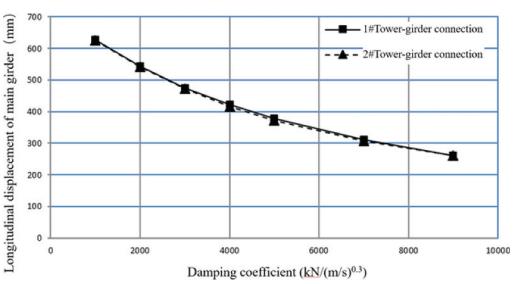

Figure 5. The relationship between relative displacement of tower-beam and damping coefficient.

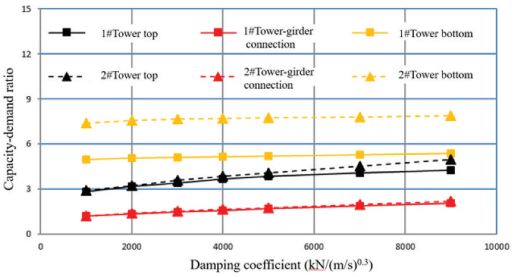

Figure 6. The relationship between capacity-demand ratio of key sections of towers and damping coefficient.

According to Figures 5 and 6, increasing the damping coefficient C can effectively reduce the longitudinal displacement of the main beam and improve the energy demand ratio of the key section of the bridge tower. To control the relative longitudinal displacement of the tower beam to be around 400mm, the damping coefficient C should be at least 4000kN/(m/s) $^{0.3}$. Therefore, a viscous damper with C=4000kN/(m/s) $^{0.3}$ can be selected for vibration reduction.

4.2 *Transverse damping design*

The aim of transverse seismic reduction design is to reduce the relative displacement of pier beams and control the lateral seismic internal force of bridge piers, usually using elastic-plastic steel dampers. The constitutive relationship of the steel damper is shown in Figure 7 (Wen et al., 2021). Yield strength, yield displacement, and post yield stiffness ratio are key design parameters of the steel damper. The preset yield displacement is 10mm, and the post yield stiffness ratio is 2%. The yield strength F_y is used as the control variable parameter (with a value range of 1000kN to 5000kN).

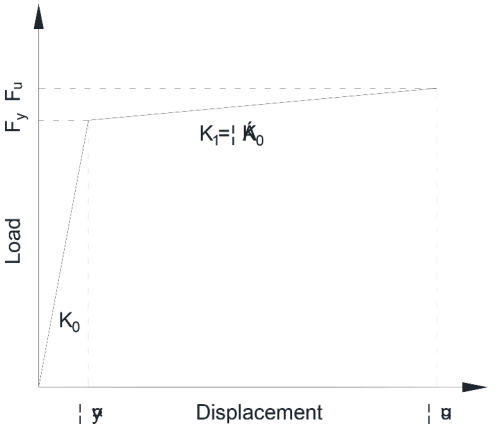

Figure 7. Constitutive relationship of steel dampers.

Figure 8 shows the relationship between the relative displacement of the pier beam and the yield force of the damper. As the yield force increases, the relative displacement of the pier beam first decreases rapidly and then tends to flatten out. However, an increase in the stiffness of the damper will also lead to an increase in the internal force distributed by the bridge pier. According to the relationship between the energy demand ratio at the pier bottom and the yield force of the damper shown in Figure 9, when the yield force increases, the energy demand ratio of the bridge pier will significantly decrease. Therefore, the yield force value of the damper is limited. Taking into account the displacement control effect and pier performance, a 2000kN damper can be applied.

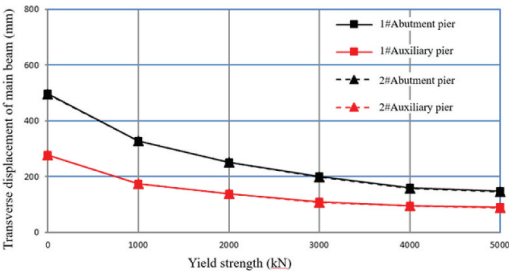

Figure 8. Relationship between relative displacement of pier-beam and yield strength.

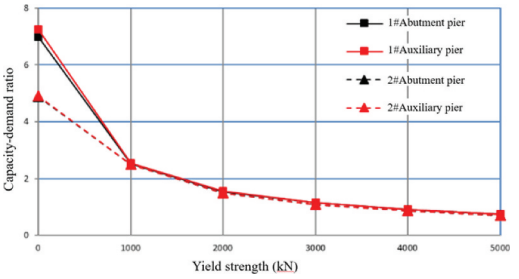

Figure 9. Relationship between capacity-demand ratio at pier bottom and yield strength.

Table 6. Capacity and demand after optimization using dampers.

Case	Location	Moment (kN·m)	Flexural capacity (kN·m)	Capacity-demand ratio
L+V	1# Tower-beam connection	798278	1266000	1.59
	2# Tower-beam connection	763613	1271000	1.66
T+V	1#Tower pile foundation	18810	20800	1.11
	2#Tower pile foundation	18681	20490	1.10

After using viscous dampers and steel dampers for seismic reduction design, the system can meet the corresponding seismic performance targets under both E1 and E2 earthquakes. Under longitudinal earthquake exaction, the longitudinal displacement of the main beam end is about 400mm. Under transverse earthquake exaction, the relative displacement of the pier beam at the abutment pier is about 250mm, and the relative displacement of the pier beam at the auxiliary pier is about 150mm.

Considering the uneven lateral displacement of the main beam, a transverse steel damper with a yield strength of 7000kN is installed at the bridge tower in this article. After optimization, the relative displacement of the tower beam at the bridge tower is about 180mm, the relative displacement of the pier beam at the abutment pier is 180mm, and the relative displacement of the pier beam at the auxiliary pier is 150mm.

5 CONCLUSIONS

This paper conducts dynamic analysis and seismic optimization design for a double tower cable-stayed bridge constructed in a high-intensity area. The longitudinal displacement of the main beam is controlled by hydraulic viscous dampers, and the lateral energy dissipation is provided by steel dampers. This article analyzes the reasonable design parameters of the

damping device to achieve good seismic performance of the structure. The main research conclusions are as follows:

1. Under the transverse E1 earthquake, the support will undergo lateral shear, resulting in changes in the dynamic characteristics of the bridge. Therefore, it is necessary to reset the support conditions when conducting seismic verification calculations.
2. Under the exaction of earthquakes, semi floating cable-stayed bridges generate significant relative displacement between towers and beams in the longitudinal direction. Viscous dampers can effectively optimize the relative displacement of tower beams and improve the seismic performance of bridge towers, and the higher the damping coefficient, the better the effect of viscous dampers.
3. For the purpose of wind resistance, steel dampers are used horizontally for displacement control. Increasing the yield strength of the steel damper can better control the relative displacement of the pier beam, but excessive stiffness will lead to an increase in the internal force allocated to the bridge pier, weakening the seismic resistance of the pier bottom section.
4. Installing a transverse steel damper at the bridge tower can make the lateral displacement of the main beam more uniform.

A coupled thermal-mechanical-phase field model for concrete under fire

Kunting Miao, Zichao Pan, Xurui Fang & Airong Chen
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: Motivated by the fact that fire can induce structural and irreversible damage to concrete structures, this paper aims to investigate the thermal response of concrete structures when exposed to fire. A coupled thermal-mechanical-phase field model is developed to reveal the thermal field and thermal induced cracking process induced by fire condition. The coupling of thermal field and mechanical-phase field is achieved by phase field-dependent thermal conductivity, as well as temperature-dependent material properties and thermal strain caused by thermal expansion. Several numerical examples are presented to demonstrate the effect of crack on thermal conduction and thermal induced crack due to thermal expansion. The developed model provides a valuable tool for analyzing the thermal behavior of concrete under fire conditions.

1 INTRODUCTION

Fire hazard is a major threat to engineering structures such as bridges and buildings, as it can severely degrade their mechanical properties and durability (Lo Monte et al., 2019). Concrete is a common choice for load-bearing structures in engineering structures due to its high strength, stiffness and durability. However, prolonged fire exposure can significantly deteriorate the mechanical properties of concrete, reducing the structural bearing capacity and ductility. Therefore, it is crucial to study the damage distribution and evolution of concrete members under fire hazard.

Concrete is a composite material that consists of different components. Each component has a different thermal expansion coefficient, which means that they expand at different rates when exposed to fire. This causes thermal stress in the concrete, especially during fire hazard. Thermal induced cracks may occur in the concrete if the thermal stress exceeds the concrete strength. Scholars have conducted sufficient experimental research on the spalling process and mechanism of concrete in the past decades (Mindeguia et al., 2014, Kalifa et al., 2001). Experimental research is an effective method to investigate the thermal response of concrete structures, but it still has several limitations, which prompted scholars to explore numerical simulation as an alternative approach to study the thermal behaviour of concrete.

Numerical research methods of concrete fracture behaviour can be classified into two main categories: discontinuous numerical methods and continuous numerical methods. Discontinuous methods include discrete element method (Peng et al., 2020, Jiao et al., 2021), extended finite element method (Lou et al., 2023, Mora and Niffenegger, 2022), discontinuous deformation analysis method (Jiao et al., 2015, Li et al., 2022), etc. Despite the wide application of the discontinuous numerical methods in fracture modelling of various materials, they still face some challenges, such as the high sensitivity of the results to the initial configuration and the need for additional fracture criteria to simulate the fracture process. A continuous numerical method based on continuum damage mechanics is the alternative to the discontinuous numerical method. This method uses a damage variable to model the entire process of crack initiation and propagation (Fu et al., 2020, Tang and Tang, 2015, Zhao et al., 2017). However,

DOI: 10.1201/9781003483755-465

these theoretical models lack key parameters that describe the damage smeared scale, resulting in strong sensitivity to mesh size and division direction.

Researchers have explored new alternatives to overcome the limitations of the discontinuous and continuous numerical methods mentioned above. One of them is the phase field fracture model. Compared with other numerical methods, the phase field fracture model does not require any additional fracture criteria, as the fracture development follows the principle of minimum total system energy. The phase field fracture model is a multi-field coupling model, which can easily incorporate other multi-physical fields. Therefore, the phase field fracture model has been widely applied to the coupled thermo-mechanical problem (Wu et al., 2022, Peng et al., 2023, Zhou et al., 2022, Cheng et al., 2022b, Cheng et al., 2022a). The phase-field fracture model has been shown to be an effective tool for simulating thermal fracture in concrete, but some issues remain unresolved: Cracking can create gaps between concrete pieces, which reduce the thermal conductivity. However, some existing studies ignore the degradation of thermal conductivity, and some use the same degradation function in phase field to model the degradation of thermal conductivity, which lacks physical significance.

This study investigates the thermal induced crack phenomenon of concrete under fire conditions using a phase field fracture model. The manuscript is organized as follows: Section 2 presents the theoretical framework of the phase field model for concrete. Section 3 describes the developed coupled thermal-mechanical-phase field model and examines the effect of crack on thermal conductivity and the effect of thermal expansion on thermal behaviour of concrete under fire. Section 4 concludes the study and discusses the main findings.

2 PHASE FIELD MODEL

2.1 *Theory and governing equations of phase field model*

The main ideal of phase field model is to use a phase field variable d to regularize the sharp crack into a finite width dispersed crack. Figure 1 illustrates an arbitrary solid Ω with ∂ Ω and Γ representing the external boundary of solid and internal crack boundaries, respectively. Dirichlet-type and Neumann-type boundary conditions $\partial\Omega_u$ and $\partial\Omega_f$ denotes displacement and force on the boundaries of solid, respectively. The phase field variable d ranges from [0,1], and the values $d = 0$ and $d = 1$ indicate the intact and fully damaged states, respectively.

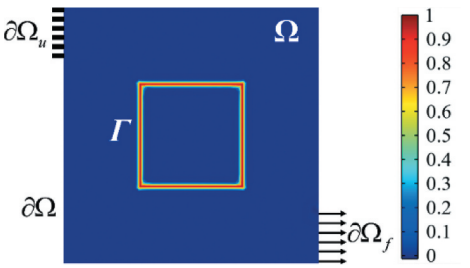

Figure 1. Diagram of dispersion crack in phase field model.

Francfort and Marigo introduced the fracture energy into the total potential energy and proposed the F-M variational principle (Francfort and Marigo, 1998). In the F-M variational principle, the total potential energy is composed of elastic energy, fracture energy and external energy:

$$W = \int_{\Omega} \Psi(\varepsilon, d)\mathrm{d}V + \int_{\Omega} G_c\gamma(d, \nabla d)\mathrm{d}V - \int_{\Omega} b \cdot u dV - \int_{\partial\Omega} f \cdot u\mathrm{d}S \tag{1}$$

where $\boldsymbol{b}$ is body force on the body Ω; $\boldsymbol{f}$ is traction on the boundary ∂ Ω_f; G_c is the critical energy release rate; $\gamma(d, \Delta d)$ is the crack surface density; $\Psi(\varepsilon, d)$ is the modified strain energy density and can be expressed as:

$$\Psi(\varepsilon, d) = \omega(d)\Psi_0(\varepsilon) \tag{2}$$

where $\omega(d)$ is a degradation function; $\Psi_0(\varepsilon)$ is the strain energy density for undamaged solids.

Another characteristic of the phase field method is that fracture evolution is a process that minimizes the total potential energy of the solid. Based on F-M variational principle, the governing equation of the phase field model can be derived by executing the first variation of the total potential energy functional W for the displacement field and the phase field, and make it equal to 0. Then the governing equations of phase field model are obtained:

$$\begin{cases} \nabla \cdot [\omega(d)\sigma] + b = 0 & \text{in } \Omega \\ -G_c \nabla \cdot \left(\frac{\partial \gamma(d,\nabla d)}{\partial \nabla d}\right) + G_c \frac{\partial \gamma(d,\nabla d)}{\partial d} + \frac{\partial [\omega(d)\Psi_0(\varepsilon)]}{\partial d} = 0 & \text{in } \Omega \end{cases} \tag{3}$$

The boundary condition can be expressed as:

$$\begin{cases} w(d)\sigma \cdot n - f = 0 & \text{on } \Omega_f \\ \frac{\partial \gamma(d,\nabla d)}{\partial \nabla d} \cdot n = 0 & \text{on } \Omega \end{cases} \tag{4}$$

To ensure the irreversibility of cracking, a historical variable $\boldsymbol{H}$ was introduced to replace $\Psi_0(\varepsilon)$ in the Eq.(3) (Miehe et al., 2010):

$$H = \max\{\Psi_0(\varepsilon(x, \tau))\} \tag{5}$$

2.2 *Details of functions in phase field model*

Depending on the degradation mode of the energy density function, phase field models can be classified into three types: isotropic, anisotropic, and hybrid type. The hybrid phase field model integrates the benefits of both isotropic and anisotropic models. It only decomposes the strain energy in the driving force of the phase field evolution to prevent compression fracture, and keeps the overall degradation of the nominal stress in the governing equation to ensure the linearity of the equation (Ambati et al., 2014). Therefore, this study adopts the phase field model proposed by Wu (Wu, 2017), which can achieve high accuracy and high efficiency in simulation.

The degradation function is related to the softening law of the material. The softening curve obtained in the previous research (Cornelissen et al., 1986) is widely used in concrete structures. Therefore, the degenerate function can be expressed as (Wu, 2017):

$$\begin{cases} \omega(d) = \frac{(1-d)^2}{(1-d)^2 + a_1 d(1 + a_2 d + a_2 a_3 d^2)} \\ a_1 = \frac{4}{\pi l_0}\frac{EG_c}{f_t^2}, a_2 = 1.3868, a_3 = 0.6567 \end{cases} \tag{6}$$

where E and f_t is the elasticity modulus and failure strength.

The crack surface density can be expressed as:

$$\gamma(d, \nabla d) = \frac{1}{\pi}\left(\frac{2d - d^2}{l_0} + l_0 |\nabla d|^2\right) \tag{7}$$

The historical variable can be expressed as:

$$H = \max\left(\frac{f_t^2}{2E_0}, \underset{t\in[0,T]}{max}\frac{\overline{\sigma_1}^2}{2E_0}\right) \tag{8}$$

where $\overline{\sigma_1}$ is the major principal value.

2.3 *Benchmark numerical example*

This section further explores the applicability of phase field models to concrete damage analysis by numerically simulating a mixed-mode problem L-shaped panel test (Wu, 2017).

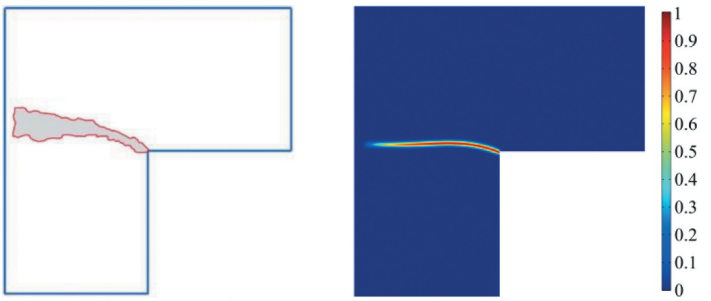

Figure 2(a) shows the geometry, loading, and boundary conditions. The Young's modulus, Poisson ratio, tensile strength and the specific fracture energy in this example are $E_0 = 2.585 \times 104$ MPa, $v_0 = 0.18$, $f_t = 2.70$ MPa and $G_c = 0.09$ N/mm. Figure 2(b) shows the meshes applied in this numerical example. To improve the computational efficiency, a finer mesh size of 0.5 mm is used only on the crack evolution path, while the remaining regions use a mesh size of 25 mm. The length scale $l_0 = 5$ mm is used in this example.

(a) Geometry, loading and boundary condition (unit: mm) (b) Finite element meshes.

Figure 2. L-shaped panel numerical example.

Figure 3 compares the crack patterns simulated by the phase field model and observed in the experiment (Winkler, 2001). The phase field model captures the experimental crack patterns accurately. Figure 4 presents the load-displacement curves from the phase field models and the experiment. The load-displacement curves obtained by the phase field model reproduces the experimental curves closely. The consistent agreement between the simulation and the experiment in both crack patterns and load-displacement curves validates the hybrid phase field model for concrete damage analysis and confirms the feasibility of using COMSOL software.

3 COUPLED THERMAL-MECHANICAL-PHASE FIELD MODEL

In the proposed coupled thermal-mechanical-phase field model, we couple the thermal, mechanical, and phase fields using the thermal strain from thermal expansion, the damage-dependent thermal conductivity, and the temperature-dependent material properties.

3.1 *Coupling mechanism of thermal and mechanical field*

High temperature degrades the mechanical properties of concrete materials. We consider the following temperature-related degradation law to calculate elasticity modulus (Pearce et al., 2004) tensile strength (Pearce et al., 2004) and critical energy release rate (Cheng et al., 2022b):

$$E = \left(1 - 0.1\frac{T-20}{100}\right)^2 E_0, 20^\circ C \leq T \leq 1020^\circ C \tag{9}$$

$$f_t = \left(1 - 0.016\frac{T-20}{100}\right) f_{t0}, 20^\circ C \leq T \leq 800^\circ \tag{10}$$

$$G_c = G_{c0} e^{15.4\left(\frac{1}{T}-\frac{1}{20}\right)} \tag{11}$$

The deformation of materials which are influenced by the temperature field depends on both mechanical load and thermal expansion. To account for the coupling of thermal and mechanical fields, the effect of thermal strain must be considered. Thus, the total strain is the sum of elastic strain ε^e and thermal strain ε^{th}:

$$\varepsilon = \varepsilon^e + \varepsilon^{th} \tag{12}$$

The thermal strain can be expressed as follows:

$$\varepsilon^{th} = \alpha(T - T_0)I \tag{13}$$

where T_0 is the initial temperature; α is the thermal expansion coefficient; $\boldsymbol{I}$ is a unit tensor. Then the constitutive model for the displacement field can be rewrite as:

$$\sigma = \left(1 - 0.1\frac{T-20}{100}\right)^2 E_0 : \left(\varepsilon - \varepsilon^{th}\right) \tag{14}$$

where $\boldsymbol{E}_0$ is the elasticity tensor of sound material.

3.2 *Coupling mechanism of thermal and phase field*

Thermal conduction process in solid can be expressed by the following equation:

$$k\nabla \cdot (\nabla T) - \rho C_p \frac{\partial T}{\partial t} + q_m = 0 \tag{15}$$

where k is the thermal conductivity; ρ is the density; C_p is the specific heat; q_m is the heat generation by solid per unit volume.

Note that the presence of cracks reduces the thermal conductivity k of concrete. Previous studies have often adopted the degradation formula to model this process. We follow and develop the previous work (Zhou et al., 2022) and divide the thermal conductivity of concrete into three stages: the intact state k_0, the fully-fractured state k_f and the transition stage k_{rf}, as illustrated in Figure 5.

The value of k_0 depend on the material. For the thermal conductivity in the fully-fractured state, we assume that the cracks are filled with air, so the value of k_f depends on the thermal conductivity of air, which can be expressed as (Nguyen et al., 2019):

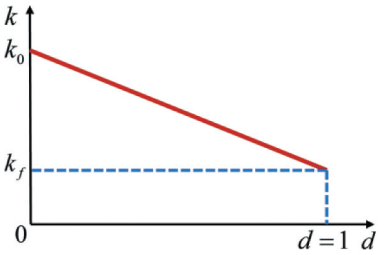

Figure 5. Damage-dependent thermal conductivity.

$$k_f = A_1 T^3 + A_2 T^2 + A_3 T + A_4 \tag{16}$$

where $A_1 = 1.5207 \times 10^{-11}$, $A_2 = -4.8574 \times 10^{-8}$, $A_3 = 1.0184 \times 10^{-4}$, $A_4 = -3.9333 \times 10^{-4}$.

We adopt the linear interpolation from the k_0 and k_f to achieve k, which can be expressed as:

$$k = (k_f - k_0)d + k_0 \tag{17}$$

3.3 *Numerical example*

3.3.1 *Effect of crack on thermal conduction*

We add a heating process to the benchmark numerical example in Section 2.3 to demonstrate the effect of crack on thermal conduction. The geometric properties and material properties remain the same as before. The heating process is induced by a specific temperature (900 □) at the bottom and right surfaces of the sample, as shown in Figure 6. We use the following parameters in this example: thermal conductivity of intact material k_0 = 1.2 W/(m*K), specific heat capacity is 500 J/(kg*K), density is 2600 kg/m^3 and the length scale l_0 = 5 mm.

Figure 7 shows the temperature distribution in concrete at different times. The temperature distribution is uniform in the region between the crack and the two temperature boundaries with heat conduction along the temperature gradient. The temperature discontinuity is evident in other regions, indicating that the crack plays an insulating role in heat conduction

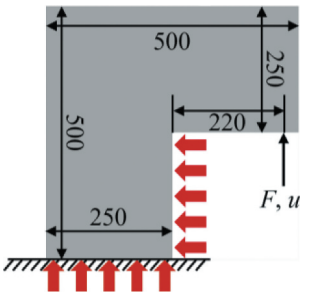

Figure 6. L-shaped panel under high temperature condition.

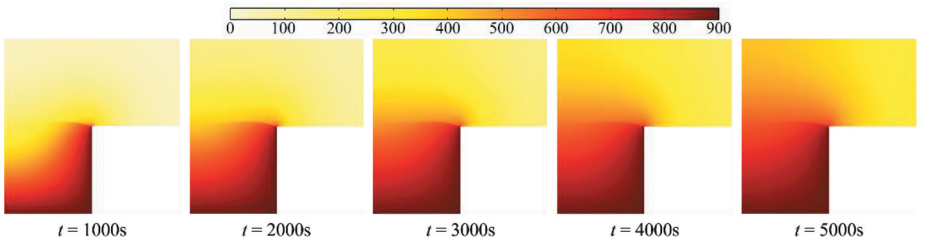

Figure 7. Temperature distribution at different times (unit: °C).

3.3.2 *Thermal induced crack*

This section examines the thermal-induced crack evolution in an arc example under thermal load. Figure 8 shows the geometry and boundary condition. We use the same material properties as in (Zhou et al., 2022). The top boundary temperature is fixed at 20 °C, while the bottom boundary temperature decreases linearly from 20 °C to -80 °C at a rate of 1 °C/s.

Figure 9 displays the crack patterns of the arc example under thermal load at different times. The bottom of arc example contracts due to the temperature drop, resulting in tensile stress. When the stress exceeds the specimen's strength, cracks start to initiate, primarily at the arch's ends. As the cooling continues, more cracks emerge in the arch's center, and they progressively deepen and expand, creating a complex crack pattern. Our simulation results demonstrate that the proposed coupled model can accurately predict the crack initiation and propagation under thermal load, and it agrees well with other numerical methods (Zhou et al., 2022, Badnava et al., 2018).

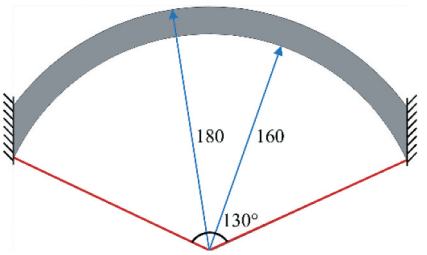

Figure 8. Geometry and boundary condition of arc example under thermal load (unit: mm).

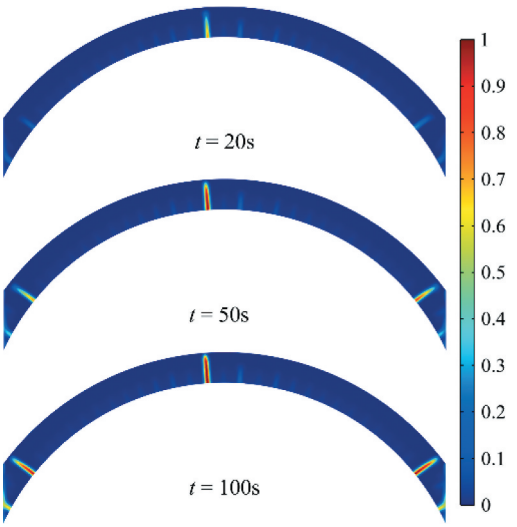

Figure 9. Crack patterns of arc examples under thermal load at different times.

4 CONCLUSION

This study presented a coupled thermal-mechanical-phase field model to simulate the thermal induced crack phenomenon of concrete. In the unified phase field framework, the coupling between the multiple fields is realized through the phase field-dependent thermal conductivity, the temperature-dependent material properties and the thermal strain caused by thermal expansion. The numerical results indicated that the crack has a significant influence on the thermal conduction and the thermal expansion can induce crack initiation and propagation.

The model can capture the complex interactions between thermal and mechanical fields. The model can be further extended to incorporate other factors such as moisture transport and chemical reactions.

ABSTRACT: Major fire events in tunnels have shown severe consequences in their structural performance, as reported in several incidents in the last decades. Particularly, due to the enclosure geometry of tunnels, intense thermal loading may develop in comparison to typical fires in buildings, which may result in more damage. Even though tunnel linings are an important component in transportation infrastructure, the understanding of their behaviour under high temperatures is limited. This paper aims to study the thermo-mechanical response of tunnels subjected to fire using nonlinear finite element analysis (NLFEA). For this purpose, recent experimental tests of large-scale reinforced concrete tunnels with and without fire protection are simulated. Different modelling approaches and strategies are discussed, and a detailed description of the constitutive model employed is presented. The results obtained in the simulations indicated that the numerical analysis can be used to investigate the thermo-mechanical behaviour of concrete structures.

1 INTRODUCTION

Traditionally, reinforced concrete (RC) structures have been regarded as good in terms of fire resistance due to the non-combustibility and low conductivity of concrete. For that reason, in many cases, RC elements do not require any additional fire protection. However, in the case of tunnels, due to the enclosure geometry, more intense fire scenarios can develop in comparison to typical fires in buildings, leading to more severe damage. In the past, several incidents related to fire events in tunnels have occurred (Lin and Chien, 2021). Even though tunnel linings are an important component in transportation infrastructure, the understanding of their behaviour under high temperatures is limited. The research on tunnels under fire has focused more on fire dynamics, smoke simulations, and evacuation strategies, and less research has been done in the areas of structural risk assessment, damage quantification, and robustness (Hua *et al.*, 2021a). As pointed out by Gernay *et al.* (2023), there are no general guidelines regarding the structural modelling of tunnels exposed to fire. In practice, a model representing the section with a 2D beam finite element is probably the most commonly used approach.

This work investigates the thermo-mechanical response of tunnels subjected to fire using nonlinear finite element analysis (NLFEA). This investigation aims to gain additional insight into the structural behaviour of tunnels in the case of a fire using advanced calculation methods. A detailed description of the constitutive model employed is presented in the

DOI: 10.1201/9781003483755-466

following sections. Then, different modelling approaches and strategies are discussed and evaluated for the representation of fire scenarios, including (i) 2D model representation (plane strain and plane stress assumptions), (ii) influence of protective coating and (iii) representation of concrete spalling. The assessment of these parameters is conducted through the simulation of recent experimental tests based on the Hong Kong-Zhuhai-Macao Bridge (HZMB) project conducted by Huaqiao University. The experimental and numerical results are compared in terms of temperature distribution and crack patterns. Finally, key outcomes and conclusions are derived about the capabilities and limitations of the simulations and the feasibility of using finite element-based analyses in the design and post-fire evaluations of tunnels.

2 CONSTITUTIVE MODEL

2.1 *Concrete model*

The concrete nonlinear behaviour is represented by the total strain fixed crack model (Feenstra *et al.*, 1998) implemented in DIANA (release 10.5). Additional constitutive relationships are used to account for the material degradation due to high temperatures based on NEN-EN -1992-1-2:2005. The tension softening is described using the relationship proposed by Hordijk (1991), which assumed that the concrete tensile behaviour depends on the tensile strength (f_{ct}) and fracture energy (G_F). The concrete behaviour in compression is based on the fracture energy-based model proposed by Feenstra (1993). This model describes the compressive stresses by a parabolic stress diagram followed by a softening branch. Similarly to the tensile behaviour, the maximum compressive strain is scaled according to a fracture energy and a crushing-band width to reduce mesh size sensitivity. In addition, the model proposed by Vecchio and Selby (1991) is considered to represent the increment in strength and ductility due to confinement. Furthermore, the influence of large strains perpendicular to the compressive direction is included using the formulation proposed by Vecchio and Collins (1993), with a minimum reduction limit of 0.4 (Hendriks and Roosen, 2022). The concrete shear behaviour is represented using the so-called damaged-based shear retention factor proposed by DeJong *et al.* (2008).

For the thermal analysis, the thermal conductivity and the volumetric specific heat are used to model the concrete heat transfer. These properties are considered to be temperature-dependent using the relations recommended in NEN-EN-1992-1-2:2005. The thermal concrete expansion is defined according to the thermal expansion coefficient. The transient creep strain (also known as load-induced thermal strain, LITS) is modelled implicitly following the approach described in NEN-EN-1992- 1-2:2005.

2.2 *Reinforcing steel model*

The reinforcing steel constitutive model assumes an elastic-perfectly plastic behaviour. Similar to concrete properties, degradation as a function of the temperature is adopted. For this purpose, the modulus of elasticity and the yield strength are assumed to depend on temperature according to NEN-EN-1992-1-2:2005. It is noteworthy to mention that since the rebar is embedded and its area is relatively small compared to concrete, the steel rebar is not explicitly considered in the thermal analysis. It is assumed that the temperature is uniform within the steel area and equal to the temperature of the surrounding concrete.

Preliminary simulations showed an unrealistic full recovery of the steel mechanical properties during the cooling phase (i.e. the period when the temperature decreases to ambient temperature), even after reaching temperatures higher than 1000ºC. To address this issue, the original constitutive model in DIANA was adapted using a user-supplied subroutine written in Fortran. The subroutine restricted the yield strength and the Young modulus values based on the maximum temperature reached during the heating phase.

3 CASE STUDY: TUNNEL TESTS BY HUAQIAO UNIVERSITY

The large-scale fire tests on tunnel segments performed by Dong *et al.* (2023) and Duan *et al.* (2021) are used as reference in this study to compare and validate the modelling choices for the fire resistance assessment in tunnels. The experimental specimens represent a reduced scale (1:5) model of an immersed tunnel segment of the Hong Kong-Zhuhai-Macao Bridge (HZMB) project. The cross-section of the scale tunnel is shown in Figure 1. The total length of the tested tunnel segment was 5.8 m, and the overall width and height were 7.59 m and 2.28 m, respectively.

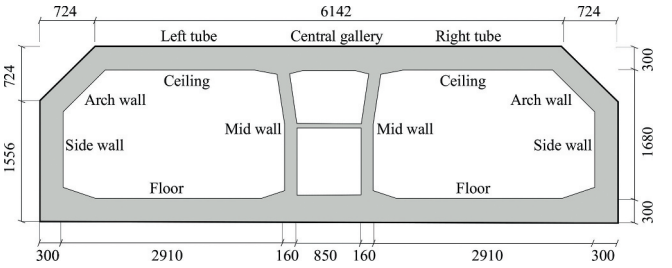

Figure 1. Cross-section of the scale tunnel, measures in mm. Adapted from Dong et al. (2023).

Before applying the thermal loading, vertical and horizontal loads were applied to the tunnel segments to represent the service load from the sediment and seawater. The total vertical load applied on the ceiling was 2427.4 kN, and the horizontal load on both sides of the walls of the tunnel was 437.2 kN. The test setup is shown in Figure 2a. During the fire test, the mechanical load was maintained constant during the heating and cooling phases. The fire scenario in the experiment conducted by Dong *et al.* (2023) considered a severe situation in which both tubes of the tunnel were exposed to fire at the same time. In the tunnel segment tested by Duan *et al.* (2021) the fire was applied in only one tube and a 30 mm sprayed coating was used.

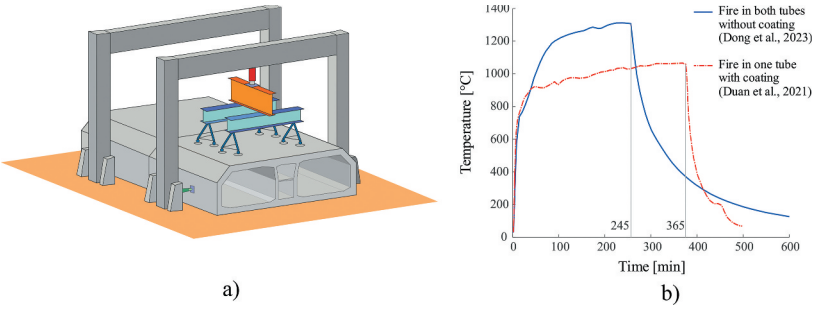

Figure 2. A) Setup during testing; b) fire scenarios for the tunnel segments tested by Dong et al. (2023) and Duan et al. (2021).

At the end of both tests, the authors reported that the capacity of the tunnel segments was sufficient to withstand the applied thermal load (during the heating and cooling phases). Despite that, the damage on the heated and unheated side of the tunnel was severe for the fire scenario on both tubes. Dong *et al.* (2023) reported that almost 100% of the exposed fire surface was affected by spalling. In the test conducted by Duan *et al.* (2021), the fire-resistive

Table 1. Fire scenarios considered in the tunnel segments.

Reference	Number of tubes exposed to fire	Fire protection	Maximum temperature	Spalling
Dong *et al.* (2023)	2	No	1344.8°C	Yes
Duan *et al.* (2021)	1	Yes	1113.7°C	No

coating performed well, and concrete spalling did not occur. However, concrete cracking was observed in the unheated side of the tunnel and even in the mid gallery and the left tube that were not exposed to fire at all. The fire scenarios are summarised in Table 1 and the recorded average furnace temperatures are shown in Figure 2b.

4 NUMERICAL MODELS FOR THERMO-MECHANICAL ANALYSIS

4.1 *Numerical models considerations*

In this work, a 2D approach was used to simulate the tunnel tests conducted by Huaqiao University. In the following sections, the fire scenarios are designated with the letters A and B, as given in Table 2. Two different modelling assumptions were compared for each tunnel test, namely, plane stress and plane strain idealisations. The former approach implies that the out-of-plane stresses are not accounted for in the simulation. In the case of the plane-strain assumption, the out-of-plane displacement (and the total strain in that direction) is considered null. It should be noted that both 2D approaches are approximations to represent the tested tunnel segments behaviour. A 2D plane-stress idealisation can be regarded as conservative since it ignores any possibility of force redistribution in the longitudinal direction of the tunnel (Gernay *et al.*, 2023). On the other hand, a 2D plane-strain idealisation can be regarded as a more reasonable alternative for the modelling of a real tunnel with several segments in the longitudinal direction. Yet, the plane strain assumption can also be regarded as conservative since it considers a uniform fire scenario along the tunnel full-length. As indicated in Table 2, additional simulations were also carried out to investigate the influence of spalling effects on the fire scenario in both tubes, leading to six simulations in total.

Table 2. Numerical models conducted for each fire scenario.

Fire scenario	Numerical model
Scenario A: fire in one tube with coating tested by Duan *et al.* (2021)	Plane strain (without spalling) Plane stress (without spalling)
Scenario B: fire in both tubes without coating tested by Dong *et al.* (2023)	Plane strain without spalling Plane stress without spalling Plane strain with spalling Plane stress with spalling

The tunnel cross-section is discretized using quadrilateral elements. For the staggered analysis, first-order isoparametric quadrilateral elements (denoted as Q4HT) are used during the thermal transfer calculations. In the subsequent mechanical analysis, these elements are automatically upgraded to second-order isoparametric elements denoted as CQ16M (for plane stress) and CQ16E (for plane strain). An average mesh size of 30 mm was adopted in the analyses (refer to Figure 3). This value was established with the aim of obtaining a sufficiently

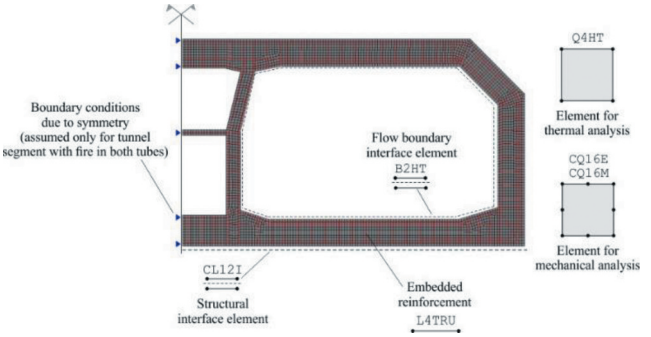

Figure 3. Typical mesh used for the numerical simulations for scenario B.

accurate nonlinear temperature distribution on the concrete cover. In the thermal analysis, the heat transfer is considered by radiation and convection mechanisms using boundary interface elements (B2HT). The furnace temperatures recorded during the test were used as an input in the thermal analyses. The interaction between the tunnel and the ground was modelled with interface elements (CL12I) with no support in tension and a high compression stiffness (75 MN/m^3), as assumed in Guo et al. (2016). No additional soil settlements or concrete primary creep strains were included in the simulation. The concrete nonlinear behaviour is represented using the constitutive model described in Section 2.

4.2 *Spalling simulation*

The loss of concrete cover due to spalling has two effects: (i) it reduces the stiffness of the member due to the reduction in the cross-section and mechanical properties, and (ii) in case of severe spalling, the reinforcement is directly exposed to fire and the heat flow inside the structure also increases. In this study, the spalling is simulated by considering a modification in the concrete thermal properties of the elements located at the exposed inner face. A 60 mm layer was defined as the spalling region at the ceiling and lateral walls. The region was created according to the average spalling depth obtained in the test. For the elements at that region, the thermal properties were adjusted during the analysis with a high value of thermal conductivity, 5 W/(m°C), and a relatively low value of thermal capacity, 10000 J/(m^3°C;). The previous values were selected based on the criteria developed by Hua *et al.* (2021b), aiming to obtain a spalling rate close to 2.6 mm/min.

4.3 *Staggered analysis considerations*

A staggered procedure is performed in DIANA to couple the thermal and mechanical analyses. Therefore, the analysis is executed in two consecutive steps with the main assumption that the temperature distribution in the structure is independent of the structural behaviour. The calculated temperature fields are then incrementally applied in a separate mechanical analysis that takes into account the thermally induced strain as well as the material degradation due to high temperatures. The regular Newton-Raphson method is employed for the iterative procedure, and the convergence at each iteration is evaluated in terms of unbalanced force, incremental displacement and relative energy. The time step increments are updated with a cutback-based automatic incremental loading procedure. This algorithm reduces the number of steps required to apply the total time (i.e. the fire duration) and automatically decreases the time increments to recover from non-convergence steps in the iterative procedure.

5 RESULTS AND DISCUSSION

5.1 *Thermal analysis results*

The computed temperature field is independent of the 2D assumption. Thus, the same temperature distributions are obtained for plane stress and plane strain idealisations. Figure 4 shows the

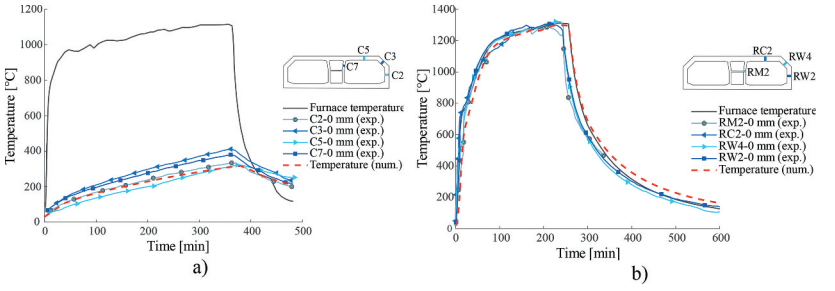

Figure 4. Temperatures at exposed surface, simulation (num.) results versus experimental (exp.) results: a) scenario A; b) scenario B.

temperature at different locations at the exposed surface for both experiments. For the tunnel with a protective coating (scenario A), the numerical simulation was able to represent the average temperature at the exposed side of the tunnel (Figure 4a). It can be noted that the coating significantly reduced the temperature in the concrete in comparison with the applied fire scenario. In the case of the tunnel without protective coating (scenario B), the temperature at the exposed concrete surface, followed almost the same furnace temperature (Figure 4b).

Figure 5 shows the temperatures measured by the thermocouples RC2 (ceiling) at 0 mm, 30 mm, and 60 mm in the fire scenario B. It is important to note that the temperature inside the concrete cross-section followed a temperature similar to that recorded at 0 mm. As stated by Dong *et al.* (2023), this result can be explained by the large spalling observed during the test. Furthermore, it is also noted that the temperature at 30 mm and 60 mm is underestimated if the spalling effect is not considered in the simulations.

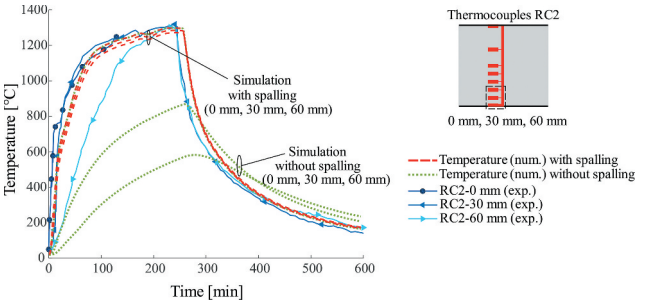

Figure 5. Temperature evolution inside the concrete section for scenario B.

5.2 *Mechanical analysis results*

According to the experiments, the tunnel capacities were sufficient to resist for both fire scenarios. This observation also holds for the numerical simulations with fire coating, in which the iterative procedure converged for all the time steps (Figure 6a). In contrast, the numerical simulations for the most severe fire scenario finished earlier due to convergence problems. The consideration of spalling contributed to reducing the fire resistance time, especially for the plane strain idealisation with spalling, in which the analysis only lasted 72 minutes. The other simulations ended during the cooling phase, as depicted in Figure 6b. It should be noted that the constitutive model assumes that damage recovery due to cracking is not possible. However, a full recovery of the thermal strain was observed during the cooling phase. Consequently, some reloading behaviour was noticed in the concrete stress evolution. It can be inferred that this inaccurate representation, together with the large number of active cracks during the cooling phase may have led to convergence problems in the numerical analyses.

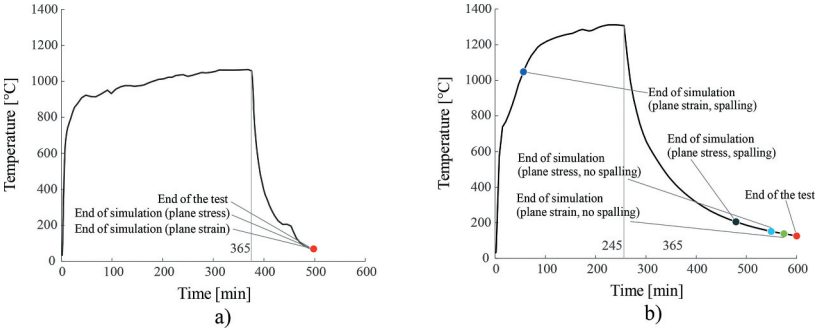

Figure 6. Applied fire scenarios and the last step converged in each numerical analyses: a) scenario A; b) scenario B.

Figure 7 shows an example of the crack pattern obtained from the simulations at the end of the heating phase for both fire scenarios. For the sake of brevity, the results are only shown for two plane stress models. According to Duan *et al.* (2021), for the fire scenario with a protective coating, the cracks were smeared over the unheated side of the tunnel and the mid-wall. This observation is in agreement with the numerical results. For the fire simulation on both tubes, the crack strain increased considerably compared to the previous fire scenario, and the maximum strain values were localised at the tunnel corners and mid-walls.

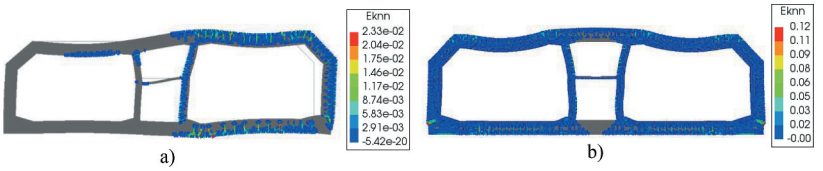

Figure 7. Comparison of crack patterns at the end of the heating phase for plane stress representation: a) scenario A; b) scenario B with explicit spalling representation. The numerical crack width can be estimated as$w = \varepsilon \cdot h$, with h = 30 mm.

The analysis of the principal compressive stresses in the simulations showed the development of a compressive ring in the tunnel cross-section. This ring was located in the concrete cover region, and it was induced by the concrete thermal expansion. For both 2D representations, it was observed that when the spalling representation was included, the compressive stresses at the ring region were visibly reduced. As shown in Figure 8, the comparison between the models with and without spalling for the plane strain idealisation provided a good understanding of the early failure when the spalling effects were included.

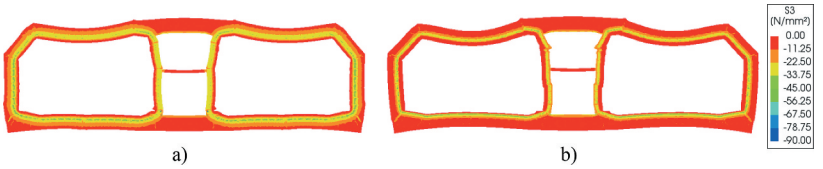

Figure 8. Principal compressive stresses for scenario B: a) plane strain and no spalling at 365 minutes; b) plane strain with explicit spalling at 72 minutes.

Overall, the moment diagrams, values and redistribution were similar in both 2D representations. It was noted that even with the coating application, the maximum moment values were similar to the ones calculated for both fire case scenarios without protection. It is pointed out that the maximum moments at the loading stage represented approximately only 10% of the maximum moment obtained during the fire event as shown in Figure 9.

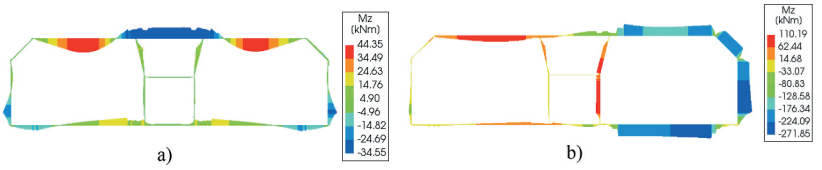

Figure 9. Bending moment diagrams for 2D plane strain representation: a) from mechanical loads b) at 365 minutes in fire scenario A.

6 CONCLUSIONS

This paper investigated the thermo-mechanical behaviour of reinforced concrete tunnel segments under fire using NLFEA. The results from different modelling strategies were compared against

experimental data reported in the literature. The main modelling assumptions included the 2D idealisation (plane stress/strain representation) and the explicit spalling simulation based on the simplified model proposed by Hua *et al.* (2021b). The numerical results from the thermal analysis indicated that the temperatures can be significantly underestimated if the spalling effects are not considered in the simulation of a tunnel without fire protection. Moreover, plane stress and plane strain idealisations provided similar numerical responses for both fire scenarios when compared to the experimental results and also in terms of internal forces. The main difference was found when the spalling effect was included. In that case, more damage was observed in the plane strain representation, and consequently, the simulation finished earlier than expected, during the heating phase. These conclusions are limited to the case study examined in this paper. Future works will focus on the developing more reliable constitutive models for the representation of concrete during the cooling process. These developments will be important for assessing the structures remaining capacity after a fire event and in the design optimisation of fire protection systems.

An unconventional barrier design

Zahra Kamranian, M.Eng, P.Eng. & Diego Penate, P.Eng.
Stantec Consulting Ltd.

Glen Norlander, P.Eng. & Fadi Oudah, PhD, P.Eng.
Norlander Oudah Engineering Ltd (NOEL)

ABSTRACT: An industrial project in northern Canada was recently completed that required multiple ultra-heavy loads to be carried by the world's largest mine trucks over a new bridge structure. The truck's Gross Vehicle Weight (GVW) was 6134 kN exceeding typical highway loads by more than 10 times. A rectangular concrete structure with two cells was selected as the most cost-effective option due to site constraints. The main access road consists of two single standard width traffic lanes travelling under the proposed bridge. Traffic on the access road is comprised of light vehicle traffic. The bridge overpass had three lanes, each with a 20 m wide diving lane. The span of the overpass was 71 meters.

Highway bridge codes do not provide guidance for barrier design appropriate to restrain heavy haul trucks. Crash test results are not available for barriers capable of withstanding these loads. This presented challenges in structural analysis and design and in the design of safety components, including safety barriers. Therefore, the geometry of the barrier, the structural design, and the support of these barriers by the bridge superstructure required advanced modelling and design. As a safety requirement for the project, the oversize barriers are designed to redirect the heavy haul trucks in the event of a collision.

Other challenges with this unique structure include rockfall simulation to model rock free-fall for regular traffic below. Any debris generated on the overpass, including haul truck material, has the potential to free fall from the top haul truck boxes and impact light-duty vehicles travelling under the bridge on the highway traffic main access road. Stantec completed a quantitative rockfall simulation to mimic the trajectory of rocks or hardened soil clumps falling from the haul trucks and provided recommendations for mitigation measures. As a result, an engineered rockfall fence was built to capture rocks and debris.

This paper presents some of the challenges of this unique heavy-load design and construction project.

1 INTRODUCTION

Stantec Consulting Ltd. (Stantec) was retained to provide engineering design and construction support for an overpass in Northern Canada. The overpass carries three lanes of heavy haul mine trucks over a regular light traffic lane under. Each heavy haul lane is approximately 20m wide.

Concrete haul road barriers measuring 3 m wide are located along the east and west sides of the bridge deck. The height from the top of the concrete barrier to the heavy haul road surface ranges from approximately 3.7 m to 3.8 m on the west side and from 4.0 m to 4.1 m on the east side. A berm divides the three haul road lanes into a single haul road lane and a double haul road lane. The total overpass width measured at the soffit of the deck is approximately 71 m. The overpass haul road double lanes will be used for ore transport while the single lane will be used for waste transport in both directions.

The light traffic road below consists of two single traffic lanes (each 4 m clear lane width) traveling under the overpass with a clearance of 5.4 m. Retaining wing walls above and

DOI: 10.1201/9781003483755-467

adjacent to the light traffic road are provided to support the overpass fill. The fill above the retaining wing wall is at a 3H:1V slope.

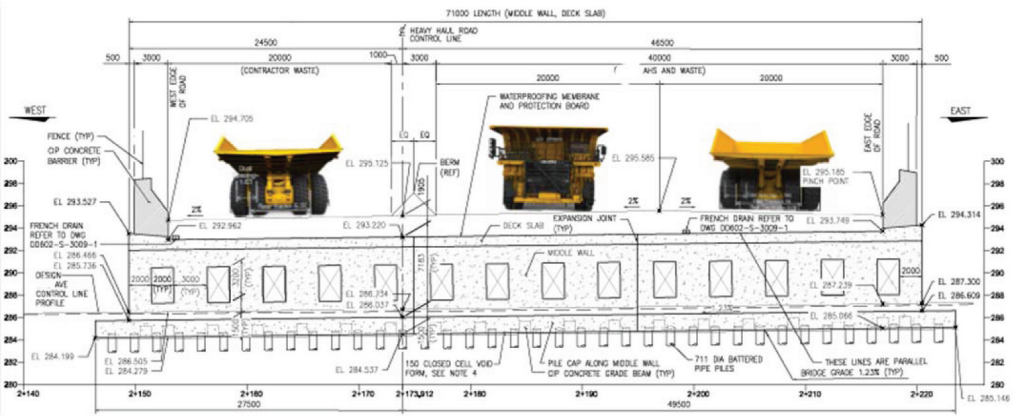

Figure 1. Bridge cross section.

CSA-S6-19 is the primary reference for bridge barrier design in Alberta. The specified requirements for bridge barrier design in CSA-S6-19 does not relate directly to the design of barriers for bridges transporting extremely heavy vehicles such as the Komatsu 980E-4. Conducting real-life crash study as recommended by literature to evaluate and design bridge barriers impacted by non-conventional vehicles is not practical for such large and expensive vehicle. Alternatively, finite element simulation was used to assess bridge barriers subjected to vehicle impact.

The scope of work for the engineering team was to design a bridge system capable of restraining the Komatsu 980E-4 haul truck within the bridge drive lanes of the proposed bridge for a defined speed and contact angle.

The scope of work included conceptualizing and designing the following items using Finite Element (FE) simulation and the principles of structural mechanics:

1. Development of the bridge barrier concept and deformation mechanism
2. Number and details of barrier blocks
3. Barrier-to-bridge deck and barrier-to-approach slab connections (via proprietary high strength thread rods)
4. Barrier-to-barrier connection (via shear keys and post-tensioning cables)
5. Detail for quick restoration of the barrier following a collision.

Different impact scenarios were investigated to investigate the worst angle of impact to the barrier. The impact velocity was considered as the maximum allowed truck velocity travelling on the heavy haul road. The point of collision was considered at the elevation of the front bumper. Different barrier options were investigated to determine the final design.

In addition, any debris generated on the overpass, including haul truck ore and waste material, has the potential to travel downslope or free fall from the top of the concrete barrier and impact light duty vehicles that travel under the bridge. As part of the detailed design, Stantec completed a quantitative rockfall simulation to mimic the trajectory for rocks or hardened soil lumps falling from the haul truck box and to provide recommendations for mitigation measures (a rockfall barrier to capture rocks).

2 HEAVY HAUL ROAD BARRIER DESIGN

The heavy haul truck barrier was designed to redirect and restrain a fully loaded maximum sized mine haul truck travelling at maximum speed back toward the drive lane without transferring significant damaging loads down to the bridge deck and its supports. The restraining

barrier system needed to be robust enough to be quickly reinstalled in position should an impact occur. The impact angle was determined from the turning radius of the specified haul truck when travelling in the furthest lane. To achieve the barrier restraint performance, the concept had to maximize the energy transferred into the barrier through direct energy transfer through mass, lifting energy loss along a sloped plane, friction energy, shear loss and energy transfer due to strain of cables.

The heavy haul truck barrier concept follows:

1. The geometry of the barrier cross section was configured to set the barrier height at the haul truck axel height when the truck is travelling on the gravel wear course.
2. The barrier width was determined to maximize the mass of each section of barrier without sacrificing too much additional width of the bridge deck the barrier rests on.
3. The barriers are constructed with keyed blocks between each barrier with a maximum length consistent with the capacity of an all-terrain crane in case of an impact where the block must be restored back into position.
4. On the impact side of the barrier, a sloped surface created a path for the truck bumper to ride up on, increasing the normal force and friction of the barrier on the deck. The truck weight reduced overturning of the barrier upon impact.
5. The barrier cross section rests on a sloped raised curb poured integral with the bridge deck. Under impact, movement of the barrier along the contact plane lifts the barrier as translation of the barrier occurs.
6. As impact occurs on an individual barrier block, steel fuses made from high strength thread bar connecting the deck to the barrier, are sized to fracture, absorbing collision energy.
7. Each block is keyed to the adjacent block but not connected with rebar. The barrier blocks transfer shear horizontally at the keys, engaging more mass from the adjacent barrier blocks, thus absorbing additional energy in the event of a collision.
8. Post tensioning strand connect the barrier segments together. The strands are anchored at each end of the bridge. The strand is lightly stressed at construction. During a collision, the strand is sized to loosely hold the assembly of barrier blocks together longitudinally, absorbing additional energy from the collision in additional strand strain and longitudinal surface friction between the curb surface and the barrier blocks. The design balances forces on the barrier for redirection of the truck against forces transferred to the bridge deck such that bridge deck and girder damage is limited.

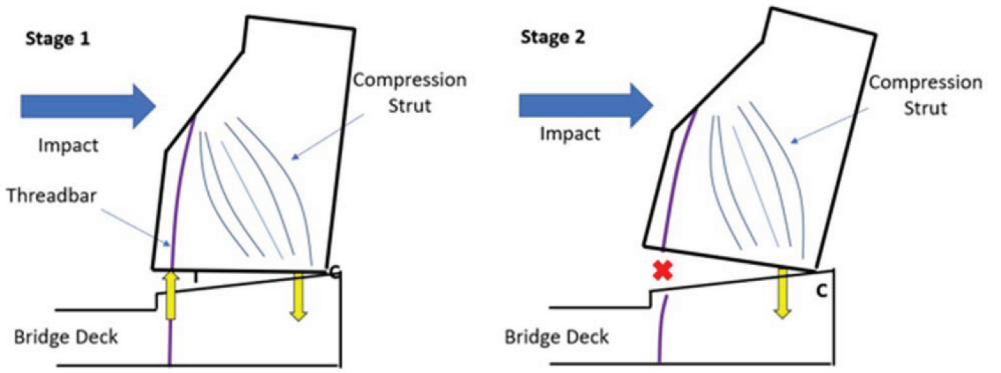

Figure 2. Schematic illustration of barrier deformation mechanism.

An iterative design procedure was employed to optimize the configuration of the barrier, size the structural fuses, and determine the number of post-tensioning strands required to connect the barrier segments. The design optimization was performed by developing detailed three-dimensional (3D) nonlinear FE models of the barrier using the dynamic FE software

LS-DYNA. The concrete barrier was modeled using solid elements with efficient formulation, while the steel reinforcing bars, and the post tensioning strands were modeled using beam elements with full integration. Nonlinear concrete material properties were utilized, and an elastic-plastic hardening material model was used for the reinforcing steel. Applicable concrete-to-concrete and concrete-to-steel friction coefficients were used. A mesh sensitivity analysis was performed to determine the optimum size of the elements. The modeled barrier was impacted by a moving mass of equivalent properties that simulate the largest haul trucks in the mining industry (kinetic energy). Multiple impact angles and velocities were assessed to cover a wide spectrum of collision scenarios. Explicit LS-DYNA solver was utilized to capture the dynamic effect associated with impact. The FE simulation proved the effectiveness of the proposed barrier system to restrain the Haul truck from completely breaking through the barrier while maintaining high effectiveness in redirecting the vehicle back to track.

Figure 3. Barrier cross section.

3 CATCHMENT FENCE DESIGN

A rockfall analysis was completed to assess the potential for rock fragments falling from the haul trucks to reach road below the overpass.

The truck type expected to travel on the overpass was a Komatsu 980E-4 model (Length: 15.72m, Width: 10.01m, Loading Height: 7.09m), and was expected to travel at a maximum speed of 40 km/hr for both staffed and autonomous trucks. The haul trucks were assumed to follow a controlled and consistent path of travel, maintaining a minimum offset of 5 m between the side of the truck and the interior face of the concrete barrier.

Based on regional experience with the local ore and waste, rock sizes ranging from coarse gravel (~50 mm diameter) to large boulders and lumped soils (~1.5 m to 2.0 m diameter) were selected as a reasonable worst-case scenario of representative rock sizes to be used in the rockfall assessment.

Typical rockfall travel modes assessed included free falling, bouncing, rolling and sliding Ritchie, (1963). Free falling with a horizontal velocity component (projectile motion) was assessed as the rockfall travel mode for the period of time between when rocks leave the truck bed to the point of first impact. The assessment assumed normal haul truck operation and did

not account for catastrophic events that could result in large rock displacements such as swerving, truck collisions or rollovers.

The stiffness of a rockfall rollout surface directly influences the speed and distance that a rock can travel, by affecting energy dissipation and friction at the points where the rock contacts the surface. It was anticipated that hard surface conditions would be present on the haul road due to dry conditions or cold temperatures (frozen surface). It was assumed that the road was relatively flat between the haul truck and the concrete barriers. Wheel ruts and other surface defects were deemed beneficial to reduce rocks speed and travel distance and were not considered in the assessment.

The Rocscience 2D statistical analysis program RocFall 6.0 was used to conduct a statistical analysis of probable rockfall trajectories and their associated kinetic energy. The locations of rockfall initiation were selected to represent the selected scenarios for truck offset from the concrete barrier (5 m, 3 m and 1m). A data collector element was modelled to record the height and total kinetic energy of the rock impacts at the expected location of the rock barrier.

An initial sensitivity analysis was completed to test the effects of rotational velocity on the simulation results, using rotational velocities ranging from 30° to 90°/s. The simulation results for impact height and total kinetic energy of rock impact did not show significant variation as compared against the case with zero rotational velocity. Therefore, rockfall analysis rotational velocity was set to zero.

A range of horizontal velocities from 20 km/hr (5.6 m/s) to 60 km/hr (16.7 m/s) were used to calculate the rock traveling distances and heights. Figure 4 provides a graphical representation of the maximum impact height results obtained from the rockfall analysis at the proposed rockfall barrier location. The impact height is measured from the surface of the haul road.

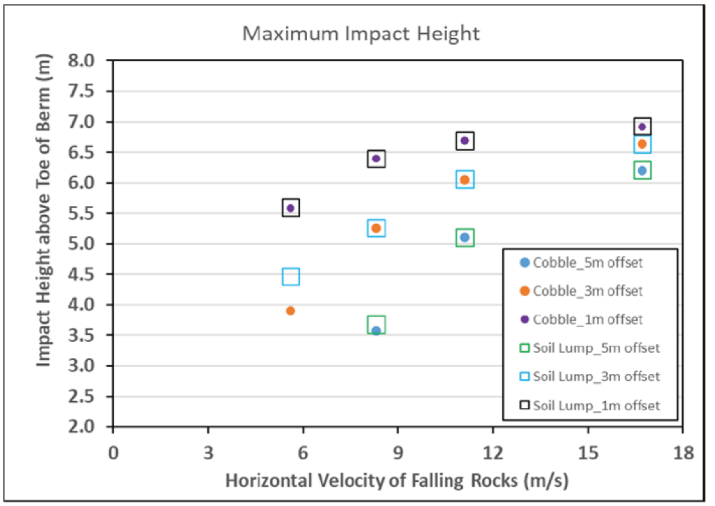

Figure 4. Rockfall maximum impact height results.

The maximum impact height occurs when the truck is offset 1.0 m from the concrete barrier, and the rocks hit the proposed rockfall barrier directly during the free fall. In this scenario, the maximum impact height does not vary greatly between rock types and is not affected by the rockfall surface parameters of the haul road and concrete barrier.

The rockfall analysis also assessed the total kinetic energy of the falling rocks at the moment of impact on the proposed rockfall barrier to be utilized for the design of the structural components and overall capacity of the rock barrier. Figure 5 provides a graphical representation of the total kinetic energy results. The total kinetic energy is presented in logarithmic scale to better visualize the range of results.

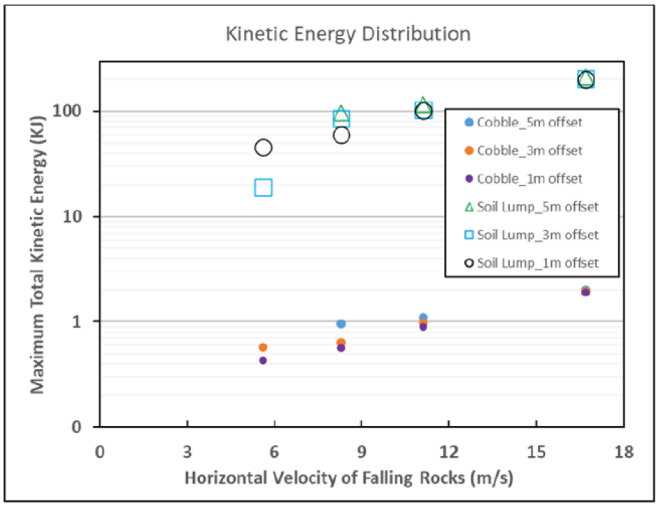

Figure 5. Maximum total kinetic energy distribution.

Based on the above results, the rockfall barrier should withstand the expected maximum total kinetic energy range between 100 and 200 kJ plus an applicable factor of safety (common range between 2.0 and 3.0) for the design. Based on this, a minimum capacity between 400 and 500 kJ for the protection barrier was recommended. The selected fence height was 3.5 m. Considering the concrete barrier height varying from 3.7 m to 4.1 m, the combined height for the rockfall protection system from the surface of the overpass road ranged from 7.2 m to 7.6 m, which satisfied the worst-case scenario required height.

Both rigid and flexible rockfall protection barriers (catchment fences) were considered acceptable solutions to contain potential rockfall.

4 CONCLUSION

The approaches that were taken for the design of the barrier and catchment fence were found satisfactory for the purpose of the project and the client's objectives.

ABSTRACT: Novel Fiber Reinforcement Polymers (FRP) systems hold significant potential for future strengthening of existing structures; however, such systems may also add complexity to the structural assessment. Material properties and structural interaction can cause response deviation compared to conventional structures, affecting both SLS and ULS. The latter can be influenced significantly, as new and extended number of failure modes and complex interfacial interaction must be considered. A novel ductile prestressing Carbon Fiber Reinforcement Polymer (CFRP) strengthening system was designed to limit failure modes and provide a tailored ductile response. The paper describes some historical results, including several steps to provide such improvements. These are supplemented by recent indicational performance, fatigue- and temperature anchor test results additionally included. The anchor system seems excellent for controlling the strengthening utilization, response, and ductility. The system resisted the fatigue exposure in all tests. Exposure of the anchored CFRP prestressing system to cycles from 90°C to 8°C for 12 hours at each temperature limit did not seem to affect the anchorage resistance and stability, where only small temperature-generated deformations were measured.

1 INTRODUCTION

Near Surface Mounted Reinforcement (NSMR) Carbon Fiber Reinforcement Polymers (CFRP) systems have shown significant potential for strengthening and capacity upgrading of existing concrete structures (Al-Mahmoud et al., 2012; El-Hacha & Rizkalla, 2004; Kalfat et al., 2013; Sabau et al., 2018; Schmidt et al., 2022; Sena-Cruz et al., 2012). Such strengthening systems are easy to mount since the weight is 20% of steels, and they provide high tensile strength (the tensile strength is more than five times higher than reinforcement steels - if utilized efficiently) along with high corrosion resistance. Different NSMR CFRP laminate cross-section geometries have been used for several decades in strengthening applications. Some of the most used geometries in civil engineering structures are rectangular-, quadratic-, and circular rods, which may be adhesively bonded into the concrete cover. However, with such a material for strengthening, increased complexity follows this since new advanced failure modes should be considered. Brittle failure modes like Intermediate Crack (IC) debonding (Rashid et al., 2008) and concrete cover separation (Corden et al., 2008) are typically experienced at failure with a relatively low ductility as the outcome. Consequently, the industry and other professionals are often reluctant to implement such strengthening applications and question whether sufficient failure warning and safety margins are present.

The system considered in this paper has provided some answers to these questions by implementing effective anchoring and system ductility (Schmidt et al., 2010, 2019, 2020, 2021), however, additional questions typically relate to behavior in the long-term and environmental

DOI: 10.1201/9781003483755-468

exposure. These are difficult to answer since no adequate long-term accelerated testing procedures are, to the author's knowledge, available for CFRP anchor systems. In addition, such systems have not yet been proven in the field, like conventional civil industry materials and applications, which incites caution.

A review of the long-term mechanical properties of FRP tendon anchor systems is given in (Zhao et al., 2020) describes stress ranges of 215-355 MPa, while the "Guideline for European Technical Approval of Post-Tensioning Kits for Prestressing of Structures" (ETAG-013)/ (EOTA, 2002) prescribes a smaller stress range of 80 MPa. Other studies of CFRP system fatigue resistance are (Elrefai et al., 2007; Xie et al., 2020). In (Elrefai et al., 2007), a large test program was conducted with varying stress ranges (130-1153 MPa). The study concluded that for stress ranges ≤ 10 % of the CFRP ultimate strength (216 MPa), the fatigue life seems infinite. Other tests were performed in (Xie et al., 2020), where the stress ranges were 36-358 MPa, and with similar conclusions.

Testing of adhesively bonded CFRP systems exposed to high temperatures has been investigated by several researchers (Karbhari & Engineer, 1996; WU et al., 2005). In addition, strengthening reduction and adhesive glass transition thresholds are often described to be reached between 50°C and 70°C by the manufacturers (depending on the adhesive used) (Michels et al., 2015; Täljsten et al., 2011). Regarding anchored and prestressed NSMR CFRP, guidelines mainly handle the unique material testing and not novel systems and material interactions. Often, standards and guidelines relate to rivaling steel prestressing systems, which may be used as a reference when testing CFRP anchoring systems (EOTA, 2002; PTI, 1998). However, it must be emphasized that prestressed CFRP systems are not directly comparable to prestressed steel systems. There are significant differences regarding anchoring of the brittle CFRP material, lack of yielding regime, anchorage mechanism failure modes, material properties, mounting procedure, etc. Consequently, the lack of direct comparison makes it challenging to interpret results and evaluate novel CFRP systems when judged based on provisions concerning steel strands- and cables. The first part of this paper (section 2) summarizes some of the main milestones of the developed ductile NSMR CFRP prestressing system. The results answer how some challenges related to CFRP strengthening may be addressed. When looking into some of the presently generated results (Schmidt et al., 2019, 2020, 2021, 2022), the main scopes related to non- and prestressing of anchored NSMR CFRP strengthening have:

- Been to investigate potentially higher utilization and failure control when using NSMR CFRP strengthening for shared activation.
- Related to the ductility combined with response- and failure control provided by the developed novel ductile strengthening system.
- Researched mounting easiness and applicability for real-life structural strengthening.

The second part concerns test results related to fatigue (section 3) and temperature exposure (section 4), which are indications of the anchorage and CFRP NSMR prestressing system long-term resistance. These tests relate to the following research questions:

- Can the developed CFRP NSMR prestressing anchor system provide a stable prestress over three months?
- Can the novel ductile anchor system meet the demands given in the ETAG-013 (EOTA, 2002) related to fatigue resistance?
- How does a temperature up to 90°C affect the prestressing magnitude and stability?

2 RESPONSE, FAILURE CONTROL, AND DUCTILITY THROUGH CFRP ANCHORING

Based on recent findings, anchoring CFRP NSMR systems seems to be a viable solution to enabling response and failure control of the system and the strengthened structure. External prestressing systems may typically be divided into two end anchored systems: i) Anchored

strengthening systems adhesively bonded to the structure and ii) freely anchored strengthening systems (without adhesive bonding to the structure). A ductile response-controlled anchor system was developed for bonded and unbonded strengthening (Schmidt et al., 2020). CFRP rod stress activation is performed before the adhesive cures when applying bonded systems. This type of application may be used to perform shared activation (Schmidt et al., 2019). For unbonded systems, the strengthening effect relies on the anchorage system alone since these are the only force transfer areas, and there is no direct strain compatibility. However, an unbonded application may open the opportunity to provide increased strengthening control and ductility. Figure 1 shows test results from beam strengthening tests with four different strengthening configurations. In the unbonded configuration, a low elastic modulus adhesive was used to ensure CFRP rod protection in the NSMR groove but also to enable some stress transfer along the concrete beam/CFRP rod bond line, especially when reaching the ultimate capacity. Figure 1. Beam strengthening results: i) An unstrengthened beam, ii) A strengthened beam but with unanchored CFRP reinforcement, iii) A strengthened beam with prestressed CFRP bonded to the structure with epoxy, and iv) A strengthened beam with prestressed CFRP in an unbonded configuration using the ductile anchoring system. Test results first presented by (Schmidt et al., 2019, 2021).

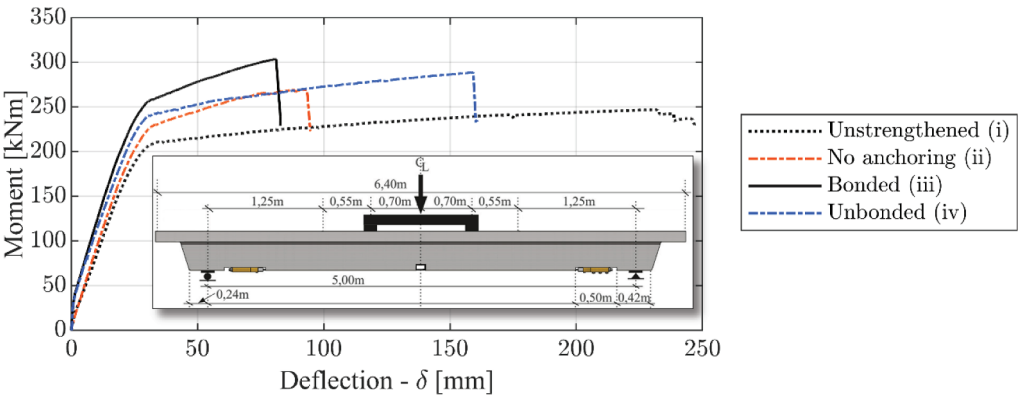

Figure 1. Results gained from un-strengthened beam (i) and strengthened beams (ii), (iii) and (iv).

It is seen that the systems provide excellent strengthening to the un-strengthened beam. Utilization of the CFRP rod up to 3300MPa was reached in the bonded configuration but at the expense of reduced ductility, which is significantly lower than the reference beam. When applying the response-controlled ductile anchorage combined with the low elasticity modulus adhesive, significantly increased ductility is achieved. In addition, a significant strengthening effect was still obtained. The ductile anchorage dictates the yielding threshold and provides strengthening support to the yielding regime provided by the internal steel reinforcement. This configuration resulted in concrete crushing strain magnitudes [Schmidt et al., 2021]. The research indicates that advanced ductile anchorage may provide excellent response and failure control to the applied strengthening system. The CFRP anchorage was designed to reduce the number of failure modes and control anchorage stresses to ensure high utilization of the CFRP rod (Schmidt et al., 2020). The brittle behavior and variation of the anchor capacity were handled by developing a ductile mechanism. Adding this mechanism to the anchorage, full control of the anchorage response was achieved through the combined system response. The ductile mechanism may be tailored to generate desired behavior with a response curve with a very small variation until the final intended collapse is reached. When collapsed, the remaining capacity of the CFRP anchor may be utilized. Figure 2 shows four examples of such tailored ductile mechanisms. An example of combined system response may be seen in (Schmidt et al., 2020).

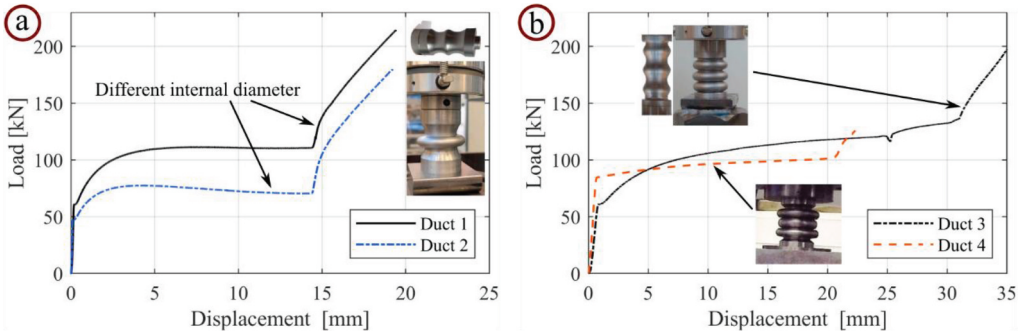

Figure 2. Examples of four tailored ductile mechanisms. a) Two ductile mechanisms with tailored changes in geometry and one deformation zone. b) Two different ductile mechanisms with three deformation zones, the design of "Duct 4" provides an almost ideal plastic response.

Using the ductile mechanism enables the applied anchorage system's significantly increased safety level. In addition, a brittle failure provided by the CFRP anchorage can be avoided by applying a ductile behavior design using the ductile mechanism. The next part of the research verifications is to take the first steps towards evaluating long-term and temperature effects.

3 FATIGUE TESTING OF THE DUCTILE CFRP ANCHOR SYSTEM

Fatigue evaluation is one of the crucial tests when performing a long-term assessment of the novel ductile CFRP anchor system. Such testing aims to prove a system has acceptable behavior for variating long-term loading exposure. According to the ETAG-013 (EOTA, 2002), post-tensioning systems shall withstand specified fatigue loads without exceeding a specified percentage loss of tensile element cross-section. Testing may consider the tensile element, the anchorage, or the coupling assembly (based on which is the weakest element). The test acceptance criteria are:

- No fatigue failure in anchorage components shall occur.
- No more than 5 % of tensile element cross section shall be lost during fatigue testing with 2 million cycles with a minimum stress range of $\Delta\sigma_p = 80\ MPa$ at a maximum load of 65 % of tensile element characteristic strength, f_{pk}.

It is specified that one test should be performed for the smallest, one for the medium, and two for the largest tendon size. The investigated system is, however, developed for one tendon size only (an 8 mm CFRP rod). Therefore, four tests are performed on this dimension. Recommendations by EMPA are very similar, only with a stress range of 10 % higher (90 MPa) and a stress level of 10 % lower. The stress levels applied in (Zhao et al., 2020) are deemed too high compared to these recommendations. The full ductile CFRP anchor system, depicted in Figure 3a, is a further developed version of the system presented and applied for strengthening a concrete bridge (Schmidt et al., 2022). Earlier versions and applications are found in (Schmidt et al., 2020, 2021, 2022). The system components include: i) tensile element (CFRP rod), ii) threaded barrel with aluminum wedge pre-set inside, iii) counteracting torque pins mounted in the barrel, iv) threaded bar, v) anchor block, vi) steering washer, vii) ductile mechanism, viii) nut. The ETAG-013 (EOTA, 2002) states that the test shall be performed in a tensile testing machine with the pulsator at a constant load cycle frequency of not more than 10 Hz and with a constant upper load, σ_{max}, of 65% of the characteristic strength of the tensile element. Figure 3b shows the cyclic loading regiment, where $\sigma_m = \sigma_{max} - \Delta\sigma_p/2$. The stress range of $\Delta\sigma_p = \sigma_{max} - \sigma_{min}$ shall be maintained constant throughout the testing, at levels corresponding to 80 MPa stress amplitude in the tensile elements for 2 million cycles.

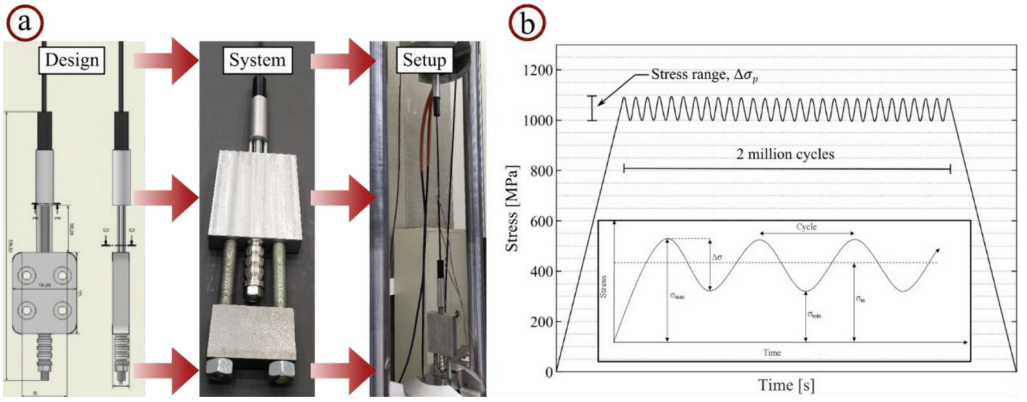

Figure 3. Fatigue test. a) Illustration of the design, assembled system, and test setup. b) Fatigue principle.

The ETAG-013 prescribes that the system to be tested shall be assembled according to the envisaged application, using all components necessary for anchoring the tendon. Unique for the presented system is that a ductile mechanism is introduced. The introduction of the ductile mechanism changes the perspective of the test. Therefore, the given fatigue test is not an individual fatigue test of the CFRP material or the anchorage but a full-system fatigue test. The evaluated and considered stress range values are seen in Table 1. Note that these are determined based on the strength of the ductile mechanism and not the CFRP strength because the ductile mechanism defines the characteristic yielding strength of the combined system. Based on the previous recommendations, the values chosen for the test are also shown in Table 1. Cyclic loading was performed using load-controlled testing with monitoring of system deformation and CFRP strain.

Table 1. Stress range values based on ETAG-013 using the ductile mechanism to define the load.

Parameter	Symbol	Value (ETAG-013) kN/(MPa)	Value (EMPA) kN/(MPa)	Chosen values kN/(MPa)
Tensile element/CFRP characteristic strength (test results)	$F_{k,CFRP}$ ($f_{k,CFRP}$)	99/(1969)	99/(1969)	99/(1969)
Ductile mechanism characteristic strength (test results)	$F_{k,DUCT}$ ($f_{k,DUCT}$)	84.4/(1679)	84.4/(1679)	84.4/(1679)
Upper load (65 % of $F_{k,DUCT}$)	F_{max} (σ_{max})	54.9/(1091)	51.4/(1023)	54.9/(1091)
Lower load ($\sigma_{max} - \Delta\sigma_p$)	F_{min} (σ_{min})	50.8/(1011)	46.9/(933)	46.9/(933)
Mean load	F_m (σ_m)	52.8/(1051)	49.2/(978)	50.9/(1013)

All four fatigue tests resisted the entire 2 million cycles without any undesirable behavior and were thus successfully performed. An example of the stress interval coupled to strain gauge measurements can be seen in Figure 4a. The four tests generated almost similar results for the deformation development. The results from one of the tests can be seen in Figure 4b.

A maximum observed deformation increase of 0.05 mm was identified while testing the full system. This magnitude seems small since it may originate in multiple components. It may be shared between the anchorage systems and the gripping jaws of the test machine. Such deformation levels are deemed insignificant in real-life applications where longer CFRP lengths typically will be used. It should be noted that eight anchors were fatigue tested through the four performed tests. The results fit well with the conclusion of (Elrefai et al., 2007) that stress levels below 10% of the ultimate capacity will not provide a fatigue failure.

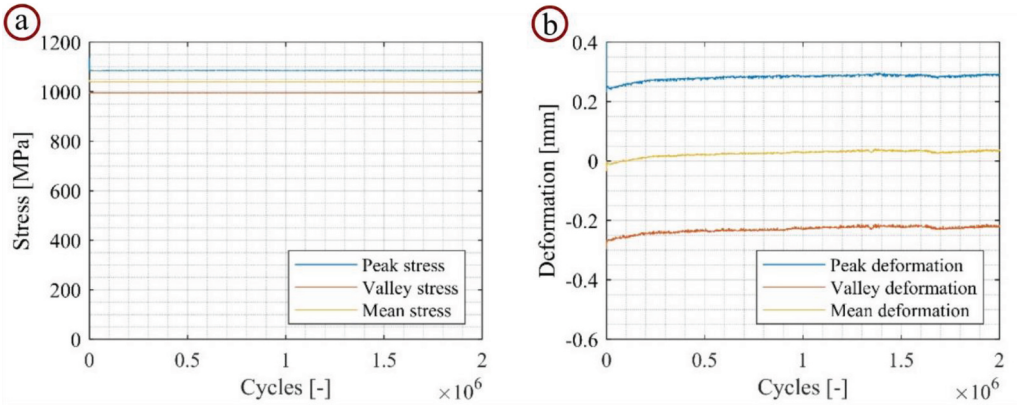

Figure 4. a) Achieved stress range in the fatigue tests. b) Deformation development for a representative test of the four tests, where similar results were achieved.

4 TEMPERATURE TESTING OF THE DUCTILE CFRP ANCHOR SYSTEM

Temperature testing was performed on four anchored CFRP NSMR systems; thus, two anchors with the full ductile system were applied. The test setup is seen placed in the temperature chamber in Figure 5c. It consisted of an H-profile with end plates used for the anchoring. A system was placed on each side of the web with a free CFRP length of approximately 260 mm.

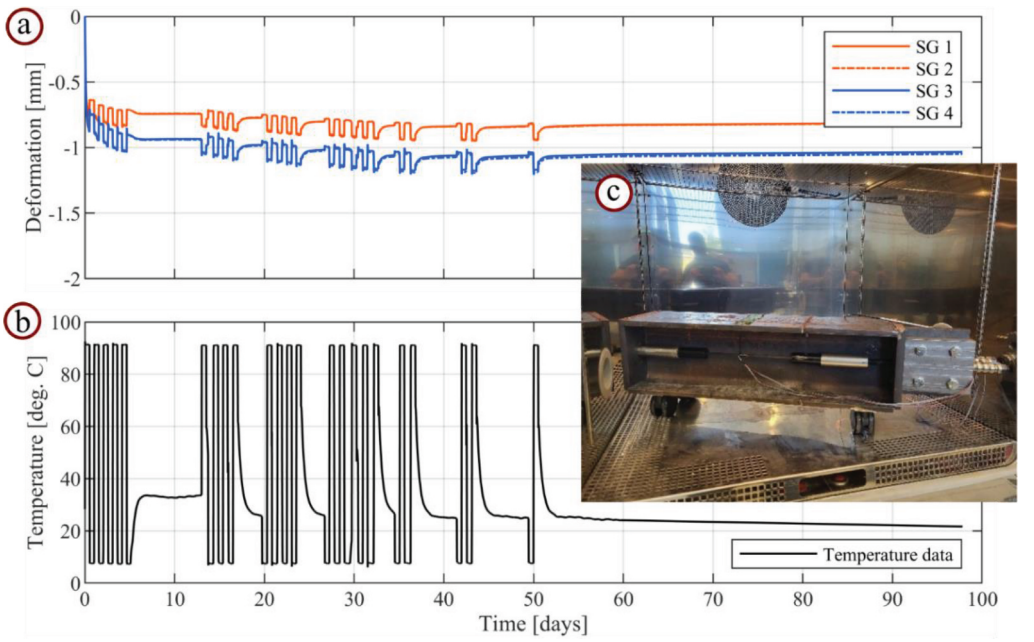

Figure 5. Temperature test data. a) Strain gauge measurements converted into equivalent system deformation. Note that 0.26 mm = 1000 μm/m. b) Temperature variation data. c) Photograph of the test setup in the climate cabinet.

Since limited information was available regarding novel system temperature testing, some assumptions had to be made to evaluate the temperature resistance. Since Denmark generally has lower environmental temperatures than southern European countries, Portugal was

chosen as a reference. This decision was based on the higher temperature levels and the state-of-the-art research in the environmental exposure of CFRP strengthening provided by (Cruz et al., 2022; Sena-Cruz et al., 2012). With a basis in "DS/EN 1991-1-5", the maximal temperature in Portugal is 40°C, and a bright light surface adds 18°C to the temperature level, resulting in a base temperature of 58 °C. With a safety factor of 1,5 applied to 58 °C, a temperature of 87 °C is reached.

Consequently, a maximum temperature of ~90 °C was chosen, significantly higher than the known degrading temperature thresholds between 55 °C - 65 °C provided by conventional adhesively bonded CFRP strengthening systems (Täljsten et al., 2011). A minimum temperature of 8 °C was used to indicate the night period. During the testing, the temperature was approximately 12 hours at the maximum and minimum temperatures. The specimens were initially prestressed to approximately 1200 MPa, which corresponds somewhat to the prestress level used when applied in situ (Schmidt et al., 2022). The applied temperature exposure is depicted in Figure 5b, and testing was performed until 98 days, 50 days with temperature variations, and 48 days at rest with a more stable temperature. The 48 days were used to evaluate if the temperature variation affected the stable stress behavior. Measurements of maximum and minimum fluctuating temperature magnitudes fit well with the test plan. But it can also be seen that there are some gaps in the curve. This was caused by functional challenges with the temperature chamber, where the temperature protocol had to be restarted multiple times. Nonetheless, the test results may serve as indicative results, and the gaps are deemed to have little influence on the current research results and scope. The measured deformation output (calculated from the strain) is seen in Figure 5a. Strain gauges 1 and 2 relate to one system, while 3 and 4 are for the other. Within the first hours of placing the system in the temperature chamber, a significant drop in prestressing (780 MPa) was observed. However, this is a natural effect when testing short systems, which will be significantly more susceptible to prestress loss provided by small deformations occurring in the system. The system deformation was only 0.62 mm and this magnitude of loss should be separated between the two anchor points (S_a = 0.31mm). For in-situ applications with longer NSMR CFRP systems, this magnitude seems insignificant but can be considered if desired. The system response after this drop follows the temperature well and does not seem to be affected any further by the 8-90 °C exposure with contraction and expansion. Additionally, after the initial stabilization, both double systems seem to have identical responses when exposed to the temperature. The results strongly indicate that the system is both stable and unaffected by the temperature exposure until the 98 days are reached (after initial stabilization). However, the tests are indication tests, and more testing will be needed when considering long-term behavior. However, when looking into previous and presented research on the system, tests indicate only small settlements when mounted in situ (Schmidt et al., 2022). The measured system settlements (approximately 6.5 m length) from in-situ testing after three weeks were identified to range from S_{CFRP} = 0.1 to 0.8 mm (presumed generated by the anchor points). Adding the obtained temperature settlement to this value, a maximum settlement at each anchor is presumed to be $\Delta L = 2 \cdot (S_a + S_{CFRP}) = 2$ (0.31 mm + 0.8 mm) = 2.22 mm. Consequently, a resulting stress reduction may be calculated from settlements gained from the anchor points of a NSMR CFRP strengthening system of 6.5 m length and a CFRP rod E-modulus of 165GPa, see Eq. (1). This loss should be considered for prestressing but no issue for future system implementation. The 56MPa loss generated at a length of 6500mm correspond to approximately 4,5% of a 1200MPa prestress level.

$$\frac{\Delta L}{L} \cdot E_{CFRP} = \frac{2.22\text{mm}}{6500\text{mm}} \cdot 165\text{GPa} \sim 56\text{MPa} \tag{1}$$

5 CONCLUSION

A ductile NSMR CFRP prestressing strengthening system has been developed and researched recently. Present research results seem very promising where desired designed response

control, ductility, high safety, and prestress stability have been investigated. Consequently, the next step was to perform the system's initial long-term and temperature testing. Indicating results of such testing is described in this paper. In the fatigue tests, the specimens resisted an applied fatigue loading protocol of 2 million cycles, with no significant deformation during testing (maximum observed deformation of 0.05 mm).Consequently, the demands from ETAG-013, as well as the recommendations from EMPA, were fulfilled. Although the system resisted the recommended protocol, it seems to be an open question if the stress ranges are representative of the actual real-life application, which should be investigated further. In the temperature tests, the base prestressing levels seemed unaffected by the temperature exposure from 8°C to 90°C during 12 hours for 50 days (after an initial loss in the first couple of hours). An anchorage settlement of 0.31 mm was observed, mainly from this initial drop. However, this settlement seems insignificant when relating to in-situ applications where longer strengthening systems are typically used. For instance, for a system length of 6.5 m, the anchorage loss will result in a total prestressing loss of approximately 56 MPa (40MPa anchorage- and 16MPa temperature related settlement), deemed acceptable. Prestressing seemed stable up to the termination of the test at 98 days. More testing is needed to investigate the results and verify them further. During the development, challenges seem associated with introducing novel systems in civil engineering since these systems are usually compared to traditional building materials and applications and have already been proven to have civil applications. However, from a sustainability perspective, this may be a significant obstacle that can be solved if sustainable solutions have the desired effect on the building industry.

ACKNOWLEDGEMENT

We sincerely thank S&P Clever Reinforcement Company AG Denmark for their invaluable support in the ongoing research project. Furthermore, the contributions from former students are greatly appreciated. In addition, a great thank you to the technical staff at DTU and AAU. Thank you to Perstrup Beton Industry A/S. Also, a great thank you to Reinholdt W. Jorck og Hustrus foundation for their acknowledgment and funding.

Analytical study on the effects of flange size on the axial force introduced in the rivet

K. Yamamoto & K. Nozaka
Ritsumeikan University, Kyoto, Japan

ABSTRACT: Replacement of damaged rivets with new ones is beneficial from both mechanical and landscape perspectives; however, this method of repair is not widely adopted due to issues with constructability. Although it is acknowledged that rivets with smaller flanges can be formed with less load, the extent of axial force introduced into these rivets is not yet determined. In this study, the mechanism of axial force introduction during the rivet's cooling process and the relationship between the axial force and size of the rivet flange were numerically investigated. Results indicated that there is a minimum flange size to keep required axial force in rivets.

1 INTRODUCTION

In recent days, a damaged rivet is often replaced with high-strength bolts due to its workability (Hayase et al. 2011). However, the joint strength after replacement with high-strength bolts may be lower than that of a sound riveted joint depending on the surface condition of the base material (Hanji et al. 2021), and there are also concerns that changes in appearance may result in a loss of the historical value of rivetted bridges, which are designated as cultural heritages. Therefore, it is essential to establish a new rivet construction method that improves workability, while also considering the mechanical properties and protection of cultural values. Reducing the load required for riveting is crucial to make the equipment smaller or to ease the support of the reaction force when striking the rivet, which would improve workability during riveting. This improvement results in more application of riveting not only for the existing bridges but also for new bridges.

A new construction method proposed to decrease the required load involves using rivets with a small contact area between the rivet head and base material surface after riveting (hereafter referred to as "rivet flange area) (Yamamoto et al. 2022). However, it is unclear if a rivet with a small rivet flange area can attain an axial force of at least 70% of the yield axial force measured in general rivets (Wilson & Oliver 1930), and there are also reports suggesting that the fatigue strength of riveted joints diminishes as the axial force decreases (Hori et al. 2012). Hence, understanding the mechanism of axial force introduction in rivets is critical for ensuring the safety of new rivet construction methods. This requires determining the necessary rivet flange area to introduce an axial force equal to or greater than that of traditional rivets.

In this study, rivets with varying rivet flange areas were investigated using a finite element analysis program. Then, effects of thermal changes to both the rivet and the base material on the process of axial force introduction were discussed.

2 NUMERICAL ANALYSIS OVERVIEW

2.1 *Analysis model overview and material characteristics*

In this study, finite element analysis program MARC (MSC 2021) was utilized to perform a deformation analysis. This analysis replicated the process where the rivet undergoes plastic

DOI: 10.1201/9781003483755-469

deformation and fastens steel plates together. Following this, a thermal stress analysis was conducted to represent the cooling of the rivet after riveting. Figure 1 presents a schematic of the analysis model before the deformation analysis, while Figure 2 illustrates the rivet construction process. Figure 2 shows the rivet, inserted between steel plates, undergoing plastic deformation by a hammer, resulting in the steel plates being clamped together by the head formed after the rivet expands between the plates.

The analysis model accounted for the axial symmetry of the structure, modeling only the part indicated by the dashed line in Figure 2(a) using axially symmetrical shell elements. This approach resulted in a 3D analysis model incorporating stress and strain components in the circumferential direction. Deformation analyses were conducted for 10 different cases, involving two rivet shaft diameters (19 mm and 22 mm) and five shaft lengths. The hole diameter was set to the shaft diameter plus 1.5 mm, while the steel plate thickness and hammer shape remained consistent in each model.

For the deformation model, the steel plate was assigned Young's modulus of 200,000 N/mm² and Poisson's ratio of 0.3. The rivet hammer was treated as a rigid body, and the rivet itself had Young's modulus of 2000 N/mm² and Poisson's ratio of 0.3. This study builds upon a previous study (Yamamoto et al. 2022), which readers are encouraged to refer to for detailed information. The method of deformation analysis used here also follows that previous study (Yamamoto et al. 2022), and hence the specifics are not reiterated in this document.

Subsequently, a thermal stress analysis was conducted based on the results from the deformation analysis. This involved analyzing a state where the rivet, having undergone plastic deformation in the shaft and formed a head part, was subjected to thermal changes applied to both the steel plate and rivet. The stress state from the deformation phase was not carried over into this analysis. A total of 20 scenarios were evaluated in the thermal stress analysis, applying the material properties of two types of steel (ss400 and sm490) to 10 different shapes derived from the deformation analysis as stated in Table 1.

The focus of this study is to elucidate the influence of the rivet flange area on the axial force introduced during the cooling phase and the associated displacements in various parts due to rivet contraction. The contact analysis covered all free surfaces of the steel plate, rivet, and hammer, assuming zero frictional force during contact. No boundary conditions were set, allowing the rivet to expand and contract freely, except for boundary conditions of $x = 0$ and $y = 0$, which were applied only to nodes within the area enclosed by solid lines in Figure 3.

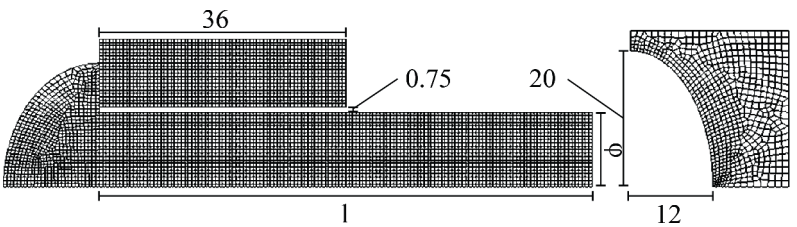

Figure 1. Overview of analysis model (units: mm).

Table 1. Analysis case.

φ	l				
mm	mm				
19	61	66	72	75	80
22	61	66	72	75	80

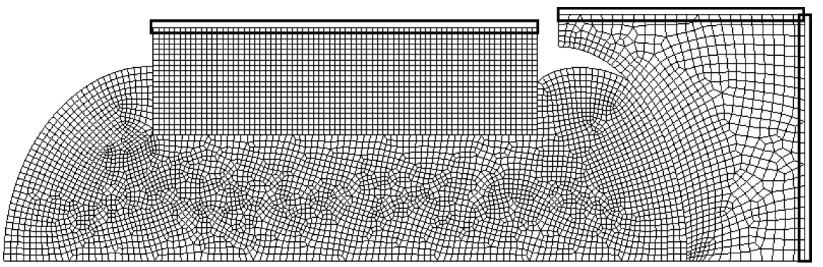

Figure 3. Example of analysis model.

In actual riveting process, thermal changes and stress generation occur while forming the heated rivet with a hammer. However, given that hammering is a brief process, it is believed that these thermal changes are negligible. The impact on the introduced axial force is primarily attributed to deformation during cooling and the conditions of restraint. Therefore, to simplify the analysis, the stress generated during the forming process was omitted in this study. The Young's modulus of the rivet used in the thermal stress analysis is set as shown in Figure 4, and the linear expansion coefficient is set based on previous research (Kim et al. 2005) as shown in Equations (1) and (2). The steel plate was assumed to be SM490Y, and the yield stress was set to 355 N/mm^2. In a previous study (Kim et al. 2005), analysis was conducted with the assumption that the yield stress of the steel material was constant below 400 °C.

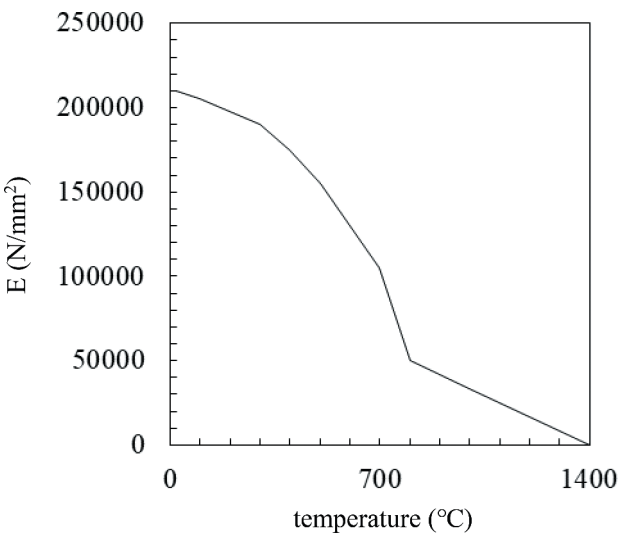

Figure 4. Young's modulus.

In this study, a polylinear approximation of the true stress-equivalent plastic strain relationship is used for the rivet, as illustrated in Figure 5. This approximation was based on the relationship between stress and strain at high temperatures for steel materials, outlined in the Recommendations for Fire Resistant Design of Steel Structures (Architectural Institute of Japan 2017).

$$20 < T < 600^{\circ}\mathrm{C} : \alpha = (0.0005173 \times \mathrm{T} + 1.1897) \times 10^{-5} \quad (1)$$

$$T > 600^{\circ}\mathrm{C} : \alpha = 1.5 \times 10^{-5} \quad (2)$$

where α = linear expansion coefficient; T= temperature.

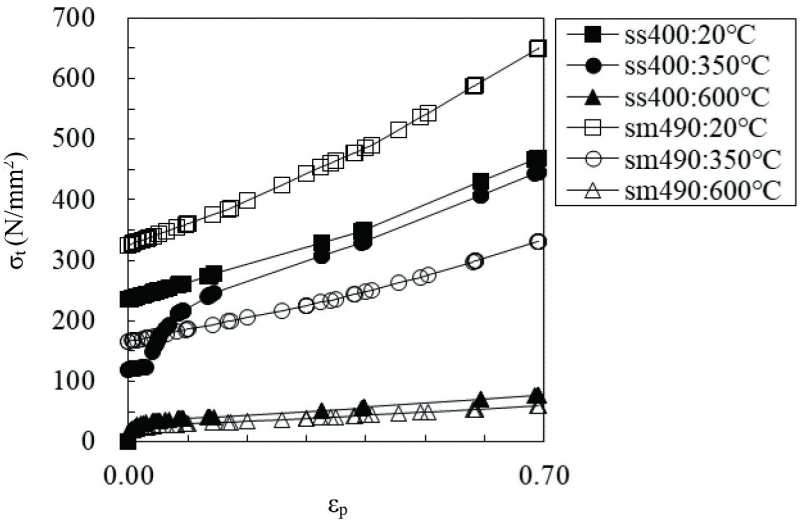

Figure 5. True stress-equivalent plastic strain relationship.

To ensure clarity of the figure, true stress-equivalent plastic strain relationships at other temperatures set in this study were not included. Any temperatures without a specified true stresse-quivalent plastic strain relationship was interpolated from the input data. Young's modulus of the hammer was set at 200,000 N/mm². Although yield stress was not assigned, its impact on the analysis results is minimal because the rivet and hammer cease contact shortly after analysis begins due to rivet contraction. Furthermore, Poisson's ratio was set to 0.3 for all rivets, steel plates, and hammers, in line with parameters from a previous study (Kim et al. 2005).

2.2 *Temperature history*

The actual temperature of the steel plate surface and the rivet head, on the side supporting the reaction force, was measured using thermocouples and infrared thermal cameras (Suehiro et al. 2020) (Hirohata et al. 2021). However, attaching a thermocouple to a rivet can impede the riveting process, and a shaft inserted into a rivet hole is not measurable with a thermal camera, making it challenging to track the temperature history of the rivet head and shaft on the driving side. Understanding the overall temperature history of the rivet is crucial for analytical study on its cooling process and identifying the mechanism behind the introduction of axial force. Therefore, as a preliminary step to the analysis, a test specimen as depicted in Figure 6, was fabricated to measure the actual temperature history of the rivet and steel plate. This specimen featured a slit along the shaft direction, allowing visibility of the rivet in the hole. The temperature history of the shaft part, post-riveting, was recorded using an infrared thermal camera, focusing on the portion visible through the slit.

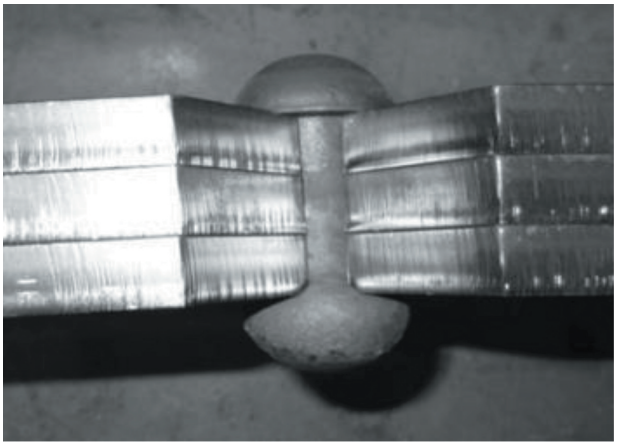

Figure 6. Example of specimen.

Figure 7 presents the approximate values derived from the measured temperature history. A polylinear approximation of these measurements was input into the analysis program. In the simulation, the rivet was cooled from 1000 °C to 95 °C within one second. Simultaneously, the steel plate, initially at 20 °C, experienced a temperature increase to a maximum of 290 °C due to heat transfer from the rivet, before also cooling down to 95 °C. During these measurements, thermocouples were employed alongside infrared thermal cameras to record temperatures. These results were then compared, and the most accurate temperatures were selected for use. In this study, we thought that the timing of the thermal change in the rivet and steel plate was important, and we decided to use the measurement results.

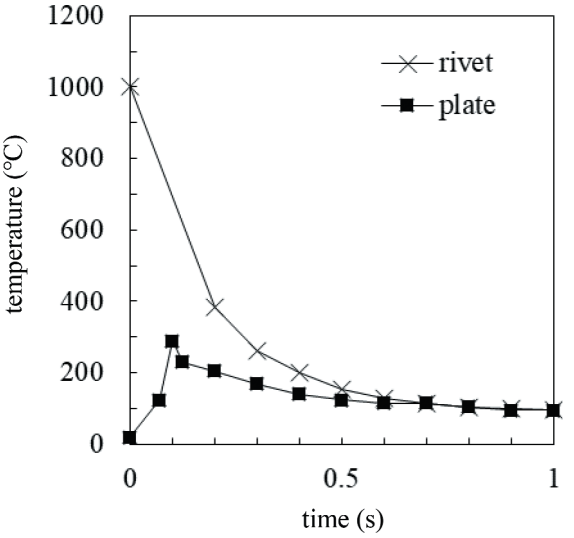

Figure 7. Temperature history.

3 RESULTS AND DISCUSSIONS

3.1 *Displacement in axial direction of each part of rivet due to cooling*

Firstly, displacement of each part of the rivet at the end of the analysis were focused to determine the mechanism by which the axial force is introduced as the rivet cools. Figure 8 displays

a detailed view of the rivet flange area on the side where the head forms during driving (termed the "driving side"). Table 2 lists the lengths of the rivet shafts and the corresponding rivet flange areas on the driving side. The rivet flange part was defined as the difference in the y-coordinate between the node at the outer edge of the hole and the nearest node on the steel plate among those in contact with both the rivet head and steel plate. It was observed that rivets with longer shaft lengths and larger shaft diameters possess a greater volume, leading to the formation of a larger rivet flange area after driving.

Figure 9 shows the node positions at the outer edges of the rivet head and rivet flange part, both on the side supporting the reaction force during rivet driving (referred to as the "supporting side") and driving side. In this discussion, the nodes at the outermost edges of the rivet flange area on the supporting and driving sides are designated as L1 and R1, respectively. The nodes at the top of the rivet head on the supporting and driving sides are labeled L2 and R2. Furthermore, for this study, the x-coordinate of each node at the beginning of the analysis was set to 0. The displacement that occurred in the x-axis direction from the initial position by the end of the analysis was recorded as the final displacement.

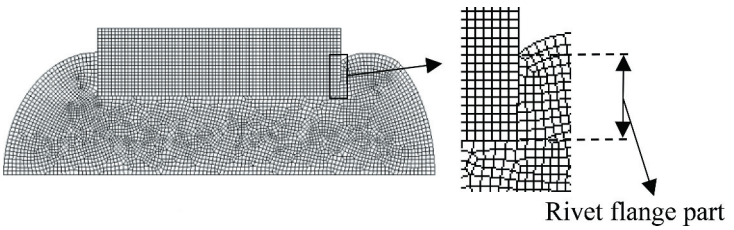

Figure 8. Rivet flange part.

Table 2. Rivet shaft length and rivet flange area.

rivet length	ss400:φ19	ss400:φ22	sm490:φ19	sm490:φ22
mm	mm^2	mm^2	mm^2	mm^2
61	29.1	76.1	29.6	75.8
66	96.7	155.7	95.8	158.1
72	159.9	298.0	160.4	298.1
75	208.2	358.6	209.6	358.4
80	352.9	518.0	353.0	518.2

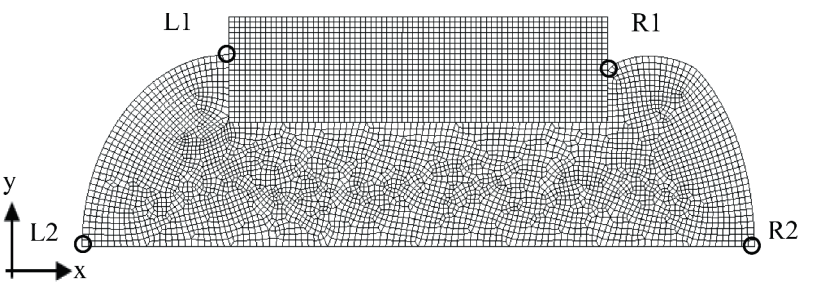

Figure 9. Displacement measurement position.

Next, Figure 10 depicts the relationship between the displacement difference of nodes L2 and R2 and the ratio of the rivet flange area on the driving side to the cross-sectional area of the rivet shaft (termed "shaft cross-sectional area ratio"). On the vertical axis, the difference is shown between the absolute displacement values of L2 and R2. Larger values indicate more displacement towards the rivet contraction direction in node L2 on the supporting side when compared to node R2 on the driving side. The shaft cross-sectional area ratio is used for comparison across rivets with different shaft diameters.

Given that the rivet maintains a higher temperature than the steel plate and the steel plate remain relatively hard until the end of the analysis, the displacement (contraction) in the positive x-axis direction of the rivet flange area, including nodes L1 and R1, is limited, as is the contraction of the rivet head's top. Rivets with smaller flange areas on the driving side exert a weaker force to constrain the contraction of the rivet head's top, leading to greater contraction displacement at the driving side's top when compared to the supporting side.

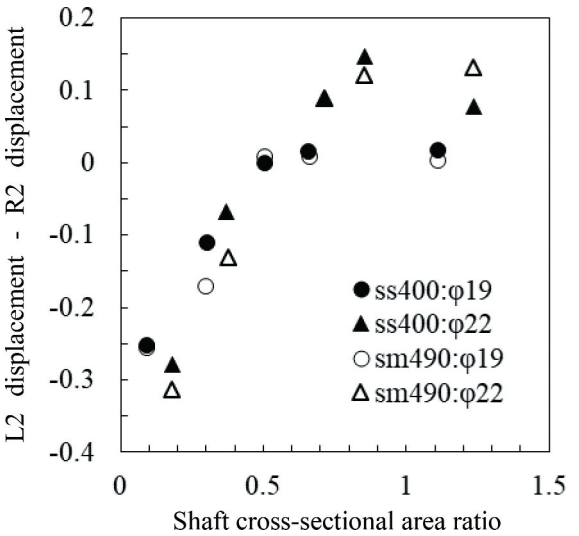

Figure 10. L2 displacement - R2 displacement and shaft cross-sectional area ratio.

Figure 10 indicates that rivets with smaller shaft cross-sectional area ratios, resulting from smaller driving side flange area, exhibit larger contraction displacement at the rivet head's top on the driving side than on the supporting side. Furthermore, as the rivet flange area ratio increases, the displacement difference between the supporting and driving sides tends to reduce. For the φ19 model, when the shaft cross-sectional area ratio exceeds 0.50, the decrease in displacement difference slows down and levels off to approximately 0 mm. When the φ22 model exhibited a shaft cross-sectional area ratio that exceeded 0.86, the decrease in displacement difference became more gradual, and the displacement in the contraction direction of the supporting side with respect to the driving side converged to approximately +0.1 mm.

Differences were observed in the convergence value of the displacement difference between the two sides across models with varying shaft diameters. This variation is attributed to the consistent shape of the rivet head on the supporting side in all models. Specifically, in the φ22 model, which has a larger hole diameter, the rivet flange area on the supporting side is smaller compared to that in the φ19 model. Consequently, the force constraining the displacement in the contraction direction of the rivet is weaker on the supporting side in the φ22 model.

3.2 *Relationship between the shape of the rivet flange part and the axial force in the rivet shaft*

Figure 11 shows the relationship between the ratio of the axial force introduced with respect to the yield axial force ("yield axial force ratio") and the shaft cross-sectional area ratio. The axial force introduced was calculated by multiplying the stress at the end of the analysis with the area affected by this stress. Based on the figure, it is obvious that the yield axial force ratio increases with the shaft cross-sectional area ratio. Additionally, it is observed that the yield axial force ratio converges to approximately 0.9 for the φ19 model and 0.85 for the φ22 model when their respective shaft cross-sectional area ratios exceed 0.66 and 0.71.

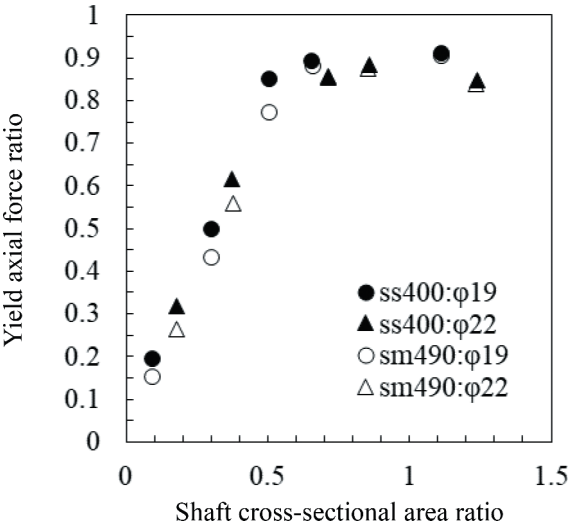

Figure 11. Yield axial force ratio and shaft cross-sectional area ratio.

The outcomes discussed are believed to stem from the fact that the increases in the shaft cross-sectional area ratio, as described in Section 3.1, led to reduced displacement differences between the supporting and driving sides, ultimately resulting in convergence. Moreover, it was verified that an axial force amounting to at least 70% of the yield axial force was introduced when the shaft cross-sectional area ratio exceeded 0.50 in the φ19 model and 0.71 in the φ22 model. It is also notable that when the yield axial force ratio did not reach a convergence value, rivets with the same shape using sm490 material, which has a higher yield axial force, exhibited a lower yield axial force ratio when compared to those using ss400 material. However, in cases where the convergence value of the yield axial force ratio was achieved, the yield axial force ratios for ss400 and sm490 were equivalent.

The results indicate that an increase in both the rivet flange area and the shaft cross-sectional area ratio leads to a stronger force that constrains the contraction of the rivet. This, in turn, decreases the displacement difference in the contraction direction at the top of the rivet head on both sides, thereby enhancing the introduced axial force. In this study, the maximum yield axial force achieved was approximately 0.9 for the φ19 model and 0.85 for the φ22 model.

4 CONCLUSION

In this study, numerical analyses were conducted to understand the effect of the size of the flange area between the rivet head and the base material surface after driving on the introduced axial force and to elucidate the mechanism by which the axial force is introduced during the cooling process of the rivet.

The main results obtained from this study are described below.

1) It was demonstrated that contraction at the rivet flange area is constrained, and that contraction occurs in the rivet head on both the supporting and driving sides, leading to the introduction of the axial force.
2) It was shown that by increasing the rivet flange area to at least 50% for the φ19 rivets and 71% for the φ22 rivets of the shaft cross-sectional area, an axial force amounting to at least 70% of the yield axial force was introduced.
3) It was demonstrated that increasing the rivet flange part constrained the contraction and, in turn, increased the axial force. However, it was also shown that the rate of increase in the introduced axial force relative to the yield axial force became gradual when the rivet flange area reached at least 66% for the φ19 rivets and 71% for the φ22 rivets of the shaft cross-sectional area. This indicates the upper limit to the axial force that can be introduced.

Because only numerical analyses have been conducted in this study, experimental verifications were expected to be conducted in near future.

Novel Fe-SMA bonding method for repair of U-rib butt welds in OSDs

Z.L. Lv, X. Jiang & X.H. Qiang
Tongji University, Shanghai, China

H.L. Wu & J.M. Ding
Tongji Architectural Design, Shanghai, China

ABSTRACT: U-rib butt welded connection is one of typical fatigue prone details in orthotropic steel bridge decks (OSDs). The U-rib butt welded connection plays a role in connecting longitudinal beams in the bridge deck system. Once the U-rib butt weld cracks, it will reduce the stiffness of the bridge deck system and threaten the safety of the bridge structures. In this case, the immediate need is to find an effective reinforcement method. This paper proposes a novel Fe-based shape memory alloy (Fe-SMA) bonding reinforcement method for cracked U-rib butt welded connection in OSDs. The innovative Fe-SMA materials can proactively produce prestressing recovery stress by thermal activation and introduce residual compressive stress closed to crack tips, resulting in extending fatigue life of structures. Two full-scale single U-rib specimens were in-itially subjected to fatigue load to generate fatigue cracks. Then the cracked U-rib butt welded connections were strengthened by externally bonded Fe-SMA plates, and fatigue test was conducted to investigate the effectiveness of Fe-SMA bonding method. The experimental results showed that the active reinforcement method can significantly improve the fatigue performance of U-rib butt welds. The Fe-SMA plates can generate 20–59.1 compressive stresses in the U-rib butt weld areas. The average fatigue strength of the reinforced specimen is 130MPa.

1 INTRODUCTION

U-rib butt-welded connections in orthotropic steel bridge decks are subjected to repeated vehicle loads, making them vulnerable to fatigue cracking. The fatigue cracks in the U-rib butt-welded connections were reported worldwide, such as Kinuura Bridge in Japan (Xiao et al., 2006), XiHouMen Bridge in China (Ma et al., 2018), and Fatih Sultan Mehmet Bridge in Turkey (Shakir et al., 2018). As the fatigue cracks significantly affect the structural integrity and durability of the bridge, it is imperative to thoroughly investigate an effective way to address fatigue cracking issues and extend the service life of U-rib butt-welded connections.

Traditional crack repairing methods for metallic structures are drilling holes, welding, and bolting. These techniques show some shortcomings, such as the introduction of high stress concentration and adverse welding residual stress. As an alternative to conventional repair reinforcements, carbon fiber reinforced polymer (CFRP) has been successfully applied to repair damaged steel structures (Tafsirojjaman et al., 2022; Jiang et al., 2023). Compared to non-prestressed CFRP, using prestressed CFRP can achieve better fatigue reinforcement effect (Täljsten et al., 2009). However, prestressing CFRP required hydraulic jacks and complex fixtures, which is sometimes difficult or even impossible due to a lack of space in steel bridge decks.

Fe-based shape memory alloys (Fe-SMA) are advanced materials that can offer an easy-to-implement prestressing procedure, which can be used as a more effective way for the prestressing strengthening of civil structures. Recently, the application of Fe-SMA has been mainly focused on cracked steel plates (Qiang et al., 2023) and steel beams (Wang et al., 2023).

DOI: 10.1201/9781003483755-470

However, limited information is available concerning the butt-welded connections repaired by Fe-SMA plates. In this paper, two cracked U-rib specimens with two butt welds were prepared, and a novel Fe-SMA bonding method was developed for the fatigue repair of the U-rib butt-welded connections.

2 STRENGTHENING TEST

2.1 *Strengthening mechanism*

The deformed Fe-SMA materials can return to their original shape through a heating and cooling process, namely the shape memory effect. A novel Fe-SMA bonding method was proposed, as shown in Figure 1. The prestrained Fe-SMA plates are fully bonded to cracked steel plates, with a middle activation area heated to produce recovery stress, while the other two ends remain unheated and withstand the recovery stress. And the cracked steel plates are subjected to the pre-compressive stresses that act against the tensile stresses. Therefore, the use of Fe-SMA is expected to repair cracked butt-welded joints, thereby extending the remaining service life.

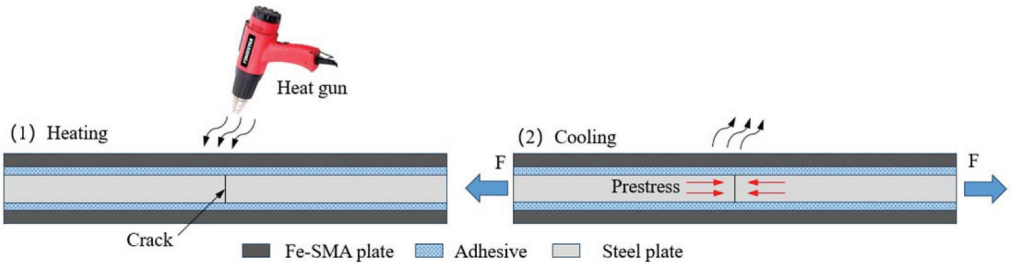

Figure 1. Side view of crack steel plate strengthened with Fe-SMA plates.

2.2 *Specimen design*

Two single U-rib specimens with butt-welded connections were designed according to the reference (Jiang et al., 2023), as shown in Figure 2. The butt-welded connections utilized single-side groove welds, with a backing plate width and thickness of 60 and 4mm, respectively. Weld A and Weld C in Figure 1 refer to the U-rib butt joints, while Weld B corresponds to a butt joint with the top plate. In order to expedite the testing progress, Weld A was intentionally positioned at the mid-span. The steel plates used in the tests were Grade Q345. First of all, the tested specimens were subjected to fatigue loading to produce real fatigue cracks. It was found that crack initiated at the arc transition of U-rib welds with a length of 90 mm and 80 mm, respectively. After fatigue cracking, three prestrained Fe-SMA plates with a dimension of 400 mm×105 mm×3 mm were bonded to the web and bottom plates, as shown in Figure 3. A two-component epoxy resin adhesive was used, and it has a glass transition temperature of 80 °C. The reinforcement procedures mainly included base surface treatment, adhesive application, and one-week maintenance.

2.3 *Activation test*

The heated activation was performed on the specimens using a heat gun after maintenance, with an activation temperature of 200 °C. The heating area was the middle 50 mm region, and the ice bags were set at the anchorage areas to prevent heat transfer, as shown in Figure 4. Taking the SU1 specimen as an example, activation test results were shown in Figure 5. It can be observed that the temperature at the measurement points in the middle of the three Fe-SMA plates reached 200 °C within 2 minutes of activation. Meanwhile, the highest

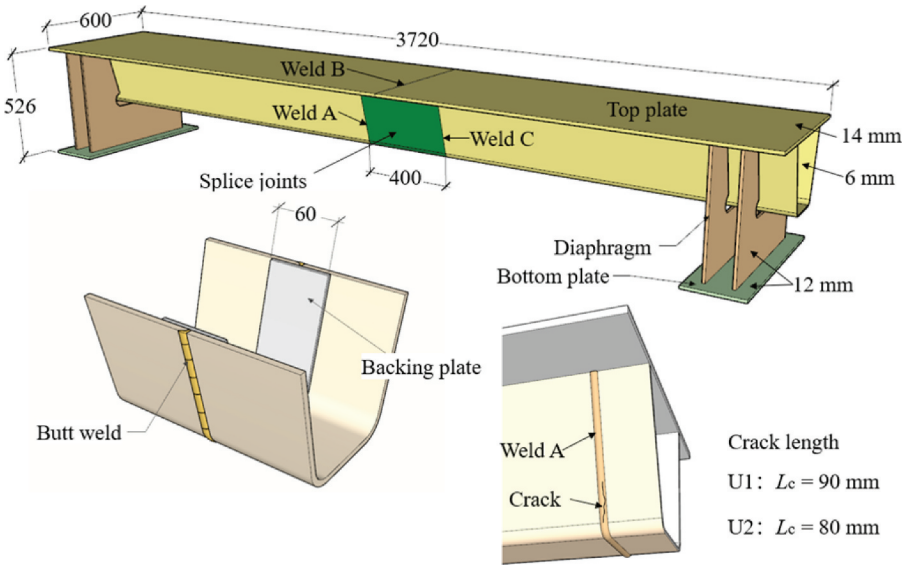

Figure 2. Tested specimen (Unit: mm).

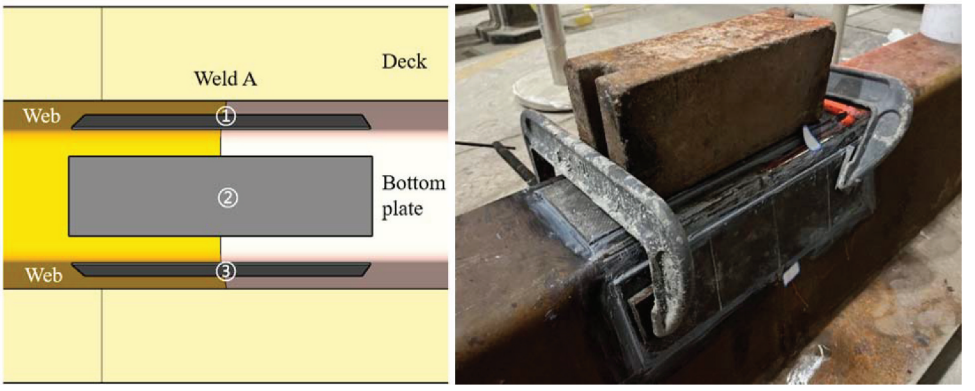

Figure 3. Specimens strengthened by Fe-SMA plates.

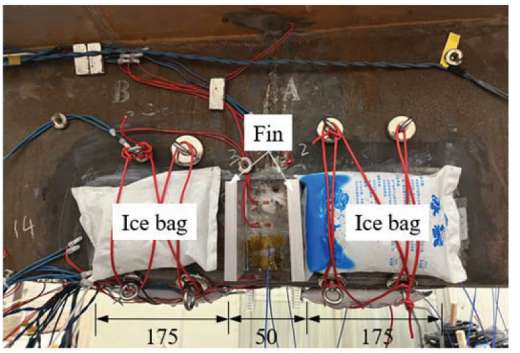
temperature in the adhesive anchorage area was 60 °C, which is lower than the glass transition temperature of 80 °C. After cooling to room temperature, the distribution of pre-stress in the reinforced area was measured, as shown in Figure 5(b). The reinforced area achieved a prestress range of -20–59.1 MPa. The arc transition zone obtained a larger pre-stress due to the superposition of adjacent Fe-SMAs, making it more beneficial for fatigue loading. Another specimen SU2 achieved compressive prestresses ranging from -26.6 to -53.2 MPa.

3 FATIGUE TEST

3.1 *Test set-up and fatigue loading*

A fatigue test was conducted after the activation test, as illustrated in Figure 6. All specimens were subjected to single-point fatigue loading at the mid-span, with a fatigue loading frequency of 100 Hz. The load range was determined based on the stress ranges of the actual



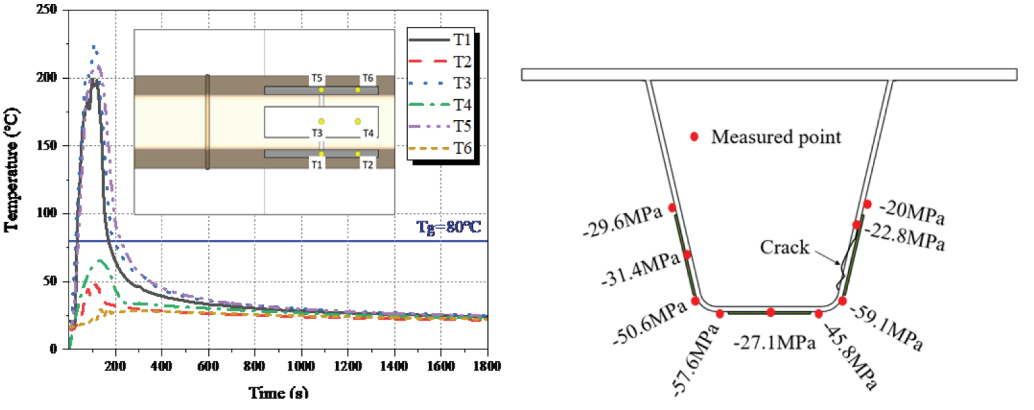


Figure 4. Schematic view of Fe-SMA activation (units: mm).

(a) Temperature distribution (b) Prestress distribution

Figure 5. Activation test results of SU1.

bridge and was appropriately increased according to the loading conditions. The specific loading history is presented in Table 1. During the loading process, the data and failure modes of the specimens were recorded until the reinforcement system completely failed.

Figure 6. Loading set-up.

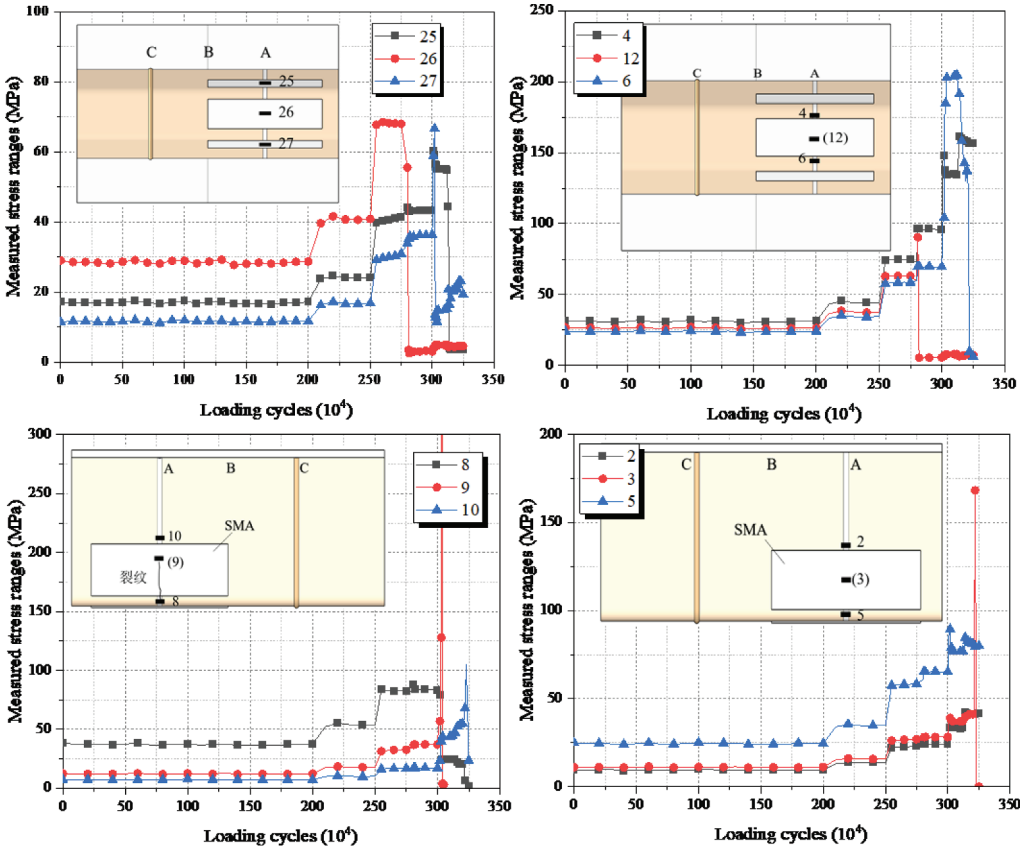
Table 1. Fatigue loading.

No.	α (%)	Load range (kN)	Loading cycles (10^4 times)	Equivalent stress range (MPa)
SU1	12.2	15−35	0−200	101.3
		20−50	200−250	
		25−75	250−300	
		35−105	300−325	
SU2	10.9	15−35	0−200	106.1
		20−50	200−300	
		25−75	300−450	
		35−105	450−467.8	

Note: the initial damage degree α is defined as the ratio of initial crack length (L_c) and the full length (L_t) of the U-rib section.

3.2 *Fatigue failure modes*

During the fatigue reinforcement test, it was found that all reinforced specimens failed due to partial debonding of the Fe-SMA plate and crack propagation in the welded joint. Figure 7 records the variation of stress ranges monitored by strain gauges with the number of cycles. During the first 2.5 million fatigue cycles, the stress ranges at all measurement points remained stable, indicating that no fatigue failure was found in the reinforcement system. When the loading cycles were at



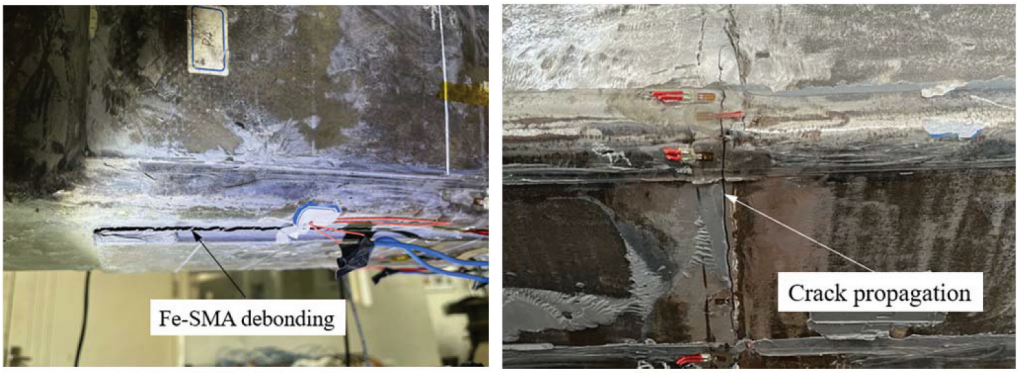


Figure 7. Measured stress ranges versus loading cycles of specimen SU1.

2.82 million cycles, as shown in Figure 8(a), debonding occurred at the end of the bottom Fe-SMA, resulting in a rapid decrease in stress ranges at measuring point 26 and buried measuring point 12. At the same time, the stress ranges at the measuring points 4 and 6 significantly increased due to the loss of prestress, while the stress ranges at the measuring points on both sides of the web plate slightly increased. However, the initial crack did not propagate further because the Fe-SMA on both sides of the web plate still worked synergistically. Subsequently, the load range was further increased, leading to the debonding failure of the Fe-SMA plates on the crack side. Then the strain gauges (measuring points 8 and 9) at the crack tip failed, indicating the crack began to extend. When the reinforcement system completely failed (i.e., all three Fe-SMA 8strips experienced end debonding), the fatigue crack quickly experienced unstable propagation. At the same time, a significant increase in deformation at the mid-span of the specimen was observed, leading to the cessation of loading. The final failure modes of the specimen are shown in Figure 8(b). It can be seen that the newly developed cracks continued to propagate along both ends of the initial crack until they reached the middle of the bottom plate, indicating that the specimen had lost its load-bearing capacity.

(a) Fe-SMA debonding (b) Crack propagation

Figure 8. Fatigue failure modes.

3.3 *Fatigue evaluation*

According to Miner's cumulative damage principle, the fatigue strength of the welded joints after reinforcement is assessed. Table 2 records the results of the fatigue improvement of the specimens after repair. The fatigue strength of each welded joint before repair met the requirements of Grade 71 specified in the China steel bridge specifications. However, even after sufficient fatigue loading cycles, fatigue cracks can still appear in this detail. Therefore, after repair with Fe-SMA plates, the cracked specimens regain an average fatigue strength of 130 MPa. In addition, in order to facilitate a unified comparison of fatigue life, the equivalent fatigue life of each specimen is calculated using equation (1). The calculated results indicated that the bonded Fe-SMA plates could substantially extend the fatigue life, with an extension ration of 1.03 to 4.09.

$$N_e = N_R \times \left(\frac{\Delta\sigma_R}{\Delta\sigma_c}\right)^m \tag{1}$$

Table 2. Fatigue evaluation of SMA-strengthened specimens.

		Fatigue strength (MPa)		Equivalent fatigue life (10^4 times)	
No.	α (%)	Before repairing	After repairing	Before repairing	After repairing
SU1	12.2	117.8	119.1	914.3	943.1
SU2	10.9	88.0	140.8	381.1	1558.9

where NR = actual loading cycles; $\Delta\sigma_R$ = equivalent stress range; $\Delta\sigma_c$ = fatigue strength at two million cycles; and m = 3.

4 CONCLUSIONS

(1) Activation tests show that thermally activated Fe-SMA plates can introduce pre-stresses ranging from -20 to -59.1 MPa near the welds of U-ribs, thereby actively strengthening the structure. After reinforcement with Fe-SMA bonding, the fatigue performance of the cracked specimens significantly improved, with the average fatigue strength of the reinforced specimens reaching 130 MPa. The equivalent fatigue life of the specimens at different damage levels increased by 1.03 and 4.09 times, respectively.
(2) The Fe-SMA with localized debonding cannot continue to bear the load and resulted in a loss of applied prestress. However, the remaining Fe-SMA strips continue to work in coordination with the original structure. Therefore, Fe-SMA bonding reinforcement can provide a warning effect before structural failure, thereby avoiding sudden structural rupture.
(3) The proposed self-prestressing technology based on Fe-SMA does not require complex anchoring devices or tensioning equipment and can quickly achieve prestressed reinforcement using the shape memory effect. Bonding Fe-SMA adhesively barely impairs the parent structures and can meet the requirements for non-destructive repair of real bridges.

Z.Y. Yang
Organization Department of Pinghu Municipal Committee, Pinghu, China

ABSTRACT: Based on the crack-stop holes, the Fe-based shape memory alloys (Fe-SMA) plates were used to repair fatigue cracks at the diaphragm cutouts of orthotropic steel deck (OSD) bridges, using its inherent stiffness and shape memory effect. In the experimental research, a total of 6 specimens were designed for fatigue test, including 2 specimens repaired solely by crack-stop holes and 4 specimens repaired by Fe-SMA plates. After completing the reinforcement, significant local stiffness and compressive stresses can be introduced at the edge of crack-stop holes, which can effectively reduce the stress concentration at the cracked region, postpone the initiation of fatigue cracks, and inhibit crack propagation after secondary-cracking. The fatigue life of specimens repaired by Fe-SMA plates is 3.73~12.68 times that of specimens repaired solely by crack-stop holes, indicating that bonding Fe-SMA plates based on crack-stop holes is an effective method for repairing cracked diaphragm cutouts in steel bridges.

1 GENERAL INSTRUCTIONS

The orthotropic steel decks (OSDs), with their advantages of light self-weight, high load-carrying capacity, substantial torsional stiffness, and convenient construction, have been widely used in large-span bridges (Pfeil & Battista 2005, Freitas et al. 2013). However, the fatigue cracking of the OSD bridges is particularly prominent under the influence of welding defects, residual stress, stress concentration, and increasing traffic volume (Maljaars 2012, Li et al. 2019). Since the occurrence of fatigue cracks in the OSDs of Severn Bridge in the United Kingdom in 1971, numerous fatigue cracks have been reported in the OSD bridges in various countries (Wolchuk 1990, Tsakopoulos & Fisher 2003, Miki 2006). Engineering research experience indicates that the majority of OSDs, subjected to heavy traffic loads, develop fatigue issues after several years or decades of service (Fisher & Roy 2011, Editorial Department of China Journal of Highway and Transport 2021).

Within the OSD bridges, the longitudinal U-ribs are continuously connected through the transverse diaphragms. To release rotational constraints on the U-ribs at the diaphragms, arc-shaped cutouts of the diaphragms are incorporated below the U-ribs. However, these diaphragm cutouts in the OSD bridges will experience significant stress concentration under vehicle-induced vibrations and cyclical wheel loads. Furthermore, in earlier constructions of OSD bridges, the arc-shaped cutouts were mainly made via flame-cutting technology. Extensive data indicates that this method could induce residual tensile stresses of over 200 MPa at the flame-cut region, and the stress response under the combined action will result in severe fatigue cracking (Zhang et al. 2015, Yokozeki & Miki 2016).

For fatigue cracks in steel structures, various external reinforcement can be carried out using steel plates, carbon fiber-reinforced polymer (CFRP), and Fe-SMA through connections such as bolts or bonding (Izadi et al. 2018a, Lepretre et al. 2018, Jiang et al. 2024). As an alloy, Fe-SMA

*Corresponding author: jiangxu@tongji.edu.cn

DOI: 10.1201/9781003483755-471

possesses excellent properties in strength, plasticity, and production processing, making it highly advantageous for structural reinforcement (Cladera et al. 2014). By utilizing the shape memory effect of Fe-SMA, prestressed reinforcement can be achieved through heating activation, eliminating the need for complex mechanical equipment such as jacks and anchors (Izadi et al. 2018b, Wang et al. 2021). In addition, the crack-stop hole is convenient in operation and fast in construction, which can effectively reduce the stress concentration in the local cracked region and noticeably improve the fatigue performance of structures, making it particularly suitable for repairing the fatigue cracks in OSD bridges (Makabe et al. 2014, Fu et al. 2017).

The authors proposed a novel repair method of Fe-SMA plates covering crack-stop holes for the cracked diaphragm cutouts, introduced the repair scheme and operational process, and successfully applied it to the reinforcement of Sutong Bridge and Hangzhou Bay Bridge in China (Qiang et al. 2023a, b, c). This paper conducted fatigue tests on the diaphragms repaired by crack-stop holes and Fe-SMA plates, aiming to verify the feasibility and practicality of the proposed method. The fatigue life improvement, failure modes, and stress responses at the hole edge were analyzed through data monitoring and on-site observations.

2 FATIGUE LOADING TEST

2.1 *Diaphragm repair scheme*

Based on the actual dimensions of steel bridges in engineering, the authors studied the stress state at the arc-shaped cutouts of the diaphragm using multi-scale numerical simulations (Lv et al. 2021, Qiang et al. 2023d). To ensure that the specimen size is suitable for the testing

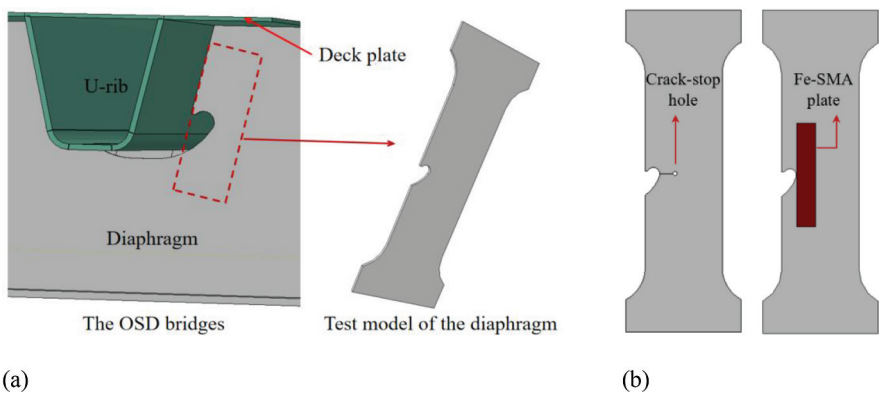

Figure 1. Selection of diaphragm model: (a) intercept position, (b) reinforcement.

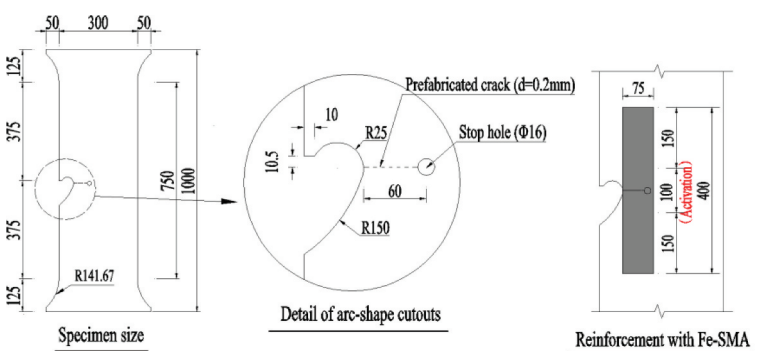

Figure 2. Geometry of diaphragm specimens (unit: mm).

equipment, the diaphragm test model is selected as depicted in Figure 1, and the geometric dimensions are presented in Figure 2. For the diaphragm specimens, the thickness is 12 mm, the minimum effective width is 175.3 mm, and the prefabricated crack with a length of 60 mm is located at the minimum cross-section.

Six cracked diaphragm specimens were designed, two of which were repaired using crack-stop holes (S-H Group), while the other four were repaired by the Fe-SMA plates covering crack-stop holes (S-FH Group). The arc-shaped cutouts were made via flame cutting and polished to simulate practical engineering conditions. The cracks and crack-stop holes were prefabricated by wire cutting. The Fe-SMA plates were selected with different thicknesses and activation temperatures. The key parameters of the reinforcement scheme are listed in Table 1.

Table 1. Specimens design and reinforcement parameters.

Repair method	Name	Stop hole size	Activation temperature	Thickness of Fe-SMA plate
Crack-stop holes	S-H-1	Φ16 mm	None	None
	S-H-2	Φ16 mm	None	None
Fe-SMA plates covering crack-stop holes	S-FH-1	Φ16 mm	200°C	1.75 mm
	S-FH-2	Φ16 mm	200°C	2 mm
	S-FH-3	Φ16 mm	150°C	2 mm
	S-FH-4	Φ16 mm	None	1.75 mm

2.2 *Specimen loading system*

The MTS 311.31S electro-hydraulic servo testing machine, depicted in Figure 3, was utilized for fatigue loading, with a clamping area of 130×130 mm at the upper and lower ends. During the loading process, the HBM 1615B acquisition system was used to monitor real-time data such as load, displacement, and strain. In the S-H group, 5 strain gauges were arranged on the diaphragm surface at distances of 2 mm, 15 mm, 30 mm, 60 mm, and 90 mm from the hole edge. In the S-FH group, 7 strain gauges were arranged on the diaphragm, positioned at distances of 2 mm,

Figure 3. Fatigue loading device.

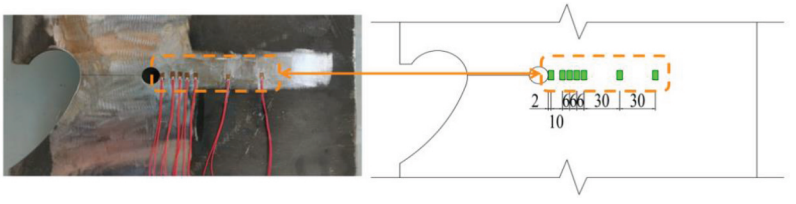

Figure 4. Strain measuring points.

12 mm, 16 mm, 18 mm, 24 mm, 30 mm, 60 mm, and 90 mm from the hole edge. The strain gauges were symmetrically arranged on both sides of the diaphragm, as shown in Figure 4.

The fatigue loading was performed using a tension–tension sine-wave load with a frequency of 10 Hz. Based on the stress response obtained from numerical simulations at the diaphragm cutouts (Lv et al. 2021, Qiang et al. 2023d), the nominal stress amplitude of diaphragm specimens was selected within the range of 45~55 MPa while appropriately expanding the load level to save the cost of fatigue test. Additionally, the stress ratio was chosen as 0.1. The specific load values are summarized in Table 2.

Table 2. Design value of fatigue load.

Name	Stress amplitude (MPa)	Stress ratio	Peak load (kN)	Valley load (kN)	Load amplitude (kN)
S-H-1	45	0.1	105.2	10.5	94.7
S-H-2	55	0.1	128.6	12.9	115.7
S-FH-1	55	0.1	128.6	12.9	115.7
S-FH-2	55	0.1	128.6	12.9	115.7
S-FH-3	55	0.1	128.6	12.9	115.7
S-FH-4	55	0.1	128.6	12.9	115.7

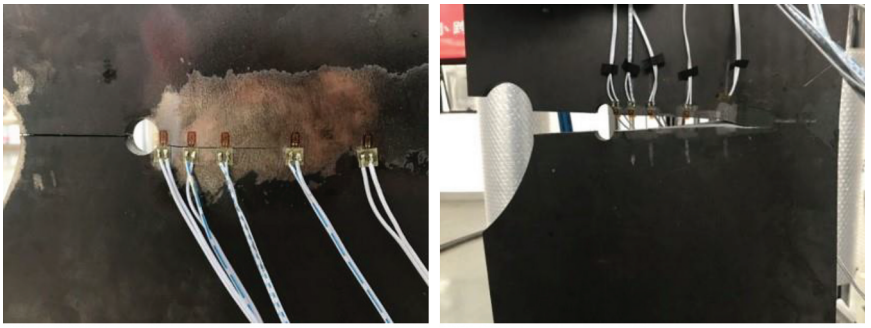
3 ANALYSIS OF TEST RESULTS

3.1 *Comparison on fatigue life*

The fatigue life, failure life, and crack propagation life of each specimen are summarized in Table 3. During the fatigue loading process, fatigue cracks were observed in the specimens when their length reached about 2 mm. Detecting fatigue cracks at shorter lengths proved challenging due to their limited visibility. Therefore, in this study, the fatigue life is defined as the number of load cycles corresponding to a crack length of 2 mm, the failure life is defined as the number of load cycles corresponding to a crack length of 70 mm, and the crack propagation life refers to the number of load cycles from the occurrence of secondary fatigue cracks to the crack propagation to 70mm.

Since all specimens were repaired by crack-stop holes to eliminate the original crack tip, the process from the beginning of loading to the initiation of cracking took a relatively long time. The nominal stress amplitude of specimens S-H-2 and the specimens in S-FH group was 55 MPa. Therefore, the enhancement effect of fatigue life is conducted using the loading results of the aforementioned diaphragm specimens.

Table 3. Cracking life of specimens.



Name	Fatigue life ($\times 10^4$)	Failure life ($\times 10^4$)	Crack propagation life ($\times 10^4$)	Improvement of Fatigue life	Propagation life
S-H-1	82.74	107.28	24.54	—	—
S-H-2	38.41	49.47	11.06	1	1
S-FH-1	282.50	317.01	34.51	7.35	3.12
S-FH-2	486.90	511.47	24.57	12.68	2.22
S-FH-3	406.30	457.73	51.43	10.58	4.65
S-FH-4	143.40	169.72	26.32	3.73	2.38

Comparing specimens S-H-2 and S-FH-4, after bonding the Fe-SMA plates based on the crack-stop hole, the increased local stiffness can effectively reduce the stress amplitude at the hole edge, and the fatigue life of S-FH-4 is 3.73 times that of S-H-2. Similarly, when comparing specimens S-H-2 and S-FH-1, the additional precompression is introduced while increasing the local stiffness of the cracked region by bonding and activating the Fe-SMA plates, significantly improving the fatigue performance of the diaphragm. The fatigue life of S-FH-1 is 7.35 times that of S-H-2.

Under the same activation temperature of Fe-SMA, the fatigue life of the diaphragm repaired by bonding 2.00 mm Fe-SMA plates (S-FH-2) is 12.68 times that of the diaphragm repaired solely by crack-stop hole (S-H-2). When considering the same thickness of 2.00 mm for Fe-SMA plates, the fatigue life of S-FH-3, with Fe-SMA activated at 150□, is 10.58 times that of S-H-2. These findings indicate that bonding 2.00 mm Fe-SMA plates can more effectively increase the local stiffness of the cracked region and introduce precompression, thereby achieving a better repair effect.

3.2 *Failure mode analysis*

The inclusion of a crack-stop hole eliminates the existing crack tip, as the source of fatigue propagation. However, stress concentration occurs at the hole edge. After a prolonged period of loading, fatigue cracks initiated at the hole edge and continued to propagate during subsequent loading cycles, as depicted in Figure 5. Notably, factors such as uneven internal defects and eccentric loading on the diaphragm may result in deviations between the crack initiation points and the hole edge center.

(a) (b)

Figure 5. Fatigue failure of specimens S-H group: (a) cracking deviation from the hole center, (b) cracking along the hole center.

For the S-FH group, the diaphragm specimens basically underwent three main stages during the loading process: crack initiation, stable crack propagation, and accelerating crack propagation caused by continuous damage accumulation. Ultimately, failure occurred due to the continuous increase in crack length, resulting in insufficient residual bearing capacity of the cracked section, as illustrated in Figure 6. The Fe-SMA plates can effectively enhance the local stiffness of the cracked region, and the activated Fe-SMA can additionally introduce precompression of 40~60 MPa (Qiang et al. 2023a, Qiang et al. 2023c). As a result, the fatigue life and failure life of the specimens in S-FH group are significantly higher than those of the specimens in S-H group. Notably, due to the longer fatigue life of S-FH-2, the bonded interface accumulated damage continuously with fatigue loading, resulting in debonding failure between the Fe-SMA plate and diaphragm, significantly shortening the stage of stable crack propagation.

4 STRESS RESPONSE AT HOLE EDGE

4.1 *S-H group*

The strain monitoring results at a distance of 2 mm from the hole edge provide insights into the cracking condition of diaphragms. Therefore, the stress calculation results at the distance of 2 mm from the hole edge (referred to as stress a-1 and b-1 on both sides of the diaphragm) have been selected for analysis.

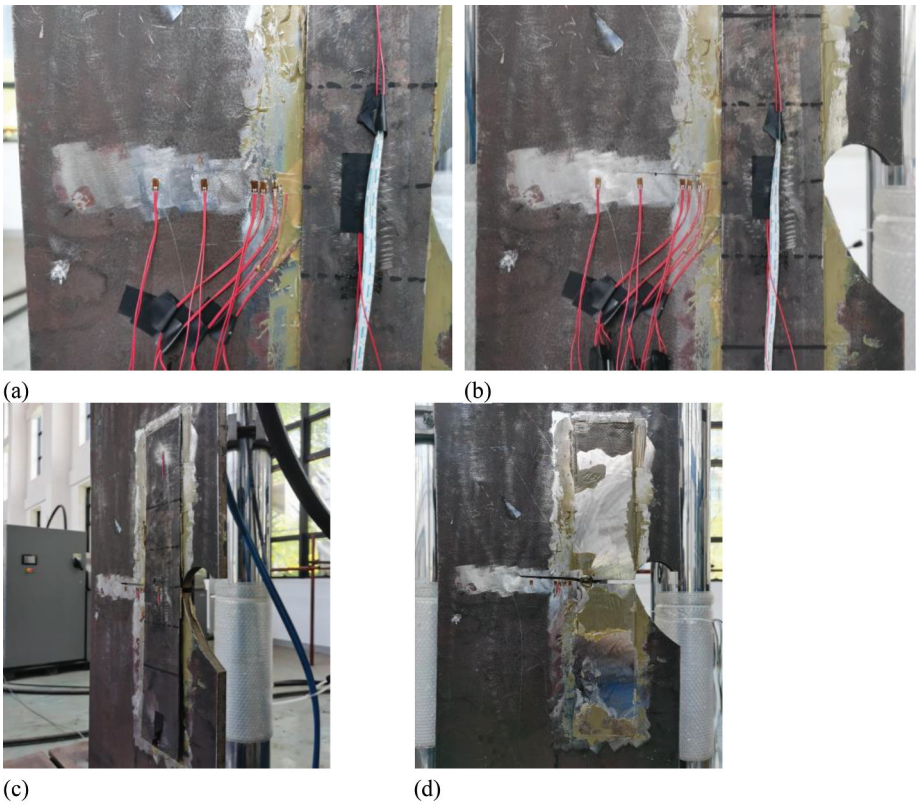


Figure 6. Fatigue failure of specimens in S-FH group: (a) stable crack propagation, (b) accelerating crack propagation, (c) debonding of the Fe-SMA plate, (d) final destructive form.

The data for the specimens in S-H group remained relatively stable throughout the loading process, and the stress results calculated at positions a-1 and b-1 were also close, as depicted in Figure 7. The average stress amplitudes at the hole edges of specimens S-H-1 and S-H-2 are measured as 302.06 MPa and 367.02 MPa, respectively.

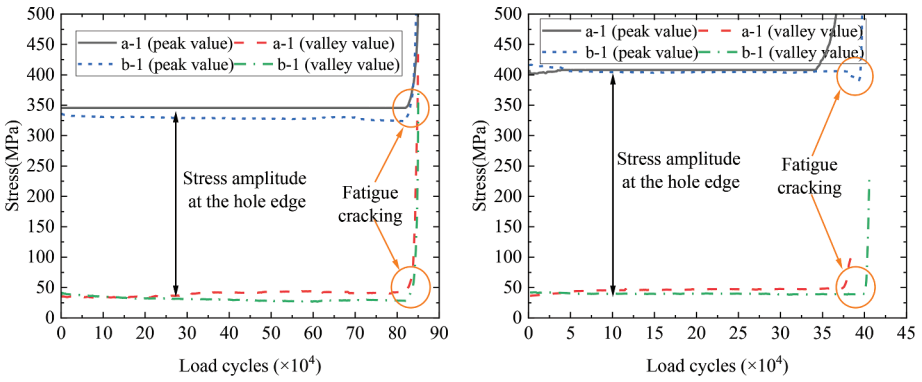

Figure 7. Stress response at hole edges of S-H group: (a) S-H-1, (b) S-H-2.

4.2 *S-FH group*

For the specimens in S-FH group, the stress amplitude at the hole edge increased significantly during the early stages of fatigue loading due to the creep of Fe-SMA, resulting in a loss of reinforcement effect, as shown in Figure 8.

After entering the stress stabilization stage, the strain monitoring data remained relatively stable. The average stress amplitudes at the hole edges of specimens S-FH-1, S-FH-2, S-FH-3, and S-FH-4 are 215.93 MPa, 191.92 MPa, 202.13 MPa, and 256.16 MPa, respectively.

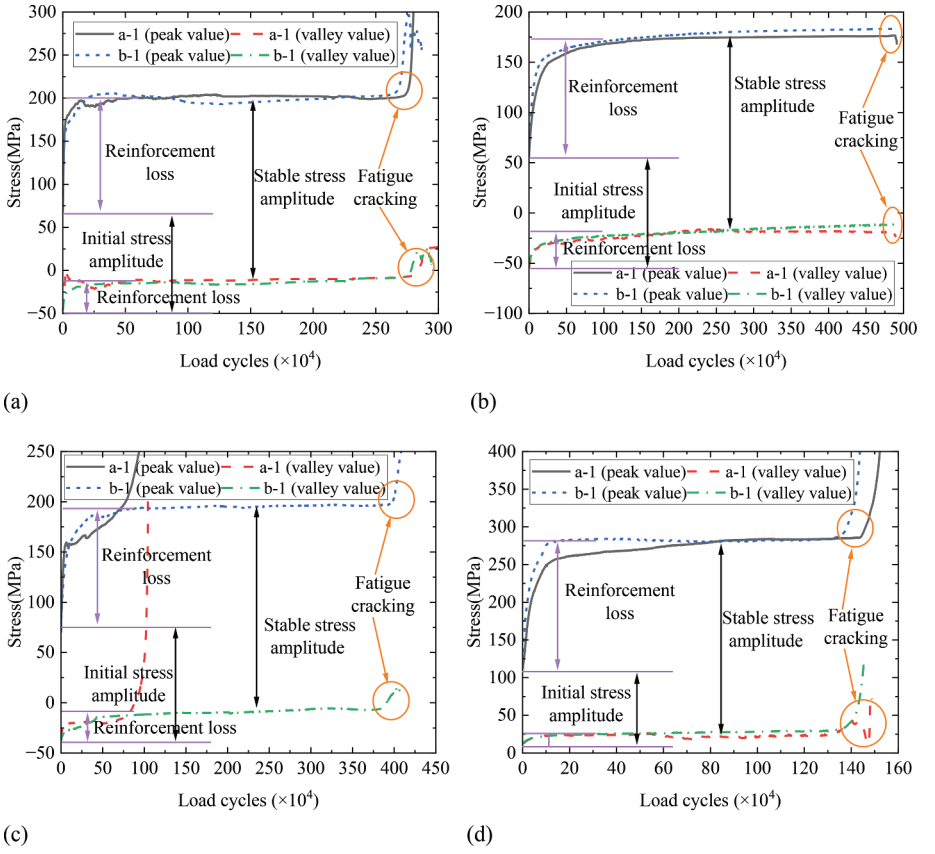

Figure 8. Stress response at hole edges of S-FH group: (a) S-FH-1, (b) S-FH-2, (c) S-FH-3, (d) S-FH-4.

5 CONCLUSIONS

Based on the proposed repair method of Fe-SMA plates covering crack-stop holes, this paper conducted the fatigue test on the repaired diaphragms and obtained their fatigue life, failure modes, and stress responses at hole edges. The main conclusions are as follows:

(1) The crack-stop hole eliminates the crack tip, which is the prominent factor in fatigue propagation. However, the hole edge becomes a new location for stress concentration and potential initiation of fatigue cracks. For the diaphragm reinforced by Fe-SMA, the Fe-SMA plates do not experience debonding before the diaphragm failure when its fatigue life is short. However, for longer fatigue lives, the Fe-SMA plates may experience debonding before the diaphragm failure due to significant cumulative damage at the bonded interface.

(2) Bonding Fe-SMA plates can significantly increase the stiffness of the cracking region and effectively reduce the stress amplitude. Based on this, activating Fe-SMA can further introduce precompression, reducing the average stress of the cracking region. The fatigue life of the diaphragm repaired by activated Fe-SMA plates with a thickness of 2 mm is 12.68 times that of the diaphragm repaired solely by the crack-stop hole.
(3) In the initial loading stage, Fe-SMA experiences creep under fatigue load, leading to a gradual increase in the stress amplitude at the edge of crack-stop holes. The repair system of Fe-SMA plates covering crack-stop holes exhibits a loss of reinforcement effect, with the reinforcement loss stage accounting for approximately 1/6 of the entire loading process. Once the creep of Fe-SMA is essentially completed, the specimens enter the stable bearing stage.

Experimental study on seismic performance of different failure modes of RC shear keys

H. Mei & A.X. Guo
Key Lab of Smart Prevent and Mitigation of Civil Engineering Disasters of the Ministry of Industry and Information Technology, Harbin Institute of Technology, Harbin, China

ABSTRACT: The capacity of horizontal failure shear keys is larger than diagonal and sliding failure modes owing to its secondary stiffness-strengthening stage. Nevertheless, the seismic performance of shear keys with horizontal failure mode has received limited attention yet. This investigation involved the design and fabrication of ten reinforced concrete (RC) exterior shear key specimens. A quasi-static experiment was conducted to assess the seismic performance of these shear key under cyclic load effects. The concerned properties include crack development, force-displacement relationship, rotation deformation and the stress distribution. The experimental results indicate that the failure mode is dependent on the capacity ratio between reinforcements. Horizontal failure shear key exhibits apparent second-rising of stiffness after its peak capacity, while the diagonal and sliding failure shear key undergo continuous decline under substantial deformations. Comparing the measured data with existing prediction models indicates that the models are more applicable to shear keys with diagonal failure mode as opposed to the others.

1 INTRODUCTION

Bridges as crucial components of transportation must endure seismic impacts. The vulnerability of bridges super- and sub-structures largely depends on the lateral restraints. The shear keys fixed to cap-beam serve as critical components for this purpose, and have been widely utilized in small- and medium-size bridges due to the reparability and detectability of damages. However, it must be designed also to prevent damages to pier columns as a sacrificial fuse. As per the AASHTO (2012), shear keys should be designed with over-strength that is further related to the capacity of piles and swing walls. Caltrans (2000) suggested a design method by incorporating a reduction factor to ensure its earlier failure. Insufficient researches in this aspect has led to severe damages during major earthquakes in the past decades. Examples can be given with respect to Wenchuan earthquake in China (K. Kawashima et al., 2009) and seismic incidents in Chile (F. Schanack et al., 2012), in which the poor shear key design resulted in bridge destruction. The 2011 Great East Japan Earthquake caused various bridges damaged due to the shear key design (M. Akiyama et al., 2013), prompting specific revision to the local design code for skewed bridges.

In recent decades, extensive studies have delved into the mechanical properties of shear keys, considering factors like friction and rebar shear key strength. Numerous models were proposed to predict their seismic resistance. S.H. Megally et al. (2001) conducted experimental tests to address the behavior of these components under monotonic lateral forces, in which significant distinctions were observed between two failure modes. P.F. Silva et al. (2009) extensively used the experimental results to propose an analytical mode with specific focus on exterior shear keys. Han & Zhou (2017a,b) investigated vertical exterior shear keys and identified two failure modes using six shear key specimens. Analytical formulas were proposed in

DOI: 10.1201/9781003483755-472

their research based on the test results. In engineering practice, the shear keys with diagonal failure mode are mostly adopted, while the sliding failure mode is also implemented to for post-disaster repair. However, both failure modes exhibit a continuous decline in resistance after the peak values, leading to potential risks to the bridge decks owing to inadequate lateral limits. Whereas, the horizontal failure shear keys demonstrate a secondary strengthening stage, so that they can be used to enhance protections for bridges in face of multiple earthquake events and multi-hazard actions. However, studied on such shear keys are limited yet.

Therefore, this study conducted a series of laboratory test on RC shear key specimens with horizontal, diagonal and sliding failures. Five specimens with ten shear key units were constructed, with the quasi-static method adopted along with monotonic cyclic loading. The primary contents of paper are organized as follows: 1) the introduction of specimen design and test setups were presented in section 2; 2) section 3 illustrates the major test results, with emphasis on crack development; 3) the seismic performance of each failure mode of shear key is analyzed in section 4, focusing on peak capacity, deformation, rotation angle and stress variations. In this section, the measured results are also compared with existing models in terms of peak capacity and envelope pattern; 4) concluding remarks are provided in the last section.

2 SPECIMEN DESIGN

2.1 *Details of tested specimens*

The experimental test employed five specimens with each containing two test units of RC shear keys. These specimens were designed with a 1:3 geometric scaling. The specimens measure 1840 mm in length, 540 mm in width and 1100 mm in height, with a 400 mm high foundation base to ensure adequate reaction force. Detailed geometric layouts and rebar arrangement are illustrated in Figure 1. The reinforcements in shear key specimen consist of vertical, horizontal and distributed components. Based on existing shear key studies, the capacity ratio (V_v/V_h) is the key factor that essentially determined shear key failure modes. Consequently, two rebar configurations were employed, with monolithic and construction joints also introduced to achieve horizontal, diagonal and sliding failure modes. Table 1 provides the detailed parameters for each test unit group. In this table, specimens SKH1-SKH4 were

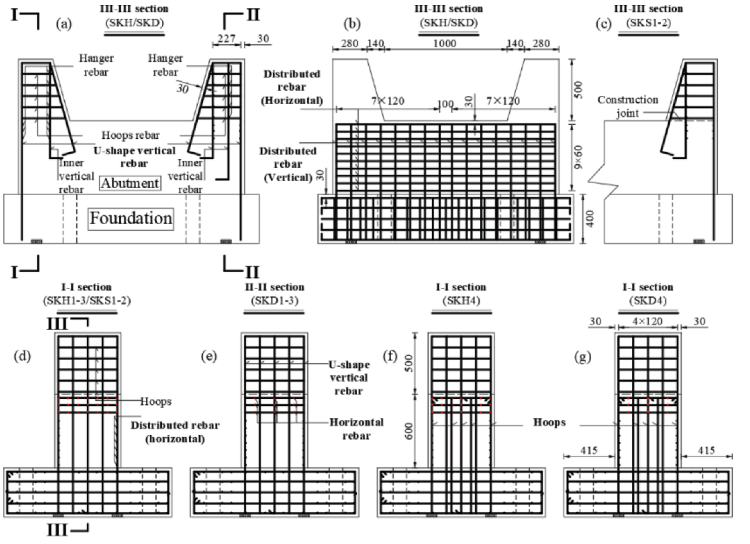

Figure 1. Geometry layout and reinforcement configuration.

designed with higher capacity ratio at 2.40, while SKD1-SKD4 had a lower ratio at 0.80. Figure 1(a)-(b) presents the layouts of corresponding reinforcement.

The U-shaped rebar was used along the inclined surface to accommodate the non-uniform shear key section. Group SKH has less vertical reinforcement than group SKD to satisfy strong horizontal constraints. Note that all specimens in the same group shared the same lateral constraints except for SKH4 and SKD4, where transverse hoops replaced the original distributed rebar, see Figure 1(f)-(g). The cross section of SKH and SKD groups ware presented in Figure 1(d) and (e), in which 21 and 9 horizontal rebar was used with the diameter of 16 mm. For shear keys with sliding failure mode, the capacity ratio is identically set as group SKH, whereas a dry construction joint was further introduced between the shear key and the abutment, see Figure 1(c). This study used C40 concrete (fcu,k = 40 MPa) and HRB400 (fy = 400 MPa) rebar for horizontal and vertical reinforcements, while HRB300 (fy = 300 MPa) rebar was used for distributed and hoop rebar. Concrete strength was measured using standard tests, with an average compression strength of 45 MPa. The rebar strength is also tested and takes the mean value of 450 MPa and 325 MPa for HRB400 and HRB300 rebar, respectively.

Table 1. Reinforcement configuration of shear key specimens.

		Horizontal reinforcement			Vertical reinforcement				
Group	Specimen	Configuration	Total area (mm^2)	Rebar ratio (%)	Configuration	Total area (mm^2)	Rebar ratio (%)	Capacity ratio	Special layout
SKH	SKH1	21Φ16	4220	1.30	15Φ12	1696	0.75	2.49	Distributed rebar

2.2 *Experimental setups*

Figure 2(a) illustrates the test facility schematic, with a 2000 kN electro-hydraulic servo actuator with a ±200 mm stroke for horizontal force application. The actuator was fixed on a reaction wall to transmit forces to shear key specimens via a steel frame system. A linkage component was used to connect the two steel H-shape beams shown in this figure, and the forces were applied directly through the two loading cells at the opposite side. A distribution beam was employed to balance the vertical reaction, with a 500 kN loading effects generated by a hydraulic jack on the top, while four steel rollers below were used to eliminate the interface friction, which was recorded during the initial loading phase. It was found that the friction was minor and thus excluded from the test results in order to obtain the exact resistance. The actuator was loaded to contact the specimen by following the specified loading protocol. Note that only the shear key unit on one side was tested at each time, followed by the remaining tested in the opposite direction.

To accommodate the monotonic behavior of this component during seismic events, the quasi-static loading method was performed on all specimens with monotonic-cyclic loads. Besides, a hybrid loading protocol was designed for the loading control, as shown in Figure 3. The first phase was controlled by the loading forces that increase at 100 kN increment. The second phase was controlled by the displacements with varying intervals at different

stages: 2 mm (10-20 mm), 5 mm (20-50 mm), 10 mm (50-100 mm) and 20 mm (>120 mm). The first force-controlled phase included two cycles for each level while the displacement-controlled phase included three cycles. While the typical experimental tests on RC structures were stopped at 85% peak strength, they were subjected to extensively deformation with at least 100 mm deformation to highlight their post-buckling properties.

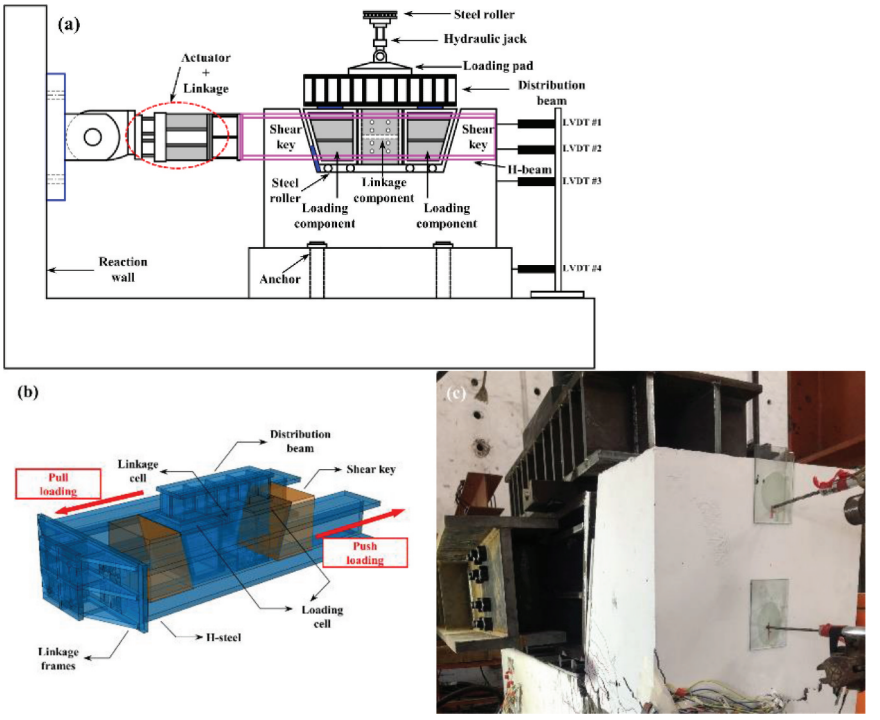

Figure 2. Geometry layout and reinforcement configuration.

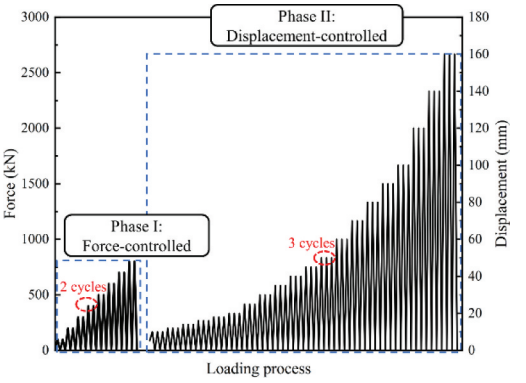

Figure 3. Loading protocol during experimental testing.

Four LVDT sensors were sued to measure the shear key deformation at different heights in the vertical direction, as seen in Figure 4(a). The measured results at points A-D correspond to the top shear key movement, the displacement at the load-applying height, the abutment deformation and the base sliding distance, respectively. On this basis, the exact deformation

of shear key at the loading height can be calculated by $\delta_2' = \delta_2 - \delta_4$ to eliminate the influence of base sliding. In this study, 32 strain gauges were used to investigate the strain distribution of reinforcements in different positions, as shown in Figure 4(b)-(c). In addition, six grouped strain gauges were installed on the abutment concrete surface to obtain the complex stress conditions, see Figure 4(d).

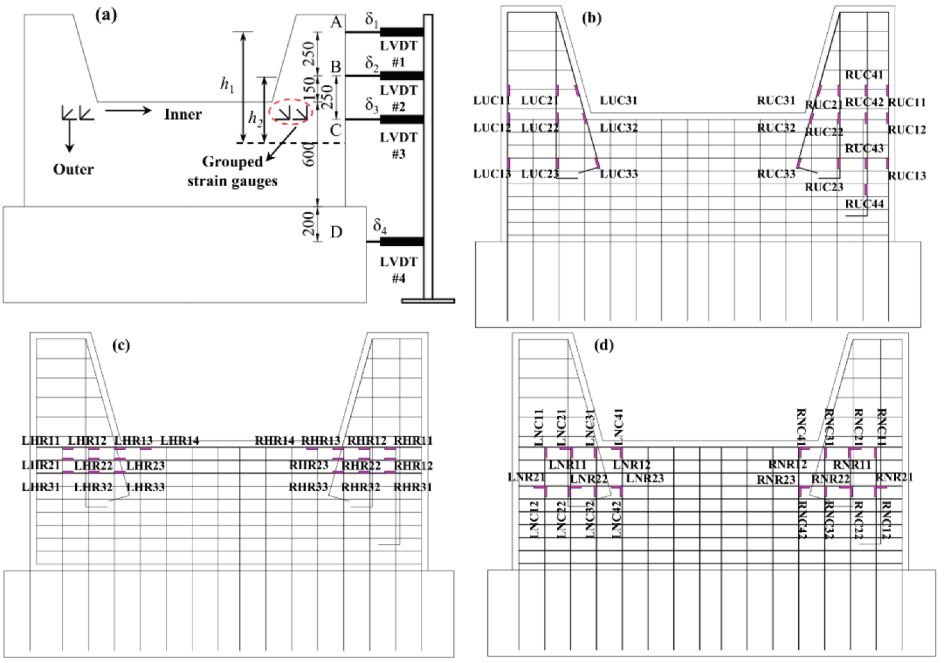

Figure 4. Loading protocol during experimental testing.

3 EXPERIMENTAL OBSERVATION

Figure 5 presents the crack development in different failure modes. The test results show that specimens SKH1-SKH3 experienced horizontal shear failure, with the major crack near the interface, see Figure 5(a). The first crack initiated at 100 kN for this failure mode, and the peak capacity was accompanied with significant rebar fractures. It should be noted that SKH3 exhibits unusually higher peak capacity due to the incorrect operation and was thus excluded from the succeeding discussions. To prevent this in other tests, loading setups is fastened to ensure before the other experiments. In comparison, specimens SKD1-SKD4 exhibits diagonal failure mode due to the lower capacity ratio at 0.80. The diagonal failure shear key had a larger angle of major crack, with the initial crack emerging at around 200 kN, as shown in Figure 5(b), and more minor cracks were observed before the peak capacity was reached. The main failure pattern of this failure mode is related to extensive concrete cracks. The sliding failure shear key also exhibits major cracks parallel to the interface because of the absent concrete connection, and the crack further extended to the backwall edge and then turns downward to form a significant crack, as seen Figure 5(c). The first crack was observed at around 100 kN, and the cracks were found to develop sooner to the backwall edge. Similar to the horizontal failure mode, the sliding failure shea key also exhibited successive rebar fractures as the load magnitude rises.

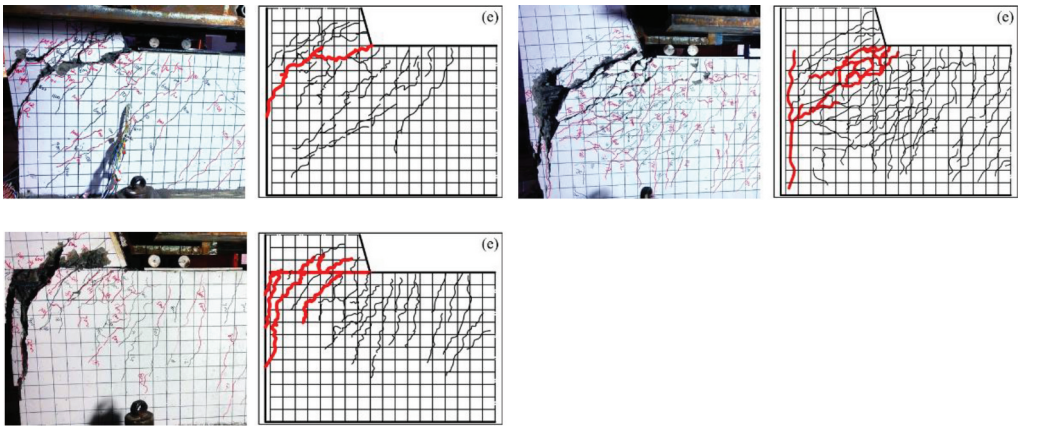

Figure 5. Development of concrete cracks on specimens: (a) horizontal failure; (b) diagonal failure; (c) sliding failure.

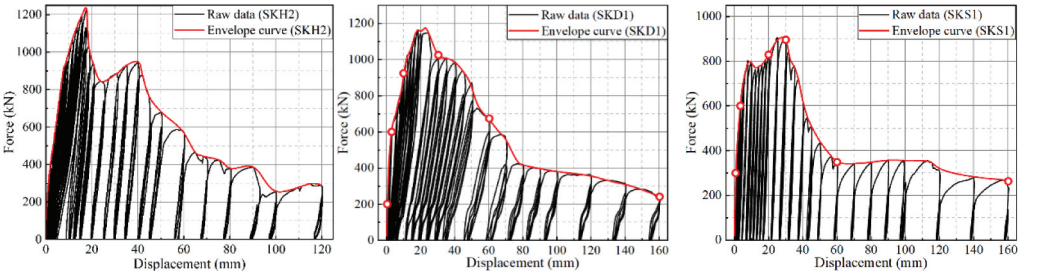
Figure 6 indicates the force-displacement relationship for each failure mode. It is found that the horizontal failure shear key has an initial stiffness at around 322 kN/mm, whereas the diagonal failure shear key takes a mean value of 455 kN/mm. In comparison, the sliding failure shear key shows the lowest stiffness at around 271 kN/mm. For the horizontal failure mode, the unloading stiffness remains constant throughout the loading process, while the diagonal failure shear keys indicate a downward trend. The sliding failure mode also exhibits a well-maintained stiffness in this process. Notably, the horizontal failure shear key yielded a second-rising stage after the first peak capacity. By comparison, the capacity of diagonal and sliding failure shear keys decreases continuously after the peak value. Comparing the damage development in SKH1-3 and SKH4, as well as SKD1-3 and SKD4 implies that the hoop rebar has negligible to the maximum resistance of RC shear keys, whereas it can result in the earlier capacity decline for the horizontal failure shear key, and the lower ultimate strength for both diagonal and horizontal failure modes.



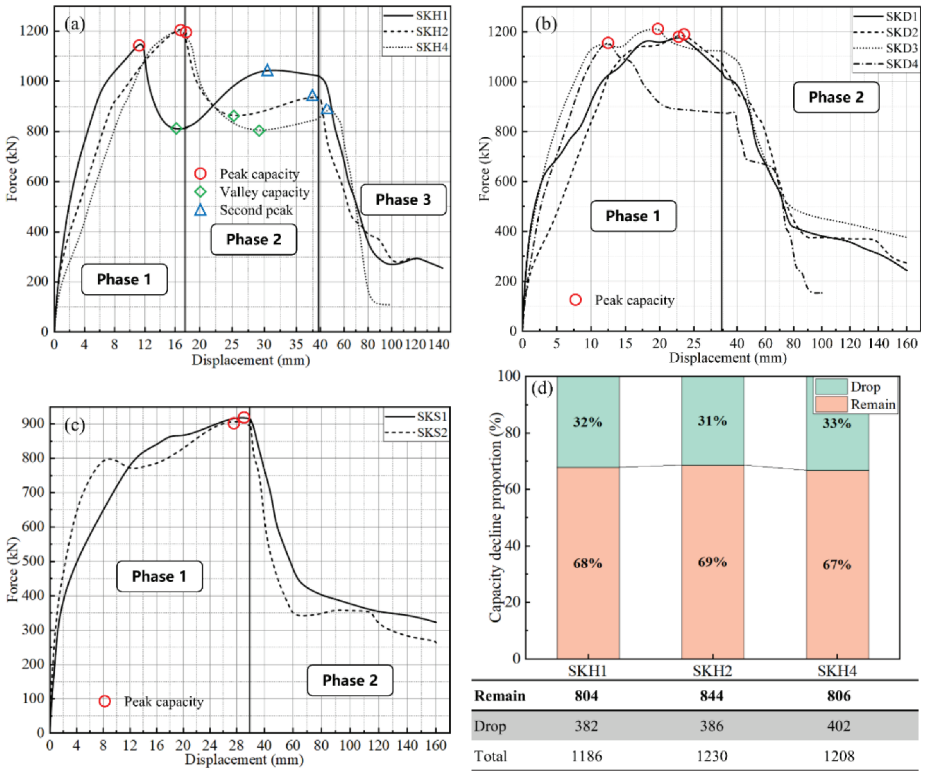


Figure 6. Force-displacement relationship of specimens: (a) horizontal failure; (b) diagonal failure; (c) sliding failure.

4 TEST RESULT ANALYSIS

4.1 *Load-displacement relationship*

Figure 7 illustrates the piecewise stages of envelope curves for different failure modes. The nonuniform scaling of the horizontal axis at different stages better highlights mechanical

characteristics. Figure 7(a) shows that horizontal failure shear keys have three phases including the elastic stage before first peak, the second-rising stage between the first and second peaks, and the softening stage after the second peak. Some vertical reinforcement in this failure mode fails when the peak capacity is reached, and the second resistance increase is associated with the hardening effect of the vertical reinforcement. Fig. 7(d) shows resistance reduction after reaching peak values, with early reinforcement fracture reducing capacity by approximately 32% on average compared to peak strength. Comparing envelope curves in diagonal and sliding failure modes in Figure 7(b)-(c), both exhibit two phases in the entire protocol: elastic stage before peak strength and a succeeding softening stage. The second rising stage disappears for the diagonal failure mode as abutment concrete crashes at peak strength, diminishing constraints on vertical reinforcement and causing resistance decrease. Whereas, the two-stage envelope curve results from nonuniform stress in vertical reinforcement for the sliding failure mode.

	SKH1	SKH2	SKH4
Remain	**804**	**844**	**806**
Drop	382	386	402
Total	1186	1230	1208

4.2 *Comparison with existing models*

Several researchers and design codes emphasize the significance of estimating the mechanical properties of RC shear keys, leading to the proposal of various analytical models for predicting peak capacity and envelope curves. In Figure 8 the test results are compared with existing models, presenting the average capacity for each failure mode through shadow regions. Megally's (2001) model shows relatively good estimation for peak capacity in diagonal failure shear keys, while Zielinski's (1995) method exhibits poor applicability. AASHTO method

overestimates strength, while Caltrans significantly underestimates capacity. Prediction accuracy diminishes for horizontal failure mode due to limited related research. Specifically, the sliding failure shear key has poor peak strength estimation, with errors exceeding 7% for the Megally-friction (2001) model, indicating that existing codes struggle to predict the peak capacity of this shear key type.

Additionally, experimental outcomes are compared with existing research in terms of the force-displacement relationship throughout the loading process using Megally's analytical model (Figure 9). Sliding failure shear key results are excluded due to the model's initial development for monolithically-casted shear keys. The model agrees well with both horizontal and diagonal failure shear keys before reaching peak capacity, with overestimation for horizontal failure mode and underestimation for diagonal failure mode. However, Megally's method poorly represents the post-peak capacity for horizontal failure shear keys, lacking the second-strengthening stage and defining a plateau stage instead, as shown in Figure 9(a). The model also significantly overestimates capacity after 60 mm. In contrast, the model exhibits relatively good agreement with diagonal failure shear keys, accurately predicting post-peak capacity before the plateau-like stage but considerably underestimating ultimate strength, with a capacity difference exceeding 300 kN, see Figure 9(b).

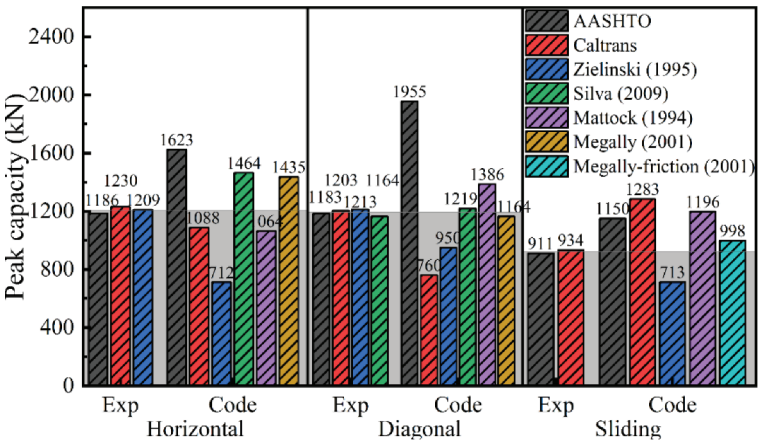

Figure 8. Comparison of peak capacity between test results and existing models.

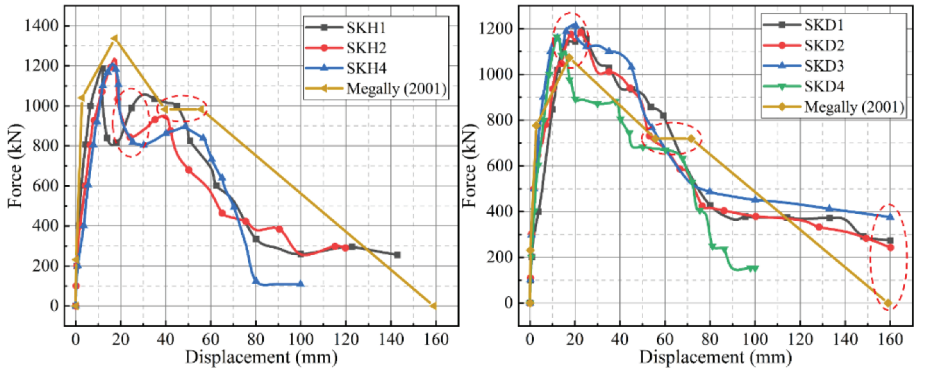

Figure 9. Comparison of envelope curves for shear keys with different failure modes: (a) horizontal failure mode; (b) diagonal failure mode.

5 CONCLUSION

This study conducts a quasi-static experiment on the seismic performance of RC exterior shear keys with three failure modes. Ten experiments were performed on exterior shear keys exhibiting horizontal, diagonal, and sliding failure modes. The conclusions are summarized as follows:

(1) The seismic performance of RC shear keys varies based on the reinforcement configuration. The capacity ratio of horizontal and vertical reinforcements significantly influences the failure mode under cyclic action. The study indicates horizontal failure occurs when the ratio approaches 2.49, while a ratio close to 0.80 results in diagonal failure.
(2) The force-displacement relationship reveals distinctive behaviors. The exterior shear key with horizontal failure exhibits a secondary stiffness strengthening capacity. The shear key with diagonal failure starts with the largest initial stiffness, gradually decreasing, while the sliding failure shear key has the least stiffness due to the absence of concrete.
(3) Peak resistance is influenced by factors such as horizontal, vertical, distributed reinforcement, and interface state. For horizontal failure shear keys, vertical reinforcement determines capacity, while with insufficient horizontal constraint, resistance depends on horizontal reinforcement capacity, leading to diagonal failure.
(4) Existing codes and research provide acceptable capacity estimates for diagonal failure shear keys but poorly predict those with horizontal or sliding failure modes. Further research is needed for accurate capacity prediction in these cases.
(5) Existing model of shear key envelope curve shows relatively good agreement with diagonal failure mode in terms of the curve shape but underestimates the peak capacity and ultimate strength. However, it has limited applicability to horizontal failure shear key due to the poor prediction toward peak capacity, second-strengthening stage and post-peak capacity.

Progressive failure analysis of strengthened masonry arch bridges

T. Kamiński
Wrocław University of Science and Technology, Wrocław, Poland

C. Costa
CONSTRUCT-LESE, Polytechnic Institute of Tomar (IPT), Tomar, Portugal

ABSTRACT: The paper focuses on the numerical analysis of strengthening solutions dedicated to masonry arch bridges. It concentrates on the longitudinal behaviour of the arch of single-span bridges. The analysed methods are related to the addition of specific structural components on both sides of the arch – extrados and intrados. Two basic solutions are studied based on a rigid or flexible layer corresponding to the most common techniques being applied to these bridges around the world. A comparison of the selected strengthening techniques is given considering their impact on the bridge's structural behaviour under incremental static loadings. Particular attention is paid to the analysis of the progressive failure being developed along with the increasing load. For this purpose, an advanced nonlinear Finite Element models using a meso-modelling technique are presented and selected results showing the mechanical performance of the structure before and after strengthening are provided. The interpretation of the bridge model response is based on the analysis of the evolution of the structural failure modes up to the maximum load capacity of the bridges, namely in terms of the interaction of internal forces M-N in representative arch cross-sections determined also analytically. Conclusions are formulated to identify optimum reinforcement solutions regarding both the sectional as well as the global performance of the structures.

1 INTRODUCTION

1.1 *Arch strengthening methods*

Common strengthening solutions for the arch barrel involve inserting a new flexible or rigid layer on the arch intrados or extrados which prevent the formation of the hinges' mechanisms improving the arch behaviour in the longitudinal direction.

Adding thin flexible layers on the arch extrados (FLEX/EXT) or intrados (FLEX/INT) are strengthening solutions which refer to the addition of composite materials based on new layers of FRP laminates or composite materials reinforced with fibre fabric of different materials, such as Steel, Carbon, Glass, PBO, and Basalt, based on a polymeric (FRP) or a cementitious matrix (FRCM/FRM/TRM). Reinforcement with longitudinal steel rebars embedded near the arch surface may be also represented by FLEX type solutions.

The addition of a thick rigid layer either in the extrados (RIG/EXT) or in the intrados (RIG/INT) of the arch barrel represents also a frequent strengthening solution comprising the addition of a concrete shell, which can be reinforced with rebars or reinforcement meshes made of steel or FRP. This type of solution was used in the cases of the Remondes bridge and Tavira bridge, where a reinforced concrete layer was applied in the intrados and extrados, respectively, as part of a global reinforcing intervention as reported by Costa *et al.* (2008). Strengthening solutions grouped into RIG type also refer to the addition of a (thick) layer of a cementitious matrix reinforced with fibres, usually made of steel, e.g. SFRM, or the addition

DOI: 10.1201/9781003483755-473

of ultrahigh-performance concrete (UHPC) applied on the intrados of a stone arch bridge, as reported in Wang *et al.* (2022). Also considered rigid layer solution is the addition of an RC trough or ribbed cover, as reported in Iacobini *et al.* (2020).

1.2 *Analytical description of strengthening*

The cross-section resistance of the selected arch-strengthening solutions including the addition of a (thin) flexible layer or a (thick) rigid layer, may be interpreted analytically in terms of the M-N interaction diagrams (Alecci *et al.* 2016, Simoncello *et al.* 2019). The applied assumptions consider a perfect bond between the reinforcement and the masonry units, the Bernoulli principle and no sliding between masonry units. Besides, any damage due to traction is concentred in the arch radial mortar joints having zero tensile strength. Opening in the radial joints may also occur in the zone of the reinforcing layer where also no tensile strength is admitted.

M-N interaction diagrams, representing the strengthened cross-section resistance are evaluated considering both the positive and negative bending moment combined with a compressive axial force. Figure 1a, b shows a scheme of the strengthened solutions with a thin flexible tensile resistant layer in the intrados and with a thick compressive resistant layer in the extrados. It also defines the corresponding strains and stresses distributions. F_m and F_r represent the resultant forces of the stress distributions in both materials, masonry and reinforcement, respectively.

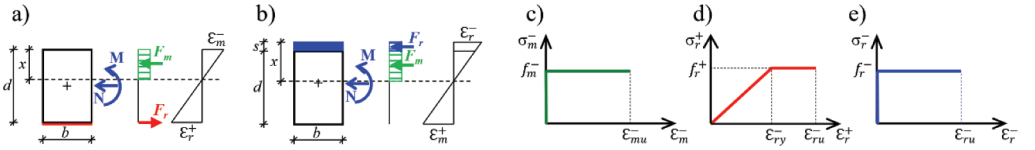

Figure 1. Strain and strength distributions of the strengthened cross-section under M-N for: a) a flexible layer, b) a rigid layer. σ-ε constitutive relationships for: c) masonry, d) flexible reinforcement, e) rigid reinforcement.

The stress-strain (σ-ε) relationships defined for masonry and reinforcements are also schematically represented in Figure 1. The masonry behaviour is characterised by a compressive resistant material with a simplified rigid-plastic σ-ε evolution with constant compressive strength f_m and a maximum strain of ε_{mu}^-. It results in rectangular stress distribution of the compressed zone of the cross-section up to the neutral axis depth (x). No tensile strength is assigned to masonry. The tensile strength assured by the flexible layer follows an elastic-plastic constitutive behaviour (Figure 1d) with the maximum stress equal to f_r^+. No compressive strength is set for the layer. A simplified rigid plastic stress-strain (σ-ε) relationship is also adopted for the rigid layer reinforcement material (Figure 1e) as well as no tensile strength is assigned to it. The maximum admissible compressive ε_{ru}^- values are set equal to the masonry compressive strain ε_{mu}^-.

The envelope of the M-N interaction is evaluated considering the internal forces' equilibrium and strain compatibility conditions at the cross-section level of both strengthening solutions. Compressive N force is assumed negative. The envelope of the M-N is further normalized in terms of the ν, μ and ω parameters (Equation 1), based on the masonry compressive strength f_m. ν and μ represent the normalized axial force and bending moment and ω represent the mechanical reinforcement ratio, where for the flexible layer $F_r = A_r f_r^+$ (A_r stands for area of the flexible reinforcement) and for the rigid solution $F_r = sbf_r^-$ (with s and b representing the thickness and width of the rigid reinforcement layer as shown in Figure 1).

$$\nu = \frac{N}{bdf_m},\ \mu = \frac{M}{bd^2 f_m},\ \omega = \frac{F_r}{F_m} = \frac{F_r}{bdf_m} \tag{1}$$

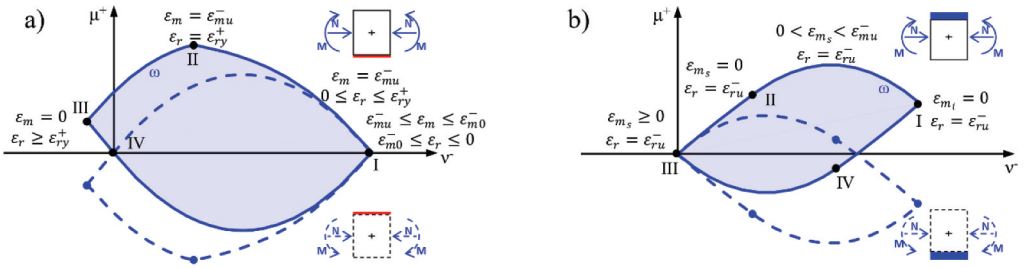

Figure 2. μ-ν generic envelopes of a strengthened cross-section for: a) a flexible, b) a rigid reinforcement.

Finally, for both study cases, the μ-ν interaction diagrams are obtained representing different failure conditions, as shown schematically in the multi-branch envelopes in Figure 2. Each branch represents a different failure condition, by defining the internal forces' equilibrium and strain compatibility conditions with the corresponding material stress-strain domain defined according to the σ-ε behaviour shown in Figure 1.

For the flexible strengthening solution, four cases of failure conditions are considered to set the corresponding branches of the μ-ν envelope shown in Figure 2a. The failure conditions of the first case (from I to II) are determined by the masonry compression failure with $\varepsilon_m = \varepsilon_{mu}^-$ and the reinforcement tensile strains ranging from 0 to ε_{ry}^+. The second case (from II to III) corresponds to the limit condition determined by the reinforcement failure in tension ($\varepsilon_r = \varepsilon_{ry}^+$) and the masonry compressive strain ε_m falling from ε_{mu}^- to 0. The third case (from III to IV) involves reinforcement stresses in the elastic regime with $\varepsilon_r \leq \varepsilon_{ry}^+$ and $\varepsilon_m = 0$. The fourth branch of the ν-μ envelope (from IV to I) is defined for a negative bending moment and a compressive axial force, with the cross-section resistance assured by the masonry in compression, neglecting the strength of the flexible reinforcement layer under compression.

For the rigid strengthening solution, four cases of failure conditions are considered to set the corresponding branches of the μ-ν envelope with the analytical ν and μ expressions and their strain domain. For the first case (from I to II) the failure conditions are determined by the compressive strength of the masonry and the reinforcement layer above the neutral axis, with no tensile strength of the masonry fibres below the neutral axis. The maximum strain at the reinforcement top fibre corresponds to $\varepsilon_r = \varepsilon_{ru}^-$ and at the masonry top fibre evolves from a strain value lower than ε_{mu}^- to 0, when the neutral axis passes below and in the interface of both materials, respectively. In the second case (from II to III) the neutral axis is in the reinforcement layer, which evolves from the bottom fibre to the top, with the maximum strain at the top fibre equal to ε_{ru}^-. Branch III-IV (third case) is associated with a negative bending with the neutral axis in the masonry zone. Branch IV-I (fourth case) corresponds to the neutral axis in the reinforcement zone, evolving from the reinforcement-masonry interface to the reinforcement top fibre, when the entire cross-section is under compression. Both envelopes should be present upside down when the reinforcing layer is located on the opposite side of the arch.

2 NUMERICAL MODELLING STRATEGY

The utilized Finite Element model of the structure comprises two-dimensional plane strain problem taking into account (see Figure 3): the arch barrel, the soil above the arch barrel and in the access zones of the bridge, a loading element and a reinforcing layer. Except its self-weight the bridge is subjected to an external loading simulating a pressure of a vehicle single axle.

The arch barrel is modelled as a continuous area defined by means of an advanced non-linear elastic-plastic at compression and low-tensile-resistant constitutive material model – the most adequately representing masonry. A meso-modelling technique (Kamiński & Bień 2013) to discretize the arch is used which is based on division of the arch barrel area into masonry

segments with homogenised properties (with compressive strength f_b) and into layers of radial joints between them. The distinguished radial joints comprise the areas where cracking may occur forming a plastic hinge. The material of the joints defined by a plastic-damage model (Lubliner et al. 1989) corresponds to a constitutive model of concrete. The initial yield stresses at compression and are tension equal to typical values: f_m = 4 MPa and f_t = 0.1 MPa correspondingly.

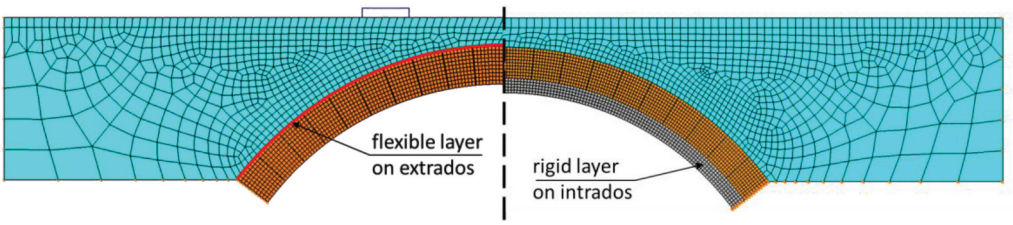

Figure 3. FE model of a masonry arch bridge strengthened with: a flexible (left) or a rigid (right) layer.

The other main properties of material assumed in analyses are shown in Table 1 where: E_b, E_m, E_r, E_s – Young modulus of masonry segments, mortar, reinforcement and soil; γ_s, γ_M, γ_r – unit weights of soil, masonry and reinforcement; ϕ_s – friction angle of soil, δ_s – dilation angle of soil, c – cohesion of soil, φ_c – coefficient of friction between arch and soil.

	f_b	f_m	f_t	f_r^+	f_r^-	E_b	E_m	E_r	E_s	γ_s	γ_M	γ_r	ϕ_s	δ_s	c	φ_c
Material parameter	[MPa]					[GPa]				[kg/m^3]			[º]	[º]	[kPa]	[-]
value	10	4.0	0.1	0.1/1000	16	5.0	2.0	20/200	50	2000	1850	2500	50	20	5	0.4

At the boundary between the backfill and the arch or the rigid layer the contact elements are defined. They represent interaction between the contacting bodies by means of compressive and shear forces but without transfer of tension. The live load is applied by means of a rigid block acting on the upper surface of the soil. In all analyses the load is located at the quarter of the span. The boundary conditions limit the horizontal translation of the rigid body.

The two types of the arch barrel reinforcement are considered in the numerical model by means of additional FE elements. The first one, corresponding to a thin flexible tensile resistant layer – is modelled by means of 1-dimensional truss-type elements embedded inside host 2D elements representing the masonry arch located along the intrados or extrados of it (see Figure 3a). The displacements of the embedded element nodes are constrained to the interpolated values of the corresponding degrees of freedom of the host element. The second type – a thick rigid compressive resistant layer – is modelled using additional 2D elements defined outside the masonry arch and fixed to it (Figure 3b). The mechanical properties of rigid/flexible reinforcement types (including tensile f_r^+ and compressive strength f_r^- and Young modulus E_r) are given in Table 1.

The numerical analysis considering geometrical nonlinearity and large displacements is carried out incrementally in two consecutive steps: in the first step, the self-weight of all structural components is applied, and in the second step, the live load acting through the rigid block is added. The incremental application of the live load is determined by means of the vertical displacement of the reference point of the loading block, which enables the development of the global failure and continuation of the analysis in the post-critical phase. Thus, the ultimate load level P_{ult} may be reached, which is defined by the highest value of the applied load taken e.g. from the relationship between the vertical displacement of the loading block and the load P.

3 ANALYSIS OF STRENGHTENING EFFECTS

3.1 *Procedure of the progressive failure analysis*

All the analysed case studies have the same basic geometry corresponding to a typical structural system for masonry arch bridges, defined by: arch clear span L = 5 m, arch rise r = 1,25 or 2,5 m, arch thickness d = 0,4 m, number of arch segments n = 40, backfill height over the crown t = 0,3 m and length of the loading block w = 0,5 m. The strengthened cases differ for the flexible layer by the reinforcement ratio ω = 0,10÷0.20 or for the rigid layer by the thickness s = 0,05÷0.15 m.

The interaction of normalised forces μ and v in arch sections may present the effect and mechanism of reinforcing in a clear and legible way. For this purpose, discrete integration of peripheral stress σ_{22} distribution in arch sections, obtained from the FE model, takes place and the corresponding generalized forces M and N are calculated for every section giving the so-called "interaction line" for the whole arch. Additionally, the forces are normalised according to Equation 1 and then referred to the μ-v envelopes shown in Figure 2. This procedure can be applied both to the unstrengthened and strengthened arches. In the diagram, letters indicating the position of the plastic hinges are also given.

For presentation of the progressive failure development, various levels of the applied concentrated force P_i are analysed which are related to reaching the critical effects in a sectional or global response of the arch, namely:

1. compressive yield strength f_m of masonry at the edge fibre of a section, $P_1 = P(f_m)$,
2. tensile yield strength f_r^+ of a flexible reinforcement or compressive yield strength f_r^- of a reinforcing rigid layer at the edge fibre of a section, $P_2 = P(f_r)$,
3. ultimate compressive strain ε_{mu} in masonry at the edge fibre of a section, $P_3 = P(\varepsilon_m)$,
4. the ultimate load P_{ult} related to loss of stability of the whole arch, $P_4 = P_{ult}$.

The order of getting the aforementioned critical effects along with the increasing loading may vary between different arch geometries (r/L and d/L), type and amount of strengthening or for other loading scenarios. Various order of the limit criteria being reached can be noticed, e.g. in Figure 7 and Figure 10. Showing the interaction line evolution along with the increasing load P referred to the considered μ-ν interaction envelopes provides the most comprehensive demonstration of the effect of the applied strengthening solutions.

3.2 *Analysis results*

In the first step, the unstrengthened arches are analysed. For two cases (with r/L equal to 1/4 or 1/2), the calculated evolution of the interaction line within the μ-v envelope for the characteristic load levels $P(f_m)$, $P(\varepsilon_m)$ and P_{ult}, is presented in Figure 4a, b. It is visible that the interaction lines for P_{ult} touch the envelope in all extreme points (where hinges A-D are forming) while the lines for lower P_i do not fully reach it. The legends in the diagrams describe the interaction lines in the order according to their evolution along with the increasing load P. For the same cases, the relationships between the applied force P and displacement u of the arch at the point located under the force are calculated and shown in Figure 4c, d. In the obtained P-u diagrams the characteristic load levels P_i are indicated which describe the behaviour in the critical arch sections (at plastic hinges A-D). It can be noticed that the location of the sections where the failure appears may change depending on the bridge geometry.

The effect of strengthening with a flexible layer located on intrados or extrados is depicted by means of a distribution of peripheral stresses σ_{22} shown on a deformed region of the arch (Figure 5) as well as using the interaction lines shown against the μ-v envelope for a bridge with r/L = ¼, d = 0,40 m and varying $\omega \approx \omega_{opt}$ (Figure 6). Additionally, P-u relationships for the selected cases are presented in Figure 7.

In the diagrams in Figure 6, the interaction lines for the following P_i evolve, starting from $P(f_{m,D})$, through $P(\varepsilon_{m,D})/P(\varepsilon_{m,B})$ up to P_{ult}, approaching the envelope branches related to strengthening in the vicinity of two sections (at hinges forming on the edge of the arch

opposite to the strengthening layer), i.e. B & D for reinforcement on the intrados and A & C – for extrados, while the other two hinges develop as for the unstrengthened arch. For clarity, the μ-v envelope for the unstrengthened section is also given here with a grey dotted line.

In case of FLEX/INT with the increase of ω (from 0,15 to 0,20) tensile failure of reinforcement at hinge B for load $P(f_{r,B})$ stops to be reached before P_{ult} and the interaction line at P_{ult} reaches branch II-III of μ-v envelope related to failure of masonry instead of the branch I-II. However, observing P-u relationships after this increase of ω all the P_i related to masonry failure remain at similar levels as well as the P_{ult} increase is insignificant.

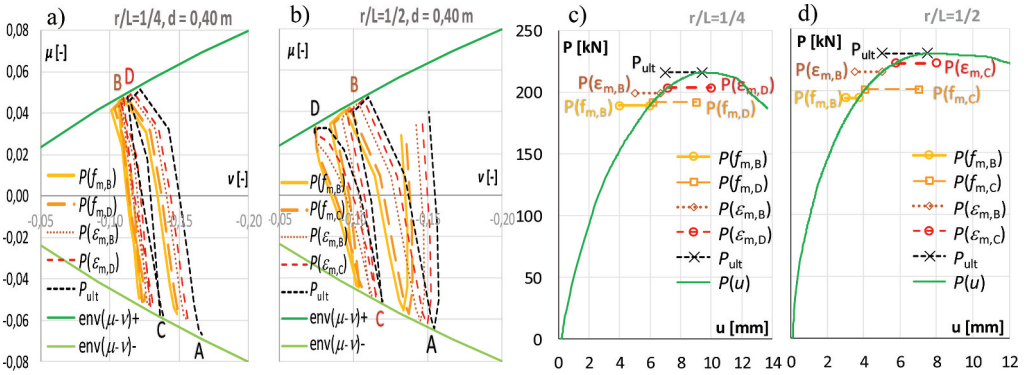

Figure 4. Analysis of the unstrengthened arches: the interaction line evolution within μ-v envelope for the characteristic load levels P_i for arches with: r/L = 1/4 (a) and r/L = 1/2 (b); corresponding P-u diagrams with indicated critical load levels P_i for: r/L = 1/4 (c) and r/L = 1/2 (d).

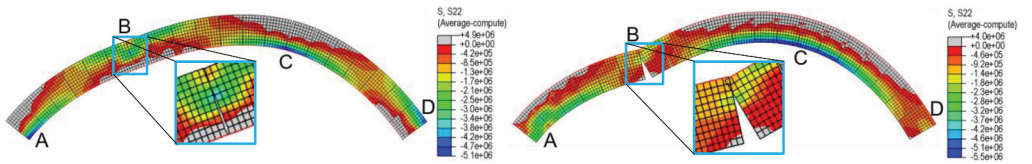

Figure 5. Distribution of stresses σ_{22} triggered by the $P(f_r)$ for FLEX/INT (left) and FLEX/EXT (right).

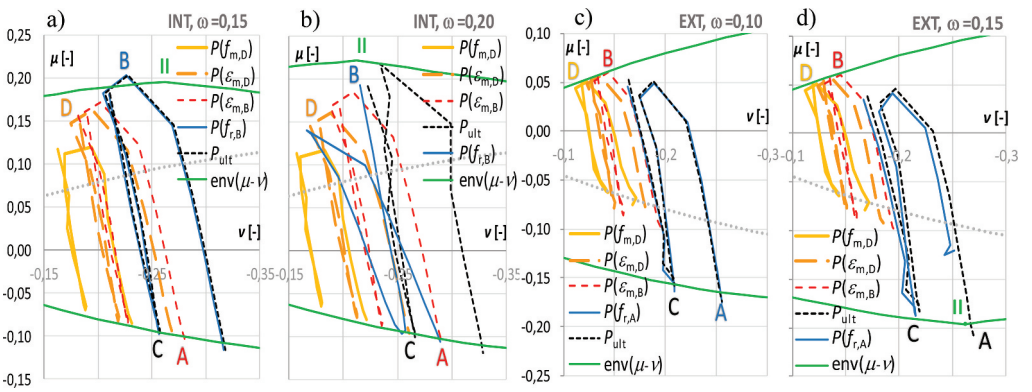

Figure 6. The interaction line evolution within μ-v envelope corresponding to the characteristic load levels P_i for arches strengthened with FLEX/INT (a), (b) and FLEX/EXT (c), (d) for different ω.

Regarding FLEX/EXT, in consequence of the increase of ω (from 0,10 to 0,15) failure at $P(f_{r,A})$ is no more reached before P_{ult} and the interaction line at hinge A at load P_{ult} reaches

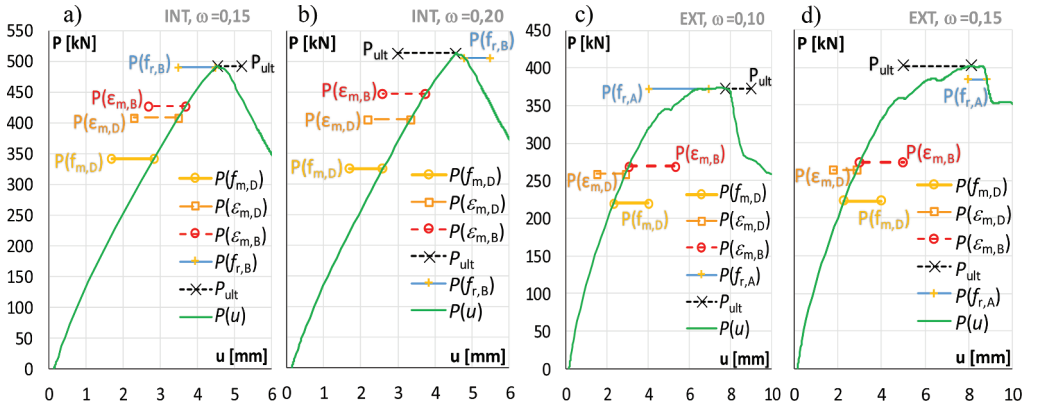

Figure 7. *P-u* diagrams with indicated critical load levels P_i for FLEX/INT (a), (b) and FLEX/EXT (c), (d).

point II of the μ-v envelope. Likewise for FLEX/INT with the same arch geometry, after this increase of ω all the P_i related to masonry failure remain at similar levels as well as the P_{ult} increase is small.

In all the cases it may be noticed that for initial P_i levels the interaction line is quite remote from μ-v branches related to the reinforcing effect and reaches them at P_{ult} only. It means that for lower loads the flexible reinforcement is not utilised significantly. For FLEX/EXT, at higher P_i values, the interaction line in turn moves away from the μ-v branch corresponding to unstrengthened sections which shows redistribution of internal forces. It is related to yielding and softening at compression at hinges B & D of the arch which is visible e.g. in Figure 5 (right) when observing concentration of stresses at some distance from extrados in these sections. It leads to dislocation of the hinges to positions more remote from extrados and in consequence transmitting lower bending moment (resulting in lower μ). These effects are not visible in case of unstrengthened arches.

The effect of strengthening with a rigid layer is evaluated on the same arch geometry and in an analogical way to the flexible layer. Distribution of stresses σ_{22} at P_{ult} is given in Figure 8 for strengthening with a rigid layer located on the intrados or extrados. The presented case is with s = 0,15 m ($\omega \approx \omega_{opt}$).

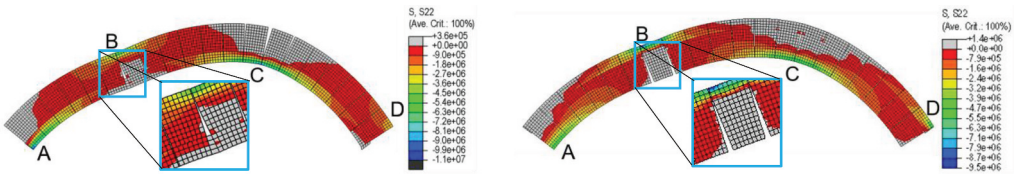

Figure 8. Distribution of stresses σ_{22} triggered by the P_{ult} for strengthening with RIG/INT (left) and RIG/EXT (right).

For selected cases of rigid reinforcement, the evolution of the interaction lines is presented in Figure 9. In each diagram, the interaction lines, starting from the considered initial phase of the loading, evolve in both directions towards branches of both signs of the envelope related to strengthening in regions of all sections A-D. It indicates early mobilization of the rigid reinforcement at the loading process. Larger evolution takes place however at hinges forming on the arch side with the strengthening layer. *P-u* relationships for the cases are presented in Figure 10 and by analysing them together with the Figure 9 some additional findings can be obtained. In case of RIG/INT along with increasing s (from 0,05 to 0,10 m) compressive failure of reinforcement at hinge C for load $P(f_{r,C})$ stops to be reached before P_{ult}. In case of

RIG/EXT together with increasing s (from 0,10 to 0,15 m) $P(f_{r,B})$ instead of being the first failure type moves to the post-critical phase. In all cases if the failure of the rigid reinforcement in a second section is going to appear, it happens in the post-critical phase only. Observing the RIG cases at the loading process it can be noted that, on the contrary to FLEX cases, the failures of the reinforcing layer and masonry always occur in different sections. It is also worth noting that strengthening with a rigid layer may lead in selected sections to a dangerous tensioning of the whole masonry part as it is shown in Figure 8.

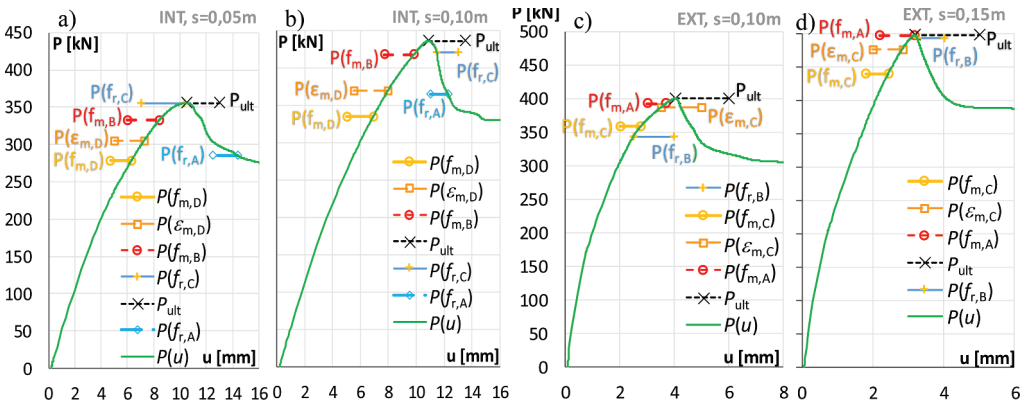

Figure 10. P-u diagrams with indicated critical load levels P_i for RIG/INT (a), (b) and RIG/EXT (c), (d).

4 SUMMARY AND DISCUSSION

On the basis of the study it can be concluded that consideration of different limit criteria provides more comprehensive information on the progressive failure of the arch during loading process, useful in evaluation of strengthening solutions. It occurs evident that the presence of reinforcement changes this gradual performance.

For a flexible layer an optimum value ω_{opt} can be defined corresponding to the case when interaction line (usually at section B) at P_{ult} reaches connection of two branches of the μ-ν envelope (point II in Figure 2). Such a situation corresponds to simultaneous failure of masonry and reinforcement in this section at the global collapse. Regarding the solutions based on a rigid layer an optimum value ω_{opt} can be also related to simultaneous failure of masonry and reinforcement at the global collapse but occurring in different sections.

According to the adopted analytical solution for a flexible reinforcing layer the relationship between ν, μ and ω_{opt} related to the position of point II on the envelopes can be express by formulae expressed in Equation 2 & 3, which assuming $x_{opt}/d = \varepsilon_{mu}/(\varepsilon_{mu} + \varepsilon_{ru}{}^{+})$ take a form:

$$\omega_{opt} = \nu + \frac{x_{opt}}{d} = \nu + 0,412 \tag{2}$$

$$\mu = \frac{\nu}{2} + \frac{x_{opt}}{d}\left(1 - \frac{x_{opt}}{2d}\right) = 0,5\nu + 0,327 \tag{3}$$

It defines domain of ν values belonging to (-0,41; 0) where optimum strengthening solution corresponding to ω_{opt} can be found. It means e.g. that for ν < - 0,41 any flexible layer will not provide an optimum utilization of both materials – masonry and reinforcement. At the same time it provides a valuable information on the range of ω_{opt} values corresponding to potential ν values. An important finding is also $\omega_{\max}$ = 0,41 (for ν = 0) which is the limit value above which the optimum solution cannot be found if the section is to belong to an arch – with a compressive resultant axial force. Finally, one can obtain also μ value corresponding to ν at ω_{opt}.

It is also found that generally for more flat arches (r/L = ¼) the variation of ν along the arch for any phase of loading is lower than for semi-circular ones. Besides, at P_{ult} noticeably lower displacement occurs for flat arches than for the latter ones. Similar findings are for strengthened arches.

ACKNOWLEDGEMENTS

The presented analyses were carried based on a grant from WCSS of Wroclaw University of Science and Technology. Rapid repair of bridge beams and decks with prefabricated FRP panels

M. Ehsani
QuakeWrap, Inc. Tucson, USA

ABSTRACT: Typical repair techniques for bridge girders and decks are often time-consuming and require long periods of traffic control that add significantly to the project cost. In some projects, where the bridge is crossing a body of water, the low headroom below the bridge can make these repairs even more challenging. The introduction of Fiber Reinforced Polymer (FRP) products in recent years has shortened repair times in many cases. However, even when conventional FRP products are used, repairs can still be time-consuming and difficult.

This paper presents a recent type of FRP laminate developed by the author. These laminates consist of flat panels, typically 900mm wide by any length. The laminates are flat on one face but have protruding T profiles on the other face. That face is also grit-coated for improved bonding to concrete. These panels can be cut to desired width and length and connected to the bottom and sides of a beam or slab, creating an annular space between the panels and the host structure. The annular spaced is filled with non-shrink grout or concrete. The T profiles act as reinforcing bars that are permanently attached to the panel, making the panel behave as a stay-place-form that includes reinforcing bars. In most cases, the tensile strength of the flat panel and the T profiles add sufficient strength to eliminate the need for any additional reinforcing bars.

The panels are non-corroding, ensuring a long service life for the repaired structure. Moreover, the panels act as an impervious barrier, keeping moisture and oxygen away and significantly reducing the corrosion rate of the host structure. The repairs are ideal for projects with limited access or when long delays in traffic are deemed unacceptable. A case study using a similar solution at the Port of Galveston will also be presented.

1 INTRODUCTION

Corrosion of reinforcing steel in structural elements has always been a concern. Billions of dollars are spent annually to repair corroded concrete beams, columns, walls, etc. worldwide. In the late 1980s the author introduced the use of non-metallic Fiber Reinforced Polymer (FRP) products for repair and strengthening of deteriorated beams (Saadatmanesh and Ehsani 1988). In that original concept, fabrics made with glass or carbon fibers are saturated with epoxy in the field and applied to the exterior surface of the concrete. By the next day, when the epoxy cures, the FRP reaches a tensile strength 2-3 times that of steel. That system has been used on thousands of projects worldwide and several countries have developed design guidelines for such repairs.

However, there are some limitations associated with the above repair technique. For example, the surface of the concrete must be flat prior to the application of FRP. This requires patching the damaged portion of the concrete, and waiting for the patching material to dry before FRP can be applied. These add significant time delays to the project. Secondly, application of FRP fabric as a wet layup method underwater is very difficult. The saturated fabric must be pressed to remain in fill contact with the structure while the epoxy cures. In the presence of moving water and wave action, this becomes impractical, especially on large flat surfaces such as bridge abutment walls and foundations. These challenges led the author to develop the new system described in this paper.

DOI: 10.1201/9781003483755-474

2 HISTORY OF THE DEVELOPMENT

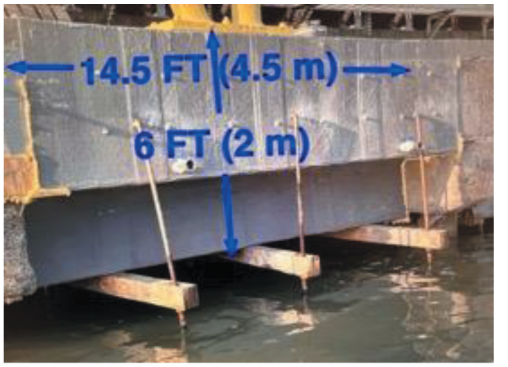
In 2016 the author introduced a proprietary FRP solution for repair and strengthening of structures (Ehsani 2021). The technique involves constructing semi rigid shells that are connected to the host structure, creating an annular space between the structure and the shell. This annular space is filled with epoxy grout or concrete in a subsequent step. The shell will permanently stay in place, protecting the host structure from damage by water and oxygen. A main advantage of this system is that it eliminates the need for patching of the damaged surface and waiting for the patching material to cure. It also allows repairs to be performed underwater without the need for any coffer dams. Both attributes result in significant time and cost savings on projects.

2.1 *Repair of walls*

The above product is referred to as Sheet Pile Repair (SPiRe®). One technique to make these panels is by using the sandwich construction method. A 3-10 mm thick proprietary core is sandwiched between one or more layers of resin saturated glass or carbon fabric. The panels are 1200mm (4-ft) wide and are supplied in lengths up to 10m (30 ft). The panel thickness typically ranges from 10 to 20 mm (0.4 to 0.8 in.). Details of the application of this product were presented at a previous IABMAS conference (Ehsani 2022). To summarize, the panels are connected with J bolts to the deteriorated sheet pile; the edges of the panels are bonded with an epoxy seal to create an impervious stay-in-place form in front of the deteriorated wall. The length of the panels can be trimmed in the field to match the height of the wall at any location.

The annular space between the SPiRe® panels and the sheet pile is filled with concrete or grout. If needed, reinforcing bars can also be added in the annular space. The entire operation can be performed underwater without the need for any coffer dams. The combination of the SPiRe® panels and the grout provide an impervious protective coating for the wall that will prolong its service life by depriving the corrosion process from oxygen and moisture. The non-corroding FRP panels ensure a long maintenance-free service life for the repair system. Since its debut shown in this video to repair a 282 m (926 ft) seawall in Chesapeake VA in 2017, the product has been successfully used on a number of projects. The most recent project is the ongoing repair of 1 km (0.62 miles) of a seawall at the Port of Melbourne Australia.

2.2 *Repair of beams and decks*



Repair of slabs or beams from below is a time-consuming process. The task becomes even more challenging when there is little headroom available, for example, when a bridge deck is too close to a body of water. In such cases, once the damaged concrete is removed, the forming of the beam and slab with such tight access adds significant time to the repair. Once the formwork is removed after the repairs, the host structure is exposed and subject to the same aggressive environment as in the past which could lead to the return of corrosion.

The same sandwich construction product SPiRe® can be used to build custom-sized shells that act as the stay-in-place form for the repair. This system was recently utilized to repair a portion of the deck at the Port of Galveston, Texas (Figure 1). The concrete beam and deck were severely corroded, and it was assumed that 50% of the longitudinal steel bars in the beam were lost to corrosion. The owners planned to repair the deck with conventional timber forms and remove them once the repair was complete. But assembling the heavy forms and their removal proved to be too costly.

Realizing the cost-savings, the owner became interested in trying the newly developed SPiRe®system in its inaugural application for such repairs. As shown in Figure 1a, spacers and glass FRP rebars were attached to the inside face of the shells. These shells were lifted and secured with anchors to the host beams and deck. The annular space was filled with non-shrink concrete that was pumped through grout ports. The shells will remain in place permanently, protecting the host structure from future exposure to seawater and corrosion. Figure 1c shows the project near completion where the main beams and deck have been repaired; repairs of the transverse beams are ongoing with the same process.

3 INTRODUCING SPIRE®+

As noted above, the original SPiRe® system acts only as a stay-in-place form but does not provide any structural strengthening benefit unless the annular space is filled with an epoxy grout to bond the shell to the host structure. Of course, adding reinforcing bars in the annular space will create a structural wall but this requires additional labor. To overcome this shortcoming, we have developed a new type of patent pending FRP panel dubbed SPiRe®+ that offers all the advantages of the original SPiRe® system plus a strengthening feature Ehsani 2023). These panels are made of glass FRP in a continuous pultrusion process. Various tows and glass roving in fabric form are saturated in a polyester resin bath and are pulled through a mold that compresses all these materials together. As the materials travel through the mold, they are subjected to heat to cure them quickly. Both the flat portion and the T profiles have a high glass fiber content, providing a tensile strength of about 207 MPa (30 ksi) for the panels.

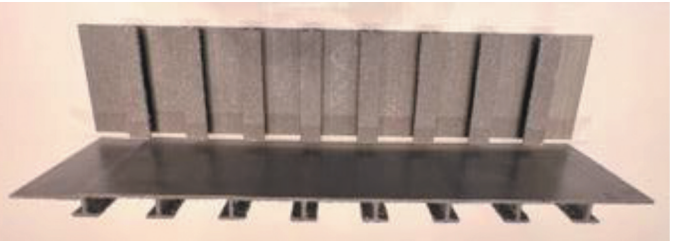

Figure 2. Front and back side view of SPiRe®+ panels.

The panels are 914 mm (3-ft) wide which is easy to lift and handle. Standard lengths are 3.6m and 5.5m (12 and 18 ft) long and can be trimmed to shorter lengths in the field. For larger projects, the panels can be manufactured in any length.

The outside face of the panels is smooth. However, the inside face includes protruding T profiles (Figure 2). The interior surface of the panels is coated with a layer of epoxy and sand to provide a grit-coated rough surface for improved bonding to concrete. This unique feature allows for bonding of the panels to the concrete; the T profiles behave as reinforcing bars for the repaired structure. The panels weigh 15.5 kg/m^2 (3.2 lb/ft^2).

3.1 *Test results*

To demonstrate the strength of the panels and the effectiveness of the grit-coated surface in transfer of loads, a beam or slab specimen was tested under flexure. A 200mm (8-in.) wide by 2900mm (9.5-ft) long piece of SPiRe®+ was cut such that it included two T profiles. This panel

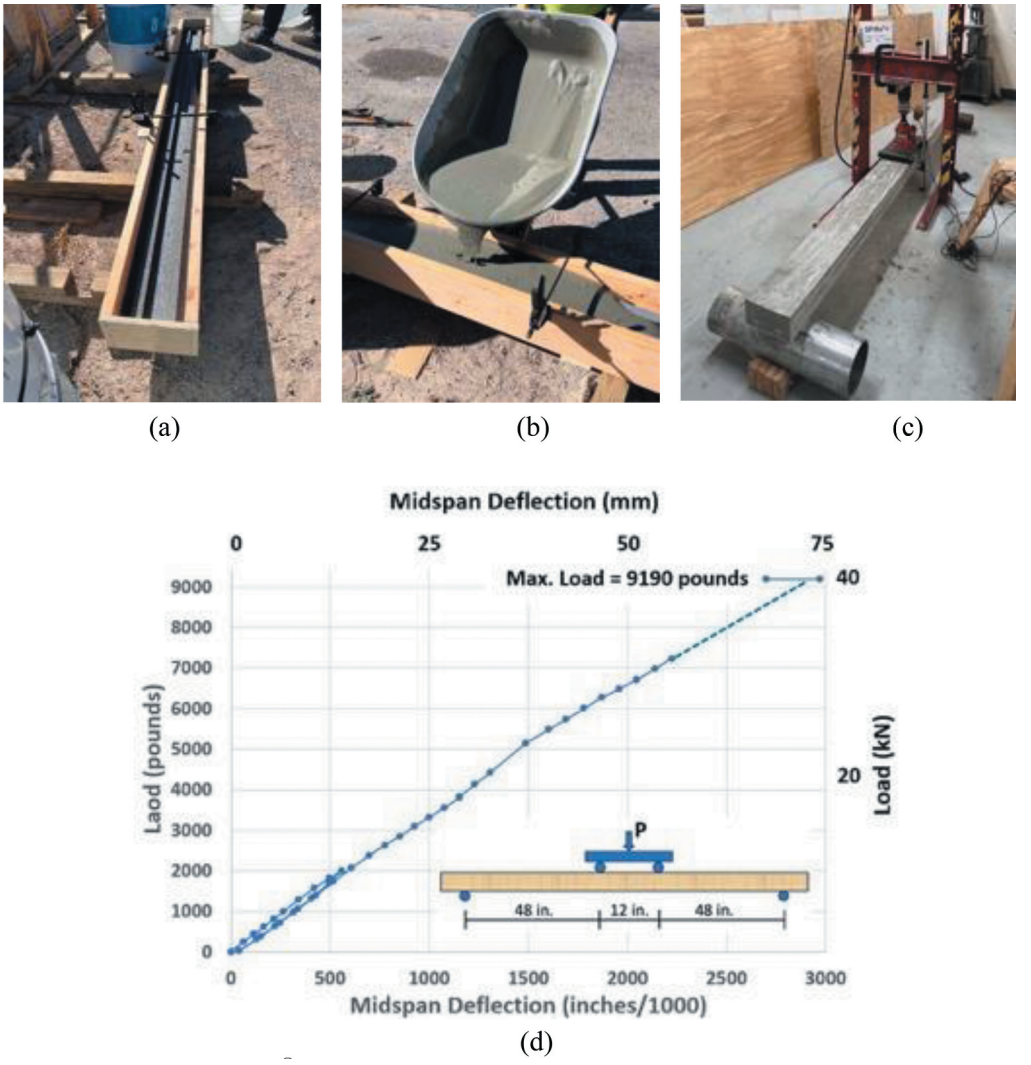

Figure 3. Testing of SPiRe®+: (a) form preparation, (b) flowable grout, (c) test set up, and (d) load vs. deflection response.

was used as the base of a form and 100mm (4-in) high timber was placed around all four sides (Figure 3a). A commercial grade, non-shrink, Precision Grout by Quikrete was mixed with water at a rate of 5 liters per 22.7 kg (50-pound) bag. This resulted in a mix consistency between flowable and liquid (Figure 3b) that should achieve a compressive strength of 48 MPa (7000 psi) in 7 days. The specimen was moist cured until it was tested on the 7th day.

The specimen was subjected to 4-point bending on a span of 2740mm (9 ft) as shown in Figure 3c. The specimen was first loaded incrementally to 9 kN (2000 pounds) and gradually unloaded. The unloading slope was similar to the initial loading slope and no permanent deflection was recorded. Next, the specimen was reloaded incrementally up to 32.16 kN (7230 lbs), at which time the displacement dial was removed to prevent any potential damage. As the specimen was loaded, at a load of 40.88 kN (9190 lbs), the testing frame started to twist, and the test was stopped. There was no sign of damage on the tension or compression face of the specimen. Several small cracks about 1mm wide and 50-60mm long were distributed fairly uniformly along the length of the beam, indicating good bond between the SPiRe®+ panel and the grout.

It is clear that if the testing frame had not failed, the specimen could have resisted additional loads. Nevertheless, even assuming the load of 40.88 kN as the failure load, this corresponds to a maximum moment of 12.46 kNm (110 k-in) for the 200mm (8-in.) wide panel. In terms of comparison with steel reinforcement for a similar slab with a cross section of 200mm wide x 100mm thick (8 in. x 4 in.), this SPiRe®+ panel is equivalent to 20mm, 400 MPa bars provided at a spacing of 90mm (No. 6 Gr. 60 steel bars at a spacing of 3.5 in.). This is a significant amount of reinforcement for strengthening most existing structures.

In addition to the ease of installation, the presence of the SPiRe®+ panels will permanently protect the host structure from corrosion caused by exposure to the environment.

3.2 *Repair of walls*

Installation of SPiRe®+ for repair of a seawall or bulkhead is similar to the original SPiRe®. In repairing a seawall, for example, L bolts are inserted and connected to the seawall on an approximately 1m x 1m (3 ft x 3 ft) grid. The SPiRe®+ panels are connected to these bolts using washers and nuts. The distance between the panels and the front face of the wall can be easily adjusted with the all-thread bolt and nut. A sealant is applied to the overlapping joint to create a watertight connection and successive panels are installed until the desired length of the wall is covered. Next, the bottom and edges of the annular space are sealed before concrete or grout is placed in the annular space. This can be achieved either by the tremie method or by using pumps and grout ports.

For repair of other structures, such as a beam, the panels can be cut to the desired width and their edges are bonded together using angles that are made of the same GFRP materials. These panels can be assembled in advance to create a shell that is lifted as one unit and secured to the beam before the annular space is filled with grout. Alternatively, individual panels can be secured to the host structure and their edges bonded together at the same time. In case any additional reinforcement is needed, GFRP rebars can be inserted between the T profiles using special spacers that we provide.

3.3 *Repair of beams and decks*

Conventional repair of bridge girders is very time consuming and often requires disruption of traffic (Figure 4a). The panels provide major cost and time saving in such projects. For repair of a deteriorated bridge beam, for example, the panels can be cut to the required width and their edges can be bonded using L-shaped angles, epoxies and bolts. The beam surface needs minimal preparation or patching of the damaged areas; in fact, an uneven and rough surface is preferred over a smoothly finished one. The entire repair assembly can be lifted quickly and secured to the underside of the bridge or slab with anchor bolts. The annular space between the SPiRe®+ panels and the beam is filled with concrete. The entire operation may be completed in one night when the traffic on the roadway is light.

Figure 4. Repair of bridge girders with SPiRe®+ system allows fast repair of bridges and eliminates disruption of traffic.

Figure 5. Repair of bridge girders and decks over water by attaching segments of SPiRe®+ panels directly to the bridge.

If the bridge crosses a waterway and is close to the surface of the water, the low headroom below the bridge makes the repairs very costly (Figure 5). The crew can assemble the formwork of desired size and shape in advance and deliver it to the site on a barge. The workers can hoist the lightweight forms up and secure it with anchor bolts to the underside of the bridge. Alternatively, individual flat panels can be bolted to the bridge; the edges of these panels can be epoxied and/or bolted together to create the desired covered area directly on the bridge. At this point, the annular space between the panels and the bridge is filled with concrete.

3.4 *Additional flexural and shear reinforcement*

As stated earlier, the panels provide significant flexural capacity and for most repair and retrofit projects, there is no need for additional flexural reinforcement. Nonetheless, if necessary, additional reinforcing bars can be connected to the panels using the rebar holders shown in Figure 6. In such cases, it is recommended to use nonmetallic GFRP bars that will not corrode.

In most applications for repair of slabs or walls, there is no need for increasing the shear capacity of the element. However, if the retrofit of a girder or beam requires shear capacity enhancement, U-shaped stirrups made with non-corroding GFRP bars can be used. These can be attached to the shell shown in Figure 4 prior to lifting the shell. Alternatively, when individual panels shown in Figure 5 are being utilized, the shear reinforcement can be positioned around the beam before the panels are secured to the beam.

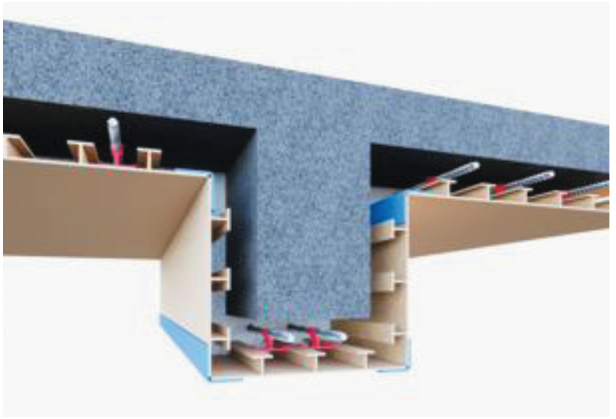

Figure 6. Additional flexural reinforcement connected to special rebar holders.

3.5 *Protection of coastal communities from flooding*

The versatility of the SPiRe®+ panels affords them many opportunities for use in the construction industry. For example, recent climate change and global warming has resulted in significant flooding of communities along riverbanks. Many coastal communities worldwide are spending millions of dollars to protect buildings and their residents from these events. One solution shown in this video is to attach the panels to the top of an existing seawall. As many panels as needed can be added, with a sealant applied to the overlapping joint region, to create a wall of desired height and length. Additional panels will be installed on the land side. These land and water side panels get connected together using through bolts. The annular space between the panels is filled with concrete.

The wall can be erected very quickly and at a low cost. Furthermore, the wall has no corroding materials such as steel, ensuring a long maintenance-free service life. As shown in Figure 7, landscaping, planters and pedestrian walkways can also be added on the land side to make the solution more appealing to the residents.

Figure 7. Application of SPiRe®+ panels to extend the height of seawalls in protecting communities from flooding due to rising sea levels.

3.6 *Advantages of the proposed solution*

The repair system presented here offers significant advantages over conventional repair methods. While the benefits may vary from project to project, some of the key benefits of this system include:

- ✓ Eliminating or minimizing traffic disruption and road closures
- ✓ Eliminating the need for patching of damaged concrete and surface preparation
- ✓ Significant savings in repair time

- ✓ Eliminating the need for coffer dams to perform the repairs
- ✓ Reducing potential construction errors since the reinforcing elements are built into the panels
- ✓ Providing a permanent impervious barrier encapsulating the host structure to keep moisture and chemicals out, thus prolonging the service life of the host structure, and
- ✓ Being a long-lasting repair since the panels include no corroding materials (e.g. steel).

All the above advantages result in significant time and cost savings on many repair and retrofit projects.

4 SUMMARY AND CONCLUSIONS

This paper presents a new product developed by the author following his 4 decades of experience in creating solutions for repair and strengthening of the infrastructure. A unique GFRP panel is described that is very versatile and can be used in many applications for repair of existing seawalls, bridge beams, decks, etc. Other applications for addressing sea level rise due to global warming are also covered. The panels offer tremendous strength, eliminating the need for additional reinforcing bars in most applications. The non-corroding panels also form an impervious barrier to keep moisture and oxygen away from the host structure, significantly reducing its corrosion rate.

Incremental repair method for corroded bolted connection

E. Yamaguchi, N. Tamada, U. Agvaanluvsan, T. Takai & M. Wada
Kyushu Institute of Technology, Kitakyushu, Japan

ABSTRACT: For the repair work of a corroded bolted connection, common practice is to use temporary bents or a bypass member over the connection. The costs of these methods are quite high and the traffic needs be regulated. The present study explores a repair method that requires no bents, no bypass member and no traffic regulation. The method is to conduct repair in an incremental fashion: the repair work proceeds gradually, part by part. Its validity is investigated by FEA. For the best accuracy, a bolt is to be modelled by 3-D solid elements, but the computational cost is very high. The employment of connector elements is therefore tried and its effectiveness is confirmed by the comparison with the results of solid element analysis and experiment, using a small connection model. The proposed method is then applied to a 4×23 bolted connection. The validity is verified by FEA with connector elements.

1 INTRODUCTION

One of the most critical phenomena that could control the service life of a steel bridge is corrosion. Because of the complexity of its geometry, the quality of coating tends to be lower in a bolted connection than that in the other part of a steel bridge and water tends to be stuck in a bolted connection. As a result, a bolted connection is often found severely corroded. An example is given in Figure 1. The location of the connector is on the top flange of the beam in a steel moment frame supporting an elevated expressway. There seemed water leakage at the end of the bridge, leading to the corrosion.

(a) Overview (b) Bolted connection

Figure 1. Corroded bolted connection.

For the safety of a bridge, a corroded bolted connection has to be repaired. Bolts are to be replaced and a splice plate is to be replaced or reinforced. To conduct such a repair work safely, common practice is to use temporary bents or an extra member called a bypass member over the connection. Either work is accompanied by the regulation of traffic. Not only construction cost but also social cost would occur.

DOI: 10.1201/9781003483755-475

Figure 2. Connection with 6×1 bolt layout.

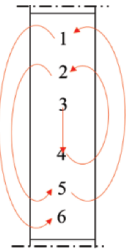

Figure 3. Bolt-removal order.

The present study explores a repair method that requires neither a bent nor a bypass member. It wouldn't impose traffic regulation, either. In short, in the method, some of the bolts would be removed, the unevenness of the corroded splice-plate surface over the area of the bolt removal is fixed, a slice of plate would be put on that region and new bolts are installed. The procedure is repeated until the repair of the whole corroded area is completed. This repair procedure is as it were an incremental method.

During the repair work, safety margin is reduced upon the bolt removal. Safety has to be ensured during the entire period of the repair work. The objective of the present study is to propose the incremental repair method and investigate its validity.

2 MODELING OF BOLT

The finite element method is the mainstay of the present study. At the current state, it is possible to model a bolt by 3-D solid elements as it is. However, the computational cost including the modelling would become very high. It cannot be a choice from a practical point of view.

The software called ABAQUS (Dassault Systemes Simulia Corp. 2013) is to be used in this study. It has a connector element which connects two nodes and controls their relative motion. The present study tries to apply this element to simulate the mechanical behavior of a bolt. The connector element is so simple that computational cost would be much smaller than that of the 3-D solid element analysis. Therefore, the present study first explores a possibility for using a connector element to model the mechanical behavior of a bolt.

A connection with the 6×1 bolt layout (Figure 2) is studied. As a repair work, bolts are replaced herein. The order of the bolt replacement is illustrated in Figure 3. The connection is analyzed by two models, the sophisticated model using 3-D solid elements and the connector-element model. The replacement of a bolt is simulated by the disappearance of a bolt followed by the appearance of a bolt in the analysis.

Tensile load is applied to the connection. The opening displacement, the gap between the base plates, changes during the repair work and is computed in each analysis.

The numerical results are presented in Figure 4. The dotted line is the opening displacement obtained by the 3-D solid elements analysis while the dash-dotted line by the connector element analysis. Both show the gradual increase of the opening displacement with the progress of the repair, and the difference between the two numerical results appears quite small. It can be stated then that the employment of the connector element for modelling a bolt is justified.

To see the validity of the present numerical approach, experiment is conducted. Three specimens are prepared and tested. Figure 5 shows one of the specimens with one bolt removed; the hole indicates the location of the removed bolt. The experimental results are shown in Figure 6. There is variability in the experimental results, but the difference is quite small and

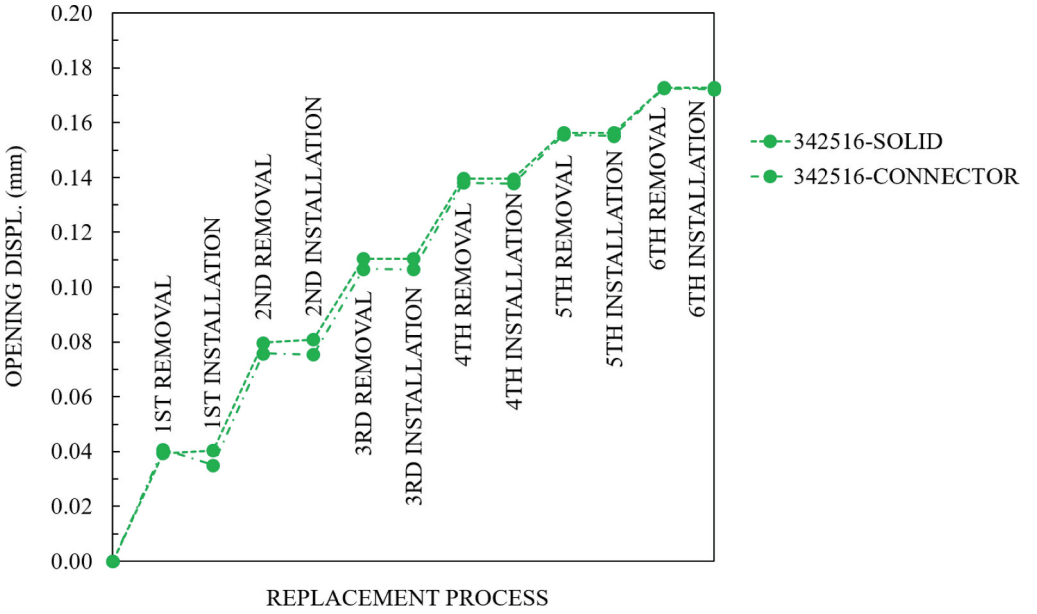

Figure 4. Opening displacement by FEA.

Figure 5. Test specimen with one bolt removed.

insignificant. Figure 7 shows the experimental results together with the numerical results. There is a discrepancy between the numerical and experimental results, but the difference decreases with the increase of the opening displacement and it becomes insignificant. The numerical approach employed in the present study is thus validated by the experiment.

3 REPAIR OF CORRODED BOLTED CONNECTION

Based on the existing corroded bolted connection, a bolted connection model is constructed and the proposed repair method is applied to it. Due to symmetry, only a half of the bolted connection is considered, which is shown in Figure 8. Each splice plate in the half model has the 4×23 bolt layout. The thickness of the base plate is 19 mm, the thickness of the top splice plate 11 mm and the thickness of the bottom splice plate 12 mm. The top splice plate and the bolts are supposedly corroded badly.

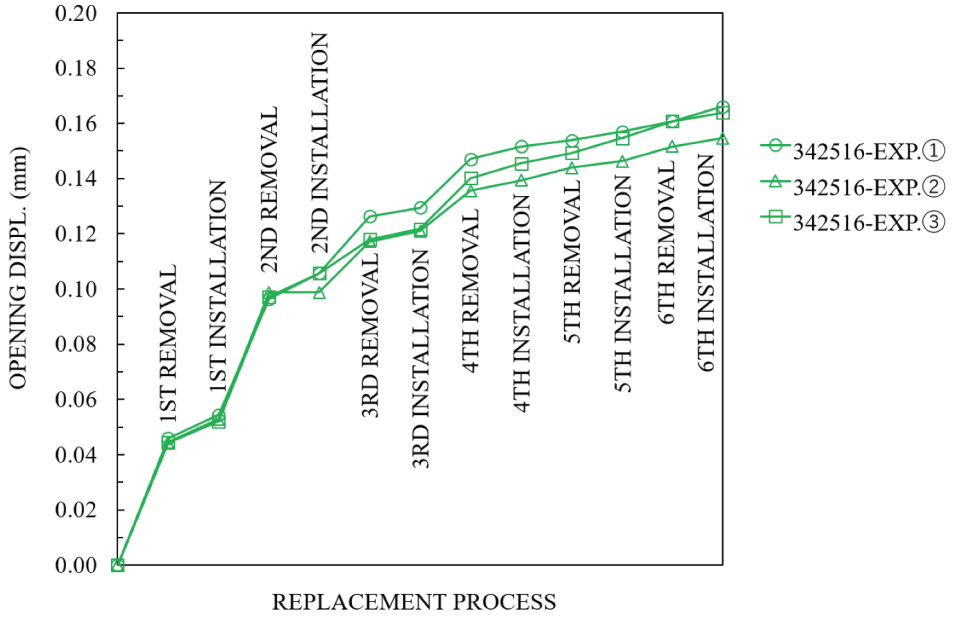

Figure 6. Opening displacement by experiment.

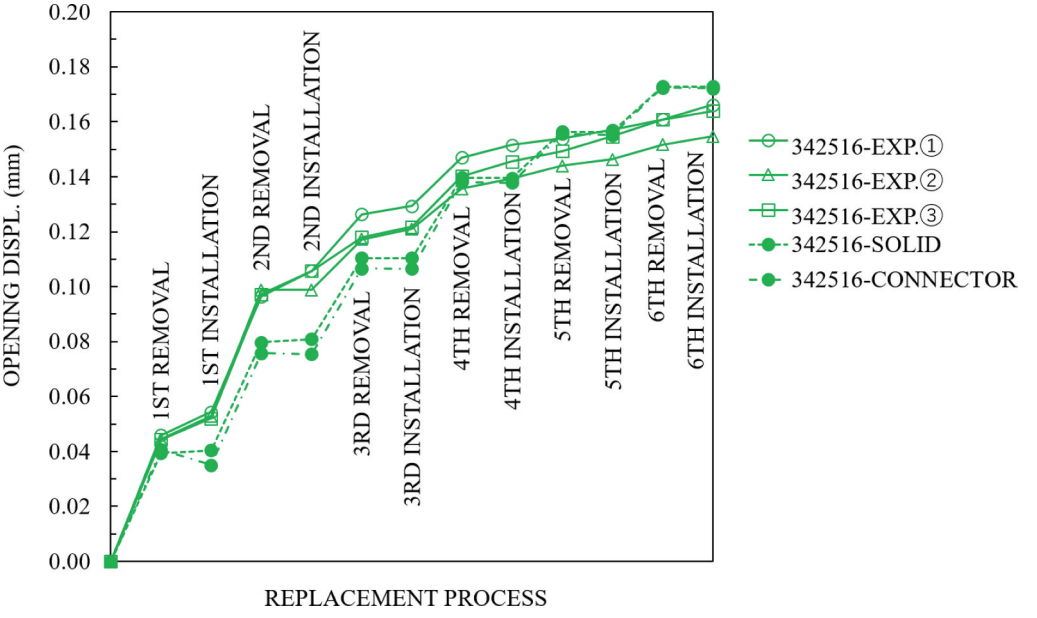

Figure 7. Comparison of FEA and experimental results.

To take account of the deterioration due to corrosion, the thickness of the top splice plate is reduced by 3 mm and the axial force in each bolt by 25% (Shimozato et al. 2013). The repair work is to remove bolts, place a slice of plate for reinforcement and install new bolts. The repair is conducted bolt-column area by bolt-column area. The thickness of the additional slice of plate is 12 mm. As shown in Figure 9, the bottom splice plate consists of 5 smaller plates, Plates

A to E, because of the presence of the longitudinal stiffeners. The repair work is therefore carried out for each area of those 5 splice plates.

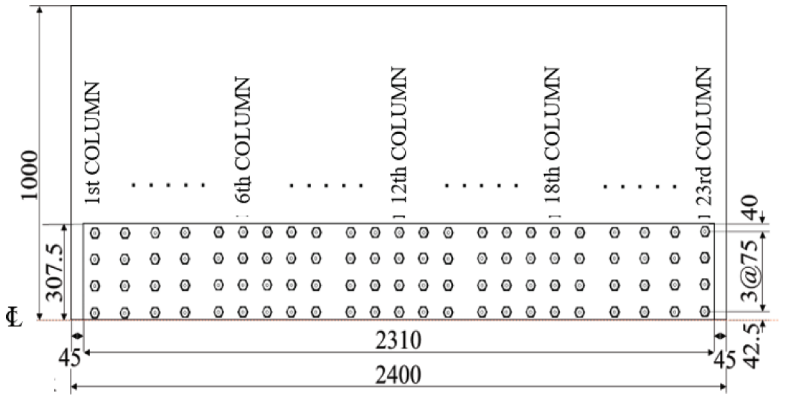

Figure 8. 4×23 bolted connection.

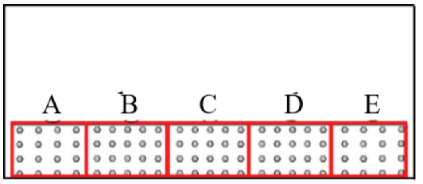

Figure 9. Bottom splice plate.

The safety is lowered by the removal of bolts, and the splice plates may start sliding on the base plate at that moment. The load that causes the opening displacement of 0.2 mm can be assumed the slip load. If the removal of bolts leads to the slip load smaller than the design load, that bolt removal cannot be admitted.

In the present study, the slip load is computed by FEA. Shell elements are employed for the base plate and the splice plates while connector elements are used for bolts. The coefficient of friction between the base plate and the additional plate is assumed 0.5, following the work by Tamba et al. (2014).

Three repair patterns, Patterns (a) to (c), are studied. In all these patterns, the repair is conducted bolt-column area by bolt-column area, and the difference lies in order of area to be repaired. In Pattern (a), the repair is done in order of Plates A, B, C, D and E. In each plate, the repair is carried out from the bolt-column area near the edge of the connection. In Patterns (b) and (c), the repair order is Plates C, B, D, A and E. In Pattern (b), the repair of each plate starts from the bolt-column area near the center of the connection, while in Pattern (c), the repair from the bolt-column area near the center of the plate.

Figure 10 shows the slip loads. When the bolts in the 1st bolt column are removed, the slip load is smallest in each pattern. The smallest slip load is observed in Pattern (a). The repair processes of Patterns (b) and (c) are exactly the same up to the repair of the 5th bolt column. The difference between Pattern (b) and (c), therefore, appears only at the removal of the bolts in the 6th bolt column, and the slip load of Pattern (b) is smaller. Although in all the patterns, the slip load is well above the design load ensuring the safety of the method, the safest repair procedure out of the three is Pattern (c). This result indicates that it is better to carry out repair from the plate near the center of a connection and, in each plate, from the column near the center of the plate.

4 CONCLUDING REMARKS

The incremental repair method for a corroded bolted connection was proposed. Even when a column of bolts was removed, the safety of the connection has been found unthreatened: the sliding load is much larger than the design load. It would be even safer if repair is carried out from

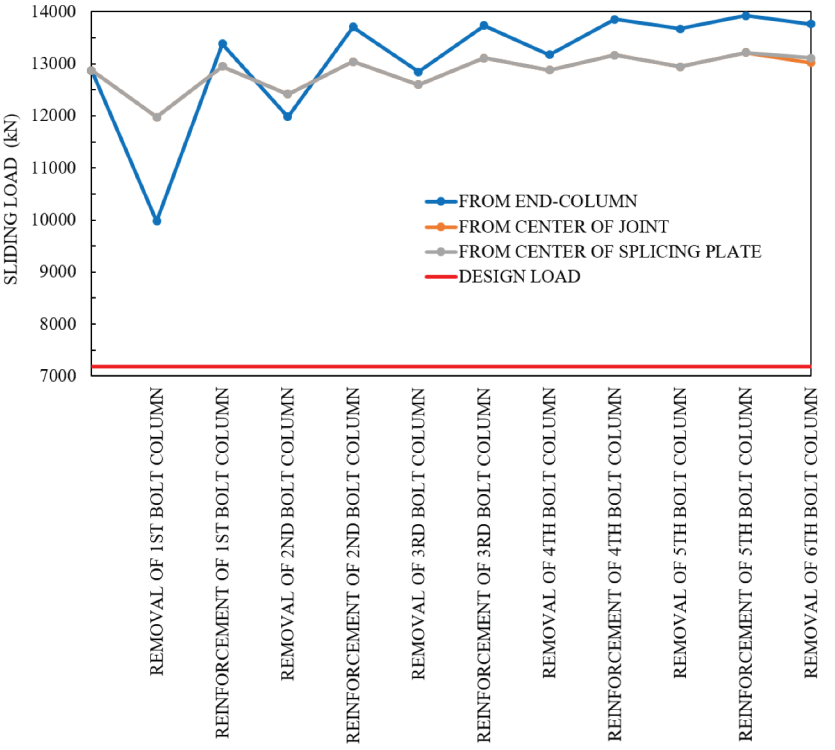

Figure 10. Sliding load.

the bottom splice-plate near the center of a connection and in each splice plate, from the area of the column of bolts near the center of the plate. The proposed incremental repair method requires no bents or no bypass member. Traffic regulation is not needed, either. The method is thus very practical and it could reduce the repair cost for a corroded bolted connection considerably.

In the present study, the validity of the application of the connector element to the modeling of a bolt has been concluded also. This conclusion is very useful from a practical point of view, as the usage of the connector element helps reduce computational time for the analysis of a bolted connection significantly.

A 2D TBI model to study lateral dynamics in ship impact event

D. Riboldi, L. Bernardini & A. Collina
Department of Mechanical Engineering, Politecnico di Milano, Milano, Italy

ABSTRACT: This paper presents a simplified 2D train-bridge dynamic interaction simulation tool to model the scenario of a ship collision against one of the piers of a bridge located on an oversea connection. Being rolling and lateral motion of each carbody of a train predominant in train motion following a ship collision event during train transit, only these two components of vehicle dynamics are considered. The bridge structure is modelled by means of a modal approach, ship impact is represented through a time dependent force, taken from literature. The proposed simplified model enables a fast check, thanks to a time-efficient simulation, during early bridge design phase, in terms of lateral carbody acceleration, so as to get an early representation of the influence of ship collision events on train lateral dynamics. In fact, the proposed model allows the user to test and investigate a large variety of scenarios, in terms of train and structure properties as well as loading features, in a fast and efficient way, without loss of relevant information. Moreover, this approach would enhance structure and train dynamic interaction understanding, highlighting the role played by train lateral dynamics and its interaction with bridge dynamics, in critical scenarios.

1 INTRODUCTION

Runability analysis represents an important stage in the design phase of bridges and viaducts. When dealing with structures built over large rivers or sea strait, ship collision events occurrence must be taken into account. This scenario is even more required considering that the number of bridges is constantly increasing, as long as the traffic of large and heavy ships sailing seas and rivers. In recent years many researchers dealt with this topic: there are many articles in literature since there are many variables that must be considered when performing runability analysis, some of them are herein briefly recalled.

There is a variety of bridge types with different specifications and features: for example, floating spans bridges may be used, as studied in (Sha et al. 2017), or cable stayed bridges, due to their lower cost in the construction stage and good design flexibility (Zhou et al. 2021). Because of their role in supporting the deck, piers are inherently at risk when dealing with lateral ship collision events (Gholipour et al. 2018), (Bernardini et al. 2023).

Moreover, it is important to consider the composition of the superstructure as it can be crucial in case of a ship deck-house collision, that may represent a very critical scenario. Sha et al. made a FEM-based study on this particular case, focusing on reinforced concrete (RC) and steel girders (Sha et al. 2017). Moreover, since the variety of vessels is significant, scholars carried out investigations considering different types of impact loads, such as barge impact which is featured by a load history that reaches linearly the primary peak and, then, the force reduces before growing again, non-linearly, in correspondence of the plastic deformation phase of the barge structure, creating a secondary peak, as presented in (Xie et al. 2022). On the other hand, when dealing with vessels, two categories can be distinguished, consisting in vessels with and without front bulb respectively. The first one has been investigated, among the others, by (Wei Fan et al. 2016) using a FEM approach to model the force-deformation curve of the bulb to have a deeper understanding on how the energy is exchanged between ship and bridge, and, consequently, the impact force. The authors in (AbuBakar and Dow 2019), instead, opted for

DOI: 10.1201/9781003483755-476

a full-scale experiment for the same purpose. Also in this case, as for the barge, the weight, speed and angle of the boat during the collision was found to play a pivotal role. In the framework of train bridge interaction, also train parameters influence on runability assessment must be considered; among them, the vehicle speed (Li et al. 2015), which is of interest also because the use of high-speed trains is growing (Olmos and Astiz 2023), technical parameters such as suspensions stiffness of the carbody, damping and mass, as well as the composition of the train. In addition, the position of the train at the instant in which the collision occurs can also affect vehicle accelerations and, therefore, passengers' safety (Li et al. 2015). A comprehensive review of train-bridge dynamic interaction problem in the events of wind, waves, ship impact and earthquakes actions are presented in (Li et al. 2022).

From the existing literature, it is possible to notice that the majority of articles regards examinations that are carried out using FEM analysis or full-scale experiments. While the latter can provide accurate solutions, on the other hand, they are not so immediate, given the impossibility to conduct an experiment using natural dimensions, and it may be quite difficult to perform also meaningful scaled tests. Moreover, while being versatile, FEM analysis is time-consuming when large infrastructures are considered, requiring a long time to simulate the scenario of interest with all the different design options, as it may occur on the early design stage of a bridge.

The aim of the 2D Train-Bridge-Interaction (TBI) simplified model which will be presented in this paper is to provide a more time-efficient simulation tool suitable for early design stage of bridges, and early-stage determination of the most critical scenarios. Designers could make use of this kind of tool to simulate a large variety of scenarios and make a first selection of the most critical ones in terms of runability analysis, from lateral dynamics perspective. Once most critical scenarios are defined, a more refined analysis (i.e., with 3D approaches) may be performed.

Compared to other papers dealing with vertical train-bridge dynamic interaction simulation, such as (Lou and Zheng 2007) and (Kohl et al. 2023), in this work, the focus is on lateral dynamics that will be investigated since it is crucial in case of ship impact.

The article is organized with the following outline: Section 2 is devoted to the description of the simulation model. In Section 3, the outcomes of a set of simulations are illustrated and critically discussed. Finally, in Section 4, conclusions are drawn.

2 MODEL DESCRIPTION

The developed 2D model for the simulation of train-bridge lateral dynamics is set up as follows: bridge dynamics is modelled by means of a modal approach (Cheli and Diana 2015), while each train coach through a 2 degrees-of-freedom lumped parameters model. Lateral and roll degrees-of-freedom of each carbody are considered, while the bogies are considered to fully participate to the lateral motion of the deck, according to the scheme in Figure 1.

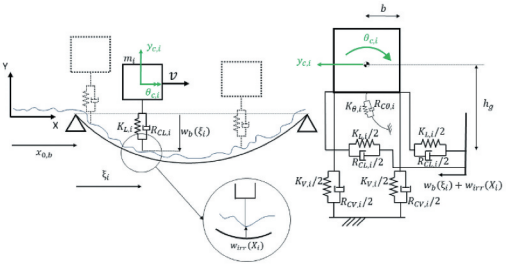

Figure 1. Top view of the scheme of the 2D VBI model developed in this work. A mass for each coach composing the entire train is considered.

The vehicle is represented through a sprung mass, considering vertical, lateral and torsional (anti-roll bar) stiffnesses, in charge of modelling secondary suspension effect: lateral track irregularity is also taken into account in the simulation, and, in the present work, it was calculated from the PSD reported in (ORE B176 1989).

The equations of motion were written according to Lagrange formulation which relies on the definition of kinetic, potential energies, as well as the dissipative function and the virtual work performed by external forces not considered in the computation of the aforementioned functions.

Therefore, according to the modal approach theory (Cheli and Diana, 2015), the kinetic energy of the whole system can be written in the following additive form:

$$T = \sum_{i=1}^{m} \left(\frac{1}{2} M_{c,i} \dot{y}_{c,i}^2 + \frac{1}{2} J_{c,i} \dot{\theta}_{c,i}^2 \right) + \frac{1}{2} \int_0^L m_b \left(\frac{\partial w}{\partial t} \right)^2 dx \tag{1}$$

where m is the number of coaches that are considered, $\mathrm{M_{c,i}}$ is the i-th carbody mass, $\dot{y}_{c,i}$ the velocity and $\dot{\theta}_{c,i}$ the rolling speed of the i-th car considered in the simulation. The second part of kinetic energy expression, including the integral (L is the length of the bridge), comes from the analytical derivation of the kinetic energy of the bridge; m_b is the mass per unit length of the bridge, while $(\partial w/\partial t)$ is the lateral speed of any section of the bridge which must be integrated over the length L to obtain the kinetic energy of the structure. Therefore, w represents the lateral displacement of the bridge (w_b in Figure 1). It is worth mentioning that in the present work the lateral mode shapes of the bridge are introduced as analytical modes of a simply supported beam. The obtained mode shapes are close to the ones of a complete viaduct structure composed of deck and piers (Bernardini et al. 2023). Then, the potential energy is computed as follows:

$$V = \sum_{i=1}^{m} \left(\frac{1}{2} K_{L,i} \left(y_{c,i} - w(\xi_i, t) + h_{g,i} \theta_{c,i} - w_{irr}(X_i) \right)^2 + \frac{1}{2} K_{\theta,i} \theta_i^2 + \frac{1}{2} K_{V,i} (b_i \theta_i)^2 \right) + \frac{1}{2} \int_0^L EJ \left(\frac{\partial^2 w}{\partial x^2} \right)^2 dx \tag{2}$$

Where $K_{L,i}$ and $K_{V,i}$ are the stiffnesses of the secondary spring of each i-th coach, respectively in lateral (y) and vertical (z) directions. Referring to Figure 1, it is important to notice that $K_{V,i} = 2K_{V,sg}$ and $K_{L,i} = 2K_{L,sg}$, while $K_{\theta,i}$, instead, represents the stiffness of the anti-roll bar of the coach, connecting carbody and bogie frame, for the roll motion only. The parameter h_g is the height of the center of gravity (c.o.g.) of the carbody with respect to the elastic center of the springs of the secondary suspensions, b is half lateral distance between left and right secondary springs. Moreover, $\mathrm{y_c}$ and θ_c represents the two degrees-of-freedom of the train model, $w_{irr}(X_i)$ represents the lateral track irregularity contribution, which exists also outside the bridge span (for $X_i \geq 0$), evaluated at the position $X_i = vt - x_{0,i}$, where $x_{0,i}$ represents the distance of the i-th coach from the absolute initial position (where irregularity starts). Moreover, the position $\xi_i = vt - x_{0,i} - x_{0,b}$ represents the position of the i-th carbody from the beginning of the bridge, where t is the simulation time. Finally, E is the Young Modulus and J is the inertia moment of the bridge structure. Considering a modal approach is adopted for modelling bridge dynamics, the overall potential energy can be written as follows:

$$V = \sum_{i=1}^{m} \left(\frac{1}{2} K_{L,i} \left(y_{c,i} - \sum_{j=1}^{n} \Phi_j(\xi_i) q_j(t) + h_{g,i} \theta_{c,i} - w_{irr}(X_i) \right)^2 + \frac{1}{2} K_{\theta,i} \theta_i^2 + \frac{1}{2} K_{V,i} (b_i \theta_i)^2 \right) + \frac{1}{2}^T [K_s] \underline{q} \tag{3}$$

where $\Phi_j(\xi_i)$ is the j-th mode shape function calculated in correspondence of ξ_i, while $\underline{q}(t)$ contains the modal coordinates (Cheli and Diana 2015), describing bridge lateral motion. Furthermore, while m stands for the number of coaches, n stands for the number of modes considered in the simulation. Finally, $[K_s]$ is defined as the structural modal stiffness matrix of the bridge.

The dissipative functions can be written as follows:

$$D = \sum_{i=1}^{m} \left(\frac{1}{2} R_{CL,i} \left(\dot{y}_{c,i} - \frac{\partial w}{\partial t}(\xi, t) + h_{g,i} \dot{\theta}_{c,i} - \left. \frac{\partial w_{irr}(x)}{\partial x} \right|_{x=X_i} \frac{dx}{dt} \right)^2 + \frac{1}{2} R_{C\theta,i} \dot{\theta}_i^2 + \frac{1}{2} R_{CV,i} (b_i \dot{\theta}_i)^2 \right) + \frac{1}{2} \dot{\underline{q}}^T [C_s] \dot{\underline{q}} \tag{4}$$

where R_{CL} and R_{CV} are the lateral and vertical damping values of the secondary suspension of each carbody, while $[C_s]$ is the structural modal damping matrix of the bridge. No damping is associated to the anti-roll bar. The term related to the lateral speed of the bridge can be expressed, computing the derivative, as:

$$\frac{\partial w}{\partial t}(\xi,t)=\sum_{j=1}^{n}\left.\frac{\partial\Phi_j(x)}{\partial x}\right|_{x=\xi_i}\frac{dx}{dt}q_j(t)+\sum_{j=1}^{n}\Phi_j(\xi_i)\frac{\partial q_j(t)}{\partial t}=\sum_{j=1}^{n}\Phi'_j v q_j+\sum_{j=1}^{n}\Phi_j\dot{q}_j \tag{5}$$

$\dot{y}_c$ and $\dot{\theta}_c$ now represents the speeds of the 2 degrees-of-freedom coach model.

$[C_s]$, as mentioned before, is the structural modal damping matrix related to the bridge expressed as Rayleigh damping (with $\alpha = 0.1$ and $\beta = 0.001$):

$$[C_s]=\alpha[M_{bb}]_{nxn}+\beta[K_s]_{nxn} \tag{6}$$

Finally, the time-dependent force term $F(t)$, modelling the ship impact event occurred at ξ_k position, is introduced in the equation of motion of the system obtaining the following formulation:

$$[M]\underline{\ddot{z}}+[C]\underline{\dot{z}}+[K]\underline{z}=\underline{\dot{b}}+\underline{b}+c_p[\Phi_1(\xi_k),\Phi_2(\xi_k),\ldots,\Phi_n(\xi_k),0,\ldots,0]^T F(t) \tag{7}$$

where the coefficient c_p considers that the motion at the impact point is close to the base of the pier, reducing the modal amplitude with respect to the deck level. The terms $\underline{b}$ and its time derivative $\underline{\dot{b}}$ come from dissipative and potential functions: these terms are due to track lateral irregularity $w_{irr}(x)$, which acts as an external input along the lateral direction. The term $\underline{b}$ is defined as follows:

$$\underline{b}=\begin{Bmatrix}\underline{b_b}\\ \underline{b_t}\end{Bmatrix} \tag{8}$$

where:

$$\underline{b_b}=\sum_{i=1}^{m}\left(K_{L,i}\begin{Bmatrix}-\Phi_1(\xi_i)\\ -\Phi_2(\xi_i)\\ \vdots\\ -\Phi_n(\xi_i)\end{Bmatrix}w_{irr}(X_i)\right) \tag{9}$$

and:

$$\underline{b_t}=\begin{Bmatrix}K_{L,1}\\ K_{L,1}h_{g,1}\\ \vdots\\ K_{L,m}\\ K_{L,m}h_{g,m}\end{Bmatrix}w_{irr}(X_i) \tag{10}$$

Equation (7) describes the lateral motion of the system in case of ship collision event: at this stage, it is important to observe that, while mass matrix is constant throughout the whole simulation, damping and stiffness matrices changes in time according to vehicles motion on the structure. By updating these two matrices, time instant by time instant, it is possible to model vehicle bridge lateral dynamic interaction. The time integration of the equation of motion was performed considering Newmark algorithm as provided in (Rao 2018).

3 RESULTS

The simulations are carried out considering train and bridge parameters collected in Table 1. For the bridge model, ten mode shapes are considered. The first lateral frequency of the bridge is $f_1 = 0.6\ Hz$ which is equivalent to the lateral-roll frequency of coach P_1, while P_2 lateral-roll frequency is equal to 0.51 Hz.

Table 1. Bridge and train main parameters.

Bridge parameters				
Mass (m_b)	66000		kg/m	
Young modulus (E)	29000		MPa	
Inertia moment (J)	350		m^4	
Length (L)	180		m	
1st Natural frequency(f_1)	0.6		Hz	
Train Parameters				
Coach type	P_1		P_2	
Mass	51000	kg	58000 kg	kg
Rotational inertia	1.65e5	$kg \cdot m^2$	1.8e5	$kg \cdot m^2$
Secondary suspension parameters

2nd Natural frequency (roll-lateral)	1.36	Hz	1.27	Hz

Figure 2(a) illustrates the time history of the barge impact used in this work. The plotted force has a similar shape to the one adopted in (Xie et al. 2022). The adopted force quickly reaches the peak value of 15 MN in the linear phase, then, during buckling unstable phase there happen a rapid drop of impact force. After that, there is plastic deformation phase of the barge structure which causes a nonlinear increase of impact force, which grows slowly finally reaching an extreme value of 4.3 MN. Last, in the unloading phase, the barge and whole bridge begin to separate from each other, the elastic deformation recovers, thus, the impact force decreases rapidly.

The presented force is applied according to the system Equation (7), considering a proper scaling factor (c_p=0.167 in this case), to take into account the location of the impact point on the pier.

The structure lateral displacement and accelerations, evaluated at midspan, are plotted in Figure 2(b): a displacement peak of 12 mm is produced by the impact at midspan, comparable to what was obtained in (Xie et al. 2022) and (McVay et al. 2009), with an acceleration peak of 0.95 m/s^2. The bridge span length is equal to 180 m, and the train is running at a constant forward speed equal to 100 km/h. At the simulation starting time (t=0s) the first coach is positioned 80 m before the beginning of the bridge: moreover, a distance of 25 m is considered between one carbody center of mass and the others. A convoy consisting of four coaches is adopted in the presented simulations: two different coach types are considered, namely P_1 and P_2, whose main properties are collected in Table 1. The train configuration is P_1-P_2-P_1-P_2. In Figure 2(b), vertical dashed and labeled lines identify the time instants at which each coach of

the convoy enters and leaves the bridge. In Figure 2(b) it is clearly visible the time instant at which the impact occurs, which happens when the first coach of the train is crossing the bridge at a section 45 m after bridge entrance. Moving from structure perspective to the vehicle point of view, Figure 3 shows the accelerations of the two coach's degrees-of-freedom (y and θ) for each of the four coaches composing the train convoy. Before the impact, it is possible to notice that the only source of excitation of the vehicle lateral motion is due to track geometrical irregularity. The motion due to the occurrence of the impact can be clearly observed given higher accelerations amplitude for the two degrees-of-freedom of each rail vehicle.

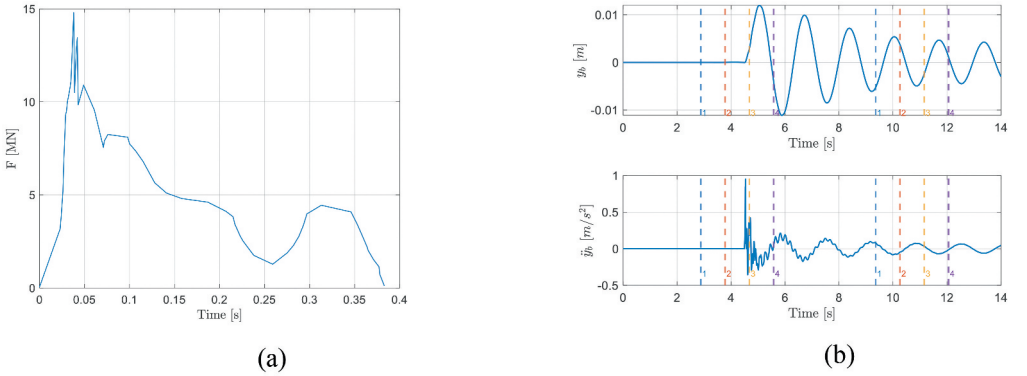

Figure 2. (a): Time history of the impact force considered in the presented simulations. (b): Lateral displacement and acceleration of the bridge evaluated at midspan.

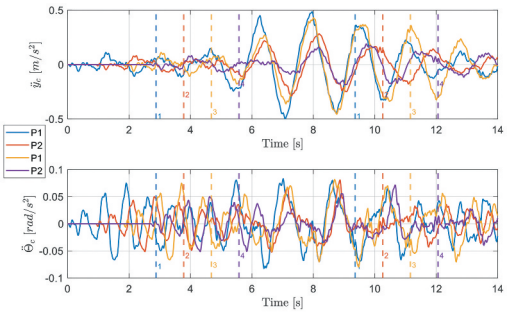

Figure 3. Lateral and rolling accelerations of the train coaches (P1-P2-P1-P2).

A set of simulations was performed from 100 km/h to 250 km/h, considering a step of train speed of 25km/h. In Figure 4(a), peaks of vehicle lateral accelerations are plotted as a function of train travelling speed: it is possible to observe that, for the considered speed range, coaches with a frequency corresponding to the one associated to bridge first lateral mode shape (P_1) present higher accelerations compared to coaches with a frequency that is further from 0.6 Hz (P_2). This outcome is valid for each considered speed, in fact, the peak values of the lateral and roll acceleration associated with P1 coaches are always larger than the ones featuring P2. Moreover, another aspect which is worth pointing out is that larger speeds do not always lead to higher lateral acceleration peaks: this result may be due to the time on which the train travels over the bridge structure once excited by the ship impact event. The faster is the forward speed, the lower is the time interval spent by the train over the structure, and therefore the lower is the amount of energy received in input by the train from the bridge, cycle by cycle. This reasoning can also explain while for speed higher than 175 km/h the rear coach shows

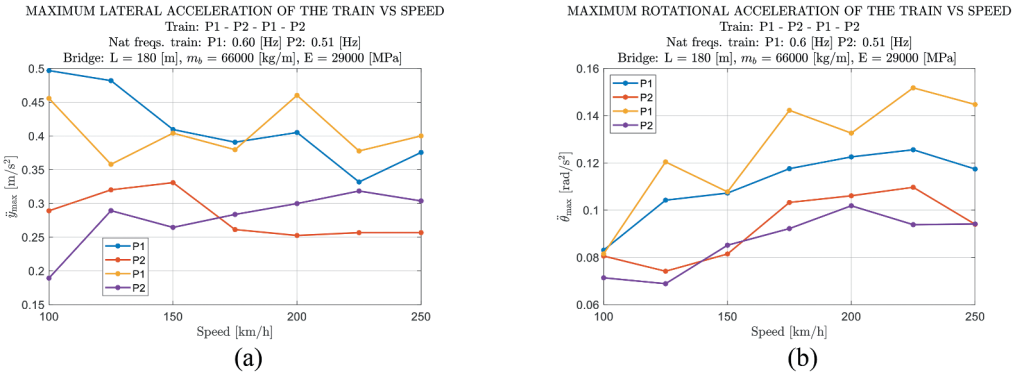

Figure 4. (a). Carbody lateral acceleration peaks plotted as a function of train speed for each coach of the train convoy. (b): Carbody roll acceleration peaks plotted as a function of train speed for each coach of the train convoy.

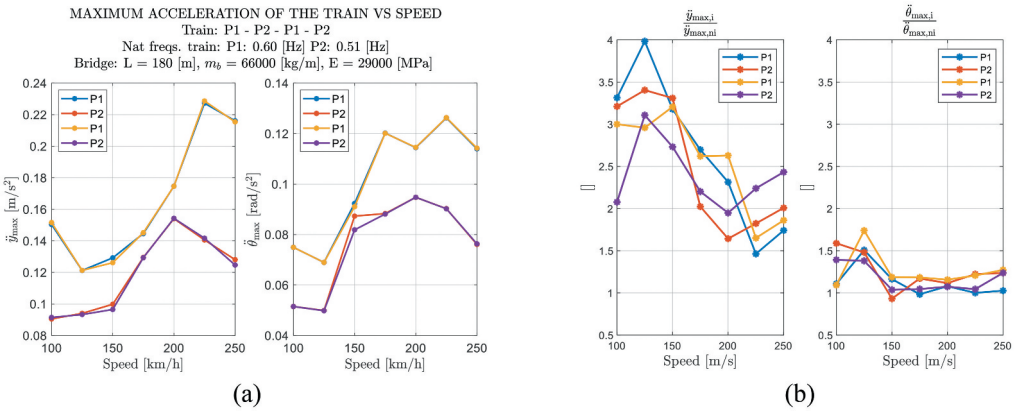

Figure 5. (a). Carbody lateral and roll acceleration peaks plotted as a function of train speed for each coach of the train convoy without impact event. (b): accelerations peak ratios.

larger lateral acceleration peaks than the leading one. In fact, this outcome may be the result of a larger time spent over the excited structure (by rear coaches), which becomes a more relevant aspect, when the travelling speed increases and the whole transit interval reduces. Concerning coach roll motion, a different behavior with speed from the one depicted in Figure 4(a) can be observed in Figure 4(b): in fact, for this parameter, the values at the highest speed (250 km/h) are always larger than the ones at the lowest speed (100 km/h). In Figure 5(a) accelerations peak values are plotted as a function of train speed, in case no impact is considered in the simulation. To better investigate and quantify the effect played by ship collision occurrence on vehicle dynamics, Figure 5(b) illustrate the ratios between peak accelerations in case of ship impact event divided by the same parameter when no impact is considered. From Figure 5(b), it is clear that the modeled ship impact affects lateral acceleration peaks more than roll ones.

4 CONCLUSIONS

In this work a simplified 2D VBI tool is presented, with the purpose to preliminarily investigate train lateral dynamic behavior in case of ship impact events. Each coach of the train is modelled through a 2 degrees-of-freedom system including lateral and roll motion of each

carbody, considering only the secondary suspension as well as carbody inertial terms. Bridge dynamic is modelled through a modal approach. The model allows for the consideration of vehicle bride dynamic interaction in lateral direction, assuming the bogie lateral motion coincident with bridge deck lateral motion. The model is integrated in time domain, enhancing a deeper understanding of the role of ship impact events on train running behavior. As a first outcome obtained by the presented simulation model, it was found that carbodies with lateral frequencies closer to bridge ones will result in higher accelerations compared to vehicles with frequencies that are further, as observed in (Bernardini et al. 2023) using a 3D TBI tool. As a practical outcome, the model aims at being a tool for a fast definition of scenarios that can result in more severe and critical runability conditions, starting from a wider set, saving time and computational costs, that can be allocated to a smaller group of simulations to be carried out with complete train-bridge interaction models. Future outlooks of this work consist in introducing bump stops elements in the vehicle model, as well as using, instead of analytical mode shapes, the ones extracted from a FE model of a bridge with a deck structure sustained by piers.

Energy absorption of bolted connection up to tensile ultimate state

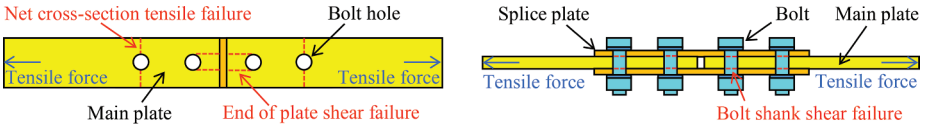
T. Takai, K. Tanii & S. Masudome
Kyushu Institute of Technology, Kitakyushu, Japan

ABSTRACT: The tensile resistance of the main plate of a bolted connection is reduced by making bolt holes. The structures are sometimes exposed to excessive forces, such as earthquake action. The resistance and energy absorption are important performances against such forces. High energy absorption can realize a ductile structure. However, the energy absorption of the bolted connection needs to be clearer because the bolted connection is usually designed based on resistance. In this study, the energy absorption of bolted connections was investigated by a finite element analysis. At first, the numerical model was checked by reproduction analysis of some experiments focused on failure modes and the stress-strain model. A parametric study was conducted to clear the energy absorption. The energy absorption was evaluated and discussed, focusing on the failure modes.

1 INTRODUCTION

Bolted connection is used for steel structures and bridges. The tensile resistance is reduced by making bolt holes. The structures are sometimes exposed to excessive forces, such as earthquake action. The resistance and energy absorption are important performances against such forces. High energy absorption can realize a ductile structure. However, the energy absorption behaviour of the bolted connection needs to be clearer because the bolted connection is usually designed based on resistance. In this study, the energy absorption of bolted connections was investigated by a finite element analysis. The reproduction analysis of some tensile experiments was conducted to check the validity of the analysis. The reproduction analysis compared some cases focused on failure modes and stress-strain models. A parametric study was conducted to clear the energy absorption of some dimensions. The energy absorption, including resistance and elongation under the ultimate state, was evaluated and discussed, focusing on the failure modes.

2 VALIDATION OF NUMERICAL MODEL



2.1 *Procedure of validation check*

Before the parametric study, the validation of numerical analysis was checked by the reproduction analysis of some tensile experiments. The results of the experiments were obtained from published papers. The reproduction analysis was conducted to simulate the experiment using finite element software. The failure modes and the tensile load-elongation curves obtained from the analysis were compared with the experiments. The matching of not only the load but also the elongation is a significant concern because this study discusses energy absorption.

2.2 *Failure modes of bolted connection in tension*

Figure 1 illustrates the failure modes of bolted connection in tension. A net cross-section tensile, bolt shank and end-of-plate shear failures are well-known failure modes. In actuality, one of the three modes is generated. The failure mode is determined by the minimum resistance in three modes.

Figure 1. Failure modes of bolted connection in tension.

2.3 *Tensile experiments of bolted connection*

Table 1 summarizes the dimensions of the specimens. Moriyama et al. (2018) conducted tensile experiments on bolted connections and obtained net cross-section tensile failure modes. Three F10T M16 bolts (JIS B 1186, 2013) were placed in half of the specimen. The diameters of the bolt shank and hole were 16 and 18 mm, respectively. The steel grade of the plates was SS400 (JIS G 3101, 2020). The width of the main plate was 120 mm. The pitch and edge distance of the bolts were the same as 72 mm. The gauge length to measure the elongation was 348 mm from the centre of the specimen. They also obtained a bolt shank shear failure mode. The outline of the specimen was almost the same as the former specimen. However, the width of the main and splice plates was 216 mm. The wider plate gives higher tensile resistance in the net cross-section and causes the bolt shank shear failure instead of the net cross-section tensile failure. Toda et al. (2014) conducted tensile experiments on bolted connections and obtained end-of-plate shear failure modes. An F10T M16 bolt was placed in half of the specimen. The steel grade of the plates was SM400A (JIS G 3106, 2020). The width of the main plate was 120 mm. The gauge length for elongation was 225 mm from the centre of the specimen. The material property of F10T in shear failure in end-of-plate was unknown; they were filled with the minimum value defined in the specification (JIS Z 1186, 2013)

Table 1. Dimensions of specimens.

	Mode		Net cross-section tensile failure	Bolt shank shear failure	End-of-plate shear failure
Main plate and splice plate	Steel grade		SS400	SS400	SM400A
	Thickness	(mm)	9	19	9
	Yield point	(N/mm^2)	304	283	302
	Tensile strength	(N/mm^2)	449	442	468
Bolt	Steel grade		F10T	F10T	F10T
	Size		M16	M16	M16
	Diameter of hole	(mm)	18	18	17.8
	Proof stress	(N/mm^2)	1046	1052	900
	Tensile strength	(N/mm^2)	1114	1093	1000

Figure 2 shows tensile load-elongation curves (P-δ) and absorbed energy-elongation curves (E-δ) from the experiments. The former curves were obtained from the published papers using graph digitizer software. The latter curves were obtained by the trapezoidal integral of the former curves. The maximum load and the absorbed energy until the maximum load were important characteristics considering the resistance against the excessive force. So, the absorbed energy was calculated until the maximum load.

2.4 *Methods of numerical analysis*

The finite element analysis was conducted using Abaqus standard 6.13. Figure 3 shows the finite element models. One-eighth of the connections were modelled considering the symmetry.

The stress-strain relationship was modelled by the tri-linear type or n-th power hardening law. Although only the yield point and tensile strength were obtained from the papers, the other

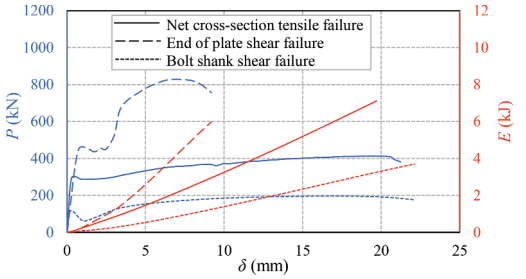

Figure 2. Experimental P-δ and E-δ.

values were required for the tri-linear model. Takai & Otsuka (2021) proposed a tri-linear stress-strain model with some regression expressions between material properties. At first, a nominal stress-nominal strain relationship was modelled with the yield point and tensile strength from the papers and other values from the regression expressions. After that, the nominal relationship was converted into a true stress-true strain relationship. Table 2 summarizes the values of the tri-linear models. The Young's modulus and Poisson's ratio are listed in Table 3.

The n-th power hardening law model is written as

$$\sigma = C\varepsilon^n \,, \tag{1}$$

where σ is stress, ε is strain, and C and n are material constants. The method to determine the constants was referred to JIS Z 2253 (2015). The two-point method was employed in this study. By right, the two points were chosen after reaching the strain rate defined in the specification. n is obtained by

$$n = \frac{\ln\sigma_T - \ln\sigma_S}{\ln\varepsilon_T - \ln\varepsilon_S}, \tag{2}$$

where σ_S is a stress after the strain rate, σ_T is tensile strength, ε_S is a strain after the strain rate, and ε_T is the strain at tensile strength. In this study, the former stress and strain were chosen the yield point to determine the constant. In another way, the material constants can be determined by the conditional expression of the beginning of necking at tensile strength in the metallic material tensile test (Hollomon, 1945). The condition at tensile strength is expressed as

$$\frac{d\sigma}{d\varepsilon}\Big|_{\sigma=\sigma_T} = \sigma_T \,. \tag{3}$$

By plugging Equation (1) into Equation (3) the constants are determined as

$$n = \varepsilon_T \,, \tag{4}$$

and

$$C = \frac{\sigma_T}{\varepsilon_T^{\varepsilon_T}} \,. \tag{5}$$

Table 4 summarizes the determined material constants of the n-th power hardening law models.

Figure 4 compares the stress-strain models. Case-1 is the case of the tri-linear stress-strain model. Case-2 is the case of the tri-linear model, which ignored the third slope. Case-3 is the case of the n-th power hardening law model determined by the two-point method. Case-4 is the case of the n-th power hardening law model determined by the condition of necking initiation.

The frictional coefficient was adjusted to reproduce the experimental slip load. The frictional coefficient in the bearing area between a bolt shank and a hole was 0.2 times that of other frictional areas to gain the stability of the contact calculation. The fracture model was selected as ductile damage as defined by the relationship between the fracture strain and stress triaxiality shown in the previous study (Li et al., 2020). The displacement damage evolution was set at 2.6 mm for plates and 1.4 mm for bolts (Tanii & Takai, 2022).

2.5 *Results*

Figure 5 shows the obtained tensile load-elongation curves (P-δ) and absorbed energy-elongation curves (E-δ). The elongation was obtained from the gauge length described in section 2.3. Table 5 summarizes the results of the experiments and numerical analysis. As a result, Case-2 gave a result similar to the experiment. Although the other case differed by 10-70% from the experiment, the differences in absorbed energy between Case-2 and the

Figure 5. Obtained *P*-δ and *E*-δ.

experiment were around 5-10%. Figure 6 shows the von Mises stress distribution of Case-2. The failure modes obtained from numerical cases were the same as the experimental failure modes. By the numerical analysis in this study, Case-2, which adopted the tri-linear stress-strain model which ignored the third slope, was in good agreement with the experimental results rather than other tri-linear and *n*-th power hardening law cases. From these results, the latter parametric study was conducted using the conditions of Case-2.

3 PARAMETRIC STUDY

3.1 *Study cases*

The parametric study was conducted to clear the energy absorption (Tanii & Takai, 2022). Table 6 summarizes the study cases. The focused parameters are the slip/yield strength ratio and the number of bolts. The ratio is obtained by dividing a slip resistance by the yield resistance of the main or splice plates.

Table 5. Results of experiment and numerical analysis.

Mode	Case	Result			Difference		
		Maximum load (kN)	Elongation at max. load (N/mm^2)	Absorbed energy (kJ)	Maximum load (%)	Elongation at max. load (%)	Absorbed energy (%)

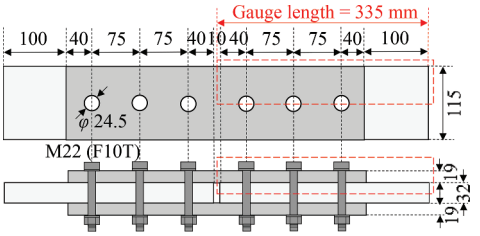

Figure 7. Shape of bolted connection (n3-b06).

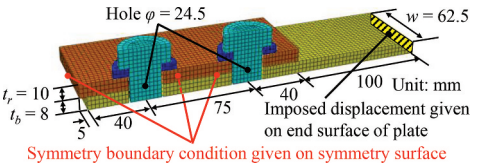

Figure 8. Outline of numerical model (n2-b06).

3.2 *Methods*

Figure 8 shows an outline of a numerical model. The connection components were meshed with 8-node linear reduced integration solid elements. The target length of the element was 2 mm. Considering the symmetry of the connection, one-eighth of the connections highlighted with the red dashed frame in Figure 7 were modelled. The symmetry boundary condition was given on the symmetry planes. The stress-strain relationship was the same as that of Case-2 of the tensile failure in net cross-section in Table 2, which ignored the third slope. In step-1 of the calculation, the bolt preload was installed by the bolt load function in Abaqus. In step-2, the tensile force was given by imposed displacement on the end surface of the main plate.

* Yield and failure mode: Net means net cross-section tensile mode. Bolt means bolt shank shear mode. End means end-of-plate shear mode.

3.3 *Results and discussion*

Table 8 summarizes the results obtained from the parametric study. Figure 9 compares the maximum loads, elongation at maximum load, and absorbed energy.

The maximum load for the same number of bolt rows is greater for smaller β. In the case of net cross-sectional tensile failure, the higher the maximum load, the greater the elongation at the maximum load. Therefore, the energy absorption was greater for smaller β. However, in end-of-plate or bolt shank shear failure cases, the absorbed energies were smaller than that in net cross-section tensile failure, although the maximum load was higher than that in the tensile failure. That is because the elongation at the maximum load was small in those cases.

Hence, the bolted connection, which occurs in net cross-section tensile failure, gives higher energy absorption and a more ductile structure. However, end-of-plate or bolt shank shear

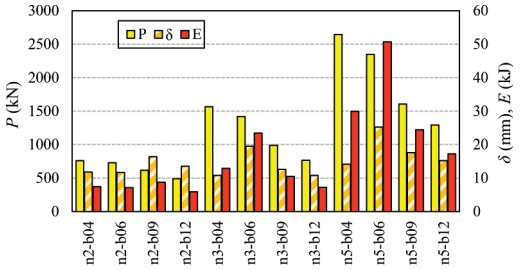

Figure 9. Maximum load, elongation, and absorbed energy.

failure gives smaller absorbed energy and is less ductile than net cross-section tensile failure, although they give high maximum loads.

4 CONCLUSION

This study investigated the absorbed energy of bolted connections in excessive tensile force. At first, validation of numerical analysis was checked by reproduction analysis of previous experiments. From the analysis, the case with the tri-linear stress-strain model, which ignored the third slope, was in good agreement with the experiment rather than other tri-linear and *n*-th power hardening law stress-strain cases. A parametric study was conducted to investigate the absorbed energy in other cases. The bolted connection, which occurs in net cross-section tensile failure, gives higher energy absorption and a more ductile structure. However, end-of-plate or bolt shank shear failure gives smaller absorbed energy and is less ductile than net cross-section tensile failure, although they give a higher maximum load.

ABSTRACT: Post-tensioned (PT) rocking piers have received considerable attention as an advantageous solution for seismic resilient structures. Their self-centering capacity, the advantages related to the column-uplifting mechanisms, and the possibility of being combined with energy dissipation devices largely contributed to this increasing attention. Simultaneously, Geotechnical Seismic Isolation (GSI) has emerged as a technique to reduce the seismic vulnerability of structures. The GSI a technique is based on design of a suitable interface between the foundation of the structure and the surrounding terrain. Such an interface can work as seismic isolation and energy dissipation mechanism. This research investigates the use of GSI for PT rocking piers equipped with external energy dissipation devices. The main focus of the investigation is the comparative assessment of the effectiveness of external dissipators and GSI to ascertain if the two protection mechanisms can synergize and collaboratively enhance the safety of the structure. The investigation employs numerical simulations through the direct integration of the equation of motion of the studied system. The outcomes of the parametric analysis are presented in gain maps that illustrate the effectiveness of the coupling within a designated parameter plane. Preliminary results show that GSI could be effective in combination with external dampers in reducing the seismic effects on rocking piers.

1 INTRODUCTION

Historically, self-centering structures have been widely used as seismic-resistant structures for their limited residual displacements. Additionally, starting from the last decades of the previous century, particular attention has been paid to rocking structural systems, and a significant number of researchers tried to make full use of their gravity-recentering ability for the design of seismic-resistant structures. The category of rocking structural systems comprises a variety of structures, the most common being rocking podiums, rocking frames and walls, and rocking piers. The inherent self-centering and energy dissipation abilities of rocking structural systems can be enhanced with the addition of supplementary devices aimed at reducing the displacement seismic demand of such structures and, consequently, mitigate their possible damage.

In the case of rocking piers, which are the focus of the present study, the seismic response is usually improved with three main protection strategies: *i*) base isolation (Rele et al., 2021), *ii*) use of internal post-tensioned (PT) tendons (Liu et al., 2018), *iii*) use of connection elements with dissipative behaviour at the rocking interface or external dissipative devices (EDDs) (Li et al., 2021, Sarti et al., 2016). Such a classification is proposed solely for the sake of clarity

DOI: 10.1201/9781003483755-478

since, in most cases, multiple strategies are applied at the same time in order to obtain dissipative controlled rocking. Both Zhong & Christopoulos (2022) and Piras et al. (2022) provide extensive literature reviews on rocking piers. The first one contains a comprehensive overview of self-centering rocking structures and focuses more on experimental works, whereas the second focuses on rocking bridge substructure systems and reviews other dissipation solutions proposed in the literature.

Relatively recently, Geotechnical Seismic Isolation (GSI) has emerged as a technique to reduce the seismic vulnerability of structures (Tsang 2008). Differently from the protection strategies presented above, GSI does not directly modify the characteristics of the structure to be protected but works on the interface between the foundation of the structure and the surrounding terrain. Thus, the main protection mechanism is based on the modification of the soil-structure interaction. Engineered soils, geosynthetics (geogrids, geotextiles), and granular materials like sand and gravel are commonly used in GSI systems. Their properties are tailored to achieve the desired isolation effect. GSI systems mostly involve three main protection mechanisms for the main structure. The first uses the modified foundation soil to alter the system's dynamic response by shifting its fundamental frequency (Aloisio et al. 2022, Tsang 2023). This mechanism is usually realized either through a layer of low-modulus material or through a sliding interface and its conceptual base is the same as the traditional base isolation mechanism. The second protection mechanism uses the dissipative properties of the engineered soil to reduce or filter the energy directed to the structure (Hazarika et al. 2023). The third mechanism relies on deliberate sliding control between the structural foundation and the encompassing geomaterials (Banović et al. 2022).

This paper proposes an initial investigation into the possible improvement in the seismic behaviour of rocking piers due to the application of EDDs and GSI. In particular, the focus is on the evaluation of the relative effectiveness of the two protection strategies. The authors aim to ascertain if the effectiveness of GSI is comparable to that of EDDs and if the two protection strategies can synergize and lead to a significant improvement in the seismic dynamics of rocking piers when used simultaneously. The model of a pier with a single unbound post-tensioned tendon located in the center of its cross-section and equipped with two viscous EEDs and GSI is used for the investigation. The GSI is modeled as in Tsang (2023) where the foundation is connected to the ground with both translational and rotational springs and dashpots. The models for the cases where EDDs or GSI are not considered are obtained from this reference model removing the unneeded terms in the equations of motion. The equations of motion of the reference structure (i.e. the pier with both EDD and GSI) are derived through a Lagrangian approach. The impact conditions needed to complete the mathematical model follow from the assumption of the conservation of the angular and linear momenta. The investigation employs numerical simulations through the direct integration of the equation of motion of the studied system. The outcomes of the parametric analysis are presented in maps that illustrate the maximum rotation of the pier with respect to the critical rotation that would lead to the pier overturning. Preliminary results show that GSI could be effective in combination with external dampers in reducing the seismic effects on rocking piers.

2 ROCKING PIER MODEL AND GSI MODELS

The pier investigated in this paper is modeled as a rigid block linked to a rigid oscillating base and to an additional mass at its top. The oscillating base represents the pier's foundation, and the connection is established through two viscous dampers. The additional mass schematizes the substructure above the pier, encompassing the deck and any other supplementary mass. Such a mass is assumed to remain horizontal during the motion.

In the case of GSI, the setup originally suggested by Tsang (2008) is adopted. As shown in Figure 1a, in this configuration, the base of the pier is embedded in a layer of low-modulus material, providing simultaneous support and confinement to the rigid base. These two elements are assumed to move cohesively in response to external excitation. Conversely, when GSI is not considered, the low-modulus material layer is replaced with a layer of natural soil (NS). The effect of

the layer of low-modulus material is modeled through two couples of springs and dashpots (Figure 1b) that act on the translation and rotation of the foundation of the pier, respectively.

Concerning the pier, the geometric configuration of the rigid block is that of a symmetric parallelepiped with a base of $2b_p$, a height of $2h_p$, and a unitary depth of $d_p = 1$, orthogonal to the representation of Figure 1b. The position of the center of mass of the pier m_p, denoted as G_p (Figure 1b and d), aligns with the geometric center of the parallelepiped, assuming uniform material composition with mass density ρ.

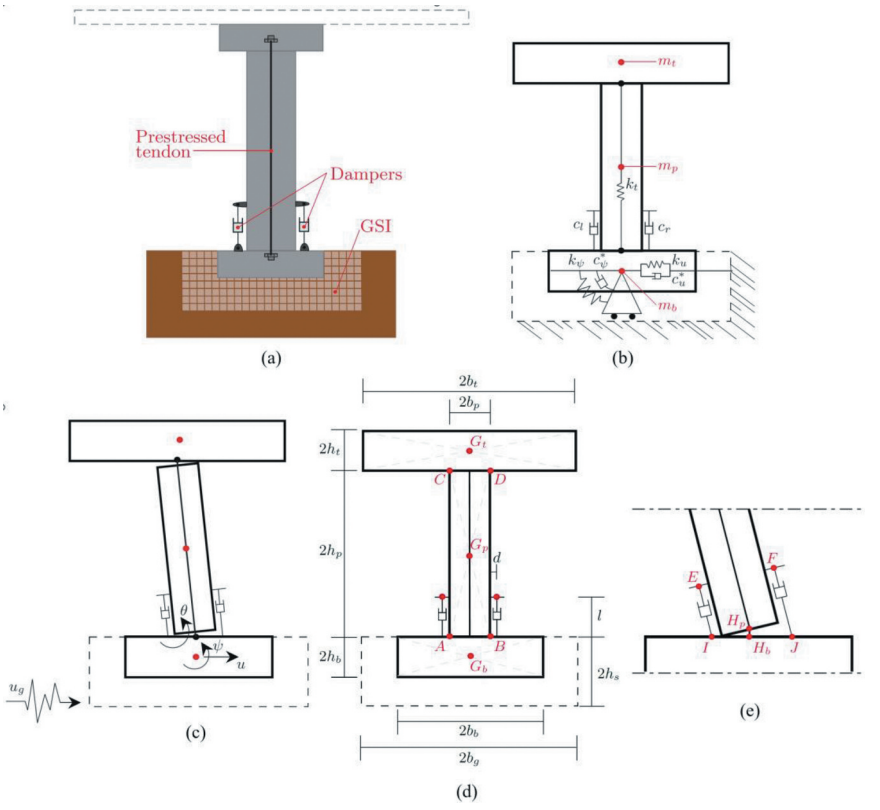

Figure 1. Schematic representation of the studied system (a); positions of the centers of masses; springs and dashpots used in the model (b); positive directions of the Lagrangian parameters (c); notable points used to describe the behavior of the pier (d) and (e).

In the proposed model, it is assumed that both free flight and sliding are prevented. Given this assumption, three distinct phases of motion can occur: rest, full contact, and rocking. The rest phase is the simplest, where neither the pier nor the oscillating base undergoes relative displacements with the soil. In the full contact phase, the oscillating base moves with respect to the ground, but there is no rocking of the pier. Finally, in the rocking phase, both base oscillation and rocking occur simultaneously. The equations of motions of the rocking phase can be written considering three Lagrangian parameters: the rocking angle $\theta = \theta(t)$, the rotation of the oscillating base $\psi = \psi(t)$, and its translational displacement $u = u(t)$. Figure 1c shows the positive directions of these Lagrangian parameters. The equations of motions of the other phases can be derived from the equations of motions of the rocking phase by removing unnecessary terms and equations.

2.1 *Equations of motion*

This section presents the derivation of the equations of motion for the complete rocking in the case of rocking occurring around point A (i.e. the bottom left vertex of the rigid body); those for rocking occurring around point B can be derived with the same approach and are not

presented for the sake of brevity. The equations of motion of the rocking pier are obtained by the well-known Lagrange's equation

$$\frac{d}{dt}\left(\frac{\partial L(t)}{\partial \dot{q}_l(t)}\right) - \frac{\partial L(t)}{\partial q_i(t)} = Q_i(t), \tag{1}$$

where the Lagrangian $L(t) = T(t)$-$V(t)$ is the difference between kinetic energy $T(t)$ and potential energy $V(t)$, $q_i(t)$ is one of the three Lagrangian parameters, and $Q_i(t)$ is the non-potential forces corresponding to $q_i(t)$. The kinetic energy $T(t)$ can be derived as

$$\begin{aligned} T(t) = \tfrac{1}{2}\big[&\big(J_b + J_p + J_t\big)\big(\dot{\boldsymbol{\Psi}}(t)\cdot\dot{\boldsymbol{\Psi}}(t)\big) + J_p\big(\dot{\boldsymbol{\theta}}(t)\cdot\dot{\boldsymbol{\theta}}(t)\big) + \\ &m_b(\dot{\mathbf{x}}_{G_b}(t)\cdot\dot{\mathbf{x}}_{G_b}(t)) + m_p\big(\dot{\mathbf{x}}_{G_p}(t)\cdot\dot{\mathbf{x}}_{G_p}(t)\big) + m_t(\dot{\mathbf{x}}_{G_t}(t)\cdot\dot{\mathbf{x}}_{G_t}(t))\big]. \end{aligned} \tag{2}$$

In Equation 2, J_b, J_p, and J_t are the polar inertia of the oscillating base, column, and top mass with respect to their centers of mass. The rotation vectors $\boldsymbol{\psi}(t)$ and $\boldsymbol{\theta}(t)$ are defined as $\boldsymbol{\psi}(t) = \{0,\ 0,\ \psi(t)\}^{\mathrm{T}}$ and $\boldsymbol{\theta}(t) = \{0,\ 0,\ \theta(\mathrm{i})\}^{\mathrm{T}}$, respectively. Vectors $\mathbf{x}_{Gb}(t)$, $\mathbf{x}_{Gp}(t)$, and $\mathbf{x}_{Gt}(t)$ define the positions of the respective centers of mass referred to an inertial reference system with an origin that is initially coincident with the left base vertex of the rigid block, i.e. point A in Figure 1b. They are functions of the Lagrangian parameters ($u(t)$, $\psi(t)$, and $\theta(t)$) and of the external ground excitation $x_g(t)$.

The potential energy $V(t)$ reads:

$$\begin{aligned} V(t) = &\big[m_p\big(\mathbf{x}_{G_p}(t) - \mathbf{x}_{G_p}(0)\big) + m_t(\mathbf{x}_{G_t}(t) - \mathbf{x}_{G_t}(0))\big]\cdot g + \frac{1}{2}[k_u(\boldsymbol{u}(t)\cdot\boldsymbol{u}(t)) + \\ &k_\psi(\boldsymbol{\psi}(t)\cdot\boldsymbol{\psi}(t)) + 2\big\|\mathbf{x}_{H_p}(t) - \mathbf{x}_{H_b}(t)\big\|\cdot\big(2k_t\big\|\mathbf{x}_{H_p}(t) - \mathbf{x}_{H_b}(t)\big\| + \sigma_0\big)\big]\ , \end{aligned} \tag{3}$$

with $g = \{0,\ g,\ 0\}^{\mathrm{T}}$ and $u(t) = \{u(t),\ 0,\ 0\}^{\mathrm{T}}$, where g is the gravity acceleration. In the equation, k_u and k_ψ are the translational and rotational stiffness coefficients of the GSI, whereas k_t is the axial stiffness of the unbound tendon. Vectors $\mathbf{x}_{Hp}(t)$ and $\mathbf{x}_{Hb}(t)$ provide the positions of the middle point of the base of the rigid block (i.e. point H_p in Figure 1c) and the position of the corresponding point on the oscillating base H_b. Consequently, the norm $\big\|\ \mathbf{x}_{Hp}(t) - \mathbf{x}_{Hb}(t)\big\|$ corresponds to half of the elongation of the unbound tendon due to rocking. Lastly, σ_0 is the prestress in the unbound tendon.

Since all non-conservative forces are dissipative forces, it is possible to write the non-potential forces $Q_i(t)$ in terms of a dissipative function $R(t)$ as $Q_i(t) = -\partial R(t)/\partial \dot{q}_i\,(t)$. Such dissipative function accounts for the viscous damping due to the GSI and external dampers and is written as

$$\begin{aligned} R(t) = &\frac{1}{2}\big[c_\psi(\dot{\boldsymbol{\psi}}(t)\cdot\dot{\boldsymbol{\psi}}(t)) + c_u(\dot{\mathbf{u}}(t)\cdot\dot{\mathbf{u}}(t)) + c_l\frac{d}{dt}(\|\mathbf{x}_{\mathrm{E}}(t) - \mathbf{x}_I(t)\| - \\ &\Big\|\mathbf{x}_E(\mathbf{0}) - \mathbf{x}_I(\mathbf{0})\|\Big)^2 + C_r\frac{d}{dt}\Big(\Big\|\mathbf{x}_F(\mathbf{t}) - \mathbf{x}_J(\mathbf{t})\| - \Big\|\mathbf{x}_F(\mathbf{0}) - \mathbf{x}_J(\mathbf{0})\|\Big)^{\mathbf{2}}, \end{aligned} \tag{4}$$

where c_u and c_ψ are the dissipative coefficients of the GSI model, whereas c_l and c_r are the dissipative coefficients of the left and right external viscous dampers, respectively. In Equation 4, the terms multiplied by c_l and c_r represent the time derivative of the elongation of the two dampers.

To complete the mechanical model, uplift and impact conditions are also derived. The uplift occurrence is verified by comparing the total translational acceleration acting on the column during integration in the full-contact phase (i.e. the total acceleration on the column computed from the full-contact equations) with the total acceleration acting on the column in the case of incipient uplift (i.e. the total acceleration computed from the rocking equations, where θ and it two first time derivative are neglected). The impact conditions, which provide the values of the Lagrangian parameters after an impact are derived by imposing the conservation of *i*) the angular momentum around the rocking vertex of the column, *ii*) the angular momentum around the center of rotation of the base of the pier, and *iii*) the conservation of

the horizontal momentum. Solving the three conservation equations, it is possible to find the post-impact values $u(t_i^+)$, $\theta(t_i^+)$, and $\psi(t_i^+)$ as functions of the post-impact quantities $u(t_i^-)$, $\theta(t_i^-)$, and $\psi(2t_i^-)$.

2.2 *Geotechnical seismic isolation model*

The model presented by Tsang & Pitilakis (2019) is used to model the basic configuration of the GSI system first proposed by Tsang (2008). Such a configuration assumes that the foundation of the pier is completely embedded in a layer of low-modulus material. The GSI layer has the shape of a rectangular prism of dimensions $2b_{\mathrm{GSI}}\times 2h_{\mathrm{GSI}}\times 2d_{\mathrm{GSI}}$, where $2d_{\mathrm{GSI}}$ is the dimension orthogonal to the schematic cross-section shown in Figure 1d. This paper assumes that the material used for the GSI is a rubber–soil mixture (RSM), which is usually widely proposed in the literature because of its compatibility with the natural environment and the availability of materials. The characteristics of such material (i.e. small-strain shear modulus $G_{max,\mathrm{GSI}}$, density ρ_{GSI}, and Poisson's ratio ν_{GSI}, as well as the characteristics of the natural soil that it replaces (i.e $G_{max,\mathrm{NS}}$, ρ_{NS}, and ν_{NS}) are also taken from Tsang & Pitilakis (2019).

The mechanical behaviour of the GSI is modeled by two sets of springs and dashpots. The first one, with stiffness and damping coefficients denoted as k_u and c_u, acts on the translation degree of freedom u. Similarly, the second one, which has coefficients denoted as k_ψ and c_ψ, works on the rotation ψ and its first derivative with respect to time. All of the four coefficients are functions of the geometric and mechanic characteristics of the GSI system (i.e., b_g, h_g, d_g, $G_{max,\mathrm{GSI}}$, ρ_{GSI}, and ν_{GSI}). Following Tsang (2023), k_u is modeled as:

$$k_u = k_b f_t f_w f_{lx} f_{lex}. \tag{5}$$

The stiffness coefficient k_b originates from the shearing interaction between the foundation base and the underlying soil. The effect of the embedment depth D is accounted for by f_t, whereas f_w, instead, accounts for the lateral interaction between embedded foundation walls and surrounding material. The last two, f_{lx} and f_{lex}, are additional stiffening factors, that account for the underlying stiffer layer of the NS and an additional embedment effect.

The damping coefficient c_u is modeled as:

$$c_u = k_u \frac{\xi_{eq} T_{SSFS}}{\pi} + c_b + c_s + c_p \tag{6}$$

The first term is the coefficient of the equivalent linear viscous damping due to the material internal damping that accounts for the hysteretic behaviour of the material. In Equation 6, ξ_{eq} is the equivalent viscous damping coefficient and T_{SSFS} is the fundamental natural period of the structure. It should be noted that the value of T_{SSFS} for a rocking structure is purely conventional since the column is modeled as a rigid body and not as a flexible structure The other three terms model the radiation damping which accounts for the energy loss as elastic waves propagate away from the foundation into an open half-space. Specifically, c_b refers to the shear generated between the base of the foundation and the soil, c_s to the shear between the lateral surfaces of the foundation in the direction of the motion and the soil, and c_p to the pounding due to the two lateral surfaces of the foundation in the direction orthogonal to the motion.

The rotation stiffness coefficient k_ψ is also expressed as the product of multiple factors as:

$$k_\psi = k_r \alpha_\psi f_{emb} f_{l\psi} f_{le\psi}. \tag{7}$$

In Equation 7, the rotational stiffness of the surface foundation k_r is conceptually analogous to k_b Such a rotational stiffness is multiplied by dynamic stiffness modifier α_0 which is dependent on T_{SSFS}. Both f_{emb} and $f_{le\psi}$ are stiffening factors that are functions only of the geometry of the GSI system and in particular of D. Lastly, $f_{le\psi}$ accounts for a further stiffening effect due to the stiffer original NS that underlies the low-modulus GSI layer.

Lastly, the damping coefficient c_ψ is modeled as:

$$c_\psi = k_\psi \frac{\xi_{eq} T_{SSFS}}{\pi} + c_r + c_{emb}. \tag{8}$$

As in Equation 6, the first term of Equation 8 corresponds to the equivalent linear viscous damping due to the material internal damping. The damping coefficient c_r, instead, refers to the rocking of the surface foundation. The last term,c_{emb}, accounts for the interaction of the lateral walls of the foundation with the surrounding material that generates compression-extension waves, shear weaves, and torsional weaves. The explicit definition of the four coefficients, as well as the exact definition of each of their factors/terms, can be found in Tsang & Pitilakis (2019).

3 PRELIMINARY ANALYSES

This paper presents the initial result of a larger campaign of parametric analyses performed to understand the influence of the geometric and mechanic characteristics of PT tendon, EDDs, and GSI on the seismic behaviour of the rocking pier. For this purpose, the ground motion record of the 1994 Northridge earthquake used in Tsang & Pitilakis (2019) is considered as seismic input. The seismic record is scaled to have a PGA = 1g. The dimensions of the column used in the following analyses are $2b_p$ = 0.5m and $2h_p$ = 4m; whereas the dimensions of the pier's foundations are $2b_b$ = 1.5m, $2h_b$ = 0.8m, and d_b = 2m. The mass of the superstructure is set to m_t = 10,400kg and the damping coefficient of the EDDs to $c_r = c_l$ = 225kNs/m. The mechanical characteristics of the RSM layer are $G_{max,GSI}$ = 5.88MPa, ρ_{GSI} = 1200kg/m^3, and ν_{GSI} = 0.4, while those of the NS are $G_{max,NS}$ = 120.3 MPa, ρ_{NS} = 1600kg/m^3, and ν_{NS} = 0.4. The reference values for the diameter and prestress of the PT tendons are d_{ten} = 10.0mm and respectively. The reference dimensions of the RSM layer are $2b_{GSI}$ = 1.7m, $2h_{GSI}$ = 2m, and $2d_{GSI}$ = 2.2m.

The first analysis, whose results are shown in Figure 2, is used to evaluate the sensitivity of the compared mechanical systems to the characteristics of the PT tendon. In particular, three different mechanical systems are compared: the rocking pier without EDDs and GSI (Figure 2a), the rocking pier equipped with EDDs (Figure 2b), and the rocking pier equipped with both EDDs and GSI (Figure 2c). For all the three systems the diameter of the PT tendon d_{ten} is varied between 5mm and 25mm while the prestress covers the range $\sigma_0 = 5{\cdot}10^6$ -$50{\cdot}10^6$N. For each combination of values, the equations of motion are integrated and the maximum total rotation of the pier $\zeta = \max(\psi + \theta)$ is collected. The metric used to represent the results is the ratio between this value and the critical angle of the column $\alpha_{crit} = \text{arctg}(b_b/h_b)$, i.e. $\Delta\zeta = \zeta/\alpha_{crit}$. Such a ratio corresponds to the percentage of the capacity of the column assuming the overturning as the limit state. This choice is made to provide a reference for the comparison; in an actual structure, the maximum rotation would be constrained by other factors such as the maximum elongation of the EDDs as well as the maximum lateral displacement allowable for the superstructure.

Figure 2a shows that when DDEs and GSI are not considered the seismic behaviour of the pier in terms of maximum rotation is negligibly affected by the value of the prestress in the tendon, especially for higher values of the stiffness of the tendon that is proportional to d_{ten}. That can be understood by noticing that the contour plots are almost vertical; for a given value of d_{ten} the difference in $\Delta\zeta$ can be attributed to the nonlinearity of the problem. Differently, the values of $\Delta\zeta$ strongly decrease as d_{ten} increases up to a value of approximately 12mm; after such a value the dependence of $\Delta\zeta$ on d_{ten} is largely reduced and the maximum angle reached during the motion is approximately 35% of the critical angle. When the EDDs are introduced into the system (Figure 2b), the maximum rotation reached by the pier during the motion reduces. Such a reduction is larger for smaller values of d_{ten} for which an approximate 10% reduction in $\Delta\zeta$ occurs. The reduction decreases after the threshold value of d_{ten} = 12mm to about 5% of the value reached without EDDs. The results still appear not to be significantly affected by σ_0, and this tendency is confirmed even when the GSI is considered (Figure 2c). Figure 2c shows that the combined effect of DDEs and GSI largely reduces the values of $\Delta\zeta$, especially for low values d_{ten} with the maximum value of $\Delta\zeta$ that drops from 0.685 in Figure 2a to 0.375 in Figure 2c. The introduction of the GSI further reduces the dependence of $\Delta\zeta$ on d_{ten}. However, smaller values of can be observed for smaller d_{ten} and a relative minimum can be roughly observed for 22mm < d_{ten} < 23mm.

The second analysis, presented in Figure 3, compares the seismic behaviour of the systems equipped with GSI for different base dimensions of the RSM layer. Figure 3a refers to the system with GSI and without EDDs, while Figure 3b refers to the system with both GSI and EDDs. Both the longitudinal and the orthogonal base dimensions of the RSM layer start from values that correspond to those of the pier's foundation plus 10cm for each side and are increased up to exceed the dimensions of the pier's foundation of 1m (i.e. 50cm for each side).

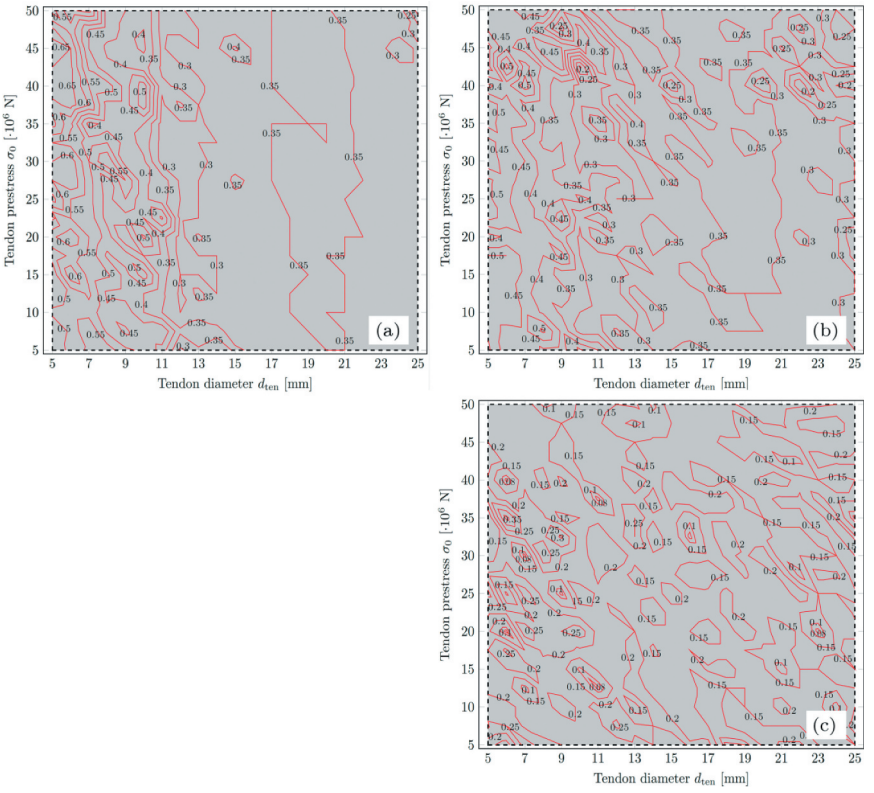

Figure 2. Contour plots of $\Delta\zeta$ as a function of the diameter and prestress of the PT tendon: (a) rocking pier; (b) system with EDDs; (c) system with GSI and EDDs.

Figures 3a and 3b show that although the dimensions of the RSM layer affect the values of the four parameters that characterize the GSI, there are only minor changes in the maximum rotation of the pier compared to the results of Figure 2c. Additionally, the comparison of the two graphs in Figure 3 clarifies that the effect of the EDDs is limited and almost negligible. However, the introduction of the EDDs changes the values for which the minimum values of $\Delta\zeta$ are obtained. There are concurrent reasons that justify this evidence. The first one is that the reduction due to the GSI for this seismic input is so high that there is no room to evaluate the effectiveness of the EDDs; this is shown by the small values assumed by $\Delta\zeta$ in all the parameters' plane. The second reason is that the GSI reduces the time spent in the rocking phase and, since for the chosen seismic inputs the maximum rotation occurs soon after the uplift, there is not enough time to benefit from the effects of the EDDs that are more evident later in the motion. However, this finding should be confirmed by assuming in the analyses different values of the EDDs' damping coefficients. Although limited, the initial analyses presented in this paper justify the necessity to further investigate the possibility of adopting the GSI as a protection mechanism for rocking piers with and without the addition of EDDs.

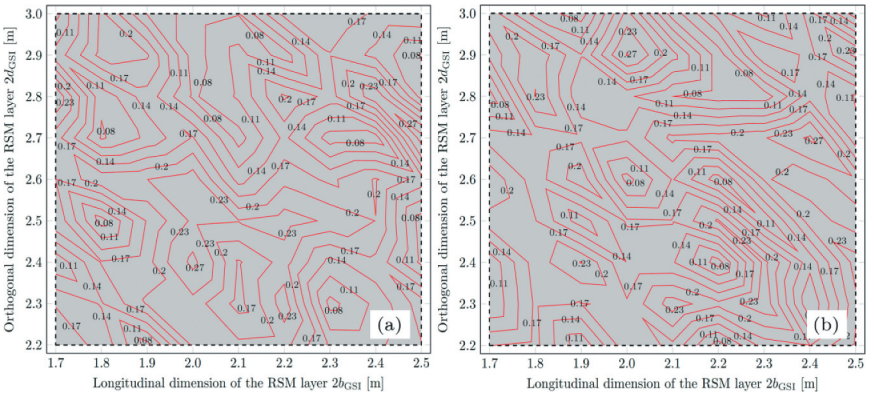

Figure 3. Contour plots of $\Delta\zeta$ as a function of the geometric characteristics of the RSM layer: (a) system with GSI; (b) system with GSI and EDDs.

4 CONCLUSIONS

The present study focuses on the seismic protection of PT rocking piers through GSI. In particular, through detailed models and computer simulations, the study scrutinizes the collaborative potential of GSI and EDDs in improving the resilience of rocking piers. Preliminary findings obtained through parametric analyses suggest a positive impact when GSI and EDDs collaborate. This discovery hints at a potential way to enhance the safety of bridges during earthquakes and contributes to ongoing discussions about earthquake-resistant design, paving the way for further exploration and testing in real-world scenarios.

ABSTRACT: The research on the flexural behavior of concrete- steel composite girders with tubular flanges was studied in this paper. Bending tests of concrete- steel composite girders with tubular flanges were conducted to obtain the failure mode and flexural capacity. The numerical simulation and parameter analysis of concrete- steel composite girders with tubular flanges were carried out. Based on the elastic-plastic analysis theory, a simplified calculation model of flexural capacity of the steel-concrete composite girder with tubular flanges was established. The design requirements were put forward for the steel-concrete composite girders with tubular flanges. The results show that the strength of the steel has a greater influence on the ultimate flexural capacity of steel-concrete composite girders than the strength of the concrete. With the increase of the thickness and width of the bottom flange, the ultimate flexural capacity of steel-concrete composite girders increases and the corresponding vertical ultimate displacement decreases accordingly. The proposed simplified calculation formula can be used to estimate the flexural bearing capacity of composite girders with tubular flanges.

1 INTRODUCTION

The utilization of steel-concrete composite girders with tubular flanges in various structural applications, particularly in bridges and high-rise buildings, offers notable advantages, garnering increasing adoption in China and yielding significant economic and social benefits. These girders, formed by substituting traditional flat plate flanges with circular, square, or rectangular tubular flanges, exhibit enhanced ductility, ample safety margins, and superior seismic performance, particularly suitable for seismic-prone regions (Sause 2015). Despite their practical engineering success, relatively little global research has been conducted on composite girders with circular tubular flanges (Wang 2017, Dong 2009). Previous studies by Kim and Sause analyzed the structural characteristics and developed calculation methods for composite girder bridges with circular tubular flanges, primarily focusing on elastic working stage properties (Kim 2008, Wang 2015). Wang et al. conducted experimental research on the bending performance of such composite girders, extracting mechanical characteristics and establishing formulas for ultimate bending capacity under construction and service conditions (Wang 2008a, Wang 2008b, Zhu 2012). However, these formulas, albeit insightful, are complex and challenging to apply in practical engineering scenarios. Additionally, due to limited specimen numbers, a comprehensive formula characterizing ductility for these composite girders has remained elusive. In this study, building upon bending test results, a nonlinear finite element model considering slip at the steel-concrete interface was developed. Through numerical simulations and systematic parameter analysis, the flexural capacity and ductility of composite girders with circular tubular flanges were thoroughly examined. Leveraging the findings from numerical

DOI: 10.1201/9781003483755-479

models, a practical calculation method for ultimate flexural capacity and displacement ductility coefficient was proposed, validated through numerical verification and parameter fitting, aiming to enhance the applicability of these composite girders in engineering practice.

2 BENDING TEST

A total of three composite girders with circular tubular flange were designed for the bending test, and all other design parameters were identical except for the different widths of the bottom flange, which was numbered CTFCGB-1 to CTFCGB-3. The design parameters are shown in Table 1. The total length of the test girder is 4300 mm, and the calculated span is 4000 mm. The total height of the test girder is 500mm. The width of the concrete plate is 600 mm with a thickness of 80mm. The outer diameter of the circular tube is 133 mm with a thickness of 4 mm. The height of the web is 271 mm with a thickness of 6mm. The thickness of the bottom flange is 16mm. The transverse stiffeners with a thickness of 12 mm were set at the end support and loading points. The test girder adopted Q235B steel and C40 concrete. The connection between steel girder and the concrete deck involves two rows of shear studs with a diameter of 10 mm and a length of 55 mm. The longitudinal steel bars and stirrups inside the concrete plate are all made of round steel bars with the R235 steel grade and the diameter of 6 mm. The steel tube is filled with self-compacting high-performance concrete inside the steel tube.

Table 1. Design parameters of test girders.

No.	Concrete grade	Longitudinal steel bars	Stirrups	Stud spacing/mm	Width of bottom flange/mm
CTFCGB-1	C40	14Φ6	Φ6@80	65	150
CTFCGB-2	C40	14Φ6	Φ6@80	65	260
CTFCGB-3	C40	14Φ6	Φ6@80	65	300

2.1 *Loading and instrumentation*

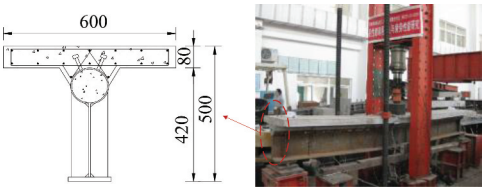

Figure 1. Loading device for test girders.

A 1000kN hydraulic jack is used for bending loading, and the load is measured by a force sensor connected to the jack. The resistance strain gauges with 5 mm and HJ strain gauges are used to measure the strain of steel girder and concrete plate. The displacement of the test girder and the end slip between steel tubes and infilled concrete are measured using a dial gauge. The relative slip at the interface between the steel girder and the concrete flange is measured using a YHD guide rod extensometer. The strain and displacement during the test are collected using a TDS-602 static data acquisition instrument. CTFCGB-1 girder adopts four-point bending loading with a pure bending zone of 1000 mm at the mid-span. CTFCGB-2 and CTFCGB-3 girders adopt the three-point bending loading procedure. Specially, a four-point bending loading is additionally conducted on the CTFCGB-3 girder with a maximum load controlled within 200 kN. The loading device for the test girder is shown in Figure 1.

2.2 *Experimental results*

Observing the test results, it was found that there was almost no relative slip between the steel tube and the infilled concrete for all test girders. There were no signs of instability or damage to the web. There is no visible relative sliding or lifting at the interface between the steel girder and the concrete plate. The failure mode of the test girder shows typical bending failure characteristics. The failure process was that the bottom flange of the steel girder first yielded, followed by continuous plastic development and stress redistribution. Finally, the concrete plate underwent crushing failure, and the test girder reached the ultimate flexural capacity and failed. The typical failure mode of the test girder is shown in Figure 2(a). The bending moment – deflection curves of test girders at mid-span are shown in Figure 2(b). It can be seen that the stress response of the test girder can be divided into three stages. From the beginning of loading to the yielding of the bottom flange of the steel girder, the mid-span deflection grows linearly with the load, and the overall performance of the test girder is good and in the elastic working stage (section OA). With the increase of load, the bottom flange of the steel girder starts to yield, and the yielding region extends to the inside of the cross-section and both sides of the span with the increase of load. The stiffness of the test girder cross-section decreases, the internal force in the cross-section is redistributed, the deflection grows faster, and the load-deflection curve shows an obvious nonlinear relationship. The test girder is in the elastic-plastic working stage (section AB). When the load reaches the ultimate flexural capacity, the concrete plate undergoes compression crushing, and then the capacity decreases sharply, and the test girder is in the destructive stage (section BC).The main mechanical characteristic results of the test girder are shown in Table 2. Where M_{yt} and δ_{yt} are the yield bending moment and the corresponded deflection respectively. M_{ut} and δ_{ut} are the ultimate bending moment and the corresponded deflection respectively.

Table 2. Main mechanical characteristic results.

3 NUMERICAL ANALYSIS

3.1 *Element and materials*

This study employs ABAQUS software for numerical simulation of the flexural performance of composite girders featuring circular tubular flanges. The simulation incorporates C3D8I elements for modeling the concrete plate and the infilled concrete within the circular tube, employing 9 integration points along the thickness direction. The steel girder is represented using S4 elements with 5 integration points along the thickness direction. Additionally, steel bars within the concrete plate are modeled using T3D2 elements, individually embedded in the concrete plate through a coupled translational freedom method. To emulate longitudinal and transverse

sliding, as well as vertical lifting effects between concrete plates and steel girders, three orthogonal mechanical spring connection elements (SPRING2) are utilized to simulate shear studs.

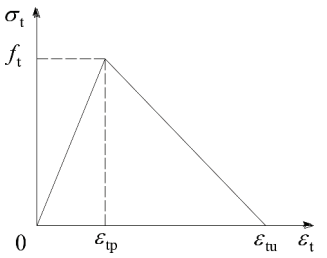

Figure 3. Linear softening model for the concrete.

Considering the distinction between elastic-plastic behavior of the concrete, the compressive constitutive model before the point of 1/3 σ_p was taken as a linear elastic relationship. The concrete adopts a linear softening model with inclined upward and downward lines, as shown in Figure 3. Where σ_t and ε_t are the uniaxial tensile stress and strain respectively. f_t is the peak uniaxial tensile stress. ε_{tp} and ε_{tu} are the strain and the peak strain for the peak uniaxial tensile stress respectively. In this paper, ε_{tu} is taken as 0.1. The tensile strength of the concrete has little effect on the mechanical performance of composite girders. It is assumed that the uniaxial tensile damage of the concrete increases linearly with the cracking strain until the maximum damage reaches 0.9 at the ultimate strain.

The constitutive relationship of the steel adopts a double line isotropic strengthening model, and the strength and elastic modulus are determined based on the test results in Table 3. The Poisson's ratio is 0.3, and the hardening slope is taken as 1/200 of the initial elastic modulus.

Table 3. Material properties

Material	Grade	Yield strength/Mpa	Ultimate strength/MPa	Elastic Modulus/GPa
Steel bars	Φ6	310	460.0	210.0
Steel plate	Q235B	312	430.0	200.0
Studs	Φ10×55	310	460.0	210.0
Infilled concrete	C40	-	56.3	37.1
Concrete plate	C40	-	50.4	36.2

3.2 *Relative slip between concrete and steel girder*

The shear slip relationship between shear studs has a significant impact on the flexural capacity and deformation performance of steel-concrete composite girders. Currently, the highly recognized fraction form (Buttry 1965) and index form (Ollgaard 1971) are:

$$\frac{V}{V_u} = \begin{cases} \frac{\alpha(s-\gamma)}{1+\beta(s-\gamma)} \\ (1-e^{-ns})^m \end{cases} \tag{1}$$

where V is the shear force of the studs. V_u is the ultimate shear capacity of the studs. s is the slip displacement of the studs. α, β, γ are the regression fraction parameters of slip. m, n are the regression index parameters of slip. In this paper, $m = 0.4$ and $n = 0.71$ are used for representing the slip relationship.

For the peak slip and ultimate slip of studs, the calculation formulas (Oehlers 1995) are adopted, which are:

$$s_p/d_s = 0.45 - 0.0021 f_{cc} \tag{2}$$

$$s_u/d_s = 0.41 - 0.0030 f_{cc} \tag{3}$$

where s_p is the peak slip of the studs. s_u is the ultimate slip of the studs, which is defined as the slip corresponding to the reduction of the ultimate capacity of the bolt to 95% after reaching its ultimate capacity.d_s is the diameter of the studs. f_{cc} is the axial compressive strength of concrete cylinders. The contact relationship between concrete plates and steel girders adopts normal hard contact, while ignoring the bonding effect of the contact surface.

3.3 *Numerical model and verify*

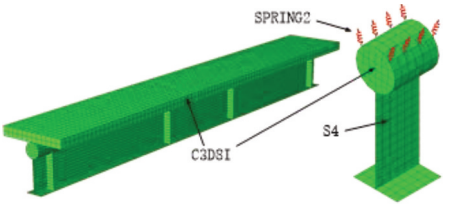

Figure 4. Finite element model.

A calculation model based on the actual size of the test girder was established, employing structured grid division technology to control concrete element size at 50 mm and steel girder element size at 25mm, ensuring adequate calculation accuracy. The finite element model of the composite girder with circular tubular flange, shown in Figure 4, adopts simply supported boundary conditions and node displacement loading. It incorporates material plastic deformation, boundary slip effect, and contact relationship, necessitating nonlinear iterative techniques for solution. Employing the arc length method, the model utilizes a displacement convergence criterion with a tolerance of 0.5%. Comparison results of bending moment and deflection obtained by FE method and test under yield and ultimate capacity limit states are presented in Table 4, with M_{yc} and δ_{yc}denoting numerical results of yield bending moment and corresponding deflection, while M_{uc} and δ_{uc} represent numerical results of ultimate bending moment and corresponding deflection.

Table 4. Comparison of FE method and test results at yield states and ultimate states.

No.	M_{yt} (kN·m)	δ_{yt} (mm)	M_{ut} (kN·m)	δ_{ut} (mm)	M_{yc} (kN·m)	δ_{yc} (mm)	M_{uc} (kN·m)	δ_{uc} (mm)	M_{yc}/M_{yt}	δ_{yc}/δ_{yt}	M_{uc}/M_{ut}	δ_{uc}/δ_{yt}

3.4 *Parametric analysis*

The flexural failure of composite girders is typically controlled by either plastic hinge formation or overall lateral bending torsional instability. Key parameters influencing the type of failure include the girder span, web height-to-thickness ratio, compression flange width-to-thickness ratio, and spacing between transverse stiffeners. This study focuses primarily on the mechanical performance of composite girders under the plastic failure mode to avoid lateral bending torsional instability. To ensure this, the aforementioned parameters must be rigorously controlled in finite element parameter adjustments. The model design maintains the same span and stiffener arrangement as the test girders, with compression flanges and webs designed as dense sections. A total of 48 finite element model girders were analyzed, considering three sets of key parameters: concrete plate thickness (h_f), outer diameter of circular tube (R), and bottom flange width (b_t). The height of the steel girder (h_s) remains constant at 420 mm across all models, resulting in a corresponding decrease in web height (h_w) with increasing R. Table 5 presents the design parameters and ultimate flexural capacity calculation results of the model girders. The finite element analysis indicates that the composite girder with a b_t of 300 mm exhibits limited

yielding due to its relatively high stiffness. At ultimate capacity, the plastic hinge at the mid-span section may not fully develop, particularly with smaller hf values such as 60mm. Notably, the bottom flange reaches yield state first upon girder failure, aligning with plastic design requirements wherein steel plate yield precedes. Additionally, various states of plasticity—fully plastic, incomplete plastic, and intermediate—are observed in girder sections at ultimate

capacity. All composite girders experience plastic failure, accurately representing diverse girder sections in engineering design and fulfilling parameter selection design goals effectively.

As the width of the bottom flange increases, the ultimate flexural capacity of the composite girder rises proportionally. Specifically, when bt increases from 150 mm to 200mm, 250mm, and 300mm, steel consumption and ultimate flexural capacity increase by 14.3%, 28.7%, and 43.1%, and by 16.1%, 28.9%, and 35.6%, respectively. The ratio of elastic flexural capacity to ultimate flexural capacity also increases with bt, indicating improved initial stiffness. However, the amplification of ultimate flexural capacity and initial stiffness gradually diminishes with uniform bt increments, suggesting a limit to efficiency due to concrete flange thickness constraints.Regarding the thickness of the concrete plate, an increase leads to higher girder height, affecting ultimate flexural capacity due to height and concrete-to-steel girder height ratio changes. As hf increases from 60 mm to 80 mm and 100mm, ultimate flexural capacity rises by 7.0% and 12.6%, respectively, with a slight increase in initial stiffness.Concerning the diameter of the circular tube, a rise from 84 mm to 105mm, 133mm, and 168 mm results in increased steel consumption and flexural capacity. However, the increase amplification diminishes with higher bt but increases thereafter. Interestingly, initial stiffness remains mostly unchanged with R variations. It's noted that flexural capacity may not monotonically increase with R, and there's a possibility of capacity decrease within a certain range due to minimal impact from tube diameter changes.

4 CALCULATION METHOD FOR ULTIMATE BENDING MOMENT

The simplified plastic theory method assumes that the steel reaches its yield strength regardless of tension or compression, which is basically consistent with the actual stress state of the composite girder under the ultimate flexural capacity. Due to the fact that the infilled concrete within steel tube is closer to the position of the plastic neutral axis, the contribution of the infilled concrete to the bending capacity is relatively small and can be ignored in the calculation of the ultimate bending moment. The following three situations should be analyzed when calculating the ultimate bending moment for the composite girder with tubular flange M_{pl} based on the plastic theory.

When the plastic neutral axis is inside concrete plate, the Mpl can be calculated by Equation 4 to Equation 5.

$$M_{pl} = A_{cc}f_c y_1 + A_t f_y y_2 + A_w f_y y_3 + A_b f_y y_4 \tag{4}$$

$$A_{cc} = b_e x = \frac{A_s f_y}{f_c} \tag{5}$$

where A_c and A_s are the area of the section for the concrete plate and the steel girder, respectively. A_{cc}, A_t, A_w, A_b, y_1, y_2, y_3, y_4 are the cross-sectional areas and corresponding distance from centroids of the compression region of the concrete plate, the circular steel tube, the web, and the bottom plate to plastic neutral axis, respectively. f_c is the axial compressive strength of the concrete plate. f_y is the yield strength of the steel. b_e is the effective width of the concrete plate. x is the height of the compression region of the concrete plate. h is the height of the composite girder. h_b is the thickness of the bottom flange. t_t and t_w are the thickness of the circular steel tube and the web respectively.

When the plastic neutral axis is located inside the circular steel tube, the M_{pl} can be calculated by Equation 6 to Equation 8.

$$M_{pl} = A_c f_c y_1 + A_w f_y y_3 + A_b f_y y_4 + A_{tc} f_y y_5 + A_{tt} f_y y_6 \tag{6}$$

$$A_{tc} = \frac{A_s f_y - A_c f_c}{2 f_y} \tag{7}$$

$$x = h_f + \frac{R}{2}\left[1 - \cos\left(\frac{A_{tc}}{A_t}\pi\right)\right] \tag{8}$$

where A_{tc}, A_{tt}, y_5, y_6 are the cross-sectional areas and corresponding distance from centroids of the circular steel tube in the compression and tensile region to plastic neutral axis, respectively.

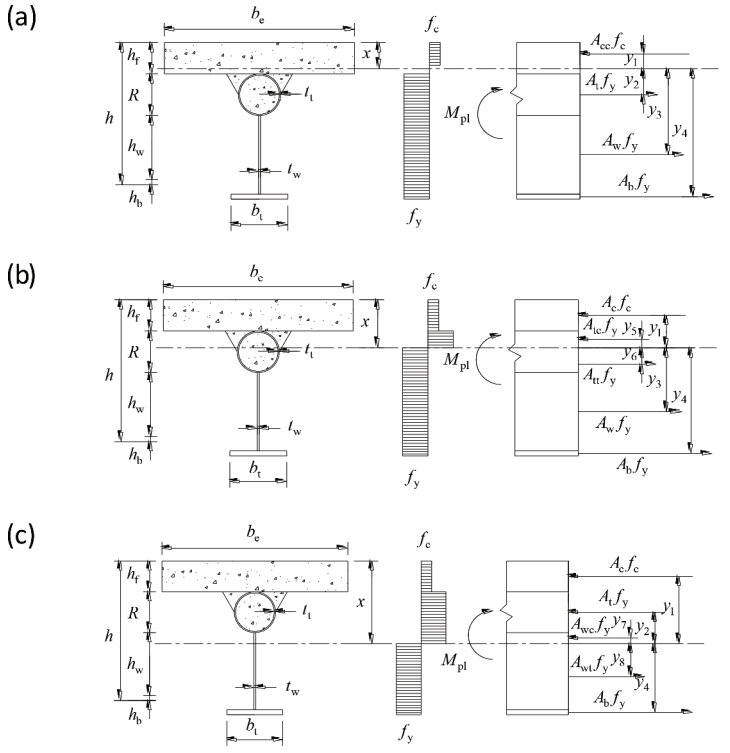

Figure 5. Calculation diagram: (a) Plastic neutral axis inside concrete plate; (b) Plastic neutral axis inside the circular steel tube; (c) Plastic neutral axis inside the web.

When the plastic neutral axis is located within the web, the M_{pl} can be calculated by Equation 9 to Equation 10.

$$M_{pl} = A_c f_c y_1 + A_t f_y y_2 + A_b f_y y_4 + A_{wc} f_y y_7 + A_{wt} f_y y_8 \tag{9}$$

$$A_{wc} = \frac{A_s f_y - 2A_t f_y - A_c f_c}{2f_y} \tag{10}$$

where A_{wc}, A_{wt}, y_7, y_8 are the cross-sectional areas and corresponding distance from centroids of the web in the compression and tensile region to plastic neutral axis, respectively.

The comparison results between the calculated value obtained by the formula in this paper M_{pl} and the finite element result M_{uc} is shown in Table 5. It can be seen that the prediction of the ultimate flexural capacity for the composite girder under the fully plastic state is slightly lower, for the composite girder under the incomplete plastic state is slightly higher, and for the composite girder under the intermediate plastic state composite beam is accurate. The ratio of the M_{pl}/M_{uc} is 0.91 to 1.09 with an average value of 0.98, which indicating that the formula for ultimate bending moment established based on simplified plastic theory in this paper has a high calculation accuracy.

5 CONCLUSION

(1) The bending moment vers deflection curves calculated by the nonlinear numerical model considering the plastic constitutive relationship of concrete damage, and the slip and fracture of shear studs is in good agreement with the test results, which can simulate the flexural process of the composite girder with circular tubular flanges well.

(2) Increasing the width of the bottom flange of the steel girder and the thickness of the concrete plate can effectively increase the ultimate flexural capacity of the composite girder with circular tubular flanges, but the diameter of the circular tube has a relatively small impact.
(3) Based on the flexural performance of test girders and numerical models, a simplified plastic theory is applied to derive the calculation formula for the ultimate flexural capacity of the composite girder with circular tubular flange. The calculation results are in good agreement with the finite element results, and have a high calculation accuracy for calculating the ultimate flexural capacity for the composite girder with circular tubular flange.

ABSTRACT: To study the flexural performance of high strength steel-UHPFRC composite girders, flexural tests, numerical simulation, and theoretical analysis were comparatively carried out on high strength steel-UHPFRC composite girders and high strength steel concrete composite girders. The failure mode, flexural stiffness, ultimate capacity and corresponded deformation were compared and analyzed. The finite element models with multi-scaled of high strength steel-UHPFRC composite girders were established, and the parameter analysis was carried out. The simplified calculation method applicable to the flexural capacity of high strength steel-UHPFRC composite girders was proposed. The results show that the flexural behavior of the flange of high strength steel-UHPFRC composite girders is significantly improved, and the number of cracks is significantly reduced with smaller widths. Compared with high strength steel concrete composite girders, the flexural stiffness and yield load of high strength steel-UHPFRC composite girders in the elastic stage are increased by 17.4% and 7.1%, respectively. The cracking load in the elastic-plastic stage is increased by 10.2%, and the flexural capacity and ductility in the ultimate state are increased by 10.8% and 26.8%, respectively. The variable parameter analysis results show that the yield strength and ductility of the composite girder can be significantly improved by increasing the strength of the UHPFRC.

1 INTRODUCTION

The steel-concrete composite bridge, known for its efficient assembly and structural simplicity (Nie 2011), faces challenges like low compactness and limited durability (Editorial 2021; Shao et al. 2017). To address these issues, Ultra-High-Performance Fiber-Reinforced Concrete (UHPFRC) is introduced, offering enhanced durability with features like robust impermeability and corrosion resistance (Graybeal et al. 2020; Chen et al. 2014; Brühwiler, 2020; Paschalis et al. 2021). This material has prompted extensive research on the flexural performance of steel-UHPFRC composite girder bridges, aiming to improve their usability and longevity. Scholars have investigated various aspects of steel-UHPFRC composite girder bridges. Yoo et al. (2016) proposed a novel type of steel-Ultra-High Performance Concrete (UHPC) composite girder and analyzed its flexural performance compared to traditional steel-concrete composite girders. Liu et al. (2018) conducted experimental comparisons, highlighting the reduced bridge deck thickness in steel-UHPC composite girders. Zhu et al. (2020, 2021) explored the flexural performance of steel-UHPC waffle slab composite girders, suggesting adjustments to steel strength or geometric dimensions for better compatibility with UHPC. Deng (2020) proposed a plastic calculation method for the ultimate flexural capacity of steel-UHPC composite girders.

DOI: 10.1201/9781003483755-480

This paper focuses on investigating the flexural performance and damage mechanisms of high-strength steel-UHPFRC composite girders through comparative bending tests. Using numerical analysis and parameter studies, scaled and full-scale models are analyzed to propose a simplified calculation method for determining flexural capacity..

2 TEST METHODS

2.1 *Test design*

The high-strength steel-UHPFRC composite girder (HSUCB) and high-strength steel-concrete composite girder (HSCCB) were designed with identical geometric dimensions. Both girders have a length of 3300 mm and a span of 3000 mm. The girder height is 374 mm, with flange thickness set at 80 mm. Studs were arranged in a double-row configuration, spaced 100 mm transversely and 55 mm longitudinally, adhering to complete shear connection design standards. The flanges and web of the steel girder were constructed from Q420 steel plate, while stiffeners were fashioned from Q235 steel plate. Reinforcement bars consisted of R235 round steel bars, with a longitudinal reinforcement rate of 0.88% and a transverse reinforcement rate of 1.29%.

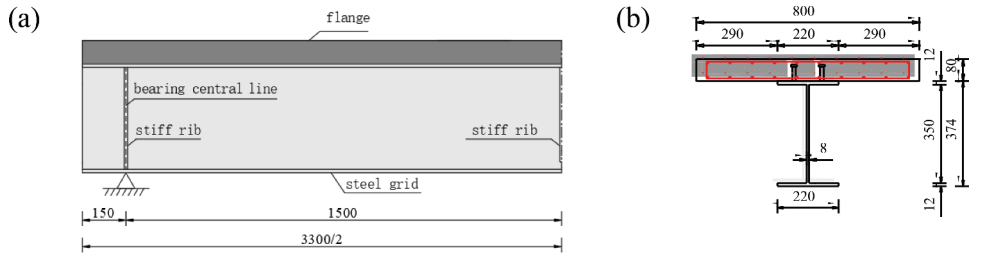

Figure 1. Test girder configuration: (a) elevation plan; (b) cross section.

Figure 2. Loading device.

2.2 *Loading and measurement point layout*

The test girders are simply supported. Four- point loading is applied for the test girders at mid-span with a spread beam uniformly distributing the load. These two girders have the same test point. The strain gauges were used for the composite girders to analyze the strain distribution patterns. The displacement meter was arranged on the bottom surface of the bottom flange of the steel girders to measure deflection at mid-span of the girders. Two slip meters are symmetrically located at the interface of the steel girders and concrete plates at the ends to assess relative slips.

2.3 *Analysis of test results*

After the bending test, analysis of deflection, strain, relative slip, and strain distribution along the girder's height was conducted. Experimental results reveal critical points: the natural bond

between the steel girder and UHPFRC plate peels off at 1105kN, bottom flange yields at 1238kN, transverse cracks appear at 1505kN, and UHPFRC plate crushes at 1698kN, reaching the limit state. HSUCB girder exhibits superior cracking resistance, strength, and elastic flexural stiffness compared to HSCCB girder. Both girders utilize flange compressive strength fully in the limit state, with the bottom flange entering the strengthening stage. High-strength steel-UHPFRC composite girder enhances overall performance, with stronger natural bonding between UHPFRC plates and high-strength steel girders. Moreover, the slip effect in high-strength steel-concrete composite girders becomes more apparent during flexural processes. The tensile properties of high-strength steel girders are fully utilized by matching with UHPFRC plates, further improving performance.

3 NUMERICAL ANALYSIS

3.1 *Test girder finite element model*

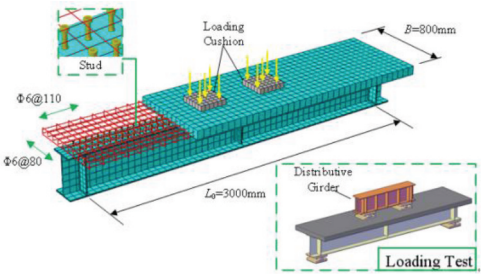

Figure 3. Finite element model.

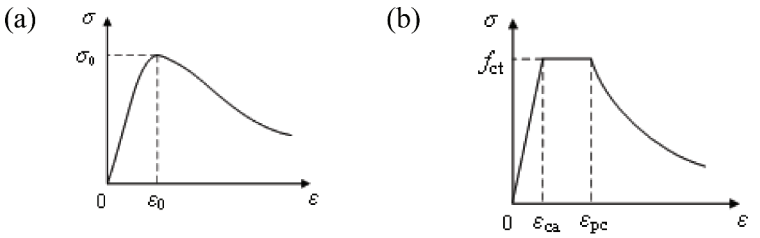

Figure 4. Constitutive model for UHPFRC: (a) Compressive; (b) tensile.

To further analyze the flexural behavior of high-strength steel-UHPFRC composite girders, a nonlinear finite element model at the scale of the test girder was developed using ABAQUS software. The finite element model is illustrated in Figure 3. In this model, reinforcement bars and studs are embedded in the concrete plate, and the steel girder is rigidly connected to the stiffeners and studs. The interaction between the concrete plate and the steel girder is modeled as a hard contact, with interface friction simulated using penalty functions. The UHPFRC adopts the constitutive model proposed in the literature (YANG et al. 2008) and corrected based on the measured results, the constitutive model is shown in Figure 4. The steel adopts the multilinear constitutive model and corrected based on the experimental results. The stiffening ribs, reinforcement bars, and studs adopt the material constitutive relationships defined for the same materials in the literature (ZHU 2018).

3.2 *Analysis of calculation results*

Figure 5 illustrates the load-versus-strain curves for the UHPFRC plate and steel girder at the mid-span section of the HSUCB girder. The compressive strain in the UHPFRC plate, as

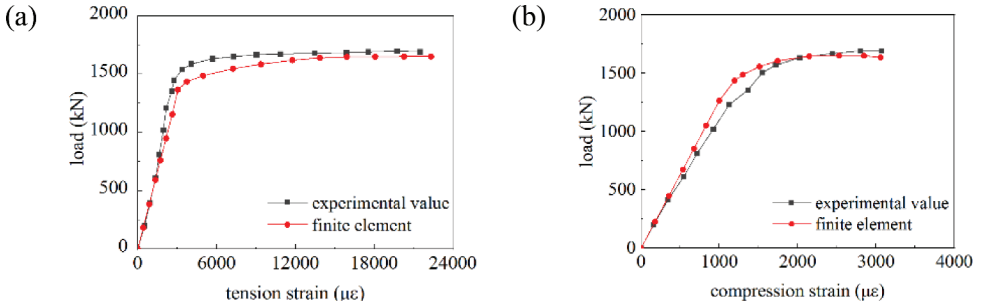

Figure 5. Load vers strain curve of mid-span section for HSUCB girder: (a) Load vers tension strain curves; (b) Load vers compression strain curves.

shown in Figure 5a, aligns well between test and numerical models during the elastic stage, with a measured strain of 2944με and a FE-to-test ratio of 0.92. The load-versus-tensile-strain curve for the steel girder, depicted in Figure 5b, indicates a close fit between FE and test results. The FE model slightly overestimates the yield tensile strain by 9% and yields a yield strength 2% lower than the measured value. However, the FE ultimate tensile strain is 3% higher than the measured value, demonstrating overall good agreement. Figure 6a compares the load-deflection curves from FE analysis and test results, showing a good fit in both elastic and elastic-plastic stages. Ratios of FE-to-test values for yield strength, deflection, and flexural stiffness are 1.02, 0.98, and 1.04, respectively, in the elastic stage, and 0.97 and 0.92 for flexural bending moment and deflection at the ultimate state, indicating consistent performance between FE and test results.Figure 6b compares load-versus-slip curves at the end of the HSUCB girder between FE model and test girder. In the elastic stage, relative slip is minimal, with a slight discrepancy between FE and test results. At the ultimate state, FE slip value is 6% higher than the measured value, indicating a slightly different behavior in the failure stage. Overall, the FE model effectively captures the development of interface slip and its failure value at the end of the girder.

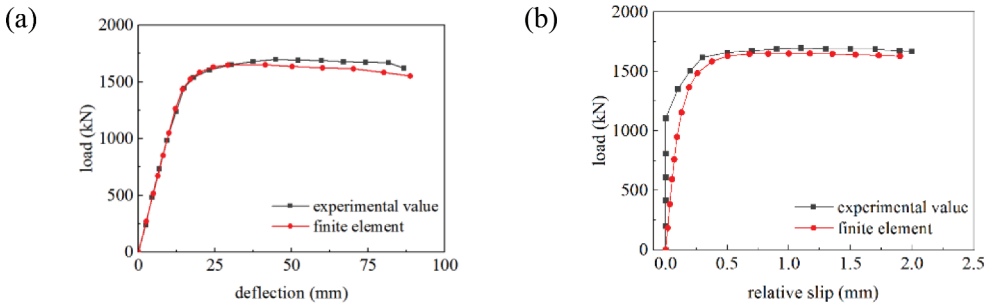

Figure 6. Curves for HSUCB girder: (a) load vers deflection curves; (b) load vers slip curves.

3.3 *Parameter analysis*

Based on the finite element model analysis, variable parameter studies were conducted on the steel strength grade, UHPFRC strength grade, UHPFRC plate thickness, and bottom flange thickness of the steel girder. These studies aimed to investigate their influence on the flexural performance of the high-strength steel-UHPFRC composite girder. Figure 7 illustrates the load-deflection curves under each parameter analysis.In Figure 7a, the load-deflection curves for model girders with UHPFRC strengths of 100 MPa, 120 MPa, and 150 MPa are presented. Increasing UHPFRC strength grade leads to a significant improvement in yield strength (up by 22%) and ductility (up by 29%). However, the magnitude of improvement decreases gradually due to the potential occurrence of steel girder yielding before UHPFRC

plate yielding when their strength designs are matched.Figure 7b displays load-deflection curves for composite girders with different steel grades when using UHPFRC flanges with a strength of U120. Increasing steel grade from Q345 to Q690 results in notable enhancements in strength, stiffness, and deformation of the combined steel-UHPFRC beams.In Figure 7c, load-deflection curves for model girders with varying UHPFRC plate thicknesses are shown. Each 10 mm increase in plate thickness leads to a 5% increase in yield strength and flexural load capacity, with minimal effect on ductility but noticeable improvements in strength and stiffness.Figure 7d depicts load-deflection curves for model girders with different bottom flange thicknesses of steel girders. Increasing flange thickness enhances flexural stiffness, yield strength, and flexural load capacity. However, it reduces ductility, indicating a trade-off between stiffness and ductility when adjusting flange thickness.Overall, these parameter studies provide insights into optimizing the design of high-strength steel-UHPFRC composite girders to achieve desired performance characteristics.

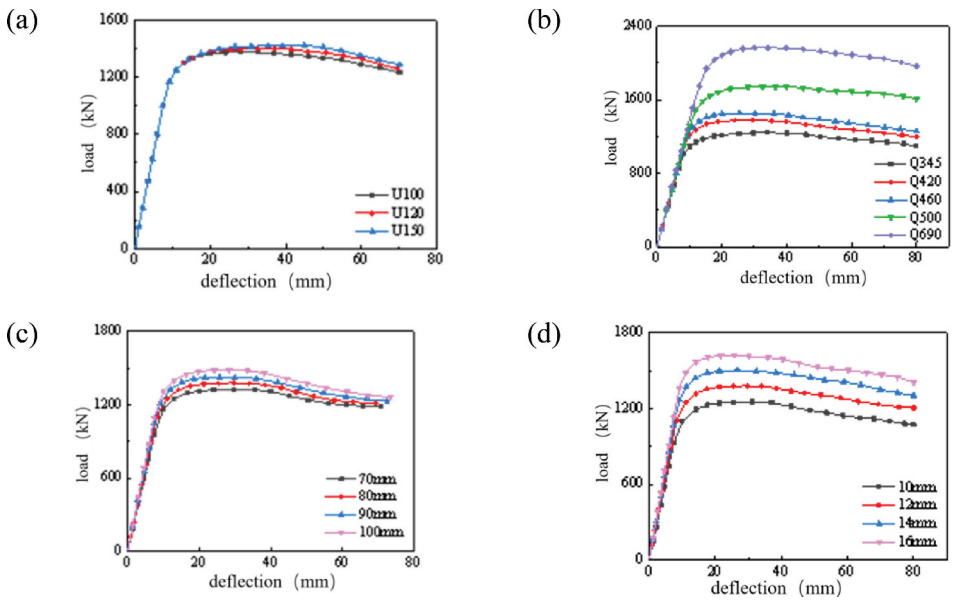

Figure 7. Parameter analysis results: (a) UHPFRC strength grade; (b) steel grade; (c) UHPFRC plate thickness; (d) bottom flange thickness of steel girder.

3.4 *Full-scale finite element model*

To further investigate the flexural performance of high-strength steel-UHPFRC composite girders, a full-scale numerical simulation study was conducted. The span of the full-scale model was 53m. The width of the UHPFRC bridge deck is 3m with a thickness of 20cm. Studs were arranged in four rows with transverse and longitudinal spacing of 100mm and 200mm, respectively. The cross-sectional dimensions are illustrated in Figure 8. The steel girders were adopted Q420 steel plates, and the stiffeners were made of Q345 steel plates. Longitudinal and transverse reinforcement bars within the UHPFRC bridge decks adopted HRB400 steel bars. The constitutive relationship model was consistent with scaled models, and the full scaled model of the high -strength steel- UHPFRC composite girder were shown in Figure 8.

3.5 *Analysis of calculation results of full-scale girders*

A comparison was made between the distribution of the strain along the height of the HSUCB girder and HSCCB girder by the full-scale model and the test results. The results indicated that the strain development stages of the UHPFRC plate and the steel girder for full-

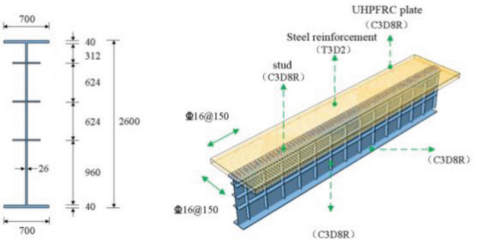

Figure 8. Full-scale girder 1/4 model (unit: mm).

scale models are similar to the scaled models. However, the plastic strain development in the bottom flange of the steel girder for full-scale model was more significant. The full-scale girders exhibit a noticeable relative slip in elastic stage, but the slip growth rate in the elastic-plastic stage is slower. At the ultimate state, the slip values are essentially the same as that observed in the test girders.

4 THEORETICAL ANALYSIS

4.1 *Calculation formula of ultimate bending moment based on equivalent stress*

The flexural capacity of high-strength steel-UHPFRC composite girders can be precisely obtained through integration, but the algorithm is relatively complex, resulting in lower computational efficiency. To simplify calculations while ensuring accuracy, equivalent stress α and equivalent height coefficients β are introduced. Experimental results indicate that under ultimate limit states, the high-strength steel-UHPFRC composite girder did not satisfy the plane section assumption, but the UHPFRC concrete and steel girder individually conformed to the plane section assumption. At the ultimate state, the bottom flange and the web of the steel girder yielded. The UHPFRC plate experienced compression failure, and the bottom surface of the UHPFRC plate reached the ultimate tensile strain. The stress vers strain curve of UHPFRC is equated to a rectangle, enabling the establishment of a practical formula for calculating bending moment under the ultimate state, as shown in Figure 9.

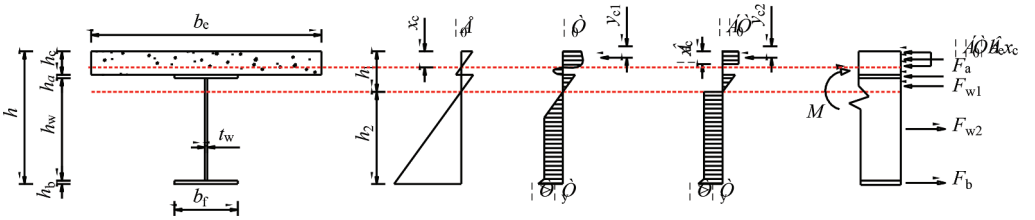

Figure 9. Calculation diagram of ultimate bending moment based on equivalent stress.

$$M_{uce} = \alpha\sigma_0\beta b_e h_c\left(h_1 - \frac{\beta h_c}{2}\right) - \int_{h_c-x_c}^{h_c-x_c+h_a} \varepsilon E_s b_f y\mathrm{d}y - \int_{h_c-x_c+h_a}^{h_1-x_c} \varepsilon E_s t_w y\mathrm{d}y + \frac{\sigma_y t_w (h_2-h_b)^2}{2} + \int_{h-x_c-h_b}^{h-x_c} \varepsilon E_{s1} b_f y\mathrm{d}y \quad (1)$$

where h_1 is the distance from the top surface of the UHPFRC plate to the neutral axis of the steel girder. h_2 is the distance from the bottom surface of the girder to the neutral axis of the steel girder. h is the total height of the composite girder. h_a and h_b are the thicknesses of the top flange and bottom flange of the steel girder, respectively. h_c is the thickness of the UHPFRC plate. h_w

and t_w are the height and thickness of the web of the steel girder, respectively. b_f is the width of the flange of the steel girder. σ_y is the yield stress of the steel girder. y is the distance of the integral unit from the neutral axis.

4.2 *Calculation formula of bending capacity based on limit equilibrium*

4.2.1 *Simplified formula of flexural capacity considering interface slip*

According to the test results, when the high-strength steel-UHPFRC composite girders use flexible studs, there is still slip at the ultimate state under the complete shear design. To simplify the design calculation, a calculation diagram based on the ultimate balance method is established as shown in Figure 10.

According to the test results, when the high-strength steel-UHPFRC composite girders use flexible studs, there is still slip at the ultimate state under the complete shear design. To simplify the design calculation, a calculation diagram based on the ultimate balance method is established as shown in Figure 10. It is assumed that the axial pressure of the UHPFRC plate is equal to the sum of the longitudinal shear force transmitted by the studs. According to the equilibrium condition, Equation 2 can be obtained.

$$x_c\sigma_0 b_e + b_f h_a \sigma_y + t_w h_1 \sigma_y = h_2 t_w \sigma_y + b_f h_b \sigma_y \tag{2}$$

where h_1 and h_2 are the height of the compression region and the tension region of the web, respectively.

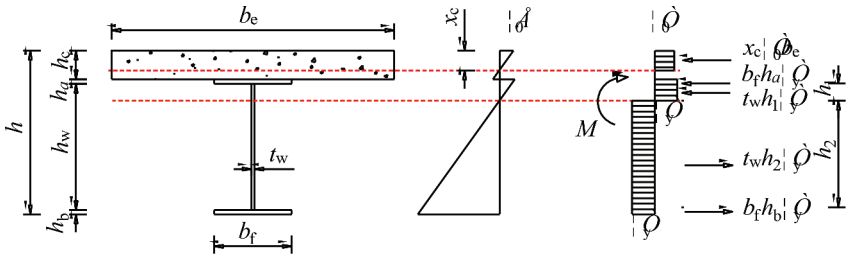

Figure 10. Calculation diagram of bending capacity in limit equilibrium.

The ultimate bending moment of the high-strength steel- UHPFRC composite girder can be obtained by Equation 3.

$$\begin{aligned} M_{us} = {} & x_c\sigma_0 b_e \frac{x_c}{2} - b_f h_a \sigma_y \left(\frac{h_a}{2} + h_c - x_c\right) - t_w h_1 \sigma_y \left(\frac{h_1}{2} + h_a + h_c - x_c\right) \\ & + h_2 t_w \sigma_y \left(\frac{h_2}{2} + h_1 + h_a + h_c - x_c\right) + b_f h_b \sigma_y \left(\frac{h_b}{2} + h_w + h_c - x_c\right) \end{aligned} \tag{3}$$

4.2.2 *Simplified formula of ultimate bending moment without considering slip*

To compare the effect of slip on the ultimate bending moment of high-strength steel-UHPFRC composite girder, a simplified formula without considering slip is also derived. The calculation diagram is established as shown in Figure 11. Equation 4 can be obtained from the equilibrium conditions.

$$h_1 b_e \sigma_0 = h_w b_f \sigma_y + h_a b_f \sigma_y + h_b b_f \sigma_y \tag{4}$$

where h_1 and h_2 are the height of the compression region and the tension region of the UHPFRC plate, respectively.

The simplified calculation formula of ultimate bending moment without considering slip can be obtained by Equation 5.

$$M_{uc} = h_1 b_e \sigma_0 \frac{h_1}{2} + h_a b_f \sigma_y \left(\frac{h_a}{2} + h_2\right) + h_w b_f \sigma_y \left(\frac{h_w}{2} + h_a + h_2\right) + h_b b_f \sigma_y \left(\frac{h_b}{2} + h_2 + h_a + h_w\right) \tag{5}$$

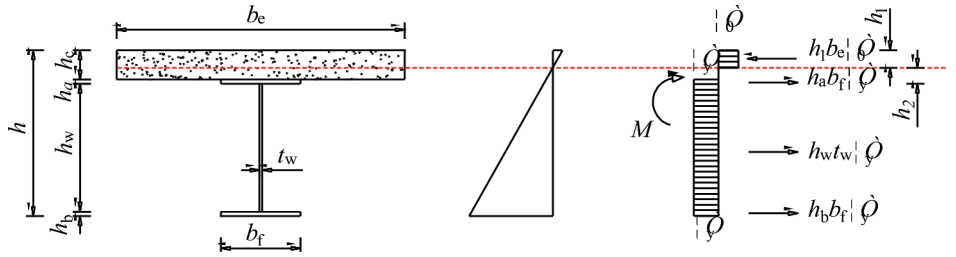

Figure 11. Calculation diagram of ultimate bending moment without considering slip.

4.3 *Verification and analysis*

Table 1. Calculation results of bending capacity of the scale test girder.

Test girder	M_{uce}(kN · m)	M_{us}(kN · m)	M_{uc}(kN · m)	M_{ut}(kN · m)	$\frac{M_{uce}}{M_{ut}}$	$\frac{M_{us}}{M_{ut}}$	$\frac{M_{uc}}{M_{ut}}$
HSUCB	957	912	1119	1019	0.94	0.90	1.09
Full-scale	77882	97554	70415	86535	0.90	1.12	0.81

A comparison and validation of the ultimate bending moment obtained by the test, the calculation formula based on equivalent stress, and the calculation formula based on limit equilibrium are conducted. The comparative results for the scaled models and the full-scale models are presented in Table 1. Where, M_{uce} is the results of the simplified calculation formula based on equivalent stress considering slip. M_{us} is the results of simplified calculation formula based on the limit equilibrium method considering slip. M_{uc} is the results of simplified calculation formula based on the limit equilibrium method without considering slip. M_{ut} is the test results. M_{ue} is the numerical results of the full-scale model.

Comparative analysis results reveal that when using the limit equilibrium method, the calculation method considering slip is relatively reduced by 18 compared to that without considering slip, while the reduction is 38% for the full-scale model girder. This indicates the slip effect has a significant reduction in ultimate flexural capacity for high-strength steel-UHPFRC composite girders. Additionally, it is observed that when calculating the ultimate flexural capacity of full-scale high-strength steel-UHPFRC composite girders using the limit equilibrium method, due to increased geometric dimensions, the simplification of stress to a rectangular shape may lead to greater calculation discrepancies. Therefore, it is recommended to use the equivalent stress coefficients proposed in this paper for the design calculation of flexural capacity for the high-strength steel-UHPFRC composite girder, with suggested values α of 0.90 to 0.95 and β of 0.75 to 0.80.

5 CONCLUSION

A comprehensive investigation encompassing experimental research, numerical simulations, and theoretical analyses of high-strength steel-UHPFRC composite girders' flexural performance yields several key conclusions. Firstly, under identical structural dimensions, these girders demonstrate significantly enhanced flange failure modes compared to high-strength steel-concrete composite girders. This is evidenced by a 17.4% increase in flexural stiffness during the elastic stage and a 7.1% boost in yield bending moment. Moreover, a notable 10.2% increase in cracking moment is observed in the elastic-plastic stage alongside reduced crack width. At the ultimate state, the ultimate bending moment rises by 10.8%, while ductility experiences a substantial 26.8% improvement. Secondly, with a consistent stud arrangement, high-strength steel-UHPFRC composite girders exhibit a 21.4% reduction in slip value compared to their concrete counterparts, indicating enhanced interaction between UHPFRC and studs. Thirdly, the finite element model shows excellent agreement with experimental results, underscoring significant enhancements in yield strength and ductility with increased

UHPFRC strength. Strengthening steel improves yield strength and ultimate bending moment but compromises ductility. Increasing UHPFRC plate thickness by 43% yields notable improvements in flexural stiffness and ultimate bending moment, while a 60% increase in bottom flange thickness results in a 22% boost in flexural stiffness, 50% increase in yield strength, and 29% increase in ultimate bending moment. Lastly, simplified calculation formulas integrating integration and equivalent coefficients offer high accuracy and simplicity. It is recommended to utilize equivalent stress coefficients ranging from 0.90 to 0.95 and equivalent height coefficients ranging from 0.75 to 0.80 for analyzing and calculating flexural capacity in high-strength steel-UHPFRC composite girders.
